Preface

There are two different APIs that can be used to write Oracle NoSQL Database (Oracle NoSQL Database) applications: the original Key/Value API, and the Table API. In addition, the Key/Value API is available in Java and C. The Table API is available in Java, C, node.js (Javascript), and Python. This document describes how to write Oracle NoSQL Database applications using the Table API in node.js.

Note

Most application developers should use one of the Table drivers because the Table API offers important features, including secondary indexes. Also, the Key/Value API will eventually be deprecated.

This document provides the concepts surrounding Oracle NoSQL Database, data schema considerations, as well as introductory programming examples.

This document is aimed at the software engineer responsible for writing an Oracle NoSQL Database application.

Conventions Used in This Book

The following typographical conventions are used within in this manual:

Class names are represented in monospaced font, as are method names. For example: “The Configuration class is used to describe properties about a Store handle.”

Variable or non-literal text is presented in italics. For example: “Go to your KVHOME directory.”

Program examples are displayed in a monospaced font on a shaded background. For example:

```javascript
//Include nosqldb-oraclejs module
var nosqldb = require('nosqldb-oraclejs');

// Create a configuration object
var configuration = new nosqldb.Configuration();
configuration.proxy.startProxy = false;
configuration.proxy.host = 'localhost:7010';
configuration.storeHelperHosts = ['n1.example.org:5000'];
configuration.storeName = 'kvstore';
configuration.username = 'jsapp-username';
```

In some situations, programming examples are updated from one chapter to the next. When this occurs, the new code is presented in monospaced bold font. For example:

```javascript
...
// Store handle configuration and open skipped for brevity
...
store.on('open', function () {
    console.log('Store opened');

    var fieldRange = new nosqldb.Types.FieldRange(
        "dateOfBirth", "1994-05-01", true,
        "1994-05-30", true);

    store.indexIterator('myTable', 'DoB', {
        fieldRange: fieldRange
    },
    function (err, iterator) {
        if (err)
            throw err;
        else {

            // Configure Iterator event done
            iterator.on('done', function() {
                store.close();
            });

            console.log("Retrieved rows:");

            iterator.forEach(function (err, returnRow) {
                if (err)
                    throw err;
                else
                    console.log(returnRow.row);
                    console.log('
');
            });
    
    });
}).on('close', function() {
    console.log('Store closed.');
}).on('error', function(error) {
    console.log(error);
});
store.open();

Note

Finally, notes of special interest are represented using a note block such as this.
Chapter 1. Developing for Oracle NoSQL Database

You access the data in the Oracle NoSQL Database KVStore using node.js drivers that are provided for the product. In addition to the node.js drivers, several other drivers are also available. They are:

1. Java Table Driver
2. Java Key/Value Driver
3. C Table Driver
4. C Key/Value Driver
5. Python Table Driver

Note

New users should use one of the Table drivers unless they require a feature only available in the Key/Value API. The Key/Value API will eventually be deprecated.

The Java and C Key/Value driver provides access to store data using key/value pairs. All other drivers provide access using tables. In addition, the Java Key/Value driver provides Large Object (LOB) support that as of this release does not appear in the other drivers. However, users of the Java Tables driver can access the LOB API, even though the LOB API is accessed using the Key/Value interface.

Users of any of the Table drivers are able to create and use secondary indexing. The Java and C Key/Value drivers do not provide this support.

To work, the C Table, Python Table, and node.js Table drivers require use of a proxy server which translates network activity between the driver and the Oracle NoSQL Database store. The proxy is written in Java, and can run on any machine that is network accessible by both your client code and the Oracle NoSQL Database store. However, for performance and security reasons, Oracle recommends that you run the proxy on the same local host as your driver, and that the proxy be used in a 1:1 configuration with your drivers (that is, each instance of the proxy should be used with just a single driver instance).

Regardless of the driver you decide to use, the provided classes and methods allow you to write data to the store, retrieve it, and delete it. You use these APIs to define consistency and durability guarantees. It is also possible to execute a sequence of store operations atomically so that all the operations succeed, or none of them do.

The rest of this book introduces the node.js APIs that you use to access the store, and the concepts that go along with them.

Note

Oracle NoSQL Database is tested with Java 7.
The node.js driver is compatible with Node.js 0.10.26 and later. It is also compatible with io.js 1.7.1 and later.

### Installing the Driver

To run your node.js clients, you need to have the nosqldb-oraclejs module installed locally or globally. You can install nosqldb-oraclejs in the node.js driver directory by using the following command:

```
npm install [-g] nosqldb-oraclejs
```

nosqldb-oraclejs is the module name of the Oracle NoSQL Database node.js Client driver published on [http://www.npmjs.org](http://www.npmjs.org). If `-g` is specified, the command installs the specified module so that it is globally accessible.

Then, to use the module, include nosqldb-oraclejs in your client code:

```
var nosqldb = require('nosqldb-oraclejs');
```

### Using the Proxy Server

The proxy server is a Java application that accepts network traffic from the node.js Table driver, translates it into requests that the Oracle NoSQL Database store can understand, and then forwards the translated request to the store. The proxy also provides the reverse translation service by interpreting store responses and forwarding them to the client.

The proxy server can run on any network-accessible machine. It has minimal resource requirements and, in many cases, can run on the same machine as the client code is running.

Before your node.js client can access the store, the proxy server must be running. It requires the following jar files to be in its class path, either by using the `java -cp` command line option, or by using the `CLASSPATH` environment variable:

- kvclient.jar
- kvproxy.jar

**Note**

The proxy server, kvclient and their dependencies reside in the `MODULE_INSTALL/node_modules/nosqldb_oraclejs/kvproxy` directory.

The proxy server itself is started using the `oracle.kv.proxy.KVProxy` command. At a minimum, the following information is required when you start the proxy server:

- `-helper-hosts`

  A list of one or more host:port pairs representing Oracle NoSQL Database storage nodes that the proxy server can use to connect to the store.

- `-port`

  The port where your client code can connect to this instance of the proxy server.
-store

The name of the store to which the proxy server is connecting.

A range of other command line options are available. In particular, if you are using the proxy server with a secure store, you must provide authentication information to the proxy server. (Note that the proxy server itself connects to a single store using a single user credential. If multiple stores or users are required, then multiple proxy servers must be used.) In addition, you will probably have to identify a store name to the proxy server. For a complete description of the proxy server and its command line options, see Proxy Server Reference (page 94).

The examples provided in this guide were written to work with a proxy server that is connected to a kvlite instance which was started with default values. The location of the kvclient.jar and kvproxy.jar files were provided using a CLASSPATH environment variable. The command line call used to start the proxy server was:

```bash
nohup java oracle.kv.proxy.KVProxy -port 7010 \
-helper-hosts localhost:5000 -store kvstore
```

Usage of kvlite is described in Introduction to Oracle KVLite (page 10).

**Connecting to the Store**

To perform store operations, you must establish a network connection between your client code and the store. There are three pieces of information that you must provide:

- The name of the store. The name provided here must be identical to the name used when the store was installed.

- The network contact information for one or more helper hosts. These are the network name and port information for nodes currently running in the store. Multiple nodes can be identified. You can use one or many. Many does not hurt. The downside of using one is that the chosen host may be temporarily down, so it is a good idea to use more than one.

- Identify the host and port where the proxy is running. You also do this using the configuration object.

If you are connecting to a secured store, you must also provide some authentication information. This is described in Setting the Security Properties for a Proxy Server (page 9).

For example, suppose you have an Oracle NoSQL Database store named "kvstore" and it has a node running on n1.example.org at port 5000. Further, suppose you are running your proxy on the localhost using port 7010. Then you would open and close a connection to the store in the following way:

```javascript
//Include nosqldb-oraclejs module
var nosqldb = require('nosqldb-oraclejs');

// Create a configuration object
var configuration = new nosqldb.Configuration();
```
configuration.proxy.startProxy = false;
configuration.proxy.host = 'localhost:7010';
configuration.storeHelperHosts = ['n1.example.org:5000'];
configuration.storeName = 'kvstore';

// Create a store with the specified configuration
var store = nosqldb.createStore(configuration);

store.on('open', function () {
    console.log('Store opened.');
    // Perform store operations here
    store.close();
}).on('close', function() {
    console.log('Store closed.');
    store.shutdownProxy();
}).on('error', function(error) {
    console.log('Error in the store.');
    console.log(error);
});

store.open();

### Connecting to a Secure Store

If you are using a secure store, then your proxy server must first be configured to authenticate to the store. See [Securing Oracle NoSQL Database Proxy Server (page 95)] for details.

Once your proxy server is capable of accessing the secure store, you must at a minimum indicate which user your driver wants to authenticate as when it performs store access. To do this, use configuration.username.

For more information on using secure stores, see [Working with a Secured Store (page 8)].

//Include nosqldb-oraclejs module
var nosqldb = require('nosqldb-oraclejs');

// Create a configuration object
var configuration = new nosqldb.Configuration();
configuration.proxy.startProxy = false;
configuration.proxy.host = 'localhost:7010';
configuration.storeHelperHosts = ['n1.example.org:5000'];
configuration.storeName = 'kvstore';
configuration.username = 'jsapp-username';

// Create a store with the specified configuration
var store = nosqldb.createStore(configuration);

store.on('open', function () {
    console.log('Store opened.');
    // Perform store operations here
    store.close();
};
Automatically Starting the Proxy Server

Your client code can start the proxy server on the local host when it opens the store using `configuration.proxy.startProxy`. To do this, set its value to `true` and also specify the location of the `kvproxy.jar` using `configuration.proxy.KVPROXY_JAR`. Also, specify the location of the `kvclient.jar` using `configuration.proxy.KVCLIENT_JAR`.

For example:

```javascript
var nosqldb = require('nosqldb-oraclejs');
var configuration = new nosqldb.Configuration();
configuration.proxy.startProxy = true;
configuration.proxy.host = 'localhost:7010';
configuration.proxy.KVCLIENT_JAR = 
    'node_modules/kvproxy/kvclient.jar';
configuration.proxy.KVPROXY_JAR = 
    'node_modules/kvproxy/kvproxy.jar';
configuration.storeHelperHosts = ['n1.example.org:5000'];
configuration.storeName = 'kvstore';

var store = nosqldb.createStore(configuration);

store.on('open', function () {
    console.log('Store opened.');
    // Perform store operations here
    store.close();
});
store.open();
```

Be aware that if your proxy is connecting to a secure store, you also must indicate which user to authenticate as, and you must indicate where the security properties file is located on the host where the proxy server is running. To do this, use `configuration.username` and `configuration.proxy.securityFile`.

```javascript
var nosqldb = require('nosqldb-oraclejs');
var configuration = new nosqldb.Configuration();
```
configuration.proxy.startProxy = true;
configuration.proxy.host = 'localhost:7010';
configuration.proxy.KVCLIENT_JAR =
    'node_modules/kvproxy/kvclient.jar';
configuration.proxy.KVPROXY_JAR =
    'node_modules/kvproxy/kvproxy.jar';
configuration.storeHelperHosts = ['n1.example.org:5000'];
configuration.storeName = 'kvstore';
configuration.username = 'jsapp-username';
configuration.proxy.securityFile = 'KVROOT/security/client.security';

var store = nosqldb.createStore(configuration);

store.on('open', function () {
    console.log('Store opened.');
    // Perform store operations here
    store.close();
}).on('close', function() {
    console.log('Store closed.');
    store.shutdownProxy();
}).on('error', function(error) {
    console.log('Error in the store.');
    console.log(error);
});
store.open();

For information on configuring your proxy server to connect to a secure store, see Securing Oracle NoSQL Database Proxy Server (page 95).

The Configuration Class

The Configuration class is used to describe properties about a Store handle. Most of the properties are optional; however, you must identify the store name and helper hosts.

The properties that you can provide using Configuration are:

- connectionAttempts
  The number of attempts the driver will make to connect to the server before failing.

- defaultConsistency
  Consistency is a property that describes how likely it is that a record read from a replica node is identical to the same record stored on a master node. For more information, see Consistency Guarantees (page 69).

- defaultDurability
  Durability is a property that describes how likely it is that a write operation performed on the master node will not be lost if the master node is lost or is shut down abnormally. For more information, see Durability Guarantees (page 75).
• iteratorBufferSize

  The number of rows buffered by Iterators or Streams.

• proxy

  Proxy server configuration. See the next section.

• readZones

  An array of zone names to be used as read zones. For more information on read zones, see the Oracle NoSQL Database Administrator’s Guide.

• requestTimeout

  Configures the amount of time the client will wait for an operation to complete before it times out.

• storeHelperHosts

  Helper hosts are hostname/port pairs that identify where nodes within the store can be contacted. Multiple hosts can be identified using an array of strings. Typically an application developer will obtain these hostname/port pairs from the store's deployer and/or administrator. For example:

  ```javascript
  var config = new nosqldb.Configuration();
  config.storeHelperHosts=['n1.example.org:3333','n2.example.org:3333']
  ```

• storeName

  Identifies the name of the store.

• username

  The name of the user you want to authenticate to the store as. This property should only be used when your proxy server is configured to connect to a secure store.

The ProxyConfiguration Class

The ProxyConfiguration class is used to describe properties about the proxy server you are using to connect to the store.

The number of properties you can specify using this class are too numerous to describe here (see the Oracle NoSQL node.js Driver for Tables API Reference for a complete listing), but the most common properties you will set are:

• startProxy

  Boolean indicating whether the driver should automatically start the proxy server if it is not already running.

• host
The hostname:port pair used to connect to the proxy server.

- **securityFile**

  The properties file containing the security information required to connect to a secure store. For information on secure stores and security properties, see Setting the Security Properties for a Proxy Server (page 9).

- **KVCLIENT_JAR**

  The path where the kvclient.jar file is located. This information is only required if you are attempting to automatically start the proxy server.

- **KVPROXY_JAR**

  The path where the kvproxy.jar file is located. This information is only required if you are attempting to automatically start the proxy server.

## Working with a Secured Store

Oracle NoSQL Database can be installed such that your client code does not have to authenticate to the store. (For the sake of clarity, most of the examples in this book do not perform authentication.) However, if you want your store to operate in a secure manner, you can require authentication. Note that doing so will result in a performance cost due to the overhead of using SSL and authentication. While best practice is for a production store to require authentication over SSL, some sites that are performance sensitive may want to forgo that level of security.

Authentication involves sending username/password credentials to the store at the time the proxy server connects to the store. The proxy server gets the username that it uses from the client code connecting to it. The rest of the credential information is contained in a security properties file that must be installed on the same local host as the proxy server. Be aware that the connection from your driver code to the proxy server is not secure. It is therefore recommended that you run your proxy server and your driver code on the same physical host.

A store that is configured to support authentication is automatically configured to communicate with clients using SSL in order to ensure privacy of the authentication and other sensitive information. When SSL is used, SSL certificates need to be installed on the machines where your proxy server runs in order to validate that the store that is being accessed is trustworthy.

Configuring a store for authentication is described in the Oracle NoSQL Database Security Guide.

## Configuring SSL

If you are using a secure store, then all communications between your proxy server and the store is transported over SSL, including authentication credentials. You must therefore configure your client code to use SSL. To do this, you identify where the SSL certificate data is, and you also separately indicate that the SSL transport is to be used.
Identifying the Trust Store

When an Oracle NoSQL Database store is configured to use the SSL transport, a series of security files are generated using a security configuration tool. One of these files is the client.trust file, which must be copied to any machine running a proxy server.

For information on using the security configuration tool, see the Oracle NoSQL Database Security Guide.

Your proxy server must be told where the client.trust file can be found because it contains the certificates necessary to establish an SSL connection with the store. You indicate where this file is physically located on your machine using the oracle.kv.ssl.trustStore property.

Setting the SSL Transport Property

In addition to identifying the location of the client.trust file, you must also tell your proxy server to use the SSL transport. You do this by setting the oracle.kv.transport property.

Setting the Security Properties for a Proxy Server

When an Oracle NoSQL Database secure store is installed, a file is generated called client.security. This file contains security properties that are needed by your proxy server. Copy this file to the machine that will run your proxy server, along with your client.trust file and the login.passwd file. All of these files were created during the installation process.

You may need to edit your client.security file to adjust the location of files for the local host. When you get done, client.security should look something like this:

```
oracle.kv.auth.username=root
oracle.kv.auth.pwdfile.file=/security/login.passwd
oracle.kv.transport=ssl
oracle.kv.ssl.trustStore=/security/client.trust
oracle.kv.ssl.protocols=TLSv1.2,TLSv1.1,TLSv1
oracle.kv.ssl.hostnameVerifier=dnmatch(CN=NoSQL)
```

Once these files are in place and are edited correctly, when your client code creates a store connection, it must identify both the location of the client.security file on the disk where the proxy server is running, as well as the username the client wants to authenticate as. See Connecting to the Store (page 3) for an example of how this is done.
Chapter 2. Introduction to Oracle KVLite

KVLite is a single-node, single shard store. It usually runs in a single process and is used to develop and test client applications. KVLite is installed when you install Oracle NoSQL Database.

**Note**

KVLite supports only non-authenticated access to the store. That is, you cannot configure KVLite such that your code can authenticate, or log in, to it. If you are developing code for a store that requires authentication, then you must install a test store that is configured for authentication access in the same way as your production store.

See **Working with a Secured Store** (page 8) for information on configuring your proxy server to connect to a secure store. For information on configuring a store to require authentication, see the Oracle NoSQL Database Security Guide.

**Starting KVLite**

You start KVLite by using the kvlite utility, which can be found in KVHOME/lib/kvstore.jar. If you use this utility without any command line options, then KVLite will run with the following default values:

- The store name is kvstore.
- The hostname is the local machine.
- The registry port is 5000.
- The directory where Oracle NoSQL Database data is placed (known as KVROOT) is ./kvroot.
- The administration process is turned on using port 5001.

This means that any processes that you want to communicate with KVLite can only connect to it on the local host (127.0.0.1) using port 5000. If you want to communicate with KVLite from some machine other than the local machine, then you must start it using non-default values. The command line options are described later in this chapter.

For example:

```bash
> java -Xmx256m -Xms256m -jar KVHOME/lib/kvstore.jar kvlite
```

**Note**

To avoid using too much heap space, you should specify -Xmx and -Xms flags for Java when running administrative and utility commands.

When KVLite has started successfully, it writes one of two statements to stdout, depending on whether it created a new store or is opening an existing store:
Created new kvlite store with args:
-root ./kvroot -store <kvstore name> -host <localhost> -port 5000
-admin 5001

or

Opened existing kvlite store with config:
-root ./kvroot -store <kvstore name> -host <localhost> -port 5000
-admin 5001

where <kvstore name> is the name of the store and <localhost> is the name of the local host. It takes about 10 - 60 seconds before this message is issued, depending on the speed of your machine.

Note that you will not get the command line prompt back until you stop KVLite.

Stopping and Restarting KVLite

To stop KVLite, use ‘C from within the shell where KVLite is running.

To restart the process, simply run the kvlite utility without any command line options. Do this even if you provided non-standard options when you first started KVLite. This is because KVLite remembers information such as the port value and the store name in between run times. You cannot change these values by using the command line options.

If you want to start over with different options than you initially specified, delete the KVROOT directory (.kvroot, by default), and then re-run the kvlite utility with whatever options you desire. Alternatively, specify the -root command line option, making sure to specify a location other than your original KVROOT directory, as well as any other command line options that you want to change.

Verifying the Installation

There are several things you can do to verify your installation, and ensure that KVLite is running:

- Start another shell and run:
  ```sh
  jps -m
  ```
  The output should show KVLite (and possibly other things as well, depending on what you have running on your machine).

- Run the kvclient test application:
  1. cd KVHOME
  2. java -Xmx256m -Xms256m -jar lib/kvclient.jar

This should write the release to stdout:

```
12cR1.M.N.O...
```
• Compile and run the example program:

1. cd KVHOME

2. Compile the example:

   javac -g -cp lib/kvclient.jar:examples examples/hello/*.java

3. Run the example using all default parameters:

   java -Xmx256m -Xms256m -cp lib/kvclient.jar:examples hello.HelloBigDataWorld

Or run it using non-default parameters, if you started KVLite using non-default values:

   java -Xmx256m -Xms256m -cp lib/kvclient.jar:examples hello.HelloBigDataWorld -host <hostname> -port <hostport> -store <kvstore name>

---

**kvlite Utility Command Line Parameter Options**

This section describes the command line options that you can use with the kvlite utility.

Note that you can only specify these options the first time KVLite is started. Most of the parameter values specified here are recorded in the KVHOME directory, and will be used when you restart the KVLite process regardless of what you provide as command line options. If you want to change your initial values, either delete your KVHOME directory before starting KVLite again, or specify the -root option (with a different KVHOME location than you initially used) when you provide the new values.

• **-admin <port>**

  If this option is specified, the administration user interface is started. The port identified here is the port you use to connect to the UI.

• **-help**

  Print a brief usage message, and exit.

• **-host <hostname>**

  Identifies the name of the host on which KVLite is running. Use this option ONLY if you are creating a new store.

  If you want to access this instance of KVLite from remote machines, supply the local host's real hostname. Otherwise, specify localhost for this option.

• **-logging**

  Turns on Java application logging. The log files are placed in the examples directory in your Oracle NoSQL Database distribution.

• **-port <port>**
Identifies the port on which KVLite is listening for client connections. Use this option ONLY if you are creating a new store.

• -root <path>

Identifies the path to the Oracle NoSQL Database home directory. This is the location where the store's database files are contained. The directory identified here must exist. If the appropriate database files do not exist at the location identified by the option, they are created for you.

• -store <storename>

Identifies the name of a new store. Use this option ONLY if you are creating a new store.
Chapter 3. Introducing Oracle NoSQL Database Tables and Indexes

Using the Table API (in one of the supported languages) is the recommended method of coding an Oracle NoSQL Database client application. They allow you to manipulate data using a tables metaphor, in which data is organized in multiple columns of data. An unlimited number of subtables are supported by this API. You can also create indexes to improve query speeds against your tables.

Note

You should avoid any possibility of colliding keys if your store is accessed by a mix of clients that use both the Table and the Key/Value APIs.

Defining Tables

Before an Oracle NoSQL Database client can read or write to a table in the store, the table must be created. There are several ways to do this, but this manual focuses on using Table DDL Statements. These statements can be submitted to the store using the command line interface (CLI), but the recommended approach is to submit them to the store programmatically. Both methods are described in this section.

The DDL language that you use to define tables is described in Table Data Definition Language Overview (page 84). This section provides a brief overview of how to use that language.

As an introductory example, suppose you wanted to use a table named `myTable` with four columns per row: `item`, `description`, `count`, and `percentage`. To create this table, you would use the following statement:

```
CREATE TABLE myTable (
    item STRING,
    description STRING,
    count INTEGER,
    percentage DOUBLE,
    PRIMARY KEY (item) // Every table must have a primary key
)
```

Note

Primary keys are a concept that have not yet been introduced in this manual. See Primary and Shard Key Design (page 22) for a complete explanation on what they are and how you should use them.

To add the table definition to the store, you can add it programmatically using the `Store.executeFuture()` or `Store.execute()` methods. (The latter method executes the statement synchronously.) In order to use these methods, you must establish a connection to the store. This is described in Connecting to the Store (page 3).

For example:
... // Store handle configuration and open skipped for brevity ...

store.on('open', function () {

    console.log('Store opened');

    store.execute('CREATE TABLE IF NOT EXISTS myTable (' +
        'id STRING, ' +
        'description STRING, ' +
        'count INTEGER, ' +
        'percentage DOUBLE, ' +
        'PRIMARY KEY (item)) ',
    function(err){
        if (err)
            throw err;
        else {
            console.log('Table creation succeeded.');
            store.close();
        }
    });
});

store.on('close', function() {
    console.log('Store closed.');
});

store.on('error', function(error) {
    console.log(error);
});

store.open();

**Executing DDL Statements using the CLI**

You can execute DDL statements using the CLI's execute command. This executes DDL statements synchronously. For example:

```
kv-> execute "CREATE TABLE myTable (  
> item STRING,  
> description STRING,  
> count INTEGER,  
> percentage DOUBLE,  
> PRIMARY KEY (item))"
Statement completed successfully
kv->
```

**Supported Table Data Types**

You specify schema for each column in an Oracle NoSQL Database table. This schema can be a primitive data type, or complex data types that are handled as objects.

Supported data types for Oracle NoSQL Database are:

- Array
An array of values, all of the same type.

- **Binary**
  Implemented as a byte array with no predetermined fixed size.

- **Boolean**
- **Double**
- **Enum**
  An enumeration, represented as an array of strings.

- **Fixed Binary**
  A fixed-sized binary type (byte array) used to handle binary data where each record is the same size. It uses less storage than an unrestricted binary field, which requires the length to be stored with the data.

- **Float**
- **Integer**
- **Long**
- **Map**
  An unordered map type where all entries are constrained by a single type.

- **Records**
  See the following section.

- **String**

For the node.js driver, these datatypes are handled in the following way:

<table>
<thead>
<tr>
<th>Oracle NoSQL Database Datatype</th>
<th>node.js Datatype</th>
</tr>
</thead>
<tbody>
<tr>
<td>Array</td>
<td>Javascript array. See Using Arrays (page 48).</td>
</tr>
<tr>
<td>Binary</td>
<td>Base64 encoded buffer. See Using Binary (page 49).</td>
</tr>
<tr>
<td>Boolean</td>
<td>Javascript boolean</td>
</tr>
<tr>
<td>Double</td>
<td>Javascript number</td>
</tr>
<tr>
<td>Enum</td>
<td>Javascript string. See Using Enums (page 50).</td>
</tr>
<tr>
<td>Fixed Binary</td>
<td>Base64 encoded buffer. See Using Fixed Binary (page 51).</td>
</tr>
</tbody>
</table>
### Record Fields

As described in Defining Child Tables (page 18), you can create child tables to hold subordinate information, such as addresses in a contacts database, or vendor contact information for an inventory system. When you do this, you can create an unlimited number of rows in the child table, and you can index the fields in the child table's rows.

However, child tables are not required in order to organize subordinate data. If you have very simple requirements for subordinate data, you can use record fields instead of a child tables. In general, you can use record fields instead of child tables if you only want a fixed, small number of instances of the record for each parent table row. For anything beyond trivial cases, you should use child tables. (Note that there is no downside to using child tables even for trivial cases.)

The assumption when using record fields is that you have a fixed known number of records that you will want to manage (unless you organize them as arrays). For example, for a contacts database, child tables allow you to have an unlimited number of addresses associated for each user. But by using records, you can associate a fixed number of addresses by creating a record field for each supported address (home and work, for example).

For example:

```sql
CREATE TABLE myContactsTable (  
  uid STRING,  
  surname STRING,  
  familiarName STRING,  
  homePhone STRING,  
  workPhone STRING,  
  homeAddress RECORD (street STRING, city STRING, state STRING,  
    zip INTEGER CHECK(zip >= 00000 and zip <= 99999)),  
  workAddress RECORD (street STRING, city STRING, state STRING,  
    zip INTEGER CHECK(zip >= 00000 and zip <= 99999)),  
  PRIMARY KEY(uid))
```

Alternatively, you can create an array of record fields. This allows you to create an unlimited number of address records per field. Note, however, that in general you should use child tables in this case.

```sql
CREATE TABLE myContactsTable (  
  uid STRING,  
  surname STRING,  
  familiarName STRING,  
  homePhone STRING,  
  workPhone STRING,  
  homeAddress [RECORD (street STRING, city STRING, state STRING,  
    zip INTEGER CHECK(zip >= 00000 and zip <= 99999))],  
  workAddress [RECORD (street STRING, city STRING, state STRING,  
    zip INTEGER CHECK(zip >= 00000 and zip <= 99999))],  
  PRIMARY KEY(uid))
```
uid STRING,
surname STRING,
familiarName STRING,
homePhone STRING,
workPhone STRING,
addresses ARRAY(RECORD (street STRING, city STRING, state STRING,
    zip INTEGER CHECK(zip >= 00000 and zip <= 99999)),
    PRIMARY KEY(uid))

---

### Defining Child Tables

Oracle NoSQL Database tables can be organized in a parent/child hierarchy. There is no limit to how many child tables you can create, nor is there a limit to how deep the child table nesting can go.

By default, child tables are not retrieved when you retrieve a parent table, nor is the parent retrieved when you retrieve a child table.

To create a child table, you name the table using the format: `<parentTableName>.<childTableName>`. For example, suppose you had the trivial table called `myInventory`:

```sql
CREATE TABLE myInventory (
    itemCategory STRING,
    description STRING,
    PRIMARY KEY (itemCategory)
)
```

We can create a child table called `itemDetails` in the following way:

```sql
CREATE TABLE myInventory.itemDetails (
    itemSKU STRING,
    itemDescription STRING,
    price FLOAT,
    inventoryCount INTEGER,
    PRIMARY KEY (itemSKU)
)
```

Note that when you do this, the child table inherits the parent table's primary key. In this trivial case, the child table's primary key is actually two fields: `itemCategory` and `itemSKU`. This has several ramifications, one of which is that the parent's primary key fields are retrieved when you retrieve the child table. See Retrieve a Child Table (page 35) for more information.

### Table Evolution

In the event that you must update your application at some point after it goes into production, there is a good chance that your tables will also have to be updated to either use new fields or remove existing fields that are no longer in use. You do this through the use of the `ALTER TABLE` statement. See Modify Table Definitions (page 90) for details on this statement.
Note that you cannot remove a field if it is a primary key field. You also cannot add primary key field during table evolution.

Tables can only be evolved if they have already been added to the store.

For example, the following statements evolve the table that was created in the previous section. Note that these would be submitted to the store, one after another, using either the API or the CLI.

```
ALTER TABLE myInventory.itemDetails (ADD salePrice FLOAT)
ALTER TABLE myInventory.itemDetails (DROP inventoryCount)
```

## Creating Indexes

Indexes represent an alternative way of retrieving table rows. Normally you retrieve table rows using the row's primary key. By creating an index, you can retrieve rows with dissimilar primary key values, but which share some other characteristic.

Indexes can be created on any field which is an indexable datatype, including primary key fields. See Indexable Field Types (page 20) for information on the types of fields that can be indexed.

For example, if you had a table representing types of automobiles, the primary keys for each row might be the automobile's manufacturer and model type. However, if you wanted to be able to query for all automobiles that are painted red, regardless of the manufacturer or model type, you could create an index on the table's field that contains color information.

### Note

Indexes can take a long time to create because Oracle NoSQL Database must examine all of the data contained in the relevant table in your store. The smaller the data contained in the table, the faster your index creation will complete. Conversely, if a table contains a lot of data, then it can take a long time to create indexes for it.

```
CREATE TABLE myInventory.itemDetails (
  itemSKU STRING,
  itemDescription STRING,
  price FLOAT,
  inventoryCount INTEGER,
  PRIMARY KEY (itemSKU)
)
```

To create an index, use the CREATE INDEX statement. See CREATE INDEX (page 91) for details. For example:

```
CREATE INDEX inventoryIdx on myInventory.itemDetails(inventoryCount)
```

Similarly, to remove an index, use the DROP INDEX statement. See DROP INDEX (page 92) for details.

```
DROP INDEX inventoryIdx on myInventory.itemDetails
```
Be aware that adding and dropping indexes can take a long time. You might therefore want to run these operations asynchronously using the Store.executeFuture() method.

```javascript
... 
// Store handle configuration and open skipped for brevity 
...

store.on('open', function () {
  console.log('Store opened');

  store.executeFuture('CREATE INDEX inventoryIdx on ' +
    'myInventory.itemDetails(inventoryCount)',
    function(err){
      if (err)
        throw err;
      else {
        console.log('Index creation succeeded.');
        store.close();
      }
    });
}).on('close', function() {
  console.log('Store closed.');
}).on('error', function(error) {
  console.log(error);
});
store.open();
```

### Indexable Field Types

Fields can be indexed only if they are declared to be one of the following types. For all complex types (arrays, maps, and records), the field can be indexed if the ultimate target of the index is a scalar datatype. So a complex type that contains a nested complex type (such as an array of records, for example) can be indexed if the index's target is a scalar datatype contained by the embedded record.

- Integer
- Long
- Float
- Double
- String
- Enum
- Array

In the case of arrays, the field can be indexed only if the array contains values that are of one of the other indexable scalar types. For example, you can create an index on an
array of Integers. You can also create an index on a specific record in an array of records. Only one array can participate in an index, otherwise the size of the index can grow exponentially because there is an index entry for each array entry.

- Maps

As is the case with Arrays, you can index a map if the map contains scalar types, or if the map contains a record that contains scalar types.

- Records

Like Arrays and Maps, you can index fields in an embedded record if the field contains scalar data.

See Indexing Non-Scalar Data Types (page 55) for examples of how to index supported non-scalar types.
Chapter 4. Primary and Shard Key Design

*Primary keys* and *shard keys* are important concepts for your table design. What you use for primary and shard keys has implications in terms of your ability to read multiple rows at a time. But beyond that, your key design has important performance implications.

**Primary Keys**

Every table must have one or more fields designated as the primary key. This designation occurs at the time that the table is created, and cannot be changed after the fact. A table’s primary key uniquely identifies every row in the table. In the simplest case, it is used to retrieve a specific row so that it can be examined and/or modified.

For example, a table might have five fields: `productName`, `productType`, `color`, `size`, and `inventoryCount`. To retrieve individual rows from the table, it might be enough to just know the product’s name. In this case, you would set the primary key field as `productName` and then retrieve rows based on the product name that you want to examine/manipulate.

In this case, the table statement you use to define this table is:

```sql
CREATE TABLE myProducts (  
  productName STRING,  
  productType STRING,  
  color ENUM (blue,green,red),  
  size ENUM (small,medium,large),  
  inventoryCount INTEGER,  
  // Define the primary key. Every table must have one.  
  PRIMARY KEY (productName)  
)
```

However, you can use multiple fields for your primary keys. For example:

```sql
CREATE TABLE myProducts (  
  productName STRING,  
  productType STRING,  
  color ENUM (blue,green,red),  
  size ENUM (small,medium,large),  
  inventoryCount INTEGER,  
  // Define the primary key. Every table must have one.  
  PRIMARY KEY (productName, productType)  
)
```

On a functional level, doing this allows you to delete multiple rows in your table in a single atomic operation. In addition, multiple primary keys allows you to retrieve a subset of the rows in your table in a single atomic operation.

We describe how to retrieve multiple rows from your table in Reading Table Rows (page 33). We show how to delete multiple rows at a time in Using multiDelete() (page 30).
Data Type Limitations

Fields can be designated as primary keys only if they are declared to be one of the following types:

- Integer
- Long
- Float
- Double
- String
- Enum

Partial Primary Keys

Some of the methods you use to perform multi-row operations allow, or even require, a partial primary key. A partial primary key is, simply, a key where only some of the fields comprising the row’s primary key are specified.

For example, the following example specifies three fields for the table’s primary key:

```
CREATE TABLE myProducts (
  productName STRING,
  productType STRING,
  productClass STRING,
  color ENUM (blue,green,red),
  size ENUM (small,medium,large),
  inventoryCount INTEGER,
  // Define the primary key. Every table must have one.
  PRIMARY KEY (productName, productType, productClass)
)
```

In this case, a full primary key would be one where you provide value for all three primary key fields: productName, productType, and productClass. A partial primary key would be one where you provide values for only one or two of those fields.

Note that order matters when specifying a partial key. The partial key must be a subset of the full key, starting with the first field specified and then adding fields in order. So the following partial keys are valid:

```
productName
productName, productType
```

Shard Keys

Shard keys identify which primary key fields are meaningful in terms of shard storage. That is, rows which contain the same values for all the shard key fields are guaranteed to be stored on
the same shard. This matters for some operations that promise atomicity of the results. (See Executing a Sequence of Operations (page 80) for more information.)

For example, suppose you set the following primary keys:

```plaintext
PRIMARY KEY (productType, productName, productClass)
```

You can guarantee that rows are placed on the same shard using the values set for the `productType` and `productName` fields like this:

```plaintext
PRIMARY KEY (SHARD(productType, productName), productClass)
```

Note that order matters when it comes to shard keys. The keys must be specified in the order that they are defined as primary keys, with no gaps in the key list. In other words, given the above example, it is impossible to set `productType` and `productClass` as shard keys without also specifying `productName` as a shard key.

---

### Row Data

There are no restrictions on the size of your rows, or the amount of data that you store in a field. However, you should consider your store’s performance when deciding how large you are willing to allow your individual tables and rows to become. As is the case with any data storage scheme, the larger your rows, the longer it takes to read the information from storage, and to write the information to storage.

On the other hand, every table row carries with it some amount of overhead. Also, as the number of your rows grows very large, search times may be adversely affected. As a result, choosing to use a large number of tables, each of which use rows with just a small handful of fields, can also harm your store’s performance.

Therefore, when designing your tables’ content, you must find the appropriate balance between a small number of tables, each of which uses very large rows; and a large number of tables, each of which uses very small rows. You should also consider how frequently any given piece of information will be accessed.

For example, suppose your table contains information about users, where each user is identified by their first and last names (surname and familiar name). There is a set of information that you want to maintain about each user. Some of this information is small in size, and some of it is large. Some of it you expect will be frequently accessed, while other information is infrequently accessed.

Small properties are:

- name
- gender
- address
- phone number

Large properties are:
• image file
• public key 1
• public key 2
• recorded voice greeting

There are several possible ways you can organize this data. How you should do it depends on your data access patterns.

For example, suppose your application requires you to read and write all of the properties identified above every time you access a row. (This is unlikely, but it does represent the simplest case.) In that event, you might create a single table with rows containing fields for each of the properties you maintain for the users in your application.

However, the chances are good that your application will not require you to access all of a user's properties every time you access his information. While it is possible that you will always need to read all of the properties every time you perform a user look up, it is likely that on updates you will operate only on some properties.

Given this, it is useful to consider how frequently data will be accessed, and its size. Large, infrequently accessed properties should be placed in tables other than that used by the frequently accessed properties.

For example, for the properties identified above, suppose the application requires:

• all of the small properties to always be used whenever the user's record is accessed.

• all of the large properties to be read for simple user look ups.

• on user information updates, the public keys are always updated (written) at the same time.

• The image file and recorded voice greeting can be updated independently of everything else.

In this case, you might store user properties using a table and a child table. The parent table holds rows containing all the small properties, plus public keys. The child table contains the image file and voice greeting.

```
CREATE TABLE userInfo (  
surname STRING,  
familiarName STRING,  
gender ENUM (male,female),  
street STRING,  
city STRING,  
state STRING,  
zipcode STRING,  
userPhone STRING,  
publickey1 BINARY,  
publickey2 BINARY,  
```
Because the parent table contains all the data that is accessed whenever user data is accessed, you can update that data all at once using a single atomic operation. At the same time, you avoid retrieving the big data values whenever you retrieve a row by splitting the image data and voice greeting into a child table.
Chapter 5. Writing and Deleting Table Rows

This chapter discusses two different write operations: putting table rows into the store, and then deleting them.

Write Errors

There are many errors that you should handle whenever you perform a write operation to the store. Some of the more common errors are described here. For simple cases where you use default policies or are not using a secure store, you can probably avoid explicitly handling these. However, as your code complexity increases, so too will the desirability of explicitly managing these errors.

The first of these is `DurabilityException`. This error indicates that the operation cannot be completed because the durability policy cannot be met. For more information, see Durability Guarantees (page 75).

The second is `RequestTimeoutException`. This simply means that the operation could not be completed within the amount of time provided by the store's timeout property. This probably indicates an overloaded system. Perhaps your network is experiencing a slowdown, or your store's nodes are overloaded with too many operations (especially write operations) coming in too short of a period of time.

To handle a `RequestTimeoutException`, you could simply log the error and move on, or you could pause for a short period of time and then retry the operation. You could also retry the operation, but use a longer timeout value.

You can also receive an `IllegalArgumentException`, which will be thrown if a Row that you are writing to the store does not have a primary key or is otherwise invalid.

You can also receive a general `FaultException`, which indicates that some error occurred which is neither a problem with durability nor a problem with the request timeout. Your only recourse here is to either log the error and move along, or retry the operation.

Finally, if you are using a secure store that requires authentication, you can receive `AuthenticationFailureException` or `AuthenticationRequiredException` if you do not provide the proper authentication credentials. When using a secure store, you can also see `UnauthorizedException`, which means you are attempting an operation for which the authenticated user does not have the proper permissions.

Writing Rows to a Table in the Store

Writing a new row to a table in the store, and updating an existing row are usually identical operations (although methods exist that work only if the row is being updated, or only if it is being created — these are described a little later in this section).

Remember that you can only write data to a table after it has been added to the store. See Introducing Oracle NoSQL Database Tables and Indexes (page 14) for details.
To write a row to a table in the store:

1. Create a store handle and open it.

2. Construct a Row node.js object. Each name in the object's name:value pairs must correspond to field name that has been declared for the table to which you will write the row.

3. Use the Store.put() method to write the row to the store. This method has two required arguments. The first identifies the table to which you want to write the row. The second accepts the Row object you constructed in the previous step.

For example:

```javascript
var nosqldb = require('nosqldb-oraclejs');

// Create a configuration object
var configuration = new nosqldb.Configuration();
configuration.proxy.startProxy = false;
configuration.proxy.host = 'localhost:7010';
configuration.storeHelperHosts = ['localhost:5000'];
configuration.storeName = 'kvstore';

// Open the store with the specified configuration
var store = nosqldb.createStore(configuration);

store.on('open', function () {
    console.log('Store opened');

    var row = {item: "Bolts",
                description: "Hex head, stainless",
                count: 5,
                percentage: 0.2173913};

    store.put('myTable', row,
               function (err) {
                   if (err)
                       throw err;
                   else {
                       console.log("Row inserted.");
                       store.close();
                   }
               });
}).on('close', function() {
    console.log('Store closed.');
}).on('error', function(error) {
    console.log(error);
});
store.open();
```
Writing Rows to a Child Table

To write to a child table, first create the row in the parent table to which the child belongs. You do this by populating the parent row with data. Then you write the child table's row(s). When you do, you must specify the primary key used by the parent table, as well as the primary key used by the child table's rows.

For example, in Defining Child Tables (page 18) we showed how to create a child table. To write data to that table, do this:

```javascript
var nosqldb = require('nosqldb-oraclejs');

// Create a configuration object
var configuration = new nosqldb.Configuration();
configuration.proxy.startProxy = false;
configuration.proxy.host = 'localhost:7010';
configuration.storeHelperHosts = ['localhost:5000'];
configuration.storeName = 'kvstore';

// Create a store with the specified configuration
var store = nosqldb.createStore(configuration);

store.on('open', function () {
    console.log('Store opened');
    
    var parentRow = {itemCategory:'Bolts',
                     description:'Metric & US sizes'};
    store.put('myInventory', parentRow,
               function (err) {
                   if (err)
                       throw err;
                   else
                       console.log("Parent row inserted.");
               });

    var childRow = {itemCategory:'Bolts',
                    itemSKU:'1392610',
                    itemDescription:"1/4-20 x 1/2 Grade 8 Hex",
                    price:11.99,
                    inventoryCount:1457};
    store.put('myInventory.itemDetails', childRow,
               function (err) {
                   if (err)
                       throw err;
                   else
                       console.log("Child row inserted.");
                       store.close();
               });
```

Other put Operations

Beyond the very simple usage of the Store.put() method illustrated above, there are three other put operations that you can use:

- **Store.putIfAbsent()**

  This method will only put the row if the row's primary key value DOES NOT currently exist in the table. That is, this method is successful only if it results in a create operation.

- **Store.putIfPresent()**

  This method will only put the row if the row's primary key value already exists in the table. That is, this method is only successful if it results in an update operation.

- **Store.putIfVersion()**

  This method will put the row only if the value matches the supplied version information. For more information, see Using Row Versions (page 67).

Deleting Rows from the Store

You delete a single row from the store using the Store.delete() method. Rows are deleted based on a PrimaryKey, which you construct using a Javascript object. You can also require a row to match a specified version before it will be deleted. To do this, use the Store.deleteIfVersion() method. Versions are described in Using Row Versions (page 67).

When you delete a row, you must handle the same errors as occur when you perform any write operation on the store. See Write Errors (page 27) for a high-level description of these errors.

```javascript
var primaryKey = {id:0};
store.delete('myTable', primaryKey,
function (err) {
    if (err)
        throw err;
    else
        console.log("Row deleted.");
});
```

Using multiDelete()

You can delete multiple rows at once in a single atomic operation, so long as they all share the shard key values. Recall that shard keys are at least a subset of your primary keys. The result
is that you use a partial primary key (which happens to be a shard key) to perform a multi-delete.

To delete multiple rows at once, use the Store.multiDelete() method.

For example, suppose you created a table like this:

```sql
CREATE TABLE myTable (
    itemType STRING,
    itemCategory STRING,
    itemClass STRING,
    itemColor STRING,
    itemSize STRING,
    price FLOAT,
    inventoryCount INTEGER,
    PRIMARY KEY (SHARD(itemType, itemCategory, itemClass), itemColor, itemSize)
)
```

With tables containing data like this:

- Row 1:
  
  itemType: Hats
  itemCategory: baseball
  itemClass: longbill
  itemColor: red
  itemSize: small
  price: 12.07
  inventoryCount: 127

- Row 2:
  
  itemType: Hats
  itemCategory: baseball
  itemClass: longbill
  itemColor: red
  itemSize: medium
  price: 13.07
  inventoryCount: 201

- Row 3:
  
  itemType: Hats
  itemCategory: baseball
  itemClass: longbill
  itemColor: red
  itemSize: large
  price: 14.07
  inventoryCount: 39
Then in this case, you can delete all the rows sharing the partial primary key Hats, baseball, longbill as follows:

```javascript
var primaryKey = {itemType:'Hats',
                  itemCategory:'baseball',
                  itemClass:'longbill'};
store.mulitDelete('myTable', primaryKey,
                 function (err) {
                   if (err)
                     throw err;
                   else
                     console.log("Rows deleted.");
                 });
```
Chapter 6. Reading Table Rows

There are several ways to retrieve table rows from the store. You can:

1. Retrieve a single row at a time using the Store.get() method.

2. Retrieve rows associated with a shard key (which is based on at least part of your primary keys) using the Store.multiGet() method.

3. Retrieve table rows that share a shard key, or an index key, using the Store.tableIterator() method.

4. Retrieve and process records from each shard in parallel using a single key as the retrieval criteria. Use one of the TableAPI.tableIterator() or TableAPI.tableKeysIterator() methods that provide parallel scans.

5. Retrieve and process records from each shard in parallel using a sequence of keys as the retrieval criteria. Use one of the TableAPI.tableIterator() or TableAPI.tableKeysIterator() methods that provide bulk retrievals.

Each of these are described in the following sections.

Read Errors

Several errors can occur when you attempt a read operation in the store. The first of these is ConsistencyException. This error indicates that the operation cannot be completed because the consistency policy cannot be met. For more information, see Consistency Guarantees (page 69).

The second error is RequestTimeoutException. This means that the operation could not be completed within the amount of time provided by the store's timeout property. This probably indicates a store that is attempting to service too many read requests all at once. Remember that your data is partitioned across the shards in your store, with the partitioning occurring based on your shard keys. If you designed your keys such that a large number of read requests are occurring against a single key, you could see request timeouts even if some of the shards in your store are idle.

A request timeout could also be indicative of a network problem that is causing the network to be slow or even completely unresponsive.

To handle a RequestTimeoutException, you could simply log the error and move on, or you could pause for a short period of time and then retry the operation. You could also retry the operation, but use a longer timeout value.

You can also receive an IllegalArgumentException, which will be thrown if a Row that you are writing to the store does not have a primary key or is otherwise invalid.

You can also receive a general FaultException, which indicates that some error occurred which is neither a problem with consistency nor a problem with the request timeout. Your only recourse here is to either log the error and move along, or retry the operation.
You can also receive a `MetadataNotFoundException`, which indicates that a client's metadata may be out of sync. It extends `FaultException` and can be caught by applications to trigger the need for a refresh of their metadata, and in particular, Table handles obtained via `TableAPI.getTable()`.

Finally, if you are using a secure store that requires authentication, you can receive `AuthenticationFailureException` or `AuthenticationRequiredException` if you do not provide the proper authentication credentials. When using a secure store, you can also see `UnauthorizedException`, which means you are attempting an operation for which the authenticated user does not have the proper permissions.

## Retrieving a Single Row

To retrieve a single row from the store:

1. Create a store handle and open it.
2. Construct a `Row node.js` object. Each name/value pair in the object must correspond to the primary key and value for the row that you want to retrieve. In this case, the full primary key must be present in the object.
3. Retrieve the row using `Store.get()`. This performs the store read operation.
4. The retrieved row can be obtained using the `GetResult.currentRow()` method.

For example, in [Writing Rows to a Table in the Store](page 27) we showed a trivial example of storing a table row to the store. The following trivial example shows how to retrieve that row.

```javascript
var nosqldb = require('nosqldb-oraclejs');

// Create a configuration object
var configuration = new nosqldb.Configuration();
configuration.proxy.startProxy = false;
configuration.proxy.host = 'localhost:7010';
configuration.storeHelperHosts = ['localhost:5000'];
configuration.storeName = 'kvstore';

// Open the store with the specified configuration
var store = nosqldb.createStore(configuration);

store.on('open', function () {
    console.log('Store opened');

    var primaryKey = {item: "Bolts"};

    store.get('myTable', primaryKey,
        function (err, result) {
            if (err)
                throw err;
            else {
                console.log("Row retrieved.");
            }
    });
```
Retrieve a Child Table

In Writing Rows to a Child Table (page 29) we showed how to populate a child table with data. To retrieve that data, you must specify the primary key used for the parent table row, as well as the primary key for the child table row. For example:

```javascript
// Store handle configuration and open skipped for brevity
...

store.on('open', function () {
    console.log('Store opened');

    var primaryKey = {itemCategory: "Bolts",
                     itemSKU: '1392610'};

    store.get('myInventory.itemDetails', primaryKey,
              function (err, result) {
                  if (err)
                      throw err;
                  else {
                      console.log("Row retrieved.");
                      console.log(result.currentRow);
                      store.close();
                   }
              });

}).on('close', function() {
    console.log('Store closed.');
}).on('error', function(error) {
    console.log(error);
});

store.open();
```

For information on how to iterate over nested tables, see Iterating with Nested Tables (page 42).

Using multiGet()

Store.multiGet() allows you to retrieve multiple rows at once, so long as they all share the same shard keys. You must specify a full set of shard keys to this method.
Use `Store.multiGet()` only if your retrieval set will fit entirely in memory.

For example, suppose you have a table that stores information about products, which is designed like this:

```sql
CREATE TABLE myTable (  
  itemType STRING,  
  itemCategory STRING,  
  itemClass STRING,  
  itemColor STRING,  
  itemSize STRING,  
  price FLOAT,  
  inventoryCount INTEGER,  
  PRIMARY KEY (SHARD(itemType, itemCategory, itemClass), itemColor, itemSize)
)
```

With tables containing data like this:

- **Row 1:**
  - `itemType`: Hats
  - `itemCategory`: baseball
  - `itemClass`: longbill
  - `itemColor`: red
  - `itemSize`: small
  - `price`: 12.07
  - `inventoryCount`: 127

- **Row 2:**
  - `itemType`: Hats
  - `itemCategory`: baseball
  - `itemClass`: longbill
  - `itemColor`: red
  - `itemSize`: medium
  - `price`: 13.07
  - `inventoryCount`: 201

- **Row 3:**
  - `itemType`: Hats
  - `itemCategory`: baseball
  - `itemClass`: longbill
  - `itemColor`: red
  - `itemSize`: large
  - `price`: 14.07
  - `inventoryCount`: 39

In this case, you can retrieve all of the rows with their `itemType` field set to Hat and their `itemCategory` field set to baseball. Notice that this represents a partial primary key, because `itemClass`, `itemColor` and `itemSize` are not used for this query.
// Store handle configuration and open skipped for brevity

store.on('open', function () {
  console.log('Store opened');

  var shardKey = {itemType: "Hats",
                  itemCategory: "baseball",
                  itemClass: "longbill"};

  store.multiGet('myTable', shardKey, null,
         function (err, result) {
            if (err)
              throw err;
            else {
              console.log("Retrieved rows:");

              for (var key in result.returnRows)
                console.log(result.returnRows[key].row);

              store.close();
            }
        });
  }).on('close', function() {
    console.log('Store closed.');
  }).on('error', function(error) {
    console.log(error);
  });
store.open();

Notice in the previous example that you can iterate over the results, which are returned in a MultiGetResult object. This object contains the result set in an array held by the returnRows property. Each element in this array provides the retrieved row (accessible using the row property), as well as the table name (returnRows[x].table) and row version information (returnRows[x].version).

Iterating over Table Rows

Store.tableIterator() provides non-atomic table iteration.

Store.tableIterator() does not return the entire set of rows all at once. Instead, it batches the fetching of rows in the iterator, to minimize the number of network round trips, while not monopolizing the available bandwidth. Also, the rows returned by this method are in unsorted order.

Note that this method does not result in a single atomic operation. Because the retrieval is batched, the return set can change over the course of the entire retrieval operation. As a result, you lose the atomicity of the operation when you use this method.
This method provides for an unsorted traversal of rows in your table. If you do not provide a key, then this method will iterate over all of the table's rows.

When using this method, you can optionally specify:

• A FieldRange object, which defines a range of values to be retrieved for the specified key.

• A list of parent and ancestor tables to include in the iteration.

• A ReadOptions object, which allows you to specify a consistency policy for the operation, as well as an upper bound on the amount of time that the operation is allowed to take. Consistency policies are described in Consistency Guarantees (page 69)

• An iteration direction. FORWARD and REVERSE are supported.

For example, suppose you have a table that stores information about products, which is designed like this:

```
CREATE TABLE myTable (
    itemType STRING,
    itemCategory STRING,
    itemClass STRING,
    itemColor STRING,
    itemSize STRING,
    price FLOAT,
    inventoryCount INTEGER,
    PRIMARY KEY (SHARD(itemType, itemCategory, itemClass), itemColor, itemSize)
)
```

With tables containing data like this:

• Row 1:
  
  itemType: Hats
  itemCategory: baseball
  itemClass: longbill
  itemColor: red
  itemSize: small
  price: 12.07
  inventoryCount: 127

• Row 2:
  
  itemType: Hats
  itemCategory: baseball
  itemClass: longbill
  itemColor: red
  itemSize: medium
  price: 13.07
  inventoryCount: 201

• Row 3:
Then in the simplest case, you can retrieve all of the rows related to 'Hats' using
Store.tableIterator() as follows. Note that this simple example can also be accomplished
using the Store.multiGet() method. If you have a complete shard key, and if the
entire results set will fit in memory, then multiGet() will perform much better than
tableIterator(). However, if the results set cannot fit entirely in memory, or if you do
not have a complete shard key, then tableIterator() is the better choice. Note that reads
performed using tableIterator() are non-atomic, which may have ramifications if you are
performing a long-running iteration over records that are being updated.

```
// Store handle configuration and open skipped for brevity
...

// Open the store with the specified configuration
var store = nosqldb.createStore(configuration);

store.on('open', function () {
    console.log('Store opened');

    var key = {itemType: "Hats"};

    store.tableIterator('myTable', key, null,
        function (err, iterator) {
            if (err)
                throw err;
            else {
                // Configure Iterator event done
                iterator.on('done', function() {
                    store.close();
                });
        });
```
Specifying Field Ranges

When performing multi-key operations in the store, you can specify a range of rows to operate upon. You do this using a FieldRange object, which is accepted by any of the methods which perform bulk reads. This object is used to restrict the selected rows to those matching a range of field values.

For example, suppose you defined a table like this:

```sql
CREATE TABLE myTable (  
surname STRING,  
familiarName STRING,  
userID STRING,  
phoneNumber STRING,  
address STRING,  
email STRING,  
dateOfBirth STRING,  
PRIMARY KEY (SHARD(surname, familiarName), userID)
)
```

The surname contains a person's family name, such as Smith. The familiarName contains their common name, such as Bob, Patricia, Robert, and so forth.

Given this, you could perform operations for all the rows related to users with a surname of Smith, but we can limit the result set to just those users with familiar names that fall alphabetically between Bob and Patricia by specifying a field range.

A FieldRange is created using the FieldRange class, which you provide to the method you are using to perform the multi-read operation using the Options object. This class requires the name of the primary key field for which you want to set the range, as well the range values, including whether they are inclusive.
In this case, we will define the start of the key range using the string "Bob" and the end of the key range to be "Patricia". Both ends of the key range will be inclusive.

In this example, we use TableIterator, but we could just as easily use this range on any multi-row read operation, such as the Store.multiGet() or Store.multiGetKeys() methods.

```javascript
...
// Store handle configuration and open skipped for brevity
...

// Open the store with the specified configuration
var store = nosqldb.createStore(configuration);

store.on('open', function () {
  console.log('Store opened');

  // Using a partial primary key for
  // this iteration
  var key = {surname: "Smith"};

  var fieldRange = new nosqldb.Types.FieldRange(
    "familiarName", "Bob", true,
    "Patricia", true);

  store.tableIterator('myTable', key, {
    fieldRange: fieldRange,
    // Must be UNORDERED because we are iterating
    // using a partial primary key.
    direction: nosqldb.Types.Direction.UNORDERED
  },
  function (err, iterator) {
    if (err)
      throw err;
    else {

      // Configure Iterator event done
      iterator.on('done', function() {
        store.close();
      });

      console.log("Retrieved rows:");

      iterator.forEach(function (err, returnRow) {
        if (err)
          throw err;
        else
          console.log(returnRow.row);
          console.log('n');
      });
    }
  });
```

Iterating with Nested Tables

When you are iterating over a table, or performing a multi-get operation, by default only rows are retrieved from the table on which you are operating. However, you can use the options object for the retrieval method to specify that parent and child tables are to be retrieved as well.

When you do this, parent tables are retrieved first, then the table you are operating on, then child tables. In other words, the tables' hierarchical order is observed.

The parent and child tables retrieved are identified using a text array, which is then provided to the options object's includedTables property.

When operating on rows retrieved from multiple tables, it is your responsibility to determine which table the row belongs to.

For example, suppose you create a table with a child and grandchild table like this:

```sql
CREATE TABLE prodTable (
    prodType STRING,
    typeDescription STRING,
    PRIMARY KEY (prodType)
)
CREATE TABLE prodTable.prodCategory (  
    categoryName STRING,
    categoryDescription STRING,
    PRIMARY KEY (categoryName)
)
CREATE TABLE prodTable.prodCategory.item (  
    itemSKU STRING,
    itemDescription STRING,
    itemPrice FLOAT,
    vendorUID STRING,
    inventoryCount INTEGER,
    PRIMARY KEY (itemSKU)
)
```

With tables containing data like this:

- Row 1:

  prodType: Hardware
  typeDescription: Equipment, tools and parts
• Row 1.1:
  
  categoryName: Bolts  
  categoryDescription: Metric & US Sizes  

• Row 1.1.1:
  
  itemSKU: 1392610  
  itemDescription: 1/4-20 x 1/2 Grade 8 Hex  
  itemPrice: 11.99  
  vendorUID: A8LN99  
  inventoryCount: 1457

• Row 2:
  
  prodType: Tools  
  typeDescription: Hand and power tools

• Row 2.1:
  
  categoryName: Handtools  
  categoryDescription: Hammers, screwdrivers, saws  

• Row 2.1.1:
  
  itemSKU: 1582178  
  itemDescription: Acme 20 ounce claw hammer  
  itemPrice: 24.98  
  vendorUID: D6BQ27  
  inventoryCount: 249

In the following example, notice that we identify which table we are displaying by examining the `ReturnRow`'s `table` property.

```javascript
...  
// Store handle configuration and open skipped for brevity  
...

store.on('open', function () {
  console.log('Store opened');

  // Using an empty primary key for
  // this iteration
  var key = {};

  // Identify the child tables to include
  // in the iteration.
  var includeTables = ['prodTable.prodCategory',
                        'prodTable.prodCategory.item'];

  store.tableIterator('prodTable', key, {
```
function (err, iterator) {
    if (err)
        throw err;
    else {

        // Configure Iterator event done
        iterator.on('done', function() {
            store.close();
        });

        console.log("Retrieved rows:");

        iterator.forEach(function (err, retRow) {
            if (err)
                throw err;
            else {
                // It is necessary for our code to
                // identify which table we are
                // displaying.
                if (retRow.table == 'prodTable') {
                    console.log('Type: ' + retRow.row.prodType);
                    console.log('Description: ' + retRow.row.typeDescription);
                } else if (retRow.table == 'prodTable.prodCategory') {
                    console.log('
	Category: ' + retRow.row.categoryName);
                    console.log('	Description: ' + retRow.row.categoryDescription);
                } else {
                    console.log('
	SKU: ' + retRow.row.itemSKU);
                    console.log('
	Description: ' + retRow.row.itemDescription);
                    console.log('
	Price: ' + retRow.row.itemPrice);
                    console.log('
	Vendor UID: ' + retRow.row.vendorUID);
                    console.log('
	Inventory Count: ' + retRow.row.inventoryCount);
                    console.log('
');
                }
            }
        });
    }
}
Reading Indexes

You use Store.indexIterator() to retrieve table rows using a table's indexes. Just as when you use TableIterator to read table rows using a table's primary key(s), when reading using indexes you can set options such as field ranges, traversal direction, and so forth. By default, index scans return entries in forward order.

For example, suppose you defined a table like this:

```sql
CREATE TABLE myTable (
    surname STRING,
    familiarName STRING,
    userID STRING,
    phonenumber STRING,
    address STRING,
    email STRING,
    dateOfBirth STRING,
    PRIMARY KEY (SHARD(surname, familiarName), userID)
)

CREATE INDEX DoB ON myTable (dateOfBirth)
```

This creates an index named DoB for table myTable based on the value of the dateOfBirth field. To scan through that index, do the following:

```javascript
... // Store handle configuration and open skipped for brevity ...

store.on('open', function () {
    console.log('Store opened');

    store.indexIterator('myTable', 'DoB', {},
        function (err, iterator) {
            if (err)
                throw err;
            else {

                // Configure Iterator event done
                iterator.on('done', function() {
                    store.close();
                });
            }
        });
```

```javascript
});
}).on('close', function() {
    console.log('Store closed.');
}).on('error', function(error) {
    console.log(error);
});
store.open();
```
In the previous example, the code examines every row indexed by the DoB index. A more likely, and useful, example in this case would be to limit the rows returned through the use of a field range. You do that by constructing a FieldRange object. When you do this, you must specify the field to base the range on. Recall that an index can be based on more than one table field, so the field name you give the object must be one of the indexed fields.

For example, if the rows hold dates in the form of yyyy-mm-dd, you could retrieve all the people born in the month of May, 1994 in the following way. This index only examines one field, dateOfBirth, so we give that field name to the FieldRange object:

```javascript
var fieldRange = new nosqldb.Types.FieldRange(
  "dateOfBirth", "1994-05-01", true,
  "1994-05-30", true);

store.indexIterator('myTable', 'DoB', {
  fieldRange: fieldRange
},
function (err, iterator) {
  if (err)
    throw err;
  else {
    // Configure Iterator event done
    iterator.on('done', function() {
```

...
store.close();

console.log("Retrieved rows:");

iterator.forEach(function (err, returnRow) {
  if (err)
    throw err;
  else
    console.log(returnRow.row);
    console.log('\n');
});

store.open();
Chapter 7. Using Data Types

Many of the types that Oracle NoSQL Database offers are easy to use (such as integers and strings). Examples of their usage has been scattered throughout this manual. However, some types are a little more complicated, and so their usage may not be obvious. This chapter briefly shows how to use Arrays, Maps, Records, Enums and Binary data types.

Using Arrays

Arrays are a sequence of values all of the same type.

When you declare a table field as an array, you use the ARRAY() statement.

To define a simple two-field table where the primary key is a UID and the second field contains array of strings, you use the following DDL statement:

```sql
CREATE TABLE myTable (
    uid INTEGER,
    myArray ARRAY(STRING),
    PRIMARY KEY(uid)
)
```

CHECK constraints are supported for array values. See CHECK (page 88) for more details.

DEFAULT and NOT NULL constraints are not supported for arrays.

To write the array:

```javascript
var row = {
    uid: 0,
    myArray: ['One', 'Two', 'Three'],
};

console.log("Putting row");
store.put('myTable', row,
    function (err) {
        if (err)
            throw err;
        else {
            console.log("Row inserted.");
        }
    }
);
```

To retrieve and use the array:

```javascript
var primaryKey = {uid: 0};
store.get('myTable', primaryKey,
    function (err, returnRow) {
        if (err)
            throw err;
        else {
            var myArray = returnRow.currentRow.myArray;
        }
    }
);`
Using Binary

You can declare a field as binary using the BINARY statement. You then read and write the field value as a base64 encoded buffer.

If you want to store a large binary object, then you should use the LOB APIs rather than a binary field, which are only available using the Java Key/Value API. For information on using the LOB APIs, see the Oracle NoSQL API Large Object API introduction.

Note that fixed binary should be used over the binary datatype any time you know that all the field values will be of the same size. Fixed binary is a more compact storage format because it does not need to store the size of the array. See Using Fixed Binary (page 51) for information on the fixed binary datatype.

To define a simple two-field table where the primary key is a UID and the second field contains a binary field, you use the following statement:

```sql
CREATE TABLE myTable (
    uid INTEGER,
    myByteArray BINARY,
    PRIMARY KEY(uid)
)
```

CHECK, DEFAULT and NOT NULL constraints are not supported for binary values.

To write the binary field, use a base64 encoded byte array.

```javascript
var file64 = new Buffer(fs.readFileSync('image.jpg')).toString('base64');
var row = { uid: 0,
    myByteArray: file64}
store.put('myTable', row,
    function (err) {
        if (err)
            throw err;
        else {
            console.log("Row inserted.");
        }
    });
```

To read the binary field, retrieve it as you would any data field. Here, we base64 decode the store object, and stream it to disk without storing it in memory.

For example:
Using Enums

Enumerated types are declared using the `ENUM()` statement. You must declare the acceptable enumeration values when you use this statement.

To define a simple two-field table where the primary key is a UID and the second field contains an enum, you use the following DDL statement:

```sql
CREATE TABLE myTable (
    uid INTEGER,
    myEnum ENUM (Apple,Pears,Oranges),
    PRIMARY KEY (uid)
)
```

CHECK constraints are not supported for enumerated fields.

DEFAULT and NOT NULL constraints are supported for enumerated fields. See DEFAULT (page 89) for more information.

Enum values are handled as strings.

To write the enum:

```javascript
var row = {uid: 0,
    myEnum: 'Pears',
};

store.put('myTable', row,
    function (err) {
        if (err)
            throw err;
        else {
            console.log("Row inserted.");
        }
    });
```

To read the enum:

```javascript
var primaryKey = {uid: 0};
store.get('myTable', primaryKey,
    function (err, returnRow) {
        if (err)
            throw err;
        else {
            fs.writeFileSync('image-retrieved.jpg',
                returnRow.currentRow.myByteArray,
                'base64');
            store.close();
        }
    });
```
Using Fixed Binary

You can declare a fixed binary field using the BINARY() statement. When you do this, you must also specify the field's size in bytes. You then read and write the field value using a base64 encoded buffer. However, if the buffer does not equal the specified size, then IllegalArgumentException is thrown when you attempt to write the field.

If you want to store a large binary object, then you should use the LOB APIs rather than a binary field. For information on using the LOB APIs, see Oracle NoSQL API Large Object API.

Fixed binary should be used over the binary datatype any time you know that all the field values will be of the same size. Fixed binary is a more compact storage format because it does not need to store the size of the array. See Using Binary (page 49) for information on the binary datatype.

To define a simple two-field table where the primary key is a UID and the second field contains a fixed binary field, you use the following DDL statement:

```
CREATE TABLE myTable (
  uid INTEGER,
  myFixedByteArray BINARY(10),
  PRIMARY KEY (uid)
)
```

CHECK, DEFAULT and NOT NULL constraints are not supported for binary values.

To write the byte array:

```
var fixed64 = new Buffer('1234567890').toString('base64');
var row = {uid: 0,
  myFixedByteArray: fixed64
};

store.put('myTable', row,
  function (err) {
    if (err)
      throw err;
    else {
      // returns as a string
      console.log('myEnum: ' + returnRow.currentRow.myEnum);
      store.close();
    }
  }
});
```
To read the fixed binary field, use a base64 encoded buffer:

```javascript
var primaryKey = {uid: 0};
store.get('myTable', primaryKey,
  function (err, returnRow) {
    if (err)
      throw err;
    else {
      var fba = returnRow.currentRow.myFixedByteArray;
      var buf = new Buffer(fba, 'base64').toString('utf-8');
      console.log(buf);
      store.close();
    }
  });
```

## Using Maps

All map entries must be of the same type. Regardless of the type of the map's values, its keys are always strings.

The string "[]" is reserved and must not be used for key names.

When you declare a table field as a map, you use the MAP() statement. You must also declare the map element's data types.

To define a simple two-field table where the primary key is a UID and the second field contains a map of integers, you use the following DDL statement:

```
CREATE TABLE myTable (  
  uid INTEGER,
  myMap MAP(INTEGER),
  PRIMARY KEY (uid)
)
```

CHECK constraints are supported for map fields. See CHECK (page 88) for more information.

DEFAULT and NOT NULL constraints are not supported for map fields.

To write the map:

```javascript
var mmap = {field1: 1, field2: 2, field3: 3};
var row = {uid: 0,  
  myMap: mmap
};

store.put('myTable', row,  
  function (err) {
    if (err)
      throw err;
  });
```
else {
    console.log("Row inserted.");
}
});

To read map field2:

```javascript
var primaryKey = {uid: 0};
store.get('myTable', primaryKey,
    function (err, returnRow) {
        if (err)
            throw err;
        else {
            console.log(returnRow.currentRow.myMap.field2);
            store.close();
        }
    });
```  

### Using Embedded Records

A record entry can contain fields of differing types. However, embedded records should be used only when the data is relatively static. In general, child tables provide a better solution over embedded records, especially if the child dataset is large or is likely to change in size.

Use the RECORD() statement to declare a table field as a record.

To define a simple two-field table where the primary key is a UID and the second field contains a record, you use the following DDL statement:

```sql
CREATE TABLE myTable (
    uid INTEGER,
    myRecord RECORD(firstField STRING, secondField INTEGER),
    PRIMARY KEY (uid)
)
```

CHECK, DEFAULT and NOT NULL constraints are not supported for embedded record fields. However, these constraints can be applied to the individual fields in an embedded record. See Field Constraints (page 88) for more information.

To write the embedded record, create it as a Javascript object:

```javascript
var mrec = {firstField: "An embedded record", secondField: 3388};
var row = {uid: 0, myRecord: mrec};
store.put('myTable', row, 
    function (err) {
        if (err)
            throw err;
        else {
            ```
```javascript
console.log("Row inserted.");
}
});

Then, you can read the field in the usual way:

```javascript
var primaryKey = {uid: 0};
store.get('myTable', primaryKey,
  function (err, returnRow) {
    if (err)
      throw err;
    else {
      console.log(returnRow.currentRow.myRecord);
      store.close();
    }
  })
);
Chapter 8. Indexing Non-Scalar Data Types

We describe how to index scalar data types in Creating Indexes (page 19), and we show how to read using indexes in Reading Indexes (page 45). However, non-scalar data types (Arrays, Maps and Records) require more explanation, which we give here.

Index creation is accomplished using the CREATE INDEX statement. See CREATE INDEX (page 91) for details on this statement.

Indexing Arrays

You can create an index on an array field so long as the array contains scalar data, or contains a record with scalar fields.

Note

You cannot index a map or array that is nested beneath another map or array. This is not allowed because of the potential for an excessively large number of index entries.

Be aware that indexing an array potentially results in multiple index entries for each row, which can lead to very large indexes.

To create the index, first create the table:

```
CREATE TABLE myArrayTable (
    uid INTEGER,
    testArray ARRAY(STRING),
    PRIMARY KEY(uid)
)
```

Once the table has been added to the store, create the index:

```
CREATE INDEX arrayFieldIndex on myArrayTable (testArray)
```

In the case of arrays, the field can be indexed only if the array contains values that are of one of the other indexable types. For example, you can create an index on an array of Integers. You can also create an index on a specific record in an array of records. Only one array should participate in an index, otherwise the size of the index can grow exponentially because there is an index entry for each array entry.

To retrieve data using an index of arrays, create an index key object that identifies the array field and value that you want to retrieve.

When you perform the index lookup, the only records that will be returned will be those which have an array with at least one item matching the value set for the index key object. For example, if you have individual records that contain arrays like this:

Record 1: ["One", "Two", "Three"]
Record 2: ["Two", "Three", "One"]
Record 3: ["One", "Three", "One"]
Record 4: ["Two", "Three", "Four"]

and you then perform an array lookup on the array value "One", then Records 1 - 3 will be returned, but not 4.
For example:

```javascript
// construct the index key
var indexKey1 = {testArray: ["One"]);

store.indexIterator(
    'myArrayTable',          // table name
    'arrayFieldIndex',       // index name
    {indexKey: indexKey1},   // set the index key
    function (err, iterator) {
        iterator.on('done', function () {
            store.close();
        });

        iterator.forEach(function (err, currentRow) {
            console.log(currentRow.row);
        });
    });
```

### Indexing Maps

You can create an index on a map field so long as the map contains scalar data, or contains a record with scalar fields.

**Note**

You cannot index a map or array that is nested beneath another map or array. This is not allowed because of the potential for an excessively large number of index entries.

To create the index, define the map as normal. Once the map is defined for the table, there are several different ways to index it:

- Based on the map's keys without regard to the actual key values.
- Based on the map's values, without regard to the actual key used.
- By a specific map key. To do this, you specify the name of the map field and the name of a map key using dot notation. If the map key is ever created using your client code, then it will be indexed.
- Based on the map's key and value without identifying a specific value (such as is required by the previous option in this list).

### Indexing by Map Keys

You can create indexes based on a map's keys without regard to the corresponding values.

Be aware that creating an index like this can potentially result in multiple index entries for each row, which can lead to very large indexes. In addition, the same row can appear in a result set, so the duplicate entries must be handled by your application.

First create the table:
CREATE TABLE myMapTable (  
  uid INTEGER,  
  testMap MAP(INTEGER),  
  PRIMARY KEY(uid) 
)

Once the table has been added to the store, create the index using the KEYOF statement:

CREATE INDEX mapKeyIndex on myMapTable (KEYOF(testMap))

Data is retrieved if the table row contains the identified map with the identified key. So, for example, if you create a series of table rows like this:

function writeRow(store, uid, map) {
  var row = {  
    uid: uid,  
    testMap: map  
  };  
  store.put('myMapTable', row,  
    function (err) {  
      if (err)  
        throw err;  
      else {  
        console.log("Row inserted.");  
      }  
    }  
  );
}

... // Store handle configuration and open skipped for brevity ...

store.on('open', function () {  
  console.log('Store opened');

  writeRow(store, 12345, {field1: 1, field2: 2, field3: 3});  
  writeRow(store, 12, {field1: 1, field2: 2});  
  writeRow(store, 666, {field1: 1, field3: 4});

  store.close();
}).on('close', function() {  
  console.log('Store closed.');  
}).on('error', function(error) {  
  console.log(error);  
});

store.open();

then you can retrieve any table rows that contain the map with any key currently in use by the map. For example, “field3”.
Note that we use a simple Javascript object to represent the map. Because the index we are using is based on the map's key, we can provide any value we want for the map's key value. Here we just use null, but any other value would provide identical results.

```javascript
function getIndexByFieldName(store, fieldName) {
    var obj = {};
    obj[fieldName] = null;
    var indexKey1 = {testMap: obj}

    store.indexIterator('myMapTable', 'mapKeyIndex',
        {indexKey: indexKey1},
        function (err, iterator) {
            iterator.forEach(function (err, currentRow) {
                console.log(currentRow.row);
            });
        });
}
...
// Store handle configuration and open skipped for brevity...
...
store.on('open', function () {
    console.log('Store opened');
    getIndexByFieldName(store, "field3");
    store.close();
}).on('close', function() {
    console.log('Store closed.');
}).on('error', function(error) {
    console.log(error);
});
store.open();
```

**Indexing by Map Values**

You can create indexes based on the values contained in a map without regard to the keys in use.

Be aware that creating an index like this can potentially result in multiple index entries for each row, which can lead to very large indexes. In addition, the same row can appear in a result set, so the duplicate entries must be handled by your application.

First create the table:

```sql
CREATE TABLE myMapTable (  
    uid INTEGER,
    testMap MAP(INTEGER),
);```
Once the table has been added to the store, create the index using the ELEMENTOF statement:

```
CREATE INDEX mapElementIndex on myMapTable (ELEMENTOF(testMap))
```

Data is retrieved if the table row contains the identified map with the identified value. So, for example, if you create a series of table rows like this:

```javascript
function writeRow(store, uid, map) {

    var row = {
        uid: uid,
        testMap: map
    };
    store.put('myMapTable', row,
        function (err) {
            if (err)
                throw err;
            else {
                console.log("Row inserted.");
            }
        }
    );

    // Store handle configuration and open skipped for brevity
    ...
}
...
store.on('open', function () {
    console.log('Store opened');

    writeRow(store, 12345, {field1: 1, field2: 2, field3: 3});
    writeRow(store, 12, {field1: 1, field2: 2});
    writeRow(store, 666, {field1: 1, field3: 4});

    store.close();
}).on('close', function() {
    console.log('Store closed.');
}).on('error', function(error) {
    console.log(error);
});
store.open();
```

then you can retrieve any table rows that contain the map with any value currently in use by the map. For example, a value of "2".

Notice in the following example that we use the special string "[]" for the index key's field value. The field name must be that string or we will not access the proper index.

```javascript
function getIndexByMapValue(store, mv) {

    console.log('Retrieving rows with value ' + mv);

    var rows = store.find('myMapTable', {ELEMENTOF: "[]"}, function (err, results) {
        if (err)
            throw err;
        else {
            console.log(results.length + ' rows found.
```

...
Indexing by a Specific Map Key Name

You can create an index based on a specified map key name. Any map entries containing the specified key name are indexed. This can create a small and very efficient index because the index does not contain every key/value pair contained by the map fields. Instead, it just contains those map entries using the identified key, which results in at most a single index entry per row.

To create the index, first create the table:

```sql
CREATE TABLE myMapTable (  
  uid INTEGER,  
  testMap MAP(INTEGER),  
  PRIMARY KEY(uid)  
)  
```

Once the table has been added to the store, create the index by specifying the key name you want indexed using dot notation. In this example, we will index the key name of "field3":

```sql
CREATE INDEX mapField3Index on myMapTable (testMap.field3)  
```

Data is retrieved if the table row contains the identified map with the indexed key and a specified value. So, for example, if you create a series of table rows like this:

```javascript
var obj = {};  
obj['[]'] = mv;  
var indexKey1 = {testMap: obj};  

store.indexIterator('myMapTable', 'mapElementIndex',  
  {indexKey: indexKey1},  
  function (err, iterator) {  
    iterator.forEach(function (err, currentRow) {  
      console.log(currentRow.row);  
    });  
  });  
}
```

...// Store handle configuration and open skipped for brevity ...

```javascript
store.on('open', function () {  
  getIndexByMapValue(store, 2);  
  store.close();  
}).on('close', function() {  
  console.log('Store closed.');  
}).on('error', function(error) {  
  console.log(error);  
});  
store.open();  
```
function writeRow(store, uid, map) {
    var row = {
        uid: uid,
        testMap: map
    };
    store.put('myMapTable', row,
        function (err) {
            if (err)
                throw err;
            else {
                console.log("Row inserted.");
            }
        });
}

... Store handle configuration and open skipped for brevity ...

store.on('open', function () {
    console.log('Store opened');
    
    writeRow(store, 12345, {field1: 1, field2: 2, field3: 3});
    writeRow(store, 12, {field1: 1, field2: 2});
    writeRow(store, 666, {field1: 1, field3: 4});

    store.close();
}).on('close', function() {
    console.log('Store closed.');
}).on('error', function(error) {
    console.log(error);
});

store.open();

then you can retrieve any table rows that contain the map with key "field3" (because that is what you indexed) when "field3" maps to a specified value — such as "3". If you try to do an index lookup on, for example, "field2" then that will fail because you did not index "field2".

function getIndexByField3KeyName(store, mv) {
    var indexKey1 = {testMap: {field3: mv}};
    
    store.indexIterator('myMapTable', 'mapField3Index',
        {indexKey: indexKey1},
        function (err, iterator) {
            iterator.forEach(function (err, currentRow) {
                console.log(currentRow.row);
            });
        };
    }
Indexing by Map Key and Value

In the previous section, we showed how to create a map index by specifying a pre-determined key name. This allows you to perform map index lookups by providing both key and value, but the index lookup will only be successful if the specified key is the key that you indexed.

You can do the same thing in a generic way by indexing every key/value pair in your map. The result is a more flexible index, but also an index that is potentially much larger than the previously described method. It is likely to result in multiple index entries per row.

To create an index based on every key/value pair used by the map field, first create the table:

```sql
CREATE TABLE myMapTable (
    uid INTEGER,
    testMap MAP(INTEGER),
    PRIMARY KEY(uid)
)
```

Once the table has been added to the store, create the index by using both the KEYOF and ELEMENTOF keywords:

```sql
CREATE INDEX mapKeyValueIndex on myMapTable 
    (KEYOF(testMap),ELEMENTOF(testmap))
```

Data is retrieved if the table row contains the identified map with the identified key and the identified value. So, for example, if you create a series of table rows like this:

```javascript
function writeRow(store, uid, map) {
    var row = {
        uid: uid,
        testMap: map
    };
    
    // Store handle configuration and open skipped for brevity
    
    store.on('open', function () {
        console.log('Store opened');
        getIndexByField3KeyName(store, 3);
        store.close();
    }).on('close', function() {
        console.log('Store closed.');
    }).on('error', function(error) {
        console.log(error);
    });
    
    store.open();
}
```

```javascript
store.on('open', function () {
    console.log('Store opened');
    getIndexByField3KeyName(store, 3);
    store.close();
}).on('close', function() {
    console.log('Store closed.');
}).on('error', function(error) {
    console.log(error);
});
store.open();
```
store.put('myMapTable', row,
    function (err) {
        if (err)
            throw err;
        else {
            console.log("Row inserted.");
        }
    });
}

then you can retrieve any table rows that contain the map with specified key/value pairs — for example, key “field3” and value “3”.

To retrieve based on this kind of an index, you must provide:

• the special string ‘[]’ with the desired map value; and

• the field name with null for a map value.

You do this in node.js in the following way:

```javascript
function getIndexByKeyAndValue(store, fn, mv) {

    // declare and initialize the object
    var indexKey1 = {};
    indexKey1['testMap'] = {};

    // Now set the information to the object so that the
    // proper index is used, and data is retrieved by our
    // desired values.
    indexKey1.testMap['[]'] = mv;  // set the map value
```

then you can retrieve any table rows that contain the map with specified key/value pairs — for example, key “field3” and value “3”.

To retrieve based on this kind of an index, you must provide:

• the special string ‘[]’ with the desired map value; and

• the field name with null for a map value.

You do this in node.js in the following way:

```javascript
function getIndexByKeyAndValue(store, fn, mv) {

    // declare and initialize the object
    var indexKey1 = {};
    indexKey1['testMap'] = {};

    // Now set the information to the object so that the
    // proper index is used, and data is retrieved by our
    // desired values.
    indexKey1.testMap['[]'] = mv;  // set the map value
```
Indexing Embedded Records

You can create an index on an embedded record field so long as the record field contains scalar data. To create the index, define the record as normal. To index the field, you specify the name of the embedded record and the name of the field using dot notation.

To create the index, first create the table:

```sql
CREATE Table myRecordTable (uid INTEGER, myRecord RECORD (firstField STRING, secondField INTEGER), PRIMARY KEY (uid))
```

Once the table has been added to the store, create the index:

```sql
CREATE INDEX recordFieldIndex on myRecordTable (myRecord.secondField)
```

Data is retrieved if the table row contains the identified record field with the specified value. So, for example, if you create a series of table rows like this:

```javascript
function writeRow(store, uid, record) {
    indexKey1.testMap[fn] = null; // set the field name
    store.indexIterator('myMapTable', 'mapKeyValueIndex',
        {indexKey: indexKey1},
        function (err, iterator) {
            iterator.forEach(function (err, currentRow) {
                console.log(currentRow.row);
            });
        }
    );
}
...
// Store handle configuration and open skipped for brevity
...
store.on('open', function () {
    console.log('Store opened');
    getIndexByKeyAndValue(store, "field3", 3);
    store.close();
}).on('close', function() {
    console.log('Store closed.');
}).on('error', function(error) {
    console.log(error);
});
store.open();
```
```javascript
var row = {
  uid: uid,
  myRecord: record
};
console.log("Putting row");
store.put('myRecordTable', row,
  function (err) {
    if (err)
      throw err;
    else {
      console.log("Row inserted.");
    }
  });
console.log("Row put");
}

... // Store handle configuration and open skipped for brevity ...

store.on('open', function () {
  console.log('Store opened');

  writeRow(store, 12345, {firstField: "String field for 12345",
  secondField: 3388});
  writeRow(store, 345, {firstField: "String field for 345",
  secondField: 3388});
  writeRow(store, 111, {firstField: "String field for 111",
  secondField: 12});
  store.close();
}).on('close', function() {
  console.log('Store closed.');
}).on('error', function(error) {
  console.log(error);
});
store.open();
```

then you can retrieve any table rows that contain the embedded record where "secondField"

is set to a specified value. (The embedded record index that we specified, above, indexed
myRecord.secondField.)

You retrieve the matching table rows, and iterate over them in the same way you would any
other index type. For example:

```javascript
...
  // Store handle configuration and open skipped for brevity ...
  ...
  store.on('open', function () {
```
```javascript
console.log('Store opened');
var indexKey1 = {'myRecord': {'secondField': 3388}}

store.indexIterator('myRecordTable', 'recordFieldIndex',
    {indexKey: indexKey1},
    function (err, iterator) {
        iterator.forEach(function (err, currentRow) {
            console.log(currentRow.row);
        });
        store.close();
    }
).on('close', function () {
    console.log('Store closed.');
}).on('error', function (error) {
    console.log(error);
});
store.open();
```
Chapter 9. Using Row Versions

When a row is initially inserted in the store, and each time it is updated, it is assigned a unique version token. The version is always returned by the method that wrote to the store (for example, Store.put() returns the token as an option for putCallback()). The version information is also returned by methods that retrieve rows from the store.

There are two reasons why versions might be important.

1. When an update or delete is to be performed, it may be important to only perform the operation if the row’s value has not changed. This is particularly interesting in an application where there can be multiple threads or processes simultaneously operating on the row. In this case, read the row, examining its version when you do so. You can then perform a put operation, but only allow the put to proceed if the version has not changed (this is often referred to as a Compare and Set (CAS) or Read, Modify, Write (RMW) operation). You use Store.putIfVersion() or Store.deleteIfVersion() to guarantee this.

2. When a client reads data that was previously written, it may be important to ensure that the Oracle NoSQL Database node servicing the read operation has been updated with the information previously written. This can be accomplished by passing the version of the previously written data as a consistency parameter to the read operation. For more information on using consistency, see Consistency Guarantees (page 69).

Versions are managed using the Version class. In some situations, it is returned as part of another encapsulating class, such as the ReturnRow class.

The following code fragment retrieves a row, and then writes that row back to the store only if the version has not changed:

```javascript
... // Store handle configuration and open skipped for brevity ...

store.on('open', function () {
  console.log('Store opened');

  store.indexIterator('myTable', 'DoB', {},
    function (err, iterator) {
      if (err)
        throw err;
      else {
        // Configure Iterator event done
        iterator.on('done', function() {
          store.close();
        });

        iterator.forEach(function (err, returnRow) {
          if (err)
```
throw err;
else {
    var version = returnRow.version;
    
    /// Do work on the row here
    store.putIfVersion('myTable',
        returnRow.row,
        version,
        function (err) {
            if (err)
                throw err;
            else
                console.log("Row rewritten");
        }
    )
    
    // Do work on the row here
    store.putIfVersion('myTable',
        returnRow.row,
        version,
        function (err) {
            if (err)
                throw err;
            else
                console.log("Row rewritten");
        }
    )
    
    store.open();
Chapter 10. Consistency Guarantees

The KV store is built from some number of computers (generically referred to as nodes) that are working together using a network. All data in your store is first written to a master node. The master node then copies that data to other nodes in the store. Nodes which are not master nodes are referred to as replicas.

Because of the relatively slow performance of distributed systems, there can be a possibility that, at any given moment, a write operation that was performed on the master node will not yet have been performed on some other node in the store.

Consistency, then, is the policy describing whether it is possible for a row on Node A to be different from the same row on Node B.

When there is a high likelihood that a row stored on one node is identical to the same row stored on another node, we say that we have a high consistency guarantee. Likewise, a low consistency guarantee means that there is a good possibility that a row on one node differs in some way from the same row stored on another node.

You can control how high you want your consistency guarantee to be. Note that the trade-off in setting a high consistency guarantee is that your store's read performance might not be as high as if you use a low consistency guarantee.

There are several different forms of consistency guarantees that you can use. They are described in the following sections.

Note that by default, Oracle NoSQL Database uses the lowest possible consistency possible.

Specifying Consistency Policies

To specify a consistency policy, use one of:

- Types.SimpleConsistency()
- Types.TimeConsistency()
- Types.VersionConsistency()

Each of these are described in the following sections.

Once you have selected a consistency policy, you can put it to use in one of two ways. First, you can use it to define a default consistency policy using the Configuration object when you open your Store handle. Specifying a consistency policy in this way means that all store operations will use that policy, unless they are overridden on an operation by operation basis.

The second way to use a consistency policy is to override the default policy using a ReadOptions class instance you provide to the Store method that you are using to perform the store read operation.

The following example shows how to set a default consistency policy for the store. We will show the per-operation method of specifying consistency policies in the following sections.
var nosqldb = require('nosqldb-oraclejs');

// Create a configuration object
var configuration = new nosqldb.Configuration();
configuration.proxy.startProxy = false;
configuration.proxy.host = 'localhost:7010';
configuration.storeHelperHosts = ['localhost:5000'];
configuration.storeName = 'kvstore';
configuration.defaultConsistency = new Types.Consistency(
    Types.SimpleConsistency.ABSOLUTE
);

// Open the store with the specified configuration
var store = nosqldb.createStore(configuration);

---

**Using Simple Consistency**

You can use `Types.SimpleConsistency()` to specify certain rigid consistency guarantees. There are three such instances that you can use:

1. **Types.SimpleConsistency.ABSOLUTE**
   
   Requires that the operation be serviced at the master node. In this way, the row(s) will always be consistent with the master.
   
   This is the strongest possible consistency guarantee that you can require, but it comes at the cost of servicing all read and write requests at the master node. If you direct all your traffic to the master node (which is just one machine for each partition), then you will not be distributing your read operations across your replicas. You also will slow your write operations because your master will be busy servicing read requests. For this reason, you should use this consistency guarantee sparingly.

2. **Types.SimpleConsistency.NONE_REQUIRED**
   
   Allows the store operation to proceed regardless of the state of the replica relative to the master. This is the most relaxed consistency guarantee that you can require. It allows for the maximum possible store performance, but at the high possibility that your application will be operating on stale or out-of-date information.

3. **Types.SimpleConsistency.NONE_REQUIRED_NO_MASTER**
   
   Requires read operations to be serviced on a replica; never the Master. When this policy is used, the read operation will not be performed if the only node available is the Master.
   
   Where possible, this consistency policy should be avoided in favor of the secondary zones feature.

For example, suppose you are performing a critical read operation that you know must absolutely have the most up-to-date data. Then do this:
Using Time-Based Consistency

A time-based consistency policy describes the amount of time that a replica node is allowed to lag behind the master node. If the replica's data is more than the specified amount of time out-of-date relative to the master, then a ConsistencyException is thrown. In that event, you can either abandon the operation, retry it immediately, or pause and then retry it.

In order for this type of a consistency policy to be effective, the clocks on all the nodes in the store must be synchronized using a protocol such as NTP.

In order to specify a time-based consistency policy, you use the `Types.TimeConsistency()` function. This function requires the following information:

- `permissibleLag`
  
  The number of milliseconds the replica is allowed to lag behind the master.

- `timeoutMs`
The number of milliseconds that describes how long the replica is permitted to wait in an attempt to meet the permissible lag limit. That is, if the replica cannot immediately meet the permissible lag requirement, then it will wait this amount of time to see if it is updated with the required data from the master. If the replica cannot meet the permissible lag requirement within the timeout period, a ConsistencyException is thrown.

The following sets a default time-based consistency policy of 2 seconds. The timeout is 4 seconds.

```javascript
var nosqldb = require('nosqldb-oraclejs');
// Create a configuration object
var configuration = new nosqldb.Configuration();
configuration.proxy.startProxy = false;
configuration.proxy.host = 'localhost:7010';
configuration.storeHelperHosts = ['localhost:5000'];
configuration.storeName = 'kvstore';
configuration.defaultConsistency =
    new Types.TimeConsistency(2000, 4000);

// Open the store with the specified configuration
var store = nosqldb.createStore(configuration);
```

### Using Version-Based Consistency

Version-based consistency is used on a per-operation basis. It ensures that a read performed on a replica is at least as current as some previous write performed on the master.

An example of how this might be used is a web application that collects some information from a customer (such as her name). It then customizes all subsequent pages presented to the customer with her name. The storage of the customer's name is a write operation that can only be performed by the master node, while subsequent page creation is performed as a read-only operation that can occur at any node in the store.

Use of this consistency policy might require that version information be transferred between processes in your application.

To create a version-based consistency policy, use the Types.VersionConsistency() function. When you do this, you must provide the following information:

- **version**

  The Version that the read must match.

- **timeout**

  The number of milliseconds that describes how long the replica is permitted to wait in an attempt to meet the version requirement. That is, if the replica cannot immediately meet the version requirement, then it will wait this amount of time to see if it is updated with
the required data from the master. If the replica cannot meet the requirement within the timeout period, a ConsistencyException is thrown.

For example, the following code performs a store write, collects the version information, then uses it to construct a version-based consistency policy.

```javascript
... // Store handle configuration and open skipped for brevity ...

store.on('open', function () {
    console.log('Store opened');

    var row = {item: "Bolts",
                description: "Hex head, stainless",
                count: 5,
                percentage: 0.2173913};

    var matchVersion = null;
    store.put('myTable', row,
              function (err, putResult) {
                  if (err)
                      throw err;
                  else {
                      console.log("Row inserted.");
                      matchVersion =
                          putResult.currentRowVersion;
                      store.close();
                  }
              });

}).on('close', function() {
    console.log('Store closed.');
}).on('error', function(error) {
    console.log(error);
});
store.open();

At some other point in this application's code, or perhaps in another application entirely, we use the matchVersion captured above to create a version-based consistency policy.

```
1000);

var primaryKey = {item: "Bolts"};

var readOptions = nosqldb.Types.ReadOptions (.versionConsistency,
1000);

store.get('myTable', primaryKey, readOptions,
function (err, result) {
    if (err)
        throw err;
    else {
        console.log("Row retrieved.");
        console.log(result.currentRow);
        store.close();
    }
});

}).on('close', function() {
    console.log('Store closed.');
}).on('error', function(error) {
    console.log(error);
});

store.open();
Chapter 11. Durability Guarantees

Writes are performed in the Oracle NoSQL Database store by performing the write operation (be it a creation, update, or delete operation) on a master node. As a part of performing the write operation, the master node will usually make sure that the operation has made it to stable storage before considering the operation complete.

The master node will also transmit the write operation to the replica nodes in its shard. It is possible to ask the master node to wait for acknowledgments from its replicas before considering the operation complete.

Note

If your store is configured such that secondary zones are in use, then write acknowledgements are never required for the replicas in the secondary zones. That is, write acknowledgements are only returned by replicas in primary zones. See the Oracle NoSQL Database Administrator’s Guide for more information on zones.

The replicas, in turn, will not acknowledge the write operation until they have applied the operation to their own database.

A durability guarantee, then, is a policy which describes how strongly persistent your data is in the event of some kind of catastrophic failure within the store. (Examples of a catastrophic failure are power outages, disk crashes, physical memory corruption, or even fatal application programming errors.)

A high durability guarantee means that there is a very high probability that the write operation will be retained in the event of a catastrophic failure. A low durability guarantee means that the write is very unlikely to be retained in the event of a catastrophic failure.

The higher your durability guarantee, the slower your write-throughput will be in the store. This is because a high durability guarantee requires a great deal of disk and network activity.

Usually you want some kind of a durability guarantee, although if you have highly transient data that changes from run-time to run-time, you might want the lowest possible durability guarantee for that data.

Durability guarantees include two types of information: acknowledgment guarantees and synchronization guarantees. These two types of guarantees are described in the next sections. We then show how to set a durability guarantee.

Note that by default, Oracle NoSQL Database uses a low durability guarantee.

Setting Acknowledgment-Based Durability Policies

Whenever a master node performs a write operation (create, update or delete), it must send that operation to its various replica nodes. The replica nodes then apply the write operation(s) to their local databases so that the replicas are consistent relative to the master node.
Upon successfully applying write operations to their local databases, replicas in primary zones send an \textit{acknowledgment message} back to the master node. This message simply says that the write operation was received and successfully applied to the replica's local database. Replicas in secondary zones do not send these acknowledgement messages.

\textbf{Note}

The exception to this are replicas in secondary zones, which will never acknowledge write operations. See the \textit{Oracle NoSQL Database Administrator's Guide} for more information on zones.

An acknowledgment-based durability policy describes whether the master node will wait for these acknowledgments before considering the write operation to have completed successfully. You can require the master node to wait for no acknowledgments, acknowledgments from a simple majority of replica nodes in primary zones, or acknowledgments from all replica nodes in primary zones.

The more acknowledgments the master requires, the slower its write performance will be. Waiting for acknowledgments means waiting for a write message to travel from the master to the replicas, then for the write operation to be performed at the replica (this may mean disk I/O), then for an acknowledgment message to travel from the replica back to the master. From a computer application's point of view, this can all take a long time.

When setting an acknowledgment-based durability policy, you can require acknowledgment from:

- All replicas. That is, all of the replica nodes in the shard that reside in a primary zone. Remember that your store has more than one shard, so the master node is not waiting for acknowledgments from every machine in the store.

- No replicas. In this case, the master returns with normal status from the write operation as soon as it has met its synchronization-based durability policy. These are described in the next section.

- A simple majority of replicas in primary zones. That is, if the shard has 5 replica nodes residing in primary zones, then the master will wait for acknowledgments from 3 nodes.

\textbf{Setting Synchronization-Based Durability Policies}

Whenever a node performs a write operation, the node must know whether it should wait for the data to be written to stable storage before successfully returning from the operation.

As a part of performing a write operation, the data modification is first made to an in-memory cache. It is then written to the filesystem's data buffers. And, finally, the contents of the data buffers are synchronized to stable storage (typically, a hard drive).

You can control how much of this process the master node will wait to complete before it returns from the write operation with a normal status. There are three different levels of synchronization durability that you can require:

- \texttt{NO\/SYNC}
The data is written to the host's in-memory cache, but the master node does not wait for the data to be written to the file system's data buffers, or for the data to be physically transferred to stable storage. This is the fastest, but least durable, synchronization policy.

- WRITE_NO_SYNC

The data is written to the in-memory cache, and then written to the file system's data buffers, but the data is not necessarily transferred to stable storage before the operation completes normally.

- SYNC

The data is written to the in-memory cache, then transferred to the file system's data buffers, and then synchronized to stable storage before the write operation completes normally. This is the slowest, but most durable, synchronization policy.

Notice that in all cases, the data is eventually written to stable storage (assuming some failure does not occur to prevent it). The only question is, how much of this process will be completed before the write operation returns and your application can proceed to its next operation.

**Setting Durability Guarantees**

To set a durability guarantee, use the `Durability` class. When you do this, you must provide three pieces of information:

- The acknowledgment policy.
- A synchronization policy at the master node.
- A synchronization policy at the replica nodes.

The combination of policies that you use is driven by how sensitive your application might be to potential data loss, and by your write performance requirements.

For example, the fastest possible write performance can be achieved through a durability policy that requires:

- No acknowledgments.
- NO_SYNC at the master.
- NO_SYNC at the replicas.

However, this durability policy also leaves your data with the greatest risk of loss due to application or machine failure between the time the operation returns and the time when the data is written to stable storage.

On the other hand, if you want the highest possible durability guarantee, you can use:

- All replicas must acknowledge the write operation.
• SYNC at the master.
• SYNC at the replicas.

Of course, this also results in the slowest possible write performance.

Most commonly, durability policies attempt to strike a balance between write performance and data durability guarantees. For example:

• Simple majority of replicas must acknowledge the write.
• SYNC at the master.
• NO_SYNC at the replicas.

Note that you can set a default durability policy for your Store handle, but you can also override the policy on a per-operation basis for those situations where some of your data need not be as durable (or needs to be MORE durable) than the default.

For example, suppose you want an intermediate durability policy for most of your data, but sometimes you have transient or easily re-created data whose durability really is not very important. Then you would do something like this:

First, set the default durability policy for the Store handle:

```javascript
var nosqldb = require('nosqldb-oraclejs');

// Create a configuration object
var configuration = new nosqldb.Configuration();
configuration.proxy.startProxy = false;
configuration.proxy.host = 'localhost:7010';
configuration.storeHelperHosts = ['localhost:5000'];
configuration.storeName = 'kvstore';
configuration.defaultDurability =
  new nosqldb.Types.Durability(
    nosqldb.Types.SyncPolicy.SYNC, //Master sync
    nosqldb.Types.ReplicaAckPolicy.SIMPLE_MAJORITY, //Ack policy
    nosqldb.Types.SyncPolicy.NO_SYNC); //Replica sync

// Open the store with the specified configuration
var store = nosqldb.createStore(configuration);
```

In another part of your code, for some unusual write operations, you might then want to relax the durability guarantee so as to speed up the write performance for those specific write operations:

```javascript
store.on('open', function () {
    console.log('Store opened');

    var row = {item: "Bolts",
                description: "Hex head, stainless",
                count: 5,
```

percentage: 0.2173913);

var durability = new nosqldb.Types.Durability(
   nosqldb.Types.SyncPolicy.NO_SYNC,
   nosqldb.Types.ReplicaAckPolicy.NONE,
   nosqldb.Types.SyncPolicy.NO_SYNC);

var writeOptions = new nosqldb.Types.WriteOptions(
   durability,
   1000);

store.put('myTable', row, writeOptions,
   function (err) {
      if (err)
         throw err;
      else {
         console.log("Row inserted.");
         store.close();
      }
   });
}).on('close', function() {
   console.log('Store closed.');
}).on('error', function(error) {
   console.log(error);
});
store.open();
Chapter 12. Executing a Sequence of Operations

You can execute a sequence of write operations as a single atomic unit so long as all the rows that you are operating upon share the same shard key. By atomic unit, we mean all of the operations will execute successfully, or none of them will.

Also, the sequence is performed in isolation. This means that if you have a thread running a particularly long sequence, then another thread cannot intrude on the data in use by the sequence. The second thread will not be able to see any of the modifications made by the long-running sequence until the sequence is complete. The second thread also will not be able to modify any of the data in use by the long-running sequence.

Be aware that sequences only support write operations. You can perform puts and deletes, but you cannot retrieve data when using sequences.

When using a sequence of operations:

• All of the keys in use by the sequence must share the same shard key.

• Operations are placed into a list, but the operations are not necessarily executed in the order that they appear in the list. Instead, they are executed in an internally defined sequence that prevents deadlocks.

The rest of this chapter shows how to use the Operation object and Store.executeUpdates() to create and run a sequence of operations.

Sequence Errors

If any operation within the sequence experiences an error, then the entire operation is aborted. In this case, your data is left in the same state it would have been in if the sequence had never been run at all — no matter how much of the sequence was run before the error occurred.

Fundamentally, there are two reasons why a sequence might abort:

1. An internal operation results in an error that is considered a fault. For example, the operation throws a DurabilityException. Also, if there is an internal failure due to message delivery or a networking error.

2. An individual operation returns normally but is unsuccessful as defined by the particular operation. (For example, you attempt to delete a row that does not exist). If this occurs AND you specified true for the abortIfUnsuccessful parameter when the operation was created using Operation.push() then a TableOpExecutionException is thrown. This error contains information about the failed operation.

Creating a Sequence

You create a sequence by constructing an array of Operation objects. For each object, you specify the necessary operation information using the object's push() method. Each element in the array represents exactly one operation in the store.
For example, suppose you are using a table defined like this:

```sql
CREATE TABLE myTable (  
  itemType STRING,  
  itemCategory STRING,  
  itemClass STRING,  
  itemColor STRING,  
  itemSize STRING,  
  price FLOAT,  
  inventoryCount INTEGER,  
  PRIMARY KEY (SHARD(itemType, itemCategory, itemClass), itemColor, itemSize)
)
```

With tables containing data like this:

- **Row 1:**
  - itemType: Hats
  - itemCategory: baseball
  - itemClass: longbill
  - itemColor: red
  - itemSize: small
  - price: 12.07
  - inventoryCount: 127

- **Row 2:**
  - itemType: Hats
  - itemCategory: baseball
  - itemClass: longbill
  - itemColor: red
  - itemSize: medium
  - price: 13.07
  - inventoryCount: 201

- **Row 3:**
  - itemType: Hats
  - itemCategory: baseball
  - itemClass: longbill
  - itemColor: red
  - itemSize: large
  - price: 14.07
  - inventoryCount: 39

And further suppose that this table has rows that require an update (such as a price and inventory refresh), and you want the update to occur in such a fashion as to ensure it is performed consistently for all the rows.

Then you can create a sequence in the following way:
var operations = [];
var row = {
    itemType: "Hats", itemCategory: "baseball",
    itemClass: "longbill",
    itemColor: "red", itemSize: "small",
    price: 12.07, inventoryCount: 127
};
operations.push (new nosqldb.Types.Operation('newTable',
    nosqldb.Types.OperationType.PUT, row,
    nosqldb.Types.ReturnChoice.ALL, true, null));

row = {
    itemType: "Hats", itemCategory: "baseball",
    itemClass: "longbill",
    itemColor: "red", itemSize: "medium",
    price: 13.07, inventoryCount: 201
};
operations.push (new nosqldb.Types.Operation('newTable',
    nosqldb.Types.OperationType.PUT, row,
    nosqldb.Types.ReturnChoice.ALL, true, null));

row = {
    itemType: "Hats", itemCategory: "baseball",
    itemClass: "longbill",
    itemColor: "red", itemSize: "large",
    price: 14.07, inventoryCount: 309
};
operations.push (new nosqldb.Types.Operation('newTable',
    nosqldb.Types.OperationType.PUT, row,
    nosqldb.Types.ReturnChoice.ALL, true, null));

Note in the above example that we update only those rows that share the same shard key. In this case, the shard key includes the itemType, itemCategory, and itemClass fields. If the value for any of those fields is different from the others, we could not successfully execute the sequence.

**Executing a Sequence**

To execute the sequence we created in the previous section, use the Store.executeUpdates() method:

```javascript
... // Store handle configuration and open skipped for brevity ...

store.on("open",function (err) {
    if (err)
        throw err;

    store.executeUpdates(operations, function(err, result) {
```

...
if (err)
    throw err;
else {
    console.log("Inserted rows.");
    store.close();
}
});

}).on('close', function() {
    console.log('Store closed.');
}).on('error', function(error) {
    console.log(error);
});

store.open();

Note that if any of the above errors are thrown, then the entire sequence is aborted, and your
data will be in the state it would have been in if you had never executed the sequence at all.

Store.executeUpdates() can optionally take a WriteOptions object. This object allows you
to specify:

• The durability guarantee that you want to use for this sequence. If you want to use the
default durability guarantee, do not set this property, or set it to null.

• A timeout value that identifies the upper bound on the time interval allowed for processing
the entire sequence. If you provide 0, the default request timeout value is used.

• A ReturnChoice value that indicates whether you want to return the value resulting from
the operation, the row's version, both of these things, or nothing.

For an example of using WriteOptions, see Durability Guarantees (page 75).
Appendix A. Table Data Definition Language Overview

Before you can write data to tables in the store, you must provide a definition of the tables you want to use. This definition includes information such as the table's name, the name of its various rows and the data type contained in those rows, identification of the primary and (optional) shard keys, and so forth. To perform these definitions, Oracle NoSQL Database provides a Data Definition Language (DDL) that you use to form table and index statements. These statements can be used to:

- Define tables and sub-tables.
- Modify table definitions.
- Delete table definitions.
- Define indexes.
- Delete index definitions.

Table and index statements take the form of ordinary strings, which are then transmitted to the Oracle NoSQL Database store using the appropriate method or function. For example, to define a simple user table, the table statement might look like this:

```
CREATE TABLE Users (  
id INTEGER,  
firstName STRING,  
lastName STRING,  
PRIMARY KEY (id)
)
```

For information on how to transmit these statements to the store, see Introducing Oracle NoSQL Database Tables and Indexes (page 14).

For overview information on primary and shard keys, see Primary and Shard Key Design (page 22).

For overview information on indexes, see Creating Indexes (page 19).

The remainder of this appendix describes in detail the DDL statements that you use to manipulate table and index definitions in the store.

Name Constraints

The following sections use all uppercase to identify DDL keywords (such as STRING, CHECK, CREATE TABLE, and so on). However, these keywords are actually case-insensitive and can be entered as lower-case.

The DDL keywords shown here are reserved and cannot be used as table, index or field names.
Table, index and field names are case-preserving, but case-insensitive. So you can, for example, create a field named `MY_NAME`, and later reference it as `my_name` without error. However, whenever the field name is displayed, it will display as `MY_NAME`.

Table and index names are limited to 32 characters. Field names can be 64 characters. All table, index and field names are restricted to alphanumeric characters, plus underscore ("_"). All names must start with a letter.

**DDL Comments**

You can include comments in your DDL statements using one of the following constructs:

```sql
id INTEGER, /* this is a comment */
firstName STRING, // this is a comment
lastName STRING, # this is a comment
```

**CREATE TABLE**

To create a table definition, use a `CREATE TABLE` statement. Its form is:

```sql
CREATE TABLE [IF NOT EXISTS] table-name (  
    field-definition, field-definition-2 ...,  
    PRIMARY KEY (field-name, field-name-2...),  
    [COMMENT "comment string"]
)
```

where:

- `IF NOT EXISTS` is optional, and it causes table creation to be silently skipped if a table of the given name already exists in the store, and the table's definition exactly matches the provided definition. No error is returned as a result of the statement execution.

  If this statement phrase is not specified, then an attempt to duplicate a table name in the store results in a failed table creation.

- `table-name` is the name of the table. This field is required. If you are creating a sub-table, then use dot notation. For example, a table might be named `Users`. You might then define a sub-table named `Users.MailingAddress`.

- `field-definition` is a comma-separated list of fields. There are one or more field definitions for every table. Field definitions are described next in this section.

- `PRIMARY KEY` identifies at least one field in the table as the primary key. A primary key definition is required for every table. For information on primary keys, see Primary Keys (page 22).

  To define a shard key (optional), use the SHARD keyword in the primary key statement. For information on shard keys, see Shard Keys (page 23).

  For example:

  ```sql
  PRIMARY KEY (SHARD(id), lastName)
  ```
• COMMENT is optional. You can use this to provide a brief description of the table. The comment will not be interpreted but it is included in the table's metadata.

Field Definitions

When defining a table, field definitions take the form:

```
field-name type [constraints] [COMMENT "comment-string"]
```

where:

• **field-name** is the name of the field. For example: `id` or `familiarName`. Every field must have a name.

• **type** describes the field's data type. This can be a simple type such as INTEGER or STRING, or it can be a complex type such a RECORD. The list of allowable types is described in the next section.

• **constraints** describes any limits placed on the data contained in the field. That is, minimum or maximum values, allowable ranges, or default values. This information is optional. See Field Constraints (page 88) for more information.

• COMMENT is optional. You can use this to provide a brief description of the field. The comment will not be interpreted but it is included in the table's metadata.

Supported Data Types

The following data types are supported for table fields:

• **ARRAY**

  An array of data. All elements of the array must be of the same data type, and this type must be declared when you define the array field. For example, to define an array of strings:

  ```
  myArray ARRAY(STRING)
  ```

  Note that field constraints can be applied to array value. For example:

  ```
  myArray ARRAY(INTEGER CHECK(ELEMENTOF(myArray) > 0 and \ ELEMENTOF(myArray) < 100))
  ```

  See CHECK (page 88) for a description of the CHECK statement.

• **BINARY**

  Binary data.

• **BINARY(Length)**

  Fixed-length binary field of size `length` (in bytes).

• **BOOLEAN**
A boolean data type.

- **DOUBLE**
  
  A double.

- **ENUM**
  
  An enumerated list. The field definition must provide the list of allowable enumerated values. For example:
  
  ```
  fruitName ENUM(apple, pear, orange)
  ```

- **FLOAT**
  
  A float.

- **INTEGER**
  
  An integer.

- **LONG**
  
  A long.

- **MAP**
  
  A data map. All map keys are strings, but when defining these fields you must define the data type of the data portion of the map. For example, if your keys map to integer values, then you define the field like this:
  
  ```
  myMap MAP(INTEGER)
  ```

  Note that field constraints can be applied to mapped value. For example:
  
  ```
  myMap MAP(INTEGER CHECK(ELEMENTOF(myMap) > 0 and \n  ELEMENTOF(myMap) < 13))
  ```

  See **CHECK (page 88)** for a description of the CHECK statement.

- **RECORD**
  
  An embedded record. This field definition must define all the fields contained in the embedded record. All of the same syntax rules apply as are used for defining an ordinary table field. For example, a simple embedded record might be defined as:
  
  ```
  myEmbeddedRecord RECORD(firstField STRING, secondField INTEGER)
  ```

  Data constraints, default values, and so forth can also be used with the embedded record's field definitions.

- **STRING**
  
  A string.
Field Constraints

Field constraints are used to define information about the field, such as the allowable range of values and default values. For example:

```sql
    day_of_month CHECK (day_of_month >= 1 AND day_of_month <= 31)
```

Not all data type support constraints, and individual data types do not support all possible constraints.

CHECK

Use CHECK to specify an allowable range of values. The symbols `AND`, `<`, `<=`, `>`, and `>=` are all supported. `<` and `>` specifying exclusive ranges, and `<=` and `>=` specifying inclusive ranges. For example:

```sql
    myInt INTEGER CHECK(myInt > 10 and myInt < 20)
```

For simple data types, (INTEGER, LONG, FLOAT, DOUBLE, STRING), use the field's name to specify the range, as shown in the previous example.

For STRING datatypes, the range specifies the string's value range based on a lexicographical comparison of the Unicode value of each character in the string. For example:

```sql
    myString STRING CHECK(myString > "aaa" and myString < "zzz")
```

causes the string ccc to be within the valid range, but CCC or cccc would not be. If you specify numbers for the range, then the number is interpreted as a string range. In this case:

```sql
    myString STRING CHECK(myString > 10 and myString < 20)
```

means that 11 is allowable, but 21 or aaa would not be.

For MAP and ARRAY datatypes, CHECK can be used to constraint the range of allowable values. Use `ELEMENTOF()` to refer to the MAP's or ARRAY's value. For example:

```sql
    myMap MAP(INTEGER CHECK(ELEMENTOF(myMap) > 10))
```

or:

```sql
    myArray ARRAY(INTEGER CHECK(ELEMENTOF(myArray) > 100 AND ELEMENTOF(myArray) < 1000))
```

CHECK is not supported for BINARY, BOOLEAN, ENUM, or RECORD datatypes, although CHECK is supported for the individual fields defined by RECORD:

```sql
    myRec RECORD(a STRING, b INTEGER CHECK(b >= 0 AND b <= 10))
```

COMMENT

All data types can accept a COMMENT as part of their constraint. COMMENT strings are not parsed, but do become part of the table's metadata. For example:

```sql
    myRec RECORD(a STRING, b INTEGER COMMENT "Comment string")
```

or
myInt INTEGER CHECK(myInt > 10 and myInt < 20) COMMENT "Comment string"

### DEFAULT

All fields can accept a DEFAULT constraint, except for ARRAY, BINARY, MAP, and RECORD. The value specified by DEFAULT is used in the event that the field data is not specified when the table is written to the store.

For example:

```sql
id INTEGER DEFAULT -1,
description STRING DEFAULT "NONE",
size ENUM(small,medium,large) DEFAULT medium,
inStock BOOLEAN DEFAULT FALSE
```

### NOT NULL

NOT NULL indicates that the field cannot be NULL. This constraint requires that you also specify a DEFAULT value. Order is unimportant for these constraints. For example:

```sql
id INTEGER NOT NULL DEFAULT -1,
description STRING DEFAULT "NONE" NOT NULL
```

### Table Creation Examples

The following are provided to illustrate the concepts described above.

```sql
CREATE TABLE users (
  id INTEGER,
  firstName STRING,
  lastName STRING,
  age INTEGER,
  PRIMARY KEY (id),
  COMMENT "This comment applies to the table itself"
)

CREATE TABLE usersNoId (
  firstName STRING,
  lastName STRING COMMENT "This comment applies to this field only",
  age INTEGER CHECK (age > 0 AND age < 150),
  ssn STRING NOT NULL DEFAULT "xxx-yy-zzzz",
  PRIMARY KEY (SHARD(lastName), firstName)
)

CREATE TABLE users.address (
  streetNumber INTEGER,
  streetName STRING,  // this comment is ignored by the DDL parser
  city STRING,
  zip INTEGER CHECK(zip > 11111 AND zip < 99999),
  addrType ENUM (home, work, other),
  PRIMARY KEY (addrType)
)
```
CREATE TABLE complex (  
    COMMENT "this comment goes into the table metadata"  
    id INTEGER,  
    PRIMARY KEY (id), # this comment is just syntax  
    nestedMap MAP(RECORD( m MAP(FLOAT), a ARRAY(RECORD(age INTEGER)))),  
    address RECORD (street INTEGER, streetName STRING, city STRING, \  
        zip INTEGER COMMENT "zip comment"),  
    friends MAP (STRING),  
    floatArray ARRAY (FLOAT),  
    aFixedBinary BINARY(5),  
    days ENUM(mon, tue, wed, thur, fri, sat, sun) NOT NULL DEFAULT tue  
)

Modify Table Definitions

Use ALTER TABLE statements to either add new fields to a table definition, or delete a currently existing field definition.

You cannot modify an existing field directly. Instead, you must delete the field, then add the field back using the new definition. Note that this will cause all existing data associated with the current field to be deleted.

ALTER TABLE ADD field

To add a field to an existing table, use the ADD statement:

```sql
ALTER TABLE table-name (ADD field-definition)
```

See Field Definitions (page 86) for a description of what should appear in `field-definitions`, above. For example:

```sql
ALTER TABLE Users (ADD age INTEGER)
```

You can also add fields to nested records. For example, if you have the following table definition:

```sql
CREATE TABLE u (id INTEGER,  
    info record(firstName String)),  
    PRIMARY KEY(id))
```

then you can add a field to the nested record by using dot notation to identify the nested table, like this:

```sql
ALTER TABLE u(ADD info.lastName STRING)
```

ALTER TABLE DROP field

To delete a field from an existing table, use the DROP statement:

```sql
ALTER TABLE table-name (DROP field-name)
```

For example, to drop the age field from the Users table:

```sql
ALTER TABLE Users (DROP age)
```
Note that you cannot drop a field if it is the primary key.

**DROP TABLE**

To delete a table definition, use a DROP TABLE statement. Its form is:

```sql
DROP TABLE [IF EXISTS] table-name
```

where:

- IF EXISTS is optional, and it causes the drop statement to be ignored if a table with the specified name does not exist in the store. If this phrase is not specified, and the table does not currently exist, then the DROP statement will fail with an error.

- `table-name` is the name of the table you want to drop.

Note that dropping a table is a lengthy operation because all table data currently existing in the store is deleted as a part of the drop operation.

If child tables are defined for the table that you are dropping, then they must be dropped first. For example, if you have tables:

```sql
myTable
myTable.childTable1
myTable.childTable2
```

then `myTable.childTable1` and `myTable.childTable2` must be dropped before you can drop `myTable`.

**CREATE INDEX**

To add an index definition to the store, use a CREATE INDEX statement. Its form is:

```sql
CREATE INDEX [IF NOT EXISTS] index-name ON table-name (field-name)
```

When indexing a map field, the previous syntax is acceptable, as are any of the following:

```sql
CREATE INDEX [IF NOT EXISTS] index-name ON table-name (KEYOF(field-name))
```

or

```sql
CREATE INDEX [IF NOT EXISTS] index-name ON table-name (ELEMENTOF(field-name))
```

or

```sql
CREATE INDEX [IF NOT EXISTS] index-name ON table-name (KEYOF(field-name),ELEMENTOF(field-name))
```

where:

- IF NOT EXISTS is optional, and it causes the CREATE INDEX statement to be ignored if an index by that name currently exists. If this phrase is not specified, and an index using the
specified name does currently exist, then the CREATE INDEX statement will fail with an error.

- **index-name** is the name of the index you want to create.
- **table-name** is the name of the table that you want to index.
- **field-name** is the name of the field that you want to index.
- **KEYOF** is a keyword that causes index entries to be created based on keys contained in a map.
- **ELEMENTOF** is a keyword that causes index entries to be created based on the values contained in a map.

For example, if table Users has a field called lastName, then you can index that field with the following statement:

```
CREATE INDEX surnameIndex ON Users (lastName)
```

Note that depending on the amount of data in your store, creating indexes can take a long time. This is because index creation requires Oracle NoSQL Database to examine all the data in the store.

For a description of using indexes with non-scalar data types, see Indexing Non-Scalar Data Types (page 55).

**DROP INDEX**

To delete an index definition from the store, use a DROP INDEX statement. Its form when deleting an index is:

```
DROP INDEX [IF EXISTS] index-name ON table-name
```

where:

- **IF EXISTS** is optional, and it causes the DROP INDEX statement to be ignored if an index by that name does not exist. If this phrase is not specified, and an index using the specified name does not exist, then the DROP INDEX statement will fail with an error.
- **index-name** is the name of the index you want to drop.
- **table-name** is the name of the table containing the index you want to delete.

For example, if table Users has an index called surnameIndex, then you can delete it using the following statement:

```
DROP INDEX IF EXISTS surnameIndex ON Users
```

**DESCRIBE AS JSON TABLE**

You can retrieve a JSON representation of a table by using the DESCRIBE AS JSON TABLE statement:
DESCRIBE AS JSON TABLE table_name [(field-name, field-name2, ...)]

or

DESC AS JSON TABLE table_name [(field-name, field-name2, ...)]

where:

- *table_name* is the name of the table you want to describe.
- *field-name* is 0 or more fields defined for the table that you want described. If specified, the output is limited to just the fields listed here.

Map and Array fields support the use of ELEMENTOF() to restrict the JSON representation to just the map or array element.

**DESCRIBE AS JSON INDEX**

You can retrieve a JSON representation of an index by using the DESCRIBE AS JSON INDEX statement:

DESCRIBE AS JSON INDEX index_name ON table_name

where:

- *index_name* is the name of the index you want to describe.
- *table_name* is the name of the table to which the index is applied.

**SHOW TABLES**

You can retrieve a list of all tables currently defined in the store using the SHOW TABLES statement:

SHOW [AS JSON] TABLES

where *AS JSON* is optional and causes the resulting output to be JSON-formatted.

**SHOW INDEXES**

You can retrieve a list of all indexes currently defined for a table using the SHOW INDEXES statement:

SHOW [AS JSON] INDEXES ON table_name

where:

- *AS JSON* is optional and causes the resulting output to be JSON-formatted.
- *table_name* is the name of the table for which you want to list all the indexes.
Appendix B. Proxy Server Reference

The proxy server command line options are:

```bash
nohup java -cp KVHOME/lib/kvclient.jar:kvproxy/lib/kvproxy.jar
oracle.kv.proxy.KVProxy -help
-port <port-number> Port number of the proxy server. Default: 5010
-store <store-name> Required KVStore name. No default.
-helper-hosts <host:port,host:port,...> Required list of KVStore hosts and ports (comma separated).
-security <security-file-path> Identifies the security file used to specify properties for login. Required for connecting to a secure store.
-username <user> Identifies the name of the user to login to the secured store. Required for connecting to a secure store.
-read-zones <zone,zone,...> List of read zone names.
-max-active-requests <int> Maximum number of active requests towards the store.
-node-limit-percent <int> Limit on the number of requests, as a percentage of the requested maximum active requests.
-request-threshold-percent <int> Threshold for activating request limiting, as a percentage of the requested maximum active requests.
-request-timeout <long> Configures the default request timeout in milliseconds.
-socket-open-timeout <long> Configures the open timeout in milliseconds used when establishing sockets to the store.
-socket-read-timeout <long> Configures the read timeout in milliseconds associated with the underlying sockets to the store.
-max-iterator-results <long> A long representing the maximum number of results returned in one single iterator call. Default: 100
-iterator-expiration <long> Iterator expiration interval in milliseconds.
-max-open-iterators <int> Maximum concurrent opened iterators. Default: 10000
-num-pool-threads <int> Number of proxy threads. Default: 20
-max-concurrent-requests <int> The maximum number of concurrent requests per iterator. Default: <num_cpus * 2>
-max-results-batches <int> The maximum number of results batches that can be held in the proxy per iterator. Default: 0
-help Usage instructions.
-version Print KVProxy server version number.
-verbose Turn verbose flag on.
```

Always start the Oracle NoSQL Database store before starting the proxy server.
When connecting to a non-secured store, the following parameters are required:

- -helper-hosts
- -port
- -store

When connecting to a secured store, the following parameters are also required:

- -security
- -username

Note

Drivers are able to start and stop the proxy server on the local host if properly configured. See Automatically Starting the Proxy Server (page 5) for details.

Securing Oracle NoSQL Database Proxy Server

If configured properly, the proxy can access a secure installation of Oracle NoSQL Database. To do this, the -username and -security proxy options must be specified.

The following example describes how to add security to an Oracle NoSQL Database single node deployment. The example also shows how to initiate a connection to the Oracle NoSQL Database replication nodes.

To install Oracle NoSQL Database securely:

```
java -Xmx256m -Xms256m -jar KVHOME/lib/kvstore.jar makebootconfig -root KVROOT -port 5000 -admin 5001 -host node01 -harange 5890,5900 -store-security configure -pwdmgr pwdfile -capacity 1
```

1. Run the makebootconfig utility with the required -store-security option to set up the basic store configuration with security:

2. In this example, -store-security configure is used, so the security configuration utility is run as part of the makebootconfig process and you are prompted for a password to use for your keystore file:

   Enter a password for the Java KeyStore:

3. Enter a password for your store and then reenter it for verification. In this case, the password file is used, and the securityconfig tool will automatically generate the following security related files:

   Enter a password for the Java KeyStore: ************
   Re-enter the KeyStore password for verification: ************
   Created files:
   security/client.trust
Note

In a multi-host store environment, the security directory and all files contained in it should be copied to each server that will host a Storage Node. For more information on multiple node deployments see the Oracle NoSQL Database Security Guide.

4. Start the Storage Node Agent (SNA):

```bash
nohup java -Xmx256m -Xms256m \
-jar KVHOME/lib/kvstore.jar start -root KVROOT&
```

When a newly created store with a secure configuration is first started, there are no user definitions available against which to authenticate access. To reduce risk of unauthorized access, an admin will only allow you to connect to it from the host on which it is running. This security measure is not a complete safeguard against unauthorized access. It is important that you do not provide local access to machines running KVStore. In addition, you should perform steps 5, 6 and 7 soon after this step to minimize the time period in which the admin might be accessible without full authentication. For more information on maintaining a secure store see the Oracle NoSQL Database Security Guide.

5. Start runadmin in security mode on the KVStore server host (node01). To do this, use the following command:

```bash
java -Xmx256m -Xms256m \n-jar KVHOME/lib/kvstore.jar \nrunadmin -port 5000 -host node01 \n-security KVROOT/security/client.security
```

Logged in admin as anonymous

6. Use the configure -name command to specify the name of the KVStore that you want to configure:

```bash
kv-> configure -name mystore
Store configured: mystore
```

7. Configure the KVStore by deploying a Zone, a Storage Node, and an Admin Node. Then, create a Storage Node Pool. Finally, create and deploy a topology.

```bash
kv-> plan deploy-zone -name mydc -rf 1 -wait
Executed plan 2, waiting for completion...
Plan 2 ended successfully
kv-> plan deploy-sn -zn zn1 -port 5000 -host node01 -wait
Executed plan 3, waiting for completion...
Plan 3 ended successfully
kv-> plan deploy-admin -sn sn1 -port 5001 -wait
```
Executed plan 4, waiting for completion...
Plan 4 ended successfully
kv-> pool create -name mypool
kv-> pool join -name mypool -sn sn1
Added Storage Node(s) [sn1] to pool mypool
kv-> topology create -name mytopo -pool mypool -partitions 30
Created: mytopo
kv-> plan deploy-topology -name mytopo -wait
Executed plan 5, waiting for completion...
Plan 5 ended successfully

8. Create an admin user. In this case, user root is defined:
kv-> plan create-user -name root -admin -wait
Enter the new password: ********
Re-enter the new password: ********
Executed plan 6, waiting for completion...
Plan 6 ended successfully

9. Create a new password file to store the credentials needed to allow clients to login as the admin user (root):

```
java -Xmx256m -Xms256m -jar KVHOME/lib/kvstore.jar securityconfig 
pwdfile create -file KVROOT/security/login.passwd
java -Xmx256m -Xms256m -jar KVHOME/lib/kvstore.jar securityconfig pwdfile secret 
-file KVROOT/security/login.passwd -set -alias root
Enter the secret value to store: ********
Re-enter the secret value for verification: ********
Secret created
OK
```

**Note**

The password must match the one set for the admin in the previous step.

10. At this point, it is possible to connect to the store as the root user. To login, you can use either the -username <user> runadmin argument or specify the "oracle.kv.auth.username" property in the security file.

In this example, a security file (mylogin.txt) is used. To login, use the following command:

```
java -Xmx256m -Xms256m -jar KVHOME/lib/kvstore.jar runadmin -port 5000 -host localhost -security mylogin
Logged in admin as root
```

The file mylogin.txt should be a copy of the client.security file with additional properties settings for authentication. The file would then contain content like this:
Then, to run KVProxy and access the secure Oracle NoSQL Database deployment:

```java
java -cp KVHOME/lib/kvclient.jar:KVPROXY/lib/kvproxy.jar
oracle.kv.proxy.KVProxy -helper-hosts node01:5000 -port 5010
-store mystore -username root -security mylogin
```

INFO: PS: Connect to Oracle NoSQL Database mystore nodes : localhost:5000
Nov 21, 2014 12:59:13 AM oracle.kv.proxy.KVProxy <init>
INFO: PS: ... connected successfully
Nov 21, 2014 12:59:13 AM oracle.kv.proxy.KVProxy startServer
INFO: PS: Starting listener ( Half-Sync/Half-Async server - 20
no of threads on port 5010)

**Note**

Because this proxy server is being used with a secure store, you should limit the proxy server's listening port (port 5010 in the previous example) to only those hosts running authorized clients.

**Troubleshooting the Proxy Server**

If your client is having trouble connecting to the store, then the problem can possibly be with your client code, with the proxy and its configuration, or with the store. To help determine what might be going wrong, it is useful to have a high level understanding of what happens when your client code is connecting to a store.

1. First, your client code tries to connect to the ip:port pair given for the proxy.

2. If the connection attempt is not successful, and your client code indicates that the proxy should be automatically started, then:

   a. The client driver will prepare a command line that starts the proxy on the local host. This command line includes the path to the java command, the classpath to the two jar files required to start the proxy, and the parameters required to start the proxy and connect to the store (these include the local port for the proxy to listen on, and the store's connection information).

   b. The driver executes the command line. If there is a problem, the driver might be able to provide some relevant error information, depending on the exact nature of the problem.
c. Upon command execution, the driver waits for a few seconds for the connection to complete. During this time, the proxy will attempt to start. At this point it might indicate a problem with the classpath.

Next, it will check the version of kvclient.jar and indicate if it is not suited.

After that, it will check the connection parameters, and indicate problems with those, if any.

Then the proxy will actually connect to the store, using the helper-hosts parameter. At this time, it could report connection errors such as the store is not available, security credentials are not available, or security credentials are incorrect.

Finally, the proxy tries to listen to the indicated port. If there's an error listening to the port (it is already in use by another process, for example), the proxy reports that.

d. If any errors occur in the previous step, the driver will automatically repeat the entire process again. It will continue to repeat this process until it either successfully obtains a connection, or it runs out of retry attempts.

Ultimately, if the driver cannot successfully create a connection, the driver will return with an error.

3. If the driver successfully connects to the proxy, it sends a verify message to the proxy. This verify message includes the helper-host list, the store name, the username (if using a secure store), and the readzones if they are being used in the store.

If there is anything wrong with the information in the verify message, the proxy will return an error message. This causes the proxy to check the verify parameters so as to ensure that the driver is connected to the right store.

4. If there are no errors seen in the verify message, then the connection is established and store operations can be performed.

To obtain the best error information possible when attempting to troubleshoot a connection problem, start the proxy with the -verbose command line option. Also, you can enable assertions in the proxy Java code by using the java -ea command line option.

Between these two mechanisms, the proxy will provide a great deal of information. To help you analyze it, you can enable logging to a file. To do this:

Start the proxy with the following parameter:

```
java -cp KVHOME/lib/kvclient.jar:KVPROXY/lib/kvproxy.jar
-Djava.util.logging.config.file=logger.properties
oracle.kv.proxy.KVProxy -helper-hosts node01:5000 -port 5010
-store mystore -verbose
```

The file logger.properties would then contain content like this:

```
# Log to file and console
```
Configuration parameters control the size and number of rotating log files used (similar to java logging, see `java.util.logging.FileHandler`). For a rotating set of files, as each file reaches a given size limit, it is closed, rotated out, and a new file is opened. Successively older files are named by adding "0", "1", "2", etc. into the file name.
Appendix C. Third Party Licenses

All of the third party licenses used by the Oracle NoSQL Database node.js driver are described in the LICENSE file, which you can find in the nosqldb-oraclejs directory, which exists where you install your Javascript modules.
