16. Either edit the flexfield in the Register Flexfield Metadata wizard and provide the fully qualified name of the search view object or execute the following SQL statement to register it. Replace search-view-object with the fully qualified name for the search view object. Replace product-table with the name of the product table that the flexfield extends.

    ```sql
    UPDATE FND_DF_ADFBC_USAGES
    SET EFF_SEARCH_VIEW_OBJECT = 'search-view-object'
    WHERE TABLE_NAME='product-table'
    AND ENTITY_OBJECT='product-table-entity-object';
    ```
24.7 Defining and Registering Extensible Flexfields

After you create the flexfield’s extension tables and their entity objects and view objects, you can define and register the extensible flexfield’s usage. The definition of an extensible flexfield usage includes the following information:

- The flexfield’s code, name, and description.
- The flexfield usage’s code, name, and description.
- The name of the product table for which the flexfield is implemented (the primary table), and the view object and application module for that table.
- The name of the base extension table that contains the columns to be used as flexfield segments. This name should have a suffix of _B.
- The name of the context column in the base extension table. This should be CONTEXT_CODE.
- The names of the columns in the base extension table that are to be used as flexfield segments.
- If the flexfield is enabled for translations, the name of the translation extension table, which should have a suffix of _TL, and the translation extension view, which should have a suffix of _VL.
- Flexfield ADF Business Component usage information, including the Oracle Metadata Services (MDS) root packages for its usage — the name of the root package for all business components that model the flexfield. Each usage must have its own package name.
- If the flexfield has custom modelers, the names of the custom modeler. For information about custom modelers, see How to Customize the Runtime Business Component Modeler for Extensible Flexfields and How to Customize the Runtime User Interface Modeler for Extensible Flexfields.

After the implementors configure the flexfield, the definition of an extensible flexfield also contains the following information:

- A complete list of the ContextCode values that can appear in the flexfield context segment.
- Information about the segments that are associated with the ContextCode values. Each ContextCode value is associated with its own set of these segments.
- A complete list of the CategoryCode values that belong to the extensible flexfield, and the contexts that are associated with each category, page, and usage.
- Validation rules that are associated with the segments. Each segment can have its own LOV or validation rules.

24.7.1 How to Register Extensible Flexfields

You can use either of the of the following methods to define and register an extensible flexfield usage:

- Flexfield Registration Metadata wizard
24.7.1.1 Using the Flexfield Registration Metadata Wizard to Register and Define Extensible Flexfields

Use the **Register new flexfield** operation to register and define an extensible flexfield from the Flexfield Registration Metadata wizard. To make subsequent additions and changes to the flexfields, you use the **Edit flexfield operation**.

**Before you begin:**

- Create the extensible flexfield tables as described in *Creating Extensible Flexfield Data Tables*.
- Create entity objects for the extensible flexfield tables as described in *Creating and Configuring Extensible Flexfield Entity Objects*.
- Create view objects for the extensible flexfield tables as described in *Creating and Configuring Extensible Flexfield View Objects*.
- Ensure that entity objects exist for the primary table (the product table that the extensible flexfield extends).

**To register and define an extensible flexfield using the Flexfield Registration Metadata wizard:**

1. From the **File** menu, choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Flexfield Registration Metadata**, and click **OK**.
3. On the Choose Operation page of the Flexfield Registration Metadata wizard, select **Register new flexfield** as shown in the following figure, and then click **Next**.
4. On the Basic Information page, select **Extensible Flexfield** from the *Type* dropdown list.

5. Provide the following values:
   - **Code**: Type a code that uniquely identifies the flexfield.
   - **Name**: Type a descriptive name for the flexfield.
   - **Description**: Type a short description of the flexfield.
   - **Application**: Select the application name that has been assigned for the product area.
   - **Module**: Select the module that owns the flexfield. This is typically the application or logical business area (LBA) with which the flexfield is delivered.

6. Click **Next**.

7. On the Product Table page, set the following values to define the flexfield usage.
   - Flexfield usage code, name, and description.
   - The name of the product table for which the flexfield is implemented, and the view object and application module for the product table.
   - Provide the search view object, if it exists. This is an SQL-based view object that is based on the entity object that was used for the base category view object as described in **Creating a Declarative SQL-Based View Object to Enable Searching**.
Note:
You need a search view object only if the flexfield is enabled for business intelligence or there is a need to expose the flexfield’s segments in the search user interface for the product table that the flexfield is extending, as described in Incorporating Extensible Flexfields into a Search Form.

- The name of the root package to be used for the generated business components that model the flexfield usage.
- The object name prefix for the flexfield usage. For example, PartsEFF. This prefix is used to derive the names of objects that are generated for the flexfield usage.

8. Click Next.

9. From the Extension Table page, specify the name of the base extension table for the flexfield, and the table’s entity object and view object.

10. Select the database columns in the Available list that you want to use for the flexfield segments and move them to the Selected list.

The wizard assumes that the CATEGORY_CODE column is to be used for the category code and that the CONTEXT_CODE column is to be used for the context code.

11. Click Next.

12. On the Extension TL Table page, complete the following steps if a translation extension table exists for the flexfield:
   a. Select Enable translatable attributes.
   b. Provide the name of the translation extension table.
   c. Provide the names of the entity object and view object for the translation extension table, and the name of the entity object for the translation extension view. These are the objects that you created in How to Create and Configure Extensible Flexfield Entity Objects.
   d. In the Available list in the Columns region, move the CONTEXT_CODE column to the Selected list.
   e. Select the database columns in the Available list that you want to map to flexfield segments and move them to the Selected list.

13. Click Next.

14. On the Advanced Options page, enter the name of the flexfield’s custom business component modeler and custom user interface modeler if you have created these modelers for the flexfield.

15. Click Next.

16. On the Summary page, optionally select Launch Flexfield Business Components Wizard if you are ready to create business components for the flexfield.

17. Click Finish.
18. Add entries to the FND_EF_CATEGORIES_B and FND_EF_CATEGORIES_TL tables for the root category code. In the FND_EF_CATEGORIES_B table, set the PARENT_CATEGORY_CODE to null to indicate that it is the root category. All other category rows for this column points to the root or its child categories.

An extensible flexfield requires at most, one root category, and at least one entry in the FND_EF_CATEGORIES_B table, and, if one exists, the FND_EF_CATEGORIES_TL table. Add additional entries only if you are shipping your application with some categories already defined.

The extensible flexfield category’s schema definition object, or XSD file, is included in its parent category’s XSD file. Thus, the parent category can load the schema for any child category.

---

**Note:**

The CATEGORY_CODE and PARENT_CATEGORY_CODE values are used in the flexfield’s element in the XML schema for web services. You can maximize the readability of the schema by naming the codes with a leading alphabetic character followed by alphanumeric characters. The use of spaces, underscores, multibyte characters, and leading numeric characters, which are all encoded in XML schemas, make the codes in the schema element difficult to read.

---

### 24.7.1.2 Using the Setup APIs to Register and Define Extensible Flexfields

In addition to using the Flexfield Registration Metadata wizard, you can use the FND_FLEX_EF_SETUP_APIS PL/SQL API package to register new extensible flexfield usages and to add the flexfield metadata.

You can learn about the FND_FLEX_EF_SETUP_APIS PL/SQL package by running the following command, which stores package documentation and usage examples in the `<db_name>_<user_name>_FND_FLEX_EF_SETUP_APIS_<date>.plsqldoc` file.

```
sqlplus <fusion_user>/<fusion_pwd>@<fusion_db> \
@/ORACLE/fusionapps/atgpf/applcore/db/sql/flex/fnd_flex_pkg_doc.sql \
FND_FLEX_EF_SETUP_APIS
```

After you register the flexfield, you must add entries for the root category code to the FND_EF_CATEGORIES_B and FND_EF_CATEGORIES_TL tables. Set the PARENT_CATEGORY_CODE to null to indicate that it is the root category.

An extensible flexfield requires at least one entry in the FND_EF_CATEGORIES_B table and, if one exists, the FND_CATEGORIES_TL table. Add additional entries only if you are shipping your application with some categories already defined.

---

**Note:**

The CATEGORY_CODE and PARENT_CATEGORY_CODE values are used in the flexfield’s element in the XML schema for web services. You can maximize the readability of the schema by naming the codes with a leading alphabetic character followed by alphanumeric characters. The use of spaces, underscores, multibyte characters, and leading numeric characters, which are all encoded in XML schemas, make the codes in the schema element difficult to read.
24.8 Creating Extensible Flexfield Business Components

To incorporate an extensible flexfield into your application, you must create business components for the flexfield usage.

The following figure shows the extensible flexfield business components for a product table. In this example, the flexfield is not translatable. The developer has created an entity object and view object from the base extension table to support contexts.

When an implementor deploys flexfield configurations, the deployment process creates the extended context entity objects, context view objects, category view objects, and category-to-context view links. Note that in this example, the C2 context is a member of two categories.
Creating Extensible Flexfield Business Components

**Figure 24-7 Extensible Flexfield Business Components**
24.8.1 How to Create Business Components For an Extensible Flexfield's Usage

You use the Create Flexfield Business Components wizard to create the flexfield business components for an extensible flexfield’s usage.

The business components that are generated will replace any existing components that are based on the same flexfield usage.

**Tip:**

After completing these steps, you can regenerate the flexfield business components programmatically at runtime to update your extensible flexfield implementation without manual intervention.

For more information, see Regenerating Flexfield Business Components Programmatically.

**Before you begin:**

- Create the flexfield entity objects as described in How to Create and Configure Extensible Flexfield Entity Objects.
- Create the flexfield view objects and the declarative SQL-based view object as described How to Create and Configure Extensible Flexfield View Objects.
- Register the flexfield as described in How to Register Extensible Flexfields.
- Build your project to ensure that the entity objects are available in classes. The modeler relies on what is in your classes.
- Ensure that you have added the Applications Core library to your project as described in Setting Up Your JDeveloper Application Workspace and Projects.
- Ensure that at least one customization class is included in the adf-config.xml file. This inclusion serves to ensure correct application behavior. It does not matter which customization class you include.

For information about customization layers, see the "Understanding Customization Layers" section in the Extensibility Guide for Developers.

**To create extensible flexfield business components:**

1. From the File menu, choose New.

2. In the New Gallery, expand Business Tier, select ADF Business Components, select Flexfield Business Components, and click OK.

3. In the Flexfield page of the Create Flexfield Components wizard, select Extensible from the Type dropdown list as shown in the following figure.
4. In the **Application** field, specify the full name of the application to which your extensible flexfield belongs.

   You can browse for the name, and filter by **ID**, **Short Name**, or **Name**.

5. In the **Code** field, specify the code of the extensible flexfield you want to use.

   You can browse for and filter by **Code**.

6. In the **Usage** section, select the table row that contains your desired extensible flexfield usage.

7. Click **Next**.

8. The Overview page displays the tasks that must be completed before the wizard can generate the business components, as shown in the following figure. The wizard will complete the necessary tasks. Click **Next**.

**Note:**

If you created a declarative SQL-based view object as described in **Creating a Declarative SQL-Based View Object to Enable Searching**, then the wizard will create a stub search view object, which you can use to expose the extensible flexfield’s attributes in a table and to incorporate the extensible flexfield in a search form. Make a note of the fully qualified path that is shown in on the Overview page for the stub search view object so that you can locate the view object and add it to an application module. If a path is not shown for the view object, then the declarative SQL-based view object was not registered in the FND_DF_ADFBC_USAGES table.
9. If the wizard needs to implement any uncompleted tasks from the Overview page, the wizard displays the automated code changes, as shown in the following figure. Review the code and click Next.

Note:
This wizard might fail with a "ClassNotFoundException" exception message. This indicates that one or more required libraries have not been automatically included in your project. You can resolve this issue by manually adding any missing libraries; then you can complete this procedure successfully.
11. Refresh the project to see the newly created flexfield business components in the Application Navigator. The components are in the package that you registered for the flexfield usage and are named using the registered prefix.

24.9 Employ an Extensible Flexfield on a User Interface Page

You can incorporate an extensible flexfield into an application with several UI variations:

- As a single task flow for multiple contexts for a single usage in one of the following layouts:
  - Single page layout: A single task flow that presents a set of contexts associated with a specified logical page, which is identified before the UI page initializes. Figure 24-1 is an example of this variation.
  - Panel splitter layout: A list of the extensible flexfield logical pages for a single usage, combined with the contexts for the selected logical page, and integrated into a single task flow. Figure 24-2 is an example of this variation.

- As a single task flow that presents a context, which is identified before the UI page initializes.

- As a complete list of the usages and pages for a given extensible flexfield in one task flow, with contexts for the selected page in a separate task flow.

- As columns in a table that displays the attributes for a specific category. The attributes from all the contexts that are associated with the category are displayed. The attributes are grouped in a column span and are labeled *context*:*segment*.

Note:

- If there is only one usage and only one logical page, use a single task flow that presents a set of contexts associated with a specified logical page, which is identified before the UI page initializes. Do not display a list of usages or pages on the left-hand side of the task flow.

- If the extensible flexfield will never have more than one usage and will never have more than one logical page, and if you do not need any features that are unique to extensible flexfields as discussed in *The Benefits of Extensible Flexfields*, consider using a descriptive flexfield instead.

- Unless you know that the extensible flexfield will contain only a small amount of information, do not embed the flexfield in the middle of a region that has other content.

For more information about task flows, see the Creating a Task Flow section in the *Developing Fusion Web Applications with Oracle Application Development Framework*. 
24.9.1 How to Expose an Extensible Flexfield Usage as a Single Task Flow for Multiple Contexts

You can easily incorporate an extensible flexfield into the UI in one of the following layouts by dragging the view object for the flexfield-enabled object from the Data Controls panel and dropping it onto the page:

- Single page layout: The extensible flexfield is incorporated as a single task flow that presents a set of contexts associated with a specified logical page and usage as shown in Figure 24-1.

- Panel splitter layout: The extensible flexfield is incorporated as a list of the logical pages for a specified usage, combined with the contexts for the user-selected logical page, and integrated into a single task flow, as shown in Figure 24-2.

Before you begin:

1. Create and configure business components to support the extensible flexfield as described in Creating Extensible Flexfield Business Components.

2. Execute the following SQL query to obtain the name of the view object for the flexfield-enabled object:

   ```sql
   SELECT VIEW_OBJECT FROM FND_DF_ADFBC_USAGES WHERE TABLE_NAME IN
   (SELECT TABLE_NAME FROM FND_DF_TABLE_USAGES TBL WHERE
   DESCRIPTIVE_FLEXFIELD_CODE = flexfield-code
   AND TBL.APPLICATION_ID = application-id
   AND TABLE_TYPE = 'BASE' AND FLEXFIELD_USAGE_CODE = flexfield-usage-code)
   ```

To add an extensible flexfield as a single flow for multiple contexts:

1. Open the page to which you want to add the extensible flexfield.

2. From the Data Controls panel, drag the view object for the flexfield-enabled object onto the page or Structure window.

3. When prompted, choose Applications and then choose Oracle Extensible Flexfield.

4. In the User Interface region in the Create Extensible Flexfield dialog, select Panel Splitter or Single Page, as shown in Figure 24-11.
5. Accept the default group code or change its value.

6. If you selected the single page layout, enter the page code for the logical page to be displayed at runtime.

7. Specify the usage code.

8. In the **Object Keys** region, specify the values to use for the category code and the primary keys. The expression/value provided is evaluated at runtime to determine the object instance for which the extensible flexfield attribute values are to be shown.

9. Click **Apply**.

10. (Optional) Complete the following steps to modify the **ReadOnly** and **_eff_param1** through **_eff_param5** properties:
   
   a. Right click in the page and choose **Go to Page Definition**.
      
   b. In **Executables** section in the page definition, select **taskFlow - ExtensibleFlexfieldRuntimeUI1** and click the **Edit** icon.
      
   c. In the **Input Parameters** region in the **Edit Task Flow Binding** dialog, set **ReadOnly** to **Y** if the page should render all segments as read-only fields. Otherwise, set to **N** or leave the parameter value blank.
      
   d. If you need to pass in custom parameters for UI customization, as described in **How to Customize the Runtime User Interface Modeler for Extensible Flexfields**, use the **_eff_param1** through **_eff_param5** parameters to specify the custom parameter values. For example, if you need to customize the page to display or not display certain segments based upon the user’s location, you can use one of these parameters to provide the location as an input parameter.

11. If you have not done so already, complete the following substeps:
   
   a. Open the **Databindings.cpx** file and add the following **EFFRuntimeAM** data control:
b. Add the following code to the Application tag at the top of the
Databindings.cpx file to enable the application to find the page
definitions for the generated UI artifacts:

```xml
PageMapClass="oracle.jbo.uicli.mom.DynamicPageMapImpl"
BaselineDefPackageName="pageDefs"
```

### 24.9.2 How to Expose the Complete Set of an Extensible Flexfield’s Usages, Logical
Pages, and Associated Contexts

To expose the complete set of usages, logical pages, and associated contexts, build a UI
page that includes a splitter with two task flows: one containing the list of extensible
flexfield usages and their associated logical pages on the left, and the other containing
the contexts associated with the selected logical page on the right.

**To build the UI page:**

1. Create a task flow for the extensible flexfield usages and a task flow for the
associated contexts.
2. Create the left and right fragment pages.
3. Use the task flows in the UI page.

#### 24.9.2.1 Creating the Task Flows

The UI page requires two task flows: one containing the list of extensible flexfield
usages and their associated logical pages, and the other containing the contexts
associated with the selected logical page.

**Before you begin:**

Create and configure business components to support the extensible flexfield as
described in *Creating Extensible Flexfield Business Components*.

**To create the two task flows:**

1. Create a page-list task flow, for example, `PageListTF`.
2. Add the following parameter to the task flow:
   - **Name:** `ContainerBean`
   - **Class:**
     ```java
     oracle.apps.fnd.applcore.flex.eff.runtime.EffCategoryPages
     ```
3. Create the context container task flow, for example, ContextPageTF.

4. Add a parameter that is the same as the one you added in Step 2 to the task flow.

24.9.2.2 Creating the Fragments

Create a left fragment for the list of flexfield usages and a right fragment for contexts.

Before you begin:

Create the page-list task flow and context container task flow as described in Creating the Task Flows.

To create the fragments:

1. Create the left and right fragment pages PageListFrag.jsff and ContextPageFrag.jsff.

2. Add the EffCatPageListContainer seeded task flow from the ViewController FlexModeler-View library to the page list fragment using the following parameters:
   - _eff_application_id: Provide the FND_EF_UI_PAGES_B.APPLICATION_ID value; for example 10010.
   - _eff_descriptive_flexfield_code: Provide the FND_EF_UI_PAGES_B.DESCRIPTIVE_FLEXFIELD_CODE value; for example EGO_ITEM_EFF.
   - _eff_category_code: Provide the FND_EF_UI_PAGES_B.CATEGORY_CODE value; for example ELECTRONICS.
   - _eff_usage_code: Provide the FND_EF_UI_PAGES_B.FLEXFIELD_USAGE_CODE value; for example, EGO_ITEM_DL.
   - _eff_containerBean: Provide #{pageFlowScope.ContainerBean}.

3. Add the EffContextsPageContainer seeded task flow from the ViewController FlexModeler-View library to the context page fragment using the following parameters:
   - _eff_application_id: Provide #{pageFlowScope._eff_application_id}.
   - _eff_descriptive_flexfield_code: Provide #{pageFlowScope._eff_descriptive_flexfield_code}.
   - _eff_category_code: Provide #{pageFlowScope._eff_category_code}.
   - _eff_usage_code: Provide #{pageFlowScope._eff_usage_code}.
   - _eff_page_code: Provide #{pageFlowScope._eff_page_code}.
   - _eff_containerBean: Provide #{pageFlowScope.ContainerBean}.
• \_eff\_category\_pk1: (optional) Provide the value for the category’s first primary key column, if applicable. For example, if the first primary key column is INVENTORY\_ITEM\_ID, and its value is 149, provide 149.

• \_eff\_category\_pk2 - (optional) Provide the value for the category’s second primary key column, if applicable. For example, if the second primary key column is ORGANIZATION\_ID, and its value is 204, provide 204.

• \_eff\_category\_pk3 through pk5: Provide the value for that primary key column, if applicable.

• \_eff\_check\_privilege: (optional) Set to Y if the view privilege is to be honored for the context regions.

4. (Optional) To make it easy for implementors to identify which region on a page contains the extensible flexfield, set the Text property for the region component that contains the extensible flexfield task flow to #{applcoreBundle.EFF\_REGION}.

5. Drag and drop the page list fragment onto the page-list task flow.

6. Drag and drop the context page fragment onto the context task flow.

24.9.2.3 Using the Task Flows in the Page

Use the task flows that you just created in Creating the Task Flows to add the usages, logical pages, and associated context lists to the page.

Before you begin:

1. Create the page-list task flow and context container task flow as described in Creating the Task Flows.

2. Create the left and right fragment pages PageListFrag.jsff and ContextPageFrag.jsff as described in Creating the Fragments.

To use the task flows in the page:

1. Open the page and add the splitter.

2. Add the page-list and context page task flows to the left and right facets of the splitter.

3. Enter the value of pageFlowScope.EffCategoryPagesBean for the ContainerBean parameter to the task flows.

4. If you have not done so already, complete the following substeps:
   a. Open the Databindings.cpx file and add the following EFRuntimeAM data control:

      <BC4JDataControl id="EFRuntimeAMDataControl"
      Package="oracle.apps.fnd.applcore.flex.eff.runtime.applicationModule"
      FactoryClass="oracle.adf.model.bc4j.DataControlFactoryImpl"
      SupportsTransactions="true" SupportsFindMode="true"
      SupportsRangesize="true" SupportsResetState="true"
      SupportsSortCollection="true" Configuration=""/>
b. Add the following code to the Application tag at the top of the Databindings.cpx file to enable the application to find the page definitions for the generated UI artifacts:

```xml
PageMapClass="oracle.jbo.uicli.mom.DynamicPageMapImpl"
BasePageDefPackageName="pageDefs"
```

### 24.9.3 How to Expose One Extensible Flexfield Context

Build an application page with a single task flow as a dynamic region on the right, and containing the context that was passed. This variation does not present an extensible flexfield usage or page-list task flow in the user interface.

**Before you begin:**

Create and configure business components to support the extensible flexfield as described in [Creating Extensible Flexfield Business Components](#).

**To expose the extensible flexfield context:**

1. Create a task flow for Pages List, for example, `PageListTF.xml`.
2. Add a managed bean called `EffCategoryPagesBean` to this task flow. It should have a class of `pageFlowScope.EffCategoryPagesBean` and a scope of `pageFlow`.
3. Create a fragment, for example `PageListFrag.jsff`, and drag and drop the `EffCatPageListContainer` task flow from the ViewController FlexModeler-View library on the fragment.
4. Add the following parameters:
   - `_eff_application_id`: Provide `#{pageFlowScope._eff_application_id}`.
   - `_eff_descriptive_flexfield_code`: Provide `#{pageFlowScope._eff_descriptive_flexfield_code}`.
   - `_eff_category_code`: Provide `#{pageFlowScope._eff_category_code}`.
   - `_eff_usage_code`: Provide `#{pageFlowScope._eff_usage_code}`.
   - `_eff_page_code`: Provide `#{pageFlowScope._eff_page_code}`.
   - `_eff_containerBean`: Provide `#{pageFlowScope.EffCategoryPagesBean}`.
   - `_eff_check_privilege`: (optional) Set to `Y` if the view privilege is to be honored for the context regions. [[Check with Gaurav whether this should be included]]
5. Place the task flow on any page on which you want the page list to appear.
6. Create a task flow, for example, `ContextsTF.xml`.
7. Add an empty fragment to this task flow, for example, `ContextsFrag.jsff`.

8. Access the page on which you would like your contexts to appear. This could possibly be the same page as in Step 5, but is likely the second facet of a splitter.

9. Drag and drop `ContextsTF.xml` as a dynamic region onto this page at the correct location.

10. When prompted for a backing bean, enter a new bean name, class, and package, for example, `ContextsRenderingBean.java`, and allow it to remain as a backing bean.

11. Open the Java file and add the following code, replacing the value for `taskFlowId` with the appropriate string:

```java
public class ContextsRenderingBean {
    private String taskFlowId = "/WEB-INF/oracle/apps/fnd/applcore/flex/eff/runtime/ui/test/flow/ContextsTF.xml#ContextsTF";
    private String newTaskFlowId = null;
    private boolean refreshRegion = false;

    public ContextsRenderingBean () {
    }

    public TaskFlowId getDynamicTaskFlowId() {
        return TaskFlowId.parse(taskFlowId);
    }

    public boolean getRefreshRegion() {
        refreshRegion = false;
        newTaskFlowId = (String) ADFContext.getCurrent().getSessionScope().get("_eff_context_tf_id");

        if (newTaskFlowId != null && taskFlowId.compareTo(newTaskFlowId) != 0) {
            taskFlowId = newTaskFlowId;
            refreshRegion = true;
        }
        return refreshRegion;
    }
}
```

12. Open the page definition for the launch page and scroll to the location of the dynamic region binding.

13. Add the following refresh condition setting to the `taskFlow` tag:

```
RefreshCondition="#{backingBeanScope.ContextsRenderingBean.refreshRegion}"
```

This setting provides the callback and the conditions for the refresh of the contexts region.

When you run the page and click the page link, the callback to `refreshRegion` will look up the ID for the contexts task flow and enable a refresh condition of the dynamic region.

14. If you have not done so already, complete the following substeps:

   a. Open the `Databindings.cpx` file and add the following `EFFRuntimeAM` data control:

```
<BC4JDataControl id="EFFRuntimeAMDataControl"
     Package="oracle.apps.fnd.applcore.flex.eff.
```
runtime.applicationModule="
FactoryClass="oracle.adf.model.bc4j.DataControlFactoryImpl"
SupportsTransactions="true" SupportsFindMode="true"
SupportsRangesize="true" SupportsResetState="true"
SupportsSortCollection="true" Configuration="EFFRuntimeAM"
syncMode="Immediate"
xmlns="http://xmlns.oracle.com/adfm/datacontrol"/>

b. Add the following code to the Application tag at the top of the Databindings.cpx file to enable the application to find the page definitions for the generated UI artifacts:

PageMapClass="oracle.jbo.uicli.mom.DynamicPageMapImpl"
BasePageDefPackageName="pageDefs"

24.9.4 How to Expose Extensible Flexfield Attributes in a Table

You can expose extensible flexfield attributes as columns in a table that displays attributes for a specific category. The attributes from all the contexts that are associated with the selected category are displayed. The attributes are grouped in a column span and are labeled context:segment.

Before you begin:

- If you have not done so already, add the stub search view object that was created when you ran the Create Flexfields Business Components wizard to an application module. The stub search view object is in the view folder in the package that you registered for the extensible flexfield usage in the FND_DF_ADFBC_USAGES table.

note:
The Create Flexfields Business Components wizard creates the stub search view object based on the flexfield’s declarative SQL-based view object that was registered for the flexfield usage. If no declarative SQL-based view object was registered, then a stub search view object will not exist. You must create and register the SQL-based view object as described in Creating a Declarative SQL-Based View Object to Enable Searching and then run the Create Flexfield Business Components wizard as described in How to Create Business Components For an Extensible Flexfield’s Usage.

To expose category attributes in a table:

1. Open the page to which you want to add the table with extensible flexfield columns.
2. Drag the stub search view object and drop it on the page.
3. When prompted, select Applications > Table.
4. Rearrange the columns and select table options as required. If you choose the filtering option, the table will be a filtered table.
5. Right-click in the page and choose Go to Page Definition.
6. In the source editor for the page definition, remove the AttrNames tag and its nested tags from the nodeDefinition tag in the tree tag. The tags shown in bold in Example 24-5 are examples of the tags to remove.

7. Write down the value for IterBinding.

8. In the source editor for the search page, add the following <af:column> tag to the <af:table> tag. Change iter-binding to the IterBinding value for the tree tag in the page definition. This is the value that you noted in Step 7.

```xml
<af:column headerText="header-text">
  <fnd:extensibleFlexfieldColumn
    value="#{bindings.iter-binding}" columnSpan="false"
    readOnly="true"/>
</af:column>
```

The columnSpan="false" tag turns off column grouping for the table. The value is set to false by default. Set columnSpan to true if you want to group the columns.

9. Open the source code in which you will call the executeQuery method for the view object.

10. Add a call to the EFFSearchUtil.prepareEFFDeclarativeVOForCategory method followed by a call to the view object's executeQuery method.

    The prepareEFFDeclarativeVOForCategory method prepares the declarative view object with all the attributes that pertain to the specified category.

    Example 24-4 shows the API for the prepareEFFDeclarativeVOForCategory method.

11. After the call to the executeQuery method, call the DescriptiveFlexfield.updateFlexColumns method with the table component object as the argument.

    This method refreshes the table to add the flexfield columns for the category.

Example 24-3  AttrNames Tag to Remove from the Page Definition

```xml
<tree
  IterBinding="j_ExtendedDeclarativePublic1Iterator"
  id="j_ExtendedDeclarativePublic1">
  <nodeDefinition DefName="oracle.apps.fnd.applcore.flex.eff.test.genjbo.base.model.view.
    j_ExtendedDeclarativePublicVO" Name="j_ExtendedDeclarativePublic10">
    <AttrNames>
      <Item Value="Description"/>
      <Item Value="ItemType"/>
      <Item Value="Name"/>
      <Item Value="CategoryCode"/>
    </AttrNames>
  </nodeDefinition>
</tree>
```

Example 24-4  prepareEFFDeclarativeVOForCategory API

```java
@param effDeclarativeViewObject : The view object instance on which the table has been built. This should be an instance of j_ExtendedDeclarative<group>VO

@param categoryCode : The category for which to render the table.
```
public static void prepareEFFDeclarativeVOForCategory(
  ViewObjectImpl effDeclarativeViewObject,
  String categoryCode
)

24.10 Incorporating Extensible Flexfields into a Search Form

You can include extensible flexfield view object attributes as search criteria in a query search form. The search form will include an Add Fields button, which displays a list of the flexfield view object attributes. End users can select which attributes of the flexfield view object to use as search criteria.

24.10.1 How to Incorporate an Extensible Flexfield into a Search Form

You incorporate an extensible flexfield into a query search form by dropping a view criteria component from the Data Controls panel onto the page.

Before you begin:

- If you have not done so already, add the stub search view object that was created when you ran the Create Flexfields Business Components wizard to an application module. The stub search view object is in the view folder in the package that you registered for the extensible flexfield usage in the FND_DF_ADFBC_USAGES table.

  Note:
The Create Flexfields Business Components wizard creates the stub search view object based on the flexfield's declarative SQL-based view object that was registered for the flexfield usage. If no declarative SQL-based view object was registered, then a stub search view object will not exist. You must create and register the SQL-based view object as described in Creating a Declarative SQL-Based View Object to Enable Searching and then run the Create Flexfield Business Components wizard as described in How to Create Business Components For an Extensible Flexfield's Usage.

- If the desired view criteria for the stub search view object does not exist, create it. The view criteria must contain the flexfield’s CategoryCode attribute. The operator for the CategoryCode attribute must be set to Equals.

To incorporate an extensible flexfield into a search form:

1. Open the search page to which you want to add the extensible flexfield.

2. From the Data Controls panel, expand the stub search view object, expand Named Criteria, and drag the desired view criteria onto the page or Structure window.

3. Use the stub search view object to create a results panel and a query panel as described in the Creating Query Search Forms section in the section in the Developing Fusion Web Applications with Oracle Application Development Framework.

4. Right-click in the page and choose Go to Page Definition.

5. In the source editor for the page definition, remove the AttrNames tag and its nested tags from the nodeDefinition tag in the tree tag. The tags shown in bold in Example 24-5 are examples of the tags to remove.
6. Write down the value for IterBinding.

7. In the Structure window for the search page, select the af:query component.

8. In the Property Inspector, expand Behavior and set the QueryListener property to FlexEFFSearchUtilBean.effQueryListener.

9. In the source editor for the search page, add the following <af:column> tag to the <af:table> tag. Change iter-binding to the IterBinding value for the tree tag in the page definition. This is the value that you noted in Step 6.

   <af:column headerText="header-text">
     <fnd:extensibleFlexfieldColumn
       value="#{bindings.iter-binding}"
       readOnly="true"/>
   </af:column>

Example 24-5  AttrNames Tag to Remove from the Page Definition

   <tree
      IterBinding="j_ExtendedDeclarativePublic1Iterator"
      id="j_ExtendedDeclarativePublic1">
     <nodeDefinition
       DefName="oracle.apps.fnd.applcore.flex.eff.test.genjbo.base.model.view.j_ExtendedDeclarativePublicVO"
       Name="j_ExtendedDeclarativePublic10">
       <AttrNames>
         <Item Value="Description"/>
         <Item Value="ItemType"/>
         <Item Value="Name"/>
         <Item Value="CategoryCode"/>
       </AttrNames>
     </nodeDefinition>
   </tree>

24.11 Preparing Extensible Flexfield Business Components for Oracle Business Intelligence

Oracle Business Intelligence is a comprehensive collection of enterprise business intelligence functionality that provides the full range of business intelligence capabilities including interactive dashboards, full ad hoc, proactive intelligence and alerts, enterprise and financial reporting, real-time predictive intelligence, and more.

Extensible flexfields are modeled using polymorphic view objects, which are not compatible with Oracle Business Intelligence. To enable an extensible flexfield to be used by Oracle Business Intelligence, the corresponding polymorphic view objects must be flattened into a usable static form.

If an extensible flexfield is business-intelligence enabled and a declarative SQL-based view object is registered for the flexfield, then, when you create business components for the extensible flexfield, the business component modeler generates a stub view object for business intelligence alongside the standard extensible flexfield polymorphic view object.

At runtime, the implementor can select which individual flexfield segments to make available for use with Oracle Business Intelligence. Those segments are included in a flattened view object that is generated from the stub view object. Administrators must then import the flexfield into the Oracle Business Intelligence repository to make it available for Oracle Business Intelligence.
24.11.1 How to Enable an Extensible Flexfield for Oracle Business Intelligence

To cause the business component modeler to generate the stub view object for business intelligence, you must business-intelligence enable the flexfield. Use the setup APIs to set the flexfield's BI_ENABLED flag business-intelligence as described in Using the Setup APIs to Register and Define Extensible Flexfields.

You can optionally use the setup APIs to provide flattened fact names for the flexfield’s entity details. You provide a flattened fact name by setting the BI_FLATTENED_FACT_NAME value.

24.11.2 How to Flatten the Extensible Flexfield Model for a Business Intelligence-Enabled Extensible Flexfield

When you create business components for a business intelligence-enabled extensible flexfield, the business component modeler recognizes the business intelligence-enabled setting. A view object that is flattened for Oracle Business Intelligence is generated alongside the standard extensible flexfield polymorphic view object.

Before you begin:

1. Ensure that a business intelligence application module and a business intelligence view object exist for the product table for which you are implementing the extensible flexfield. For information, see Designing and Securing View Objects for.

2. Create a declarative SQL-Based view object as described in Creating a Declarative SQL-Based View Object to Enable Searching.

3. Ensure that the declarative SQL-Based view object was registered for the flexfield, either by using the Register Flexfield Metadata wizard to provide the fully qualified name of the search view object or by executing the following SQL statement to register it. Replace search-view-object with the fully qualified name for the search view object. Replace product-table with the name of the product table that the flexfield extends.

   ```sql
   UPDATE FND_DF_ADFBC_USAGES
   SET EFF_SEARCH_VIEW_OBJECT = 'search-view-object'
   WHERE TABLE_NAME='product-table'
   AND ENTITY_OBJECT='product-table-entity-object';
   
   4. Enable the flexfield and the desired segments for Oracle Business Intelligence as described in How to Enable an Extensible Flexfield for.

To produce a business intelligence-enabled flattened extensible flexfield model:

1. Create extensible flexfield business components as described in How to Create Business Components For an Extensible Flexfield’s Usage.

   For a flexfield that is business intelligence-enabled, the Create Flexfield Business Components wizard generates a stub view object, which is named object-name-prefixEFFBFIFlattenedVO, and other business components under a directory called analytics in the package root directory. These are generated in addition to the standard extensible flexfield view object.

2. Complete the following steps to link the stub view object to the business intelligence view object for the product table.
a. From the File menu, choose New.

b. In the New Gallery, go to Business Tier > ADF Business Components and select Flexfield View Link.

c. Click OK to access the Create Flexfield View Link wizard.

 d. On the Name page, from the Package dropdown list, specify a package for the view link.

Caution:
You cannot move the view link to a different package after you create it. Instead, you must delete the view link and re-create it with the new package name.

 e. In the Name field, enter a name for the view link.

 f. Click Next.

 g. In the Select Source View Object tree, expand the available objects from your current project and select the master view object, which is the business intelligence view object for the product table.

h. In the Select Destination Flexfield tree, expand the application and select the destination flexfield usage, which is the stub view object.

i. In the View Link Accessor Name field, enter an appropriate name for the view link accessor.

j. Click Next.

k. On the Source Attributes page, click Finish.

For extensible flexfields, the Source Attributes page is informational only. The wizard uses the primary key attributes of the source view object to define the view link.

Note:
You can skip the Properties page because view link-specific properties are not supported.

l. On the Summary page, click Finish.

3. (Optional) To control how the extensible flexfield attributes appear in the Oracle Business Intelligence presentation layer, edit the application module that contains the stub view, and then, in the Custom Properties section in the General navigation tab, add one or more of the following properties:

- To display only the attributes in the stub view object that have a specific context usage or category code, add one of the following custom properties and values to the application module:
  
  - FND_ACFF_SHOW_ATTRIBUTES_WITH_PROPERTY_stub-vo-instance-name = "FND_ACFF_EFF_CONTEXT_USAGE=propertyvalue"
For example, the following custom property specifies that when displaying the attributes from the ItemEFFBIFlattenedVO view object, only the attributes that have the FND_ACFF_EFF_CONTEXT_USAGE property with a value of EGO_ITEM_DL will be displayed in the presentation layer:

\[
\text{FND_ACFF_SHOW_ATTRIBUTES_WITH_PROPERTY}\_\text{stub-vo-instance-name} = "\text{FND_ACFF_EFF_CATEGORY_CODE=propertyvalue}\"
\]

**Note:**

If the property is not set, then all attributes appear in the presentation layer.

- To specify how to arrange the attributes in the presentation layer, add one of the following properties:
  - To arrange the attributes by context within category, add the following custom property:
    \[
    \text{FND_ACFF_EFF_BI_PRESENTATION_OPTION}\_\text{stub-vo-instance-name} = "\text{FLAT_CATEGORY_CONTEXT_FOLDER_LIST}\"
    \]
    The attributes will be displayed in context folders within each applicable category folder.
  - To arrange the attributes by category within context, add the following custom property:
    \[
    \text{FND_ACFF_EFF_BI_PRESENTATION_OPTION}\_\text{stub-vo-instance-name} = "\text{FLAT_CATEGORY_FOLDER_LIST_NESTED_CONTEXT}\"
    \]
    The attributes will be displayed in category folders within each applicable context folder. This is the default option.

**Note:**

If the FND_ACFF_EFF_BI_PRESENTATION_OPTION\_stub-vo-instance-name option is not defined, then the attributes are arranged by category within context.
Business Intelligence Publisher provides a mechanism to extract data from a remote server using web service calls to a View Object. Applications developers can define data sources as View Objects in their application and then create a data model in BI Publisher to retrieve the data to use in their reports. Application developers must register an AM with BI Publisher which includes the View Objects which will fetch data for the reports. To allow users to use Extensible Flexfield segment attributes to define reports in BI Publisher, these flexfield segments need to view link the stub for a flattened View Object generated by Flex Modelers. The flattened View Object will include all segments defined in the flexfield across contexts and categories.

24.13 Loading Seed Data

Any implementation of flexfields in Oracle Fusion Applications typically requires application seed data, which is the essential data that enables flexfields to work properly in applications. Flexfield seed data can be uploaded and extracted using Seed Data Loader.

After you complete the registration process described in How to Register Extensible Flexfields, your flexfield seed data consists of the information that you registered for your flexfield, such as the tables and columns reserved for your flexfield. For a customer flexfield, the seed data contains only this registration data.

If your flexfield is a developer flexfield, you also serve as the implementor. In addition to the registration data, your flexfield seed data might include contexts, segments, and value sets that you have defined for your flexfield. You can use the Oracle Fusion Middleware Extensions for Applications (Applications Core) Setup application, as described in Deploying Flexfields in a Standalone WebLogic Server Environment, to configure a flexfield.

Use the Manage Extensible Flexfields and Manage Value Sets tasks or use the PL/SQL APIs to create contexts, segments, and value sets, and then use the seed data loader to extract your seed data. To protect flexfield seed data from customer edits, use the Manage Extensible Flexfields task to set flags to mark flexfield pages and contexts as protected. Use the Manage Value Sets task to set the flag to protect a value set.

Only the user with the SEED_DATA_FROM_APPLICATION_USER user name can modify protected flexfield pages, contexts, and value sets from the setup tasks, such as the Manage Extensible Flexfields and Manage Value Sets tasks.

For information about extracting and loading seed data, see Initializing Oracle Fusion Application Data Using the Seed Data Loader.

24.14 Customize the Extensible Flexfield Modelers

You can customize the modelers that generate the extensible flexfield business component and UI artifacts to add additional product-specific logic. For example, you might want the modeler to set a specific JavaServer Pages (JSP) Expression Language (EL) expression on a generated segment's ReadOnly property.

24.14.1 How to Customize the Runtime Business Component Modeler for Extensible Flexfields

To extend the runtime business component modeler for extensible flexfields, override the EFFBCModelerFactory.getCustomEFFBCModeler method, shown in Example 24-6, in the custom runtime business component modeler factory for extensible flexfields.
An example of the PIMBCModelerFactory.java override for this method is shown in Example 24-7.

Example 24-6  getCustomEFFBCModeler Method

```java
/**
 * Implementing teams need to override this method and provide the custom BC Modeler here (for example, PIMBCModeler).
 * @param namespace the namespace
 * @param flexDef the flexfield def
 * @param entityUsage the entity usage
 * @param writer the modeler writer
 * @param conf the configuration
 * @param categoryDef the category def
 * @param categoryContextDef the category context def
 * @param categoryCode the category code
 * @param contextCode the context code
 * @param appShortName the application short name
 * @param flexCode the flexfield code
 * @param connUrl the connection url
 * @param isInterface the interface flag
 * @return the custom EFF BC Modeler instance.
 */
protected EFFBCModeler getCustomEFFBCModeler(FlexfieldNamespace namespace,
                                              FlexfieldDef flexDef,
                                              FlexfieldEntityUsage entityUsage,
                                              BCModelerWriter writer,
                                              Map<BCModeler.Option, Object> conf,
                                              CategoryDef categoryDef,
                                              CategoryContextDef categoryContextDef,
                                              String categoryCode,
                                              String contextCode,
                                              String appShortName,
                                              String flexCode,
                                              String connUrl,
                                              boolean isInterface)
{
    return new EFFBCModeler(namespace, flexDef, entityUsage, writer, conf,
                              categoryDef, categoryContextDef, categoryCode,
                              contextCode, appShortName, flexCode, connUrl,
                              isInterface);
}
```

Example 24-7  PIMBCModelerFactory.java Override

```java
protected EFFBCModeler getCustomEFFBCModeler(FlexfieldNamespace namespace,
                                              FlexfieldDef flexDef,
                                              FlexfieldEntityUsage entityUsage,
                                              BCModelerWriter writer,
                                              Map<BCModeler.Option, Object> conf,
                                              CategoryDef categoryDef,
                                              CategoryContextDef categoryContextDef,
                                              String categoryCode,
                                              String contextCode,
                                              String appShortName,
                                              String flexCode,
                                              String connUrl,
                                              boolean isInterface)
{
    return new PIMBCModeler(namespace, flexDef, entityUsage, writer, conf,
                              categoryDef, categoryContextDef, categoryCode,
                              contextCode, appShortName, flexCode, connUrl,
```

Customize the Extensible Flexfield Modelers
24.14.2 How to Customize the Runtime User Interface Modeler for Extensible Flexfields

If the UI artifacts that are generated for an extensible flexfield business component do not fulfill application requirements, you can create wrapper implementation classes for the framework's customizer interfaces. These wrapper implementation classes enable some control over the XML code that the modeler generates for the UI artifacts just before it persists the generated task flows and JavaServer Faces (JSF) page fragments. The implementation classes are in the oracle.apps.fnd.applcore.flex.uimodeler.customizers package.

To customize an extensible flexfield business component's generated UI artifacts:

1. Create wrapper classes for the default customizer implementation classes.
2. Create a wrapper of the metadata provider implementation class.
3. Register the metadata provider wrapper class in the metadata for the flexfield's business component.

24.14.2.1 Create the Customizer Wrapper Class

Extend the default customizer implementation classes from the oracle.apps.fnd.applcore.flex.uimodeler.customizers package to customize the following UI artifacts:

- Context JSF fragment
- Segment components in the generated context task flow
- Page links in the generated links task flow
- Page task flow
- Search task flow

24.14.2.1.1 How to Customize the Context JSF Page Fragment

To customize the JSF page fragment for a single row context, create a wrapper class for the SingleRowContextRegionCustomizerImpl implementation class and override the customizeGeneratedSingleRowContextFragment method.

To customize the JSF page fragment for a multiple row context, create a wrapper class for the MultiRowContextRegionCustomizerImpl implementation class and override the customizeGeneratedMultiRowContextFragment method.

24.14.2.1.2 How to Customize the Segment Components in the Generated Context Task Flow

To customize which segment components in the generated context task flow will be read-only for single and multirow contexts, create a wrapper class for the ContextComponentsCustomizerImpl implementation class and override the getAttributeComponentReadonlyELExpression method. This method returns the value of the readonly property for a given segment component in the context task flow, as shown in Example 24-8.

Example 24-8  Sample getAttributeComponentReadonlyELExpression Method

```java
public String getAttributeComponentReadonlyELExpression(
    Transaction tx, ViewDef contextViewDef) {
```
24.14.2.1.3 How to Customize the Page Links in the Generated Links Task Flow

To customize which page links in a generated links task flow will be rendered, create a wrapper class for the PageListCustomizerImpl implementation class and override the getPageLinkRenderedProperty method. This method returns the value of the rendered property for a page link.

24.14.2.1.4 How to Customize the Page Task Flow

To customize which context task flows will be rendered in a page task flow, create a wrapper class for the ContainerPageCustomizerImpl implementation class and override the getContextTFRenderedELExpression method. This method returns the value of the region tag for a context task flow.

If implementors have defined a view privilege on a context, then the application checks if the context is present in either the base or translation extension table before verifying whether the end user has view privileges for the context. By default, the application uses the primary keys of the product table plus the context code and category code to search for a matching row in the extension tables. If your application uses a different method for associating extension table rows with product table rows, you must override the prepareSqlQueryForMatchingEffLineId method in the oracle.apps.fnd.appcore.flex.eff.runtime.EffCategoryPagesBean.java class to return the search query that is to be used to find a matching row. This method takes the security object, the context code, the category code, and the category row as input parameters and it returns the query in String form.

24.14.2.1.5 How to Customize the Search Task Flow

To customize the search task flow, create a wrapper class for the SearchRegionCustomizerImpl implementation class. Table 24-3 shows the ways in which you can customize the search task flow and the methods to override to perform the customizations.

<table>
<thead>
<tr>
<th>Customization</th>
<th>Method to Override</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Set the list of actions required in the search results table.</td>
<td>getResultTableActionMenu</td>
<td>Use the ResultsTableActionMenu inner class to define the menu properties and entries.</td>
</tr>
<tr>
<td>Set the managed bean for the generated task flow.</td>
<td>getSearchManagedBeanClass</td>
<td>The manage bean must extend oracle.apps.fnd.appcore.flex.eff.search.ui.bean.DefaultEffSearchManagedBean.</td>
</tr>
<tr>
<td>Customization</td>
<td>Method to Override</td>
<td>Notes</td>
</tr>
<tr>
<td>-------------------------------------------------------------------------------</td>
<td>---------------------------------------------------------</td>
<td>----------------------------------------------------------------------</td>
</tr>
<tr>
<td>Alter properties in the product table component for search results.</td>
<td>getApplicationsTablePropertiesMap</td>
<td>This method returns a hashmap of name-value pairs of the properties to be set.</td>
</tr>
<tr>
<td>Alter properties in the ADF Table that is in the product table component for search results.</td>
<td>getADFTablePropertiesMap</td>
<td>This method returns a hashmap of name-value pairs of the properties to be set, as shown in Example 24-9.</td>
</tr>
<tr>
<td>Customize the query panel properties.</td>
<td>getQueryPanelPropertiesMap</td>
<td>This method returns a hashmap of name-value pairs of the properties.</td>
</tr>
<tr>
<td>Get a handle to the document object model (DOM) object of the generated search region and its pageDef.</td>
<td>customizeGeneratedSearchTaskflowRegion</td>
<td>Use DOM objects to customize generated artifacts only if there is no other way to perform for the customization.</td>
</tr>
<tr>
<td>Customize the readOnly property for a component in search results table column.</td>
<td>getResultsTableColumnComponentReadOnlyELExpression</td>
<td>This method returns a JSP EL expression.</td>
</tr>
<tr>
<td>Customize the properties on the search results table column for an attributeDef.</td>
<td>getResultsTableColumnPropertiesMap</td>
<td>This method returns a hashmap of name-value pairs of the properties.</td>
</tr>
<tr>
<td>Set the task flow data control scope to shared.</td>
<td>getSearchTaskFlowDataControlScope</td>
<td>The task flow can be generated with either a SHARED scope or an ISOLATED scope. The default is ISOLATED. Override this method to set the scope to SHARED.</td>
</tr>
<tr>
<td>Add custom toolbar components.</td>
<td>getAdditionalToolbarComponentDefinitions</td>
<td>Use the AdditionalToolbarComponentDefinition inner class to provide metadata for the required component. You can add components of type CHOICELIST, BUTTON, SPACER, and SEPARATOR.</td>
</tr>
</tbody>
</table>
Table 24-3  (Cont.) Methods to Override to Customize the Search Task Flow

<table>
<thead>
<tr>
<th>Customization</th>
<th>Method to Override</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Set the default search criteria on the search page as it is loaded.</td>
<td>getDefaultSearchCriteriaName</td>
<td>NA.</td>
</tr>
<tr>
<td>Customize the generated search task flow XML.</td>
<td>customizeGeneratedSearchTaskflow</td>
<td>This method returns a handle to the DOM object for the generated task flow XML. You should use DOM objects to customize generated artifacts only if there is no other way to perform the customization.</td>
</tr>
</tbody>
</table>

Example 24-9  Sample getADFTablePropertiesMap Method

```java
public HashMap getADFTablePropertiesMap()
{
    HashMap propertiesMap = new HashMap(10);
    propertiesMap.put("filterVisible","false");
    propertiesMap.put("columnStretching","column:description");
    propertiesMap.put("inlineStyle","width:100%;");
    return propertiesMap;
}
```

24.14.2.1.6 How to Create a Metadata Provider Implementation Class

If you have created customizer wrapper classes for a flexfield business component, you must create a wrapper of the default UIModelerMetadataProviderImpl implementation class for that business component. This class is in the oracle.apps.fnd.applcore.flex.uimodeler package.

Override the appropriate methods in the following list to return the names of the custom wrapper classes. For example, if you created a custom wrapper class to customize the search task flow, you would override the getSearchRegionCustomizerClassName method, as shown in Example 24-10. Override only the methods that correspond to the classes for which you have created custom wrappers. In the case of a SearchRegionCustomizerImpl custom wrapper, the method that you override depends on whether the wrapper customizes the interface search UI or the regular search UI. If the wrapper customizes the interface search UI, override the getInterfaceSearchRegionCustomizer method. Otherwise, override the getSearchRegionCustomizerClassName method.

- getApplicationContextCustomizerClassName
- getContainerPageCustomizerClassName
- getPageListCustomizerClassName
- getSearchRegionCustomizerClassName
- getInterfaceSearchRegionCustomizer
- getSingleRowContextRegionCustomizerClassName
getMultiRowContextRegionCustomizerClassName

Example 24-10  Sample getSearchRegionCustomizerClassName Method

```java
public String getSearchRegionCustomizerClassName() {
    return "oracle.apps.myProduct.myApp.items.eff.ItemSearchRegionCustomizer";
}
```

24.14.2.1.7 How to Register the Metadata Provider Class for the Business Component

For the user interface modeler to use your custom wrapper classes at runtime, you must register the metadata provider class. To register the class, set the ADFUI_MODELER column for the business component’s row in the FND_DF_FLEXFIELDS_B table to the name of the UIMetadataProviderImpl implementation class that you created for the business component.

24.15 Testing Flexfields

You can test specified flexfields from JDeveloper using the Run with Flexfields dialog or the Debug with Flexfields dialog. You can also test the flexfields by running the application from an Integrated WebLogic Server instance. For more information, see Testing Flexfields.

24.16 Making Extensible Flexfields Available to Web Services

You can make extensible flexfields available to web service clients and enable the clients to perform create, read, update, and delete (CRUD) operations on the flexfield data rows.

24.16.1 How to Make an Extensible Flexfield Available to Web Services

To make web service access available for an extensible flexfield, associate the flexfield usage’s stub search view object with the service-backed view object for the product table that the extensible flexfield extends. Then add a SERVICE_PROCESS_CHILDREN property to the view link and create service data object (SDO) classes for the service-backed view object.

The stub search view object serves as a placeholder for resolving build time dependencies. When the flexfield is deployed, the flexfield modelers generate a view object with the same name in the MDS repository, and generates the view object’s XML schema definition (XSD). Because of the name space configuration, the generated view object and XSD are picked up instead of the view object that is shipped with the application. The XSD that is generated for the stub search view object includes references to the XSD definitions for the child categories and contexts that the implementor defines at runtime. At runtime, the application uses view object polymorphism to obtain the category and context view objects that extend from the stub search view object.

Before you begin:

- Ensure that a stub search view object exists for the flexfield usage. The stub search view object is in the view folder in the package that you registered for the extensible flexfield usage in the FND_DF_ADFBC_USAGES table. The name of the stub search view object begins with `j_` and ends with the name of the usage’s view object. You can use the following SQL statement to determine the package name and view object name for the flexfield usage.

```sql
SELECT PACKAGE_NAME, VIEW_OBJECT
FROM FND_DF_ADFBC_USAGES
```
WHERE TABLE_NAME IN
(SELECT TABLE_NAME FROM FND_DF_TABLE_USAGES TBL WHERE
DESCRIPTIVE_FLEXFIELD_CODE = flexfield-code AND
TBL.APPLICATION_ID = application-id AND
TABLE_TYPE = 'BASE' AND
FLEXFIELD_USAGE_CODE = flexfield-usage-code)

Note:
The Create Flexfields Business Components wizard creates the stub search view object based on the flexfield's declarative SQL-based view object that was registered for the flexfield usage. If no declarative SQL-based view object was registered, then a stub search view object will not exist. You must create and register the SQL-based view object as described in Creating a Declarative SQL-Based View Object to Enable Searching and then run the Create Flexfield Business Components wizard as described in How to Create Business Components For an Extensible Flexfield’s Usage.

- A service-backed view object must exist for the product table that the flexfield extends, as described in the Creating View Objects Backed by SDO Services section in the Developing Fusion Web Applications with Oracle Application Development Framework.

**To expose an extensible flexfield as a web service:**

1. Create a view link as described in the How to Create a Master-Detail Hierarchy for Entity-Based View Objects section in the Developing Fusion Web Applications with Oracle Application Development Framework.

   a. On the View Objects page, in the Select Source Attribute tree expand the service-based view object in the desired package. In the Select Destination Attribute tree expand the stub search view object.
      
      For entity-based view objects, notice that in addition to the view object attributes, relevant associations also appear in the list.

   b. Select the primary key and CategoryCode attributes in both Source and Destination trees. Then click Add to add the association to the table that is below the trees.

   c. Click Finish.

2. In the Application Navigator, double-click the view link that you just created.

3. In the overview editor, expand the Custom Properties section and add a SERVICE_PROCESS_CHILDREN property set to true, if one does not already exist.

4. Open the service-based view object.

5. In the overview editor click the Java navigation tab.

6. In the Java Classes section, click the Edit icon to generate and configure Java implementation classes.

7. In the Select Java Options dialog, select Generate Service Data Object Class and click OK.
24.17 Access Information About Extensible Flexfield Business Components

The consumers of an extensible flexfield might need to programmatically access an extensible flexfield, for instance, to further process the data that has been entered for an extensible flexfield, to add additional validation, or to perform change control. The oracle.apps.fnd.applcore.flex.runtime.util.common.ExtensibleFlexfieldUtil package provides methods for obtaining the handles to the artifacts that are generated in a customer's instance.

24.17.1 How to Access Information About Extensible Flexfield Business Components

Use the methods in oracle.apps.fnd.applcore.flex.runtime.util.common.ExtensibleFlexfieldUtil to get the names of the following Java business objects (JBOs) that are generated for an extensible flexfield:

- Context entity object: Use `getContextEoName`, which is shown in Example 24-11.
- Context view object: Use `getContextVoName`, which is shown in Example 24-12.
- Context entity association between base and extension entity objects: Use `getCategoryContextAssocName`, which is shown in Example 24-13.
- Context entity/view object attribute for a given segment code: Use `getContextAttributeName`, which is shown in Example 24-14.
- Categories: Use the various methods shown in Example 24-15.
- Search view object attributes: Use `getSearchVoAttributeNames`, which is shown in Example 24-16.

**Example 24-11 Method to Get EFF Context Entity Object Name**

```java
/**
 * @param appId - application id
 * @param flexCode - flexfield code (e.g. EGO_ITEM_UA)
 * @param flexUsageCode - flexfield usage code (e.g. EGO_ITEM_DL)
 * @param txn - DB transaction
 * @param contextCode - context code (e.g. Voltage)
 * @param tableType - table type (e.g. EXTENSION)
 * @param effGroup - eff grouping entity name (public / private)
 * @return
 */
public static String getContextEoName(Long appId, String flexCode,
                                       String flexUsageCode,
                                       DBTransaction txn,
                                       String contextCode,
                                       String tableType,
                                       String effGroup)
```

**Example 24-12 Method to Get EFF Context View Object Name**

```java
/**
 * @param appId - application id
 * @param flexCode - flexfield code (e.g. EGO_ITEM_UA)
 * @param flexUsageCode - flexfield usage code (e.g. EGO_ITEM_DL)
 */
```
Example 24-13 Method to Get Name for EFF Context Entity Association Between Base and Extension Entity Objects

/**
 * @param appId - application id
 * @param flexCode - flexfield code (e.g. EGO_ITEM_UDA)
 * @param flexUsageCode - flexfield usage code (e.g. EGO_ITEM_DL)
 * @param txn - DB transaction
 * @param contextCode - context code (e.g Voltage)
 * @param tableType - table type (e.g. EXTENSION)
 * @param effGroup - eff grouping entity name (public / private)
 * @return
 */
public static String getCategoryContextAssocName(Long appId, String flexCode,
        String flexUsageCode,
        DBTransaction txn,
        String contextCode,
        String tableType,
        String effGroup)

Example 24-14 Method to Get Attribute Name for EFF Context Entity/View Object Given Segment Code (FND_DF_SEGMENTS_VL(SEGMENT_CODE))

/**
 * Get the attribute name for the EFF context view / entity object given the segment code.
 * @param segmentCode - segment code for attribute name.
 * @return attribute name
 */
public static String getContextAttributeName(String segmentCode)

Example 24-15 EFF Category Methods

public static String getCategoryAmNameForWebServices()
public static String getCategoryAmNameForDataEntry()
public static String getCategoryAmNameForInterfaceGeneric()
public static String getCategoryAmNameForInterfaceCategory()
public static String getCategoryAmNameForSearchGeneric()
public static String getCategoryAmNameForSearchCategory()
public static String getCategoryVoNameForDataEntry()
public static String getCategoryVoNameForWebServices()
public static String getCategoryVoNameForInterfaceGeneric()
public static String getCategoryVoNameForInterfaceCategory()
public static String getCategoryContextViewLinkNameForInterfaceGeneric()
public static String getCategoryContextViewLinkNameForInterfaceCategory()
public static String getCategoryContextViewLinkNameForSearchCategory()
public static String getCategoryContextViewLinkNameForSearchGeneric()
public static String getCategoryContextViewLinkNameForWebService()
public static void useServiceProvider()
public static String getCategoryVoNameForSearchCategory()
public static String getCategoryVoNameForSearchGeneric()

Example 24-16  Method to Get Hash Map of View Object Attribute Names for EFF Search View Object
/**
 * Get a map of segment codes to search view object attribute names
 * @param flexUsageCode - flexfield usage code (e.g. EGO_ITEM_DL)
 * @param contextCode - context code (e.g Voltage)
 * @param segmentCodeList - segment codes for the map.
 * @return map of attribute names with key of segment codes
 */
public static HashMap<String, String> getSearchVoAttributeNames(
    String flexUsageCode,
    String contextCode,
    ArrayList<String> segmentCodeList)

24.18 Use the Advanced Features of Extensible Flexfields

Extensible flexfields support the use of interface tables for loading extensible flexfield data. In addition, extensible flexfields support parallel sets of extensible flexfield artifacts.

24.18.1 How to Support Interface Loading of Extensible Flexfield Data

If a consumer of the flexfield wants to support interface loading of extensible flexfield data, create interface tables that correspond to the product (primary) table and the base extension table. If the flexfield has a translation extension table, also create a corresponding interface table for the translation extension table, and create a view for that interface table using a definition statement similar to that shown in Example 24-1. Create entity objects and view objects for these tables and view. Then add entries to the FND_DF_TABLE_USAGES and FND_DF_ADFBC_USAGES tables as shown in Table 24-4 and Table 24-5.

When the flexfield is deployed, a parallel set of ADF Business Components artifacts are created. You can use these artifacts to insert data into the interface tables.

Table 24-4  FND_DF_TABLE_USAGES Values for Flexfield Interface Tables

<table>
<thead>
<tr>
<th>Column</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>ENTERPRISE_ID</td>
<td>The enterprise ID.</td>

<tr>
<td>VIEW_OBJECT</td>
<td>The view object for this table.</td>
</tr>
<tr>
<td>ENTITY_OBJECT_TL</td>
<td>When adding an entry for an interface table that corresponds to the translation extension table, provide the name of the entity object for the interface table that corresponds to the translation extension table.</td>
</tr>
<tr>
<td>EFF_SEARCH_VIEW_OBJECT</td>
<td>When adding an entry for an interface table that corresponds to the base extension table, provide the name of the declarative SQL-based view object that was created to support searching, if one exists.</td>
</tr>
</tbody>
</table>
24.18.2 How to Support Parallel Sets of Extensible Flexfield Artifacts for Different Uses

If you require parallel sets of extensible flexfield artifacts generated for different uses (for example, public view objects and private view objects), replicate the entries in the FND_DF_ADFBC_USAGES table for that flexfield and use a different group name. When the business components are generated for the flexfield, a separate set of components is generated for each group name.

The following figure shows example entries for a flexfield usage. The FND_DF_TABLE_USAGES table contains rows for the product table (USGA_BASE), the usage base extension table (USGA_EFF_B), and the usage translation extension table (USGA_EFF_TL). The FND_DF_ADFBC-USAGES table contains two entries for each entry in the FND_DF_TABLE_USAGES table — one for the Private group and one for the Public group. Each row names the entity object and the view object. The rows for the translation extension table also name the entity object from the translation extension table. Note that not all columns are shown.

**Note:**
In this example, the Public group is necessary because the product that is using the flexfield usage requires a parallel set of extensible flexfield artifacts generated for public view objects.

**Figure 24-12 Example Entity Detail Entries**

This chapter discusses how to use key flexfields in Oracle Fusion applications to access data that is presented by different customers using different combinations of fields, and to customize the presentation of that information to customers in a way that is most appropriate for them.

This chapter includes the following sections:

- Introduction to Key Flexfields
- Completing the Producer Tasks for Key Flexfields
- Completing the Consumer Tasks for Key Flexfields in Reference Mode
- Employing Key Flexfield UI Components on a Page.

25.1 Introduction to Key Flexfields

A key flexfield is a key that is composed of segments, in which one or more segments may have a meaning. The key, or code, uniquely identifies an object such as an account, an asset, a part, or a job, that implementors can configure to validate any way they wish. The definition of a key flexfield provides a list of possible combinations of key flexfield segment values, known as code combinations. Each type of code combination is called a structure. Each structure is identified by a string that is called the structure code. Much like the context values in descriptive flexfields, a key flexfield structure code indicates how database columns are organized to store the code combinations.

25.1.1 Benefits of Key Flexfields

Key flexfields provide a way for Oracle Fusion applications to represent objects such as accounting codes, part numbers, or job descriptions, which combine multiple fields (or segments) into a single object of concatenated segments.

Most customers use codes made up of meaningful segments to identify various business objects. For example, a customer might have a part number "PAD-NR-YEL-8 1/2x14" indicating a notepad, narrow-ruled, yellow, and 14 inches by 8 1/2. Key flexfields enable developers of Oracle Fusion applications to provide customers with flexible code data structures that implementors can set up however they like using key flexfield segments. Key flexfields enable an implementor to customize Oracle Fusion applications to show a customer’s codes any way they want them. For example, a different customer might have a different code for the same notepad, such as "8x14-PD-Y-NR", and the implementor can easily customize Oracle Fusion applications to meet that different need. Key flexfields let developers satisfy different customers without having to reprogram the applications.

You can use key flexfields in many applications. For example, you could use a Part flexfield in an inventory application to uniquely identify parts. Your Part flexfield
could contain such segments as product class, product code, size, color and packaging code. You could define valid values for the color segment, for example, to range from 01 to 10, where 01 means red, 02 means blue, and so on. You could even specify cross-validation rules to describe valid combinations of segment values. For example, products with a specific product code may be available only in certain colors.

25.1.2 How Key Flexfields Are Modeled in Oracle Application Development Framework

Flexfields are modeled as a collection of Oracle Application Development Framework (Oracle ADF) polymorphic view rows, as described in Working with Polymorphic View Rows section in the Developing Fusion Web Applications with Oracle Application Development Framework guide.

In a polymorphic collection, each view row can have its own set of attributes, and all rows have at least one common attribute, the discriminator. The discriminator determines which view row type is used. Given a collection of polymorphic view rows, each row can be a different type. When a polymorphic collection of rows is created, Oracle ADF selects the correctly-typed view definition for the row to be added based on the value of the discriminator attribute.

Key flexfield segments are exposed as view row attributes in the order that they are defined in the flexfield’s metadata. The code combination ID (CCID) and structure instance number (SIN) segments are exposed as attributes in the base view object of the polymorphic collection. Every code combination structure is modeled as an extended view object of the base view object. That is, an extended view object is created for every structure instance number. These extended view objects, which are referred to as subtype view objects, expose the key flexfield segments as subtype-specific view attributes. The structure instance number is exposed as the discriminator attribute of the polymorphic view rows. For more information about code combination IDs and structure instance numbers, see Creating the Combinations Table.

You use the Create Entity Objects wizard to generate the base view object that is based on the key flexfield definition, then create a view link to connect the reference view object (the view object for the database table that the key flexfield extends) and the base view object. You can then use the base view object to add the flexfield to a user interface page. For more information about the generation of base and subtype view objects, see How to Create Key Flexfield Business Components.

Because flexfield view objects are modeled as polymorphic view objects, you can use key flexfield view objects in the same manner that you use any other polymorphic view objects, and they will behave in the same way. This includes support for flexfields in ADF Desktop Integration. For more information, see the Oracle Fusion Middleware Developing Applications with Oracle ADF Desktop Integration guide.

25.1.3 Secondary Usage Feature

A key flexfield configuration can be shared with other product tables through the secondary usage feature. To share a key flexfield configuration with another product table, you include one or all of the primary usage segment columns in that product table. The product table that contains the shared segment columns is referred to as a secondary table. When you work with a primary usage you are working in reference mode. When you work with a secondary usage, you are working in secondary mode.

Note:
Secondary usage is sometimes referred to as a partial usage.
There are two types of secondary usages:

- All-segment secondary usage: In this mode, the secondary table has columns for all of the key flexfield segments.
- Single-segment secondary usage: In this mode, the secondary table has only one key flexfield segment column.

### 25.1.4 Participant Roles

As mentioned in Participant Roles, this guide uses the owner and implementor roles to clarify and group flexfield development activities.

The owner is the developer (or development team) who determines that a particular flexfield is needed or would be useful within a particular Oracle Fusion application, and makes a flexfield available. The owner then incorporates the flexfield into an application. With key flexfields, the owner can be either a producer or a consumer, or can assume both roles.

The producer is the developer who determines that a particular key flexfield is needed or would be useful within a particular application, and makes it available. The producer's product owns the combinations table, which supports that flexfield by storing the key flexfield values.

A consumer incorporates a key flexfield into the application, which is typically different from the producer's application. The consumer typically stores a code combination ID (CCID), which identifies a row in the combinations table, in a product table, and works with the structural and seed data and the business components that have been configured by the key flexfield producer.

An implementor configures a flexfield on behalf of the customer by specifying the structure of the flexfield and specifying the prompt, length, and data type of each flexfield segment.

For more information about owners, producers, consumers, and implementors see Participant Roles. For information about the combinations table, see Creating the Combinations Table.

### 25.1.5 Complete the Key Flexfield Development Process

Before you start to incorporate key flexfields into your application, you must determine whether you should complete the producer portion or the consumer portion of the key flexfield development process.

- If you have determined that a particular key flexfield is needed or would be useful within a particular application, and there is not yet a combinations table to support it, see the producer development tasks covered in Understanding the Key Flexfield Producer Development Tasks.
- If there is already a combinations table for the key flexfield that you want to implement, see the consumer development tasks covered in Understanding the Key Flexfield Consumer Development Tasks.

To incorporate key flexfield secondary usages into your application, see Completing the Development Tasks for Key Flexfields in Secondary Mode.

To employ key flexfield code-combination filters in your application, see Working with Code-Combination Filters for Key Flexfields.
Figure 25-1 provides an overview of producer and consumer roles as they apply to the creation and configuration of the necessary key flexfield business components and associated artifacts. Understanding the Key Flexfield Producer Development Tasks and Understanding the Key Flexfield Consumer Development Tasks define the producer phases and summarize the steps for creating the components and artifacts shown in Figure 25-1.

25.1.5.1 Maintenance Mode and Dynamic Combination Insertion

By default, key flexfield user interface elements do not allow new code combination values entered into the application user interface to be saved. However, you might want to enable the entry of new code combinations in either of the following ways:

- A combination maintenance page enables application implementors and administrators to manage key flexfield code combinations, including the ability to enter new code combinations and update existing code combinations for a flexfield. This is called working in maintenance mode.

- You can enable end users to enter values on an application page that constitute ad-hoc new code combinations, even if the users are not authorized to perform maintenance tasks directly. This is known as dynamic combination insertion.

For example, when entering a transaction, an Oracle General Ledger user can enter a new expense account code combination for an account that does not yet exist. Your application creates the new account by inserting the new combination into the combinations table in the background.
Note:

If you configure the key flexfield for dynamic combination insertion, you must build a maintenance model and a maintenance application module as described in Building a Writable Maintenance Model, and use the setup APIs to register the maintenance application module in the flexfield metadata. For information about the setup APIs, see Registering and Defining Key Flexfields Using the Setup APIs.

The key flexfield producer builds the appropriate models to support maintenance mode and dynamic combination insertion.

25.1.5.2 Cross-Validation Rules and Custom Validation

When you decide to support maintenance mode or dynamic combination insertion for a key flexfield, you can also implement advanced validation capability for the new code combinations that are entered.

Cross-Validation Rules

A cross-validation rule applies a pair of filters to new code combinations that are proposed for a key flexfield by implementors.

At registration time, you must enable the key flexfield for cross-validation. Then you create a maintenance user interface that administrators of your application can subsequently use to define each cross-validation rule as a pair of code-combination filters: one to establish the condition for evaluating the rule, and the other to specify which code combinations are valid under that condition.

Custom Validation Callouts

There are two PL/SQL custom validation callout procedures that can be defined for a given key flexfield: one for application development use, and one reserved for customers. These callouts can be used to enforce any custom validation logic that you want to apply to new code combinations beyond what has been defined for cross-validation rules.

You define custom validation logic with a standard signature for the customer callout. You then register your callout with the key flexfield. The custom validation callout will automatically be called before any new combination is inserted using dynamic insertion in C and PL/SQL.

25.1.5.3 Understand the Key Flexfield Producer Development Tasks

If you have determined that a particular key flexfield is needed within an application, and there are not yet columns in the product table to support it, you must define the necessary metadata and provide the appropriate business components so that flexfield consumers can make use of your flexfield.

To complete the producer development tasks:

1. Develop the key flexfield.
   
   See How to Develop Key Flexfields.
   
   Optionally, you can also do the following at registration time:
   
   • Implement segment labels.
     
     For more information, see How to Implement Key Flexfield Segment Labels.
• Enable cross-validation or register custom validation callout procedures.
  For more information, see How to Implement Cross-Validation Rules and Custom Validation.

2. Create and configure the key flexfield business components.

As shown in Figure 25-1, the producer activities occur in two phases. The first phase produces a writable maintenance model, and the second phase produces a read-only reference model:

• In producer phase 1, you create an updatable entity object for your combinations table and a master view object that is based on the updatable entity object. Next, using the updatable entity object, you create key flexfield business components for a maintenance model and define a view link between the master view object and the key flexfield view objects. Then you create the maintenance application module.

• In producer phase 2, you optionally configure the maintenance application module to accept dynamic combination insertion calls, and implement the appropriate Java class in the user interface to invoke dynamic insertion. You create a read-only reference entity object for your combinations table, and using this entity object, create key flexfield business components for a reference model.

See How to Create Key Flexfield Business Components.

Tip:

After completing this task, you can regenerate the flexfield business components programmatically at runtime to update your key flexfield implementation without manual intervention. For more information, see Regenerating Flexfield Business Components Programmatically.

3. Optionally, share your key flexfield business components with other developers using an ADF library.
  For more information, see How to Share Key Flexfield Business Components.

4. Optionally, build a user interface for key flexfield maintenance.
  For more information, see How to Build a Key Flexfield Maintenance User Interface.

5. Optionally, implement key flexfield advanced features such as code combination constraints or API access to segment labels, or access flexfields from an Excel worksheet using ADF Desktop Integration.
  For more information, see Using Key Flexfield Advanced Features in Reference Mode.

6. Optionally, define, implement, and invoke key flexfield code-combination filters.
  For more information, see Working with Code-Combination Filters for Key Flexfields.

25.1.5.4 Understand the Key Flexfield Consumer Development Tasks

You can incorporate a producer’s key flexfields in your own application. For example, you might have an expenses table that references an account key flexfield in the Oracle General Ledger application.
If your product table already has a foreign-key reference to the key flexfield's combinations table, and the flexfield producer who owns that metadata has provided you with the appropriate business components, you can proceed to incorporate the flexfield into your application. You should have already created an entity object and view object for the product table, which is referred to as the reference table.

To complete the consumer development tasks:

1. As shown in Figure 25-1, create a view link between the view object for the reference table and the polymorphic view objects for the key flexfield’s reference model.
   
   See How to Create Key Flexfield View Links.

2. Nest the key flexfield application module instance in the product application module.
   
   See How to Nest an Instance of the Key Flexfield Application Module in the Product Application Module.

3. Add a key flexfield view object instance to the product application module.
   
   See How to Add an Instance of a Key Flexfield View Object to the Product Application Module.

4. Add your key flexfield to an application page.
   
   See Employing Key Flexfield UI Components on a Page.

5. Configure the key flexfield user interface components.
   
   See How to Configure Key Flexfield UI Components.

After completing these tasks, you can test specified flexfields from JDeveloper using the Run with Flexfields dialog or the Debug with Flexfields dialog. You can also test the flexfields by running the application from an Integrated WebLogic Server instance. For more information, see Testing Flexfields.

After you have completed the key flexfield development process and delivered your application, implementors can use the Manage Key Flexfields task flow to define and configure the structures, structure instances, segments, and segment instances for each key flexfield. This will determine how the flexfield's segments will be populated, organized, and made available to end users within the application.

To make the Manage Key Flexfields task flow available to application implementors and administrators, you register it with Oracle Fusion Functional Setup Manager. For more information, see Integrating Flexfield Task Flows into .

### 25.2 Complete the Producer Tasks for Key Flexfields

To prepare key flexfields for modeling in Oracle JDeveloper, you must ensure that columns for the flexfields you require are defined in your application database. You also might need to define more advanced features such as key flexfield secondary usages, code-combination filters, or the enabling of cross-validation rules and custom validation callout procedures. All of these features require you to modify your application database.
Note:

To incorporate a key flexfield secondary usage into your application, you must have already defined and registered the key flexfield primary usage on which it is based. See Registering and Defining Key Flexfields Using the Setup APIs, then continue to Completing the Development Tasks for Key Flexfields in Secondary Mode.

To employ key flexfield code-combination filters in your application, see Working with Code-Combination Filters for Key Flexfields.

The product table and its key flexfield columns must be registered in the Oracle Fusion Middleware Extensions for Applications (Applications Core) data dictionary before a flexfield can be defined on it. For more information, see Using the Database Schema Deployment Framework.

Any implementation of flexfields in Oracle Fusion applications typically requires application seed data, which is the essential data to enable flexfields to work properly in applications. Flexfield seed data can be uploaded and extracted using the seed data loader.

After you complete the registration process described in How to Develop Key Flexfields, your flexfield seed data consists of the information that you registered for your flexfield, such as the tables and columns reserved for your flexfield.

For information about extracting and loading seed data, see Initializing Oracle Fusion Application Data Using the Seed Data Loader.

25.2.1 How to Develop Key Flexfields

Key flexfields enable you to represent objects such as accounting codes, part numbers, or job descriptions, that combine multiple columns (or segments) into a single object of concatenated segments.

To develop a key flexfield:

1. Create a combinations table that includes the key flexfield segments.
2. Create foreign key columns to associate a product table with the combinations table. The product table is referred to as the reference table.
3. Optionally, include the key flexfield segments in product tables for secondary usages.
4. Optionally, create filter columns for defining which key flexfields the user can filter.
5. Enable the use of flexfield combinations on application pages.
6. Register and define the key flexfield.
7. Optionally enable the multiple structure and data set features.
8. Optionally reuse one or all key flexfield segments in a product table.
9. Register the entity details for each usage.
25.2.1.1 Create the Combinations Table

Each key flexfield must have one corresponding table known as the combinations table.

Note:
The product table and its key flexfield columns must be registered in the Applications Core data dictionary before a flexfield can be defined on it. For more information, see Using the Database Schema Deployment Framework.

The combinations table must have a code combination ID (CCID) column (type NUMBER) that identifies each data row.

The combinations table can have an optional structure instance number (SIN) column (type NUMBER) with generated values that identify different validation sources for a given structure. These generated values are unique within a given flexfield. Multiple SIN values exist for a key flexfield if you elect to define the flexfield with multiple alternate structure instances.

A given structure (arrangement of segments) can have several structure instances. The structure instances share the same arrangement of segments, but use different value sets to validate the segments (for example, one group of value sets for the United States and another for France). Each structure instance is identified by a SIN.

The combinations table might also have a data set number (DSN) column (type NUMBER), but only if you have elected to data set-enable your key flexfield code combinations. A DSN column enables you to tag sets of combination codes with your own numeric IDs. For example, you can use it to stripe (partition) the data into subsets by ORGANIZATION_ID. ADF Business Components supports the DSN by including it as part of the table’s primary key. Your SQL code can then select code combinations from this table using a more qualified primary key.

Note:
Data sets are used by specific application-development teams. If your team does not use data sets, you can ignore the references to DSNs in this guide.

A DSN is not the same thing as a set ID. Set ID partitioning is not supported by flexfields. For information about set IDs, see Managing Reference Data with SetIDs.

The table’s primary key is composed of a combination of the CCID, SIN, and DSN columns depending on the conditions listed in Table 25-1.

Table 25-1  Primary Key Configuration

<table>
<thead>
<tr>
<th>Column</th>
<th>Include in the Primary Key</th>
</tr>
</thead>
<tbody>
<tr>
<td>CCID</td>
<td>Always</td>
</tr>
<tr>
<td>SIN</td>
<td>When the flexfield is multiple structure-enabled or is multiple structure instance-enabled</td>
</tr>
<tr>
<td>DSN</td>
<td>When the flexfield is DSN-enabled</td>
</tr>
</tbody>
</table>
The combinations table must include the columns listed in Table 25-2. These columns indicate whether a combination is enabled and active. The column names and data types must match exactly.

**Table 25-2  Required Combinations Table Columns**

<table>
<thead>
<tr>
<th>Column</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ENABLED_FLAG</td>
<td>VARCHAR2(1)</td>
<td>A Y value indicates that the combination is enabled. Any other value indicates that the combination is not enabled.</td>
</tr>
<tr>
<td>START_DATE_ACTIVE</td>
<td>DATE</td>
<td>If a date is specified and the current validation date is earlier than the specified date, the combination is not active. There must not be a default database value for this column.</td>
</tr>
<tr>
<td>END_DATE_ACTIVE</td>
<td>DATE</td>
<td>If a date is specified and the current validation date is later than the specified date, the combination has expired. There must not be a default database value for this column.</td>
</tr>
</tbody>
</table>

Include one column for each flexfield segment that you or your customers might wish to customize. You need at least as many columns as the maximum number of segments an end user would ever want in a single key flexfield structure. The columns must be of type VARCHAR2 or NUMBER. If the type is VARCHAR2, the length must be at least 30 characters.

**Tip:**

There are no constraints on how to name the segment columns. However, these columns are typically named using the patterns SEGMENTn_VARCHAR2 and SEGMENTn_NUMBER. This convention makes it easy to identify the key flexfield segments. It also makes it easier to name the columns for secondary usages of the key flexfield.

If the key flexfield defines value attributes, you must include one derived value attribute column of type VARCHAR2 for each value attribute. For more information about value attributes, see How to Implement Key Flexfield Segment Labels.

**Note:**

The combinations table may contain other columns than those described here. If the key flexfield is dynamic insert-enabled, these other columns should either allow null values or they should have default database values.

25.2.1.2 Create Foreign Key Columns to Enable the Use of Flexfield Combinations on Application Pages

To permit the use of flexfield code combinations on different application pages, you must include foreign key references to your combinations table's primary key configuration, as shown in Table 25-1, in other product tables. That way, you can
display or enter valid combinations using forms that are not based on your combinations table. When you build an application that uses key flexfields, you include foreign key references in the product tables wherever you reference the flexfield. The product tables that contain the foreign key references are referred to as reference tables.

**Note:**
A page whose underlying entity objects contain a foreign key reference to the combinations table is referred to as a code-combination reference page, while a page whose underlying entity objects use the combinations table itself is referred to as a combination maintenance page.

### 25.2.1.3 Include Segment Columns in Secondary Tables
You can reuse a key flexfield definition over a product table by including some or all of the key flexfield’s segment columns in the product table. The product table that contains the redefined segment columns is referred to as a secondary table. If a SIN or DSN is used, the secondary table must either include those columns or a column from which the SIN or DSN can be derived.

### 25.2.1.4 Create Filter Columns
You can use the key flexfield code-combination filter feature to represent a subset of combinations. For each filter that you want to include in the application user interface, you define a dedicated column of type `XMLType`. You can define the column in an existing reference table or you can create one or more dedicated tables just to store filter columns.

For more information, see [Working with Code-Combination Filters for Key Flexfields](#).

### 25.2.1.5 Register and Define Key Flexfields Using the Setup APIs
Before you can use a key flexfield in an application, you must first define and register the flexfield using procedures from the `FND_FLEX_KF_SETUP_APIS` PL/SQL package. This package also has procedures for updating, deleting, and querying flexfield definitions.

The definition of a key flexfield includes the following information:

- The code, name, and description of the flexfield.
- The primary usage code (also referred to as the master usage code). This code is typically the same code as the flexfield.
- The name of the combinations database table.
- The names of the database table columns to be used as flexfield segments.
- The name of the CCID column.
- The names of the SIN and DSN columns, if they exist.

**Before you begin:**

Create the combinations table as described in [Creating the Combinations Table](#).

To learn how to generate documentation about using the procedures in the following steps, see [What You May Need to Know About the Key Flexfield Setup API](#).
To register and define a key flexfield:

1. Run the `fnd_flex_kf_setup_apis.create_flexfield(...)` procedure to register the key flexfield and its primary usage.

2. Run the `fnd_flex_kf_setup_apis.create_segment_column_usage(...)` procedure for each segment column to register the segment columns.

3. (Optionally) Register the entity details as described in Registering Entity Details Using the Setup APIs. This step must be completed before you can generate the flexfield usage’s business components.

25.2.1.6 What You May Need to Know About the Key Flexfield Setup API

In the key flexfield development process, you use the `FND_FLEX_KF_SETUP_APIS` PL/SQL package to manage flexfield registration data.

You can learn about the `FND_FLEX_KF_SETUP_APIS` PL/SQL package by running the following command, which produces package documentation and usage examples to the `<db_name>_<user_name>_FND_FLEX_KF_SETUP_APIS_<date>.plsqldoc` file.

```
sqlplus <fusion_user>/<fusion_pwd>@<fusion_db> \
@/ORACLE/fusionapps/atgpf/appcore/db/sql/flex/fnd_flex_pkg_doc.sql \
FND_FLEX_KF_SETUP_APIS
```

25.2.1.7 Enable Multiple Structure, Multiple Structure Instance, and Data Set Features

To enable the multiple structure, multiple structure instance, or data set features for a registered key flexfield, you must run the `enable_feature(...)` procedure from the `FND_FLEX_KF_SETUP_APIS` PL/SQL package. To enable the multiple structure feature or multiple structure instance feature, you provide the SIN column name. To enable the data set feature, you provide the DSN column name.

To learn how to generate documentation about using the `enable_feature(...)` procedure, see What You May Need to Know About the Key Flexfield Setup API.

25.2.1.8 Reuse Key Flexfield Segments in Another Table

Key flexfield secondary usage enables you to capture the values of a key flexfield’s segments in a product table. You can capture all of the flexfield’s segments, or just one.

For information about reusing a key flexfield’s segments, see Completing the Development Tasks for Key Flexfields in Secondary Mode.

25.2.1.9 Register Entity Details Using the Setup APIs

When you build the flexfield business components and create flexfield-specific application module instances, the flexfield modeler requires the following information about the flexfield usage:

- The full class name of the entity object. For the primary usage, this is the entity object that was defined for the combinations table. For a secondary usage, this is the entity object that was defined for the secondary table.

- A prefix from which to derive the names of generated objects.

- The package in which to place the generated business components. Each usage must have its own package name.
You register entity details using the `create_adfbc_usage(...)` procedure from the `FND_FLEX_KF_SETUP_APIS` PL/SQL package.

**Before you begin:**

1. Register the usage as described in *Registering and Defining Key Flexfields Using the Setup APIs*.
2. Ensure that the entity object for the usage’s table exists.

To learn how to generate documentation about using the `create_adfbc_usage(...)` procedure, see *What You May Need to Know About the Key Flexfield Setup API*.

**To register the entity details using the registration application:**

- Run the `fnd_flex_kf_setup_apis.create_adfbc_usage(...)` procedure to register the entity object, package name, and object name prefix for the flexfield usage.

### 25.2.2 How to Implement Key Flexfield Segment Labels

A segment label identifies the purpose of a particular segment in a key flexfield.

Usually an application needs some method of identifying a particular segment for some application purpose such as security or computations. However, because a key flexfield can be customized so that segments appear in any order with any prompts, the application needs a mechanism other than the segment name or order to use for segment identification. Segment labels serve this purpose.

You can think of a segment label as an identification tag for a segment. It identifies a segment that application implementors and administrators should include when customizing the key flexfield. By defining segment labels when you define your key flexfield, you ensure that implementors customize the flexfield to include the segments that your application needs.

For example, the Oracle General Ledger application must be able to identify which segment in the Accounting flexfield contains the primary balance information and which segment contains natural account information. Because you can customize the Accounting flexfield so segments appear in any order with any prompts, Oracle General Ledger needs a segment label to internally specify the correct segment for each purpose. When you define your Accounting flexfield, you must specify which segment labels apply to which segments.

You ensure that the implementor or administrator will define these key segments by defining two segment labels, `GL_BALANCING` and `GL_ACCOUNT`. When customizing your accounting flexfield, the implementor ties the `GL_BALANCING` and `GL_ACCOUNT` segment labels to particular key segments. As the developer, you need not know which key segment becomes the natural account or primary balance segment, because the key flexfield takes care of returning natural account and primary balance information to your application at runtime.

Oracle General Ledger also uses key flexfields that have segment labels identifying the cost center segment (`FA_COST_CTR`), management segment (`GL_MANAGEMENT`), and intercompany segment (`GL_INTERCOMPANY`). Other applications, such as Human Resources, use segment labels as well. Human Resources uses segment labels to control who has access to confidential information in its flexfield segments.
When you use segment labels with a key flexfield, you might also need to define value attributes in which you qualify a value by applying a value attribute to it when the value set is used with a segment that has a segment label.

Note:
For information about retrieving segment label information, see How to Access Segment Labels Using the Java API.

25.2.2.1 Define Key Flexfield Segment Labels

You should define and register segment labels if you want to ensure that the application implementor or administrator customizes your key flexfield to include the segments that your application needs. For example, Oracle General Ledger defines account and balancing segment labels in the Accounting flexfield to ensure that implementors define the account and balancing segments.

When you register a key flexfield, you can define segment labels for it.

Segment labels can be unique, required, or global. You specify a segment label as unique if you want the implementor to tie it to at most one segment of the flexfield. You specify a segment label as required if you want the implementor to tie it to at least one segment. You specify a segment label as global if you want it to apply to all segments. Any key flexfield segment can have any number of segment labels applied.

Table 25-3 shows the results of setting these flags on a segment label in various combinations.

<table>
<thead>
<tr>
<th>Global Flag</th>
<th>Required Flag</th>
<th>Unique Flag</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>N</td>
<td>N</td>
<td>N</td>
<td>0+ (Zero or more segments)</td>
</tr>
<tr>
<td>N</td>
<td>N</td>
<td>Y</td>
<td>0,1 (Zero or one segment)</td>
</tr>
<tr>
<td>N</td>
<td>Y</td>
<td>N</td>
<td>1+ (One or more segments)</td>
</tr>
<tr>
<td>N</td>
<td>Y</td>
<td>Y</td>
<td>1 (Exactly one segment)</td>
</tr>
<tr>
<td>Y</td>
<td>-</td>
<td>-</td>
<td>ALL (All segments; global flag overrides the other flags.)</td>
</tr>
</tbody>
</table>

For example, in the Oracle General Ledger Accounting flexfield, the Account segment label is required and unique because Oracle General Ledger requires one and only one account segment.

You create segment labels using the create_segment_label(...) procedure from the FND_FLEX_KF_SETUP_APIS PL/SQL package.

Before you begin:
Define the key flexfield as described in Registering and Defining Key Flexfields Using the Setup APIs.

To learn how to generate documentation about using the create_segment_label(...) procedure, see What You May Need to Know About the Key Flexfield Setup API.

To define key flexfield segment labels:

- Run the fnd_flex_kf_setup_apis.create_segment_label(...) procedure to register the label and label code for the key flexfield.

25.2.2.2 Use Value Attributes

When you use segment labels with a key flexfield, you might also need to define value attributes.

Every value in a value set has accompanying properties that provide supplemental information about the value, such as a description, an internal code, and start and end dates. In addition to these standard properties, you can further qualify a value by applying a value attribute to it when the value set is used with a segment that has a segment label. There are three types of value attributes:

- **Flexfield value attributes**: The FND_VS_VALUES_B table contains 20 available value attribute columns, called FLEX_VALUE_ATTRIBUTE1 through FLEX_VALUE_ATTRIBUTE20, which are globally defined across all Oracle Fusion applications.

- **Custom value attributes**: The FND_VS_VALUES_B table also contains 10 additional value attribute columns, called CUSTOM_VALUE_ATTRIBUTE1 through CUSTOM_VALUE_ATTRIBUTE10. Customers cannot modify or reassign the standard value attribute columns, but they can use these custom columns for their own implementations of value attributes.

- **SUMMARY_FLAG**: This is a predefined system value attribute, for use with the GL# key flexfield only.

Create value attributes using a procedure from the FND_FLEX_KF_SETUP_APIS PL/SQL package.

Before you begin:

1. Define the key flexfield as described in Registering and Defining Key Flexfields Using the Setup APIs.
2. Define the segment label as described in Defining Key Flexfield Segment Labels.

To define key flexfield segment labels:

- Run the fnd_flex_kf_setup_apis.create_value_attribute(...) procedure to register the value attribute and attribute code for the segment label.

25.2.3 How to Implement Cross-Validation Rules and Custom Validation

Use procedures from the FND_FLEX_KF_SETUP_APIS PL/SQL package to prepare the application database for cross-validation rules and custom validation. When you register a key flexfield in your application database, you can also enable cross-
validation rules and register a customer custom validation callout procedure for the flexfield, so new code combinations entered on a code-combination maintenance page or using dynamic combination insertion can be validated.

At runtime, when a new code combination is entered, the validation APIs are called in the following order:

1. Cross-validation rules
2. Developer custom validation callout procedure
3. Customer custom validation callout procedure

### 25.2.3.1 Implement Cross-Validation Rules

To implement a cross-validation rule for a key flexfield, use a procedure from the FND_FLEX_KF_SETUP_APIS PL/SQL package to enable the flexfield to use cross-validation rules in your application database. Then, build a user interface that administrators can use to maintain their own rule definitions.

**Before you begin:**

Before you can build a user interface for maintaining a key flexfield's cross-validation rules, you must first have created and configured the business components for the key flexfield.

For more information, see How to Create Key Flexfield Business Components.

To learn how to generate documentation about using the FND_FLEX_KF_SETUP_APIS PL/SQL package, see What You May Need to Know About the Key Flexfield Setup API.

**To implement cross-validation rules:**

1. To enable a key flexfield to use cross-validation rules, set the value of the flexfield's CVR_ENABLED_FLAG column in the FND_KF_FLEXFIELDS_B table to Y. This flag is a required VARCHAR2 (1).

   **Note:**
   Setting the value of CVR_ENABLED_FLAG to Y enables support for any cross-validation rules you define for the flexfield. Support for cross-validation is somewhat resource-intensive, so assess each key flexfield to determine if cross-validation is really necessary.

   For example, if the creation of new code combinations for a given key flexfield will be a tightly controlled process that requires organizational oversight, cross-validation might be redundant.

2. To enable administrators to define cross-validation rules that are appropriate for their organizations, develop a runtime maintenance utility that they can use to define and maintain their own rows in a dedicated repository table, FND_KF_CROSS_VAL_RULES, as shown in Table 25-4.
Table 25-4  FND_KF_CROSS_VAL_RULES Cross-Validation Repository Table

<table>
<thead>
<tr>
<th>Column</th>
<th>Type</th>
<th>Null Allowed?</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ENTERPRISE_ID</td>
<td>NUMBER(18)</td>
<td>No</td>
<td>(Primary key) Enterprise ID.</td>
</tr>
<tr>
<td>STRUCTURE_INSTANCE_ID</td>
<td>NUMBER(18)</td>
<td>No</td>
<td>(Primary key) Structure Instance ID.</td>
</tr>
<tr>
<td>RULE_CODE</td>
<td>VARCHAR2(30)</td>
<td>No</td>
<td>(Primary key) Developer key for this rule.</td>
</tr>
<tr>
<td>DESCRIPTION</td>
<td>VARCHAR2(240)</td>
<td>Yes</td>
<td>Rule description.</td>
</tr>
<tr>
<td>CONDITION_FILTER</td>
<td>XMLTYPE</td>
<td>Yes</td>
<td>Flexfield filter defining where the rule should be applied. A null value means to apply the rule globally.</td>
</tr>
<tr>
<td>VALIDATION_FILTER</td>
<td>XMLTYPE</td>
<td>Yes^1</td>
<td>Flexfield filter defining the validation that must be true.</td>
</tr>
<tr>
<td>ERROR_MSG_APPLICATION_ID</td>
<td>NUMBER(18)</td>
<td>Yes</td>
<td>Message application.</td>
</tr>
<tr>
<td>ERROR_MSG_NAME</td>
<td>VARCHAR2(30)</td>
<td>Yes</td>
<td>Message to display if rule is violated. If a null value, displays the default message.</td>
</tr>
<tr>
<td>ENABLED_FLAG</td>
<td>VARCHAR2(1)</td>
<td>No</td>
<td>Valid values are Y (yes) and N (no).</td>
</tr>
<tr>
<td>START_DATE_ACTIVE</td>
<td>DATE</td>
<td>Yes</td>
<td>Standard start date.</td>
</tr>
<tr>
<td>END_DATE_ACTIVE</td>
<td>DATE</td>
<td>Yes</td>
<td>Standard end date.</td>
</tr>
<tr>
<td>WHO columns^2</td>
<td>Varies depending on the WHO column</td>
<td>Varies depending on the WHO column</td>
<td>Standard WHO columns.</td>
</tr>
</tbody>
</table>

^1 Although the validation filter column must allow null values in the data model, it is still a required value that is logically necessary for cross-validation to work.

^2 For more information about WHO columns, see About Using WHO Column Features.

The primary key for this table is the combination of the ENTERPRISE_ID, STRUCTURE_INSTANCE_ID, and RULE_CODE columns.

The cross-validation rule itself is the combination of a condition filter (when to apply the rule) and a validation filter (how to validate the code combination) in the corresponding XMLType columns of the repository table. These filters are compatible with, and supported by the same infrastructure that supports code-combination filters, as described in Working with Code-Combination Filters for Key Flexfields.
The value of each of these filters should be a logical combination of boolean expressions. At runtime, all filters from the repository table that match the application, key flexfield, and SIN of the newly submitted code combination are retrieved, converted into SQL fragments, and used to validate the proposed code combination.

The condition filter establishes the condition that a proposed new code combination must fulfill to qualify for validation. If it qualifies, the code combination is evaluated against the validation filter. This is demonstrated by Example 25-1.

This means that even though this combination would have failed the validation filter, it is still considered valid because the validation filter was not applied. A code combination fails cross-validation only if it passes the condition filter, but fails the validation filter.

Note:

There are no artificial restrictions on what each filter can contain. If you set the condition filter to a null value, all new code combinations for the flexfield will qualify to be evaluated with the validation filter.

Use the code-combination filter infrastructure to create a separate code-combination maintenance page for each key flexfield that supports cross-validation rules as described in How to Add Code-Combination Filters to Your Application, How to Remove Code-Combination Filters from Your Application, and How to Employ Code-Combination Filters on an Application Page.

Example 25-1 Applying a Cross-Validation Rule

The condition filter specifies a value range for one segment:

\[ \text{segment1} \leq '10' \]

If the condition is met, the validation filter is applied:

\[ (\text{segment2} = '20') \text{ OR } (\text{segment2} = '30') \]

If the proposed code combination is three segments with the following values, the validation will succeed:

\[ \begin{align*}
\text{segment1} &= '8' \\
\text{segment2} &= '30' \\
\text{segment3} &= '70'
\end{align*} \]

If the proposed values are as follows, the condition is not met, and the code combination will not be subject to the validation filter:

\[ \begin{align*}
\text{segment1} &= '12' \\
\text{segment2} &= '40' \\
\text{segment3} &= '70'
\end{align*} \]

25.2.3.2 Implement Custom Validation

To implement custom validation, create and register a PL/SQL validation procedure.
To implement custom validation with a custom validation callout procedure:

1. Write a PL/SQL custom validation procedure.
2. Register the procedure as the customer callout along with the key flexfield to which it will apply.

The PL/SQL validation procedure must have the signature shown in Example 25-2.

**Example 25-2 PL/SQL Validation Procedure Signature**

```plsql
type FLEX_VAL_CTX_RECORD is record (
    VALIDATION_DATE DATE);

procedure MY_VALIDATION_CALLOUT (
    NEW_CODE_COMBINATION in my_comb_table%ROWTYPE,
    VALIDATION_CONTEXT in FLEX_VAL_CTX_RECORD);
```

*my_comb_table* is the name of the combinations table for this key flexfield. When passed, every column in the *NEW_CODE_COMBINATION* record will be populated with the values of the combination that is about to be inserted. Payload columns (columns that are not part of the primary key) in the combinations table that are not related to the flexfield will be passed as null values.

*VALIDATION_CONTEXT* is a record containing any additional usage-specific context that may be useful. Currently this record contains only a *VALIDATION_DATE* field. If there is no validation date, then a null value will be passed for *VALIDATION_DATE*.

The API is expected to raise an exception (with an error message) if validation fails. If an exception is raised, then the dynamic insert operation will be aborted, and the message in the exception displayed to the end user. The log will also record the entire call stack, including the fact that the exception was raised from a custom validation callout procedure. If the API returns without exception, it will be considered a success.

After you have written the custom validation callout procedure, you can register it with the key flexfield. These procedures are registered in the FND_KEY_FLEXFIELDS_B key flexfield registration table as shown in Table 25-5.

**Table 25-5 Key Flexfield Custom Validation Callouts**

<table>
<thead>
<tr>
<th>Column</th>
<th>Type</th>
<th>Null Allowed?</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>DEVELOPER_VAL_CALLOUT</td>
<td>VARCHAR2(80)</td>
<td>Yes</td>
<td>PL/SQL validation callout procedure for development use.</td>
</tr>
<tr>
<td>CUSTOMER_VAL_CALLOUT</td>
<td>VARCHAR2(80)</td>
<td>Yes</td>
<td>PL/SQL validation callout procedure for customer use.</td>
</tr>
</tbody>
</table>

To learn how to generate documentation about using the FND_FLEX_KF_SETUP_APIS PL/SQL package, see What You May Need to Know About the Key Flexfield Setup API.

### 25.2.4 How to Create Key Flexfield Business Components

You must define view objects that are based on each key flexfield combinations table. A key flexfield’s base view object has the code combination ID (CCID) column and the optional structure instance number (SIN) column as its only attributes. The SIN, if
applicable, is also the discriminator. For information about base view objects, see How Key Flexfields Are Modeled in .

Figure 25-2 shows a sample configuration of a product view object that uses key flexfields.

The base view object is extended to define view object rows of different structure codes. Each structure code corresponds to a view object definition that includes the appropriate flexfield columns for that structure, in addition to the inherited CCID and SIN columns. Although flexfield view objects carry both SINs and structure codes, only SINs are used to link to the product view object.

**Figure 25-2  Key Flexfields Modeled as ADF Business Components**

If the combinations table has other fixed (nonflexfield) columns, then they are not included in these view objects.

No Java implementation classes are generated for key flexfield view objects. The product view object may or may not have Java implementation classes.

When you create and configure your key flexfield business components, you can decide whether to support maintenance mode (for administrators) or dynamic combination insertion (for end users). For most implementations of a key flexfield, there are two major tasks that you will typically need to complete:

1. **Build a writable maintenance model.**
   
   This model supports building a maintenance mode application, and it supports dynamic combination insertion. It is always required unless you want all end user access to code combinations to be strictly read-only.

2. **Build a read-only reference model.**
   
   This is needed so that you or a consumer of your key flexfield can build a page with a foreign key reference to the combinations table, which is the most likely way that end users will access the key flexfield. This type of page is referred to as a code-combination reference page.

   You can build this model in one of the following ways:

   - **Without dynamic combination insertion support.**
     
     To accomplish this, build your read-only reference model.
• With dynamic combination insertion support.

To accomplish this, you must enable dynamic combination insertion in the maintenance model, and then build the read-only reference model.

Before you begin:

One or more required libraries might have not been automatically included in your project. You must ensure that all required libraries, notably the BC4J Service Runtime, Java EE 1.5 and Java EE 1.5 API libraries, are included.

Using the Create Entity Objects wizard, create application entity objects based on the combinations tables you have defined. Confirm the following:

• At least one customization class is included in the adf-config.xml file. This inclusion serves to ensure correct application behavior. It does not matter which customization class you include.

For information about customization layers, see the "Understanding Customization Layers" section in the Extensibility Guide for Developers.

• These entity objects are directly modeled on the combinations tables; hence they contain the fixed (nonflexfield) columns, if any, along with all of the flexfield columns. In general, all columns should be included.

• The entity objects have primary keys defined.

• The **Persistent** property of every flexfield-related attribute is set to `true`.

• The CCID column is of data type `java.lang.Long`.

• The SIN column, if it exists, is of data type `java.lang.Long`.

• The DSN column, if it exists, is of data type `java.lang.Long`.

• NUMBER type segment columns are of data type `java.math.BigDecimal`.

• VARCHAR2 type segment columns are of data type `java.lang.String`.

• The package name and the object name prefix for each entity object are registered with the ADF Business Components usage to which it will provide data, as described in Registering Entity Details Using the Setup APIs.

### 25.2.4.1 Build a Writable Maintenance Model

A writable maintenance model is the first element required to support a code-combination maintenance page and dynamic combination insertion in your application.

To build a writable maintenance model:

1. Create the maintenance model key flexfield business components.

2. Link the business components to the master view object.

3. Create the maintenance application module.

4. Optionally, implement a method to override the automatic locking of code combinations that are to be inserted or updated, which occurs by default.

#### 25.2.4.1.1 How to Create Key Flexfield Business Components for a Maintenance Model

The first element in a writable maintenance model is a set of business components.
To implement this model, you must select the **Maintenance Mode** checkbox when you encounter it on the Usage Settings page, as described in the following procedure.

**Before you begin:**

1. Create an updatable entity object for the combinations table and add it as an ADF Business Components usage for your key flexfield, as described in *Registering Entity Details Using the Setup APIs*.

   The entity object that you select must allow maintenance operations such as Update or Insert. The entity object class must extend the `oracle.apps.fnd.applcore.oaext.model.KFFMEntityImpl` class, and the entity definition class must extend the `oracle.apps.fnd.applcore.oaext.model.KFFMEntityDefImpl` class.

   **Caution:**
   Disable the delete capability for the combinations table, because the deletion of previously created combinations might invalidate foreign key references. If you want to disallow the use of a combination, then disable the combination instead of deleting it.

2. Create a master view object for the combinations table based on the same updatable entity object.

   This view object typically contains your payload attributes, and should not include flexfield attributes.

   In the master view object, ensure that the CCID attribute’s **Display** control hint is set to **Hide**.

3. Build the project to ensure that the entity objects are available in the project’s classes. The Create Flexfield Business Components wizard relies on what is in the project’s classes.

**To create key flexfield business components:**

1. In the Application Navigator, right-click the project and choose **New**.

2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Flexfield Business Components**, and click **OK**.

3. On the Flexfield page of the Create Flexfield Business Components wizard, select **Key** from the **Type** dropdown list, as shown in **Figure 25-3**.
4. In the **Application** field, specify the full name of the application to which your key flexfield belongs.
   
   You can browse for the name, and filter by **ID**, **Short Name**, or **Name**.

5. In the **Code** field, specify the code of the key flexfield you want to use.
   
   You can browse for and filter by **Code**.

6. In the **Usage** section, select the table row that contains the primary usage of the key flexfield as it is defined on its combinations table. Every key flexfield has exactly one primary usage.
   
   To identify the primary usage, the **Usage Code** field for this type is typically the same as the flexfield code. The **Table Name** field displays the name of the combinations table, and the text in the **Description** field does not contain the prefix (**Partial**) or (**Partial Single**) in parentheses.
   
   You must select the primary usage in this procedure because you are generating key flexfield business components for the combinations table for your maintenance model.

7. On the **Path** page, select the path of the directory structure in which to create the flexfield business components and click **Next**.

8. On the **Entity Object** page shown in Figure 25-4, select the entity object for the combinations table. It must allow maintenance operations such as update or insert, and include all of the attributes that will be referenced by the flexfield. For the key flexfield primary usage, this includes attributes that represent the CCID, SIN, and segment columns, and the DSN column if it exists in the combinations table.

   **Note:**

   If you select a polymorphic entity object, ensure that the **InheritPersonalization** property for every subtype entity is set to **true**.
9. You might wish to select an entity object for which the key flexfield attributes are defined as transient (not based on database table columns). If you need to do this, then select The names of flexfield attributes match the names of registered columns exactly; do not check the underlying columns.

When a key flexfield entity object attribute is transient, there is no matching underlying column name. When you select this option, the system will match the entity object attribute names to the key flexfield column names, and use the matching attributes to access the flexfield data. Ensure that the entity object has a full set of attributes with matching names before you select this option.

This entity object must be registered under the primary usage. There is no need to register another table for this purpose, even if the entity object is based on some other table. See Registering Entity Details Using the Setup APIs, for more information about registering ADF Business Components usage.

Caution:
The Create Flexfield Business Components wizard is case-sensitive. All column names — and the names of the flexfield entity object attributes associated with them — must be uppercase.

10. Click Next. The Usage Settings page appears.

Because you specified the primary usage of the key flexfield on the Flexfield page of this wizard, this page contains a Maintenance Mode checkbox.

Select Maintenance Mode to build your maintenance model.

11. Click Next. The Naming page displays the entity object’s package name and object name that you registered for the usage, as described in Registering Entity Details Using the Setup APIs. Click Next.

12. On the Summary page, review your choices and click Finish.
The business components generated will replace any existing ones that are based on the same flexfield.

**Note:**

This wizard might fail with a "ClassNotFound" exception message. This indicates that one or more required libraries have not been automatically included in your project, notably the BC4J Service Runtime, Java EE 1.5 and Java EE 1.5 API libraries. You can resolve this issue by manually adding any missing libraries; then you can complete this procedure successfully.

13. Refresh the project to see the newly created flexfield business components in the Application Navigator.

**25.2.4.1.2 How to Link the Master View Object to the Maintenance Model Key Flexfield Business Components**

You must create a flexfield view link from the master view object for the combinations table to the maintenance key flexfield business components. This enables your maintenance user interface to access all of the combinations table columns using the linked view objects for the combinations table entity object.

The master view object and the key flexfield's base view object are linked through the combination of a CCID, and SIN, and if present, a DSN.

**To create a view link for the key flexfield maintenance model:**

1. In the Application Navigator, right-click the project and choose **New**.

2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Flexfield View Link**, and click **OK**.

3. In the Create Flexfield View Link wizard, on the Name page, provide a package name and a view link name, and click **Next**.

4. In the **Select Source View Object** tree, expand the available objects from the current project and select the master view object for the combinations table, as shown in **Figure 25-5**.
5. In the **Select Destination Flexfield** tree, expand the available flexfield view objects from your project and select your maintenance key flexfield view object as the destination.

6. In the **View Link Accessor Name** field, enter an appropriate name for the view link accessor.

7. Click **Next** to access the Source Attributes page.

**Note:**

For key flexfields in maintenance mode, the Source Attributes page is informational only. The primary key attributes of the source view object will be used to define the view link.

If you see any controls on this page for selecting source attributes, you are not using maintenance mode business components. Return to **Building a Writable Maintenance Model** and re-create your maintenance mode business components according to the instructions.

8. Click **Finish** to go to the Summary page.

**Note:**

You can skip the Properties page because view link-specific properties are not supported.

9. On the Summary page, review the summary, then click **Finish**.

### 25.2.4.1.3 How to Create the Maintenance Application Module

You must create the maintenance application module for the key flexfield. The application module contains the combination view object, the maintenance model view link, and the key flexfield's application module that was created when you created the business components in **How to Create Key Flexfield Business Components for a Maintenance Model**.

---

**Figure 25-5  Create Flexfield View Link Wizard — View Objects Page**

![Create Flexfield View Link Wizard](image-url)
For more information about creating application modules and nesting application model instances, see the Implementing Business Services with Application Modules chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.

Before you begin:

1. Create the business components as described in How to Create Key Flexfield Business Components for a Maintenance Model.

2. Create the view link as described in How to Link the Master View Object to the Maintenance Model Key Flexfield Business Components.

To create the maintenance application module:

1. In the Application Navigator, right-click the project and choose New.

2. In the New Gallery, expand Business Tier, select ADF Business Components and then Application Module, and click OK.

3. In the Create Application Module wizard, on the Name page, provide a package name and an application module name, and click Next.

4. In the Data Model page, move the master view object for the combinations table and the maintenance model view link to the Data Model list, as shown in Figure 25-6.

**Figure 25-6  Create Application Module Wizard — Data Model Page**

Tip:
The object name prefix and package name are used to name the flexfield business components, and are defined in the database along with the key flexfield.

5. Click Next. The Application Modules page appears.
6. On the Application Modules page, in the Available tree, move the appropriate key flexfield application modules to the Selected list, as shown in Figure 25-7. Include the key flexfield application module that was created when you created the business components in How to Create Key Flexfield Business Components for a Maintenance Model.

**Figure 25-7  Create Application Module Wizard — Application Modules Page**

![Image of Application Modules page from Create Application Module Wizard]

**Note:**
For each key flexfield, only one instance of the application module is needed. For example, even though two view links may have been created to access the same flexfield, only one instance of the flexfield application module is needed in the product application module.

7. When you complete the Create Application Module wizard, right-click the new application module instance and choose Run to test it.

**Note:**
The maintenance application module must have a configuration named appmodule_nameLocal. By default, this is created for you. For example, if the application module is called MyKffMaintAM, then a configuration named MyKffMaintAMLocal must exist.

**Tip:**
You can publish a key flexfield application module instance as a web service. For more information about creating and testing a key flexfield service interface, see How to Publish Key Flexfield Application Modules as Web Services.
25.2.4.1.4 How to Manage Code Combination Locking

The `oracle.apps.fnd.applcore.oaext.model.KFFMEntityImpl` class, which is extended by your code combination entity object class, enables automatic code combination locking by default. The method `doDML(int, TransactionEvent)` is overridden to lock the code combination to be inserted or updated. The lock is removed when the transaction is committed or rolled back.

If you wish to completely overwrite `doDML` with your own implementation, you can turn the automatic locking off by calling `setAutoCombinationLockEnabled(false)`, then calling `lockCombination(DBTransaction)` on your own. For more information, see the Java documentation for `oracle.apps.fnd.applcore.oaext.model.KFFMEntityImpl`.

25.2.4.2 Enable Dynamic Combination Insertion

This task is necessary only if you want to permit end users to create new code combinations spontaneously on an application page. You must have already built a writable key flexfield maintenance model. For more information, see How to Create Key Flexfield Business Components.

To enable this feature, you define an application module that you configure for dynamic combination insertion, then implement the appropriate Java class in the user interface. You can create a basic implementation of dynamic combination insertion under the simplest conditions, create a more sophisticated version that includes added combination attributes, or, if custom validation procedures or cross-validation rules are registered with the flexfield, create a version that makes information available to the custom validation procedures.

25.2.4.2.1 Enable Dynamic Combination Insertion

To enable dynamic combination insertion, the key flexfield must be set to allow dynamic combination insertion, and the full name of the maintenance application module that will implement `KFFCombinationCreator` must be registered with the key flexfield.

To enable dynamic combination insertion:

1. Issue the following SQL update statement to enable dynamic combination insertion:

   ```
   update fnd_kf_flexfields_b
   set dynamic_combo_creation_flag = 'Y'
   where application_id = :app_id
   and key_flexfield_code = :kff_code
   ```

   Set the `:app_id` to the `application_id` that was specified when the flexfield was created, and set `:kff_code` to the flexfield's `key_flexfield_code`. For more information, see What You May Need to Know About the Key Flexfield Setup API.

2. Issue the following SQL statement to set the name of the application module to be used for dynamic combination insertion:

   ```
   update fnd_kf_flexfields_b
   set application_module_name = 'fully qualified name of application module'
   where application_id = :app_id
   and key_flexfield_code = :kff_code
   ```
The name of the application module must be fully qualified; for example, mycompany.myproduct.flex.kff1.applicationModule.Kff1AM.

Set the :app_id to the application_id that was specified when the flexfield was created, and set :kff_code to the flexfield's key_flexfield_code. For more information, see What You May Need to Know About the Key Flexfield Setup API.

### 25.2.4.2.2 Insert a Code Combination — the Simplest Case

In the simplest case, you need only replace the existing base object class, oracle.apps.fnd.applcore.aoext.model.OAApplicationModuleImpl, with oracle.apps.fnd.applcore.aoext.model.KFFCombinationCreatorImpl. KFFCombinationCreatorImpl extends OAApplicationModuleImpl.

This implementation is possible only under the following conditions:

- You have no custom Java application module class for this application module.
- Only one key flexfield application module instance is nested in this application module, and that nested instance is the one that represents the key flexfield of interest.
- You do not need to update any columns of the combinations table, including the value attribute columns.

### 25.2.4.2.3 Insert a Code Combination with Added Combination Attributes

To insert a code combination with added combination attributes, you implement the KFFCombinationCreator Java class in the maintenance application module, and you create a Java implementation of the maintenance application module. You can optionally initialize the columns.

1. In the maintenance application module, implement the Java class oracle.apps.fnd.applcore.aoext.model.KFFCombinationCreator from the oracle.apps.fnd.applcore.aoext.model package.

   The class has only one method defined:

   ```java
generic void createKeyFlexfieldCombination(Long sin, Long dsn, List<Object> segValues);
```

   This method has the following parameters:

   - **sin**: The structure instance number. This should be null if this key flexfield does not allow multiple structures.
   - **dsn**: The data set number. This should be null if this key flexfield does not use data set numbers.
   - **segValues**: A read-only list of segment values.

   If an error occurs during creation, throw the exception FlexfieldJboException.

2. Generate a Java application module class to extend your existing base object class. By default, the base class is OAApplicationModuleImpl from the oracle.apps.fnd.applcore.aoext.model package. An example of an application module class is shown in Example 25-3.
By default, JDeveloper creates accessor methods (such as getMyKffAM1()) to all of your nested application modules. You can use these accessor methods to access the key flexfield application module, as shown in bold in Example 25-3.

If you do not need to update any combination attributes, then the implementation in the example is sufficient; otherwise, you can use the KFFCombinationAttributes object to update the value attribute columns, or use the master view object to update any other columns of the combinations table, as described in the next steps.

3. Optionally, initialize value attribute columns using KFFCombinationAttributes.

The KFFCombinationAttributes object enables you to:

- Get the segment values and their value-attribute values.
- Get the default values of the value attributes used.
- Get the list of value attribute codes for a label used in this flexfield.
- Get the current value of a value attribute column of the combinations table.
- Update a value attribute column of the combinations table.

By default, the standard value attribute columns such as START_DATE_ACTIVE, END_DATE_ACTIVE, and ENABLED_FLAG are initialized in the insertCombination call. The ENABLED_FLAG is initialized to Y. The START_DATE_ACTIVE value is set to the maximum of the START_DATE_ACTIVE values for the segments, or NULL if all values are null. The END_DATE_ACTIVE value is set to the minimum of the END_DATE_ACTIVE values for the segments, or NULL if all values are null. You have full access to these value-attribute values and can update these columns of the combinations table if you wish.

Example 25-4 demonstrates how to use the KFFCombinationAttributes object to access these values and update the value attribute columns of the combinations table.

4. If you want to initialize other columns of the combinations table, first include them in the master view object. After insertCombination is called, the new entity will be available to the master view object as well, as shown in Example 25-5, which shows an alternative version of MyKffMaintenanceAM.java.

**Example 25-3 Implementing KFFCombinationCreator**

```java
public class MyKffMaintenanceAM
    extends OAApplicationModuleImpl
    implements KFFCombinationCreator
{
    /**
     * Container's getter for MyKffAM1.
     *
     * @return MyKffAM1
     */
    public ApplicationModuleImpl getMyKffAM1()
    {
        return (ApplicationModuleImpl) findApplicationModule("MyKffAM1");
    }

    public void createKeyFlexfieldCombination(
```
Example 25-4 Using the KFFCombinationAttributes Object

```java
public void createKeyFlexfieldCombination(
    Long sin, Long dsn, List<Object> segValues)
{
    KFFCombinationAttributes combAttrs =
        ((KFFMApplicationModuleImpl)
          getMyKffAM1()).insertCombination(sin, dsn, segValues);
}

final String myLabel = "MY_LABEL";
// Get the segment values and their value-attribute values for the label.
List<FlexfieldSegmentValue> segValueList = combAttrs.getSegmentValues(myLabel);
// Loop through each segment value.
for (FlexfieldSegmentValue segValue: segValueList)
{
    // Get the segment code if needed.
    System.out.println("SegmentCode = " + segValue.getSegmentCode());
    // Get the segment value if needed.
    System.out.println("SegmentValue = " + segValue.getValue());
    // Iterate through each value attribute code for the label if needed.
    Iterator<String> it = combAttrs.getValueAttrCodeIterator(myLabel);
    while (it.hasNext())
    {
        String valAttrCode = it.next();
        FlexfieldSegmentValue.ValueAttributeValue valAttrValue =
            segValue.getValueAttributeValue(valAttrCode);
        // Value attribute code is also available in the value object.
        System.out.println("  ValueAttrCode = "
                           + valAttrValue.getValueAttributeCode());
        // Get the default value of the value attribute.
        System.out.println("  ValueAttrDefaultValue = "
                           + valAttrValue.getDefaultValue());
        // Get the value of the value attribute.
        System.out.println("  ValueAttrValue = "
                           + valAttrValue.getValue());
    }
}

System.out.println();

final String myValueAttrCode = "MY_VALUEATTRIBUTE1";
// Get the current combination value attribute.
System.out.println("\t" + myLabel + ":" + myValueAttrCode + " = "
                           + combAttrs.getValueAttribute(myLabel, myValueAttrCode));

// Update the combination value attribute.
Map<String, Object> valueMap = new HashMap<String, Object>(1);
valueMap.put(myValueAttrCode, "N");
combAttrs.setValueAttributes(myLabel, valueMap);

System.out.println();
```
/** Dealing with standard value attributes. ***/

// Get the segment values with the standard value attributes.
List<FlexfieldSegmentValue> segValueListStd = combAttrs.getSegmentValues();
// Loop through each segment value.
for (FlexfieldSegmentValue segValue: segValueListStd)
{
    System.out.println("SegmentCode = " + segValue.getSegmentCode());

    // Get the START_DATE_ACTIVE attribute.
    FlexfieldSegmentValue.ValueAttributeValue startDateActive =
    segValue.getValueAttributeValue(
        FlexfieldSegmentValue.VALUE_ATTR_START_DATE_ACTIVE);
    // Get the END_DATE_ACTIVE attribute.
    FlexfieldSegmentValue.ValueAttributeValue endDateActive =
    segValue.getValueAttributeValue(
        FlexfieldSegmentValue.VALUE_ATTR_END_DATE_ACTIVE);
    // Get the ENABLED_FLAG attribute.
    FlexfieldSegmentValue.ValueAttributeValue enabledFlag =
    segValue.getValueAttributeValue(
        FlexfieldSegmentValue.VALUE_ATTR_ENABLED_FLAG);

    System.out.println("  StartDateActive = " + startDateActive.getValue());
    System.out.println("  EndDateActive = " + endDateActive.getValue());
    System.out.println("  EnabledFlag = " + enabledFlag.getValue());
}
System.out.println();

// Get the current combination start date.
System.out.println("StartDateActive = " + combAttrs.getValueAttribute(null,
    FlexfieldSegmentValue.VALUE_ATTR_START_DATE_ACTIVE));
// Get the current combination end date.
System.out.println("EndDateActive = " + combAttrs.getValueAttribute(null,
    FlexfieldSegmentValue.VALUE_ATTR_END_DATE_ACTIVE));
// Get the current combination enabled flag.
System.out.println("EnabledFlag = " + combAttrs.getValueAttribute(null,
    FlexfieldSegmentValue.VALUE_ATTR_ENABLED_FLAG));

// You can update the standard value attributes by calling
// combAttrs.setValueAttributes(Map).

Example 25-5 Calling insertCombination to Make the New Entity Available to the
Master View Object

public void createKeyFlexfieldCombination(
        Long sin, Long dsn, List<Object> segValues)
    {
            KFFCombinationAttributes combAttrs =
            ((KFFMApplicationModuleImpl)
                getMyKffAM1()).insertCombination(sin, dsn, segValues);

            // In this example, the key flexfield allows multiple structures.
            // The order of the key values must match the order of the keys;
            // see ADF Business Components Java documentation for more details.
            Key keyValues = new Key(new Object[] {
                combAttrs.getCodeCombinationID(),
                sin});
    }
// getMyKffComboAttrVO() is generated when a view object instance named
// "MyKffComboAttrVO" is present. You can always call
// findViewObject to find the
// view object if no accessor method is available.
OAViewObjectImpl vo = getMyKffComboAttrVO();
Row[] rows = vo.findByKey(keyValues, 1);
if (rows != null && rows.length == 1)
{
    rows[0].setAttribute("MyCombinationAttr1", "Y");
} else
{
    throw new FlexfieldJboException("Unable to find the newly created combination: CCID = "+
combAttrs.getCodeCombinationID()
+ ", SIN = "+sin);
}

25.2.4.2.4 Insert a Code Combination that Uses Custom Validation Procedures or Cross-Validation Rules

If custom validation procedures or cross-validation rules are registered with the flexfield, you must create a Java class for the maintenance application module that implements the KFFCombinationCreatorProxy class. This makes the information in the KFFCombinationCreatorProxy.Context object, such as the validation date, available to the custom validation procedures.

1. In the maintenance application module, generate a Java class that implements KFFCombinationCreatorProxy from the oracle.apps.fnd.appcore.oaext.model package and extends your existing base object class. By default, the base class is OAApplicationModuleImpl from the same package. An example of an application module class is shown in Example 25-3.

Note:

KFFCombinationCreatorProxy is a sub-interface of KFFCombinationCreator.

2. Optionally, initialize value attributes, as described in Step 3 of Inserting a Code Combination with Added Combination Attributes.

3. Optionally, initialize other columns of the combinations table, as described in Step 4 of Inserting a Code Combination with Added Combination Attributes.

Example 25-6 Implementing KFFCombinationCreatorProxy

public class MyKffMaintenanceAM extends OAApplicationModuleImpl implements
KFFCombinationCreatorProxy
{
    /**
     * Container's getter for MyKffAM1.
     *
     * @return MyKffAM1
     */
public ApplicationModuleImpl getMyKffAM1()
{
    return (ApplicationModuleImpl) findApplicationModule("MyKffAM1");
}

@Override
public void createKeyFlexfieldCombination(
    Long sin, Long dsn, List<Object> segValues)
{
    // Delegated to the method that takes "context".
    this.createKeyFlexfieldCombination(sin, dsn, segValues, null);
}

@Override
public void createKeyFlexfieldCombination(final Long sin, final Long dsn,
    final List<Object> segValues,
    final Context context)
{
    KFFCombinationAttributes combAttrs =
    {
        ({KFFMApplicationModuleImpl) getMyKffAM1()}.insertCombination{
            sin, dsn, segValues, context);
    }
}

### 25.2.4.3 Build a Read-Only Reference Model

A set of business components that constitute a read-only reference model is needed so that you or a consumer developer can build a code-combination reference page, which is typically a transaction page for a product table that has a foreign key reference to the combinations table.

---

**Note:**

If you want to permit end users to create new code combinations spontaneously on an application page, you must have already built a writable key flexfield maintenance model and have enabled dynamic combination insertion.

For more information, see **How to Create Key Flexfield Business Components**.

---

**Before you begin:**

Create a read-only entity object for your combinations table and add it as an ADF Business Components usage for your key flexfield, as described in **Registering Entity Details Using the Setup APIs**.

**To create key flexfield business components for a read-only reference model:**

1. Complete Step 1 through Step 8 in **How to Create Key Flexfield Business Components for a Maintenance Model**.

2. On the Entity Object page, expand the tree of available models and select the read-only entity object that you created for the combinations table.

    The entity object you select must include all of the attributes that will be referenced by the flexfield. For the key flexfield primary usage, this includes
attributes that represent the CCID, SIN, and segment columns, and the DSN column if it exists in the combinations table.

3. Complete Step 9 through Step 13 in How to Create Key Flexfield Business Components for a Maintenance Model.

25.2.5 How to Share Key Flexfield Business Components

Sharing flexfield business components is just like sharing any other ADF Business Components objects. You can share the objects through an ADF Library JAR file. The developers then can import the business components that are contained in the JAR file.

For more information, see the Packaging a Reusable ADF Component into an ADF Library section in the Developing Fusion Web Applications with Oracle Application Development Framework.

25.2.5.1 Create an ADF Library JAR File

If you are the owner of the flexfield business components that you want to share, then you can create a JAR file containing those business components. Generally, an entire JDeveloper project is deployed as an ADF Library JAR file.

Create your shared ADF library containing the business components from the read-only reference model you just built, then add the business components from the writable maintenance model as well.

To create an ADF Library JAR file:

1. Right-click the project you wish to share and select Project Properties from the menu.

2. Select Deployment.

3. If a deployment profile is already listed, you can verify that it is for an ADF Library JAR file. Open the profile for editing and observe the window title to confirm that it says "Edit JAR Deployment Profile Properties.”

If you do not already have an appropriate deployment profile, you can create one:

a. In the Application Navigator, right-click the project and choose New.

b. In the New Gallery, expand General, select Deployment Profiles and then ADF Library JAR File, and click OK.

c. In the Create Deployment Profile — ADF Library JAR File dialog, enter a name for the profile and click OK.

4. Right-click the project you wish to share and select Deploy > deployment_profile_name > To JAR File.

The JAR file is created in your project's deploy directory as deployment_profile_name.jar. You can send it to other developers for use in their projects.

25.2.5.2 Import Business Components from an ADF Library

After an ADF Library JAR file has been created by one developer, another developer can import the business components that are contained in the file.
For more information, see the Adding ADF Library Components into Projects section in the Developing Fusion Web Applications with Oracle Application Development Framework.

To Import business components from an ADF library:

1. Obtain an ADF Library JAR file from another developer and save it to an accessible directory for importing.
2. Right-click the project where you want to import the components and select Project Properties.
4. Click Import, then go to the location of the ADF Library JAR file.
5. Select the ADF Library JAR file and click Open.

The business components in the JAR file are imported into your project.

25.2.6 How to Build a Key Flexfield Maintenance User Interface

Use the business components from a writable maintenance model to build a key flexfield code-combination maintenance page. Building a maintenance page is fairly straightforward. If you have already inserted a key flexfield component into a page in either form or table layout, building a maintenance page follows a similar pattern.

To enable end users to select key combinations for new rows, ensure that you provide a default value for every Structure Instance Number attribute.

25.2.6.1 Build a Key Flexfield Code-Combination Maintenance Page

Build a key flexfield code-combination maintenance page using objects from the maintenance application module that you created over the combinations table.

Before you begin:

Create a maintenance application module for the combinations table and a writable maintenance model for the flexfield usage as described in Building a Writable Maintenance Model.

To build a code-combination maintenance page:

1. From the Data Controls panel, expand the maintenance application module that you created for the combinations table.
2. Drag the master view object from the application module onto the page, and add it as either a form or a table.
3. Select the key flexfield view object and drag it onto the page. Drop the flexfield view object onto the form or table that you just created.

For more information, see Employing Key Flexfield UI Components on a Page.

25.2.6.2 Ensure Proper Handling of New Rows

When a new row that contains key flexfield columns is added on the code-combination maintenance page, every Structure Instance Number attribute must contain a valid value, so that the key flexfield user interface can be rendered with appropriate structures. Without default structures, end users will not be able to select segment values for the new row.
You can prevent application errors by defining a default value for each Structure Instance Number. Edit the Structure Instance Number attribute in either the entity object or the view object for the reference table, and do one of the following:

- If the Structure Instance Number is static, set the Value Type to Literal, and specify the static value as the default.
- If the Structure Instance Number is dynamic, set the Value Type to Expression, and enter a Groovy expression to retrieve the appropriate Structure Instance Number value and set it as the default.

---

**Note:**

Use the defaultSIN attribute in the JSPX file to define the default Structure Instance Number value for situations where no rows exist.

---

**Caution:**

The Structure Instance Number value of the first row of a user interface table determines the column structure to be used for the table. For any additional row that contains a different Structure Instance Number, the columns that are not also part of the first row's structure will not render in the table. If there are no rows, the value of the defaultSIN tag attribute from the JSPX file, if set, determines the column structure.

For an Applications Table component, if the end user deletes all rows from the table, your application can again set a new default Structure Instance Number value for the first new row, and the column structure corresponding to that Structure Instance Number will be the valid structure for the table.

For an ADF Table, the column structure (determined by the initial Structure Instance Number value) cannot be changed after the table has been created, even if all rows are deleted.

---

For more information about setting attribute defaults, see the discussion about defining default values in the Setting Attribute Properties section of the Developing Fusion Web Applications with Oracle Application Development Framework.

### 25.2.7 What Happens at Runtime: Creating New Combinations

At runtime, an instance of the registered application module is created. Whenever a new combination must be created, the following happens:

1. The createKeyFlexfieldCombination method is invoked. When KFFApplicationModuleImpl.insertCombination is called in the implementation, a lock is created to ensure that no one else can insert the same combination.

2. The transaction of the registered application module is committed or rolled back. The lock is always removed.

3. One of the following occurs:
   - If no exception is thrown, the transaction is committed.
• If any exception occurs, the transaction is rolled back.

25.3 Complete the Consumer Tasks for Key Flexfields in Reference Mode

You can reference flexfields from another (producer) application into your (consumer) application. The consumer tasks for a key flexfield primary usage (also referred to as reference mode) are:

1. Create a view link from your (consumer) product view object to the producer's key flexfield view object.
2. Nest the producer's key flexfield application module instance in the (consumer) application module for the application.
3. Add a key flexfield view object instance to the (consumer) application module for your application.

After you complete the consumer tasks, you can incorporate the key flexfield UI components into your application as described in Employing Key Flexfield UI Components on a Page.

25.3.1 How to Create Key Flexfield View Links

If a product view object references a producer’s key flexfield, you must link the product view object to the key flexfield’s base view object to create a master-detail hierarchy. You use the Create Flexfield View Link wizard two link the two view objects. The product view object and the key flexfield’s base view object are linked through the combination of a CCID, a SIN, and if present, a DSN. The key flexfield view object can have many incoming view links from various product view objects, because a key flexfield is usually referenced by many product tables. For example, an ExpenseLines view object might have a foreign key reference to the GLKff view object. For more information about view links and master-detail hierarchies, see the Defining SQL Queries Using View Objects chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.

By default, when a value set is security-enabled, any key flexfield code combination segment that uses that value set will automatically be secured. Security rules defined on the value set are propagated automatically to the combinations table, and also to any product table that references the combinations table. This means that when an end user does a search on the product table, the results shown are limited to the data referencing the code combination entries to which the user has access. You can add a custom property to the view link to disable the propagation of the security rules to the product table.

Before you begin:

• Ensure that the flexfield library JAR files that were created by the producer team have been added to your project. For more information about library JAR files, see Creating an ADF Library JAR File and Importing Business Components from an ADF Library.

• You should have already created an entity object and a view object for the reference table (the product table with a foreign key reference to the combinations table). You use the reference table’s view object for the source of the view link.

Ensure that the view object does not include flexfield attributes such as SEGMENT1 VARCHAR2, SEGMENT2 NUMBER, and so on. Ensure that you include the attributes that are needed for the foreign key reference, such as CCID,
To create a key flexfield view link:

1. In the Application Navigator, right-click the project and choose New.
2. In the New Gallery, expand Business Tier, select ADF Business Components and then Flexfield View Link, and click OK.
3. In the Create Flexfield View Link wizard, on the Name page, provide a package name and a view link name, and click Next.
4. In the View Objects page, in the Select Source View Object tree, expand the available objects from your current project and select a source view object.
5. In the Select Destination Flexfield tree, expand the available flexfield view objects from your project and select the key flexfield’s base view object with which you want to associate the source view object.
6. In the View Link Accessor Name field, enter an appropriate name for the view link accessor.
7. Click Next. The Source Attributes page appears, as shown in Figure 25-8.

Figure 25-8  Create Flexfield View Link Wizard — Source Attributes Page for Key Flexfields

8. From the Code-Combination ID dropdown list, select the source attribute that corresponds to the CCID of the destination key flexfield.
   The CCID must be mapped to type java.lang.Long.
9. If your destination key flexfield supports multiple structure instances, the Structure Instance Number dropdown list appears on the Source Attributes page. You must specify a structure instance as an additional source attribute. From the dropdown list, select the source attribute that corresponds to the SIN of the destination key flexfield.
The SIN must be mapped to type `java.lang.Long`.

---

**Note:**

The source attribute must be an entity attribute that is either persistent or is SQL-derived.

---

10. If your destination key flexfield supports multiple structure instances and is data set-enabled, the **Data Set Number** dropdown list appears on the Source Attributes page. You must specify a data set as an additional source attribute. From the dropdown list, select the source attribute that corresponds to the DSN of the destination key flexfield.

    The DSN must be mapped to type `java.lang.Long`.

11. Click **Finish** to go to the Summary page.

    **Note:**

    You can skip the Properties page because view link-specific properties are not supported.

12. On the Summary page, review the summary, then click **Finish** to create the view link.

13. Optionally, disable the automatic propagation of value set security rules to the product table by adding a custom property to the view link between the product view object and the key flexfield view object, as follows:

    ```xml
    <propertyname="FND_ACFF_MasterSecuredByFlexfield" Value="false"/>
    ```

---

### 25.3.2 How to Nest an Instance of the Key Flexfield Application Module in the Product Application Module

Use the overview editor for the product application module to nest the application module instance for the key flexfield. This is the application module instance that was created when you created the flexfield business component and was named using the prefix that you specified when you defined the usage’s entity details. The nested key flexfield application module instance shares the same transaction and entity object caches as the application module.

**Before you begin:**

You should have already created a product application module.

**To nest an instance of the key flexfield application module in the product application module:**

1. In the Application Navigator, double-click the product application module.

2. In overview editor, click the **Data Model** navigation tab.

3. On the Data Model Components page, expand the **Application Module Instances** section and, in the **Available** list, select the key flexfield application module.

    The **New App Module Instance** field below the list shows the name that will be used to identify the next instance that you add. You can change this name.
4. With the desired application module selected, move the key flexfield application module to the **Selected** list.

### 25.3.3 How to Add an Instance of a Key Flexfield View Object to the Product Application Module

You must add a flexfield view object instance that reflects the master-detail hierarchy of the view link that you created in *How to Create Key Flexfield View Links* to the product application module. You can use the data model that the application module overview editor displays to create the master-detail hierarchy of view instances. The master view object is the view object for the reference table (the product table with a foreign key reference to the combinations table), and the detail view object is the view object for the flexfield. For example, if you created a view link from the `ExpenseLines` view object to the `GLKff` view object, then `ExpenseLines` is the master and `GLKff` is the detail.

For more information about creating a hierarchy of view instances, see the "Adding Master-Detail View Object Instances to an Application Module" section in the *Developing Fusion Web Applications with Oracle Application Development Framework*.

**Before you begin:**

1. Add an instance of the view object for the reference table to the product application module, as described in the "How to Add a View Object Instance to an Application Module" section in the *Developing Fusion Web Applications with Oracle Application Development Framework*.

2. Create a view link between the reference table view object and the key flexfield view object as described in *How to Create Key Flexfield View Links*.

**To add an instance of a key flexfield view object to the product application module:**

1. In the Application Navigator, double-click the product application module.

2. In the overview editor, click the **Data Model** navigation tab.

3. Expand the **View Object Instances** section.

4. If an instance of the reference table view object does not appear in the **Data Model** list, then select it in the **Available View Objects** list and move it over. This is the master view object instance.

5. In the **Data Model** list, select the instance of the view object for the reference table (the master view object instance) so that it appears highlighted. This will be the target of the detail flexfield view instance that you will add.

6. In the **Available View Objects** list, expand the view object for the reference table and move the nested key flexfield view object (the detail view object) to the **Data Model** list. The flexfield view instance appears nested under master view instance, as shown in *Figure 25-9*. 
25.4 Employ Key Flexfield UI Components on a Page

After a key flexfield's UI components have been made available to your application, you can incorporate the flexfield into UI pages and query search forms. You can then configure the various aspects of an incorporated key flexfield UI component to customize the behavior of the flexfield as a whole, or on a segment-by-segment basis.

25.4.1 How to Employ a Key Flexfield Component on a Page

To employ a key flexfield UI component on an application page, add the flexfield to a form component or a table component, then configure the properties of the flexfield.

Note:

This section assumes you are using the data-first method of adding flexfields to your application, in which you build the data model first, then create the user interface by dragging data controls onto a page. The UI-first method is also available, but is not documented here.

Key flexfields can be implemented on the following types of pages:

- **A page with a foreign key reference to the combinations table**

  The database table (or view) for this type of page contains a foreign key reference to a combinations table that contains the actual flexfield segment columns. You create a page with a foreign key reference if you want to use your page to manipulate rows that contain code combination IDs. The database table is referred to as the reference table, and the page is referred to as the code-combination reference page.

  The primary purpose of code-combination reference pages is generally unrelated to the fact that some fields might be key flexfields. That is, the purpose of the page is to accomplish whatever business function is required (such as entering orders, receiving parts, and so on). You might have many code-combination reference pages that use a given key flexfield.
• A page with secondary usage of a key flexfield
  You can invoke the secondary usage feature of key flexfields on a page. Secondary usage occurs when one or all segments of a key flexfield that have already been defined for a combinations table are also defined for a product table. In this way, you can reuse a key flexfield definition for a product table as if it were a descriptive flexfield.

• A code-combination maintenance page
  The only purpose of a code-combination maintenance page is to create and maintain code combinations. This page is typically built by the producer. The combinations table (or a view of it) is the base table of this page and contains all the key flexfield segment columns. The combinations table also contains a unique ID column. For information about creating a code-combination maintenance page, see How to Build a Key Flexfield Maintenance User Interface.

  A typical application has one and only one code-combination maintenance page. An application might not have a code-combination maintenance page if it does not support maintenance mode for administrators.

• A page containing a search form
  An advanced search form enables end users to define criteria to search for metadata in the application’s master view object and its linked key flexfield view object. Users can select which attributes of the key flexfield view object to use as criteria. See How to Incorporate Key Flexfields into a Query Search Form for information about using key flexfields in a search form.

  Note:
  You cannot use a key flexfield in a tree table component.

In a typical application, you would have one code-combination maintenance page that maintains the key flexfield, where the key flexfield is the representation of an entity in your application. You would also have one or more code-combination reference pages with foreign key references to the same combinations table. For example, in an order entry/inventory application, you might have a code-combination maintenance page where you define new parts with a key flexfield for the part numbers.

  You would also have a code-combination reference page where you enter orders for parts, using the key flexfield to indicate what parts are included in the order. The page might also contain a code-combination filter, which you use to determine the acceptable values of your part numbers. This code-combination filter references the same key flexfield as the code-combination maintenance page and the code-combination reference page.

  The order of key flexfield segments in the application user interface corresponds to the order in which they were defined in the key flexfield metadata. You cannot reliably change that order at runtime. The user interface dynamically reads the displayed attributes from the view object and displays them in the same order that they occur in the view object. There are no attribute UI hints that you can use to override this behavior.

  Reordering key flexfield segments is not supported and can potentially create data integrity issues for code combinations, which are sequence-aware. Because of this, it is important that you plan the segment order of your key flexfields in advance.
The tasks to employ a key flexfield on a page include:

- Adding the key flexfield UI component to a form or a table
- Defining a default value for every SIN attribute to prevent application errors when a new row that contains key flexfield columns is added on an application page
- For ADF Form pages, adding code to ensure proper updating of reference mode and secondary mode SIN values
- For secondary-usage flexfield segments or for segments on a code-combination maintenance page, where the flexfield is in an ADF Table that is wrapped in an Applications Table component, adding functionality that dynamically refreshes the segment columns whenever the Applications Table component is refreshed by another component, such as a button or a search query

If you want changes in your key flexfield to trigger a partial update of another component, set the AutoSubmit UI property of the flexfield to True, and add the key flexfield ID to the PartialTriggers UI property of the other component.

**Caution:**
To ensure that the trigger works, you must append "CS" to the key flexfield ID. For example, if you want changes in the MyKeyFlex01 flexfield to trigger an update in another component, add "MyKeyFlex01CS" to that component's PartialTriggers property.

For more information about setting user interface properties, see Configuring Flexfield-Level User Interface Properties.

### 25.4.1.1 Add Key Flexfield UI Components to a Form or a Table

To incorporate a key flexfield into a UI form or table, you add the master view object to the page as a form or a table, and you drop the key flexfield view object onto the form or table.

Note that when the page creates a new row for the master view object, the value of the primary key of the row that references the key flexfield must be generated automatically, and this value cannot be changed.

**To add a key flexfield UI component to a form or a table:**

1. Create the user interface for the master view object:
   - In the Data Controls panel, select the master view object and drag it onto the page.
2. When prompted, select the type of user interface that you want to create:
   - ADF Form
   - Applications > Panel
   - ADF Table
   - Applications > Table
For an ADF Table, select the **Row Selection** option in the Edit Table Columns dialog.

3. In the Data Controls panel, select the key flexfield view object and drag it onto the page. Drop the flexfield view object onto a form or a table, and select the appropriate flexfield UI component. Figure 25-10 shows a key flexfield being dropped onto a form.

![Key Flexfield Dropped Onto a Form](image)

4. Using either sequence generation or default values, ensure that when the end user adds a row to the page, a valid value is generated for the master view object's primary key before the row is created. Also ensure that the primary key cannot be entered or edited by the user.

   **Caution:**

   You cannot use the code combination ID as part of the generated primary key.

5. If you are creating an editable table, select the table in the Structure window, expand the **Behavior** section of the Property Inspector and set the **EditingMode** attribute. If you want all the rows to be editable, then select **editAll**. If you want to enable the end user to click a row to make it editable, then select **clickToEdit**.

   If you select **clickToEdit**, then the editable row displays the concatenated flexfield segment values in an input text component. The end user can click an icon that is next to the editable flexfield to open a dialog box that has an input field for each segment. The flexfield values in the non-editable rows are displayed as read-only values. The user can click the icon that is next to a read-only flexfield value to open a window that displays the segment labels, values, and descriptions.

25.4.1.2 Ensure Proper Handling of New Rows

When a new row that contains key flexfield columns is added on an application page, every structure instance number (SIN) attribute must contain a valid value, so that the key flexfield user interface can be rendered with appropriate structures. Without default structures in reference mode, end users will not be able to select key
combinations for the new row. Without default structures in secondary mode, users will not be able to select segment values for the new row.

You can prevent application errors by defining a default value for each SIN attribute. Edit the foreign key entity object SIN attribute or the foreign key view object SIN attribute, and do one of the following:

- If the SIN value is static, set the **Value Type** to **Literal**, and specify the static value as the default.
- If the SIN value is dynamic, set the **Value Type** to **Expression**, and enter a Groovy expression to retrieve the appropriate SIN value and set it as the default.

**Note:**

For secondary-usage flexfield segments in table components, you can use the `defaultSIN` attribute in the JSPX file to define the default SIN value for situations where no rows exist.

For an Applications Table component in reference mode, the default SIN and structure for a new or modified row is just a starting point. You can always allow for runtime selection of a new structure by LOV or input field.

**Caution:**

For key flexfield secondary usages, the SIN value of the first row of a user interface table that contains secondary mode columns determines the secondary mode column structure to be used for the table. For any additional row that contains a different SIN value, the secondary mode columns that are not also part of the first row's structure will not render in the table. If there are no rows, then the value of the `defaultSIN` tag attribute from the JSPX file, if set, determines the secondary mode column structure.

For an Applications Table component, if the end user deletes all rows from the table, then your application can again set a new default SIN value for the first new row, and the secondary mode column structure corresponding to that SIN will be the valid structure for the table.

For an ADF Table, the secondary mode column structure (determined by the initial SIN value) cannot be changed after the table has been created, even if all rows are deleted.

For more information about setting attribute defaults, see the discussion about defining default values in the Setting Attribute Properties section of the Developing Fusion Web Applications with Oracle Application Development Framework.

### 25.4.1.3 Ensure Proper Updating of Reference Mode SIN values in an ADF Form or ADF Applications Table

It is best to not display the CCID or, if it is displayed, to make it a read-only field. When the end user clicks the popup icon, the popup requires the user to select a code combination whenever the SIN is changed for a row, and the CCID is set based on the user's selection.
If the CCID is not displayed in the user interface or if it is displayed as a read-only value, then you must ensure that the CCID for the current row in the view object is set to null whenever the SIN is changed by the end user.

If the form does display the CCID in an editable mode, then the application must force the end user to set the CCID to null, change the SIN value, and then enter the CCID value to update the concatenated value.

25.4.1.4 Ensure Proper Updating of Secondary Mode SIN Values in an ADF Form

When an end user makes changes to an existing ADF Form row that contains key flexfield secondary usage attributes, it might result in the need for that row to use a different structure instance. The row’s underlying view object retains the old SIN value, which produces a mismatch with the data and generates runtime errors. Your application must change the SIN value in the row so it uses the new structure instance. You add code to your page to ensure that this happens, as shown in Example 25-7.

Example 25-7   Code for Updating Modified SIN Values

```java
// Add the target for the component that contains
// the key flexfield secondary usage, which, in this case
// is a panelFormLayout component
AdfFacesContext.getCurrentInstance().addPartialTarget(pfl1);

// Get the handle of the child iterator binding. This is the same iterator
// that you get when you drag the key flexfield secondary usage onto a JSPX page
DCIteratorBinding childBinding =
    bindingControl.findIteratorBinding("Kff1PaInstanceIterator");

// Get the view object from the child iterator
ViewObject childVO = childBinding.getViewObject();

// Get the current row from this view object
ViewRowImpl childRow = (ViewRowImpl) childVO.getCurrentRow();

// Update the SIN in the child view object
KFFPViewDefImpl childViewDef = (KFFPViewDefImpl)childRow.getViewDef();
childRow.setAttribute((childViewDef.getStructureInstanceNumberAttribute()).getName(), sinValue);
```

Caution:

You cannot use this solution in an ADF Table or an Applications Table component. Dynamically changing the SIN at runtime is supported only for an ADF Form.

25.4.1.5 Dynamically Refresh Segments on a Code-Combination Maintenance Page or Secondary Usage Segments

If you have segments on a code-combination maintenance page or you have secondary usage segments, and those segments are in an ADF Table that is wrapped in an Applications Table component that is refreshed by another component, such as a button or a search query, then you must add functionality to dynamically refresh the segment columns.

To refresh the flexfield segments based on the current iterator rowset data, create a listener handler method in the flexfield’s backing bean and bind the listener to the
component that is initiating the table refresh. The listener must first call the default
listener and then call
DescriptiveFlexfield.updateFlexColumns(RichTable), where RichTable
is the binding for the table that contains the flexfield.

Example 25-8 shows an example of a custom flexfield handler for a query event. The
method first calls invokeMethodExpression to call the original query listener, and
then calls updateFlexColumns with the table component that contains the flexfield
as the parameter. Example 25-9 shows the binding of the custom flexfield handler to
the query component.

Example 25-8   Flexfield Listener

public void customKffSearchQueryListener(QueryEvent queryEvent)
{
    invokeMethodExpression(
        "#{bindings.KffCriteriaQuery.processQuery}",
        Object.class,QueryEvent.class,queryEvent);
    DescriptiveFlexfield.updateFlexColumns(appTable);
}

Example 25-9   Binding the Flexfield Listener to the Search Query

<af:query id="qryId1"
    headerText="#{applcoreBundle.QUERY_SEARCH_HEADER_TEXT}"
    disclosed="true"
    value="#{bindings.criteriaQuery.queryDescriptor}"
    model="#{bindings.criteriaQuery.queryModel}"
    queryListener="#{backingBeanScope.dffBean.customKffSearchQueryListener}"
    queryOperationListener="#{bindings.KffCriteriaQuery.processQueryOperation}"
    resultComponentId="::AT2:_ATp:ATt2"/>

Note:

You do not need to handle flexfield refreshing for standard Applications Table
create and delete operations. However, custom create and delete operations
must handle the refreshing of flexfields.

25.4.1.6 What Happens When You Add a Key Flexfield to a Page

A key flexfield is implemented in the user interface as a code combination LOV rather
than as individual segments on the page. You can enter a combination code directly
into the code combination LOV input.

Figure 25-11 shows an example of a key flexfield used in a form on an application
page.

Figure 25-11   Example of a Key Flexfield In a Form

<table>

</tbody>
</table>

**Caution:**

When your flexfield is in a table that is displayed within a popup, and the table's *contentDelivery* attribute is set to immediate, you must also set the popup's *contentDelivery* attribute to immediate to ensure that the key flexfield UI component is rendered in the table. For any other value of the popup's *contentDelivery* attribute, the flexfield column in the table will be blank.

For more information about tables and popups, see the "Using Tables, Trees, and Other Collection-Based Components" and "Using Popup Dialogs, Menus, and Windows" chapters of the *Developing Web User Interfaces with Oracle ADF Faces*.

Key flexfield segments always appear as form fields or table columns in the same order that their corresponding attributes appear in the underlying view object.

In screenreader mode, a labeled icon of three horizontal bars appears next to the key flexfield input text field. When the end user clicks the icon, instead of the standard popup, a page is displayed that shows the segment details. The user clicks **Done** to return to the prior page.

For key flexfields in forms and in tables, you can click the search icon to select a valid new flexfield code combination using individual segment values as criteria, as shown in Figure 25-13.
25.4.2 How to Incorporate Key Flexfields into a Query Search Form

In reference mode, you can include key flexfield view object attributes as search criteria in an advanced mode query search form. This form enables end users to define extemporaneously the criteria to search for metadata in the view object for the reference table, which is the product table that has a foreign key reference to the combinations table, and its linked key flexfield view object. Users can select which attributes of the key flexfield view object to use as search criteria.

To incorporate key flexfields into a query search form:

1. Set up the business component model layer.
2. Create the query search form.

25.4.2.1 Set Up the Business Component Model Layer

To set up the business component model layer for the search form, you define the view criteria in the view object for the reference table, generate the row implementation class for the reference view object, and override the getCriteriaItemClause() method in that row implementation class.

For more information about defining view criteria, see the Defining SQL Queries Using View Objects chapter of the Developing Fusion Web Applications with Oracle Application Development Framework.

Before you begin:

1. Create a view link between the view object for the reference table and the key flexfield polymorphic view object as described in How to Create Key Flexfield View Links.
2. Add the key flexfield’s view instance to the product application module as described in How to Add an Instance of a Key Flexfield View Object to the Product Application Module.

3. Nest the key flexfield application module instance in the product application module, as described in How to Nest an Instance of the Key Flexfield Application Module in the Product Application Module.

4. Ensure that the discriminator attribute in the view object for the reference table, such as the SIN attribute, is enabled to display a list of values. You can find this information on the Attributes navigator tab for the view object. Also, ensure that the Auto Submit property for the discriminator attribute is set to true in Control Hints.

For information about enabling a list of values for an attribute and setting control hints, see the Defining SQL Queries Using View Objects chapter of the Developing Fusion Web Applications with Oracle Application Development Framework.

To set up the business component model layer:

1. In the Application Navigator, double-click the view object for the reference table.

2. In the overview editor, click the Query navigation tab.

3. In the View Criteria section, click the Add icon.

4. In the Create View Criteria dialog, enter the name of the view criteria to identify its usage in your application.

5. Click Add Group, and click Add Item.

6. Select the discriminator, such as Sin, from the Attribute dropdown list.

7. Accept the default values of Equal to for the Operator and Literal for the Operand.

8. Select the Group node that you just added, and click Add Item.

9. From the Attribute dropdown list, select the view accessor for the view link between your application’s reference view object and the key flexfield view object.

10. Accept the default Exists value for Operator and Inline View Criteria for Operand.

11. Select the bottom node in the View Criteria tree as shown in Figure 25-14.

Figure 25-14  Bottom Node in View Criteria Tree
12. Select the attribute that corresponds to the discriminator, such as _STRUCTURE_INSTANCE_NUMBER, from the Attribute dropdown list.

13. Accept the default values of Equal to for the Operator and Literal for the Operand.

14. Click OK.

15. Click the Source tab and locate the view criteria that you added in Step 3. Within this view criteria, identify the nested view criteria that contains the <ViewCriteriaItem> element for _STRUCTURE_INSTANCE_NUMBER.

16. In the <CustomProperties> element, add a <Property> element. Set the Property Name to FND_ACFF_IsQueryNestedCriteria and set the Value to true as shown in bold in Example 25-10.

17. Save your changes.

Example 25-10 Property FND_ACFF_IsQueryNestedCriteria in the Nested Criteria

```xml
<ViewCriteria
    Name="AcctKffVONestedCriteria"
    ViewObjectName="oracle.apps.fnd.applcore.crmdemo.flex.acct.view.AcctKffVO"
    Conjunction="AND">
    <ViewCriteriaRow Name="vcrow487" UpperColumns="1">
        <ViewCriteriaItem
            Name="_STRUCTURE_INSTANCE_NUMBER"
            ViewAttribute="_STRUCTURE_INSTANCE_NUMBER"
            Operator="="
            Conjunction="AND"
            Required="Optional"/>
    </ViewCriteriaRow>
    <Properties>
        <CustomProperties>
            <Property Name="FND_ACFF_IsQueryNestedCriteria" Value="true"/>
        </CustomProperties>
    </Properties>
</ViewCriteria>
```

25.4.2.2 Create the Query Search Form

To create a query search form that contains a key flexfield, add an ADF Query Panel with Table component to the page and drop the key flexfield into the table. Then, create a custom bean and attach the bean to the query.

For more information about working with search forms, see the "Creating ADF Databound Search Forms" chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.

Before you begin:

1. Prepare the business model component as described in Setting Up the Business Component Model Layer.

2. If you are working with secondary-usage flexfield segments and the flexfield is an ADF Table that is wrapped in an Applications Table component, review Ensuring Proper Handling of New Rows and Dynamically Refreshing Segments on a Code-Combination Maintenance Page or Secondary Usage Segments.
To create the query search form:

1. Open the JSPX page to which you want to add the search form.

2. From the Data Controls panel, select the reference view object’s data collection and expand the Named Criteria node to display a list of named view criteria.

3. Drag the view criteria that you created in Setting Up the Business Component Model Layer and drop it onto the page or onto the Structure window.

4. From the context menu, choose Query > ADF Query Panel with Table, as shown in Figure 25-15.

Figure 25-15 Query Context Menu

5. If you are working with a secondary (partial) usage or you are working with a maintenance page, perform the following substeps to enable the execution of a saved search when the page is loaded for the first time:

   a. From the Property Inspector for the table in which the flexfield is displayed, obtain the TableId value.

   b. In the Property Inspector for the Query component, set the value of the ResultComponentId property to the TableId value.

6. In the Edit Table Columns dialog, you can rearrange any column and select table options.

7. In the Data Controls panel, select the key flexfield view object, drop it into the table, and choose Create > Oracle Key Flexfield Column to add the key flexfield to the table, as shown in Figure 25-16.
8. In the user interface project, create a custom bean that implements the `oracle.adf.view.rich.event.QueryOperationListener` interface as shown in Example 25-11.

Set `VIEW_CRITERIA_NAME` to the name of the view criteria, and set `KFF_ACCESSOR_NAME` to the view accessor from the view link between the view object for the reference table and the key flexfield view object.

This custom bean will be triggered when a value is selected from the LOV component for the discriminator attribute, such as the LOV for the SIN attribute. When invoked, the `processQueryOperation()` method is called. The `JUFormBinding` that is associated with the view criteria is accessed to extract the view criteria.

The `applyDiscriminator()` method extracts the `ViewCriteriaItem` for the discriminator attribute, gets the value that was selected from the discriminator's LOV component, and loads into the query panel the key flexfield's subtypes with a matching discriminator value.

9. Complete the following steps to attach the custom bean to the query:

   a. Open the JSPX page.

   b. In the Structure window, select `af:query`.

   c. In the Property Inspector, expand the `Behavior` section.

   d. In the `QueryOperationListener` field, enter an EL expression that resolves to the custom bean's `processQueryOperation()` method, such as `#{CustomBean.processQueryOperation}`.

Example 25-11  Custom Listener Java Class

```java
package oracle.apps.fnd.applcore.flex.test.backing;

import java.util.List;
import javax.faces.event.AbortProcessingException;
import oracle.adf.model.BindingContext;
import oracle.adf.model.binding.DCBindingContainer;
import oracle.adf.view.rich.event.QueryOperationEvent;
import oracle.adf.view.rich.event.QueryOperationListener;
import oracle.adf.view.rich.model.AttributeCriterion;
import oracle.adf.view.rich.model.Criterion;
import oracle.adf.view.rich.model.QueryDescriptor;
```
import oracle.jbo.uicli.binding.JUFormBinding;
import oracle.jbo.ViewCriteria;
import oracle.jbo.ViewCriteriaItem;
import oracle.jbo.ViewCriteriaRow;
import oracle.jbo.common.ViewCriteriaItemImpl;
import oracle.jbo.uicli.binding.JUSearchBindingCustomizer;

public class CustomBean implements QueryOperationListener{
    public CustomBean() {
        super();
    }

    private static final String BINDING_SUFFIX="Query";
    private static String VIEW_CRITERIA_NAME="PartsKFFQueryCriteria";
    private static String KFF_ACCESSOR_NAME="PartsAcctKffKffVL";
    private static String KFF_DISCRIMINATOR_ATTR_NAME="_STRUCTURE_INSTANCE_NUMBER";
    private static String MASTER_VO_ATTR_FROM_WHICH_KFF_DISC_DERIVED="Sin";

    public void processQueryOperation(QueryOperationEvent queryOperationEvent)
            throws AbortProcessingException{
        QueryDescriptor descriptor = (QueryDescriptor) queryOperationEvent.getDescriptor();
        AttributeCriterion attr = queryOperationEvent.getAttributeCriterion();
        if (queryOperationEvent.getOperation()==
            QueryOperationEvent.Operation.CRITERION_UPDATE){
            BindingContext bcx= BindingContext.getCurrent();
            DCBindingContainer bc = (DCBindingContainer) bcx.getCurrentBindingsEntry();
            JUFormBinding bnd = (JUFormBinding)
            bc.findExecutableBinding(VIEW_CRITERIA_NAME+BINDING_SUFFIX);
            if(bnd!=null){
                String vcName = JUSearchBindingCustomizer.getCriteriaName(bnd);
                applyDiscriminator(bnd, vcName);
            }
        }
    }

    public void applyDiscriminator(JUFormBinding ctr, String vcName){
        ViewCriteria vc = JUSearchBindingCustomizer.getViewCriteria(ctr, vcName);
        ViewCriteriaRow r = (ViewCriteriaRow) vc.getCurrentRow();
        List<ViewCriteriaItem> criteriaItemList = r.getCriteriaItems();
        Object proxyval = null;
        for(ViewCriteriaItem item : criteriaItemList){
            if (item.getName().equals(MASTER_VO_ATTR_FROM_WHICH_KFF_DISC_DERIVED)){
                proxyval = item.getValue();
            }
            if (item instanceof ViewCriteriaItem){
                ViewCriteriaItemImpl itemimpl = (ViewCriteriaItemImpl) item;
                if(itemimpl.getName().equals(KFF_ACCESSOR_NAME)){
                    ViewCriteria nvc = itemimpl.getNestedViewCriteria();
                    ViewCriteriaRow nvcr = (ViewCriteriaRow) nvcr.getCurrentRow();
                }
            }
        }
    }
}
List<ViewCriteriaItem> ncriteriaItemsList = nvcr.getCriteriaItems();
for(ViewCriteriaItem nitem: ncriteriaItemsList){
    if (nitem.getName().equals(KFF_DISCRIMINATOR_ATTR_NAME))
        nitem.setValue(proxyval);
}

} //if instanceof

} //end for

} //end for

} //end for

25.4.3 How to Configure Key Flexfield UI Components

You can configure various aspects of a key flexfield UI component to customize the behavior of the flexfield as a whole, or on a segment-by-segment basis. You can control your key flexfield’s behavior in the application user interface by modifying properties at the flexfield level, at the segment label level, and at the secondary usage level.

25.4.3.1 Configure Flexfield-Level User Interface Properties

Right-click a key flexfield’s UI component on the page, then select Properties from the context menu to view and modify its properties in the Property Inspector, as shown in Figure 25-17.

Figure 25-17 Key Flexfield Property Inspector — Common Tab

The significant properties on the Common, Data, Style, Behavior, and Other property tabs are listed in Table 25-6.
### Table 25-6  Key Flexfield Properties

<table>
<thead>
<tr>
<th>Tab &gt; Property</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Common &gt; Id</td>
<td>This property gives the ID of the flexfield.</td>
</tr>
<tr>
<td>Common &gt; Rendered</td>
<td>This property indicates whether the flexfield is rendered on the application page. Values can be true (default) or false. When this property is set to false, the flexfield is not sent to the client. Expression language (EL) expressions are allowed on ADF Form and ADF Table components. On ADF Table components, you use expressions to control this property on a row-by-row basis.</td>
</tr>
<tr>
<td>Common &gt; Label</td>
<td>This property is the prompt that should be rendered on the page. It is also used for the title of popup components. Note that if the Label property does not have a value, the default title of a popup component is Key Flexfield. Therefore, you must set this value to the name of the flexfield to ensure that popup components display the correct title, and not the default. The value should be applied from a resource bundle.</td>
</tr>
<tr>
<td>Common &gt; Value</td>
<td>This property is the value of the flexfield. This should be an EL expression pointing to an iterator object. This field is also visible on the Data tab.</td>
</tr>
<tr>
<td>Data &gt; Accessor</td>
<td>This property is the name of the accessor between the (consumer) product view object and the flexfield view object.</td>
</tr>
<tr>
<td>Style &gt; StyleClass</td>
<td>This property is the style class of the flexfield. A style class allows you to group a set of inline styles.</td>
</tr>
<tr>
<td>Style &gt; InlineStyle</td>
<td>This property is the inline style of the component. This is a string of CSS styles that can set individual properties such as background color, font style, or padding.</td>
</tr>
<tr>
<td>Style &gt; Width</td>
<td>This property is the width in characters of the text field in which the key flexfield value is displayed on the page. This value is 30 by default.</td>
</tr>
<tr>
<td>Behavior &gt; Required</td>
<td>This property indicates whether the key flexfield must have a value. Values of this property can be true or false (default). When this property is set to true, the page containing this key flexfield cannot be submitted unless the flexfield has a value. EL expressions are allowed on ADF Form and ADF Table components. On ADF Table components, you use expressions to control this property on a row-by-row basis.</td>
</tr>
</tbody>
</table>
### Table 25-6 (Cont.) Key Flexfield Properties

<table>
<thead>
<tr>
<th>Tab &gt; Property</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Behavior &gt; ReadOnly</td>
<td>This property indicates whether the key flexfield is rendered as read-only. Values can be <code>true</code> or <code>false</code> (default). When this property is set to <code>true</code>, the flexfield segment values are rendered, but they cannot be modified, and the associated popup or LOV lookup controls do not appear. Instead, an icon is displayed. When the mouse hovers over the icon, a window appears that displays the segment labels, values, and descriptions. This behavior overrides the <code>Disabled</code> property. EL expressions are allowed on ADF Form and ADF Table components. On ADF Table components, you use expressions to control this property on a row-by-row basis.</td>
</tr>
<tr>
<td>Behavior &gt; Disabled</td>
<td>This property indicates whether the UI control associated with this key flexfield can be operated. Values can be <code>true</code> or <code>false</code> (default). When this property is set to <code>true</code>, the flexfield segment values and the associated popup or LOV lookup controls are rendered, but are dimmed and cannot be modified or operated. The <code>ReadOnly</code> property, when set to <code>true</code>, takes precedence over this property. EL expressions are allowed on ADF Form and ADF Table components. On ADF Table components, you use expressions to control this property on a row-by-row basis. Note that the flexfield will be disabled if the current master row for the flexfield does not have a valid SIN value defined.</td>
</tr>
<tr>
<td>Behavior &gt; PartialTriggers</td>
<td>This property contains the IDs of the components that should trigger a partial update in the flexfield (<code>String[]</code>). EL expressions are allowed.</td>
</tr>
<tr>
<td>Behavior &gt; ValueChangeListener</td>
<td>This property is a method reference to a value change listener (<code>javax.faces.el.MethodBinding</code>). It requires an EL expression. The value change listener takes effect if the value of the key flexfield is changed either manually in the key flexfield text field, or by using the key flexfield LOV popup.</td>
</tr>
<tr>
<td>Behavior &gt; Binding</td>
<td>This property is an EL reference that will store the component instance on a bean (<code>oracle.apps.fnd.appcore.flex.ui.KFFComp</code>). This property requires an EL expression.</td>
</tr>
</tbody>
</table>
### Table 25-6 (Cont.) Key Flexfield Properties

<table>
<thead>
<tr>
<th>Tab &gt; Property</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Other &gt; <strong>AutoSubmit</strong></td>
<td>This property indicates whether key flexfield values that are entered by the end user should automatically be submitted directly upon entry. Values can be true or false (default). When this property is set to true, and the end user changes the value of the flexfield in the key flexfield text field or by using the key flexfield LOV popup, the new value will be submitted to the product view object immediately. When this property is set to false, the new value will be submitted only when the entire page is submitted.(^1) EL expressions are allowed on ADF Form and ADF Table components. On ADF Table components, you use expressions to control this property on a row-by-row basis.</td>
</tr>
<tr>
<td>Other &gt; <strong>DefaultSIN</strong></td>
<td>This property is for secondary usage only. It defines the default SIN value to use to define the structure when no rows exist.</td>
</tr>
<tr>
<td>Other &gt; <strong>Changed</strong></td>
<td>This property indicates whether the changed indicator icon is displayed on the component. Values can be true or false (default). When this property is set to True, the changed indicator icon is displayed. EL expressions are allowed on ADF Form and ADF Tables. On ADF Table components, you use expressions to control this property on a row-by-row basis.</td>
</tr>
<tr>
<td>Other &gt; <strong>Simple</strong></td>
<td>This property indicates whether the key flexfield's label should be hidden. Values of this property can be true or false (default). When this property is set to true, the label is hidden. Note that if the Simple property is set to true and the flexfield is placed inside a PanelLabelAndMessage component, the flexfield might not align properly with the other components in the PanelLabelAndMessage component. EL expressions are allowed on ADF Form and ADF Table components. On ADF Table components, you use expressions to control this property on a row-by-row basis.</td>
</tr>
<tr>
<td>Other &gt; <strong>Visible</strong></td>
<td>This property indicates whether the key flexfield appears on the page. Values can be true (default) or false. When this property is set to false, the key flexfield is sent to the client but the client does not display it. EL expressions are allowed on ADF Form and ADF Table components. On ADF Table components, you use expressions to control this property on a row-by-row basis.</td>
</tr>
</tbody>
</table>

\(^1\) If you want changes in your key flexfield to trigger a partial update of another component, set the **AutoSubmit UI** property of the flexfield to true, and add the key flexfield ID to the **PartialTriggers UI**
property of the other component. To ensure that the trigger works, you must append "CS" to the key flexfield ID. For example, if you want changes in the `MyKeyFlex01` flexfield to trigger a partial update in another component, add "MyKeyFlex01CS" to that component's `PartialTriggers` property.

**Note:**
The *Behavior > Mode* property defines the user interface mode of the key flexfield component.

Only the single default value is supported, which renders the key flexfield as a single LOV.

### 25.4.3.2 Configure Label-Based Segment UI Properties

Key flexfields support finer control of segments in the user interface based on their segment labels, using several additional properties that you can set in the flexfield XML with literal values or EL expressions. These properties are attributes of the `flexfieldLabeledSegmentHint` component.

**Note:**
This component can be used only to configure the segment UI properties of key flexfield secondary usages, and only if a segment label is applied.

The following properties can be used to define usage-specific behavior for one or more key flexfield segments, identified by segment label. These property settings apply to all segments that have the specified segment label assigned.

- **SegmentLabel**: This string property specifies the segment label of the segment being configured. This string property is required.
- **Rendered**: This boolean property indicates whether the segment is visible on the application page.
- **Required**: This boolean property indicates whether the segment must have a value.
- **Readonly**: This boolean property indicates whether end users can modify the segment.
- **Label**: This string property provides a display label for the UI component.
- **ShortDesc**: This string property provides a short description of the UI component. This text is commonly used by user agents, such as browsers, to display tooltip help text, in which case the behavior for the tooltip is controlled by the user agent.
- **Columns**: This integer specifies the width of the text control, in terms of the number of characters shown. The number of columns is estimated based on the default font size of the browser.
Note:

If you set a segment’s Required property to true in the flexfield metadata, for validation purposes you cannot override this by resetting it to false in the page metadata. You can, however, do the reverse: Change a nonrequired segment to be required in the page metadata.

The Label, ShortDesc and Columns properties are expected to apply to a single segment, so it is best to use them when only one segment has this segment label assigned.

The default values of these properties are derived from the flexfield metadata, but you can override the default values at the page level.

For information about using EL expressions, see the Creating ADF Data Binding EL Expressions section in the Developing Fusion Web Applications with Oracle Application Development Framework.

You apply these properties by dragging and dropping the following component from the Component Palette into the key flexfield, as a child of the keyFlexfieldPartial component:

```html
<fnd:flexfieldLabeledSegmentHint propertyname1="value"
[propertyname2="value" [propertyname3="value"
[propertyname4="value" [propertyname5="value"
[propertyname6="value" [propertyname7="value"]]]]]]>```

### 25.4.3.3 Configure Secondary Usage UI Properties

Key flexfields support finer control of secondary usages in the user interface with several additional properties that you can set with literal values or EL expressions. These properties are attributes of the keyFlexfieldPartial component. By using EL expressions at the page level, you can programmatically override the key flexfield metadata at runtime.

For example, Oracle Assets has a single page that is used for both the Create Asset and Update Asset activities. When creating an asset, the Asset Category key flexfield on this page should be updatable; when updating an asset, the flexfield should be read-only. This setting can be programmatically managed using the readOnly property based on a page parameter that indicates whether the page is in Create mode or Update mode.

The following boolean properties can be used to specify usage-specific behavior for the entire key flexfield secondary usage:

- **rendered**: Indicates whether the flexfield is visible on the application page.
- **required**: Indicates whether the flexfield must have a value.
- **readOnly**: Indicates whether end users can modify the flexfield.

The default values of these properties are derived from the flexfield metadata, but you can override them at the page level.
Note:

If you set a segment’s `required` property to `true` in the flexfield metadata, for validation purposes you cannot override this by resetting it to `false` in the page metadata. You can, however, do the reverse: Change a non-required segment to be required in the page metadata.

For information about using EL expressions, see the "Creating ADF Data Binding EL Expressions" section in the Developing Fusion Web Applications with Oracle Application Development Framework.

You apply these properties by dragging and dropping the following component from the Component Palette into the key flexfield element:

```xml
<fnd:KeyFlexfieldPartial propertyname1="value"
[propertyname2="value" [propertyname3="value"]]>  
```
This chapter discusses the development activities for taking advantage of key flexfield partial usages, code-combination filters, and other advanced features. This chapter includes the following sections:

- Introduction to Advanced Features of Key Flexfields
- Using Key Flexfield Advanced Features in Reference Mode
- Completing the Development Tasks for Key Flexfields in Secondary Mode
- Working with Code-Combination Filters for Key Flexfields

26.1 Introduction to Advanced Features of Key Flexfields

Key Flexfields have advanced features like code combination filters and reference mode. The criteria for filtering the list of code combinations that can be referenced in a given combinations table are known as code combination constraints. Combination constraints are view object properties and are not applied on any entity objects. The type of usage when there is no direct relationship between the product table and the key flexfields combinations table is known as secondary storage.

26.2 Use Key Flexfield Advanced Features in Reference Mode

Key flexfield advanced features include code combination constraints, programmatic access to segment labels, making key flexfields available for use in Oracle Business Intelligence, and working with flexfields from a worksheet using ADF Desktop Integration.

26.2.1 How to Define Code Combination Constraints

Code combination constraints are criteria for filtering the list of code combinations that can be referenced in a given combinations table. While the set of code combinations in the table is not changed, each reference table (product table with foreign key references to these code combinations) can have its own associated code combination constraints.

For example, the key flexfield MTL_SYSTEM_ITEMS has a Purchasable flag, which can be set to the value Y or N. You can implement an extra WHERE clause on the Oracle Purchasing product view object that enables Order Management to restrict the displayed items to only those with Purchasable set to Y.

Code combination constraints are applied in the following situations:
• When an end user opens a key flexfield popup window to search for a code combination.

• When the code-combination ID attribute of a view object for a reference table is set programmatically.

Code combination constraints are not applied when an existing foreign key reference to a code combination is resolved into individual segments (or a concatenated string) for display.

Combination constraints are view object properties and are not applied on any entity objects.

You create a view accessor to define a code combination constraint. You can define the following types of code combination constraints:

• Extra WHERE clause
• Validation date
• Validation rules
• Dynamic combination creation allowed

26.2.1.1 Create a View Accessor to Define a Code Combination Constraint

In a key flexfield ADF Business Components model, the code combination constraints are defined in a view object that references the code combinations (the reference view object). Although these constraints are, in a way, validation rules for code combinations, they are not ADF Business Components validators.

You define code combination constraints as bind parameter values in a view accessor. The name of this view accessor is derived from the name of the view link accessor to the key flexfield view object for which you want to constrain code combinations.

To define a code combination constraint:

1. Open the foreign key view object that references the code combinations.

2. Click the Add icon in the View Accessors section to display the View Accessors dialog.

3. Create a view accessor to the key flexfield’s base view object, as shown in Figure 26-1.
The destination of the view accessor is the key flexfield's base view object. The name of the view accessor must be derived from the name of the view link accessor to the key flexfield view object, and must take the following form:

`viewlinkaccessornameConstraints`

For example, for a view link accessor named `AcctKff`, Figure 26-1 shows the accessor name `AcctKffConstraints`.

4. Edit the view accessor to define the bind parameter values, as shown in Figure 26-2.

**Note:**

You do not need to select any view criteria for this activity. Only the bind parameter values are needed to define a code combination constraint.

If you do not see any bind parameters, it is likely that you have just re-created the business components and overwritten the old ones. You can close the application and remove it from Oracle JDeveloper. When you open the application again, JDeveloper should load the latest definitions, including the bind parameters.
There are four types of code combination constraints. To apply a constraint type, provide a value for the appropriate bind parameter for the constraint type as shown in the following list. If no value is provided, that constraint type is not enabled.

- **Extra WHERE clause**: This constraint is invoked with the bind parameter Bind_ExtraWhereClause. You can also incorporate the predefined bind parameters BindVar0 through BindVar9.
  
  For information about how to provide a value for this bind parameter, see Constraining Code Combinations by an Extra WHERE Clause.

- **Validation date**: This constraint is invoked with the bind parameter Bind_ValidationDate.
  
  For information about how to provide a value for this bind parameter, see Constraining Code Combinations by Validation Date.

- **Value attribute validation rules**: This constraint is invoked with the bind parameter Bind_ValidationRules.
  
  For information about how to provide a value for this bind parameter, see Constraining Code Combinations by Validation Rules.

- **Dynamic combination creation allowed**: This constraint is invoked with the bind parameter Bind_DynamicCombinationCreationAllowed.
  
  For information about how to provide a value for this bind parameter, see Enabling or Disabling Dynamic Combination Creation for a Specific Usage.

Edit only the bind parameters that you need, and leave the others blank. You can use Groovy expressions as bind-parameter values. This means that the constraints can come indirectly from a view attribute, the view object, or a Java method.
Note:
You can ignore the Row-level bind values exist option, because the frequency of evaluation of bind parameters is predetermined, as follows:

- View object level (evaluated once)
  - Bind_ExtraWhereClause
  - Bind_ValidationRules
- Row level (evaluated every time)
  - BindVar0 through BindVar9
  - Bind_ValidationDate
  - Bind_DynamicCombinationCreationAllowed

26.2.1.2 Constrain Code Combinations by an Extra WHERE Clause
You can use the view accessor’s Bind_ExtraWhereClause parameter to filter the list of code combinations that can be referenced in a given combinations table. The extra WHERE clause is appended to the existing WHERE clause of the key flexfield view object.

To set the Bind_ExtraWhereClause parameter:

1. Create the view accessor and open it for editing as described in How to Define Code Combination Constraints.

2. In the Edit View Accessor dialog, set the Bind_ExtraWhereClause value.

   The extra WHERE clause can use bind parameters. The value of Bind_ExtraWhereClause should be a SQL fragment that may contain references to columns of the combinations table, or the predefined bind parameters.

   To refer to the combinations table, use ${COMBINATION_TABLE}; for example, ${COMBINATION_TABLE}.MY_COLUMN.

   To refer to one of the 10 predefined bind parameters, BindVar0 through BindVar9, use a colon and the bind parameter name; for example, :BindVar3.

   The following is an example of an extra WHERE clause code combination constraint as a SQL expression:

   (:BindVar0 IS NULL) OR (${COMBINATION_TABLE}.MY_COLUMN = :BindVar0)

   You can also express this as a Groovy string constant. Be sure to escape the dollar sign with a backslash:

   "(:BindVar0 IS NULL) OR (\${COMBINATION_TABLE}.MY_COLUMN = :BindVar0)"

26.2.1.3 Constrain Code Combinations by Validation Date
You can use the view accessor’s Bind_ValidationDate parameter to filter the list of code combinations that can be referenced in a given combinations table. If you provide a value for Bind_ValidationDate, then this validation date is used instead of the current database date when searching for a code combination. The code combinations returned are those that are active on the specified date.
If a code combination's `start_date_active` attribute is NULL, it is considered to have always been active in the past, up to its `end_date_active` date. If a code combination's `end_date_active` attribute is NULL, it is considered to be active starting from its `start_date_active` date indefinitely into the future.

**Note:**

Note that a date constraint is always required when searching for a code combination. If you do not supply a validation date, the current database date will be used.

---

**To set the Bind_ValidationDate parameter:**

1. Create the view accessor and open it for editing as described in [How to Define Code Combination Constraints](#).

2. In the Edit View Accessor dialog, set the `Bind_ValidationDate` value.

   The value of `Bind_ValidationDate` should be a normalized `java.sql.Date` object; that is, the hour, minute, second, and millisecond should be set to zero. You can use the method `oracle.apps.fnd.applcore.oaext.model.OAUtility#getSQLDate` to normalize the date.

   One way to construct a normalized date for testing purposes is to use `java.sql.Date.valueOf(String s)` with the date as a literal string in the form `yyyyMMdd`. In a search user interface, the supplied validation date also affects the list of values of a segment. For example, the end user may pick a value for a segment from a list of values, then use the segment value to search for a code combination. The list of values of the segment will be constrained by the supplied validation date.

---

### 26.2.1.4 Constrain Code Combinations by Validation Rules

You use validation rules to constrain code combinations. The validation rules for a given key flexfield are authored by the product team that owns the flexfield. They are valid only for use as code combination constraints, and should not be confused with other types of validation rules. Validation rules are stored in the flexfield metadata table `FND_KF_VRULES` and are delivered along with the key flexfield definition. The rule authors are your best source of information about the applicability of the validation rules for a flexfield, and the rule codes you should use to reference them.

You can use the view accessor's `Bind_ValidationRules` parameter to filter the list of code combinations that can be referenced in a given combinations table. If you provide a value for `Bind_ValidationRules`, the validation rules are translated into a SQL fragment, and the SQL fragment is appended to the `WHERE` clause of the key flexfield view object.

**Note:**

Because key flexfield secondary usages do not include a code combination, and validation rule constraints currently apply only to code combinations, they do not apply in the case of key flexfield secondary usages.
26.2.1.4.1 How to Create Validation Rules

Use the `create_vrule(...)` procedure from the `FND_FLEX_KF_SETUP_APIS` PL/SQL package to register a flexfield segment's validation rule. Validation rules apply only to segments that are validated against a list-validated value set. If the segment is validated against a format-only value set, the validation rules are ignored.

Note that when a segment is labeled with multiple segment labels, its validation rules are joined with an `AND` operator in the `WHERE` clause.

When the `ALWAYS_APPLIED_FLAG` is set to `Y`, the validation rule is always applied, such as when a combination is validated by C or PL/SQL validation APIs or a combination is validated by a business component. When the `ALWAYS_APPLIED_FLAG` is set to `N`, the validation rule is applied only when the rule is included in the list of validation rules as an argument to C or PL/SQL validation APIs or as a `Bind_ValidationRules` parameter as described in How to Set the `Bind_ValidationRules` Parameter.

Because the names of the segment columns that the customer will use for the code combinations are not known during development, you must use the lexical references listed in Table 26-1 to refer to the segment column and value attributes in the rule's `WHERE` clause. In addition to the lexical references, the `FLEXFIELD.VALIDATION_DATE` bind variable can be used in validation rule `WHERE` clauses. No other flexfield bind variables can be used.

### Table 26-1 Lexical References

<table>
<thead>
<tr>
<th>Lexical Type</th>
<th>Lexical Code</th>
<th>Example</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>VALUE</td>
<td>VALUE</td>
<td>&amp;{VALUE.VALUE}</td>
<td>Represents the VALUE column in segment lists of values and represents the segment column in combination lists of values.</td>
</tr>
<tr>
<td>VALUE_ATTRIBUTE</td>
<td>value attribute code</td>
<td>&amp;{VALUE_ATTRIBUTE.GL_ACCOUNT _TYPE}</td>
<td>Represents the value table value attribute column in segment lists of values and represents the combination table value attribute column in combination lists of values.</td>
</tr>
</tbody>
</table>

For example, if the following `WHERE` clause were registered as a validation rule for a segment, then the derived SQL query to retrieve the segment's list of values would be similar to Example 26-1, and the derived SQL query to retrieve the combination list of values would be similar to Example 26-2.
Tip:
To learn how to generate documentation about using the FND_FLEX_KF_SETUP_APIS PL/SQL package, see What You May Need to Know About the Key Flexfield Setup API.

Example 26-1  SQL Query to Retrieve Segment’s List of Values

```sql
SELECT ...
FROM fnd_vs_values_vl fvvv
WHERE fvvv.value_set_id = :Bind_ValueSetId
AND fvvv.value like :Bind_Value
AND (GL_AFF_AWC_API_PKG.gl_valid_flex_values(
    :Bind_ValidationDate, fvvv.value) = 'Y'))
```

Example 26-2  SQL Query to Retrieve Combination List of Values

```sql
SELECT ...
FROM gl_code_combinations glcc
WHERE glcc.chart_of_accounts_id = :Bind_SIN
AND ...
AND (GL_AFF_AWC_API_PKG.gl_valid_flex_values(
    :Bind_ValidationDate, glcc.segment5) = 'Y'))
```

26.2.1.4.2 How to Set the Bind_ValidationRules Parameter

Edit the view accessor's Bind_ValidationRules parameter to specify the validation rules to be applied to constrain the code-combination filters.

To set the Bind_ValidationRules parameter:

1. Create the view accessor and open it for editing as described in How to Define Code Combination Constraints.

2. In the Edit View Accessor dialog, set the Bind_ValidationRules value.

   The value of Bind_ValidationRules should be a semicolon-separated list of rule codes; for example:

   ```sql
   VALIDATION_RULE1;VALIDATION_RULE2
   ```

   The validation rules are predefined as part of the key flexfield definition. The supplied list is the list of rules must be applied when searching for a code combination.

   Note the following cautions when constructing this list:

   - The validation rule codes are case-sensitive.
   - Space characters are preserved. For example, "VRULE1; VRULE2" will be parsed into "VRULE1" and " VRULE2" (with a leading space).
   - Unrecognized and unused rules are discarded silently. For example, if you have a validation rule for an optional label, and the label has not been assigned yet in the current flexfield definition, then the rule will be ignored at runtime.
In a search user interface, the supplied validation rules also affect the list of values of a segment. For example, the end user may pick a value for a segment from a list of values, then use the segment value to search for a code combination. The list of values of the segment will be constrained by the supplied validation rules.

26.2.1.5 Enable or Disable Dynamic Combination Creation for a Specific Usage

You can use the `Bind_DynamicCombinationCreationAllowed` parameter to control the runtime entry of new code combinations for a key flexfield usage. This constraint type takes effect only when the key flexfield allows dynamic combination insertion. For more information, see Enabling Dynamic Combination Insertion.

To set the `Bind_DynamicCombinationCreationAllowed` parameter:

1. Create the view accessor and open it for editing as described in How to Define Code Combination Constraints.
2. In the Edit View Accessor dialog, set the `Bind_DynamicCombinationCreationAllowed` value.

   The value of `Bind_DynamicCombinationCreationAllowed` can be TRUE, FALSE, or null.

   By setting this value to TRUE or FALSE, you can control whether your specific usage of the key flexfield allows dynamic insertion even though the key flexfield as a whole is enabled for dynamic insertion. Set the value to TRUE if you want your usage of the key flexfield to allow dynamic insertion. Set the value to FALSE if you do not want your usage of the key flexfield to allow dynamic insertion. Set the value to null to indicate that the key flexfield itself should determine whether dynamic combination insertion is allowed or not.

   If the key flexfield does not allow dynamic combination insertion, this constraint is ignored. `Bind_DynamicCombinationCreationAllowed` is a row-level bind parameter.

26.2.2 How to Access Segment Labels Using the Java API

Segment labels (previously known as key flexfield qualifiers) that have been assigned to segments by customers can be accessed programmatically. The information can be accessed using the flexfield application module or the flexfield view row.

Example 26-3 is an example of Java code that retrieves segment label information from a deployed flexfield using the flexfield application module.

Example 26-4 is an example of Java code that retrieves segment label information from a deployed flexfield using the flexfield view row.

For more information about segment labels, see How to Implement Key Flexfield Segment Labels. For more information about the Java API, see the Javadoc.

Example 26-3 Retrieving Segment Label Information Using the Flexfield Application Module

```java
// First find the flexfield application module:
FlexfieldApplicationModuleImpl flexAM = (FlexfieldApplicationModuleImpl) rootAM.findApplicationModule("Kff1nAM1");

// Find the attributes labeled as "SEGMENT_LABEL_G1" in structure
// "VS_FRM Chr_ON_Chr".
// If you wish to use a structure instance number, you must further
```
// cast the application module into KFFApplicationModuleImpl and call
// getStructureCode(long) to find the code.
// For example,
// KFFApplicationModuleImpl kffAM = (KFFApplicationModuleImpl) flexAM;
// String code = kffAM.getStructureCode(12345);
List<AttributeDef> attrs = flexAM.getLabeledAttributes("VS_FRM_CHR_ON_CHR",
                "SEGMENT_LABEL_G1");
for (AttributeDef attr: attrs)
{
    System.out.println(attr.getName());
    // You can get the segment code through a static method.
    System.out.println(FlexfieldViewDefImpl.getSegmentCode(attr));

    // If you somehow need to construct a WHERE clause using this attribute,
    // this is the identifier you should use.
    System.out.println(attr.getColumnNameForQuery());

    // You can find the "column name" defined in the entity. The column name
    // is typically the database column name.
    System.out.println(attr.getColumnName());
}

Example 26-4    Retrieving Segment Label Information Using the View Row

// This is just for illustration. In a real application, the
// flexfield view row should be retrieved through the view link accessor.
ViewObject vo = rootAM.findViewObject("Kff1nAM1.DefaultFlexViewUsage");
vo.executeQuery();
while (vo.hasNext())
{
    FlexfieldViewRowImpl row = (FlexfieldViewRowImpl) vo.next();
    // Given a KFF view row, you can find the labeled attributes through
    // / the view def. An empty list is returned if the given label is not used
    // in the row.
    List<AttributeDef> labeledAttrs =
        row.getFlexfieldViewDef().getLabeledAttributes("SEGMENT_LABEL_RU1");
    for (AttributeDef attr: labeledAttrs)
    {
        System.out.print(attr.getName() + "=" +
            row.getAttribute(attr.getName()) + ";");
    }
    System.out.println();
}

26.2.3 How to Prepare Key Flexfield Business Components for Oracle Business
Intelligence

Oracle Business Intelligence is a comprehensive collection of enterprise business
intelligence functionality that provides the full range of business intelligence
capabilities including interactive dashboards, full ad hoc, proactive intelligence and
alerts, enterprise and financial reporting, real-time predictive intelligence, and more.

While key flexfields are modeled using polymorphic view objects, flexfield technology
is not compatible with Oracle Business Intelligence, which also requires reference data,
such as lookups, to be modeled as view-linked child view objects. For a key flexfield to
be used by Oracle Business Intelligence, it must be flattened into a usable static form.
To make this possible, you must designate the flexfield as business intelligence-enabled.
When you create business components for this key flexfield, the business
cOMPONENT modeler recognizes the business intelligence-enabled setting, and a view
object that is flattened for business intelligence is generated alongside the standard key flexfield polymorphic view object. You must also slightly modify the process of creating key flexfield view links and application modules.

When the business intelligence-enabled and flattened key flexfield is configured as part of an application, the implementor can select which individual flexfield segments to make available for use with Oracle Business Intelligence. Only the segments that are business-intelligence enabled are included in the flattened view object. Administrators must then import the changes into the Oracle Business Intelligence repository to make them available for Oracle Business Intelligence.

### 26.2.3.1 Enable a Key Flexfield for Oracle Business Intelligence

If you want customers to be able to do business intelligence queries on whatever segments they configure for a flexfield, you must business-intelligence enable the flexfield and its segments. A flattened view object is generated only if the key flexfield is business-intelligence enabled. A segment is included in the flattened view object only if the segment is business-intelligence enabled.

You can set the flexfield’s business intelligence-enabled flag at registration time using the `fnd_flex_kf_setup_apis.create_flexfield(…)` procedure, or you can set the flag later using the `fnd_flex_kf_setup_apis.update_flexfield(…)` procedure. To learn how to generate documentation about using these procedures, see What You May Need to Know About the Key Flexfield Setup API.

You can optionally provide flattened fact names for the flexfield’s entity details. This helps to automate the process for importing the key flexfield into Oracle Business Intelligence. To provide the flattened fact name, set the `BI_FLATTENED_FACT_NAME` value when you register the entity details using the `create_adfbc_usage(…)` procedure. You can also set the flag later using the `update_adfbc_usage(…)` procedure.

Use the Manage Key Flexfields task, which is accessed from the Setup and Maintenance work area of any Oracle Fusion Setup application, to enable the segments for business intelligence. Only the segments that are business-intelligence enabled are included in the flattened view object.

If you want to map the business intelligence-enabled segments to logical dimensions in the Oracle Business Intelligence logical model, use the Manage Key Flexfields task to create segment labels and to map the labels to the logical dimensions. Then assign the labels to the appropriate flexfield segments. By mapping the segments to the dimensions, you minimize the steps for importing the flexfield into Oracle Business Intelligence.

### 26.2.3.2 Produce a Flattened Model for a Business Intelligence-Enabled Key Flexfield

When you create business components for a business intelligence-enabled key flexfield, the business component modeler recognizes the business intelligence-enabled setting, and a view object that is flattened for Oracle Business Intelligence is generated alongside the standard key flexfield polymorphic view object. You must also slightly modify the process of creating key flexfield view links and application modules.

**Before you begin:**

1. Enable the flexfield and the desired segments for Oracle Business Intelligence as described in Enabling a Key Flexfield for.
2. If your flexfield will use hierarchical (tree structured) value sets, create column-flattened versions of the affected view objects and import them into your project before continuing.

If the flattened tree view objects are not in your project, the Create Flexfield Business Components wizard will report the missing view objects as errors.

For more information, see About Designing a Column-Flattened View Object for Oracle Business Intelligence.

To produce a flattened model for a business intelligence-enabled key flexfield:

1. Create key flexfield business components as described in How to Create Key Flexfield Business Components.

When a flexfield is business intelligence-enabled, the Create Flexfield Business Components wizard generates a business intelligence-specific view object and other business components under a directory called `analytics` in the package root directory. These are generated in addition to the typical key flexfield view object. The business intelligence-specific view object is distinguished from the typical key flexfield view object by the "BI:" prefix.

2. Create a view link using the procedure described in How to Create Key Flexfield View Links. Keep the following in mind:

   - The view object that you use for the source view object can be the same source view object that you used for the base key flexfield.
   - Create the view link from the source view object to the business intelligence-specific view object, which is the view object with the "BI:" prefix as shown in Figure 26-3.

   ![Figure 26-3 Create Flexfield View Link Wizard — View Objects Page](image)

3. Create an application module for use with Oracle Business Intelligence, as described in How to Create the Maintenance Application Module. Make the following changes:
a. On the Data Model page of the Create Application Module wizard, when you create an instance of the master view object, there is no need for a child view object.

b. On the Application Modules page of the wizard, add an instance of the key flexfield Oracle Business Intelligence application module as a nested instance of this application module. You can identify the Oracle Business Intelligence application module by the `analytics` subpackage under the package root.

**Note:**
If you already have a product Oracle Business Intelligence application module, you may use it.

4. Define the custom properties required to link the master view object instance to the default view instance.

Do this in the General navigation tab of the nested instance definition of the business intelligence-enabled flexfield application module, as shown in Figure 26-4.

**Figure 26-4  Custom Properties for Business Intelligence-Enabled Application Module**

As you do this, keep the following points in mind:

- The default view instance inside the business intelligence-enabled flexfield application module is typically called `DefaultFlexViewUsage`.
- The custom property names should be formatted as `BI_VIEW_LINK_mypropertyname`.
- The custom property values should be formatted as `source_viewobjectinstance_name, viewlink_definition_name, destination_viewobjectinstance_name`.
- Use the fully qualified view object instance names for the source view object and destination view object, and the fully qualified package name for the view link definition.
• Business intelligence joins between the view object instances you specify in different application modules are created during import from Oracle Application Development Framework (Oracle ADF).

### 26.2.4 How to Publish Key Flexfield Application Modules as Web Services

You can make access to a key flexfield available through web services, which will enable you to perform create, read, update, and delete (CRUD) operations on the flexfield data rows. You accomplish this by exposing a key flexfield application module as a web service and adding support utility methods for the flexfield service data object to the product application module.

When you generate a flexfield business component, the key flexfield business component and other artifacts are developed based on the information in the flexfield metadata. As illustrated in Figure 25-2, a base view object is created for the code combination id (CCID) and structure instance number (SIN) segments. If any contexts have been configured, subtype view objects are generated for each configured context.

As an example, suppose that an application module has the master view object Fkt1 and a view link from the master view object to the detailed key flexfield view object, Global1, which is a polymorphic view object.

The Business Component Browser view shown in Figure 26-5 corresponds to a particular row in the master view object, displaying the segment structure in the key flexfield with a SIN of 11.

**Figure 26-5  Business Component Browser View of Flexfield Row with SIN = 11**

The Business Component Browser view shown in Figure 26-6 corresponds to a different row in the master view object, displaying the segment structure in the key flexfield with a SIN of 25.
To make a key flexfield accessible through a web service:

1. Expose the key flexfield application module as a web service.
2. Test the web service.

26.2.4.1 Expose a Key Flexfield Application Module as a Web Service

You make key flexfield access available through web services by doing the following:

1. Setting a custom property for the flexfield view link.
2. Adding a transient attribute to the master view object to store the concatenated flexfield key.
3. Service-enabling the master view object.
4. Creating the service interface for the product application module within which the key flexfield application module is nested.
5. Adding flexfield service data object support utility methods to the product application module.

**Note:**

In this section, master view object refers to the view object for the reference table as illustrated by Figure 25-1.
Before you begin:

1. Create the master entity object and view object for the product table that references the key flexfield.

2. Create the flexfield business component as described in Building a Read-Only Reference Model.

   **Note:**
   When you generate a flexfield business component, JDeveloper automatically service-enables the business component by generating a Service Data Object (SDO) for the base view object and for every subtype view object.

3. Create a flexfield view link between the master view object and the flexfield business component as described in How to Create Key Flexfield View Links.

4. Nest the key flexfield application module instance in the product application module as described in How to Nest an Instance of the Key Flexfield Application Module in the Product Application Module.

5. Add the key flexfield view object instance to the application module as described in How to Add an Instance of a Key Flexfield View Object to the Product Application Module.

To expose a key flexfield application module as a web service:

1. Complete the following steps to ensure that Service Data Objects (SDOs) exist for all subtype objects.
   a. In the Application Navigator verify that .xsd files exist for all flexfield subtype view objects.
   b. Open the .xsd file for the key flexfield’s base view object and verify that <include> elements exist for all the flexfield subtype view objects.

   **Figure 26-7  The Include Elements for the Flexfield Subtype SDOs**

   c. If any subtype view object SDOs are missing, edit the key flexfield’s base view object, and, on the Java navigation tab, click the Edit Java options icon.
In the Select Java Options dialog shown in Figure 26-8, select Generate Service Data Object Class, ensure that the namespace is the same location that contains the flexfield view object XML files, and click OK.

When the SDO is generated for the base view object of the key flexfield polymorphic view object, generic SDOs are automatically generated for all the base view object subtypes.

**Figure 26-8 Generating the SDO for the Key Flexfield Base View Object**

2. Edit the view link between the master view object and the flexfield view object.

3. Click the General navigation tab in the overview editor, expand the Custom Properties section, and add a SERVICE_PROCESS_CHILDREN property set to true, if one does not already exist.

4. Edit the master view object.

5. In the overview editor, add a transient attribute to store the key flexfield concatenated string.
   a. Click the Attributes navigation tab, and click the Add icon in the Attributes section.
   b. In the View Attribute dialog shown in Figure 26-9, enter a name for the attribute.
c. Set the Java attribute type to **String**.

d. Leave the **Mapped to Column or SQL** checkbox unselected. A transient attribute does not include a SQL expression.

e. Select the **Always** radio button.

f. Leave the **Expression** blank.

g. Click **OK**.

6. Click the **Java** navigation tab and click the **Edit** icon in the **Java Classes** section to generate classes for the master view object.

7. In the Select Java Options dialog shown in **Figure 26-10**, select the following checkboxes and click **OK**:

   - Generate View Object Class
   - Include bind variable accessors
   - Include custom Java data source methods
   - Generate View Row Class
   - Include accessors
   - Generate View Object Definition Class
   - Generate Service Data Object Class
8. In the Java navigation tab, click the link for the View Row Class to open it in the editor.

9. Add the code shown in bold in Example 26-5 to the setter method for the transient attribute that you created. Set the viewAccessorName to the name of the view accessor from the view link between the master view object and the key flexfield view object.

The added code stores the key flexfield concatenated string.

10. Edit the product application module in which the key flexfield application module instance, master view object instance, and flexfield view object instance are nested.

11. Click the Web Service navigation tab and click the Add icon to enable support for the service interface. If the icon is not enabled, click the Edit icon instead and edit the pages that are named in the following steps.

12. In the Service Interface page of the Create Service Interface wizard, the Web Service Name and Target Namespace fields are automatically populated with appropriate values for this application module.

Click Next to continue.

13. In the Service Custom Methods page, select the client methods in the Available list that you want to expose as part of the service interface and move them to the Selected list.
14. Click **Next** to continue.

15. In the Service View Instances page select the view objects in the **Available** list that you want to expose as part of the service interface and move them to the **Selected** list.

16. Highlight each view object on the **Selected** list to display the **Basic Operations** and **View Criteria Find Operations** lists for the operations that are available for that view object, as shown in Figure 26-11.

Select the checkbox for each operation of the view object that you want to expose in the service interface and clear the rest.

**Figure 26-11  Create Service Interface Wizard — Service View Instances Page**

17. Click **Next** to continue.

18. In the Summary page, review your choices and click **Finish** to generate the web service from the application module. You should see that the **Web Service** navigation tab now reflects the custom methods, view instances, basic operations, and view criteria find operations that you chose to expose, as shown in Figure 26-12.
19. Click Finish.

The generated service interface components appear below the application module in the Application Navigator, as shown in Figure 26-13.

Figure 26-13  Application Module Service Interface Structure

20. In the overview editor for the product application module, click the Java navigation tab.

21. If the Application Module Class and the Application Module Definition Class do not appear in the list of Java classes, click the Edit icon and generate the classes.
22. In the Java Classes section, click the link for the Application Module Class.

23. Add the utility methods shown in Example 26-6 to the application module class. These utility methods enable web service clients to obtain FlexfieldSdoSupport objects to access the flexfield's information.

Replace Flexfield with the appropriate string for the flexfield that you are working with. Use a string that describes how the flexfield will be used by the customers. For example, getLedgerSdoNamespaceAndName is better than getGLSubtypeSdoNamespaceAndName.

In the getFlexfieldSdoSupport and getFlexfieldStructureInstanceNumber methods, replace getKffMAM1 with the name of the getter method for the nested maintenance application module instance.

24. In the overview editor for the product application module, click the Web Service navigation tab for the product application module and click the Edit icon in the Service Interface Custom Methods section.

25. In the Service Custom Methods page, move the newly added public methods to the Selected list to make them available for clients and click OK.

The application module's remote server implementation class will be modified to expose these methods.

**Example 26-5  Setter Method for the Transient Attribute**

```java
/**
 * Sets <code>value</code> as the attribute value for the calculated attribute KffConcatSegment
 * @param value value to set the KffConcatSegment
 */
public void setKffConcatSegment(String value) {
    String concatAttrPrefix = FlexfieldProperty.PREFIX;
    String concatAttrPostfix = FlexfieldProperty.CONCATENATED_STORAGE_ATTR_POSTFIX;
    // Modify next line to set viewAccessorName to name of the VL
    String viewAccessorName = "put KFF view link accessor name here";
    String concatAttrName = concatAttrPrefix + viewAccessorName + concatAttrPostfix;
    setAttributeInternal(concatAttrName, value);
    setAttributeInternal(KFFCONCATSEGMENT, value);
}
```

**Example 26-6  Utility Methods for Flexfield Service Data Object Support**

```java
// Change method name as appropriate
public List<String> getFlexfieldSdoNamespaceAndName(
    String structureInstanceCode) {
    FlexfieldSdoSupport ss = getFlexfieldSdoSupport(structureInstanceCode);
    if (ss == null) {
        return null;
    }
    return Arrays.asList(ss.getSdoNamespace(), ss.getSdoName());
}

// Change method name as appropriate
public String getFlexfieldSdoPath() {
    FlexfieldSdoSupport ss = getFlexfieldSdoSupport(null);
    if (ss == null) {
        return null;
    }
    return null;
}
```
```java
return null;
}
return ss.getDiscriminatorSdoPath();
}

// Change method name as appropriate
public List<String> getFlexfieldSegmentSdoPaths(String structureInstanceCode,
                                             List<String> segmentCodes) {
    FlexfieldSdoSupport ss = getFlexfieldSdoSupport(structureInstanceCode);
    if (ss == null) {
        return null;
    }
    ArrayList r = new ArrayList(segmentCodes.size());
    for (String segmentCode : segmentCodes) {
        r.add(ss.getSegmentSdoPath(segmentCode));
    }
    return r;
}

// Change method name as appropriate
private FlexfieldSdoSupport getFlexfieldSdoSupport(String structureInstanceCode) {
    /**
     * @param structureInstanceCode set to null to get the parent (base)
     */
    // Find the nested maintenance application module instance
    KFFMApplicationModuleImpl am;
    // Change getKffMAM1 to name of the getter method for the nested KFF AM
    am = (KFFMApplicationModuleImpl) getKffMAM1();
    return am.getSdoSupport(structureInstanceCode);
}

// Change method name as appropriate
public Long getFlexfieldStructureInstanceNumber(String structureInstanceCode) {
    // Find the maintenance application module instance
    KFFMApplicationModuleImpl am;
    // Change getKffMAM1 to name of the getter method for the nested KFF AM
    am = (KFFMApplicationModuleImpl) getKffMAM1();
    return am.getStructureInstanceNumber(structureInstanceCode);
}
```

### 26.2.4.2 Test the Web Service

You can test the key flexfield web service access by providing web server connection information, deploying and manually testing the web service, and optionally writing Java client programs to call the support utility methods for the flexfield service data object to test the service.

**Before you begin:**

1. Ensure that the BC4J Service Client and BC4J Service Runtime libraries are included in your project.
2. Create a writable maintenance model as described in [Building a Writable Maintenance Model](#).
3. Expose the key flexfield maintenance application module as a web service as described in Exposing a Key Flexfield Application Module as a Web Service.

To test the web service:

1. Expand Application Resources > Descriptors > ADF Meta-INF, and open the connections.xml file.

2. Locate the Reference element for the product application module's service (ApplicationService in this example).

   This is the service that you created in Exposing a Key Flexfield Application Module as a Web Service for the product application module in which the key flexfield maintenance application module instance, master view object instance, and flexfield view object instance are nested.

3. Add the StringRefAddr elements that are shown in bold in Example 26-7. Modify the host and port number in the jndiProviderURL entry to point to an instance of Oracle WebLogic Server. The port number is typically 7101.

4. Run the remote server class for the product application module to deploy the service to an Integrated WebLogic Server instance and to manually test the web service.

   **Note:**
   The remote server class was generated when you exposed the key flexfield as a web service in Exposing a Key Flexfield Application Module as a Web Service. This class has a name that ends with ServiceImpl.java.

5. Optionally, create and run Java client programs to test invoking the web service.

   Example 26-8 is an example of how a client test program would use the support utility methods for the flexfield service data object that you added in Exposing a Key Flexfield Application Module as a Web Service.

**Example 26-7 StringRefAddr Elements to Add to Application Module Reference in connections.xml**

```xml
<Reference name="{http://xmlns.oracle.com/oracle/apps/fnd/appcore/flex/test/kff1/model/}ApplicationService"
   className="oracle.jbo.client.svc.Service" xmlns="">
   <Factory className="oracle.jbo.client.svc.ServiceFactory"/>
   <RefAddresses>
       <StringRefAddr addrType="serviceInterfaceName">
           <Contents>oracle.apps.fnd.appcore.flex.test.kff1.model.ApplicationService</Contents>
       </StringRefAddr>
       <StringRefAddr addrType="serviceEndpointProvider">
           <Contents>ADFBC</Contents>
       </StringRefAddr>
       <StringRefAddr addrType="jndiName">
           <Contents>ApplicationServiceBean#oracle.apps.fnd.appcore.flex.test.kff1.model.ApplicationService</Contents>
       </StringRefAddr>
   </RefAddresses>
</Reference>
```

---

26-24 Oracle Fusion Applications Developer's Guide
Example 26-8  Sample Java Code to Test the Web Service

```java
public void testSDOAPis()
{
    // Flexfield service data objects are created automatically based on the
    // flexfield definition. Certain information such as segment codes must be
    // transformed to be used in a service data object definition.
    AcctKffMaintService acctKffMaintService =
        (AcctKffMaintService)
            ServiceFactory.getServiceProxy(AcctKffMaintService.NAME);
    DataFactory dataFactory =
        ServiceFactory.getDataFactory(acctKffMaintService);

    // Get the namespace and name corresponding to a particular
    // structure instance code.
    List<String> accountSdoInfo =
        acctKffMaintService.getAcctSdoNamespaceAndName("CC_ACCT_LOC_PRJ_SI");
    System.out.println(accountSdoInfo);
    DataObject accountDo =
        dataFactory.create(accountSdoInfo.get(0), accountSdoInfo.get(1));
    System.out.println(accountDo);
    accountDo.set acctKffMaintService.getAcctSDOPath(),
        acctKffMaintService.getAcctStructureInstanceNumber("CC_ACCT_LOC_PRJ_SI");

    // Get segment paths for attributes COST_CENTER and LOCATION.
    List<String> segmentPaths =
        acctKffMaintService.getAcctSegmentSdoPaths("CC_ACCT_LOC_PRJ_SI",
            Arrays.asList("COST_CENTER", "LOCATION");
    System.out.println(segmentPaths);

    //Update COST_CENTER and LOCATION after obtaining their segmentPaths.
    accountDo.set (segmentPaths.get(0), "A12");
    accountDo.set (segmentPaths.get(1), "UK");
}
```
26.2.5 How to Access Key Flexfields from an ADF Desktop Integration Excel Workbook

ADF Desktop Integration makes it possible to combine desktop productivity applications with Oracle Fusion applications, so you can use a program such as Microsoft Excel as an interface to access application data.

Using ADF Desktop Integration, you can incorporate key flexfields into an integrated Excel workbook, so you can work with the flexfield data from within the workbook.

For more general information about integrating Oracle Fusion applications with desktop applications, see the Oracle Fusion Middleware Developing Applications with Oracle ADF Desktop Integration guide. This guide provides most of the information you need to complete the required activities, including the following:

- Preparing your development environment for desktop integration.
- Creating a page definition file that will expose the Oracle ADF bindings for use in Excel.
- Creating an Excel workbook to integrate with the key flexfield.
- Preparing your Excel workbook to access the column containing the flexfield.
- Incorporating a key flexfield as a dynamic or static column in an ADF Desktop Integration Table on a worksheet in the workbook.

**Note:**

The Oracle Fusion Middleware Developing Applications with Oracle ADF Desktop Integration guide does not make explicit reference to technologies documented in this Developer's Guide, and this guide does not repeat the content in the Developing Applications with Oracle ADF Desktop Integration guide. Therefore, you must read the Developing Applications with Oracle ADF Desktop Integration guide for a full understanding of how to use ADF Desktop Integration technology in general.

In addition to the standard implementation steps covered in that guide, you must modify your implementation to accommodate flexfields, as discussed in the following sections.

There are two ways to access a key flexfield in Excel:

- Using a dynamic column in an ADF Desktop Integration Table.
  
  A web page in a popup dialog can be associated with a dynamic column, enabling end users to pick flexfield segment values. Alternatively, users can enter values directly into the segment fields. No custom code is required in either case.

  This is the most typical scenario. Each key flexfield segment is displayed as a distinct column in the ADF Desktop Integration Table. First you configure ADF Desktop Integration with a dynamic column key flexfield, and then, if necessary, you handle user-initiated structure code changes.

- Using a static column in a popup dialog associated with a single cell. Use this approach for either of the following reasons:
  
  - The key flexfield is in a non-table area of the worksheet.
The ADF Desktop Integration Table needs to expose the same key flexfield instance more than once. In this case, only one instance can be dynamic. All other instances should be exposed as static columns.

In addition to using the popup dialog, end users can enter values directly into the segment field, with the values separated by an appropriate delimiter that you specify.

**Note:**

A static column is any column for which the `DynamicColumn` property is set to `False`.

Individual flexfield segments do not appear in the worksheet. Instead, ADF Desktop Integration invokes a separate JSPX page on which the flexfield will be visible. You can use this scenario with an ADF Desktop Integration form, or either table type, by configuring ADF Desktop Integration with a static column key flexfield.

**Note:**

The titles of the popup dialog components must be set to the name of the key flexfield, such as "Account," to be consistent across Oracle Fusion Applications.

The key flexfield’s segments are part of your database table, so the flexfield is generated against the same entity object on which your worksheet view object is based.

In addition to configuring ADF Desktop Integration with the dynamic or static column key flexfield, you might also need to call a custom application module to handle the update or insert of a key flexfield data row.

### 26.2.5.1 Configure ADF Desktop Integration with a Dynamic Column Key Flexfield

When you configure the ADF Desktop Integration Table, make the following changes:

- Add the ADF Desktop Integration Model API library to your data model project.

- In your page definition for the worksheet, add the key flexfield that you want to access to the master worksheet view object as a child node. Do not add any display attribute to the child node, which expands as a dynamic column in the worksheet.

For more information about how to create a page definition file for a desktop integration project, see the *Working with Page Definition Files for an Integrated Excel Workbook* section of the *Developing Applications with Oracle ADF Desktop Integration*.

- To make the key flexfield column of the ADF Desktop Integration Table component dynamic, set the `DynamicColumn` property in the `TableColumn` array of the ADF Desktop Integration Table to `True`. A dynamic column in the `TableColumn` array is a column that is bound to a tree binding or tree node binding whose attribute names are not known at design time. A dynamic column can expand to more than a single worksheet column at runtime.
For more information about the binding syntax for dynamic columns, see the *Adding a Dynamic Column to Your ADF Table Component* section of the *Developing Applications with Oracle ADF Desktop Integration*.

- For the table’s **UpdateComponent** and **InsertComponent** properties, specify one of the following as the subcomponent to use:
  - Inputtext
  - OutputText
  - ModelDrivenColumnComponent
- For the subcomponent’s **Value** property, access the Expression Builder, expand the Bindings node and your tree binding for the table, and select the flexfield node.
- For the subcomponent’s **Label** property, access the Expression Builder, expand the Bindings node and your tree binding for the table, and select the flexfield node.

For information about the Expression Builder, see the *Using the Expression Builder* section in the *Developing Applications with Oracle ADF Desktop Integration*.

### 26.2.5.2 Handling User-Initiated Structure Code Value Changes in a Dynamic Column Key Flexfield

ADF Desktop Integration requires that to use a dynamic column implementation, the structure of the key flexfield should remain constant for all rows in a given result set. However, each time a new result set is downloaded into the table, the structure code value (and thus the structure) can be changed.

If the structure code value is set globally for the end user of the workbook, changes are not an issue. However, if the end user can control the structure code value (for example, using an LOV in a “header” form), your application must be able to respond appropriately to update the key flexfield structure.

After the end user specifies a structure code value, you must invoke the worksheet **UpSync** method to get the new value into the model. Then you can use the ADF Desktop Integration Table **Download** method to get fresh data with the new key flexfield structure.

**Note:**

For an insert-only table, the **Download** method is undesirable. For these cases, use either the ADF Desktop Integration Table **DownloadForInsert** method or the **Initialize** method to enable the ADF Desktop Integration Table component to reconfigure to accommodate the new flexfield structure.

### 26.2.5.3 Configure ADF Desktop Integration with a Static Column Key Flexfield

ADF Desktop Integration supports key flexfields by using tree bindings in an ADF Desktop Integration Table. If you are adding your key flexfield as a static column, you can alternatively use an ADF Read-Only Table. Keep in mind that ADF Read-Only Tables support static columns, but not dynamic columns. Popup dialogs support both types.
Use Key Flexfield Advanced Features in Reference Mode

Note:
A key flexfield appears as a node in the tree binding at design time. Because flexfields are built up dynamically at runtime, you will not see any attributes under the flexfield node in the page definition, but the node itself is present.

When you configure the popup dialog, make the following changes:

- You can use the column’s action set properties to make the key flexfield web page available for editing. You should include the attributes used in the web page in the table’s cached attributes unless the row will be committed immediately.

- You must choose a fixed attribute (the key flexfield CCID) to represent the flexfield in the worksheet. Add a Dialog action to the `DoubleClickActionSet` of an `InputText` or `OutputText` component, then connect the Dialog action to a JSPX page that will display the key flexfield.

For more information about how to create a page definition file for a desktop integration project, see the Working with Page Definition Files for an Integrated Excel Workbook section of the Developing Applications with Oracle ADF Desktop Integration.

For static display of a key flexfield in an ADF Desktop Integration workbook, you must create an updatable transient attribute in the view object on which the ADF Desktop Integration table is based. This transient attribute will hold the concatenated value of the key flexfield segments, separated by a delimiter. If one purpose of the worksheet is to display existing data from the database, the transient attribute should be populated using custom application module methods upon returning from a popup dialog or opening the worksheet.

26.2.5.4 Handle Update or Insert of a Key Flexfield Data Row

To handle updating or inserting a data row containing a key flexfield in an ADF Desktop Integration table, you call a custom application module method that contains appropriate code, as follows:

- To update an existing row, add your code to the `UpdateRowActionId` property of the table.

- To insert a new row, add your code to the `InsertAfterRowActionId` property of the table.

The following examples demonstrate the code needed to accomplish these tasks. Example 26-9 and Example 26-10 apply to an ADF Desktop Integration implementation with the key flexfield exposed as a dynamic column. Example 26-11 and Example 26-12 apply to an ADF Desktop Integration implementation with the key flexfield exposed as a static column.

**Example 26-9   Updating an Existing Row with a Key Flexfield Dynamic Column**

You add this code as an application module method that will be invoked from the `UpdateRowActionId` property of an ADF Desktop Integration Table. This code will be invoked for every row that is updated.

```java
Row tempRow = null;
// Get KFF child row information based on the KFF view link accessor.
KFFViewRowImpl acctRow;
ViewRowImpl kffAcctRow = (KFFViewRowImpl)linerow.getAccountLineKff();

// If it is not child row (for a new row case or cases where
```
// KFF data is not invalid/present for existing DB Row
// get a dummy row from ADF Desktop Integration helper class.

if (kffAcctRow == null) {
    tempRow = ModelHelper.getAdfdiTempChildRow(linerow, "AccountLineKff");
    kffAcctRow = (ViewRowImpl)tempRow;
}

Long kffAcctId = null;
String acctSeg=null;

// Check whether the KFF row is an instance of KFFViewRowImpl,
// which means you are updating valid KFF data.
// If not, it means you are creating new KFF data.
// Based on that, logic of deriving updated segments from worksheet differs.

if (kffAcctRow instanceof KFFViewRowImpl){
    acctRow = (KFFViewRowImpl)fkRow.getAccountLineKff();
    acctSeg = acctRow.getBufferedConcatenatedSegments();
} else {
    acctSeg = KFFViewRowImpl.getConcatenatedSegments(kffAcctRow);
}

kffAcctId = linerow.getKeyFlexfieldCombinationID("AccountLineKff",acctSeg);

// If you need dynamic insert (the creation of new segment combinations)
// from the ADF Desktop Integration worksheet, make sure the end user
// supplied a valid value for at least one segment.

if (kffAcctId==null) {
    // If there was not valid CCID obtained earlier, that means you
    // are trying to add a new combination.

    String delimiter = FlexfieldViewDefImpl.getDelimiter(kffAcctRow.getViewDef());
    List segments =
        FlexfieldViewDefImpl.getFlexfieldAttributes(kffAcctRow.getViewDef());
    StringBuffer delim = new StringBuffer();
    for (int i = 0; i < segments.size() - 1; i++) {
        delim.append(delimiter);
    }

    // If getConcatenatedSegments() returns only delimiter information,
    // that means end user has not supplied valid KFF Segment values.

    if (!acctSeg .equals(delim.toString())) {
        linerow.setKeyFlexfieldCombinationID("AccountLineKff",
            acctSeg);
    }
//Get CCID value based on segment information

kffAcctId =
    linerow.getKeyFlexfieldCombinationID("AccountLineKff", acctSeg );
}
//if kffAcctId is null

//setting CCID column with CCID value

    linerow.setDistCodeCombinationId(kffAcctId);
**Example 26-10  Inserting a New Row with a Key Flexfield Dynamic Column**

Add this code as an application module method that will be invoked from the InsertAfterRowActionId property of an ADF Desktop Integration Table. This code will be invoked for every row that is inserted.

```java
Row tempRow = null;
// Retrieve key flexfield child row information based on
// the KFF view link accessor
ViewRowImpl kffAcctRow = (ViewRowImpl)linerow.getAccountLineKff();

// If not a child row (for new row case or cases where
// KFF data is not invalid/present for existing DB Row),
// get a dummy row from ADF Desktop Integration helper class
if (kffAcctRow == null) {
    tempRow = ModelHelper.getAdfdiTempChildRow(linerow, "AccountLineKff");
    kffAcctRow = (ViewRowImpl)tempRow;
}
Long kffAcctId = null;
kffAcctId =
    linerow.getKeyFlexfieldCombinationID("AccountLineKff",
    KFFViewRowImpl.getConcatenatedSegments(kffAcctRow));

// If you need dynamic insert (creating new segment combinations)
// in the ADF Desktop Integration worksheet,
// make sure the end user supplies a valid value for at least one segment.
if (kffAcctId==null) {
    String delimiter = FlexfieldViewDefImpl.getDelimiter(kffAcctRow.getViewDef());
    List segments =
        FlexfieldViewDefImpl.getFlexfieldAttributes(kffAcctRow.getViewDef());
    StringBuffer delim = new StringBuffer();
    for (int i = 0; i < segments.size() - 1; i++) {
        delim.append(delimiter);
    }
    // If getConcatenatedSegments() return only delimiter information,
    // that means end user has not supplied valid KFF Segment values.
    if
        !KFFViewRowImpl.getConcatenatedSegments(kffAcctRow).equals(delim.toString())){
        linerow.setKeyFlexfieldCombinationID("AccountLineKff",
            KFFViewRowImpl.getConcatenatedSegments(kffAcctRow));
        // Get CCID value based on segment information.
        kffAcctId =
            linerow.getKeyFlexfieldCombinationID("AccountLineKff",
                KFFViewRowImpl.getConcatenatedSegments(kffAcctRow));
    }
}
// Set CCID column with CCID value.
linerow.setDistCodeCombinationId(kffAcctId);
```

**Example 26-11  Updating or Inserting a Row with a Key Flexfield Static Column**

This code should be added to the setter method of the transient attribute in your view object RowImpl.

```java
Example 26-11  Updating or Inserting a Row with a Key Flexfield Static Column
This code should be added to the setter method of the transient attribute in your view object RowImpl.
```
setAttributeInternal(TRANSIENTACCOUNT, value);

// Get KFF child row information based on the KFF view link accessor.

ViewRowImpl kffAcctRow = (ViewRowImpl)linerow.getAccountKff();
Row tempRow;

// If not child row (for new row case or cases where
// KFF data is not invalid/present for existing DB Row),
// Get a dummy row from ADF Desktop Integration helper class
if (kffAcctRow == null) {
    tempRow = ModelHelper.getAdfdiTempChildRow(this, "AccountKff");
    kffAcctRow = (ViewRowImpl)tempRow;
}
Long kffAcctId = null;

// If you need dynamic insert (creating new segment combinations)
// in the ADF Desktop Integration worksheet,
// make sure the end user supplies a valid value for at least one segment.

String delimiter = FlexfieldViewDefImpl.getDelimiter(kffAcctRow.getViewDef());
List segments =
FlexfieldViewDefImpl.getFlexfieldAttributes(kffAcctRow.getViewDef());
StringBuffer delim = new StringBuffer();
for (int i = 0; i < segments.size() - 1; i++) {
    delim.append(delimiter);
}

// If getConcatenatedSegments() returns only delimiter information,
// that means the end user has not supplied a valid segment value.

if (value!=null)
    if (!
        KFFViewRowImpl.getConcatenatedSegments(kffAcctRow).equals(delim.toString()))
        this.setKeyFlexfieldCombinationID("AccountKff",value);

    kffAcctId = this.getKeyFlexfieldCombinationID("AccountKff", value);
    //set your orignal attribute with CCID value.
    this.setAcctsPayCodeCombinationId(kffAcctId);
}

Example 26-12   Applying Modified Segment Values to a Cell in a Key Flexfield Static Column

You add this code as a custom application module method that will be invoked from
the ActionListener property of the OK button in the popup dialog JSPX page.

// Get a reference to your ADF DesktopIntegration table view object.
DesktopQuickInvoicesHeaderVOImpl headerVO =
    this.getDesktopQuickInvoicesHeader();

// Get a reference to the current row, which is the row from which
// popup dialog is opened
DesktopQuickInvoicesHeaderVORowImpl headerRow =
    (DesktopQuickInvoicesHeaderVORowImpl)headerVO.getCurrentRow();

// Get a reference to your key flexfield row
ViewRowImpl kffAcctRow = (ViewRowImpl)headerRow.getAccountKff();
Row tempRow;

// If that is null (for a null CCID or an invalid CCID or a new row),
26.3 Complete the Development Tasks for Key Flexfields in Secondary Mode

The most common use of a key flexfield is for a product table to have a foreign key to the primary key of the combinations table. This provides the flexibility of storing all the combinations in a single table and having references to these combinations from the product tables. However, there are circumstances where application developers might need to capture segment values in a transaction table or a setup table. In this case, the key flexfield becomes a data capturing tool, and the captured data is stored in a product table. There is no direct relationship between the product table and the key flexfields combinations table. This type of usage is called secondary usage.

There are two types of secondary usage:

- Single-segment secondary usage: Use this mode when you want to capture only one segment value in a transaction or setup table. For example, if you want to capture the default cost center value for an employee in the EMPLOYEES table in the DEFAULT_COSTCENTER column.

- All-segment secondary usage: Use this mode when you want to capture all the flexfield's segment values in a transaction or setup table. For example, if you want to capture all the segment values in a general ledger setup table for use in filling in missing values in the subledger account engine.

Note:

To incorporate a key flexfield secondary usage into your application, you must have already defined and registered the key flexfield primary usage on which it is based. See Registering and Defining Key Flexfields Using the Setup APIs, before continuing.

The development tasks for key flexfields in secondary mode consist of the following steps:

1. Complete the registration of a key flexfield secondary usage (all-segments or single-segment).

2. Create key flexfield business components that are based on the secondary usage for use in secondary mode development tasks.

3. Create a view link between your product view object and the secondary mode key flexfield.

4. The remainder of the development process is essentially the same as the consumer development process for key flexfield primary usages. You can skip the section on
creating key flexfield view links and continue with the tasks described in the following sections:

a. How to Nest an Instance of the Key Flexfield Application Module in the Product Application Module

b. How to Add an Instance of a Key Flexfield View Object to the Product Application Module

c. Employing Key Flexfield UI Components on a Page

Note:
This section contains additional information specific to key flexfield secondary usages.

d. How to Configure Key Flexfield UI Components

Note:
This section contains additional information specific to key flexfield secondary usages.

After you have completed the development tasks for secondary usages, you can incorporate the secondary usages in the application user interface as described in Employing Key Flexfield UI Components on a Page.

26.3.1 How to Register a Key Flexfield All-Segment Secondary Usage

All-segment secondary usages have a column in the product table for every segment column in the combinations table.

To register an all-segment secondary usage:

1. Add columns to your product table to represent all of the key flexfield segment columns in the combinations table. The columns that you add must match exactly in number, data type, and size, the corresponding columns in the combinations table.

   Furthermore, the column names must also be the same as in the combinations table, except for an optional prefix.

   For example, if the column names are A1 and A2 in the combinations table, then in the secondary usage they could again be A1 and A2, respectively, or with a prefix they could be X_A1 and X_A2. They cannot be B1 and Y_B2, nor any variation that does not end in the names of the combinations table columns.

2. Use the PL/SQL registration APIs in the FND_FLEX_KF_SETUP_APIS package to register the secondary usage.

   To learn how to generate documentation about using the APIs, see What You May Need to Know About the Key Flexfield Setup API.

3. Create an ADF Business Components usage for the flexfield table usage as described in Registering Entity Details Using the Setup APIs.
To implement a key flexfield secondary usage, you select the usage at design time. For more information, see *How to Create Key Flexfield Business Components*.

If you need to change a table usage after creating it, you must delete the table usage, then re-create it.

### 26.3.2 How to Register a Key Flexfield Single-Segment Secondary Usage

Single-segment secondary usages have one column in the product table to capture a single segment column in the combinations table.

**To register a single-segment secondary usage:**

1. Add the key flexfield segment column that you want to capture to your product table. The table cannot be the combinations table for the flexfield.

2. Define a segment label for the segment that you want to capture.

   The segment label must be defined as *Unique* to ensure that only one segment in a given structure can be associated with this label.

   For more information about segment labels, see *How to Implement Key Flexfield Segment Labels*.

3. Use the PL/SQL registration APIs in the `FND_FLEX_KF_SETUP_API` package to register the secondary usage.

   You must supply the `SEGMENT_LABEL_CODE` value to identify the unique segment label, and the `COLUMN_NAME` value to identify the column in your table in which the segment value will be stored.

   To learn how to generate documentation about using the APIs, see *What You May Need to Know About the Key Flexfield Setup API*.

4. Create an ADF Business Components usage for the flexfield table usage as described in *Registering Entity Details Using the Setup APIs*.

To implement a key flexfield secondary usage, you select the usage at design time. For more information, see *How to Create Key Flexfield Business Components*.

If you need to change a table usage after creating it, you must delete the table usage, then re-create it.

### 26.3.3 How to Create Key Flexfield Business Components for Secondary Usage

Zero or more secondary usages can be defined for a given flexfield, each one potentially on a different product table.

**Before you begin:**

1. One or more required libraries might have not been automatically included in your project. Ensure that all required libraries, notably the BC4J Service Runtime, Java EE 1.5 and Java EE 1.5 API libraries, are included.

2. Using the Create Entity Object wizard, create entity objects for the combinations tables that you have defined. Verify the following:

   - At least one customization class is included in the `adf-config.xml` file.
Note:
This serves to ensure correct application behavior. It does not matter which customization class you include.

For information about customization layers, see the "Understanding Customization Layers" section in the Extensibility Guide for Developers.

- These entity objects are directly modeled on the combinations tables; hence, they contain the fixed (nonflexfield) columns, if any, along with all of the flexfield columns. In general, all columns should be included.
- The entity objects have primary keys defined.
- The CCID column is of type data type `java.lang.Long`.
- The SIN column, if it exists, is of data type `java.lang.Long`.

Caution:
The SIN attribute cannot be transient with a calculated value. It can be based on a database table column, or it can be SQL-derived.

- The `NUMBER` type segment columns are of data type `java.math.BigDecimal`.
- The `VARCHAR2` type segment columns are of data type `java.lang.String`.
- The package name and the object name prefix for each entity object are registered with the flexfield usage to which it will provide data, as described in Registering Entity Details Using the Setup APIs.

3. Build your project to ensure that the entity objects are available in classes. The modeler relies on what is in your classes.

To create key flexfield business components for a secondary usage:

1. In the Application Navigator, right-click the project and choose New.
2. In the New Gallery, expand Business Tier, select ADF Business Components and then Flexfield Business Components, and click OK.
3. On the Flexfield page of the Create Flexfield Business Components wizard, select key from the Type dropdown list as shown in Figure 26-14.
4. In the **Application** field, specify the full name of the application to which your key flexfield belongs.

   You can browse for the name, and filter by **ID**, **Short Name**, or **Name**.

5. In the **Code** field, specify the code of the key flexfield you want to use.

   You can browse for and filter by **Code**.

6. In the **Usage** section, select the table row that contains the desired secondary key flexfield usage. Key flexfield usage can be one of the following types:

   - An all-segment secondary usage of the key flexfield on a product table other than the combinations table. Zero or more all-segment secondary usages can be defined for a given flexfield, each one potentially on a different product table. You can identify all-segment secondary usages by the presence of the prefix (Partial) in the **Description** field.

   - A single-segment secondary usage of the key flexfield on a product table other than the combinations table. Zero or more single-segment secondary usages can be defined for a given flexfield, each one potentially on a different product table. You can identify single-segment secondary usages by the presence of the prefix (Partial Single) in the **Description** field.

   Do not select a flexfield usage without a prefix in the **Description** field. For more information about key flexfield secondary usages, see **How to Register a Key Flexfield All-Segment Secondary Usage**.

7. Click **Next**.

8. On the Path page, select the path of the directory structure in which to create the flexfield business components and click **Next**.

9. On the Entity Object page, select the entity object to use as the data source for the key flexfield **Figure 26-15**.
Because you selected a secondary usage on the Flexfield page, you must select the entity object for the table where that usage is defined.

The entity object you select must include all of the attributes that will be referenced by the flexfield. For secondary usages, this includes attributes that represent the SIN column, the DSN column if it exists in the combinations table, and all of the flexfield segment columns.

**Note:**
If you select a polymorphic entity object, ensure that the InheritPersonalization property for every subtype entity is set to true.

**Caution:**
The Create Flexfield Business Components wizard is case-sensitive. All column names — and the names of the flexfield entity object attributes associated with them — must be uppercase.

---

**Figure 26-15** Create Flexfield Business Components Wizard — Entity Object Page

10. You might wish to select an entity object for which the key flexfield attributes are defined as transient (not based on database table columns). If you need to do this, then select The names of the flexfield attributes match the names of registered columns exactly; do not check the underlying columns.

When a key flexfield entity object attribute is transient, there is no matching underlying column name. When you select this option, the system will match the entity object attribute names to the key flexfield column names, and use the matching attributes to access the flexfield data. Ensure that the entity object has a full set of attributes with matching names before you select this option.
**Caution:**

The transient SIN attribute cannot be a calculated value; it must be SQL-derived (computed using a SQL expression).

This entity object must be registered under the primary usage as described in Registering Entity Details Using the Setup APIs. There is no need to register another table for this purpose, even if the entity object is based on some other table.

**Note:**

If the entity object with transient key flexfield attributes is not based on the primary usage, the transient attributes must be named using the same prefix as the other attributes of that entity object (and the corresponding table columns). For more information, see How to Register a Key Flexfield All-Segment Secondary Usage.

11. Click Next.

12. On the Usage Settings page, select **Mark All Segments Optional** as shown in Figure 26-16 if this secondary usage is simply to add extra information for a product row and the user should not be required to provide information for every segment.

![Figure 26-16 Create Flexfield Business Components Wizard — Usage Settings Page](image)

13. From the **Structure Instance Number** dropdown list, select the entity attribute that corresponds to the key flexfield SIN for the secondary usage. The SIN must be an attribute of type `java.lang.Long`.

If the key flexfield is data set-enabled, this page will also contain a **Data Set Number** dropdown list. From the dropdown list, select the entity attribute that
corresponds to the DSN for the secondary usage. The DSN must be an attribute of type `java.lang.Long`.

**Note:**
Each secondary usage must have its own SIN attribute. If multiple secondary usages must share the same structure instance number, you must create multiple SQL-derived or transient attributes that provide the same structure instance number. Use the entity object Java class to synchronize all SIN attributes if the structure instance number for these usages is not read-only.

**14. Click Next.**

**15. The Naming page displays the entity object's package name and object name that you registered for the usage, as described in Registering Entity Details Using the Setup APIs. Click Next.**

**16. On the Summary page, review your choices and click Finish.**

The business components generated will replace any existing ones that are based on the same flexfield.

**Note:**
This wizard might fail with a "ClassNotFound" exception message. This indicates that one or more required libraries have not been automatically included in your project, notably the BC4J Service Runtime, Java EE 1.5 and Java EE 1.5 API libraries. You can resolve this issue by manually adding any missing libraries; then you can complete this procedure successfully.

**17. Refresh the project to see the newly created flexfield business components in the Application Navigator.**

### 26.3.4 How to Create Key Flexfield View Links for a Secondary Usage

A view link is needed whenever a product view object references your key flexfield. The base view object can have many incoming view links from various product view objects, as a key flexfield is usually shared by many product tables.

**Before you begin:**
You should have already created a master view object for your entity object using the standard wizard.

Ensure that the view object does not include flexfield attributes such as `SEGMENT1VARCHAR2, SEGMENT2NUMBER`, and so on. Ensure that you include the attributes that are needed for the foreign key reference, such as `CCID, SIN`, and, if present, `DSN`. Ensure that the CCID attribute's Display control hint is set to Hide.

**To create a key flexfield view link for a secondary usage:**

1. In the Application Navigator, right-click the project and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Flexfield View Link**, and click **OK**.

3. In the Create Flexfield View Link wizard, on the Name page, provide a package name as shown in **Figure 26-17**.

![Figure 26-17 Create Flexfield View Link Wizard — Name Page](image)

4. Enter a name for the secondary mode view link.

5. Click **Next**. The View Objects page appears, as shown in **Figure 26-18**.

![Figure 26-18 Create Flexfield View Link Wizard — View Objects Page](image)

6. In the **Select Source View Object** tree, select a secondary usage view object.

7. In the **Select Destination Flexfield** tree, expand the available flexfield view objects from your project and select the key flexfield’s base view object.
8. In the **View Link Accessor Name** field, enter an appropriate name for the view link accessor.

9. Click **Next**. The Source Attributes page appears, as shown in Figure 26-19.

![Figure 26-19 Create Flexfield View Link Wizard — Source Attributes Page for Secondary Mode Key Flexfields](image)

This page is informational only. The key attributes of the source view object will be used to define the view link. The primary key attribute should be listed for this selection.

10. Click **Finish** to go to the Summary page.

    **Note:**
    
    You can skip the Properties page because view link-specific properties are not supported.

11. On the Summary page, review the summary, then click **Finish**.

    The secondary mode key flexfield view link is generated.

### 26.4 Work with Code-Combination Filters for Key Flexfields

A code-combination filter for a key flexfield is a set of query criteria that can be applied to a combinations table to specify a subset of code combinations. After you incorporate a code-combination filter into your application, end users can select key flexfield values in the user interface from the subset produced by the filter.

For example, consider the rows that are listed in Table 26-2. Note that not all columns are shown in the table.
Table 26-2  Example Combinations Table

<table>
<thead>
<tr>
<th>SIN</th>
<th>CCID</th>
<th>Summary_Flag</th>
<th>Enabled_Flag</th>
<th>Segment1_Varchar2</th>
<th>Segment2_Varchar2</th>
</tr>
</thead>
<tbody>
<tr>
<td>11</td>
<td>77</td>
<td>N</td>
<td>Y</td>
<td>8.5X12</td>
<td>YEL</td>
</tr>
<tr>
<td>11</td>
<td>78</td>
<td>N</td>
<td>Y</td>
<td>8.5x14</td>
<td>GRN</td>
</tr>
<tr>
<td>14</td>
<td>2</td>
<td>N</td>
<td>Y</td>
<td>ERGO</td>
<td>NYLON</td>
</tr>
<tr>
<td>14</td>
<td>3</td>
<td>N</td>
<td>Y</td>
<td>HGBAK</td>
<td>LEATHER</td>
</tr>
</tbody>
</table>

You could define a filter with the following conditional logic:

\[
\text{SIN}=14 \text{ and Segment1}_\text{Varchar2}='\text{ERGO}'
\]

When you apply this filter condition to the combinations table, the result listed in Table 26-3 is presented. Note that not all columns are shown in the table.

Table 26-3  Example Filter Result

<table>
<thead>
<tr>
<th>SIN</th>
<th>CCID</th>
<th>Summary_Flag</th>
<th>Enabled_Flag</th>
<th>Segment1_Varchar2</th>
<th>Segment2_Varchar2</th>
</tr>
</thead>
<tbody>
<tr>
<td>14</td>
<td>2</td>
<td>N</td>
<td>Y</td>
<td>ERGO</td>
<td>NYLON</td>
</tr>
</tbody>
</table>

Combination filter conditions for key flexfields are stored in a database column of type XMLType. This column is referred to a a filter-condition column.

There are three types of code-combination filters that you can use in your application — standard code-combination filters, code-combination filters for Oracle Business Intelligence Publisher (Oracle BI Publisher) reports, and cross-validation filters.

### 26.4.1 How to Use Standard Combination Filters

With standard code-combination filters, you determine which key flexfields your end users should be able to filter. Then you define a dedicated filter-condition column in your application database for each filter that you want to include in the application user interface. This column can be defined in an existing reference table. You can also create one or more dedicated tables just to store filter-condition columns.

The filter condition is stored in the filter-condition column as XML. At runtime, the filter condition in the XML is converted to a ViewCriteria object and applied to the key flexfield’s base view object so that when the view object is executed, the filter condition is applied and the filtered query results are produced.

In JDeveloper, you prepare business objects based on the table containing the filter-condition column, then you associate a combination filter view object attribute with the key flexfield. You can associate zero, one, or many combination filters with a given key flexfield, but only one flexfield can be addressed by a given filter.

To make the code-combination filter accessible to application implementors or administrators, add a code-combination filter UI component to an application page. Each row contains a different filter definition that can be applied to the associated key flexfield. The implementors or administrators will be responsible for populating the table with filter criteria using a provided utility.
Code-combination filters for key flexfields are supported by the XML schema FndFilter.xsd. This XML schema binds the filter XML that is defined. This schema is registered with the FUSION database schema at the following URI:

http://www.oracle.com/apps/fnd/appcore/filter/FndFilter.xsd

The XML schema is registered to the database as BINARY_XML.

You can test the filter definitions by inserting predefined XML filter criteria into the filter-condition column.

**Note:**

A PL/SQL API is provided so that you can apply filters to your SQL statements as WHERE clause conditions rather than applying them to the user interface. For more information, see How to Apply Code-Combination Filters Using the PL/SQL Filter APIs.

Code-combination filters are removed from an application by removing their accessors.

### 26.4.2 How to Use Code-Combination Filters for Oracle BI Publisher Reports

The Applications Core key flexfield filter repository enables Oracle Fusion Applications developers to include selected key flexfield segments as available parameters in an Oracle BI Publisher report submission user interface. The filter-repository mechanism translates report parameters for those segments into code-combination filter criteria, which are then translated into SQL for inclusion in the report. You accomplish this by first creating a flexfield filter view object for the public entity object FndKfEssFiltersPEO to access a provided common filter repository table, and then by adding to the report submission page a filter UI component that is based on the filter view object.

When the report job is submitted, the flexfield filter XML definition produced by the filter input criteria is saved to the filter repository. Oracle Enterprise Scheduler Service start the reporting job with the report parameters including the filter key. The filter key is passed to the flexfield lexical API, which returns the filter criteria as a SQL WHERE clause, which Oracle BI Publisher integrates into the SQL statement for its report.

To incorporate code-combination filters for Oracle BI Publisher reports into a maintenance user interface, you follow much of the same process as you would to implement standard filters. The code-combination filter procedures that follow note which procedures do not apply to these types of filters.

The kff_filter_purge(...) procedure from the fnd_flex_xml_publisher/apis PL/SQL package enables you to remove unused filters from the filter repository.

### 26.4.3 How to Use Cross-Validation Filters

A cross-validation rule applies a pair of filters to new code combinations that are proposed for a key flexfield by administrators or end users, when you have enabled the rule to work with maintenance mode or dynamic combination insertion.

After enabling cross-validation for a key flexfield at registration time, you must build a maintenance user interface that administrators can use to maintain the
implementation-specific filters that make up each rule. All filter combinations that an administrator defines for a given key flexfield are applied automatically to cross validate new code combinations as they are entered.

**Note:**

Cross-validation rule criteria should generally be created and modified only by application implementors and administrators. For end users, these rules automatically validate new code combinations in the same way that value sets automatically validate new segment values.

To incorporate cross-validation filters, you follow much of the same process as you would to implement standard filters. The code-combination filter procedures that follow note which procedures do not apply to these types of filters.

For more information about implementing cross-validation rules, see How to Implement Cross-Validation Rules and Custom Validation.

### 26.4.4 How to Prepare the Database for Standard Code-Combination Filters

A database column of type `XMLType` is required to store filter data in your database. This column is referred to as the filter-condition column. For standard code-combination filters, you must define a filter-condition column for the filter data in your database before you can associate code-combination filters with key flexfields in your application.

**Note:**

If you are implementing code-combination filters to support cross-validation rules, the required filter-condition columns already exist in the `FND_KF_CROSS_VAL_RULES` repository table. If you are implementing code-combination filters for use in the key flexfield filter repository for Oracle BI Publisher reports, these columns exist in the repository.

To prepare a standard code-combination filter for modeling:

1. Select an existing table to contain your filter, or create a new one.

   To create a table called, for example, `FND_MYFILTER_KFF1`, execute the following script:
   
   ```sql
   Create table FND_MYFILTER_KFF1 (ID Number primary key, Info Varchar2(1000));
   ```

2. Use the following `Alter` script to add a filter-condition column (for example, `Filter`) of type `XMLType` to your table:
   
   ```sql
   Alter table FND_MYFILTER_KFF1 add Filter xmltype
   XMLType column Filter
   Store as BINARY XML
   XMLSCHEMA "http://www.oracle.com/apps/fnd/applcore/flex/kff/FndFilter.xsd"
   ELEMENT "KeyFlexCodeCombinationFilter",
   ```
Note:
Your new filter-condition column must be configured as nullable.
This script is necessary because the Database Schema Deployment framework
does not support the XMLType data type.

26.4.5 How to Add Code-Combination Filters to Your Application

To add code-combination filters to your application, you complete the following tasks:

1. For standard filters only, create an entity object for the table containing the filter-
   condition column.
2. Create a view object for the filter entity object.
3. Associate the code-combination filters with key flexfields.
4. Configure, deploy, and test the code-combination filters.

26.4.5.1 Create a Filter Entity Object for a Standard Filter

For standard filters, you must create a filter-specific entity object for the table
containing the filter-condition column.

Note:
You do not need to create a filter view object if you are implementing one of
the following types of filters:

- If you are implementing code-combination filters for use in the key
  flexfield filter repository for Oracle BI Publisher reports, use the existing
  public entity object
  oracle.apps.fnd.applcore.flex.kff.model.publicEntity.F
  ndEssFiltersPEO, which became available when you added the
  Applications Core library to your data model project.
- If you are implementing code-combination filters to support cross-
  validation rules, use the provided configured entity object:
  oracle.apps.fnd.applcore.flex.kff.model.entity.KeyFlexfieldCrossValidatio
  nRuleEO

Before you begin:

1. Define a database column of XMLType to store the filter as described in How to
   Prepare the Database for Standard Code-Combination Filters.
2. To use code-combination filters, you must first have completed the Create
   Flexfield Business Components wizard for at least one key flexfield, so that your
   project contains one or more key flexfield business components.

To create the filter entity object:
1. Create an entity object (for example, Kff1Fltr1EO) for the table containing your filter-condition column.

2. Open the entity object, and, in the overview editor, click the General navigation tab.

3. Expand the Custom Properties section and add the FND_FILTER property with a value of Y. This property enables the base classes (OAEntityImpl) to recognize that the entity object contains a filter attribute.

4. Because the column type of the filter attribute is XMLType, which is not natively supported by ADF Business Components, you must edit the attribute to make it a transient attribute that is computed using a SQL expression.

   Click the Attributes navigation tab, select the filter attribute, and click the Edit icon to open the Edit Attribute dialog.

5. In the Entity Attribute dialog, click the Entity Attribute node and change the attribute from a persistent type to a calculated type, as shown in Figure 26-20.

   a. Specify the ClobDomain type.

   b. Select Derived from SQL Expression.

   c. Enter an Expression such as the following expression:

      \[ \text{Kff1Fltr1EO.filter.getClobVal()} \]

---

**Note:**

The GetClobVal() method is needed to manage the XMLType column in the database because ADF Business Components currently does not support the XMLType data type natively.
6. Click the Custom Properties node, as shown in Figure 26-21.

7. Add the custom filter properties that are listed in Table 26-4 to the filter attribute.
### Table 26-4  Custom Filter Properties

<table>
<thead>
<tr>
<th>Name</th>
<th>Value</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>FND_FILTER</td>
<td>Y</td>
<td>Indicates that the entity attribute is a filter attribute.</td>
</tr>
<tr>
<td>FND_FILTER_TABLE</td>
<td>table-name</td>
<td>Indicates the name of the underlying table on which this filter attribute is based.</td>
</tr>
<tr>
<td>FND_FILTER_COL</td>
<td>column-name</td>
<td>Indicates the name of the column on which this attribute is based in the filter table. This is needed because the entity object could be based on a database view.</td>
</tr>
<tr>
<td>FND_FILTER_TABLE_COL_PK_n</td>
<td>primary-key-column-id</td>
<td>Indicates the primary key column of the underlying filter table. If the table has a composite primary key (for example: ID1, ID2), you must add an entry for each key. For example: FND_FILTER_TABLE_COL_PK1=ID1 FND_FILTER_TABLE_COL_PK2=ID2</td>
</tr>
<tr>
<td>FND_FILTER_TABLE_ATTR_PK_n</td>
<td>view-object-attribute-name</td>
<td>Indicates the name of the view object attribute that corresponds to the attribute in the entity object that represents the filter table primary key. If the view object has attributes that correspond to multiple entity object primary key attributes, you must add an entry for each key. For example: FND_FILTER_TABLE_ATTR_PK1=I D1 FND_FILTER_TABLE_ATTR_PK2=I D2</td>
</tr>
</tbody>
</table>

26.4.5.2 Create a Filter View Object

You must create a filter view object (for example, Kff1Fltr1VO) for the filter entity object. How you create the view object depends on how you will use the filter:
• If you are implementing a standard code-combination filter, then create the view object for the entity object that you created in Creating a Filter Entity Object for a Standard Filter.

• If you are implementing the filter for use in the key flexfield filter repository for Oracle BI Publisher reports, then create the view object for the public entity object:

  oracle.apps.fnd.applcore.flex.kff.model.publicEntity.FndKfEssFiltersPEO

• If you are implementing the filter to support cross-validation rules, then create the view object for the provided cross-validation entity object:

  oracle.apps.fnd.applcore.flex.kff.model.entity.KeyFlexfieldCrossValidationRuleEO

  In the view object for the cross-validation rules, define view criteria to set the APPLICATION_ID and KEY_FLEXFIELD_CODE attributes to static values for your application and key flexfield.

26.4.5.3 Associate Code-Combination Filters with Key Flexfields

You use the Create Flexfield Filter wizard to create a view accessor from the filter view object's code-combination filter attribute to a key flexfield view object definition.

---

**Note:**

If you are implementing filters to support cross-validation rules, you must complete this procedure twice — once for the condition filter attribute and once for the validation filter attribute.

---

**To associate a code-combination filter with a key flexfield:**

1. In the Application Navigator, right-click the project and choose New.

2. In the New Gallery, expand Business Tier, select ADF Business Components and then Flexfield Filter, and click OK.

3. In the Filter Accessor dialog, expand the available view objects in your current project on the left-hand list and select the view object attribute that corresponds to the XML Filter column as shown in Figure 26-22.
4. Expand the available flexfields in your current project on the right-hand list and select a key flexfield to be filtered.

5. Enter a name for the filter accessor (with no spaces), then click **OK**.

### 26.4.5.4 Configure, Deploy, and Test Code-Combination Filters

The final task is to configure the view object, add it to a new application module for the filter, and test it.

**To configure, deploy, and test a code-combination filter:**

1. Open the filter view object and click the **General** navigation tab.
   
   This property enables the base classes (OAViewRowImpl) to recognize that the view object row contains a filter attribute.

2. Expand the **Custom Properties** section and add the property **FND_FILTER** with the **Value** set to **Y**.

3. Click the **Attributes** navigation tab and select the filter attribute.

4. Expand the **Custom Properties** section and add the property **FND_ACFF_SIN** for the selected filter attribute. Set the **Value** to the structure instance number (SIN).
   
   This property indicates the view object's SIN attribute that is associated with this filter attribute.
5. Create an application module for the filter. In the Data Model page, move the filter view object to the **Data Model** list. In the Application Modules page, move the flexfield application module, which was created when you created the flexfield business component, to the **Selected** list.

**Tip:**
You also can add the flexfield application module from the **Application Module Instances** section in the Data Model navigation tab for the application module.

6. Run the Business Component Browser to ensure that all attributes appear.

### 26.4.6 How to Employ Code-Combination Filters on an Application Page

You must add the filter view accessors that you created to an application page. This procedure applies to conventional key flexfield filters as well as to filters that you are implementing for use in the filter repository.

#### 26.4.6.1 Add Your Key Flexfield Filter to an Application Page

You add a key flexfield filter to an application page by dropping the filter view object onto the page and modifying the XML code for the filter component.

---

**Note:**
This procedure is also used to produce a user interface for defining and maintaining cross-validation rules. Complete the procedure twice — once for the accessor of the condition filter and once for the accessor of the validation filter. Both filters can be exposed on the same page.

---

**Before you begin:**

- Ensure that the Applications Core (ViewController) tag library has been added to the user interface project, as described in [Adding the Applications Core Tag Library to Your User Interface Project](#).

- Create the view object, view accessor, and application module for the code-combination filter as described in [How to Add Code-Combination Filters to Your Application](#).

**To add your key flexfield filter to an application page:**

1. In your project, create a new JSPX page.

2. Drag and drop the view object that contains your filter from the Data Controls panel onto the page as an ADF Form or an ADF Table. **Figure 26-23** shows the filter view object dropped onto the page as a form.
3. Ensure the `CreateInsert` and `Commit` actions are included on the page.

   **Note:**
   These actions enable dynamic creation of new filter definitions at runtime; they also enable you to insert new records into the filter repository.

4. If you dropped the view object onto the page as an ADF Table, select the filter column and, in the Property Inspector, set `Sortable` to `false`.

   **Note:**
   The sorting of filter columns is not supported.

5. If you dropped the view object onto the page as an ADF Form, select the filter component and, in the Property Inspector, enter the name of the flexfield in the `Label` field. This name is used in the title of the filter popup dialog.

6. By default, end users can choose to match on *all* conditions or *any* condition, as shown in Figure 26-24 and Figure 26-25. If you want to restrict the filter to match on all conditions only, add the `RestrictConjunctionToAND` property and set it to `true`, as shown in Example 26-13 and Example 26-14.

   When this property is set to `true`, the Filter dialog box does not display the Match options, as shown in Figure 26-26. All of the conditions for the same segment are joined with an OR operator and then combined with the conditions for other segments using an AND operator, as shown in Example 26-15.
Work with Code-Combination Filters for Key Flexfields

Figure 26-24  Form-Based Code-Combination Filter User Interface

Figure 26-25  Table-Based Code-Combination Filter User Interface

Figure 26-26  Filter Dialog When RestrictConjunctionToAND is Set to true

Example 26-13  Modified Form-Based Filter Code

```
<fnf:keyFlexFilter value="#{bindings.Kff1Fltr1_1Iterator}" accessor="kff1"
     label="#{bindings.Filter.hints.label}" id="kff1"
     restrictConjunctionToAND="true"/>
```
Example 26-14  Modified Table-Based Filter Code

<af:column sortProperty="Filter" sortable="false"
        headerText="#{bindings.Kff1Fltr1_1.hints.Filter.label}"
        id="c2">
  <fnd:keyFlexFilter value="#{bindings.Kff1Fltr1_1Iterator}"
        accessor="kff1" id="kff1"
        restrictConjunctionToAND="true"/>
</af:column>

Example 26-15  Joining of Segments When restrictConjunctionToAND is true

(SEGMENT1 = 'A' or SEGMENT = 'B') AND (SEGMENT2 = 10 OR SEGMENT2 = 20)

26.4.6.2 What Happens When You Add a Filter-Repository Filter to an Application Page

When you add a filter based on the public entity object FndKfEssFiltersPEO to your application page as an ADF Form, the resulting Oracle BI Publisher report submission user interface appears as shown in Figure 26-27.

Figure 26-27  Form-Based Report Submission Code-Combination Filter UI

When you add a filter-repository filter to the application page as an ADF Table, the report submission user interface appears as shown in Figure 26-28.

Figure 26-28  Table-Based Report Submission Code-Combination Filter UI
When you click **CreateInsert**, a new row is added that includes the filter XML and other required input, along with the default values for some of the columns. Your application must provide defaults for the columns as described in **Table 26-5**.

<table>
<thead>
<tr>
<th>Column</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>KeyFlexfieldCode</td>
<td>The code identifying the key flexfield to which this filter will be applicable. This is a read-only value.</td>
</tr>
<tr>
<td>StructureInstanceNumber</td>
<td>This is the SIN, the discriminator attribute for the key flexfield that is used in the key flexfield filter. While creating a new filter definition or submitting a new job, a valid value should be the default for this attribute at the view object level. The SIN is required for capturing the filter XML. This is a read-only attribute.</td>
</tr>
<tr>
<td>DataSetNumber</td>
<td>The data set number (DSN) is a secondary discriminator to the SIN. If the key flexfield is data set-enabled, a valid DSN value should be the default in the filter view object. This is a read-only attribute.</td>
</tr>
<tr>
<td>FilterId</td>
<td>The FilterId is the primary key attribute and is a unique identifier for each filter that is inserted in the filter repository. This value can be generated using a sequence or other methods for generating unique identifiers.</td>
</tr>
<tr>
<td>ApplicationShortName</td>
<td>This is the application short name of the application with which the flexfield filter is associated. You should set the default value to be the application with which your key flexfield is associated. For example, if you are using flexfield KFF1, which is associated with the Application Object Library application, your filter repository should set the default value for <strong>ApplicationShortName</strong> to be <strong>FND</strong>. This is a read-only attribute.</td>
</tr>
<tr>
<td>Filter</td>
<td>This is the XML attribute containing the <em>WHERE</em> condition that is set for a particular FilterId. The <em>WHERE</em> condition has to be populated by using the filter user interface. Depending on the SIN, the filter user interface displays the related segments for a particular key flexfield structure. Various conditions for each of the segments can be applied to generate the <em>WHERE</em> condition.</td>
</tr>
</tbody>
</table>

When you click **Commit**, the new row is inserted in the FND_KF_ESS_FILTERS database table.

### 26.4.7 How to Create Code-Combination Filter Definitions for Testing

For testing, you can use **INSERT** scripts to insert predefined XML filter criteria into the filter-condition column of your product table.

**Note:**

You can insert this data at any time after the filter-condition column has been added to the product table, and before the filter is invoked.
Use the following form to build an INSERT script:

```
Insert into filtercolumnname values(indexnum, 'filterconditionname',
XMLType('filter_xml_code'))
```

The operators supported for code-combination filters are the operators supported in
the Query panel. This includes the following data types and their operators:

- **STRING data type**: EQUALTO, NOTEQUALTO, CONTAINS, DOESNOTCONTAIN,
  LIKE, STARTSWITH, ENDSWITH, ISNULL, ISNOTNULL

- **NUMBER data type**: EQUALTO, NOTEQUALTO, NULL, ISNOTNULL, GREATER_THAN,
  LESS_THAN, GREATERTHANEQUALTO, LESSTHANEQUALTO, BETWEEN,
  NOTBETWEEN

- **DATE data type**: ISNULL, ISNOTNULL

You can also use the following hierarchical operators to query tree structures in your
filter: IS_CHILD_OF, IS_DESCENDANT_OF, IS_LAST_DESCENDANT_OF,
IS_PARENT_OF, IS_ANCESTOR_OF, IS_FIRST_ANCESTOR_OF, IS_SIBLING_OF.

For more information about trees, see Organizing Hierarchical Data with Tree
Structures.

**Example 26-16** shows some example scripts. The first one inserts a filter condition that
selects for `SEGMENT1_VARCHAR2 = 'Value04'`, and the second one selects for the
inequality `SEGMENT1_VARCHAR2 != 'Value02'`.

**Note:**

You might want to test these scripts to ensure that the database is, in fact,
performing schema validation on the XML document, by attempting to insert
XML that does not conform to this schema.

**Example 26-16  Scripts for Inserting Filter Conditions into the Application Database**

Example of EQUALTO filter:

```
Insert into KFF1_FLTR values(
1, 'EqualToFilter',
XMLType('<!-- xml version ="1.0" encoding ="UTF-8" -->
<FndFilter xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
FndFilter.xsd">
<KeyFlexFilter>
/*/keyFlexfieldCode>KFF1</keyFlexfieldCode>
<structureInstanceCode>VS_IND_CHR_ON_CHR</structureInstanceCode>
<applicationShortName>FND</applicationShortName>
<filterCriteriaRow>
<filterCriteriaItem>
<attributeName>_L10</attributeName>
<columnName>SEGMENT1_VARCHAR2</columnName>
<operator>EQUALTO</operator>
<conjunction>AND</conjunction>
<valueDataType>STRING</valueDataType>
<value>Value04</value>
<properties>
<property>
<name>TestProp</name>
<value>ValueProp</value>
```
Example of \texttt{NOTEQUALTO} filter:

\begin{verbatim}
Insert into KFF1_FLTR values(
  2, 'NotEqualToFilter',
  XMLType('<?xml version ="1.0" encoding ="UTF-8"?>
  <FndFilter xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
    FndFilter.xsd">
    <KeyFlexFilter>
      <keyFlexfieldCode>KFF1</keyFlexfieldCode>
      <structureInstanceCode>VS_IND_chr_ON_chr</structureInstanceCode>
      <applicationShortName>FND</applicationShortName>
      <properties>
        <property>
          <name>TestKff</name>
          <value>Valkff</value>
        </property>
      </properties>
    </KeyFlexFilter>
    <filterCriteriaRow>
      <filterCriteriaItem>
        <attributeName>_L10</attributeName>
        <columnName>SEGMENT1_VARCHAR2</columnName>
        <operator>NOTEQUALTO</operator>
        <conjunction>AND</conjunction>
        <valueDataType>STRING</valueDataType>
        <value>Value02</value>
        <properties>
          <property>
            <name>TestItemName</name>
            <value>ValItem</value>
          </property>
        </properties>
      </filterCriteriaItem>
      <conjunction>AND</conjunction>
      <properties>
        <property>
          <name>TestRowName</name>
          <value>ValRow</value>
        </property>
      </properties>
    </filterCriteriaRow>
  </FndFilter>'));
\end{verbatim}

\subsection{26.4.8 How to Apply Code-Combination Filters Using the PL/SQL Filter APIs}

You can take advantage of code-combination filters (including filter-repository filters) without using them in your application user interface. You use the \texttt{WHERE} clause API
for standard and cross-validation combination filters, and you use the XML API for filter repository filters.

### 26.4.8.1 Apply Standard Filters Using the WHERE Clause API

Applications Core provides a PL/SQL API for filtering at the back end. This API takes a filter condition as an input parameter in `XMLType` format, converts it to a SQL `WHERE` clause, and provides the clause as an output parameter for the segments upon which the filter condition has been defined. You use this API to integrate the `WHERE` clause into your SQL statements to include the filter conditions within your SQL scripts.

The PL/SQL combination filter `WHERE` clause API is based on the signature shown in **Example 26-17**.

The bind values are defined as shown in **Example 26-18**.

**Example 26-19, Example 26-20, and Example 26-21** demonstrate how to use the `WHERE` clause API for an `EQUALTO` condition, a `BETWEEN` condition, and multiple conditions.

**Example 26-17  WHERE Clause Signature**

```sql
FND_KF_COMBINATION_FILTER_API.BuildWhereClause(
    filter            IN XMLType,
    tableAlias        IN Varchar2,
    bindPrefix        IN Varchar2,
    sin               OUT Number,
    bindValues        OUT NOCOPY BIND_VAL_TAB,
    filterWhereClause OUT NOCOPY Varchar2);
```

/**
-- This procedure computes the WHERE clause for the filter
-- and provides it in the filterWhereClause parameter
--
-- IN Params
--     filter      XMLType  - Filter to be converted to SQL clause
--     tableAlias  Varchar2 - Alias table name to be used in SQL clause
--     bindPrefix  Varchar2 - Bind Prefix
-- OUT Params
--     sin         Number    - Structure Instance Number
--     bindValues  BIND_VAL_TAB - List of Bind Values
--     filterWhereClause Varchar2 - WHERE clause
--
**************************************************************************/

**Example 26-18  Bind Values Definition**

```sql
create or replace PACKAGE FND_KF_COMBINATION_FILTER_API AS

VARCHAR_TYPE CONSTANT Varchar2(20) := 'VARCHAR';
NUMBER_TYPE CONSTANT Varchar2(20) := 'NUMBER';
DATE_TYPE CONSTANT Varchar2(20) := 'DATE';

TYPE BIND_VALUE IS RECORD(
    NAME            Varchar2(30),
    TYPE            Varchar2(20),
    VALUEVARCHAR2  Varchar2(32767),
    VALUE_NUMBER   Number,
    VALUE_DATE     Date);

TYPE BIND_VAL_TAB IS TABLE OF BIND_VALUE INDEX BY BINARY_INTEGER;
```

Use the Advanced Features of Key Flexfields 26-59
Example 26-19   Using the WHERE Clause API for an EQUALTO Condition

Suppose that a filter condition has been defined in a combinations table as follows:

- Combinations table = FND_KF_TEST_CCT1
- Filter column = SEGMENT1_VARCHAR2
- Filter condition = 123

You would call the filter API as follows:

```java
FND_KF_COMBINATION_FILTER_API.BuildWhereClause(
    filter=>v_filter,
    tableAlias => 'FKFF1',
    bindPrefix => 'BND',
    sin => v_sin,
    bindValues => v_bind,
    filterWhereClause => v_query);
```

Use the `tableAlias` value in WHERE clauses to represent the combinations table name. In this example, `FND_KF_TEST_CCT1.SEGMENT1_VARCHAR2` should be entered as `FKFF1.SEGMENT1_VARCHAR2`.

Similarly, use the `bindPrefix` value as a prefix when referencing individual bind values, for example, `:BND1`, `:BND2`, or `:BND3`.

When invoked, the filter API in this example might produce the following values for its output parameters:

- `filterWhereClause` - `FKFF1.SEGMENT1_VARCHAR2 = :BND1`
- `sin` - 12
- `bindValues` - `bindValues(1).NAME = BND1`
  - `bindValues(1).TYPE = VARCHAR2`
  - `bindValues(1).VALUE_VARCHAR2 = 123`

With this output, you can assemble the following WHERE clause for an EQUALTO filter condition:

```sql
select code_combination_id,
       Segment1_VARCHAR2
from FND_KF_TEST_CCT1 FKFF1
where FKFF1.structure_instance_number=12
  and FKFF1.SEGMENT1_VARCHAR2=123
```

Example 26-20   Using the WHERE Clause API for a BETWEEN Condition

The following shows an example of a BETWEEN operator used as part of a filter expression of the form "attribute BETWEEN value1 AND value2".

```xml
<?xml version ="1.0" encoding ="UTF-8"?>
<KeyFlexCodeCombinationFilter
xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
xsi:noNamespaceSchemaLocation=
"http://www.oracle.com/apps/fnd/applcore/flex/kff/KeyFlexCodeCombinationFilter.xsd">
  <keyFlexfieldCode>KFF1</keyFlexfieldCode>
  <structureInstanceCode>VS_FRM_NUM_ON_CHR</structureInstanceCode>
  <applicationShortName>FND</applicationShortName>
  <filterCriteriaRow>
    <filterCriteriaItem>
```

26-60 Oracle Fusion Applications Developer's Guide
The filter expression captured in the preceding XML resolves to the following:

```
SEGMENT1VARCHAR2 BETWEEN -500 AND 1000
```

You would call the filter API as follows:

```
FND_KF_COMBINATION_FILTER_API.BuildWhereClause(
    filter=>v_filter,
    tableAlias =>'FKFF1',
    bindPrefix =>'BND',
    sin => v_sin,
    bindValues => v_bind,
    filterWhereClause => v_query);
```

When invoked, the filter API in this example might produce the following values for its output parameters:

```
filterWhereClause - FKFF1.SEGMENT1VARCHAR2 = :BND1
sin - 12
bindValues - bindValues(1).NAME = BND1
- bindValues(1).TYPE = VARCHAR2
- bindValues(1).VALUEVARCHAR2 = -500
- bindValues(2).NAME = BND2
- bindValues(2).TYPE = VARCHAR2
- bindValues(2).VALUEVARCHAR2 = 1000
```

With this output, you can assemble the following WHERE clause for a BETWEEN filter condition:

```
select code_combination_id,
    Segment1VARCHAR2
from FND_KF_TEST_CCT1 FKFF1
where FKFF1.structure_instance_number=12
and FKFF1.SEGMENT1VARCHAR2 BETWEEN -500 AND 1000
```

### Example 26-21 Using the WHERE Clause API for Multiple Conditions

The following shows an example of multiple operators used as part of a filter expression of the form "attribute1 EQUALTO value1 AND attribute2 EQUALTO value2."

```xml
<?xml version ="1.0" encoding ="UTF-8"?>
<KeyFlexCodeCombinationFilter
xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
KeyFlexCodeCombinationFilter.xsd">
    <keyFlexfieldCode>KFF1</keyFlexfieldCode>
    <structureInstanceCode>VS_FRM_NUM_ON_CHR</structureInstanceCode>
    <applicationShortName>FND</applicationShortName>
</KeyFlexCodeCombinationFilter>
```
The filter expression captured in the preceding XML resolves to the following:

SEGMENT1_VARCHAR2 = 123456 and SEGMENT2_VARCHAR2 = 123.45

You would call the filter API as follows:

```java
FND_KF_COMBINATION_FILTER_API.BuildWhereClause(
    filter=>v_filter,
    tableAlias => 'FKFF1',
    bindPrefix => 'BND',
    sin => v_sin,
    bindValues => v_bind,
    filterWhereClause => v_query);
```

When invoked, the filter API in this example might produce the following values for its output parameters:

- `filterWhereClause`:
  - FKFF1.SEGMENT1_VARCHAR2 = :BND1
  - FKFF1.SEGMENT2_VARCHAR2 = :BND2
- `sin`:
  - 12
- `bindValues`:
  - bindValues(1).NAME = BND1
  - bindValues(1).TYPE = VARCHAR2
  - bindValues(1).VALUE_VARCHAR2 = 123456
  - bindValues(2).NAME = BND2
  - bindValues(2).TYPE = VARCHAR2
  - bindValues(2).VALUE_VARCHAR2 = 123.45

With this output, you can assemble the following `WHERE` clause for a BETWEEN filter condition:

```sql
select code_combination_id,
       Segment1_VARCHAR2, Segment2_VARCHAR2
from FND_KF_TEST_CCT1 FKFF1
where FKFF1.structure_instance_number=12
  and FKFF1.SEGMENT1_VARCHAR2 = 123456
  and FKFF1.SEGMENT2_VARCHAR2 = 123.45
```
26.4.8.2 Apply Repository Filters for Oracle Enterprise Scheduler Service

The `kff_filter` PL/SQL procedure in the `fnd_flex_xml_publisher_apis.pkb` package is the public procedure for processing key flexfield repository filter lexicals. The signature is shown in Example 26-22.

Example 26-23 demonstrates how to use this API to obtain the `WHERE` clause and bind variable information for a filter in the filter repository.

**Example 26-22  `kff_filter` Signature**

```sql
/* PUBLIC PROCEDURE kff_filter EXPOSED FOR THIS PACKAGE */

PROCEDURE kff_filter
(p_lexical_name                 IN VARCHAR2,
 p_application_short_name       IN fnd_application.application_short_name%TYPE,
 p_key_flexfield_code           IN fnd_kf_flexfields_b.key_flexfield_code%TYPE,
 p_filter_id                    IN NUMBER,
 p_code_combination_table_alias IN VARCHAR2,
 x_where_expression             OUT nocopy VARCHAR2,
 x_numof_bind_variables         OUT nocopy NUMBER,
 x_bind_variables               OUT nocopy bind_variables);
```

**Example 26-23  Using the Filter Repository API**

```sql
REM dbdrv: none
SET SERVEROUTPUT ON
WHENEVER SQLERROR CONTINUE
DECLARE
  l_tableAlias VARCHAR2(30);
  l_applicationShortName fnd_application.application_short_name%TYPE;
  l_keyFlexfieldCode fnd_kf_flexfields_b.key_flexfield_code%TYPE;
  l_filterWhereClause         VARCHAR2(32767);
  l_filterId                  NUMBER;
  l_filterName                VARCHAR2(32);
  l_bindVariables fnd_flex_xml_publisher_apis.bind_variables;
  l_numOfBindVariables NUMBER;
CURSOR c_filter_id
IS
  SELECT filter_id FROM fnd_kf_ess_filters;
BEGIN
  l_filterName           := 'DefaultFilter';
  l_tableAlias           := 'DefaultTable';
  l_keyFlexfieldCode     := 'KFF1';
  l_applicationShortName := 'FND';
  DBMS_OUTPUT.PUT_LINE('kff_filter');
  FOR filter_id IN c_filter_id
    LOOP
    fnd_flex_xml_publisher_apis.kff_filter(p_lexical_name=>l_filterName,
                                         p_application_short_name=>l_applicationShortName,
                                         p_key_flexfield_code=>l_keyFlexfieldCode,
                                         p_filter_id=>filter_id.filter_id,
                                         p_code_combination_table_alias=>l_tableAlias,
                                         x_where_expression=>l_filterWhereClause,
                                         x_numof_bind_variables=>l_numOfBindVariables,
                                         x_bind_variables=>l_bindVariables);
    DBMS_OUTPUT.PUT_LINE('filter Id: ' || filter_id.filter_id);
    DBMS_OUTPUT.PUT_LINE('filter Where Clause: ' || l_filterWhereClause);
  END LOOP;
END;
```

Use the Advanced Features of Key Flexfields 26-63
26.4.9 How to Use an API to Apply XML Filters

Currently the only way data can be inserted into our Filter columns is through our Filter APIs. However some of the teams who have to insert thousands of the CVR rules are finding it a bit time consuming.

You can use a filter API to take in a list of conditions and generate filter XML to be inserted into the flexfield filter columns. The code that calls the API must pass some basic information about the key flexfield for which the Filter XML is to be generated. This information is required to correctly identify the subtype flexfield view object, which is then used to get the list of attributes.

Use the FlexFilterCriteriaItemBean class to pass the list of conditions for which the filter XML must be generated. FlexFilterCriteriaItemBean includes three attributes which are used to construct individual filter criteria.

This API is useful when having to process large amounts of data.

The following sample shows the API signature for FlexFilterCriteriaItemBean.

The following sample illustrates the use of the FlexFilterCriteriaItemBean class.

The code shown in the previous sample generates XML which produces the following condition:

\[ (_{L10}= 1 \text{ OR } _{L10} \text{ BETWEEN } 50 \text{ and } 100) \text{ AND } (_{L10}.\text{NUMONLY} \text{ BETWEEN } 2 \text{ and } 40) \text{ AND } (_{L10}.\text{ZEROFILL IS DESCENDENT OF 199}) \]

**Example 26-24  API Signature for FlexFilterCriteriaItemBean**

```java
/**
 * Creates FilterXML from a given set of conditions passed in the form of a list
 * of FilterCriteriaItem.
 * @param kffVO is the key flexfield base view object.
 * @param criteriaItems is the list of conditions which is to be converted to
 * @filter XML.
 * @param sin SIN of the subtype FlexVO for which the XML is being generated
 * @param dsn DSN if it exists. Else pass null.
 * @return Filter XML when all the arguments are valid.
 * @exception JboException
 * @exception IllegalArgumentException
 */
public static ClobDomain createFilterXML(KFFViewObjectImpl kffVO,
                                          List<KeyFlexFilterCriteriaItem> criteriaItems,
                                          Long sin, Long dsn)
```

```java
/**
 * Data Structure used to capture individual an FilterCriteriaItem.
 * This data structure can be used in the following ways to populate various
 * conditions.
 * KeyFlexFilterCriteriaItem item1 = new KeyFlexFilterCriteriaItem();
 * item1.setSegmentCode("L10");
 * item1.setOperator("=");
 * String[] values = {"1"};
 * item1.setValues(values);
 * This is equivalent to - 'ColumnName(L10) = 1'
 */
```

Work with Code-Combination Filters for Key Flexfields
KeyFlexFilterCriteriaItem item2 = new KeyFlexFilterCriteriaItem();
item2.setSegmentCode("L10_NUMONLY");
item2.setOperator("BETWEEN");
String[] values2 = {"99", "199"};
item2.setValues(values2);
This is equivalent to - 'ColumnName(L10_NUMONLY) BETWEEN 99 and 199'

KeyFlexFilterCriteriaItem item3 = new KeyFlexFilterCriteriaItem();
item3.setSegmentCode("L10_ZEROFILL");
item3.setOperator("IS_DESCENDENT_OF");
String[] values3 = {"199"};
item3.setValues(values3);
This is equivalent to - ' ColumnName(L10_ZEROFILL) IS_DESCENDENT_OF 199'

Rules to follow while creating the KeyFlexFilterCriteriaItems:
* For operators 'ISBLANK' and 'ISNOTBLANK' variable 'values' should be null.
* For operators 'BETWEEN' and 'NOTBETWEEN' variable 'values' should have 2 values.
* For other operators, variable 'values' should have only 1 value.
* This class will not validate any of the inputs. Passing the list of KeyFlexFilterCriteriaItem to createFilterXML results in an IllegalArgumentException if the rules are not followed.
* The 'conjunction' variable is used while grouping together the same 'segmentCode'.
* Always use AND for different 'segmentCode' items.
* Always use OR for the same 'segmentCode' items.

public class KeyFlexFilterCriteriaItem
{
    private String segmentCode;
    private String operator;
    private String[] values;
}

Example 26-25  Using FlexFilterCriteriaItemBean

Kff1Ref1AMImpl flexAM =
    (Kff1Ref1AMImpl)
OAUtility.createRootApplicationModule("oracle.apps.fnd.applcore.flex.test.model.applicationModule.Kff1Ref1AM", "Kff1Ref1AMLocal");
KFFViewObjectImpl kffVO = (KFFViewObjectImpl)
(flexAM.findViewObject("Kff1Instance"));

ArrayList<KeyFlexFilterCriteriaItem> r =
    new ArrayList<KeyFlexFilterCriteriaItem>(){
    KeyFlexFilterCriteriaItem item1 = new KeyFlexFilterCriteriaItem();
    item1.setSegmentCode("L10");
    item1.setOperator("=");
    item1.setValues("1");
    r.add(item1);
    KeyFlexFilterCriteriaItem item3 = new KeyFlexFilterCriteriaItem();
    item3.setSegmentCode("L10_NUMONLY");
    item3.setOperator("BETWEEN");
item3.setValues("50", "100");
r.add(item3);
KeyFlexFilterCriteriaItem item2 = new KeyFlexFilterCriteriaItem();
item2.setSegmentCode("L10");
item2.setOperator("BETWEEN");
item2.setValues("2", "40");
r.add(item2);
KeyFlexFilterCriteriaItem item4 = new KeyFlexFilterCriteriaItem();
item4.setSegmentCode("L10_ZEROFILL");
item4.setOperator("IS_DESCENDENT_OF");
item4.setValues("199");
r.add(item4);

ClobDomain filterClob = FilterManager.createFilterXML(kffVO,r,5L, null);

26.4.10 How to Remove Code-Combination Filters from Your Application

To remove a code-combination filter, you remove the accessor that was previously created to associate the filter with a particular key flexfield.

In your project, right-click the view object that contains the filter and select Remove Flexfield Filters from the menu.

If the filter view object has more than one filter attribute with an accessor defined, then you will be presented with a list of those filter accessors. Select the one that you want to remove.

26.4.11 How to Remove Filters from the Filter Repository

The filter XML is stored in the FND_KF_ESS_FILTERS table. The number of rows in a filter repository can become large. You use the kff_filter_purge(...) procedure from the fnd_flex_xml_publisher_apis PL/SQL package to purge unused filters from the filter repository. This procedure takes the filter’s ID, as shown in Example 26-26.

Example 26-26   Removing a Filter from the Filter Repository

DBMS_OUTPUT.PUT_LINE('kff_filter_purge to delete a valid filter');
l_filterId := 1001;
--valid filter id
fnd_flex_xml_publisher_apis.kff_filter_purge(p_filter_id=>l_filterId);
DBMS_OUTPUT.PUT_LINE('Filter Id: ' || l_filterId);
DBMS_OUTPUT.PUT_LINE('VALID FILTER_ID DELETED SUCCESSFULLY');
This chapter discusses how to configure flexfields with test segments, how to test your flexfield business components in Oracle Fusion applications using Integrated WebLogic Server, how to deploy a flexfield application to a Standalone Oracle WebLogic Server Environment, how to deploy flexfields, how to regenerate flexfield business components programmatically, and how to make flexfield setup task flows accessible from Oracle Fusion Functional Setup Manager.

This chapter includes the following sections:

- Introduction to Testing and Deploying Flexfields
- Deploying and Running the Flexfield Configuration User Interface
- Configuring Flexfields
- Testing Flexfields
- Deploying Flexfields in a Standalone WebLogic Server Environment
- Using the WLST Flexfield Commands to Deploy Flexfields
- Regenerating Flexfield Business Components Programmatically
- Integrating Flexfield Task Flows into
- Exporting Flexfield Business Components

27.1 Introduction to Testing and Deploying Flexfields

After you create a flexfield and verify that the pages on which you added the flexfield run without errors, you will want to test the flexfield. You can test the flexfield in one of three ways:

- Using the Run with Flexfields dialog or the Debug with Flexfields dialog from Oracle JDeveloper as described in Testing Flexfields from Oracle JDeveloper.
- Using an Integrated WebLogic Server instance as described in Testing Flexfields from Integrated WebLogic Server.
- Deploying your application to a standalone Oracle WebLogic Server instance as described in Deploying Flexfields in a Standalone WebLogic Server Environment. With this method, you can do end-to-end testing. That is, you can configure a flexfield, deploy it, and view the pages that contain the flexfield.

If you want to test a flexfield from JDeveloper or an Integrated WebLogic Server instance and the flexfield does not have any segments configured, you must first configure it as described in Configuring Flexfields so that it will appear in its pages.
Note:

If you do not have access to an application that provides the manage flexfield tasks, deploy and run a UI that provides access as described in Deploying and Running the Flexfield Configuration User Interface.

An alternative method for deploying flexfield configurations is to use Oracle WebLogic Scripting Tool (WLST) commands as described in Using the WLST Flexfield Commands to Deploy Flexfields.

In addition to using the Create Flexfield Business Components wizard to generate flexfield business components, you can create a Java program to invoke the flexfield business component modeler and thus automate the creation of the business components as described in Regenerating Flexfield Business Components Programmatically.

Integrating Flexfield Task Flows into describes the available flexfield tasks flows for integration into Oracle Fusion Functional Setup Manager.

27.2 Deploy and Run the Flexfield Configuration User Interface

To test a flexfield, the flexfield must have configured segments so that the flexfield appears in the application user interface (UI). If you need to configure a flexfield for testing from Integrated WebLogic Server, you can deploy the Applications Core (ApplCore) Setup application to an Integrated WebLogic Server instance, and then use one of the manage flexfield tasks in that application to configure the flexfield.

After you access the manage flexfield tasks, configure the flexfield as described in Configuring Flexfields.

27.2.1 How to Deploy and Run the ApplCore Setup Application to Integrated WebLogic Server

Use the fndSetup.ear file to deploy the ApplCore Setup application to an Integrated WebLogic Server instance.

Note:

You can use this deployed application to configure flexfields but you cannot use it to deploy the configurations. However, as you will generate the flexfield business components using the Tester role as described in Testing Flexfields from Integrated WebLogic Server, you do not need to deploy the configurations.

Before you begin:

- Although you will not deploy the configurations to an MDS repository, you must provide the name of a valid MDS repository and JNDI data source in the Applcore Setup application's adf-config.xml file. For information about MDS repositories, see the “Managing the Metadata Repository” chapter in the Administering Oracle Fusion Middleware.

- If you have not started an Integrated WebLogic Server instance from JDeveloper, choose Run and then choose Start Server Instance (Integrated WebLogic Server).
To deploy and run the ApplCore Setup application:

1. Copy `jdev_install/jdeveloper/jdev/oaext/external/FndSetup.ear` to a directory.

2. Complete the following steps to specify the Oracle Metadata Services (MDS) repository partition to use for the flexfield configuration metadata.
   a. Change to the directory that contains the copy of the `FndSetup.ear` file and complete the following commands to expand the enterprise archive (EAR) file.
      
      ```
      mkdir tmpDir
      cd tmpDir/
      unzip ../FndSetup.ear
      ```
   
   b. Open the `tmpDir/adf/META-INF/adf-config.xml` file in an editor and insert the `metadata-store` element shown in bold in Example 27-1 into the `metadata-store-usage` section.
      
      Replace `repository-name` with the name of an existing MDS repository. Replace `jndi-data-source` with a valid JNDI data source. The JNDI data source name is typically based on the repository name. For example the repository name might be `mds-ApplicationMDSDB` and the JNDI data source might be `jdbc/mds/mds-ApplicationMDSDBDS`.
      
      Replace `test-partition-name` with either the name of an existing partition or the name of a partition to create for the test configuration metadata.
   
   c. Change to the `tmpDir` folder.
   
   d. Execute the following commands to re-create the EAR file with the modified `adf-config.xml` file.
      
      If you are using a Linux operating system, use these commands:
      
      ```
      rm ../FndSetup.ear
      zip -r FndSetup.ear .
      mv FndSetup.ear ../
      rm -Rf tmpDir
      ```
      
      If you are using a Windows operating system, use these commands:
      
      ```
      rmdir /S /Q ..\FndSetup.ear
      zip -r FndSetup.ear .
      move FndSetup.ear ..\
      rmdir /S /Q tmpDir
      ```

3. Log in to the administration console for the Integrated WebLogic Server instance. Note that the URL for administration is commonly set to `http://localhost:7101/console`.

4. Ensure that the `FUSION_APPS_FSCM_ASYNC_WS_APPID` user principal exists in the security realm.
   a. From the Domain Structure, click Security Realm and then click `myrealm` in the Realms table.
   
   b. Click the Users and Groups tab and click the Users tab.
   
   c. If you do not see an entry for the name `FUSION_APPS_FSCM_ASYNC_WS_APPID`, click New, type
FUSION_APPS_FSCM_ASYNC_WS_APPID in the Name field, select the DefaultAuthenticator provider, type a description and a password and click OK.

5. From the Domain Structure in the administration console, click Deployments.

6. From the Summary of Deployments, click Install.

7. In the Path field, type the full path to the directory that contains the FndSetup.ear file with the modified adf-config.xml file.

8. Select FndSetup.ear and click Next.

9. Select Install this deployment as an application and click Next.

10. Click Finish.

11. Use the following URL to run the application in a browser. Replace host and port with the appropriate host and port, such as localhost and 7101. Log in with the application_developer user name and the Welcome1 password.

http://host:port/fndSetup/faces/SetupDemo_UIShellPage

See Configuring Flexfields for information about using the application to configure the flexfields.

Example 27-1  metadata-store Element to Add to the adf-config.xml File

```xml
<metadata-store-usages>
  <metadata-store-usage id="WebCenterFileMetadataStore"
    deploy-target="true" default-cust-store="true">
    <metadata-store
      class-name="oracle.mds.persistence.stores.db.DBMetadataStore">
      <property value="repository-name" name="repository-name"/>
      <property value="test-partition-name" name="partition-name"/>
      <property value="jndi-data-source" name="jndi-datasource"/>
    </metadata-store>
  </metadata-store-usage>
</metadata-store-usages>
```

27.3 Configure Flexfields

Before you can test a flexfield, you must configure flexfield segments so that the flexfield appears in the UI.

For information about implementing flexfields, do the following:

- Access the Oracle Fusion Applications Technology library.
- See the Implementing Common Features guides for your product family. Search for flexfields.

27.3.1 How to Configure Flexfields for Testing

Use the ApplCore Setup application to access the manage flexfield tasks to configure a flexfield for testing.

Before you begin:

Deploy and run the ApplCore Setup application as described in Deploying and Running the Flexfield Configuration User Interface.
To configure a flexfield for testing:

For testing purposes, use the manage flexfield tasks to create test segments.

For information about using manage flexfield tasks to create test segments, do the following:

- Access the Oracle Fusion Applications Technology library.
- See the Implementing Common Features guides for your product family. Search for flexfields.

If you are testing the flexfields from JDeveloper as described in Testing Flexfields from or from a WebLogic Integrated Server instance as described in Testing Flexfields from Integrated WebLogic Server, do not deploy the flexfield configuration.

27.4 Test Flexfields

You can test flexfields from JDeveloper or from Integrated WebLogic Server.

27.4.1 Test Flexfields from Oracle JDeveloper

The Run with Flexfields and Debug with Flexfields dialogs enable you to test specific flexfields in an application, unbounded task, or JSF page.

The first time that you run either dialog from a JDeveloper instance, the table is empty. You can add and remove flexfields as desired and you can select which flexfields to include in a run.

When you add a flexfield, its status is set to Not Synced, meaning that you must synchronize it before you can include it in a run. When you synchronize a flexfield, its business components are generated using the definitions from the current database connection. In addition, all entity usages are generated and the synchronized artifacts are stored in a local directory. If a flexfield cannot be synchronized successfully, it shows a status of Error, as shown in Figure 27-1.

When you open the dialog, the Sync Status shows the state at the time the dialog was last closed, as long as the database connection has not changed. If the database connection has changed, then the status of every flexfield is changed to Not Synced. If you changed the flexfield after the value shown for Sync Date, then you should synchronize the flexfield again before using it in a run.

When you click Run or Debug, all flexfields that have been selected to include in the run and that have a status of Success will be included in the run.
Before you begin:

1. Ensure that all required entities, view links, application modules, and so on, exist for the flexfield usages that you are testing.

2. Create test segments for the flexfield as described in Configuring Flexfields. The test segment configurations must exist in the ApplicationDB database for the project.

To test flexfields from JDeveloper:

1. From the Application Navigator, right click the project, unbounded task, JSF page, or file that you want to test (the target) and choose Run with Flexfields or choose Debug with Flexfields.

2. In the Run with Flexfields dialog (or the Debug with Flexfields dialog), click the Add icon to add flexfields to the table.

3. Optionally, select a flexfield and click the Remove icon to remove an unnecessary flexfield from the table.

4. If a flexfield that you want to test does not have a Sync Status of Success or the flexfield configuration was changed after the last time you synchronized it, select the flexfield and click the Synchronize icon to generate flexfield business components based on the current flexfield configuration in the database that is displayed for the Database Connection.

Note:

The Sync Status value for existing flexfield entries in the table reflects the status at the time the dialog was last closed. If you have made changes to a flexfield, you must synchronize it again even though it shows a Sync Status of Success.

5. Ensure that the Include in run check boxes for the flexfields that you want to test are selected.

6. Click Run (or click Debug if you are in the Debug with Flexfields dialog) to run the target in an Integrated WebLogic Server instance.
27.4.2 Test Flexfields from Integrated WebLogic Server

To test a flexfield in an Integrated WebLogic Server instance, you make it available for testing and then you use a metadata archive (MAR) profile to package and deploy the application.

27.4.2.1 How to Make Flexfields Available for Testing

Make a flexfield available for testing in an Integrated WebLogic Server instance by either importing the flexfield business component from an existing library or by generating the flexfield business component using the Tester role.

Before you begin:

1. Ensure that all required entities, view links, application modules, and so on exist either in your project, or in a library that is included in your project. Ensure that the ApplicationDB connection points to the database that contains the metadata for the flexfield that you want to test.

2. Create test segments for the flexfield as described in Configuring Flexfields.

3. If you are importing flexfield components from an existing library, the flexfield business components must be regenerated after you configure the flexfield.

To make flexfields available for testing:

You make a flexfield available for testing by doing one of the following:

- Import the flexfield business components from an existing library.
- Generate the flexfield business components that you want to test.

If you use the Create Flexfield Business Components wizard, select the Tester role on the Role page of the wizard, and specify a location for the generated business components. For more information about using the Create Flexfield Business Components wizard, see the appropriate section for the type of flexfield that want to test:

- How to Create Descriptive Flexfield Business Components
- Creating Extensible Flexfield Business Components
- How to Create Key Flexfield Business Components

27.4.2.2 How to Test Flexfields From Integrated WebLogic Server

To test a flexfield in an Integrated WebLogic Server instance, package, deploy, and run the application using a MAR profile. The MAR profile that you use points to the test business component artifacts, such as view objects, entity objects, page fragments, and task flows.

For more information about using MAR profiles, see the "How to Run an Application with Metadata in Integrated WebLogic Server" section in the Developing Fusion Web Applications with Oracle Application Development Framework.

Before you begin:

Create the test business component artifacts for the flexfield, as described in How to Make Flexfields Available for Testing.
To test a flexfield:

1. From the Application menu, choose Application Properties.

2. In the Application Properties dialog, click the Deployment navigation tab and click New to create a new deployment profile.

3. Select MAR File from the Archive Type dropdown list.

4. Enter a name for the profile, and click OK.

5. In the panel on the left-hand side of the Edit MAR Deployment Profile Properties dialog, under MAR Options, select Metadata File Groups and click New.

6. In the Create File Group dialog, enter a name for the user metadata group, as shown in Figure 27-2, and click OK.

   **Figure 27-2  New File Group in MAR Profile Properties**

7. In the User Metadata Group section, add a contributor, enter the path to your test components (a directory or archive), and click OK.

8. In the panel on the left-hand side of the Edit MAR Deployment Profile Properties dialog, under MAR Options, expand Metadata File Groups, expand the user metadata group that you just added, and select the Directories node.

9. In the Directories section, select the root package directory of the flexfield to be tested, as shown in Figure 27-3, and click OK.
Caution:

Ensure that you select the correct item. You must select the directory of the root package of the flexfield to be tested, such that only the objects that are below the level of that package come from the test directory. The root package should match the package that you previously registered with the business component's usage.

As soon as you select the package, Oracle JDeveloper automatically selects the parents all the way to the top of the folder hierarchy, but that does not mean everything under oracle is registered with Oracle Metadata Services (MDS).

10. In the Application Properties dialog, expand Run and click the MDS navigation tab.

11. Select the MAR profile that you created earlier, and click OK.

12. Test your application with the MAR profile.

Note:

If you want to run the Business Component Browser with the business components that you created for testing, you must create a temporary user library that points to the test components, and include the library in your project as the first library. This is because the flexfield view objects are generated into a temporary directory outside the scope of the application workspace.
27.5 Deploy Flexfields in a Standalone WebLogic Server Environment

You can package and deploy your flexfield Oracle Fusion application to a standalone instance of the Oracle WebLogic Server for performing end-to-end testing.

27.5.1 How to Package a Flexfield Application for Deployment

Just as with other Oracle Fusion applications, you must generate an enterprise archive (EAR) file for deployment to an instance of WebLogic Server. Before generating the EAR file, you must enable the flexfield packaging plugin.

27.5.1.1 Enable the Flexfield Packaging Plugin

The flexfield packaging plugin is required to package flexfields from either JDeveloper or the command line. This plugin maps namespaces to the Oracle Metadata Services (MDS) partition.

You enable the flexfield packaging plugin for your working environment by setting the `FLEX_DEPLOY_ADDIN_ENABLED` environment variable set to `true`. For example, in a C shell environment you would run the following command:

```
setenv FLEX_DEPLOY_ADDIN_ENABLED true
```

27.5.1.2 Generate an EAR File for the Application

To make the flexfield artifacts available at runtime, package them into the application's EAR file, which subsequently can be installed on the target server.

Before you begin:

- Complete ADF Business Components models underlying the flexfields, and ensure that all required entities, view links, application modules, and so on exist either in your project, or in a library that is included in your project.
- Enable the flexfield packaging plugin as described in Enabling the Flexfield Packaging Plugin.

To generate an EAR file:

1. From an environment in which the `FLEX_DEPLOY_ADDIN_ENABLED` environment variable has been set to `true`, complete one of the following steps:
   - From the Application Navigator in JDeveloper, right-click the application and choose **Deploy > deployment profile > to EAR file**. When the generation process is done, you can find the path to the generated EAR file in the deployment log message window.

   **Note:**

   You might need to restart JDeveloper to ensure that the `FLEX_DEPLOY_ADDIN_ENABLED` environment variable has taken effect and that the flexfield packaging plugin is enabled.

   When the plugin is enabled in JDeveloper, you will see log entries with a Flexfield prefix, such as [09:25:01 PM] Flexfield: Search library "Applications Core"...
For more information about generating EAR files from JDeveloper, see the "Deploying Fusion Web Applications" chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.

- From the command line, run the following `ojdeploy` command:

```bash
jdev_install\jdeveloper\jdev\bin\ojdeploy -profile deployment-profile \ -forcerewrite -workspace application-jws-path
```

2. Optionally, unzip the EAR file and inspect the `adf-config.xml` file to verify that the flexfield packaging plugin added the flexfield packages to the `sessiondef-config` tag and mapped all the flexfield ADF Business Components packages to a `metadata-store-usages` tag. Example 27-2 shows sample tag entries.

**Example 27-2  adf-config.xml Flexfield Tag Entries**

```xml
<adf-config
xmlns="http://xmlns.oracle.com/adf/config"
xmlns:adf="http://xmlns.oracle.com/adf/config/properties" ...
...
<mdsC:sessiondef-config>
<mdsC:package
value="oracle.apps.fnd.applcore.crmdemo.cma.model.view.link.flex;oracle.apps.fnd.applcore.
flex.test.model.entity.flex"/>
</mdsC:sessiondef-config>
...
<mds:mds-config version="11.1.1.000">
<mds:persistence-config>
<mds:metadata-store-usages>
<mds:metadata-store-usage
default-cust-store="true"
deploy-target="true"
id="WebCenterFileMetadataStore">
</mds:metadata-store-usage>
</mds:metadata-store-usages>
</mds:persistence-config>
</mds:mds-config>
...
</adf-config>
```

### 27.5.2 How to Deploy a Flexfield Application

Deploying a flexfield application to an instance of WebLogic Server requires additional steps to ensure that all the flexfields' customization metadata is stored in the proper MDS partition.

For more information about MDS configurations and deploying applications, see the "Deploying the Application" section in the Developing Fusion Web Applications with Oracle Application Development Framework.

The process for deploying a flexfield application includes the following tasks:

1. Prepare the application for deployment.
   
   a. Create an MDS partition to store flexfield customization metadata.
   
   b. Map the product application's EAR file to the MDS partition.
   
   c. Map the Oracle Fusion Middleware Extensions for Applications (ApplCore) Setup application EAR file to the MDS partition.
Deploy Flexfields in a Standalone WebLogic Server Environment

27.5.2.1 Create an MDS Partition

An MDS repository is used to store the information that enables implementors to customize applications. The flexfield packaging process requires a partition in the MDS repository that is associated with the application. You can create a partition specifically for flexfields or you can use the partition for other purposes as well. However, all Oracle Fusion applications and setup applications must use the same MDS partition for all flexfield artifacts.

If the application’s MDS repository does not have the desired partition, use Oracle WebLogic Scripting Tool (WLST) to create one.

For more information about creating and registering MDS repositories and working with WLST, see the "Managing the Metadata Repository" chapter in the Administering Oracle Fusion Middleware.

Before you begin:

Log in to the administration console for the WebLogic Server instance and verify that a Java Database Connectivity (JDBC) data source exists for the MDS repository. This data source is typically named mds-ApplicationMDSDB. Note that the URL for administration is commonly set to http://localhost:7101/console.

For more information about managing JDBC data sources, see the "Creating and Managing JDBC Data Sources" section in the Administering Oracle Fusion Middleware.

To Create an MDS Partition:

1. At the command line, enter the following line to start WLST.

   ```
   sh jdev_install/oracle_common/common/bin/wlst.sh
   ```

   On Windows, use `wlst.cmd`.

2. Enter the following WLST command to connect to the WebLogic Server instance, replacing the user name and password arguments with your user name and password.

   ```
   connect('wls_username', 'wls_password', 'wls_uri')
   ```

   The values must be wrapped in single-quotes. The `wls_uri` value is typically `t3://localhost:7101`.

3. Enter the following WLST command to create the partition.

   ```
   createMetadataPartition('mds_jdbc_data_source', 'partition_name')
   ```

   The `mds_jdbc_data_source` is the JDBC data source for the MDS repository. The `partition_name` can be any string. You might want to consult with your operations team or release team for suggested partition names.
4. Disconnect from WLST.
   
   ```java
   disconnect()
   ```

27.5.2.2 Map the EAR File to the MDS Partition

To configure the application to store the flexfield customization metadata in the desired MDS partition, use the flexfield packaging plugin to update the application’s `adf-config.xml` file with the partition name.

Before you begin:

- Ensure that the `FLEX_DEPLOY_ADDIN_ENABLED` environment variable is set to `true` in your working environment, as described in Enabling the Flexfield Packaging Plugin.
- Generate the EAR file as described in Generating an EAR File for the Application.
- Ensure that an MDS partition exists for the flexfield metadata. For more information, see Creating an Partition.
- Obtain the Java Naming and Directory Interface (JNDI) name for the MDS data source. To find this value, from the administration console for WebLogic Server instance, choose Services, then choose JDBC, and then choose Data Sources.

To map the EAR file to the MDS partition:

1. At the command line, enter the following line to start WLST.

   ```bash
   sh jdev_install/oracle_common/common/bin/wlst.sh
   ```

   On Windows, use `wlst.cmd`.

2. Enter the following WLST command to connect to the WebLogic Server instance, replacing the user name and password arguments with your user name and password.

   ```java
   connect('wls_username', 'wls_password', 'wls_uri')
   ```

   The values must be wrapped in single-quotes. The `wls_uri` value is typically `t3://localhost:7101`.

3. From WLST, execute the following commands to configure the `metadata-store` element. If the element does not exist, the commands add it. If the element already exists, the commands update it.

   ```java
   archive=getMDSArchiveConfig('product_EAR_file_pathname')
   archive.setAppMetadataRepository('mds_jdbc_data_source', 'partition_name', 'DB', 'mds_datasource_JNDI', None)
   archive.save()
   ```

   The `mds_jdbc_data_source` is the JDBC data source for the MDS repository. The `partition_name` is the name of the MDS partition that you are using to store the flexfield customization metadata for all your Oracle Fusion applications. You might need to ask your operations team or release team for the partition name. The
mds_datasource_JNDI is the JNDI name for the MDS data source, such as
jdbc/mds/mds-ApplicationMDSDBDS. For more information, see the
"registerMetadataDBRepository" section in the WLST Command Reference for
WebLogic Server.

4. Optionally, unzip the EAR file and inspect the adf-config.xml file to verify that
the flexfield packaging plugin updated the metadata-store-usage tags to add
the partition name. Example 27-3 shows sample tag entries.

Example 27-3    adf-config.xml metadata-store-usage tags with Added Partition Name

```xml
<mds:metadata-store-usages>
  <mds:metadata-store-usage default-cust-store="true"
deploy-target="true" id="WebCenterFileMetadataStore">
    <mds:metadata-store class-name="oracle.mds.persistence.stores.db.DBMetadataStore">
      <mds:property value="mds-ApplicationMDSDB" name="repository-name"/>
      <mds:property value="ffpartition" name="partition-name"/>
      <mds:property value="jdbc/mds/mds-ApplicationMDSDBDS" name="jndi-datasource"/>
    </mds:metadata-store>
  </mds:metadata-store-usage>
</mds:metadata-store-usages>
```

27.5.2.3 Map the ApplCore Setup Application to the MDS Partition

To test a flexfield, you must configure the flexfield in the same manner as an
implementor would configure it. You can use the ApplCore Setup application to
complete the flexfield configurations as described in How to Configure Flexfields for
Testing. Before using the ApplCore Setup application, you must configure the
application to store the flexfield customization metadata in the desired MDS partition,
just as you would with the product application’s EAR file.

Before you begin:

- Ensure that the FLEX_DEPLOY_ADDIN_ENABLED environment variable is set to
true in your working environment, as described in Enabling the Flexfield
  Packaging Plugin.

- Ensure that an MDS partition exists for the flexfield metadata. For more
  information, see Creating an Partition.

- Locate the ApplCore Setup application’s FndSetup.ear file. This file can
typically be found in the jdev_install/jdeveloper/jdev/oaext/external
directory.

- Obtain the JNDI name for the MDS data source. You can find this value in the
  Services > JDBC > Data Sources page in the administration console for the
  WebLogic Server instance.

To map the ApplCore Setup EAR file to the MDS partition:

1. At the command line, enter the following line to start WLST, if it is not currently
   running.

   ```bash
   sh jdev_install/oracle_common/common/bin/wlst.sh
   ```

   On Windows, use wlst.cmd.
2. If you have not yet connected to the server, enter the following WLST command to connect to the WebLogic Server instance, replacing the user name and password arguments with your user name and password.

```java
connect('wls_username', 'wls_password', 'wls_uri')
```

The values must be wrapped in single-quotes. The `wls_uri` value is typically `t3://localhost:7101`.

3. From WLST, execute the following commands.

```java
archive=getMDSArchiveConfig('ApplCore_Setup_EAR_file_pathname')
archive.setAppMetadataRepository('mds_jdbc_data_source', 'partition_name', 'DB', 'mds_datasource_JNDI', None)
archive.save()
```

The `mds_jdbc_data_source` is the JDBC data source for the MDS repository. The `partition_name` is the name of the MDS partition that you are using to store the flexfield customization metadata for all your Oracle Fusion applications. You might need to ask your operations team or release team for the partition name. The `mds_datasource_JNDI` is the JNDI name for the MDS data source, such as `jdbc/mds/mds-ApplicationMDSDBDS`.

### 27.5.2.4 Include Product Application Model Libraries in the ApplCore Setup EAR File

Before you deploy the ApplCore Setup EAR file, ensure that it contains all the model libraries that are required for your product application.

To include the product application model libraries in the ApplCore Setup EAR file:

1. In a terminal window, change to the directory that contains the `FndSetup.ear` file. This file can typically be found in the `jdev_install/jdeveloper/jdev/oaext/external` directory.

2. Execute the following commands to expand the EAR file.

   ```sh
   mkdir tmpDir
   cd tmpDir/
   unzip ../FndSetup.ear
   ```

3. If the `APP-INF/lib` folder does not exist, execute the following commands to create it.

   ```sh
   mkdir APP-INF
   mkdir APP-INF/lib
   ```

4. Copy all the library Java archive (JAR) files that your product requires to the `APP-INF/lib` folder.

5. Change to the `tmpDir` folder.

6. Execute the following commands to re-create the EAR file with the added JAR files. If you are using a Linux operating system, run these commands:
27.5.2.5 Deploy the Product and Setup Applications to the Server Domains

After you have mapped the applications as described in Mapping the EAR File to the MDS Partition and Mapping the ApplCore Setup Application to the MDS Partition and you have included the project model libraries in the ApplCore Setup application as described in Including Product Application Model Libraries in the ApplCore Setup EAR File, you can deploy the applications to the appropriate domains for your topology.

Related Links
The following documents provide additional information related to subjects discussed in this section:

- For information about creating domains, see the "Creating a WebLogic Domain" chapter in Creating WebLogic Domains Using the Configuration Wizard.
- For information about installing EAR files, see the "Install an Enterprise Application" section in the Oracle WebLogic Server Administration Console Online Help.

27.5.2.6 Prime the MDS Partition with Configured Flexfield Artifacts

The flexfield application is configured to obtain the flexfield customization metadata from the MDS partition. However, no one can log in to the application until the application has gone through an initial process to translate the flexfield metadata into artifacts that are stored in the partition. This task must be completed, even if there is no customization metadata yet. You use WLST to perform this task.

Before you begin:

Deploy the product and setup applications, as described in Deploying the Product and Setup Applications to the Server Domains.

To prime the MDS partition with flexfield metadata artifacts:

- Run the deployFlexForApp WLST command as described in How to Prepare Your Environment to Use the deployFlexForApp Command.

27.6 Use the WLST Flexfield Commands to Deploy Flexfields

You can use the Manage Key Flexfields, Manage Descriptive Flexfields, and Manage Extensible Flexfields tasks to deploy flexfields. In addition, the following WLST commands are available for priming the MDS repository with seeded flexfield artifacts and for deploying flexfields:
• **deployFlexForApp**: Use this command to prime the MDS repository with seeded flexfield artifacts. Deploys all flexfields that do not have a status of DEPLOYED. You can also use this command to deploy all flexfields regardless of their status by setting the `force` parameter to `'true'`.

• **deployFlex**: Use this command to deploy a single flexfield. Deploys the flexfield regardless of status.

• **deleteFlexPatchingLabels**: Use this command to inquire about or delete all flexfield patching labels.

• **validateFlexDeploymentStatus**: Use this command to verify that all flexfields have been successfully deployed. It creates a list of the flexfields that are ready to deploy or failed to deploy.

For information about using WLST flexfield commands, do the following:

• Access the *Oracle Fusion Applications Technology* library.

• See the Implementing Common Features guides for your product family. Search for flexfields.

For information about using the WLST command-line scripting interface, see the *Oracle Fusion Middleware Understanding the WebLogic Scripting Tool* guide.

Before you can use any WLST flexfield command from a development environment, you must first prepare the environment as described in How to Prepare Your Environment to Use the WLST Flexfield Commands. If you use the `deployFlexForApp` command in a development environment, you must complete additional steps described in How to Prepare Your Environment to Use the `deployFlexForApp` Command.

After you execute a WLST flexfield command, you can log into the application and view the pages that contain flexfields. If you have seeded any flexfield configurations by defining value sets, segments, contexts, or structures, for example, the flexfields should appear on the appropriate pages. If a flexfield has not been configured, the corresponding user interface sections will be blank.

### 27.6.1 How to Prepare Your Environment to Use the WLST Flexfield Commands

Before you can use the WLST flexfield commands, you must prepare your environment. The commands will not work until these steps are completed.

**To prepare your environment for WLST flexfield commands:**

1. The WLST flexfield commands can be executed only on the Administration Server for a domain that has a running instance of the ApplCore Setup application. For information on deploying the ApplCore Setup application, see Deploying the Product and Setup Applications to the Server Domains.

2. Ensure that the AppMasterDB data source is registered as a JDBC data source with the Administration Server and points to the same database as the ApplicationDB data source.

### 27.6.2 How to Prepare Your Environment to Use the `deployFlexForApp` Command

The `deployFlexForApp` command translates the product application’s seeded flexfield metadata into artifacts in the MDS repository. This command must be run after you configure your application to read the flexfield artifacts from the MDS.
repository and before you log into the application for the first time, even if there is no seeded flexfield metadata. For more information, see Priming the Partition with Configured Flexfield Artifacts.

To prepare your environment to use the deployFlexForApp command:

1. Configure the product application to store the flexfield customization metadata in the desired MDS partition as described in Mapping the EAR File to the MDS Partition.

2. Map the setup application as described in Mapping the ApplCore Setup Application to the MDS Partition.

3. Deploy the product application and the ApplCore Setup application as described in Deploying the Product and Setup Applications to the Server Domains.

4. Prepare your environment as described in How to Prepare Your Environment to Use the WLST Flexfield Commands.

27.7 Regenerate Flexfield Business Components Programmatically

After you complete the flexfield development activities to incorporate a flexfield into your application, you might need to update the flexfield implementation in your application at a later time by repeating the process of creating the flexfield business components.

To re-create the flexfield business components, you can use the Create Flexfield Business Components wizard, which invokes the flexfield business component modeler to generate (or regenerate) the business components. Alternatively, you can create a Java program to invoke the flexfield business component modeler and thus automate the creation of the business components without implementor interaction.

The flexfield business component modeler can be invoked through the Java application programming interface (API) only in a deployed web application. You must have the following artifacts:

- The ADF Business Components objects required for generating the flexfield business components. Typically these are entity objects. You can deploy them in a JAR file.
- The MDS repository for the generated flexfield business components. If you use a file-system based repository, the metadata path must be an existing writable path.

You either can create a new application to invoke the modeler, or, if you already have a web application for testing, you can include the Java code required for invoking the modeler in your application. The deployment process is the same as any other web application.

Your project must be set up correctly for the program to run successfully. The project configuration requirements are the same as that for the Create Flexfield Business Components wizard.

Example 27-4 demonstrates appropriate Java code for updating the business components for a descriptive flexfield.

Examine BCMModeler.Option for usage-specific settings.
Example 27-4  Java Code for Invoking the Flexfield Business Component Modeler

```java
import oracle.apps.fnd.appcore.flex.runtime.util.BCModeler;

public class Example {
    public static void main(String[] margs) {
        BCModeler.Arguments modelerArgs = new BCModeler.Arguments();

        modelerArgs.put(BCModeler.Parameter.CONNECTION_URL,
                        "jdbc:oracle:thin:user/pass@myhost.com:1999:dev1");

        // Specify where the objects should be.
        modelerArgs.put(BCModeler.Option.OUTPUT_PATH,
                         "/mytest/mds/");

        // The owner of the flexfield should have the following information.
        modelerArgs.put(BCModeler.Parameter.FLEXFIELD_TYPE, "DFF");
        modelerArgs.put(BCModeler.Parameter.APP_SHORT_NAME, "FND");
        modelerArgs.put(BCModeler.Parameter.FLEXFIELD_CODE, "FLEX_DFF1");
        modelerArgs.put(BCModeler.Parameter.TABLE_USAGE_CODE, "FLEX_DFF1");
        modelerArgs.put(BCModeler.Parameter.TABLE_NAME, "FND_DF_TEST_DFF1_T1");
        modelerArgs.put(BCModeler.Parameter.ENTITY_DEF_FULL_NAME,
                        "oracle.apps.fnd.appcore.flex.test.model.entity.Dff1EO");

        // See BCModeler.Option for more usage-specific options. Consult the owner
        // of the flexfield to see if any usage-specific option is required.
        Exception e = BCModeler.run(modelerArgs.getCommandLineArgs(false),
                                     System.out);
        if (e != null) {
            e.printStackTrace();
        }
    }
}
```

27.8 Integrate Flexfield Task Flows into Oracle Fusion Functional Setup Manager

Every Oracle Fusion application registers task flows for setup activities with a product
called Oracle Fusion Functional Setup Manager. For example, a human resources (HR)
application can register setup activities such as "Create Employees" and "Manage
Employee Tree Structure." Implementors and administrators use these registered task
flows, which are accessed from the Oracle Fusion Applications Setup and Maintenance
work area of Oracle Fusion Applications, to configure the applications by defining
custom configuration templates or tasks based on their business needs.

Note:
The registration application task flow is not available for extensible flexfields
and key flexfields. You must use the FND_FLEX_DF_SETUP_APIS PL/SQL to
register extensible flexfields as described in Defining and Registering
Extensible Flexfields. You must use the FND_FLEX_KF_SETUP_APIS
PL/SQL API to register key flexfields as described in How to Develop Key
Flexfields.
Table 27-1 lists the flexfield setup task flows. To make these task flows available to developers, implementors, or administrators, register the appropriate task.

For information about implementing your specific product family, do the following:

- Access the Oracle Fusion Applications Technology library.
- See the Implementing Common Features guides for your product family. Search for "Define Flexfields".

<table>
<thead>
<tr>

  moduleKey=modulekey  

To invoke edit mode for a specific value set:  
  mode='edit'  
  valueSetCode=vscode  

To optionally specify a page heading for the task flow:  
  pageTitle='titlestring' | Search and edit flexfield value sets. |

For related information about functional security actions and roles based on task flows, see Implementing Function Security

### 27.9 Export Flexfield Business Components

As explained in Deploying Flexfields in a Standalone WebLogic Server Environment, you can package and deploy your flexfield Oracle Fusion application to a standalone instance of Oracle WebLogic Server to perform end-to-end testing.

Deploying a flexfield generates Business Components and other metadata files in your MDS repository. These flexfield metadata files can be exported from the Metadata repository using Flexfield Task Flows explained in Integrating Flexfield Task Flows into Oracle Fusion Functional Setup Manager.

A menu Actions item, Download Flexfield Archive, is available as part of Manage Descriptive Flexfields, Manage Extensible Flexfields and Manage Key Flexfields taskflows.
Figure 27-4  Download the Flexfield Archive

When Download Flexfield Archive is selected, a dialog with a progress bar is opened where the progress of exporting flexfield metadata files from the Metadata Repository is displayed.

Figure 27-5  Download Progress Display

When Download Flexfield Archive is selected, a dialog with a progress bar is opened where the progress of exporting flexfield metadata files from the Metadata Repository is displayed.
When exporting the flexfield metadata files is completed, an archive is prepared with these artifacts.

The **Download** button becomes enabled on the progress popup. Click **Download** to download the archive file containing the flexfield metadata to the machine on which the browser is running.
This chapter provides an introduction to Oracle Enterprise Crawl and Search Framework (ECSF). It also describes how to set up ECSF.

This chapter includes the following sections:

- **Introduction to Using Oracle Enterprise Crawl and Search Framework**
- **Setting Up and Running ECSF Command Line Administration Utility**
- **Setting Up Oracle Enterprise Manager and Discovering ECSF**

### 28.1 Introduction to Using Oracle Enterprise Crawl and Search Framework

Oracle Enterprise Crawl and Search Framework (ECSF) is an Oracle Fusion Middleware search framework that enables you to quickly expose application context information on various business objects to enable full-text transactional search.

For more information, see the "Managing Search with Oracle Enterprise Crawl and Search Framework" chapter in the *Administrator’s Guide*.

#### 28.1.1 Understanding the ECSF Architecture

ECSF abstracts an underlying search engine and provides a common set of application programming interfaces (APIs) for developing search functionalities. ECSF serves as an integration layer between the search engine and the Oracle Fusion applications. **Figure 28-1** illustrates the architecture of the ECSF framework.
ECSF includes the following high-level components:

- Searchable Object Manager
- Search Designer
- Semantic Engine
- Fusion Applications Control
- ECSF Command Line Administration Utility
- Security Services
- Data Services
- Query Service

ECSF integrates with the Oracle Secure Enterprise Search (Oracle SES) engine to support application search. Oracle SES provides capabilities for crawling and indexing the metadata and objects exposed by ECSF. The Security Plug-in and Crawler Plug-in are modules on Oracle SES that interface with ECSF.

### 28.1.1.1 About Searchable Object Manager

Searchable Object Manager, serving as a metadata manager, manages searchable objects and provides the runtime interface for accessing these objects. At runtime, the Searchable Object Manager loads the searchable objects from persistent storage, validates the searchable object definitions, and provides the searchable objects to the Crawlable Factory component of the Data Service.

The Searchable Object Manager is also responsible for the life cycle management of searchable objects, which administrators can deploy, customize, and enable or disable via the Fusion Applications Control or the ECSF Command Line Administration Utility.

### 28.1.1.2 About Search Designer

The Search Designer is a page in Oracle JDeveloper 11g that provides the interface for defining the metadata that describes the business objects to be indexed. You can also use this design interface to specify the security mechanism used to protect the data, as
well as define the searchable object search characteristics, which include Advanced Search, Faceted Navigation, and Actionable Results.

28.1.1.3 About Semantic Engine

The Semantic Engine leverages the semantic information of searchable object definitions to create context around the search. It achieves this by interpreting the searchable object definitions with relation to the runtime user information during both crawl and query time. Runtime user information may include the following:

- Facets
- Actionable results
- Security
- Personalization
- Internationalization
- Data structure mapping
- Tagging, commenting, rates
- Results clustering
- Context filtering
- Custom weighting

28.1.1.4 About Fusion Applications Control

The Fusion Applications Control is an Oracle Enterprise Manager extension that provides a user interface for registering searchable objects in the ECSF schema in the Oracle Fusion Applications database, and for administering the runtime parameters of ECSF, the target search engine, and the configuration of parameters.

28.1.1.5 About ECSF Command Line Administration Utility

The ECSF Command Line Administration Utility is a standalone command line interface that provides a user interface for registering searchable objects in the ECSF schema in the Oracle Fusion Applications database. You can also use this tool for configuring and administering ECSF without external dependencies on Oracle Enterprise Manager.

28.1.1.6 About Security Service

The Security Service is the runtime server component responsible for providing security information to SES. During query time, this service retrieves the security keys of the user performing the search and passes them to Oracle SES, where they are used to filter the query results.

The Security Service server component is also invoked during crawl time to add security information (access control lists) to data before inserting or creating indexes on the search engine (Oracle SES). An access control list (ACL) is a list that identifies the users who can access the associated object and that specifies the user's access rights to that object. The ACL values generated by the Security Service during crawl time should match the corresponding keys generated during query time.
Note:

In ECSF, the generic term ACL (access control list) is used to describe how Oracle SES and ECSF pass security information and perform security checks by using the information described in the ACL.

The Security Service component is implemented as a security engine with a plug-in interface. The security plug-in determines the format of the ACL keys. For all custom security models, a new Security Plug-in must be implemented. Security Service uses Oracle Platform Security for Java to authenticate users and call the Security Plug-in to retrieve security values for a given searchable object.

For more information about security for ECSF, see Configuring ECSF Security.

28.1.1.7 About Data Service

Data Service is the primary data interface, based on a proprietary Really Simple Syndication (RSS) feed format, between ECSF and the search engine. In addition to supporting the flow of metadata between ECSF and the search engine, Data Service supports attachments, batching, and error handling.

Data Service authenticates each Oracle SES crawl request by using Oracle Platform Security for Java to validate the user credentials and permissions for crawling the data source.

The Crawlable Factory component, part of Data Service, determines how searchable objects are broken down and manages the construction of RSS feeds to the search engine.

28.1.1.8 About Query Service

The Query Service provides a search interface for the applications UI and handles all search requests. This service performs query rewrite, parameter substitution, and other preprocessing operations before invoking the underlying configured search engine.

Search results are also serviced via this service. Hooks are provided to preprocess and postprocess data, which facilitates the capability to filter search results.

28.1.1.9 About the Oracle SES Search Engine

Oracle SES enables a secure, uniform search across multiple enterprise repositories. ECSF integrates with Oracle SES technology to provide full-text search functionality in Oracle Fusion Applications.

Note:

The application server space is demarcated to identify that ECSF runs in a separate application server, outside the search engine. It is recommended, for performance reasons, that each search engine instance runs on separate hardware.

28.1.1.10 About Security Plug-in

Oracle SES provides an API for writing security plug-ins (or connectors) in Java. With this API, you can create a security plug-in to meet your requirements. ECSF Security Service interfaces with this security plug-in. The Security Plug-in invokes the Security
Service to retrieve keys, to which the user has access, for filtering the results that are delivered to the ECSF query service. A proxy user must be set up on the search engine to invoke the Security Service. The proxy user must have security privileges for the Oracle Fusion applications. For more information about security for ECSF, see Configuring ECSF Security.

28.1.1.11 About the Crawler Plug-in

The Crawler Plug-in is a search engine (Oracle SES) module that implements the modified RSS feed format between ECSF and Oracle SES. This component deserializes the data sent from ECSF, via the Data Service component, and interfaces with the Oracle SES components that creates the indexes.

28.2 Setting Up and Running ECSF Command Line Administration Utility

You can use the ECSF Command Line Administration Utility to quickly test and manage the searchable objects without having to use Oracle Enterprise Manager Fusion Applications Control.

Note:

Administrators should use Fusion Applications Control to manage the life cycle of searchable objects in the production environment.

28.2.1 Set Up the ECSF Command Line Administration Utility

Before you can run the utility, you must complete the following setup requirements:

1. Make the searchable objects accessible to the ECSF Command Line Admin Utility.

2. Set the class path to make sure it contains the required Oracle classes. ECSF provides a set of scripts that you can use to set the class path.

3. Connect to the database by performing one of the following tasks:
   • Provide the connection information in the script so that the ECSF Command Line Administration Utility automatically connects to the specified database during startup.
   • Manually connect to the database after you start the ECSF Command Line Administration Utility.

4. Provide the path of the JPS Config file.

5. Create ECSF query proxy users. To perform commands that connect to the Oracle SES server (for example, deploy, start schedule, etc.), the engine instance must be set up correctly so that its parameters have the required information. For more information, see the "Managing Search with Oracle Enterprise Crawl and Search Framework" chapter in the Administrator’s Guide.

6. (Optional) Configure the log settings.

7. (Optional) Set the startup parameter to support taking input from a text file.
28.2.2 Run the ECSF Command Line Administration Utility

After you have set up the ECSF Command Line Administration Utility, you can run the utility by any of the following ways:

- Execute the `runCmdLineAdmin.bat` script (Windows)
- Execute the `runCmdLineAdmin.sh` script (Linux)
- Start it as a Java program from a command line interface with the following command:
  ```
  java oracle.ecsf.cmdlineadmin.CmdLineAdmin
  ```

Enter a username and password when prompted.

---

**Note:**

If you enter an invalid username and password, you can either reconnect manually by using the `connect` command, or exit the ECSF Command Line Administration Utility (type `exit` or press `Ctrl-C`) and try again.

When you update passwords in the Lightweight Directory Access Protocol (LDAP) credential store from the ECSF Command Line Administration Utility, the `jps-config-jse.xml` file must contain the same LDAP information as the `jps-config.xml` file. Java Platform Security (JPS) does not propagate the changes from `jps-config.xml` to `jps-config-jse.xml` automatically.

---

All commands, responses, and error messages in the ECSF Command Line Administration Utility are logged.

To exit the ECSF Command Line Administration Utility, enter the `exit` command at the prompt.

28.2.3 About Making Searchable Objects Accessible to the ECSF Command Line Administration Utility

Make the searchable objects accessible to the ECSF Command Line Administration Utility by adding the ADF library JAR file containing the view object and entity object definitions to its class path.

The ECSF Command Line Administration Utility needs the path of the JAR file containing the searchable objects. These metadata objects are validated during register and unregister operations.

You can find the unpacked EAR files containing the searchable object JAR files for the search applications in the following locations:

- **For Linux OS:** `/net/mount1/appbase/fusionapps/applications/fscm/deploy/EarFscmSearch.ear/app-INF/lib/searchable_object_jar_file`
- **For Windows OS:** `C:\appbase\fusionapps\applications\fscm\deploy\EarFscmSearch.ear\APP-INF\lib\searchable_object_jar_file`
• For Linux OS: /net/mount1/appbase/fusionapps/applications/crm/deploy/EarCrmSearch.ear/APP-INF/lib/searchable_object_jar_file
  For Windows OS: C:\appbase\fusionapps\applications\crm\deploy\EarCrmSearch.ear\APP-INF\lib\searchable_object_jar_file

• For Linux OS: /net/mount1/appbase/fusionapps/applications/hcm/deploy/EarHcmSearch.ear/APP-INF/lib/searchable_object_jar_file
  For Windows OS: C:\appbase\fusionapps\applications\hcm\deploy\EarHcmSearch.ear\APP-INF\lib\searchable_object_jar_file

To add the ADF library JAR file containing the view object and entity object definitions to the class path for the ECSF Command Line Administration Utility, you must first create the ADF library.

The application JAR file, which contains the searchable objects that are defined in your application, is written to the deploy directory of the project.

To deploy or undeploy a searchable object, a JAR file containing the searchable object must be specified in the class path of the ECSF Command Line Administration Utility. For information, see About Setting the Class Path.

If you are deploying searchable objects from multiple applications, you must create a JAR file for each of those applications to add the searchable objects to the class path.

28.2.4 About Setting the Class Path

In order for the ECSF Command Line Administration Utility to run, the class path must contain the required Oracle classes. Modify and run scripts to set the class path, as well as optional connection information, and run the ECSF Command Line Administration Utility.

Note:

If you receive a java.lang.ClassNotFoundException exception, then add the JAR file containing that class to ADMIN_CP in the script.

The ECSF Command Line Administration Utility references the class path to obtain the location of Oracle Library home, Java home, Oracle WebLogic Server home, and the JAR files needed for the ECSF Command Line Administration Utility operations.

28.2.4.1 Set the Class Path in Windows

Modify and run the runCmdLineAdmin.bat script to set the class path in a Windows environment.

To set the class path in Windows, do the following:

1. In a text editor, open the runCmdLineAdmin.bat script from MW_HOME/Oracle_atgpf1/ecsf/modules/oracle.ecsf_11.1.1/admin.

2. Specify the Oracle Library home directory path by locating the line set ORACLE_LIBRARY_HOME=SET_ORACLE_LIBRARY_HOME and replace SET_ORACLE_LIBRARY_HOME with the ATGPF shiphome directory, for example, set ORACLE_LIBRARY_HOME=C:\mw_home\oracle_common.
3. Specify the ATGPF Library home directory path by locating the line `set ATGPF_LIBRARY_HOME=SET_ATGPF_LIBRARY_HOME` and replace `SET_ATGPF_LIBRARY_HOME` with the ATGPF shiphome directory, for example, `set ATGPF_LIBRARY_HOME=C:\mw_home\Oracle_atgpf1`.

Specify the ATGPF Library home directory path by locating the line `set ATGPF_LIBRARY_HOME=SET_ATGPF_LIBRARY_HOME` and replace `SET_ATGPF_LIBRARY_HOME` with the ATGPF Library directory, for example, `set ATGPF_LIBRARY_HOME=c:\fmwtools_view\fmwtools\mw_home\jdeveloper`.

4. Specify the Oracle WebLogic Server home directory path:
   a. Locate the following line: `set WLS_HOME=SET_WLS_HOME`
   b. Replace `SET_WLS_HOME` with the Oracle WebLogic Server home directory path, for example, `set WLS_HOME=C:\MW_HOME/wlserver_10.3`

5. Specify the Java home directory path:
   • Locate the following line: `set JAVA_HOME=SET_JAVA_HOME`
   • Replace `SET_JAVA_HOME` with the Java home directory path (where the Java executable should be located), for example, `set JAVA_HOME=C:\Java\jdk\bin`.

The version of Java used must match the version required by the Oracle build.

6. Specify the directory path of the application JAR file:
   • Locate the following line: `set APP_JAR=SET_APP_JAR`
   • Replace `SET_APP_JAR` with the directory path of the application JAR file you created in About Making Searchable Objects Accessible to the ECSF Command Line Administration Utility, for example, `set APP_JAR=C:\Jdeveloper\mywork\Application1\runtime\deploy\archive1.jar`.

7. Save the script file.

### 28.2.4.2 Set the Class Path in Linux

Modify and run the `runCmdLineAdmin.sh` script to set the class path in a Linux environment.

To set the class path in Linux, do the following:

1. In a text editor, open the `runCmdLineAdmin.sh` script from `MW_HOME/Oracle_atgpf1/ecsf/modules/oracle.ecsf_11.1.1/admin`.

2. Specify the Oracle Library home directory path by locating the line `export ORACLE_LIBRARY_HOME=SET_ORACLE_LIBRARY_HOME` and replace `SET_ORACLE_LIBRARY_HOME` with the ATGPF shiphome directory, for example, `export ORACLE_LIBRARY_HOME="/scratch/mw_home/Oracle_atgpf1"`.

Specify the Oracle Library home directory path by locating the line `export ORACLE_LIBRARY_HOME=SET_ORACLE_LIBRARY_HOME` and replace `SET_ORACLE_LIBRARY_HOME` with the Oracle Common Library directory, for example, `export ORACLE_LIBRARY_HOME="/scratch/login/`
3. Specify the ATGPF Library home directory path by locating the line `export ATGPF_LIBRARY_HOME=SET_ATGPF_LIBRARY_HOME` and replace `SET_ATGPF_LIBRARY_HOME` with the ATGPF shiphome directory, for example, `set ATGPF_LIBRARY_HOME="/scratch/fmwtools/mw_home/Oracle_atgpf1"`.

4. Specify the Java home directory path:
   - Locate the following line: `export JAVA_HOME="set_java_home"
   - Replace `set_java_home` with the Java home directory path (where the Java executable should be located), for example, `export JAVA_HOME="/Java/jdk/bin"`.
   
   The version of Java used must match the version required by the Oracle build.

5. Specify the directory path of the application JAR file:
   - Locate the following line: `export APP_JAR="set_app_jar"
   - Replace `set_app_jar` with the directory path of the application JAR file you created in About Making Searchable Objects Accessible to the ECSF Command Line Administration Utility, for example, `export APP_JAR="/Jdeveloper/mywork/Application1/runtime/deploy/archive1.jar"`.

6. Save the script file.

7. Run the script.

### 28.2.5 About Setting the Connection Information

The ECSF Command Line Administration Utility requires an Oracle Fusion Applications database, to which it can either be directly connected or connected through a remote MBean. To use the ECSF Command Line Administration Utility, you must supply the connection information.

Set the connection information in the `runCmdLineAdmin` script so that the ECSF Command Line Administration Utility automatically connects to the specified database or MBean server during startup. If you do not include the connection information in the script, then you must manually create the connection to the Oracle Fusion Applications database after you start the ECSF Command Line Administration Utility. For information, see About Manually Connecting to the Database.

The information for connecting to the database or MBean server is saved in the `runCmdLineAdmin` script for the ECSF Command Line Administration Utility to use for connecting to the Oracle Fusion Applications database at startup. You are prompted to enter a password after you start the ECSF Command Line Administration Utility.

#### 28.2.5.1 Set the Connection Information in Windows

Modify the `runCmdLineAdmin.bat` script to set the connection information in a Windows environment.

To set the connection information in Windows, do the following:
1. Open the runCmdLineAdmin.bat script, located in JDEV_INSTALL/ecsf, in a text editor.

2. Locate set CONNECT_INFO= and specify the database or MBean server, using one of the following formats:
   - connect to mbeanserver hostname port
   - Using SID:
     connect to database hostname port SID
     For example,
     set CONNECT_INFO=connect to database fusionhost123 1566 fh123.
   - Using service name:
     connect to database service hostname port servicename
     For example,
     set CONNECT_INFO=connect to database service fusionhost123 5521 myservice
   - Using database descriptor:
     connect to database descriptor 'descriptor'
     The descriptor argument must be enclosed in quotation marks and can contain either the SID or service name. For example:
     - Using SID:
       set CONNECT_INFO=connect to database descriptor
       '(DESCRIPTION=(ADDRESS=(PROTOCOL=tcp)
       (HOST=fusionhost123)(PORT=5521))
       (CONNECT_DATA=(SID=dbmsdb2)))'
     - Using service name:
       set CONNECT_INFO=connect to database descriptor
       '(DESCRIPTION=(ADDRESS=(PROTOCOL=tcp)
       (HOST=fusionhost123)(PORT=5521))(CONNECT_DATA=(SERVICE
       NAME=myservice)))'

3. Save the script file.

28.2.5.2 Set the Connection Information in Linux

Modify and run the runCmdLineAdmin.sh script to set the connection information in a Linux environment.

To set the connection information in Linux, do the following:

1. Open the runCmdLineAdmin.sh script, located in ORACLE_HOME/jdeveloper/ecsf, in a text editor.

2. Locate export CONNECT_INFO= and specify the database or MBean server, using one of the following formats:
   - connect to mbeanserver hostname port
• Using SID:
  connect to database *hostname* port *SID*
  For example,
  set CONNECT_INFO=connect to database fusionhost123 1566 fh123

• Using service name:
  connect to database service *hostname* port *servicename*
  For example,
  set CONNECT_INFO=connect to database service fusionhost123 5521 myservice

• Using database descriptor:
  connect to database descriptor 'descriptor'
  The *descriptor* argument must be enclosed in quotation marks and can contain either the SID or service name. For example:
  - Using SID:
    set CONNECT_INFO=connect to database descriptor
    'DESCRIPTION=(ADDRESS=(PROTOCOL=tcp)(HOST=fusionhost123)(PORT=5521))
    (CONNECT_DATA=(SID=dmssdb2))'
  - Using service name:
    set CONNECT_INFO=connect to database descriptor
    'DESCRIPTION=(ADDRESS=(PROTOCOL=tcp)(HOST=fusionhost123)(PORT=5521))
    (CONNECT_DATA=(SERVICE_NAME=myservice))'

3. Save the script file.

### 28.2.6 About Manually Connecting to the Oracle Fusion Applications Database

The ECSF Command Line Administration Utility requires an Oracle Fusion Applications database, to which it can either be directly connected or connected through a remote MBean, for command execution. To use the ECSF Command Line Administration Utility, you must supply the connection information.

You can supply connection information either before or after starting the ECSF Command Line Administration Utility. Supplying the connection information before startup allows the ECSF Command Line Administration Utility to automatically connect to the specified database or MBean server during startup. For information, see About Setting the Connection Information.

If you choose not to supply the connection information before startup, you must manually create the connection to the Oracle Fusion Applications database after you start the ECSF Command Line Administration Utility.

To create a connection to the Oracle Fusion Applications database directly, enter one of the following commands at the ECSF Command Line Administration prompt, then press Enter:

- connect to database
  The ECSF Command Line Administration Utility prompts you for the host name, port, and SID.
- connect to database service
The ECSF Command Line Administration Utility prompts you for the host name, port, and service name.

- **connect to database descriptor**

  The ECSF Command Line Administration Utility prompts you for the descriptor. The `descriptor` argument must be enclosed in quotation marks and can contain either the SID or service name. For example:

  - Using SID:
    
    `'(DESCRIPTION=(ADDRESS=(PROTOCOL=tcp)(HOST=fusionhost123)(PORT=5521))
    (CONNECT_DATA=(SID=dbmsdb2)))'`

  - Using service name:
    
    `'(DESCRIPTION=(ADDRESS=(PROTOCOL=tcp)(HOST=fusionhost123)(PORT=5521))
    (CONNECT_DATA=(SERVICE_NAME=myservice)))'`

  - **connect to database hostname port SID**

    You can directly pass the required values as arguments into the command.

  - **connect to database service hostname port servicename**

    You can directly pass the required values as arguments into the command.

  - **connect to database descriptor 'descriptor'*

    You can directly pass the required value as an argument into the command. The `descriptor` argument must be enclosed in quotation marks and can contain either the SID or service name. For example:

    - Using SID:
      
      `'(DESCRIPTION=(ADDRESS=(PROTOCOL=tcp)(HOST=fusionhost123)(PORT=5521))
      (CONNECT_DATA=(SID=dbmsdb2)))'`

    - Using service name:
      
      `'(DESCRIPTION=(ADDRESS=(PROTOCOL=tcp)(HOST=fusionhost123)(PORT=5521))
      (CONNECT_DATA=(SERVICE_NAME=myservice)))'`

To create a connection to the Oracle Fusion Applications database through a remote MBean, enter one of the following commands at the ECSF Command Line Administration prompt, then press Enter:

- **connect to mbeanserver**

  The ECSF Command Line Administration Utility prompts you for the required values.

- **connect to mbeanserver hostname port**

  You can directly pass the required values as arguments into the command.

The ECSF Command Line Administration Utility prompts you to enter a username and password.

### 28.2.7 How to Provide the Path of the JPS Config File

The JPS Config file (`jps-config-jse.xml`) contains the credential store information needed for running the ECSF Command Line Administration scripts. You must
provide the path of the JPS Config file by modifying the ECSF Command Line Administration scripts.

To set the JPS Config file path, do the following:

1. Open the runCmdLineAdmin.bat (Windows) or runCmdLineAdmin.sh (Linux) script, located in ORACLE_HOME/jdeveloper/ecsf, in a text editor.

2. Set the JPS_CONFIG parameter to point to the location of jps-config-jse.xml (usually at DOMAIN_HOME/config/fmwconfig/jps-config-jse.xml).

3. Save.

### 28.2.8 About Configuring the Log Settings

The scripts for the ECSF Command Line Administration Utility point to the logging configuration file (ecsfcla-logging.xml), where you can configure log settings, such as log level and log file location. The `ecsfcla-logging.xml` file is located in the same directory as the ECSF Command Line Administration scripts (`JDEV_INSTALL/ecsf`). To configure log settings, modify the property values in `ecsfcla-logging.xml` and save the file.

The location of `ecsfcla-logging.xml` can be changed by modifying the `ODL_CONFIG` parameter in the ECSF Command Line Administration scripts.

All commands, responses, and error messages in the ECSF Command Line Administration Utility are logged. The generated log files follow the format `ecsfCmdLineAdminLog*.txt`, and its default location is `JDEV_INSTALL/ecsf/log`.

### 28.2.9 About Automating the ECSF Command Line Administration Utility

You can set the ECSF Command Line Administration Utility to automatically execute a defined sequence of commands when you run the utility. To automate the ECSF Command Line Administration Utility in this way, you must configure the startup script to take inputs from a text file that you create.

The input file must contain one command per line. Any values that are not passed in with a command and for which you are typically prompted (for example, username and password) must occupy their own lines in the file. You must include a `connect` command since this is not passed in during the automated startup, and you must also include the `exit` command as the last command in the file to exit the ECSF Command Line Administration Utility. Example 28-1 illustrates a sample list of commands for an input file.

You must know all of the object IDs when you create the input file. Using the input file, you cannot create a new object and then manage it in one automation.

#### Example 28-1 Sample Input File

```plaintext
connect to database fusionhost123 1566 fh123
fusion
fusion
manage instance 1
set param "SES_ADMIN_SERVICE"="http://example.com:7777/search/api/admin/AdminService"
set param "SES_ADMIN_USERNAME" = "eqsys"
exit
```
28.2.9.1 How to Configure the Startup Script

To configure the startup script to automatically run the commands you defined in the input file, you must modify the startup script to include the AUTOMATE command in the STARTUP_PARAMS parameter.

1. Open the runCmdLineAdmin.bat (Windows) or runCmdLineAdmin.sh (Linux) script, located in ORACLE_HOME/jdeveloper/ecsf, in a text editor.

2. Set the STARTUP_PARAMS parameter to AUTOMATE and point to the location of input file. For example,

   \[\text{STARTUP_PARAMS} = \text{AUTOMATE /scratch/commands.txt}\]

   where commands.txt is the input filename.

3. Click Save.

   The output of the ECSF Command Line Administration Utility is displayed on the screen (or can be redirected), and errors are logged in the log file as usual. If the input file cannot be found, the ECSF Command Line Administration Utility runs in its usual mode and waits for the user to input a command through the prompt.

28.3 Set Up Oracle Enterprise Manager and Discovering ECSF

While you can use the ECSF Command Line Administration Utility to quickly test and manage the searchable objects, Oracle Enterprise Manager Fusion Applications Control is necessary to manage the life cycle of searchable objects in the production environment.

The ECSF runtime application needs to register its MBean to WebLogic's Domain Runtime MBean server, and the Oracle Enterprise Manager Fusion Applications Control needs to invoke all ECSF runtime operations through the MBean.

To access the Fusion Applications Control, you must install and configure Oracle Enterprise Manager (EM) to work with ECSF. You do not need to set up Oracle Enterprise Manager if you plan to use the ECSF Command Line Administration Utility to administer search.

To set up Oracle Enterprise Manager for ECSF, you must perform the following tasks:

1. Register the ECSF runtime application MBean.
2. Install Oracle Enterprise Manager.
3. Discover ECSF in Oracle Enterprise Manager.
4. Add users to the Administrators group.

Multiple developers can share one single Oracle Enterprise Manager application with the Fusion Applications Control.

28.3.1 How to Register the ECSF Runtime MBean to the Integrated WebLogic Server

The ECSF runtime application registers an MBean (oracle.ecsf.mbean.SearchRuntimeAdminMXBean) in WebLogic's Domain Runtime MBean server through a listener class (oracle.ecsf.mbean.RegisterMbeanContextListener). All ECSF runtime operations are invoked through the MBean.
To register the MBean, do the following:

1. Add the MBean listener to web.xml.
2. Create the application enterprise archive (EAR) file.
3. Configure the data sources.
4. Deploy the ECSF application.
5. Start the Oracle WebLogic Server instance.

Registering the ECSF runtime MBean to the Integrated WebLogic Server makes the MBean available to remote clients such as Fusion Applications Control in Oracle Enterprise Manager.

28.3.1.1 Add the MBean listener to web.xml

Add the MBean listener by modifying web.xml to include oracle.ecsf.mbean.RegisterMbeanContextListener.

To add the MBean listener do the following:

1. In the view-controller project in the Application Navigator, expand Web Content, then expand WEB-INF, and open web.xml.
2. Add the following <listener> element in web.xml:

   ```xml
   <listener>
     <listener-class>oracle.ecsf.mbean.RegisterMbeanContextListener</listener-class>
   </listener>
   ```
3. Save.

28.3.1.2 Creating the Application EAR File for Deployment

Create the application EAR file to be deployed. Right-click the application name and navigate to Deploy > ECSF application deployment profile > to EAR file. When the deployment is complete, you can find the generated EAR file in the JDeveloper log message window.

28.3.1.3 About Configuring Data Sources in Oracle WebLogic Server

You must configure data sources in Oracle WebLogic Server for MBean integration. Search for a data source with the JNDI name SearchDBDS. If any exist, make sure to look at the connection and validate that SearchDBDS is pointing to the correct database. If SearchDBDS is not listed, you must create a data source with jdbc/SearchDBDS as the JNDI name and with the connection information to the database against which the Fusion web application is running.

28.3.1.4 About Deploying the ECSF Application Using the EAR File

Make the MBean available by deploying the EAR file you created to Integrated WebLogic Server. Make sure that the EAR file is deployed and the application status is active in the final step.
28.3.1.5 About Starting the Oracle WebLogic Server Instance

When the MBean is available after you deploy the enterprise archive (EAR) file, you can start the Oracle WebLogic Server instance by selecting **Start Server Instance** from the **Run** menu.

28.3.2 About Installing Oracle Enterprise Manager

You must install Oracle Enterprise Manager to access the Fusion Applications Control. Installing Enterprise Manager allows you to then enable it to discover the ECSF custom application target in Oracle WebLogic Server.

28.3.3 How to Discover ECSF in Oracle Enterprise Manager

To use Fusion Applications Control in Oracle Enterprise Manager, you must first enable Oracle Enterprise Manager to discover the ECSF custom application target in Oracle WebLogic Server. When you discover ECSF in Oracle Enterprise Manager, you enable Oracle Enterprise Manager to detect and display the Fusion Applications Control. You only need to discover the ECSF custom application target in Oracle WebLogic Server once. When it is discovered, you can directly launch EM with the following URL:

http://your machine name:port/em

To discover ECSF in Oracle Enterprise Manager, do the following:

1. Invoke the target discovery page in Oracle WebLogic Server with the following URL:

   http://your machine name:port/em/faces/as/discovery/addWeblogic

2. Complete the following fields and click **Submit**:
   - **Host** (the name of the machine that hosts Oracle WebLogic Server)
   - **Port** (the Oracle WebLogic Server runtime port number, for example, 7101)
   - **Username** (for example, weblogic)
   - **Password** (for example, weblogic)

   **Note:**
   You can discover multiple Oracle WebLogic Servers by specifying a value for **Farm Name Prefix** (for example, Farm).

3. Click **Farm_DefaultDomain**.

4. At the Oracle Enterprise Manager login page (http://your machine name:port/em), log in with the following credentials:
   - Username: weblogic
   - Password: weblogic
5. To start Fusion Applications Control, navigate to Farm_DefaultDomain > Fusion Middleware > Enterprise Crawl and Search Framework and click EcsfRuntimeApp.

**Note:**
You only need to discover the ECSF custom application target in Oracle WebLogic Server once. When it is discovered, you can directly launch EM with the following URL:

```
http://your machine name:port/em
```

### 28.3.4 About Adding Users to the Administrators Group

To access the ECSF pages in Fusion Applications Control, users must be created and added to the Operator group and above on Oracle WebLogic Server.
This chapter describes how to create searchable objects in Oracle Fusion Applications. This chapter includes the following sections:

- Introduction to Creating Searchable Objects
- About Defining Searchable Objects
- About Securing Searchable Objects
- About Configuring Search Features
- About Configuring Custom Properties for Searchable Objects

29.1 Introduction to Creating Searchable Objects

Searchable objects are sets of data that make view objects available for full text search. They are used in an abstract way for exposing business data to search engines. For example, a purchase order as a searchable object would be defined as a set of searchable properties and its relationship to other searchable objects. Business data can be both structured and unstructured, such as data residing in a database, file attachments (including images), and documents.

The abstraction allows searchable objects to be bound to different contexts at runtime and to be described and used within that context. Because the binding information describes how a searchable object behaves in a given context, it is sometimes called search metadata.

To create searchable objects, you must perform the following tasks:

1. Define the searchable objects and searchable attributes.
2. (Optional) Enable the capability to crawl searchable objects with file attachments. For more information, see About Enabling Search on Fusion File Attachments.
3. (Optional) Enable the capability to crawl searchable objects with Oracle WebCenter tags. For more information, see About Enabling Search on WebCenter Tags.
4. Secure the searchable objects.
5. Configure the search features.
6. Configure the custom properties for the searchable objects.
About Defining Searchable Objects

29.2 About Defining Searchable Objects

Oracle Enterprise Crawl and Search Framework (ECSF) is used to integrate search functionality in Oracle Fusion Applications by defining searchable objects and its attributes. Defining the searchable objects enables the corresponding view objects and their attributes to search, and creates the necessary metadata for ECSF. The ECSF metadata can be packaged into an application archive and subsequently used by the ECSF runtime environment to deploy data sources into Oracle Secure Enterprise Search (Oracle SES) to perform crawl and index operations. All artifacts (for example, Java archive files, Oracle Application Development Framework objects, and so on), on which the view objects depend, must be packaged in the enterprise archive (EAR) file to make the searchable objects usable during runtime for both crawl and query operations.

Note:

You can also package ECSF metadata into metadata archive (MAR) files.

Consider the following when you define searchable objects and searchable attributes:

- Rather than reuse or functionally overload view objects designed for other purposes, construct view objects (parent and children) for search purposes (that is, include only attributes you intend to search).

- Exclude large objects (LOBs) from searchable objects unless you intend to search LOB contents.

- Restrict the use of multilevel view objects to five levels to avoid causing severe feed performance degradation.

- Collocate all servers (for example, ECSF, Oracle SES, database, and so on) and follow standard performance, scalability, and reliability network performance guidelines to minimize network latency between servers.

- Remember that feed throughput is directly proportional to the amount of data that is pulled from the database to be indexed.

- Be selective with the searchable objects to ensure that only a limited portion of data from the primary table is crawled to maximize crawling and indexing performance.

- Remember that attachments (Oracle Content Management SDK or LOBs) require record by record processing, and every record requires one additional network round-trip.

- Store attributes only when necessary. Use attributes stored in Oracle SES only for the following purposes:
  - Faceted navigation
  - Advanced search
  - Search result actions
  - Primary keys
If the value of an attribute must be searchable, then place it in the body of the searchable object.

- Use common attributes across Oracle Fusion Applications. Stored attributes common to all the searchable objects must share the same name and data type. For information about preventing conflicts, see What You May Need to Know About Preventing Search Attribute Naming Conflicts.

- Use the default security plug-in (oracle.ecsf.impl.DefaultSearchPlugin) as much as possible. Use of the default security plug-in ensures that the searchable objects are secured properly.

- Set the data type for stored attributes correctly and avoid conflicting attribute names.

- Identify the appropriate incremental crawl approach for your searchable object. Initial crawl refers to the first time data is crawled and indexed into a search engine. During initial crawl, all data intended to be crawled is sent to the search engine. All subsequent crawls are incremental crawls. During incremental crawls, only data that has been added or modified since the last crawl is sent to the search engine for indexing.

ECSF supports two mechanisms to identify newly added or modified data. You must choose and implement at least one of the following mechanisms:

- Configuring the Crawl Date Column searchable attribute property. For information, see How to Make View Object Attributes Searchable.

- Raising change events. For information, see About Raising Change Events Synchronously.

If neither mechanism is implemented, then the data that has been added or modified since the initial crawl will not be indexed, and therefore will not be searchable.

29.2.1 Understanding How to Define Searchable Objects

Before you can define searchable objects, you must be familiar with the following:

- Oracle JDeveloper and Oracle Application Development Framework technology. You must also understand how to build applications using entity objects, view objects, and view links.

- How view objects are used in ECSF. For more information, see the "Managing Search with Oracle Enterprise Crawl and Search Framework" chapter in the Administrator’s Guide.

- How to use Groovy expressions when defining search metadata. For information, see About Using Groovy Expressions in ECSF.

29.2.1.1 How to Define Searchable Objects and Attributes

To define searchable objects and searchable attributes, use the Search navigation tab of the overview editor in Oracle JDeveloper to complete the following tasks:

1. Make view objects searchable.

2. Make view object attributes searchable.
29.2.2 About Using Groovy Expressions in ECSF

ECSF indexes data based on a view object, which represents the top-level view object to crawl. Many business objects are hierarchical, and ECSF optimizes the Oracle Application Development Framework (Oracle ADF) methods of describing such hierarchies by using view links. ECSF supports multiple levels of a view hierarchy. By defining additional view objects and linking the top-level view object to the additional view objects through a view link, parent, child, grandchild, and so on relationships are formed. After a view link is set, you can reference data in those successive objects for indexing by using Groovy, a Java-like scripting language that is dynamically compiled and evaluated at runtime.

When you design your view object to be searchable, you must configure view links to generate only the Destination Accessor and not the Source Accessor.

When querying for root records during crawl time, ECSF also traverses the view link accessors to query child view objects. ECSF follows the parent view link accessors until it reaches the limit for the number of view accessor levels to be crawled. The default limit is set to 5 levels. If a parent view object has a view link accessor to its child view object, and the child view object also has a view link accessor pointing back to the parent view object, then the code cycles. It is not necessary to index the data in both parent and child view objects. When creating a view link object in Oracle JDeveloper, generate the view link accessor only in the parent view object and not in the child view object.

When defining search metadata, Groovy expressions are used to reference the attributes of view objects and the attributes of their child, grandchild, and so on view objects so that the attribute (string) values can be added into the ECSF index. You are required to enter Groovy expressions for fields such as Title, Body, and Keyword.

You can also use Groovy expressions to localize ECSF. For information, see About Localizing ECSF Artifacts.

29.2.2.1 About Referencing View Object Attributes as Variables

Groovy expressions can reference view object attributes (voAttrName) as variables. For example, you can enter the following Groovy expression in the Title field:

"Purchase Order " + RowId + " created for " + Customer + " on " + CreatedDate
Note:
View object attribute names are case-sensitive.

If the value for RowId is 1234, the value for Customer is ABC Inc, and the value for CreatedDate is 1/1/2007, then a search would return the following title value:

Purchase Order 1234 created for ABC Inc on 1/1/2007

The ECSF runtime code parses, then evaluates the expressions in the context of a view object, and returns the title with values for the variables.

Note:
To reference a stored view object attribute whose alias corresponds with an Oracle SES default search attribute (for example, Language), you must change the alias of the view object attribute to something other than any name of the Oracle SES default search attributes (for example, use alias Lang, instead of Language). Changing the alias prevents conflicts between Oracle SES and ECSF stored view object attributes. Alternatively, you can create view object transient attributes and reference them in the expressions. For more information, see What You May Need to Know about Preventing Conflicts with Default Search Attributes.

29.2.2.2 About Referencing Child View Object Attributes

Groovy expressions can also reference child view object attributes (viewLinkAccessorName.voAttrName) as variables by using the view link accessor names to access child attributes.

For example, you can enter the following Groovy expression in the Title field:

"Product Codes: " + ProductsView.ProdCode

Note:
View object attribute names are case-sensitive.

If the view object represented by the ProductsView view link accessor contains one record, and the value of its ProdCode attribute is 1XYZ, then a search would return the following title value:

Product Codes: 1XYZ

If a child view object referenced by an expression contains more than one record, then the values of all the child records are concatenated. For example, if the ProductsView view link accessor contains three records, and the values of its ProdCode attribute are 1XYZ, 2ABC, and 3STU, then a search would return the title value:

Product Codes: 1XYZ 2ABC 3STU.

The view link accessor name for a child view object is available on the view link that points to the child view object. The name of the view link accessor is the Destination value. In Figure 29-1, which shows the accessor information about the Relationship navigation tab of the view link editor, the name of the view link accessor is ZipLov.
You can also find the name of view link accessor in the `<ViewLinkAccessor>` tag of the XML source code of the view object.

Alternatively, you can use the `curdoc` keyword to access the current document, as shown in Example 29-1.

The `curdoc` keyword is used to access child documents and their attributes.

**Example 29-1 Using curdoc to Access Child Documents and Their Attributes**

```groovy
s = "";
if (curdoc.getChildDocs("ProductsView") != null) {
    for (d in curdoc.getChildDocs("ProductsView")) {
        s = s + d.attributes.ProdCode + " ";
    }
}
"Product Codes: " + s;
```

**29.2.2.3 About Referencing View Object Attributes in Multilevel Searchable Objects**

Groovy expressions can also reference view object attributes (`viewLinkAccessorName.voAttrName`, `viewLinkAccessorName.viewLinkAccessorName.voAttrName`, and so on) in searchable objects with a multilevel structure.

By default, the view link depth is set to 5. To index fewer or more than five levels of data in the view hierarchy, you must set the `oracle.ecsf.max.links.depth` property in system properties to the desired value. Figure 29-2 illustrates the Purchase Order searchable object with a five-level structure.
Figure 29-2 Searchable Object with Five Levels

Using Groovy expressions in the search metadata, you can access attributes in the levels PO Line Detail, Line Item Product, and Product Doc. For example, you can enter the following Groovy expression in the Title field:

If a grandchild view object referenced by an expression contains more than one record, then the values of all the grandchild records are concatenated. For example, if you reference view object attributes with viewLinkAccessorName.viewLinkAccessorName.voAttrName, then the result of the expression POLine.LineDetail.AttributeX is the concatenation of all AttributeX values for the LineDetail attribute of all POLine levels of the current PurchaseOrder searchable object.

29.2.2.4 About Formatting View Object Attribute Values

When writing Groovy expressions, it can be useful to generate strings that contain formatted versions of view object attribute values. For example, you may want to generate formatted strings such as "01/30/07" or "Jan 30, 2007" for an attribute value of type java.sql.Date.

To format attribute values, you must first determine the Java data types. The data types of view object attributes can vary. For example, some attributes may return simple strings, while others may return java.sql.Date, java.sql.Timestamp, or numbers like java.lang.Long.

One way to determine the types is to write a test Groovy expression that displays the type names. For example, if the view object has an attribute called Hiredate, then you can use the Groovy expression, as shown in Example 29-2, in the Body field.

The class name of the Hiredate attribute's value is displayed and can be viewed in the Data Feed:

Hiredate type: java.sql.Date.

After you determine the Java data type of a view object attribute, you can apply standard Java formatting techniques to format its value. Example 29-3 shows a sample Groovy expression for formatting a date.

The Groovy expression evaluates to:

Hire date: 01/30/2007

To format a number attribute named Qty of data type java.lang.Long using comma separators, write a Groovy expression, such as the one shown in Example 29-4.
The Groovy expression evaluates to:

*Quantity: 2,450*

**Example 29-2  Sample Groovy Expression to Determine Attribute’s Java Data Type**

'Hiredate type: ' + (Hiredate != null ? Hiredate.getClass().getName() : 'null');

**Example 29-3  Sample Groovy Expression for Formatting Dates**

fmt = new java.text.SimpleDateFormat('MM/dd/yyyy');  // create a date formatter (standard java class)
'Hire date: ' + fmt.format(Hiredate);

**Example 29-4  Sample Groovy Expression for Formatting Numbers**

fmt = new java.text.DecimalFormat('#,###,###');
'Quantity: ' + fmt.format(Qty);

### 29.2.3 What Happens When You Use Groovy Expressions in ECSF

The Groovy expressions are compiled and evaluated at runtime to display the desired string value in the crawl data feeds.

### 29.2.4 About Making View Objects Searchable

Use the Search page of the overview editor in JDeveloper, as shown in Figure 29-3, to set search property values for view objects.

**Figure 29-3  Search Page for Configuring Search Properties of View Objects**

- **Primary Table**: 
  - **Title**: 
  - **Body**: 
  - **Language Attribute**: 
  - **Search Plugin**: 
    - **Enable Real-Time Query Authorization**: 
    - **Secure View-Object Name**: 

- **Searchable Attributes**: 
  - **Search Result Actions**: 
  - **Facets**: 

**Note:**

The Search page is not editable if the view object or existing searchable object is read-only.
29.2.4.1 Set Search Property Values for View Objects

Make view objects searchable by setting search property values for them.

To set search property values for view objects, do the following:

---

**Caution:**

Do not modify the Oracle Fusion Applications Help searchable object named TopicSearchPVO.

---

1. In the overview editor, select the **Search** navigation tab.

2. Complete the **Primary Table** field by doing one of the following:
   - If the view object is based on an entity object, then select a value from the **Primary Table** dropdown menu.
   - If the view object is not based on an entity object, then enter the schema, table name, and table alias for the primary table. Use the format `DATABASE_SCHEMA.TABLENAME TABLE_ALIAS_NAME` (for example, `fusion.Emp Employee`).

You can either enter text directly into the text box or use the Select Primary Table dialog. For more information, see Using the Select Primary Table Dialog.

---

**Note:**

The table alias name you enter must match the table alias name used in the view object's SQL statement. You can view the SQL statement by selecting the view object's **Query** tab.

---

3. In the **Title** field, enter a Groovy expression to be evaluated to a string for the desired title of the search result. For more information, see About Using Groovy Expressions in ECSF.

The **Title** field allows for multiple lines of text.

You can also click the **Edit** icon to open the Edit Expression Editor, where you can enter Groovy expressions for the desired title of the search result. Click **OK** to save.

---

**Note:**

Do not include attributes of type character large object (CLOB) or binary large object (BLOB) in the Groovy expressions for the **Title**, **Body**, and **Keywords** fields, or you will receive an error. All columns with type CLOB or BLOB in a view object or its child view objects are processed as Oracle SES attachments.

---

4. In the **Body** field, enter Groovy expressions to provide additional information about the search results. This appears below the title. For more information, see About Using Groovy Expressions in ECSF.

You can also click the **Edit** icon to open the Edit Expression Editor, where you can enter Groovy expressions for the desired title of the search result. Click **OK** to save.
5. In the **Keywords** field, enter the keywords in the form of Groovy expressions. For more information, see About Using Groovy Expressions in ECSF.

You can also click the **Edit** icon to open the Edit Expression Editor, where you can enter Groovy expressions for the desired title of the search result. Click **OK** to save.

The values of the keywords are evaluated at crawl time using Groovy expressions, and sent to Oracle SES as part of the document for indexing. After they are indexed, the values of the keywords are searchable for the document with which they are associated.

6. Select the desired view object attribute from the **Language Attribute** dropdown menu to specify the language of this view object record. If the object has no language attribute, then leave it blank.

**Note:**

Currently, ECSF provides a way for you to specify if an attribute is a language field. ECSF will assume that the value of this field for each instance is the language for this instance. ECSF initially supports the Oracle Fusion Applications language code. If no language field is specified for a given searchable object, then ECSF uses the language preference of the crawler user.

7. Complete the **Search PlugIn** field by using the Search PlugIn dialog. For more information, see About Using the Search PlugIn Dialog.

8. Check the **Enable Real-Time query authorization** checkbox if you want the view object to use real-time authorization. The view object requires the proper Oracle Fusion Middleware Extensions for Applications (Applications Core) data security configuration, and ECSF will use the view-object query with security predicates from Applications Core data security to enforce query-time authorization at runtime.

9. (Optional) In the **Secure View Object Name** field, specify an alternative view object to use for authorization. ECSF will use this view object to get an authorization query with Applications Core security predicates.

10. Save the view object.

**Note:**

To save the changes made to the **Primary Table**, **Title**, **Body**, and **Keywords** fields, you must move the focus from those attributes (that is, click outside each field as you complete them).

**Note:**

If the view object is open in JDeveloper when you update the corresponding searchable object file (*view_object_name_ECSF.xml*), then you must close and reopen the view object to view the updates.
29.2.4.2 Using the Select Primary Table Dialog

Use the Select Primary Table dialog to specify the primary table for the searchable object if the view object is not based on an entity object.

To use the Select Primary Table dialog, do the following:

1. From the Search navigation tab, click the Edit icon next to the Primary Table field.

   The Select Primary Table dialog appears, as shown in Figure 29-4.

   **Figure 29-4  Select Primary Table Dialog**

2. Select the desired schema from the Database Schema dropdown menu.

3. With the Tables checkbox selected in the Object Type field, click Query to list the available tables.

4. Select the desired table name from the list under Available Objects.

5. Enter an alias for the primary table in the Table Alias field.

   **Note:**

   The table alias entered must match the table alias used in the view object’s SQL statement. You can view the SQL statement by selecting the view object’s Query tab.

6. Click OK.

   **Note:**

   You must select a primary table from the Available Objects list to save the changes.
29.2.4.3 About Using the Search Plugin Dialog

ECSF provides an extension model to allow you to extend ECSF functionality. Implement a search extension to implement any number of the following Java interfaces to extend or customize ECSF functionality:

- `oracle.ecsf.Securable`, used to implement a security extension
- `oracle.ecsf.PreIndexProcessor`, used to customize or manipulate data before it is sent to the search engine for indexing, such as for enabling advanced search on child objects (that is, attribute filtering)
- `oracle.ecsf.PostQueryProcessor`, used to customize results before search results are returned

Use the Search PlugIn dialog to specify the extension you want to use for the searchable object.

**Note:**

If you do not specify a search extension for your searchable object, then the default security extension is used. The default security extension requires you to identify a secure attribute. For information, see How to Make View Object Attributes Searchable.

**Note:**

If the search extension is in the Oracle WebLogic Server shared library, then the ECSF library (`ecsf.jar`) must be present in the shared library for ECSF to load the interface.

29.2.4.3.1 How to Use the Search Plugin Dialog

To use the dialog, do the following:

1. From the Search navigation tab, click the **Edit** icon next to the **Search PlugIn** field.

   The Search PlugIn dialog appears, as shown in Figure 29-5.
2. In the **PlugIn Class Name** field, enter the name of the custom Java class that implements the methods to determine security and resolve the URL.

**Note:**

If there is no plug-in defined in the searchable object, and you are not using a custom security extension, then this value is null and by default is set to `oracle.ecsf.impl.DefaultSearchPlugin`, which is used at runtime.

3. Optional: Enter a parameter name in the **Parameter Name** field and its corresponding value in the **Value** field, and click **Add**.

4. To update an existing parameter, select the desired parameter in the table, change its value, and then click **Update**.

5. To delete an existing parameter, select the desired parameter in the table and click **Delete**.

6. Click **OK** to save the changes.

### 29.2.5 What Happens When You Make View Objects Searchable

JDeveloper captures the search metadata for each view object and writes it to an external XML file (searchable object) for consumption by the runtime component. Each searchable object corresponds to a view object. The file naming convention is `view_object_name_ECSF.xml`, and the file is created in the same location as its corresponding view object.

**Note:**

Manually deleting an ECSF file removes the search functionality from the corresponding view object.
Caution:

Do not manually modify the contents of the `view_object_name_ECSF.xml` file. If you manually modify the search metadata in the XML file, then the changes appear in the editor window when it is closed and reopened in JDeveloper, but metadata changes are not validated. Instead, use the Search navigation tab of the overview editor in JDeveloper to modify the search metadata.

---

ECSF metadata can be packaged into an EAR file or a MAR file for consumption during crawl time and query time.

### 29.2.6 What You May Need to Know About Making View Objects Searchable

The searchable object reflects any change in the search metadata only after you save the view object. Until then, the changes are in memory. When you save the view object, the search metadata is saved to the searchable object. If there is no existing searchable object corresponding to the view object, then a new searchable object is created and stored in the same location as the view object.

In addition, if you rename or delete a view object with a corresponding searchable object, then the searchable object is likewise renamed or removed from the project.

---

### 29.2.7 About Making View Object Attributes Searchable

Making view object attributes searchable creates the necessary metadata for:

- Advanced search
- Faceted navigation
- Security
- Search result actions

**Note:**

The more attributes you make searchable, the larger the index becomes, which slows the performance of the queries.

---

Use the Search navigation tab of the overview editor in JDeveloper, shown in Figure 29-6, to set property values for view object attributes.
Using the Search navigation tab, you can perform the following tasks on view object attributes:

- Make view object attributes searchable.
- Modify searchable attributes.
- Delete searchable attributes.

### 29.2.7.1 How to Make View Object Attributes Searchable

Make view object attributes searchable by setting search property values for them.

1. In the overview editor, select the **Search** navigation tab.

2. Click the **Add** icon in the **Searchable Attributes** table header to open the Searchable Attribute Properties dialog, shown in Figure 29-7.

### Figure 29-7  Searchable Attribute Properties Dialog

3. Select the desired view object attribute from the **Attribute Name** dropdown menu.

4. Complete the remaining fields to define the property set for the searchable attribute. For information about the searchable attribute properties, see Table 29-1.
**Note:**

Before creating new stored attributes, check the list of Oracle SES attribute names and types to avoid conflicts. See *Oracle Fusion Applications Reference for Oracle SES Attributes*.

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stored</td>
<td>Select this checkbox to store the view object attribute in Oracle SES as a separate custom search attribute. The view object attribute’s Alias property will be used as the name of the custom search attribute. The Alias property can be updated and renamed to avoid name and type conflicts. See <em>What You May Need to Know About Preventing Search Attribute Naming Conflicts</em>. The attributes stored in Oracle SES are used for Advanced Search, Actionable Results, and Faceted Navigation. For more information, see <em>About Defining Search Result Actions</em> and <em>How to Implement Faceted Navigation</em>. Selecting this checkbox enables the Weight field.</td>
</tr>
<tr>
<td>Secure Attribute</td>
<td>Select this checkbox to use the attribute’s value to secure the document at crawl time and to determine which users can access the indexed object at query time.</td>
</tr>
</tbody>
</table>
Table 29-1  (Cont.) Searchable Attribute Properties

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Crawl Date Column</td>
<td>Select this date column during incremental crawls to see if that record should be recrawled. Select this checkbox to enable the crawler to detect changes to the searchable object based on the date column. You must be able to reference the Crawl Date Column checkbox in a SQL predicate for ECSF to detect added or changed data. During incremental crawls, scheduled using either the Oracle Fusion Applications Control for ECSF or ECSF Command Line Administration Utility, only objects that have been modified since the last crawl are sent to Oracle SES. If the Crawl Date Column checkbox is specified for multiple searchable attributes, then all the date columns are used in the SQL query to retrieve data that has been modified since the last crawl. The SQL query uses the OR condition to get the incremental set of data. For example, if the Crawl Date Column checkbox is selected for CREATED_DATE and LAST_UPDATE_DATE in the searchable object, and the SQL query uses select * from EMP, then the following incremental crawl SQL query is generated: Select * from EMP where (CREATED_DATE between LAST_CRAWL_TIME and CURRENT_TIME) or (LAST_UPDATE_DATE between LAST_CRAWL_TIME and CURRENT_TIME) ECSF will check the values of all attributes in the Searchable View Object (SVO) that are marked as Crawl Date columns, find the most recent one, and use the value of that column as the LastModifiedDate stored attribute's value. In other words, ECSF will pick the most recent Crawl Date column value to use as the LastModifiedDate value. This allows users to perform queries using Advanced Search for documents that were modified within a certain date range.</td>
</tr>
<tr>
<td>Weight</td>
<td>Select the Stored checkbox to enable this field. Enter a value 1 to 10 (low to high), or select from the dropdown menu, to attach a weight to the stored attribute. Weights affect the ranking of the search results. If the weight is set to 1, then the stored attribute gets no boost. If the weight is set to 2 or 3, then the stored attribute gets very low boost (added to custom attribute Headline2). If the weight is set to 4 or 5, then the stored attribute gets low boost (added to custom attribute Headline1). If the weight is set to 6 or higher, then the stored attribute gets high boost (added to custom attribute Reference Text).</td>
</tr>
<tr>
<td>Override Source</td>
<td>Select this property to allow facets to be based on child view object attributes. This feature lets a stored attribute to be defined against a child view object attribute and a facet to be defined against this stored attribute. This allows users to filter search results so that only results whose child view object attribute matches a certain value will be returned. The Override Source property will support values of the format ViewLinkAccessorName.AttributeName.</td>
</tr>
</tbody>
</table>
Note:
Only stored and secured view object attributes are available for advanced search (that is, the Stored and Secure Attribute checkboxes are selected).

5. Click OK.
6. Save the view object.

Note:
If the view object is open in JDeveloper when you update the corresponding searchable object file (view_object_name_ECSF.xml), then you must close and reopen the view object to view the updates.

29.2.7.2 How to Modify Searchable Attributes
Modify a searchable attribute by editing the search property values for the view object attribute.

1. In the overview editor, select the Search navigation tab.
2. Expand the Searchable Attributes table header to expose the table of searchable attributes.
3. Select the searchable attribute you want to modify. This highlights the entire row.
4. Click the Edit icon in the Searchable Attributes table header to open the Searchable Attribute Properties dialog, shown in Figure 29-7.
   The attribute you selected on the Search navigation tab is displayed in the Attribute Name field.
5. Select or deselect the checkboxes to modify the property set for the searchable attribute. For information about the searchable attribute properties, see Table 29-1.
6. Click OK.
7. Save the view object.

29.2.7.3 How to Delete Searchable Attributes
Deleting the searchable attributes removes the search metadata for the view object attribute.

1. In the overview editor, select the Search navigation tab.
2. Expand the Searchable Attributes table header to expose the table of searchable attributes.
3. Select the searchable attribute you want to remove. This highlights the entire row.
4. Click the Delete (red X) icon in the Searchable Attributes table header.
   The attribute you selected on the Search navigation tab is removed from the table of searchable attributes.
5. Save the view object.

29.2.8 What Happens When You Define Searchable Attributes

JDeveloper captures the search metadata for each view object, including its attributes, and writes it to an external XML file (searchable object) for consumption by the runtime component. Each searchable object corresponds to a view object and includes the view object attributes. The file naming convention is `view_object_name_ECSF.xml`, and the file is created in the same location as its corresponding view object.

During crawl time, the ECSF runtime server uses the view attributes that are annotated for searching to construct documents for indexing.

**Caution:**

Do not manually modify the contents of the `view_object_name_ECSF.xml` file. If you manually modify the search metadata in the XML file, then the changes appear in the editor window when it is closed and reopened in JDeveloper, but metadata changes are not validated. Instead, use the Search navigation tab of the overview editor in JDeveloper to modify the search metadata.

ECSF implicitly adds the following attributes to Oracle SES indexes:

- **ECSF_SO_NAME.** This attribute stores the fully qualified searchable object name that corresponds to the searchable object on which the Oracle SES data source is based.

- **ECSF_TAGS.** This attribute is created if Oracle WebCenter Portal tags are associated with the searchable object. For information, see About Enabling Search on WebCenter Tags.

- **DEFAULT_ACL_KEY.** ECSF uses this attribute to store access control list (ACL) keys for the document.

29.2.9 What You May Need to Know About Defining Searchable Attributes

The searchable object reflects any change in the search metadata only after you save the view object. Until then, the changes are in memory. When you save the view object, the search metadata is saved to the searchable object. If there is no existing searchable object corresponding to the view object, then a new searchable object is created and stored in the same location as the view object.

In addition, if you rename or delete a view object with a corresponding searchable object, then the searchable object is likewise renamed or removed from the project.

**Note:**

Do not manually delete an attribute that has a corresponding search attribute from a view object, because it causes unexpected search results.
29.2.10 What You May Need to Know about Preventing Conflicts with Oracle SES
Default Search Attributes

Oracle SES supports system-defined default search attributes that may conflict with
ECSF stored view object attributes. For example, for Purchase Order 123 you define a
stored view object attribute with the alias Language and value US. However, Oracle
SES contains a default search attribute also named Language, but it has en as its
value. When you reference the view object attribute in a Groovy expression, such as
when you define a search result action of URL type where target="http://
example.com/q=dj&lang=\"+Language, you expect the search result action to
display as http://example.com/q=dj&lang=US.

However, the search result action displays as http://example.com/
q=dj&lang=en because the Oracle SES default search attribute value overrides the
value of the ECSF stored view object attribute of the same name.

Note:
The attribute conflict does not consider case. For example, a conflict still
occurs if the stored view object attribute’s alias is LANGUAGE (all caps) and the
Oracle SES default search attribute name is Language.

The following are the Oracle SES default search attributes:

- Author
- Description
- Headline1
- Headline2
- Headline3
- Host
- Infosource
- Infosource Path
- Keywords
- Language
- LastModifiedDate
- Mimetype
- Reference Text
- Subject
- Title
- Url
- Urldepth
Author, LastModifiedDate, and Subject are the exceptions, and can be used to enhance usability of the Oracle SES UI and to decrease the number of custom attributes in Oracle SES.

To prevent a conflict between Oracle SES default search attributes and ECSF stored view object attributes, you can either change the alias of the stored view object attribute to something other than any name of the Oracle SES default search attributes, or you can create a view object transient attribute and set it as a stored attribute, and then reference the transient attribute in the expressions.

To resolve the conflict in the given example, you can change the alias value of the Language view object attribute from Language (default) to Lang. The view object attribute alias is used to retrieve the value of the view object attribute in expressions.

Alternatively, you can resolve the conflict by creating a view object transient attribute, such as one named Lang, and use it in the expressions (for example, target="http://example.com/q=dj&lang="+Lang). By default, when the values of transient attributes are sent to Oracle SES, ECSF assigns the transient attribute a unique alias. When their values return as part of query results, they will not conflict with any default search attributes in Oracle SES. When expressions containing transient attributes are evaluated, ECSF converts the transient attribute names to the aliases and retrieves the data correctly.

29.2.11 What You May Need to Know About Preventing Search Attribute Naming Conflicts

Because Oracle SES supports facets only on attributes of type STRING, if a facet is defined on a nonstring attribute, then ECSF automatically converts the stored attribute type to a string before sending the attribute to Oracle SES.

However, a conflict may occur when a stored attribute of the same name is generated for a view object with no facets. Searchable attributes in Oracle SES are unique across the entire instance, so if multiple searchable objects contain the same attribute name of different types, then only the attribute (regardless of type) of the first searchable object crawled is used by Oracle SES. ECSF does check for stored attribute conflicts. For more information, see About Checking for Stored Attribute Conflicts.

Consider the following example:

You create a view object oracle.apps.crm.ustomer360.CustomerFVO with a set of attributes and types that are based on the underlying tables that use the Oracle ADF standard UI. The view object attribute contains the following information stored as Oracle ADF metadata:

<table>
<thead>
<tr>
<th>Attribute Name</th>
<th>Attribute Alias</th>
<th>Attribute Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>Name</td>
<td>NAME</td>
<td>VARCHAR2</td>
</tr>
<tr>
<td>OrganizationId</td>
<td>ORGANIZATION_ID</td>
<td>NUMBER</td>
</tr>
<tr>
<td>Description</td>
<td>DESCRIPTION</td>
<td>VARCHAR2</td>
</tr>
</tbody>
</table>

You use the Search Designer to annotate a subset of these attributes (Name and OrganizationId) to store in Oracle SES for search purposes. For more information, see About Search Designer.
When Oracle SES crawls oracle.apps.crm.customer360.CustomerPVO, ECSF sends a document for each customer in the table. Each document contains the following attribute details:

<table>
<thead>
<tr>
<th>Attribute Alias</th>
<th>Attribute Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>NAME</td>
<td>VARCHAR2</td>
</tr>
<tr>
<td>ORGANIZATION_ID</td>
<td>NUMBER</td>
</tr>
</tbody>
</table>

In Oracle SES, NAME and ORGANIZATION_ID are created as customer attributes with the respective types. Due to the global nature of custom attributes in Oracle SES, if an attribute of the same name already exists, then no new attribute is created even if its type is different. Values for the attributes with conflicting name and type pairs are not stored in Oracle SES.

The issue surfaces when ORGANIZATION_ID is used as a facet (to enable users to narrow down the results per organization tree). ECSF implements a logic that detects whether an attribute is used for a facet. If it is used for a facet, then ECSF automatically changes the attribute type from NUMBER to VARCHAR2 because Oracle SES does not support facets on attributes with type NUMBER. This causes a conflict with the already existing ORGANIZATION_ID stored attribute of type NUMBER.

To prevent this conflict and allow Oracle SES to index both attributes, you must change the alias of the stored attribute that is used for facets. Go to the JDeveloper ADF view object attribute editor and update the Alias property value, as shown in Figure 29-8. For example, in the view object attribute editor, change the Alias value from PARTY_ID to PARTY_ID_FACET.
Before creating new stored attributes, check the list of Oracle SES attribute names and types to avoid conflicts. See *Oracle Fusion Applications Reference for Oracle SES Attributes*.

### 29.2.11.1 About Checking for Stored Attribute Conflicts

ECSF checks for stored attribute conflicts during Search Object deployment. If ECSF detects that the SO has attributes in it that will cause a conflict in SES, an error message will be shown that describes the error. Depending on the situation, the message will appear similar to one of these:

- The source attribute in runtime.EmpViewAdmin11gTest with name Host and type NUMBER conflicts with the attributes defined in these sources: Source: runtime.EmpView DataType: STRING Source: runtime.EmpView2 DataType: STRING

- The source attribute in runtime.EmpViewAdmin11gTest with name Mgr and type NUMBER conflicts with the attribute defined in SES with type STRING. This attribute is not being used by any sources.

You will have to change the SO so that the conflicting attribute either has a new name or has the same type as the attributes already defined in SES.

### 29.3 About Securing Searchable Objects

ECSF determines if a user has access to a search category depending on whether the user has permission to access the searchable objects in the category. *Search categories,*
also called search groups, are the logical collections of searchable objects that facilitate

group search on related items. Search categories are directly used for querying. If all of

the searchable objects in a search category are not accessible to the user, then that
category does not appear in the user’s category list. In this case, ECSF runtime does

not return that category when SearchCtrl.getSearchGroups() is called. However, if any one of the searchable objects in a search category is accessible to the user, then that category does appear in the user’s category list.

To secure searchable objects:

1. Set permissions for searchable objects
2. Create the security realm
3. Create the application policy store

### 29.3.1 How to Set Permissions for Searchable Objects

Set permissions for searchable objects by using the Search PlugIn dialog to enter the

permissions parameters. For information, see About Using the Search PlugIn Dialog.

To set permissions, do the following:

1. In the **PlugIn Class Name** field, enter the name of the custom Java class that
   implements the methods to determine security. If you are not using a custom
   security extension, enter oracle.ecsf.impl.DefaultSearchPlugin.

2. Add the following parameter names and values, and click Add for each name and
   value pair:
   - **Parameter Name:** FUNCTION_PERMISSION_NAME
     **Value:** PURCHASE_ORDER_VIEW_DETAILS
   - **Parameter Name:** FUNCTION_PERMISSION_ACTION
     **Value:** view
   - **Parameter Name:** FUNCTION_PERMISSION_CLASS
     **Value:** RegionPermission

   **Note:**

   The value of **FUNCTION_PERMISSION_NAME** and
   **FUNCTION_PERMISSION_ACTION** must be the same as the value of the
   permission name and action in the **jazn-data.xml** file.

3. Click OK.

The parameters are used to validate permissions in the ECSF security classes.
Searchable objects with no permissions set are accessible by all users.

### 29.3.2 How to Create the Security Realm

The user in the security realm is deployed to the Oracle WebLogic Server security

realm. Add a **jazn.com realm** to **jazn-data.xml**.

To add a security realm, do the following:
1. Expand Application Resources > Descriptors > META-INF, and open the jazn-data.xml file.

3. Navigate to jazn.com > Users, and click Add to add a user with the following information:
   
   Name: scott
   
   Credentials: weblogic

   The jazn-data.xml file is updated with the security realm, as shown in Example 29-5.

   The user Scott is associated to the jazn.com security realm.

4. Save.

   Example 29-5  jazn.com Security Realm

   <jazn-realm default="jazn.com">
   
   <realm>
   
   <name>jazn.com</name>
   
   <users>
   
   <user>
   
   <name>scott</name>
   
   <credentials>{903}O/XvB3XDx97MYp4sUSWwT3Q5KPLIEciA</credentials>
   
   </user>
   
   </users>
   
   </realm>
   
   </jazn-realm>

29.3.3 How to Create the Application Policy Store

The policy store is used to determined which users have access to which objects. Add an application policy store to jazn-data.xml.

To add the application policy store, do the following:

1. Expand Application Resources > Descriptors > META-INF, and open the jazn-data.xml file.

2. Select Application Policy Store, and click New to add a new policy store. Enter TestPermission for the display name.

3. Select Application Roles, and click Add to add a new role. Name it admin.

4. Select Application Roles, and shuttle the user scott from the Available section to the Selected section.

5. Select Application Policies, and click New to add a new policy. Enter View Orders for the display name.

6. Select the View Orders application policy, go to the Principals tab, and click Add to add a principal with the following information:

   Name: admin
   
   Class: oracle.security.jps.service.policystore.ApplicationRole
   
   Type: role
Leave the **Realm Name** field blank.

7. Go to the **Permissions** tab, and click **Add** to add a permission with the following information:

   Name: `PURCHASE_ORDER_VIEWDETAILS`
   Class: `oracle.adf.share.security.authorization.RegionPermission`
   Actions: `view`

   The `jazn-data.xml` file is updated with the application policy store, as shown in **Example 29-6**.

   The application policy store includes the values that you specified.

**Example 29-6    Application Policy Store**

```xml
<policy-store>
  <applications>
    <application>
      <name>TestPermission</name>
      <app-roles>
        <app-role>
          <name>admin</name>
          <class>oracle.security.jps.service.policystore.ApplicationRole</class>
          <members>
            <member>
              <name>scott</name>
              <class>oracle.security.jps.internal.core.principals.JpsXmlUserImpl</class>
            </member>
          </members>
        </app-role>
      </app-roles>
      <jazn-policy>
        <grant>
          <grantee>
            <display-name>
              View Orders
            </display-name>
            <principals>
              <principal>
                <type>
                  role
                </type>
                <class>oracle.security.jps.service.policystore.ApplicationRole</class>
                <name>admin</name>
              </principal>
            </principals>
            <permissions>
              <permission>
                <class>oracle.adf.share.security.authorization.RegionPermission</class>
                <name>PURCHASE_ORDER_VIEWDETAILS</name>
                <actions>view</actions>
              </permission>
            </permissions>
          </grant>
        </jazn-policy>
      </application>
    </applications>
  </policy-store>
```
29.4 About Configuring Search Features

In addition to basic and advanced search, ECSF allows you to further improve the search experience with the Actionable Results and Faceted Navigation search features, which you must configure.

---

**Note:**

No configuration is required for integrating Saved Search functionality.

---

To configure search features, you can complete the following tasks:

- Define search result actions.
- Implement faceted navigation.

29.4.1 About Defining Search Result Actions

Associating actions with the searchable objects and exposing the action links in the search results allows Oracle Fusion Applications users to run specific actions on a given search result. You can either define actions as URLs so the user can then either go to a specific web page related to the search result, or define actions as references to ADF task flow definitions so the user can then launch a specific task on the search result. For more information, see How to Add Dynamic Main Area and Regional Area Task Flows to a Page. Figure 29-9 illustrates an example of the results of a filtered search.
Clicking the title (default action URL) opens the Sonoma - Elites page. An additional action link allows the user to e-mail the owner.

You can perform the following tasks to define search result actions:

- Add search result actions
- Modify search result actions
- Delete search result actions

Use the Search navigation tab of the overview editor in JDeveloper, shown in Figure 29-3, to define actions for search results.

To define search result actions for Oracle Fusion Applications Search, you must complete additional configuration tasks. For information, see How to Use the Actionable Results API with Search.

29.4.1.1 About the Access URL

During runtime, the Access URL allows Oracle SES and the end user to access the applications from the Query page. The Access URL contains the view object name, the row’s primary keys, and the action name, the values of which are used to look up the action definition, query for the record, evaluate action parameters, and construct target URLs. The Access URL also points to the Redirect Service.
29.4.1.2 Using the Redirect Service

The Redirect Service is used for resolving URLs and redirecting users to the resolved URL. Invoking the Redirect Service improves performance when attributes referenced in the action definition not stored in the index.

The redirect logic includes the following steps following a request:

1. Use the view object name and action name to look up the action definition.
2. Use the primary key values to query for the row in the database.
   
   Attribute values are obtained from search attributes. If an action refers to unstored attributes, primary keys are used to obtain their values during redirect.
3. Construct an indexable document from the row.
4. Resolve the URL.
   
   For task action type:
   
   • Look up the task and construct a TaskFlowID.
   
   • Look up the task parameters, if there are any.
   
   • For each task parameter, evaluate the parameter value by passing the field and value map and the expression into an evaluator, add it to the resolved parameters list, then construct the URL using the same ControllerContext.getTaskFlowURL API.
   
   For URL action type:
   
   • Evaluate the parameterized URL by passing the field/value map and the expression into an evaluator.
5. Redirect the user to the resolved URL.

29.4.1.3 Add Search Result Actions

Add search result actions to associate actions to searchable objects. The action links you define display with the search results.

To add search result actions, do the following:

1. In the overview editor, select the Search navigation tab.
2. Click the Add icon in the Search Result Actions table header to open the Search Result Actions dialog, shown in Figure 29-10.
3. In the **Name** field, enter a name for the action.

**Note:**
No two actions can share the same name. This comparison is case insensitive.

4. From the **Action Type** dropdown menu, select **Task** (default) to specify a task to be performed on the search result or select **URL** to specify a web page.

**Note:**
Only bounded task flows can be launched through the URL mechanism.

5. Perform one of the following:

- If you chose **URL** for Action Type in Step 4, then in the **Action Target** field, define the action by entering a Groovy expression that generates the URL that is invoked when the user clicks the action.

  For URLs that point to an external site, you must configure the target expression to generate a fully qualified URL, which includes both the protocol (such as `http://`) and the host name (for example, `example.com`).

  For internal link URLs that point to pages on the same application from which the search is performed, configure the target expression to generate a relative URL (for example, `/EmployeeDetailPage?empId=\(+\)EmpId`). Relative URLs are invoked relative to the current host name and port number. This allows for the action to succeed on any application server on which the search is running.

  You can also click the **Edit** icon next to the **Action Target** field to use the Edit Expression Editor dialog for entering the Groovy expression. For more information, see About Using Groovy Expressions in ECSF.
The URL must be no longer than 32,000 in length. You can reference only stored attributes. For example, you can enter "http://www.example.com/search?hl=en&q=" + SRCompanyZip.

**Caution:**
Using unstored attributes results in an exception at query time when the action is resolved. Also, do not refer to child documents when defining the action definition.

- If you chose Task for Action Type in Step 4, then leave the **Action Target** field blank. However, you must define the **TaskName** and **TaskFile** properties in the Action definition. For information, see **Defining Properties for Bounded Task Flows**.

6. In the **Title** field, enter a Groovy expression to be evaluated to a string for the desired display title of the action as you would like it to appear on the Search Results page. For more information, see **About Using Groovy Expressions in ECSF**.

You can also click the **Edit** icon next to the **Title** field to use the Edit Expression Editor dialog for entering a Groovy expression.

7. Select the **Default Action** checkbox to make this action the default action to be performed on the search results.

**Note:**
You can set only one action as the default action.

8. For tasks, enter a parameter name in the **Parameter Name** field and its corresponding value in the **Value** field, then click **Add**.

Enter parameter values as Groovy expressions. You can use only stored attributes (for example, **SRNumber**) as parameters.

**Note:**
Using unstored attributes results in an exception at query time when the action is resolved. Also, do not refer to child documents when defining the action definition.

You can also click the **Edit** icon next to the **Value** field to use the Edit Expression Editor dialog for entering a Groovy expression.

Minimally, the **TaskName** and **TaskFile** parameters must be provided. The value of the **TaskName** parameter is a Groovy expression that returns the name of the task (that is, a name surrounded by double quotation marks). The value of the **TaskFile** parameter is a Groovy expression that returns the name of the task definition file. Values of other parameters are Groovy expressions that return the desired value. These parameters are passed into the task. For more information, see **About Using Groovy Expressions in ECSF**.

9. To update an existing parameter, select the desired parameter in the table, change its value, then click **Update**.
10. To delete an existing parameter, select the desired parameter in the table and click **Delete**.

11. Click **OK**.

12. To create additional search result actions, repeat Steps 2 to 11.

13. Save the view object.

### 29.4.1.4 Defining Properties for Bounded Task Flows

For bounded task flows, you must define the **TaskName** and **TaskFile** properties in the Action definition of the searchable object file (`view_object_name_ECSF.xml`). The task definition file, containing the value for **TaskName**, is usually located in the WEB-INF folder.

Edit the **TaskFile** parameter to point to the bounded task flow task definition XML file, located in the WEB-INF folder. For example, `\WEB-INF\filename`.

To define the **TaskName** and **TaskFile** properties, do the following:

1. Locate the task definition file and note its location and filename, for example, `\WEB-INF\task-flow-definition.xml`.

2. Open the task definition file, locate the `<task-flow-definition>` element, for example, `<task-flow-definition id='task-flow-definition'>` and note the value of the `id` attribute.

3. Open the searchable object file and locate the **TaskFile** parameter, then edit the value to reflect the location and filename of the task definition file, for example, `\WEB-INF\task-flow-definition.xml`.

4. Locate the **TaskName** parameter and edit the value to reflect the `id` attribute value of the `<task-flow-definition> element of the task definition file, for example, 'task-flow-definition'.

5. Save the searchable object file.

### 29.4.1.5 Modify Search Result Actions

You can modify search result actions as needed to change the action links that display with the search results.

To modify search result actions, do the following:

1. In the overview editor, select the **Search** navigation tab.

2. Expand the **Search Result Actions** table header to expose the table of actions.

3. Select the action you want to modify. This highlights the entire row.

4. Click the **Edit** icon in the **Search Result Actions** table header to open the Search Result Actions dialog, shown in Figure 29-10.

   The information of the action you selected is displayed.

5. Make the necessary changes to the desired fields. For more information about the fields, see **Adding Search Result Actions**.
6. Click OK.

7. Save the view object.

29.4.1.6 Delete Search Result Actions

You can delete search result actions to remove action links that display with the search results.

To delete search result actions, do the following:

1. In the overview editor, select the Search navigation tab.

2. Expand the Search Result Actions table header to expose the table of actions.

3. Select the action you want to delete. This highlights the entire row.

4. Click the Delete (red X) icon in the Search Result Actions table header.

   The action you selected on the Search navigation tab is removed from the table of actions.

5. Save the view object.

29.4.2 What Happens When You Define Search Result Actions

JDeveloper captures the search metadata for each view object, including the search result actions you define, and writes it to an external XML file (searchable object) for consumption by the runtime component. Each searchable object corresponds to a view object and includes the search result actions. The file naming convention is view_object_name_ECSF.xml, and the file is created in the same location as its corresponding view object.

Caution:

Do not manually modify the contents of the view_object_name_ECSF.xml file. If you manually modify the search metadata in the XML file, the changes appear in the editor window when it is closed and reopened in JDeveloper, but metadata changes are not validated. Instead, use the Search page of the overview editor in JDeveloper to modify the search metadata.

The search result actions you define during design time is parsed at runtime and appear in a table on the search results page.

29.4.3 What You May Need to Know About Defining Search Result Actions

The Name, Action Type, Action Target, and Title fields are required fields. You must input values for all three fields to save the action.
29.4.4 How to Implement Faceted Navigation

Facets are used to filter search results by attribute. A facet must point to an attribute that contains a list of values (LOV) definition. The LOV defines a way to get a list of values that make up the potential values for the attribute and can be used to filter results. To implement faceted navigation, you must perform the following tasks:

1. Create a searchable object and set it up for facets:
   a. Create a view object (base object) and identify the attributes you want to bind to facets.
   b. Create a view object (LOV object) for each of the attributes you identified in Step 1a to get a list of available values for the attributes.
   c. Create a view accessor on the base object for each LOV object to be used as a facet, and assign each LOV object to its corresponding attribute.
   d. Define the facet hierarchy. Since the faceted navigation path is hierarchical, you must form the structure so that the LOV objects form one facet definition. For each LOV object to be used as child, create a bind variable and view criteria.
      While defining the facet hierarchy, you can constrain the LOV object by the stored attribute.

2. Create the facets.

To illustrate the process of defining LOVs for facets, consider the following scenario: You want to create facet relationships for the EmpView base object. EmpView contains two stored attributes, StateID and CityID, on which you want to create facets. "City" is the child facet of "State." The values shown in the "City" facet are constrained by the value selected for "State." This scenario is used in the tasks listed in this section.

You can also configure stored transient attributes on the view object to define:

- Facets that support number or date ranges.
- Facets based on the values of multiple attributes.

Related Links

The following document provides more information about the topic discussed in this section:

- For more information, see the "Working with List of Values (LOV) in View Object Attributes" section in Developing Fusion Web Applications with Oracle Application Development Framework.

29.4.4.1 Defining Lists of Values

Defining LOVs for stored view object attributes creates facet relationships for the base object and its stored attributes. The following procedure uses the example of the EmpView base object and its two stored attributes, StateID and CityID.

To define list of values for stored view object attributes, do the following:

1. Define a view object (StatesView) to represent a list of values for a view attribute (StateID).
2. Define a view accessor for StatesView (StatesView1) on EmpView.

The view accessor lets you obtain the full list of possible values from the row set of the parent view object.

**Note:**
When you design your view object for search, make sure that you configure view links to generate only the Destination Accessor and not the Source Accessor.

3. In the Edit Attribute dialog for the stored attribute (StateID), select List of Values and select Enable List of Values.

4. Create a mapping from a child attribute to the stored attribute.

Values from the child attribute are used to filter the parent view object.

5. Specify which attribute on the view object contains the display value.
   - In the Attribute Editor, select List of Values and select Edit List UI Hints.
   - In the List UI Hints dialog, add a child attribute to display. The first attribute value is used as the display value.

6. Repeat Steps 1 to 5 to define a view object (CitiesView) to represent the stored attribute that is defined as the child facet.

**29.4.4.2 Constrain View Objects by Stored Attributes**

Constraining the CitiesView object by StateID makes sure that only the cities of the selected state are returned. Configure the CitiesView1 view accessor on EmpView so that the view criteria on CitiesView is applied when the user queries using CitiesView1. Based on the view criteria, only cities where its parent StateID is equal to the value of EmpView.StateId (that is, the currently selected state) is returned.

To constrain CitiesView by State, do the following:

1. Define a bind variable on CitiesView (StId).

2. Create a named view criteria (CitiesViewCriteria) on CitiesView.
   - On the View Criteria page of the View Criteria Editor dialog, click the Add Item button.
   - In the Criteria Items panel, define the criteria as follows:
     - Attribute: ParStateId
     - Operator: equal to
     - Operand: Bind Variable
     - Parameter: StId
     - Usage: Required
3. Click the Edit button to edit the view accessor (CitiesView1) for CitiesView on EmpView.

In the Edit View Accessor dialog, select the view criteria (CitiesViewCriteria) in the Available list and click the Move icon to add it to the Selected list, as shown in Figure 29-11.

**Figure 29-11   Edit View Accessor Dialog**

4. Map the StId bind variable on CitiesView to the StateId attribute of EmpView.

5. Ensure that the row-level bind values exist.

29.4.4.3 About Creating Search Facets

Faceted navigation allows Oracle Fusion Applications users to narrow their search results by setting filters, based on a set of predefined facets. For example, users can narrow their search results first by country, then by state, and then by city.

Search facets follow a tree structure. The root facet appears above the tree control, followed by child facets. All facets contain a name and an attribute, and can contain a child facet.

**Note:**

If you require both custom SQL query and facets for a view object, you must create the view object with the Updateable object through entity objects option and select Expert for Query Mode on the Query page.
You can define facets by creating search facets, modifying search facets, deleting root search facets, and deleting child search facets. Use the Search navigation tab of the overview editor in JDeveloper, shown in Figure 29-3, to define facets for faceted navigation.

You can create search facets to specify the root facet, facet name, an attribute, and child facets. Use the Facets dialog to add search facets.

Before you begin, define LOVs for stored view object attributes. For information, see Defining Lists of Values.

29.4.4.3.1 How to Add Search Facets

To add search facets, do the following:

1. In the overview editor, select the Search navigation tab.

2. Click the Add icon in the Facets table header to open the Facets dialog, shown in Figure 29-12.

   Figure 29-12 Facets Dialog

3. In the Facet field, enter a valid facet name for the root facet.

   Note:
   No two facets can share the same name at the searchable object level. This comparison is case insensitive.

4. Click the icon next to the Facet Display Name field to open and use the Select Text Resource dialog for selecting a text resource from an existing resource bundle, or
for creating and selecting a new text resource. For more information, see Using the Select Text Resource Dialog to Select a Matching Text Resource or Using the Select Text Resource Dialog to Create and Select a New Text Resource.

**Note:**
If no facet display name is specified, the label text of the view attribute corresponding to the facet is used as the display name. If there is no label text, then the view attribute name is used as the display name.

You can use resource bundles to localize ECSF. For information, see About Localizing ECSF Artifacts.

5. From the **Attribute Name** dropdown menu, select a searchable attribute for the root facet.

**Note:**
The Attribute Name dropdown menu lists only the searchable attributes whose `isStored` property is set to `true`. For information, see How to Make View Object Attributes Searchable.

No two facets can share the same attribute at the searchable object level.

6. To add a child facet, click **Add Facet**.

The new child facet is inserted below the selected facet in the tree structure. Any existing child facets are moved below it to the next level down in the structure.

7. Enter a name for the child facet in the **Facet** field.

**Note:**
No two facets can share the same name. This comparison is case insensitive.

8. Select an attribute for the child facet from the **Attribute Name** dropdown menu.

**Note:**
No two facets can share the same attribute.

9. Repeat Steps 5-7 to add more child facets.

10. Click **OK**.

11. Save the view object.

**29.4.4.4 About Defining a Facet to Use a Child View Object Attribute**

You can use this feature to define facets to filter result records against a child VO attribute. Without this feature, facets could only allow users to filter search results to those results where an attribute in the result record matches a certain value, such as `Color="Red"`, or `Status="Open"`. This feature allows a Stored Attribute to be defined
against a child VO attribute and for a facet to be defined against this stored attribute. Thus, users will be able to filter search results such that only results whose child VO attribute matches a certain value will be returned.

ECSF design time uses transient attributes to allow child VO attributes as searchable attributes by allowing them in the facet definitions.

The Override Source property value is expressed at the view attribute level and it is resolved at both the query time and crawl time. The Override Source drop-down list (see Figure 29-7) is populated with all the attribute names from the view links that are associated with the current VO.

The code for querying for facets will not change. At query time, a FacetPath will be converted to filters against the corresponding Stored Attributes in the facet path. With this feature, some stored attributes will contain multiple values, and the filter will select a search document if any of the values in its stored attribute matches the value in the filter.

Facet counts will work without any changes. When a stored attribute contains more than one value, each value will contribute to incrementing the count for that value.

29.4.4.4.1 Set Up a View Object with Support for Child Attributes in Facets

To set up a view object, do the following:

1. Identify the attributes you want to bind to facets in the current VO.

2. Identify the attributes you want to bind to facets from the child VO and create transient attributes on the current VO for each child attribute. (This assumes that you already established a relationship between parent and child VOs using View Link Accessors.)

3. Create a view object (LOV object) for each of the attributes you identified to create a list of available values for the attributes.

4. Create a view accessor on the base object for each LOV object to be used as a facet, and assign each LOV object to its corresponding attribute.

5. Create searchable attributes based on the attributes you created, including transient attributes. Select the Stored option for the attributes.

6. For the transient attributes, select the corresponding child view attribute name from the Override Source drop-down list in the Searchable Attributes popup. See Figure 29-7.

7. Define the facet hierarchy.

29.4.4.5 Using the Select Text Resource Dialog to Select a Matching Text Resource

Use the Select Text Resource dialog to select a text resource from an existing resource bundle.

To select a matching text resource, do the following:

1. From the Facets dialog, click the icon next to the Facet Display Name field to open the Select Text Resource dialog.

2. Select a resource bundle from the Resource Bundle dropdown menu.
Note:
If there is no resource bundle associated with the view object, then an external resource bundle is created in the application. Save the new resource bundle externally.

3. Enter values in the Display Value, Key, and Description fields to narrow down the list of matching text resources.
4. Select the desired text resource in the Matching Text Resources table.
5. Click Select. Click the Clear Selection button to clear your selection.

29.4.4.6 Using the Select Text Resource Dialog to Create and Select a New Text Resource

Use the Select Text Resource dialog to create and select a new text resource.
To create and select a new text resource, do the following:

1. From the Facets dialog, click the icon next to the Facet Display Name field to open the Select Text Resource dialog.
2. Select a resource bundle from the Resource Bundle dropdown menu.

Note:
If there is no resource bundle associated with the view object, then an external resource bundle is created in the application. Save the new resource bundle externally.

3. In the Display Value field, enter a string or any type of object to associate with the key in the page's resource bundle.
4. In the Key field, enter a string to uniquely identify a locale-specific object in the resource bundle.
5. In the Description field, enter a description of any length for the key and value pair.
6. Click Save and Select.

29.4.4.7 Modify Search Facets

You can modify existing search facets by changing the values of the facet attribute fields, adding child facets, or deleting child facets. Use the Facets dialog to modify search facets.
To modify search facets, do the following:

1. In the overview editor, select the Search navigation tab.
2. Expand the Facets table header to expose the table of root facets.
3. Select the root facet you want to modify. This highlights the entire row.
4. Click the Edit icon in the Facets table header to open the Facets dialog, shown in Figure 29-12.
5. In the tree structure, select the facet you want to modify.

6. Make your desired changes:
   
   • Change the values of the Facet Attributes fields. For more information about the fields, see About Creating Search Facets.
   
   • Add child facets. For more information, see About Creating Search Facets.
   
   • Delete child facets. For more information, see Deleting Child Search Facets.

7. Click OK.

8. Save the view object.

29.4.4.8 Delete Root Search Facets

You can delete root search facets to remove them from the table on the Search navigation tab.

To delete root search facets, do the following:

1. In the overview editor, select the Search navigation tab.

2. Expand the Facets table header to expose the table of root facets.

3. Select the root facet you want to remove. This highlights the entire row.

4. Click the Delete (red X) icon in the Facets table header.

   The root facet you selected on the Search navigation tab is removed from the table of root facets.

5. Save the view object.

29.4.4.9 Delete Child Search Facets

You can delete child search facets to remove them from the facet tree.

To delete child search facets, do the following:

1. In the overview editor, select the Search navigation tab.

2. Expand the Facets table header to expose the table of root facets.

3. Select the root facet you want to modify. This highlights the entire row.

4. Click the Edit icon in the Facets table header to open the Facets dialog, shown in Figure 29-12.

5. In the tree structure, select the facet you want to delete.

6. Click Delete.

7. Click Yes, when prompted with "Are you sure you want to delete the facets?"

   The facet you selected is removed from the tree.

8. Click OK.
9. Save the view object.

29.4.4.10 Define Facets That Support Ranges

You can define facets to support ranges for numbers and dates.

To define facets that support ranges, do the following:

1. Configure on the view object a transient attribute that summarizes the numeric or date attribute value into a range code. For example, create a transient attribute named `AmountRange` that contains the following Groovy expression for the number attribute:

   ```groovy
   if (Amount > 0 && Amount < 100) 'Range1'; else if (Amount >= 100 && Amount < 200) 'Range2'; else 'Range3';
   ```

   For a date attribute, you can create a transient attribute named `HireDate` that contains the following Groovy expression:

   ```groovy
   if (Hiredate.getYear() >= 80 && Hiredate.getYear() < 90) '80s'; else if (Hiredate.getYear() >= 91 && Hiredate.getYear() < 100) '90s'; else '2000s';
   ```

2. Define a static LOV with the range codes and display values.

3. Associate the LOV to the transient attribute.

4. Create a facet with the transient attribute in the facet definition.

29.4.4.11 Defining Derived Facets

You can define facets that are based on the values of multiple attributes. For example, `Project Status=Active if Status is not Closed AND Start Date is after Today`.

To define facets that support ranges, do the following:

1. Configure on the view object a transient attribute to classify a record into some code. For example, create a transient attribute named `Status` that contains the following Groovy expression for the number attribute:

   ```groovy
   if (Status == 'Active' && Closed != null) 'Active'; else 'Inactive';
   ```

2. Define a static LOV with the codes and display values.

3. Associate the LOV to the transient attribute.

4. Create a facet with the transient attribute in the facet definition.

29.4.5 What Happens When You Implement Faceted Navigation

JDeveloper captures the search metadata for each view object, including the search facets you define, and writes it to an external XML file (searchable object) for consumption by the runtime component. Each searchable object corresponds to a view object and includes the search facets. The file naming convention is `view_object_name_ECSF.xml`, and the file is created in the same location as its corresponding view object.

At runtime, the search interfaces provided by ECSF allow users to iterate through facets and further filter the query by selecting facet values.
Caution:
Do not manually modify the contents of the view_object_name_ECSF.xml file. If you manually modify the search metadata in the XML file, the changes appear in the editor window when it is closed and reopened in JDeveloper, but metadata changes are not validated. Instead, use the Search navigation tab of the overview editor in JDeveloper to modify the search metadata.

29.4.6 What You May Need to Know About Implementing Faceted Navigation
Facets can only be defined on attributes in the parent or top-level view object because only attributes on the parent or top-level view object can be created as index attributes in the underlying Oracle SES index. For example, if you want to create an “address” facet consisting of the following tree, Country > State > City > Zip Code, all four attributes (country, state, city, zip code) must be view object attributes in the parent or top-level view object. Attributes that are used for facets must exist on the parent view object, not on a child view object linked to the parent through a view link. If any of the information is in a child attribute, then the attribute must be joined into the parent view object.

Since facets can filter against only a single search category, faceted navigation is not supported with federated search.

29.5 About Configuring Custom Properties for Searchable Objects
You can configure custom properties for searchable objects to modify default runtime behavior or to make searchable object public.

29.5.1 How to Modify Default Runtime Behavior of Searchable Objects
The following custom properties can be set for searchable objects through the overview editor to modify default runtime behavior:

- oracle.ecsf.crawl.batch.size
- oracle.ecsf.crawl.datafeed.size
- oracle.ecsf.max.links.depth
- oracle.ecsf.split.mode
- oracle.ecsf.split.threshold

These properties, described in Table 29-1, can also be set as system parameters to apply the values to all searchable objects. For information, see How to Modify the Run Configuration of the View-Controller Project.

To configure customer properties for searchable objects, do the following:

1. In the Application Navigator, open the desired view object.
2. In the overview editor, select the General navigation tab.
3. Expand the Custom Properties section.
4. Add property name and value pairs. For more information about the properties, see Table 29-1.
29.5.2 About Making Searchable Objects Public

Making searchable objects public allows users to perform searches without needing to log in first. Public data sources do not require any user authentication and can support anonymous users.

To make a searchable object public, define the custom property `oracle.ecsf.searchableobject.public`, as shown in Example 29-7, in the `view_object_name.xml` file.

When this value is set to true, the Security attribute values for anonymous user property of the data source deployed to Oracle SES from this searchable object is set to the ACL value or values retrieved from the searchable object's plug-in class.

**Example 29-7  Custom Property for Making Searchable Objects Public**

```xml
<Properties>
  <CustomProperties>
    <Property
      Name="oracle.ecsf.searchableobject.public"
      Value="true"/>
  </CustomProperties>
</Properties>
```
This chapter describes how to configure security for ECSF.

This chapter includes the following sections:

- Introduction to Configuring ECSF Security
- Securing ECSF Credentials
- About Authorizing Users for Search Feeds
- About Securing the Searchable Application Data

30.1 Introduction to Configuring ECSF Security

ECSF secures credentials and searchable application data. The credentials are required for the ECSF engine to communicate with Oracle Secure Enterprise Search (Oracle SES) administration service, Oracle SES query service, and ECSF Security Service. ECSF also uses Secure Socket Layer (SSL) to secure the connections through which the credentials are transmitted. ECSF stores the credentials in the Credential Store Framework (CSF) of the Oracle WebLogic Server domain.

Configure the HTTP protocol to restrict the maximum post and message size to prevent denial-of-service (DoS) attacks, which makes the servlets unavailable.

30.2 Securing ECSF Credentials

Passwords are stored in the Credential Store Framework (CSF) of the Oracle WebLogic Server domain. These passwords are used to perform secure interaction between the ECSF engine and the Oracle SES server.

30.2.1 About Adding the Permission Policy

When the ECSF Runtime Server or the ECSF Client library is added to the projects in Oracle JDeveloper, the permission policy, shown in Example 30-1, is automatically added within the <jazn-policy> tag of the application's jazn-data.xml file located in src/META-INF.

Credentials are stored under mapName oracle.ecsf, oracle.apps.security, and oracle.wsm.security with a key in the format: username#engineInstanceId (for example, scott#1, where scott is the user on engine instance 1).

When the application is deployed, the policies in jazn-data.xml are merged into the system-jazn-data.xml file in WebLogic_domain/config/fmwconfig on Oracle WebLogic Server.
Note:

The following security deployment options for the application must be configured in JDeveloper for the policies to merge: policies, credentials, and users/groups.

Make sure that the policy migrates to the target Oracle WebLogic Server domain.

Related Links

The following document provides more information about the topic discussed in this section:

- For more information, see the *Oracle Fusion Middleware Applications Securing Applications with Oracle Platform Security Services* guide.

**Example 30-1 Permission Policy**

```xml
<grant>
  <grantee>
    <codesource>
      <url>file:${domain.home}/servers/${weblogic.Name}/tmp/_WL_user/oracle.ecsf/-</url>
    </codesource>
  </grantee>
  <permissions>
    <permission>
      <class>oracle.security.jps.service.credstore.CredentialAccessPermission</class>
      <name>context=SYSTEM,mapName=oracle.ecsf,keyName=*</name>
      <actions>*</actions>
    </permission>
    <permission>
      <class>oracle.security.jps.JpsPermission</class>
      <name>IdentityAssertion</name>
      <actions>execute</actions>
    </permission>
  </permissions>
</grant>
```

### 30.2.2 How to Configure Application Identities for Search

Oracle Fusion Applications include six search-related application identities that are seeded and are stored in the identity store:

- `FUSION_APPS_CRM_SES_CRAWL_APPID`
- `FUSION_APPS_FSCM_SES_CRAWL_APPID`
- `FUSION_APPS_HCM_SES_CRAWL_APPID`
- `FUSION_APPS_CRM_ECSF_SEARCH_APPID`
- `FUSION_APPS_FSCM_ECSF_SEARCH_APPID`
- `FUSION_APPS_HCM_ECSF_SEARCH_APPID`
- `FUSION_APPS_ECSF_SES_ADMIN_APPID`

Each pair of application identities, one pair for each product family, are used to integrate ECSF with Oracle Fusion Applications. The Credential Store Framework (CSF) stores the credentials to access the identities.
However, if you are developing applications on the Integrated WebLogi
instance, then you must manually configure the application identities to inte
ECSF for the crawl users: SES_ADMIN_USERNAME, SES_QUERY_PROXY_USERNAME,
and ECSF_SECURITY_USERNAME.

Note:
To prevent duplication of crawls, crawling and indexing of searchable object
data into Oracle SES must be performed by one crawler user. The single
crawler user, specified in the search engine instance parameter
ECSF_SECURITY_USERNAME, must have access to all searchable object data to
be indexed.
The required setup of a user depends on the application setup and is not
controlled by ECSF. For example, Oracle Fusion Applications includes three
application IDs that are created for crawling data:
FUSION_APPS_CRM_SES_CRAWL_APPID,
FUSION_APPS_FSCM_SES_CRAWL_APPID, and
FUSION_APPS_HCM_SES_CRAWL_APPID. You must make sure that the
proper roles, permissions, privileges, and so on are granted to the three
application IDs so they have access to the data to be crawled.

To configure the application identities, you must complete the following tasks:

1. Make sure the SearchContext is set to FusionSearchContextImpl.
2. Create the application identities.
3. Make sure the permission policies for the identity store and the JPS
   IdentityAssertion API are added to the jazn-data.xml file.

30.2.2.1 About Setting the SearchContext to FusionSearchContextImpl
In order for ECSF to handle the application identities of Oracle Fusion applications,
the SearchContext must be set to FusionSearchContextImpl. The SearchContext is
automatically set at runtime based on the runtime environment. If the SearchContext
is not set properly, then set the context using the oracle.ecsf.context system
property, for example:

-Doracle.ecsf.context='oracle.ecsf.fusion.FusionSearchContextImpl
'

For more information, see How to Modify the Run Configuration of the View-
Controller Project.

30.2.2.2 About Creating the Application Identities
Each of the crawl users (SES_ADMIN_USERNAME, SES_QUERY_PROXY_USERNAME,
and ECSF_SECURITY_USERNAME) must correspond to an application identity. Use
Oracle Enterprise Manager Fusion Applications Control for ECSF to set the crawl user
names and their corresponding passwords. For information, see the “Managing Search
with Oracle Enterprise Crawl and Search Framework” chapter in the Administrator’s
Guide.

For example, set the user names for Oracle Fusion Customer Relationship
Management to:
When the user names are set, you can update the corresponding password parameters for those users to the key names for the application identities. The format of the key name is `fullAPPID-KEY`.

This creates entries in the cwallet with the correct map/key pairs for the users.

### 30.2.2.3 About Adding the Permission Policy for the Application Identities

In order for ECSF to read and write to the application identity maps in the keystore and access the JPS Identity Assertion API, permissions must be granted to the three crawl users. The permission policies, shown in Example 30-2, are seeded in the `jazn-data.xml` file for Oracle Fusion applications and can be managed in Fusion Applications Control.

The permissions allow ECSF to read and write credential store entries that are not part of the `oracle.ecsf` map.

#### Example 30-2 Permission Policies for Application Identities

```xml
<grant>
  <grantee>
    <codesource>
      <url>file:${domain.home}/servers/${weblogic.Name}/tmp/_WL_user/oracle.ecsf/-</url>
    </codesource>
  </grantee>
  <permissions>
    <permission>
      <class>oracle.security.jps.service.credstore.CredentialAccessPermission</class>
      <name>context=SYSTEM,mapName=oracle.ecsf,keyName=*</name>
      <actions>*</actions>
    </permission>
    <permission>
      <class>oracle.security.jps.service.credstore.CredentialAccessPermission</class>
      <name>context=SYSTEM,mapName=oracle.wsm.security,keyName=FUSION_APPS_FSCM_ECSF_SEARCH_APPID-KEY</name>
      <actions>*</actions>
    </permission>
    <permission>
      <class>oracle.security.jps.service.credstore.CredentialAccessPermission</class>
      <name>context=SYSTEM,mapName=oracle.wsm.security,keyName=FUSION_APPS_HCM_ECSF_SEARCH_APPID-KEY</name>
      <actions>*</actions>
    </permission>
    <permission>
      <class>oracle.security.jps.service.credstore.CredentialAccessPermission</class>
      <name>context=SYSTEM,mapName=oracle.wsm.security,keyName=FUSION_APPS_CRM_ECSF_SEARCH_APPID-KEY</name>
      <actions>*</actions>
    </permission>
    <permission>
      <class>oracle.security.jps.service.credstore.CredentialAccessPermission</class>
      <name>context=SYSTEM,mapName=oracle.apps.security,keyName=FUSION_APPS_CRM_SES_CRAWL_APPID-KEY</name>
      <actions>*</actions>
    </permission>
  </permissions>
</grant>
```
30.3 About Authorizing Users for Search Feeds

New grants are needed to authorize users for the search feeds. You must manually update the application's `jazn-data.xml` file located in `src/META-INF` to enable authorization for users. Add the grant, shown in Example 30-3, inside the `<application>` section in the `<jazn-policy>` section.

The grantee should be the users or roles that you want to authorize to use the search feeds, as shown in Example 30-4.

The example shows how `jazn-data.xml` is modified to grant the permission to a role.

**Example 30-3  Grant for Search Feeds User Authorization**

```xml
<permission>
  <class>oracle.adf.share.security.authorization.MethodPermission</class>
  <name>ECSF_All_Services</name>
  <actions>execute</actions>
</permission>
```

**Example 30-4  Granting Permission to a Role**

```xml
<grant>
  <grantee>
    <principals>
      <principal>
        <class>oracle.security.jps.service.policystore.ApplicationRole</class>
        <name>AuthorizedUserRole</name>
      </principal>
    </principals>
  </grantee>
  <permissions>
    <permission>
      <class>oracle.adf.share.security.authorization.MethodPermission</class>
      <name>ECSF_All_Services</name>
      <actions>execute</actions>
    </permission>
  </permissions>
</grant>
```
30.4 About Securing the Searchable Application Data

ECSF secures the searchable application data by authenticating and authorizing users who use ECSF to perform searches.

30.4.1 How to Secure the Searchable Application Data

Secure the searchable application data by enabling the use of the security model for authenticating and authorizing users.

To enable the use of the security model, do the following:

1. Create users in Oracle WebLogic Server. The user credentials are stored in Oracle WebLogic Server and can be used for authentication and authorization to query Oracle SES.

2. Create a separate user and add it to the Operators group to assign that user the Oracle WebLogic Server security role of Operator to obtain execute privileges on ECSF MBean operations.

3. Create an ECSF query proxy user. For more information, see the "Managing Search with Oracle Enterprise Crawl and Search Framework" chapter in the Administrator’s Guide.

4. Set the search engine instance parameters SES_QUERY_PROXY_USERNAME and SES_QUERY_PROXY_PASSWORD. For more information, see the "Managing Search with Oracle Enterprise Crawl and Search Framework" chapter in the Administrator’s Guide.

Note:

ECSF also supports allowing authenticated users to search business objects with no security policies attached to them.
This chapter describes how to validate and test search metadata. This chapter includes the following sections:

- Introduction to Validating and Testing Search Metadata
- About Validating the Search Metadata
- Testing Searchable Objects Through a Web Browser

### 31.1 Introduction to Validating and Testing Search Metadata

Search metadata is dependent on view object metadata, which is used in such areas as title, body expression, and searchable attributes. However, changes made to the view object metadata are not automatically reflected in the search metadata. To identify those changes, you must validate the search metadata by using the Validate button in the Search page of the Oracle JDeveloper overview editor for Oracle Enterprise Crawl and Search Framework (ECSF).

Testing the searchable objects ensures that they can be registered in the Oracle Fusion Applications database without issues.

### 31.2 About Validating the Search Metadata

To make sure that you are creating correct and valid search metadata on view object metadata, you must validate the metadata before applying changes. When you run validation on the search metadata, ECSF checks for the following:

- Table and alias of the primary table exists in the view object.
- Title, body, and keywords expressions are valid.
- Search extension is valid.
- Search attributes are valid, and all the search attributes exist in the view object.
- Search actions are valid:
  - Search action names are unique.
  - Default action exists. Warning is displayed when it does not exist.
  - Title expression is valid.
- Search facets are valid:
  - Facet name is unique.
31.2.1 How to Validate Search Metadata

Use the Search navigation tab of the overview editor in JDeveloper, shown in Figure 29-3, to validate search metadata. If you identify any errors (changes to the view object metadata that are not reflected in the search metadata), you must manually fix them.

To validate search metadata through the Validate button, do the following:

1. In the overview editor, select the Search navigation tab.

2. Click the Validate button.

If validation errors occur, the Search Validation Results dialog, shown in Figure 31-1, appears.

Figure 31-1 Search Validations Dialog

![Search Validation Results](image)

The dialog shows a list of validation errors.

3. Click OK when you finish viewing the errors.

31.3 Testing Searchable Objects Through a Web Browser

Before you register searchable objects in the Oracle Fusion Applications database, you should test the searchable objects by testing the Config Feed, Control Feed, and Data Feed.

ECSF prohibits multiple feeds per searchable object, so after achieving the desired results for the Config Feed, Control Feed, and Data Feed, you must reset the state of the feeds.

31.3.1 Perform Prerequisite Steps

Before you begin testing searchable objects, do the following:

1. Set the following Java option in the Run configuration dialog to test the searchable objects through a web browser: 

```java
-Doracle.ecsf.crawl.mode.debug=true
```

For more information, see How to Modify the Run Configuration of the View-Controller Project.
2. Set up ECSF security. For information, see Configuring ECSF Security.

3. Create searchable objects. For information, see Creating Searchable Objects.

4. Run the ECSF feed servlet. For information, see How to Run the ECSF Feed Servlet.

### 31.3.2 How to Run the ECSF Feed Servlet

Running the ECSF feed servlet in debug mode provides the servlet access to HTTP GET, the method that allows you to input URLs with arguments directly into the browser.

The web.xml file is automatically updated with the ECSF feed servlet, feed servlet mapping, and filter mappings as shown in Example 31-1 when the ECSF Runtime Server library is added to the project.

To ensure that the ECSF feed servlet runs properly, do the following:

1. Set the Application Navigator to display the Java archive (JAR) files and libraries by clicking the Navigator Display Options button in the Projects panel and selecting Show Libraries, as shown in Figure 31-2.

#### Figure 31-2 Navigator Display Options

2. In the Application Navigator, expand the ECSF Runtime Server library.

3. Expand the oracle.ecsf.feed package.

4. Right-click the SearchFeedServlet.class file and select Run to start the Integrated WebLogic Server instance. A browser opens to the following feed URL:

   http://localhost:7101/approot/searchfeedservlet/%2A
You can click the Terminate (red square) button to stop the ECSF feed servlet.

**Example 31-1  ECSF Feed Servlet, Feed Servlet Mapping, and Filter Mappings**

<servlet>
  <servlet-name>SearchFeedServlet</servlet-name>
  <servlet-class>oracle.ecsf.feed.SearchFeedServlet</servlet-class>
</servlet>

<servlet-mapping>
  <servlet-name>SearchFeedServlet</servlet-name>
  <url-pattern>/searchfeedservlet/*</url-pattern>
</servlet-mapping>

<filter-mapping>
  <filter-name>JpsFilter</filter-name>
  <servlet-name>SearchFeedServlet</servlet-name>
  <dispatcher>FORWARD</dispatcher>
  <dispatcher>REQUEST</dispatcher>
  <dispatcher>INCLUDE</dispatcher>
</filter-mapping>

<filter-mapping>
  <filter-name>ServletADFFilter</filter-name>
  <servlet-name>SearchFeedServlet</servlet-name>
  <dispatcher>FORWARD</dispatcher>
  <dispatcher>REQUEST</dispatcher>
</filter-mapping>

31.3.3 How to Test the Config Feed

To test the Config Feed, run the ECSF feed servlet with a modified URL.

1. Change the feed URL http://localhost:7101/approot/searchfeedservlet/%2A by:
   - Replacing localhost with the server name of the IP address.
   - Replacing %2A with the fully qualified name of the view object, including the package path.
   - Appending /ConfigFeed to the end of the URL.

   For example, if JDeveloper is running on the Linux server wllserver.com, and the fully qualified package path of EmpVO is oracle.ecsf.EmpVO (case-sensitive), the resulting Config Feed URL would be http://wllserver.com:8988/approot/searchfeedservlet/oracle.ecsf.EmpVO/ConfigFeed.

2. Refresh the web page.

   The resulting RSS feed, the Config Feed, should resemble the feed in Example 31-2.

   If the RSS feed does not appear, then either the runtime server is not set up properly or the path to the view object is incorrect. The URL is case-sensitive.
If no attribute exists for the `<securityAttribute>` tag, you must mark at least one searchable attribute as a Secure Attribute. For information, see About Making View Objects Searchable.

3. After adding the metadata, make sure to restart the Integrated WebLogic Server instance.

Example 31-2  Sample Results of the Config Feed

```xml
<rsscrawler xmlns="http://xmlns.example.com/search/rsscrawlerconfig">
  <feedLocation>http://localhost:8988/approot/searchfeedservlet/runtime.EmpView/ControlFeed</feedLocation>
  <feedType>controlFeed</feedType>
  <errorFeedLocation>/tmp</errorFeedLocation>
  <securityType>attributeBased</securityType>
  <securityAttribute name="DEPTNO" grant="true" />
</rsscrawler>
```

31.3.4 How to Test the Control Feed

To test the Control Feed, run the ECSF feed servlet with a modified URL.

1. Locate the URL provided in the `<feedLocation>` tag of the Config Feed. For information, see How to Test the Config Feed.

   In the Config Feed shown in Example 31-2, the URL is `http://localhost:8988/approot/searchfeedservlet/runtime.EmpView/ControlFeed`.

2. Change the feed URL by replacing localhost with the server name of the IP address.

   For example, if JDeveloper is running on the Linux server `example.com`, the resulting Control Feed URL would be `http://example.com:8988/approot/searchfeedservlet/runtime.EmpView/ControlFeed`.

3. Refresh the web page.

4. At the login screen, enter the username and password.

   The resulting RSS feed, the Control Feed, should resemble the feed in Example 31-3.

Example 31-3  Sample Results of the Control Feed

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<rss xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" version="2.0">
  <channel>
    <title>Control feed for ECSF</title>
    <link>http://example.com:8988/approot/searchfeedservlet/runtime.EmpView/ControlFeed</link>
    <description>Control feed for Enterprise Crawl and Search Framework</description>
    <lastBuildDate>2008-04-06T19:20:08.159Z</lastBuildDate>
    <channelDesc xmlns="http://xmlns.example.com/orarss">
      <feedType>control</feedType>
    </channelDesc>
    <item>
      <link>http://example.com:8988/approot/searchfeedservlet/runtime.EmpView/DataFeed?Testing Searchable Objects Through a Web Browser
Validate and Test Search Metadata  31-5
```
31.3.5 How to Test the Data Feed

To test the Data Feed, run the ECSF feed servlet with a modified URL.

1. Locate the URL provided in the <link> tag under the <item> tag of the Control Feed. For information, see How to Test the Control Feed.

   In the Control Feed shown in Example 31-3, the URL is http://example.com:8988/approot/searchfeedservlet/runtime.EmpView/DataFeed?tableName=Emp&workUnitStart=AAHz%2BdADeAAA07UAAA&workUnitEnd=AAHz%2BdADeAAA07UAAV&type=ROWID.

2. Refresh the web page with the URL.

3. At the login screen, enter the username and password.

   The resulting RSS feed, the Data Feed, should resemble the feed in Example 31-4.

Example 31-4 Sample Results of the Data Feed

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<rss xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" version="2.0">
  <channel>
    <title>RSS for Oracle Applications Search</title>
    <link>http://example.com:8988/approot/searchfeedservlet/runtime.EmpView/DataFeed</link>
    <description>RSS for Oracle Applications Search</description>
    <lastBuildDate>2008-04-06T19:36:08.950Z</lastBuildDate>
    <channelDesc xmlns="http://xmlns.example.com/orarss">
      <feedType>incremental</feedType>
    </channelDesc>
    <item>
      <link><![CDATA[http://ecsf.example.com/search/runtime.EmpView?EMPNO=7839]]></link>
      <title><![CDATA[KING: 5000]]></title>
      <itemDesc xmlns="http://xmlns.example.com/orarss">
        Employee department job salary data  KING
      </itemDesc>
    </item>
  </channel>
</rss>
```
### 31.3.6 How to Reset the State of the Feeds

Resetting the feed for the searchable object recrawls the object. Reset the state of the feeds by modifying the Config Feed URL.

1. Recall the Config Feed URL of the searchable object. For information, see [How to Test the Config Feed](#).
2. Append `?forceInitialCrawl=true` to the Config Feed URL, for example, `http://example.com:8988/approot/searchfeedservlet/runtim.eEmpView/ConfigFeed?forceInitialCrawl=true`
3. Paste the resulting URL in your browser and refresh the web page.
This chapter describes how to deploy searchable objects to the Oracle Enterprise Crawl and Search Framework (ECSF) application.

This chapter includes the following sections:

- Introduction to Deploying and Crawling Searchable Objects
- Deploying Searchable Objects and Dependencies
- About Crawling Searchable Objects

32.1 Introduction to Deploying and Crawling Searchable Objects

The ECSF application must include the searchable objects before you deploy it to the application server.

32.2 Deploy Searchable Objects and Dependencies

Searchable objects and their dependencies must be deployed as part of the ECSF application’s data model and user interface projects (Model and ViewController respectively) to make the searchable objects available for search. To deploy searchable objects, you must complete the following tasks:

1. Deploy the ECSF shared library to Oracle WebLogic Server.
2. Create an application.
3. If desired, change the application name and context root of the view-controller project.
4. Modify the run configuration of the view-controller project.
5. Add the ECSF Runtime Server library and the required Java archive (JAR) files to Model and ViewController.

32.2.1 About Deploying the ECSF Shared Library to Oracle WebLogic Server

The ECSF shared library eliminates the need for ECSF libraries to be packaged into each application. Instead, applications that depend on ECSF libraries can reference the ECSF shared library that is deployed to the Oracle WebLogic Server. The ECSF shared library contains the following Java archive (JAR) files:

- ecsf.jar
- search_admin_wsclient.jar
- search_client.jar
• ses_admin_ows_proxy.jar
• soap.jar

The ECSF extension in JDeveloper controls the reference to the ECSF shared library that is deployed to Oracle WebLogic Server. When you add the ECSF Runtime Server or ECSF Client library to a project, the reference to the ECSF shared library, shown in Example 32-1, is automatically added to the WebLogic deployment descriptor file (weblogic-application.xml).

The ECSF shared library is oracle.ecsf.

If the weblogic-application.xml file does not exist, one is created and updated with the reference to the ECSF shared library.

In addition, when you deploy an application to a Oracle WebLogic Server instance and the project contains ECSF libraries, the code checks the descriptor for the ECSF shared library reference. If no ECSF shared library reference is detected in the descriptor, one is added. The WebLogic deployment descriptor also contains a list of library dependencies for the application to be deployed to the Oracle WebLogic Server instance.

The ECSF shared library is automatically deployed to the Integrated WebLogic Server instance by the ECSF extension in JDeveloper through the JDeveloper Application Development Runtime Service (ADRS). However, you must manually deploy the ECSF shared library to the standalone WebLogic Server.

Example 32-1  Reference to the ECSF Shared Library

```xml
<library-ref>
  <library-name>oracle.ecsf</library-name>
</library-ref>
```

32.2.1.1 Update the SearchDB Data Source

The ECSF shared library is automatically deployed to the Integrated WebLogic Server instance by the ECSF extension in JDeveloper through the JDeveloper Application Development Runtime Service (ADRS). When the Integrated WebLogic Server instance is first started and the ECSF shared library is automatically deployed to it, the ECSF shared library creates a SearchDB data source in the Oracle WebLogic Server domain. The data source initially contains placeholder database connection information. You must manually update the data source after the Integrated WebLogic Server instance is started to include the correct connection information.

To update the SearchDB data source, do the following:

1. In the Domain Structure tree of the Oracle WebLogic Server Administration Console, navigate to Services, then JDBC, then Data Sources.
2. On the Summary of Data Sources page, click the data source name SearchDB.
3. Click the Connection Pool tab.
4. On the Connection Properties page, replace the default values for both the Connection URL and Properties boxes with valid connection values.
5. Click Save.
32.2.1.2 Deploy the ECSF Shared Library to the Standalone WebLogic Server Instance

You must manually deploy the ECSF shared library to the standalone WebLogic Server instance. The ECSF shared library creates a SearchDB data source in the Oracle WebLogic Server domain. During the process of deploying the ECSF shared library, you must provide the database connection information for the SearchDB data source, which is deployed with the shared library.

To deploy the ECSF shared library, do the following:

1. Extend the Oracle WebLogic Server domain by using the Oracle Fusion Middleware Configuration Wizard.
   For a Linux OS, execute:
   ```bash
   $WL_HOME/common/bin/config.sh
   ```
   For a Windows OS, execute:
   ```bat
   %WL_HOME%\common\bin\config.bat
   ```

2. Select the ECSF Shared Library Extension template (oracle.ecsf_11.1.1_template.jar), which is located in oracle/jdeveloper/common/templates/applications.

3. Configure the SearchDB data source by providing valid values for the following fields:
   - DBMS Host
   - DBMS Port
   - SID
   - Username
   - User Password

4. When a new version of the ECSF shared library is available, you must redeploy it.
   a. Remove the old oracle.ecsf library.
   b. Install the library enterprise archive (EAR) file (oracle/jdeveloper/ecsflibraries/oracle.ecsf_11.1.1/oracle.ecsf.ear) with the name set as oracle.ecsf.

Note:
You can also redeploy the ECSF shared library by using the Oracle Fusion Middleware Configuration Wizard.

32.2.2 How to Create an Application

Creating the application creates Model and ViewController, which must include the searchable objects and their dependencies.

To create a new application, do the following:
1. From the File menu, select New.
2. In the New Gallery dialog, select the General category and select Applications.
3. Select the Fusion Web Application (ADF) template and click OK.
4. In the Create Fusion Web Application (ADF) dialog, enter a name and location for the application in the Application Name and Directory fields.
5. Enter a value in the Application Package Prefix field.
6. Click Finish.

### 32.2.3 How to Change the Application Name and Context Root of the View-Controller Project

If desired, change the application name and context root of the view-controller project by modifying the Java EE application settings.

To change the Java EE application settings, do the following:

1. In the Application Navigator, right-click the view-controller project and select Project Properties.
2. In the Project Properties dialog, select Java EE Application in the left panel.
3. Change the value of the Java EE Web Application Name field to EcsfApp.
4. Change the value of the Java EE Web Context Root field to approot.
5. Click OK.

   The view-controller application name is set to EcsfApp, and the context root is set to approot.

### 32.2.4 How to Modify the Run Configuration of the View-Controller Project

Modify the run configuration of the view-controller project to run ECSF in debug mode.

To modify the run configuration, do the following:

1. In the Application Navigator, right-click the view-controller project and select Project Properties.
2. In the Project Properties dialog, select Run/Debug/Profile in the left panel.
3. Select Default in the Run Configurations list, then click the Edit button.
4. In the Edit Run Configuration dialog, select Launch Settings in the left panel.
5. If desired, enter additional parameter values in the Java Options field. Table 32-1 lists the ECSF system parameters. Separate each parameter with a space.
Note:
The parameters in Table 32-1 can be set in two ways:

- Add an entry to a file named `ecsf.properties`. If this file is found in the classpath by ECSF code, the property values in that file will be used. Entries in the file should be of the format:
  
  `property=value`

- Set the parameters using the Java System Properties. For example, add `-Dproperty=value` when starting the JVM.

If a property is found in both the `ecsf.properties` file and the Java System Properties, the value in the Java System Properties will be used. In other words, the Java System Properties have higher precedence.

These parameters values can also be specified at the searchable object level. For information, see About Configuring Custom Properties for Searchable Objects.

<table>
<thead>
<tr>
<th>Parameter Name</th>
<th>Java Command-Line Entry</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>oracle.ecsf.admin.dataobject.synchinterval</td>
<td><code>-Doracle.ecsf.admin.dataobject.synchinterval=n</code></td>
<td>Defines the interval (n), in milliseconds, for synchronizing the ECSF metadata in the cache with the ECSF metadata in the database. The default value is 30000 (30 seconds).</td>
</tr>
<tr>
<td>oracle.ecsf.connection.name</td>
<td><code>-Doracle.ecsf.connection.name=ConnectionName</code></td>
<td>Specifies the name of the database connection to be used. If not specified, SearchDB is used.</td>
</tr>
<tr>
<td>oracle.ecsf.context</td>
<td><code>-Doracle.ecsf.context=co</code></td>
<td>Defines the ECSF context to be used. The value can be set to <code>oracle.ecsf.fusion.FusionSearchContextImpl</code> for Oracle Fusion Applications; otherwise, the default ECSF context is used. The Oracle Fusion Applications search context handles Fusion specific details such as application identities.</td>
</tr>
<tr>
<td>oracle.ecsf.crawl.batch.size</td>
<td><code>-Doracle.ecsf.crawl.batch.size=n</code></td>
<td>Defines the data batch size within a data feed. The value determines the number of database rows (n) that are processed per batch within a data feed. The default size is 200.</td>
</tr>
<tr>
<td>oracle.ecsf.crawl.datafeed.size</td>
<td><code>-Doracle.ecsf.crawl.datafeed.size=n</code></td>
<td>Defines the size for the data feed. The value determines the number of documents (n) per data feed. The default size is 1000.</td>
</tr>
<tr>
<td>oracle.ecsf.datasource.name</td>
<td><code>-Doracle.ecsf.datasource.name=DataSourceName</code></td>
<td>Specifies the Java Database Connectivity (JDBC) data source name, such as <code>jdbc/SearchDBDS</code>.</td>
</tr>
<tr>
<td>Parameter Name</td>
<td>Java Command-Line Entry</td>
<td>Description</td>
</tr>
<tr>
<td>--------------------------------</td>
<td>-------------------------</td>
<td>-----------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>oracle.ecsf.datesplitter.mode</td>
<td>-</td>
<td>Defines the algorithm used to split the records in the table since the last crawled time. The value can be set to DateRowId or DateOnly. DateRowId is the default value. In DateRowId mode, it takes the records since the last crawled time and splits into evenly sized workunits using rowid ranges. In DateOnly mode, it splits into workunits based on date ranges only. This may result in workunits with too many records if there are many updated records within a short amount of time. In that case, using the DateRowId mode is recommended.</td>
</tr>
<tr>
<td>oracle.ecsf.maxfacetsdefvalues</td>
<td>-</td>
<td>Specifies the maximum number of values (n) that a facet may contain. ECSF does not return the values if a facet (for example, Country) contains several values (for example, USA, Canada, and so on) that exceeds the maximum. The default value is 1000.</td>
</tr>
<tr>
<td>oracle.ecsf.maxlinks.depth</td>
<td>-</td>
<td>Specifies the maximum number of view object hierarchy levels to limit the depth of search.</td>
</tr>
<tr>
<td>oracle.ecsf.service.ws.timeout</td>
<td>-</td>
<td>Specifies the ECSF web service invocation timeout (n) in milliseconds. The default value is 90000 (90 seconds). Increasing the timeout value can resolve issues related to a slow system environment.</td>
</tr>
<tr>
<td>oracle.ecsf.split.mode</td>
<td>-</td>
<td>Defines batching strategy. When the model is simple, no batching is used. Use for simple testing. The key is defined in RelationalCrawlerImpl. Its value can be db, simple, or nothing. This value defines how the crawler splits the database table. If specified with value simple, then SimpleSplitter is used. If specified with value db (default) or nothing (value is blank, or the parameter is not included at all), then RowIdSplitter is used.</td>
</tr>
<tr>
<td>oracle.ecsf.split.threshold</td>
<td>-</td>
<td>Sets the splitting algorithm threshold to the percentage you specify (n). If the percentage of records returned by the searchable object SQL query versus the total number of records in the searchable object's primary table is less than the threshold percentage, then the view object RowIdSplitter algorithm is used. Otherwise, the default RowIdSplitter algorithm is used.</td>
</tr>
<tr>
<td>oracle.ecsf.cache.expireseconds</td>
<td>-</td>
<td>Defines the time (n), in seconds, for items to expire from the cache. The default value is 1800 (30 minutes).</td>
</tr>
</tbody>
</table>
Table 32-1  (Cont.) ECSF System Parameters

<table>
<thead>
<tr>
<th>Parameter Name</th>
<th>Java Command-Line Entry</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>oracle.ecsf.cache.expireseconds.ObjectCache</td>
<td>- Doracle.ecsf.cache.expireseconds.ObjectCache=n</td>
<td>Defines the time (n), in seconds, for items to expire from the Searchable Objects cache. The default value is 24 hours.</td>
</tr>
<tr>
<td>oracle.ecsf.cache.expireseconds.FacetDefsCache</td>
<td>- Doracle.ecsf.cache.expireseconds.FacetDefsCache=n</td>
<td>Defines the time (n), in seconds, for items to expire from the Facet Definitions cache. The default value is 24 hours.</td>
</tr>
<tr>
<td>oracle.ecsf.cache.expireseconds.GroupCache</td>
<td>- Doracle.ecsf.cache.expireseconds.GroupCache=n</td>
<td>Defines the time (n), in seconds, for items to expire from the Searchable Group cache. This cache caches a Searchable Group using Engine Instance ID and Searchable Group name. The default is the value set by oracle.ecsf.cache.expireseconds.</td>
</tr>
<tr>
<td>oracle.ecsf.cache.expireseconds.GroupsCache</td>
<td>- Doracle.ecsf.cache.expireseconds.GroupsCache=n</td>
<td>Defines the time (n), in seconds, for items to expire from the Searchable Groups cache. This cache caches Searchable Groups using Engine Instance ID. The default is the value set in oracle.ecsf.cache.expireseconds.</td>
</tr>
<tr>
<td>oracle.ecsf.cache.expireseconds.EngineInstancesCache</td>
<td>- Doracle.ecsf.cache.expireseconds.EngineInstancesCache=n</td>
<td>Defines the time (n), in seconds, for items to expire from the Search Engine Instances cache. The default is the value set in oracle.ecsf.cache.expireseconds.</td>
</tr>
</tbody>
</table>

6. Click OK.

The run configuration is set to debug mode, and other ECSF system parameters are set.

32.2.5 About Adding the ECSF Runtime Server Library and Required Java Archive Files to the Model and View-Controller Projects

You must add the ECSF Runtime Server library and one of the following sets of required Java archive (JAR) files to both the Model and view-controller projects:

- For using ECSF for crawling and querying
  - oracle/wlserver_10.3/server/lib/wls-api.jar

- For using ECSF for querying only
  - oracle/jdeveloper/webservices/lib/soap.jar
Caution:

Make sure that `cwallet.sso` and `jazn-data.xml` are part of your application before adding the Java archive (JAR) files. You can do so through the Application Navigator by navigating to Application Resources, then Descriptors, then META-INF. The `cwallet.sso` file is created when you create a database connection. To create `jazn-data.xml`, right-click the META-INF folder select New Oracle Deployment Descriptor, select `jazn-data.xml`, and click Finish.

You do not need to add the Java archive (JAR) files that are included in a library that you have already added.

### 32.2.6 About Deploying the ECSF Application

After you update the Model and view-controller projects to include the searchable objects and dependencies, you must deploy the ECSF application. For information, see Setting Up Your JDeveloper Application Workspace and Projects.

### 32.3 About Crawling Searchable Objects

Make sure that the Oracle Secure Enterprise Search (Oracle SES) engine successfully crawls the searchable objects in the Oracle Fusion applications and indexes them as documents.

#### 32.3.1 How to Verify the Crawl

Use the Oracle Enterprise Manager Fusion Applications Control and Oracle SES administration user interface to verify the crawl.

**Note:**

The feed servlet must be running for Oracle SES to successfully crawl the data.

To verify the crawl, do the following:

1. Deploy the index schedule.
   
   For more information, see "Task 4: Deploy the Index Schedules" in Administrator’s Guide.

2. Start the index schedule.
   
   For more information, see "Task 5: Start the Index Schedules" in Administrator’s Guide.

3. Use the Oracle SES administration user interface to inspect whether the crawls were successful and verify how much data is crawled.
This chapter provides information on advanced topics for Oracle Enterprise Crawl and Search Framework (ECSF), including enabling and managing search, and troubleshooting ECSF.

This chapter includes the following sections:

- Introduction to Advanced Topics for ECSF
- About Enabling Search on Fusion File Attachments
- About Enabling Search on WebCenter Tags
- About Enabling Search on Tree-Structure-based Source Systems
- About Managing Recent Searches
- Setting Up Federated Search
- About Federating Instances
- About Raising Change Events Synchronously
- About Using the External ECSF Web Service for Integration
- About Localizing ECSF Artifacts
- About Using ECSF Diagnostics
- About Troubleshooting ECSF

### 33.1 Introduction to Advanced Topics for ECSF

ECSF offers additional functionality to enhance the search experience. In addition to search on business objects, ECSF supports search on Fusion file attachments, WebCenter tags, and tree structure-based source systems. ECSF also allows you to set up federated search so that users can search across Oracle Fusion Applications product families or across multiple Oracle Secure Enterprise Search (Oracle SES) instances.

Advanced topics also include using the external ECSF web service to integrate ECSF with Oracle Fusion Applications, implementing Coherence cache for search, localizing ECSF artifacts for international users, and information for troubleshooting ECSF.

### 33.2 About Enabling Search on Fusion File Attachments

ECSF supports the capability to crawl Oracle Fusion Applications file attachments that are associated with ECSF searchable objects and stored in the Oracle WebCenter Content repository.
33.2.1 How to Make File Attachments Crawlable

References to files in the content repository are stored in a special database table and are retrieved by using a view object named `oracle.apps.fnd.appcore.attachments.uiModel.view.AttachmentsVO`. Using a view link, you can make the `AttachmentsVO` a child of another view object. If a searchable object has a child `AttachmentsVO`, then ECSF automatically makes sure that the attachments are crawled when the searchable object is crawled.

At the time the searchable object is crawled, ECSF includes a content link in the document that is sent to Oracle SES for each attachment. When Oracle SES receives the data feed and finds the content link, it calls back to ECSF to retrieve the content of the attachment. ECSF then invokes an application programming interface (API) method that retrieves the attachment content from the content server and returns it to Oracle SES. Oracle SES indexes the searchable object and attachment content as one item.

The API handles authentication and authorization.

To make file attachments crawlable, do the following:

1. Add the Applications Core (Attachments) library to your project.
   
   This adds the `Attachment-Model.jar` and `Common-Model.jar` files, located in `JDEV_HOME\jdeveloper\jdev\oaext\adflib`, to your projects.

2. Create a view link between the searchable object and the `AttachmentsVO` to make `AttachmentsVO` a child of the searchable object.

   **Note:**
   
   When you design your view object for search, make sure that you configure view links to generate only the Destination Accessor and not the Source Accessor.

3. On the searchable object, define a view link accessor that points to the view link. For information, see How to Create Attachment View Links.

33.3 About Enabling Search on WebCenter Tags

ECSF supports the capability to crawl searchable objects with Oracle WebCenter Portal tags so that tags can be used as keywords or filters for search in Oracle Fusion Applications. A tag is a meaningful term attached to an object. Tags can be used for various purposes such as categorization, to-dos, and priorities.

**Note:**

ECSF does not support search using private tags.

Tags are single words stored as space-separated strings in the application database and are retrieved by using a view object called `TagSVO` (service view object). You must create a view link to make `TagSVO` a child object. At crawl time, the view link is used to locate `TagSVO`. Figure 33-1 illustrates crawl time with tags.
Purchase Order 123 has two tags, *Computer* and *Dell*. ECSF adds the tags for each record of the searchable object to the indexable document before the document is sent to Oracle SES for indexing. ECSF also creates a reserved attribute (of type string) called *ECSF_TAGS* to store tags in Oracle SES.

At query time, users can specify tag values as keywords or as filters. When tag values are input as keywords, the tag value is treated as a query string and returns results that include the objects with the specified tag. When tag values are used as filters, the tags are added to *QueryMetaData* and the query is run with filters on *ECSF_TAGS*. Only the objects with the specified tags are returned. *Figure 33-2* and *Figure 33-3* illustrates the difference between query time without a tag and query time with a tag.

**Note:**

Tags cannot be searched as individual entities.
In Figure 33-2, the indexed document for Purchase Order 123 contains two tags, Computer and Dell. The query on John returns all the documents that contain John. The results display the title, body, and all tags for the documents.
In Figure 33-3, query on the Purchase Order John and tag Dell returns only the documents that contain John AND the Dell tag. The results display the title, body, and all tags for the documents. If both Dell and Computer were specified as tags, then the query would return only the documents that contain both tags (that is, Dell AND Computer). You cannot specify tags using the OR condition (that is, Dell OR Computer), so the query cannot return documents that contain either the Dell tag or the Computer tag.

Enabling search on WebCenter Portal tags allows tags to be added to indexable documents and stored in the reserved attribute called ECSF_TAGS in Oracle SES. Tags can then be used as keywords or filters for search.

33.3.1 How to Enable Search on WebCenter Portal Tags

Perform the following tasks to enable search on WebCenter Portal tags:

1. Create a view link between the searchable object and the TagSVO. For information, see How to Implement Tags in Search.

   **Note:**

   When you design your view object for search, make sure that you configure view links to generate only the Destination Accessor and not the Source Accessor.

   The view link must use the accessor name TagSVO so that the search extension can navigate to the child object when it crawls.
2. Add tags to the indexable document.
3. Add tags to the query.

### 33.3.2 How to Customize Search on WebCenter Portal Tags

You can also perform the following tasks to customize search on WebCenter Portal tags:

1. Modify the tags in the indexable document.
2. Register change listeners.

### 33.3.3 How to Add Tags to Indexable Documents

To crawl tags, you must use Tag APIs to add tags to indexable documents. You can use Tag APIs in the search extension code.

To add tags, do the following:

1. Create a search extension that extends `DefaultSearchPlugin`, implements `PreIndexProcessor`, and includes a method called `preIndexProcess` that adds tags to some objects.

   **Note:**
   If you place the search extension in the Oracle WebLogic Server shared library, then the ECSF library (`ecsf.jar`) must be present in the shared library in order for ECSF to load the `PreIndexProcessor` interface.

2. Redeploy and crawl the objects.

#### Example 33-1  Sample Code for Adding Tags to Indexable Documents

```java
public class runtime.TestPlugin extends DefaultSearchPlugin implements PreIndexProcessor {
    public void preIndexProcess(SearchContext ctx, List<IndexableDocument> documents) {
        for (IndexableDocument doc : documents) {
            Object ename = doc.getFieldValue("ENAME");
            if (ename != null && "Zebra".equalsIgnoreCase(ename.toString())) {
                doc.addTags(new String[] { "Black", "White", "Stripes" });
                //doc.getTags and doc.clearTags can also be used here
                for (String tag : doc.getTags()) {
                    system.err.println(tag); // print out tag to stand err
                }
            }
        }
    }
}
```

You can implement code, such as the sample code shown in `Example 33-1`, in the search extension to extend `DefaultSearchPlugin`.

This extension adds three tags (`Black`, `White`, and `Stripes`) to a user named `Zebra`. 
33.3.4 About Adding Tags for Querying

After tags are crawled into Oracle SES, you can perform keyword searches on tags or filter on tags. QueryMetaData accepts tags for querying. When one or more tags are added to QueryMetaData, the query runs with filters on ECSF_TAGS.

Example 33-2 illustrates how tags are used for querying.

Adding tags for querying forces the query to find results where indexed documents contain the added tags. When more than one tag is added, the resulting documents must contain both tags. Documents containing only one of the tags are not returned.

Query SES retrieves tags all the time. The searcher adds tags to IndexedDocument by using setTags. In case of null in the attribute, no tags are added. IndexedDocument.getTags returns all the tags in the document.

Example 33-2 Sample API for Querying With Tags

```java
public void tagTest()
{
    SearchCtrl searchCtrl = new SearchCtrl();
    SearchHits searchHits = null;
    SearchContext searchContext = null;
    QueryMetaDataImpl queryMetaData = new QueryMetaDataImpl();
    queryMetaData.setQueryString("%");
    queryMetaData.setPageSize(10);
    queryMetaData.setCurrentPage(1);
    String engineInstName = "SES";
    String groupName = "runtime.EmpView";
    SearchGroup[] sgs = new SearchGroup[]
        {searchCtrl.getSearchGroup(engineInstName, groupName);
            queryMetaData.setSearchGroups(sgs);
            searchContext = ContextFactory.getSearchContext();
            searchContext.bindUser("scott");
            try
            {
                //clear tags so query tag through keywords
                queryMetaData.clearTags();
                queryMetaData.setQueryString("Black White");
                searchHits = searchCtrl.runQuery(searchContext, queryMetaData);
                //Zebra is found

                //filter by tags
                queryMetaData.setQueryString("%");
                queryMetaData.addTag("White");
                searchHits = searchCtrl.runQuery(searchContext, queryMetaData);
                //Mickey is found

                //filter by tags
                queryMetaData.addTag("White");
                queryMetaData.addTag("Black");
                searchHits = searchCtrl.runQuery(searchContext, queryMetaData);
                //Zebra is found

                //filter by tag that exists and tag that does not exist
                queryMetaData.clearTags();
                queryMetaData.addTag("Stripes");
                queryMetaData.addTag("Dots");
                searchHits = searchCtrl.runQuery(searchContext, queryMetaData);
                //no result is found
```
33.3.5 About Modifying Tags in Indexable Documents

You can override tags in the lifecycle methods provided by ECSF. For example, if required, you can add tags to an indexable document in the `IndexablePostProcess` by using the APIs provided on the `IndexableDocument`:

- `void addTags(String[] tags)` adds a list of strings as tags to the document. Duplicates are removed.
- `Collection<String> getTags()` returns a list of tags associated with the document.
- `void clearTags()` clears tags associated with the document.

33.3.6 About Registering Change Listeners

You can extend the incremental crawling mechanism by registering change listeners, which use the WebCenter Portal tagging framework to identify objects that need to be updated in the search engine. Implement the `oracle.ecsf.ChangeListener` interface in a search extension to customize the runtime logic that detects changes in the searchable objects. Example 33-3 illustrates a sample implementation of `ChangeListener`.

The method `Iterator getChangeList (SearchContext ctx, String changeType)` returns an iterator (`ChangeIterator`) over a list of primary keys for the searchable object (`ctx.getSearchableObject`).

The primary keys returned from the change listener are logged in the ECSF change log table before an incremental control feed is constructed.

**Example 33-3    Sample Implementation of ChangeListener**

```java
public class TestPlugin extends DefaultSearchPlugin implements ChangeListener {
    public Iterator getChangeList(SearchContext ctx, String changeType) {
        return new MyChangeIterator(ctx, changeType);
    }
}

public class MyChangeIterator extends ChangeIterator {
    private Date lastTimeCrawled;
    private int mCount;
    private int mIndex = 0;

    public MyChangeIterator (SearchContext ctx, String changeType) {
        super(ctx, changeType);
        Date lastTimeCrawled = ctx.getSearchableObject().getLastTimeCrawled();
        //if this value is null, ECSF is doing an initial crawl
        if(lastTimeCrawled==null)
33.4 About Enabling Search on Tree-Structure-based Source Systems

In addition to supporting the crawling and searching of relational-based objects through view objects or Java Database Connectivity (JDBC), ECSF supports the capability to crawl data in hierarchical tree-based data structures, or tree structures, and to identify items for indexing to enable full-text search. A tree structure is a common data structure, such as a file system on a computer hard disk, used to organize a large number of items. Oracle Business Intelligence is an example of a source system that is organized in a tree structure.

By default, ECSF supports database crawling using Oracle ADF technology. To support crawling data that is organized in tree structures, you can extend the abstract implementation of the CrawlableFactory oracle.ecsf.data.tree.AbstractTreeWalker. The extension converts the data stored at tree nodes into documents that Oracle SES receives through Really Simple Syndication (RSS) feeds and indexes.

Note:
Crawling relies on the integrator’s implementation that is based on their underlying data structures and accessibility of the items to be indexed.

Note:
ECSF currently does not provide an interface for converting information in source systems to indexable documents. It is assumed that data structures of an indexable item are proprietary to the source system, and the interface for converting an item pertaining such a structure to indexable document are the responsibility of the integrator.

A searchable object holds metadata about the source system. It can be either an Oracle ADF view object with ECSF annotation or a class that extends oracle.ecsf.meta.SearchableObject. For tree structure-based source systems,
the searchable object is not view object-based, so ECSF does not load the view object. Instead, it loads a Java class that extends and implements the searchable object. When requested with a ConfigFeed URL, ECSF identifies the searchable object that holds the search metadata required by ECSF. Non-view object-based searchable objects can be grouped into search categories. Figure 33-4 illustrates the data flow for search on tree structure-based source systems.

**Figure 33-4** Data Flow for Search Using ECSF Tree Crawler

The integration of ECSF with the source system allows an Oracle SES instance to crawl the source system data. The Source System DataNode, which is exposed to the ECSF tree crawler, formulates the data structure and pulls data from the source system server using web services. ECSF converts the tree nodes into documents that Oracle SES receives through RSS feeds and indexes. The source system implements a security service. When data from the source system is indexed in the Oracle SES, it is guarded against access by the security service.

A security extension is needed to implement source and document-level security. A searchable object has a method of getting a search extension instance based on the metadata. To associate a search extension with a searchable object, configure it from the Search navigation tab of the overview editor in JDeveloper. For more information, see About Making View Objects Searchable.

ECSF also extends its attachment implementation to enable the implementer to open the stream for data pulling attachments that are associated with a particular node. For more information, see About Enabling Search on Fusion File Attachments.
33.4.1 How to Enable Search on Tree-Structure-Based Source Systems

Enable search on tree structure-based source systems by doing the following:

1. Crawling tree structures
2. Integrating search functionality for tree structures
3. Implementing administration using ECSF interfaces

33.4.2 How to Crawl Tree Structures

ECSF offers Java classes that provide support for traversing tree-structure-based data sources and identifying items for indexing.

Before you begin, install the ECSF seed data records in the ECSF schema of the Oracle Fusion Applications database using Seed Data Framework (SDF). For information, see Initializing Oracle Fusion Application Data Using the Seed Data Loader.

To implement search for tree-structure-based data sources, complete the following tasks:

1. Create a searchable object by extending the oracle.ecsf.data.tree.SearchableTreeObject class.
2. Implement a crawlable tree node to extract document metadata.
3. Extend AbstractTreeWalker to traverse the tree.
4. Implement security.
5. Implement the attachments interface to stream the documents to Oracle SES.
6. Deploy and start the ECSF servlet.
7. Configure Oracle SES to crawl ECSF.

33.4.2.1 About Creating a Searchable Object

Create a searchable object by extending the oracle.ecsf.data.tree.SearchableTreeObject class, as shown in Example 33-4. When you create a searchable object for a tree object, you create a Java class, the SearchableTreeDirectory class, that is part of your implementation Java archive (JAR) file.

You must override the initializeConfig method to create search metadata dynamically for your searchable object, including adding a custom attribute, setting the security plug-in class name, and so on.

You must override getCrawlableFactoryName() to return the class name of your extension of AbstractTreeWalker.

Override getFileName if you want to persist the last crawled timestamp in a particular location.

For information, see About Extending AbstractTreeWalker.

Example 33-4 Sample Code for SearchableTreeDirectory Class

```java
package oracle.ecsf.test.tree;
import oracle.ecsf.data.tree.SearchableTreeObject;
```
public class SearchableTreeDirectory extends SearchableTreeObject {
    //override the security plug to be used
    public void initializeConfig() {
        setPlugInName(SecurityPlugin.class.getName());

        //add a custom attribute
        //see processNode method where you must set attribute value
        //for this attribute for the indexable document
        DocumentDefinition docdef = this.getDocument();
        FieldDefinitionImpl field = new FieldDefinitionImpl("CUSTOM_ATTR");
        field.setBinding("CUSTOM_ATTR");
        //this flag indicates that this attribute be stored in SES
        field.setStored(true);
        docdef.addField(field);
    }

    //override the crawlable factory to be used
    public String getCrawlableFactoryName() {
        return FileTreeCrawler.class.getName();
    }

    //override the method to get the location and the name of the last crawled
timestamp file
    //this is optional, if it is not overridden, the default location is the
    //temporary directory of the
    //system, that is, in unix/linux, it is "/tmp" and in Windows, it is "c:/temp";
    //the default file name is
    //".ecsf." concatenated with the object name, in this case
    "oracle.ecsf.test.tree.SearchableTreeDirectory"
    public String getFileName() {
        return ".\ecsf.oracle.ecsf.test.tree.SearchableTreeDirectory";
    }
}

33.4.2.2 About Implementing a Crawlable Tree Node

A crawlable tree node represents a node in your tree structure. When crawled, each
node on the tree structure is wrapped in this object. This node is created by the
extension of AbstractTreeWalker. For more details on each method, see the
Javadoc for ECSF.

Implement a crawlable tree node by extending the
oracle.ecsf.data.tree.CrawlableTreeNode class to create a tree node class
called CrawlableTreeNodeImpl, as shown in Example 33-5, for extracting
document metadata. The tree node class models the tree structure repository.

In the processNode method, you must extract any metadata information about the
document (for example, setTitle, setKeyword, setContent) and populate the
indexable document that is passed in. You can also add any custom attributes to the
indexable documents, such as the isLeaf method that determines whether a node is a
folder or a document. This method is used by the crawlable factory to determine how
to traverse the tree.

Example 33-5    Sample Code for CrawlableTreeNodeImpl Class

package oracle.ecsf.data.tree;
import java.io.BufferedReader;
import java.io.File;
import java.io.FileReader;
import java.io.IOException;
import java.util.Date;
import oracle.ecsf.IndexableDocument;
import oracle.ecsf.meta.PrimaryKey;
import oracle.ecsf.data.tree.CrawlableTreeNode;

public class CrawlableTreeNodeImpl extends CrawlableTreeNode {
    String[] filesToHandle = new String[] {"java", "xml"};
    private File file;
    // Creates a node with a fully qualified name.
    public CrawlableTreeNodeImpl(String name) {
        super(name);
        file = new File(name);
        this.setPath(file.getPath());
        this.setName(file.getName());
    }
    // Internal. Determine whether a file should
    // be indexed.
    private boolean handleFile(File file) {
        if (file == null)
            return false;
        if (file.isDirectory())
            return false;
        for (String ext : filesToHandle) {
            if (file.getName().endsWith(ext))
                return true;
        }
        return false;
    }
    // Test if a file must be indexed.
    public boolean isIndexable() {
        return handleFile(file);
    }
    /*
     * Gets the last modified date.
     */
    public Date getLastModified() {
        if (file == null) {
            return null;
        } else {
            return new Date(file.lastModified());
        }
    }

    public void processNode(IndexableDocument doc) {
        try {
            StringBuffer indexContent = new StringBuffer();
            FileReader fileReader = new FileReader(file);
            BufferedReader br = new BufferedReader(fileReader);
            String strd = br.readLine();
            while (strd != null) {
                indexContent.append("\n" + strd);
                strd = br.readLine();
            }
            if (file.getName().endsWith("xml")) {
                PrimaryKey keys = new PrimaryKey();
                keys.put("Name", file.getName());
                keys.put("Path", file.getPath());
                doc.addAttachment(new AttachmentImpl(keys));
            }
            br.close();
        }
    }
}
fileReader.close();
doc.setContent(indexContent.toString());
doc.setFieldValue("CUSTOM_ATTR", "This is custom attributes to be saved in SES");
doc.setAttributeValue("CUSTOM_ATTR", "This value is custom attribute value");
doc.overrideAccessURL("path=" + file.getPath() + ";name=" + file.getName());
} catch (Exception e) {
    //handle errors
}

protected void init()
{
    super.init();
    if (!isLeaf())
    {
        File[] files = file.listFiles();

        if (files != null)
        {
            for (int i = 0; i < files.length; i++)
            {
                addChildNode(new CrawlableTreeNodeImpl(files[i].getAbsolutePath()));
            }
        }
    }
}

private static boolean isLink(File file) {
    try {
        if (!file.exists()) {
            return true;
        } else {
            String cnnpath = file.getCanonicalPath();
            String abspath = file.getAbsolutePath();
            return !abspath.equals(cnnpath);
        }
    } catch (IOException ex) {
        System.err.println(ex);
        return true;
    }

    public boolean isLeaf() {
        return file == null || !file.isDirectory() || isLink(file);
    }

33.4.2.3 About Extending AbstractTreeWalker

To provide the methods that enables Oracle SES to traverse tree structures and index the content items, extend AbstractTreeWalker by creating the abstract tree crawler class, called FileTreeCrawler, as shown in Example 33-6. FileTreeCrawler is invoked as a factory to create a crawlable tree node as defined in About Implementing a Crawlable Tree Node. The tree walker works with CrawlableTreeNode to provide the generic framework for traversing a tree structure and indexing the content items in the repository. It also uses TreeSplitter to divide the repository into branches to enhance the crawling performance.

When Oracle SES crawls the searchable object, an instance of FileTreeCrawler is created by ECSF. It traverses the tree structure by calling the methods defined in the FileTreeCrawler class. It goes through two passes. First, it collects only the structure information, and based on that, it forms a control feed that contains all the
folders that need to be visited for collecting documents. The `isIndexable` method determines whether a particular node is indexed by Oracle SES. You can also use it to place filters to control the type of document to be indexed.

When creating the `FileTreeCrawler` class, you must implement two constructors. One takes no parameters, and the other takes a searchable object where you can perform configurations specific to your application, if required.

**Example 33-6 Sample Code for FileTreeCrawler Class**

```java
package oracle.ecsf.data.tree;

import oracle.ecsf.meta.SearchableObject;

public class FileTreeCrawler extends AbstractTreeWalker {
    //
    // The application determine the root path.
    //
    String root="/home/cbrown";
    /**
    * Constructs a CrawlableFactory from a searchable object.
    */
    public FileTreeCrawler()
    {
        super();
    }

    public FileTreeCrawler(SearchableObject searchableObject)
    {
        super(searchableObject);
    }

    // Creates root node
    //
    public CrawlableTreeNode createCrawlable() {
        return new CrawlableTreeNodeImpl(root);
    }

    // Creates a node for a given path
    // if you cannot construct the path.
    //
    public CrawlableTreeNode createCrawlable(String path) {
        return new CrawlableTreeNodeImpl(path);
    }

    // Tests if a node is crawlable
    protected boolean isIndexable(CrawlableTreeNode node) {
        CrawlableTreeNodeImpl fNode = (CrawlableTreeNodeImpl) node;
        return fNode.isIndexable();
    }
}
```

### 33.4.2.4 About Implementing Security

Security rules on the documents indexed by Oracle SES is controlled by access control lists (ACLs). This is achieved by creating a search plug-in that implements the `oracle.ecsf.Secure` interface for the searchable object. When you implement a security extension for the searchable object, it is used to serve as the authorization module for indexed content in Oracle SES.
ECSF is secured by a pluggable security service, which is called when users try to search the indexed content. By default, ECSF provides an implementation based on Oracle Platform Security for Java. It is mainly used for authenticating and authorizing users into the system. However, if you have a non-Oracle security provider, or you want to use your own security implementation, you must extend the ECSF security service. Example 33-7 illustrates the skeleton of a security extension.

The security extension is a Java class that implements a securable interface. There are five methods available. Example 33-8 illustrates the skeleton of such class.

Your search plug-in must be assigned to the searchable object, as shown in Example 33-4.

**Example 33-7  Sample of Security Service**

```java
package oracle.ecsf.data.tree;

import oracle.ecsf.SearchContext;
import oracle.ecsf.SecurityService;
import oracle.ecsf.util.SecurityServiceFactory;

public class SecurityServiceImpl implements SecurityService{

    public String[] listSupportedFormats() {
        return new String[]{"BIEE"};
    }

    public String authenticate(SearchContext ctx, String userName, String password, String format) {
        return userName;
    }

    public String isUserValid(SearchContext ctx, String userName, String format) {
        return userName;
    }

    public String[] getSecurityValues(SearchContext ctx, String userName, String attrName, String objectId) {
        //Get keys for an attribute.
        return new String[]{};
    }
}
```

**Example 33-8  Sample Security Extension**

```java
package oracle.ecsf.data.tree;

import oracle.ecsf.IndexableDocument;
import oracle.ecsf.SearchContext;
import oracle.ecsf.SearchSecurityException;
import oracle.ecsf.Securable;

public class SecurityPlugin implements Securable{

    public boolean isAclEnabled(SearchContext ctx) {
        return true;
    }
}
```
// The ACL for the document
public String[] getAcl(SearchContext ctx, IndexableDocument doc) {
    return new String[]{"cbrown"};
}

// The keys to the ACL for the document for ctx.getUserName()
public String[] getSecurityKeys(SearchContext ctx) {
    return new String[]{};
}

// The ACL for the document, hashed against an attribute
public String[] getSecureAttrAcl(SearchContext ctx, IndexableDocument doc, String attributeName) {
    return new String[]{};
}

// The keys to the ACL for the document for ctx.getUserName(), hashed against an attribute
public String[] getSecureAttrKeys(SearchContext ctx, String attributeName) {
    return new String[]{};
}

// Returns configuration parameters for the extension, not used often
public String[] getSecurableParams()
    throws SearchSecurityException {
    return new String[]{};
}

33.4.2.5 About Implementing the Attachments Interface

Implementing the attachments interface, shown in Example 33-9, allows you to index binary files such as Word documents, Excel spreadsheets, PDF files, and so on.

After you implement this class, you can add any number of attachments to an indexable document in the processNode method of CrawlableTreeNode. The attachment must contain enough information in its primary key for you to open the attachment when requested by the read method, where you simply use the information stored in the primary key to read the document and write to the output stream passed to you.

Example 33-9 Attachments Interface Implementation

package oracle.ecsf.data.tree;

import java.io.BufferedReader;
import java.io.File;
import java.io.FileReader;
import java.io.IOException;
import java.io.OutputStream;
import java.util.HashMap;
import java.util.Map;
import oracle.ecsf.Attachment;
import oracle.ecsf.SearchContext;
import oracle.ecsf.meta.PrimaryKey;

public class AttachmentImpl implements Attachment {
    PrimaryKey primaryKey;

    public AttachmentImpl() {
    }

    public AttachmentImpl(Map map) {
        primaryKey = new PrimaryKey();
        primaryKey.putAll(map);
    }

    public AttachmentImpl(InputStream in)
        throws IOException {
        BufferedReader reader = new BufferedReader(new FileReader(in));
        // Read the attachment data...
    }

    public AttachmentImpl(String name)
        throws IOException {
        // Read the attachment data from a URL...
    }

    // Additional methods...

    @Override
    public String[] getAcl(SearchContext ctx, IndexableDocument doc) {
        return new String[]{"cbrown"};
    }

    @Override
    public String[] getSecurityKeys(SearchContext ctx) {
        return new String[]{};
    }

    @Override
    public String[] getSecureAttrAcl(SearchContext ctx, IndexableDocument doc, String attributeName) {
        return new String[]{};
    }

    @Override
    public String[] getSecureAttrKeys(SearchContext ctx, String attributeName) {
        return new String[]{};
    }

    @Override
    public String[] getSecurableParams()
        throws SearchSecurityException {
        return new String[]{};
    }

    // Additional methods...
}
public String getType() {
    return "text/xml";
}

public void initialize(SearchContext ctx, Map paramMap, PrimaryKey keys) {
    primaryKey = new PrimaryKey();
    primaryKey.putAll(keys);
}

public void read(SearchContext ctx, OutputStream stream) {
    String path = (String)primaryKey.get("Path");
    File file = new File(path);
    try {
        FileReader fileReader = new FileReader(file);
        BufferedReader br = new BufferedReader(fileReader);
        String strd = br.readLine();
        while (strd != null) {
            stream.write(strd.getBytes());
            strd = br.readLine();
        }
    } catch (IOException e) {
        //Handle errors
    }

    //Contains configuration parameters needed to read the attachment
    //This map can be an empty one as shown in this example.
    public Map getParameters() {
        Map parameters = new HashMap();
        return parameters;
    }

    //Name value pairs need to identify a specific attachment.
    public PrimaryKey getPrimaryKey() {
        return primaryKey;
    }

}

33.4.2.6 Deploy and Start the ECSF Servlet

Before Oracle SES can crawl your file system, you need an Oracle WebLogic Server instance to which you can deploy the ECSF servlet. For example, you can use the Integrated WebLogic Server container.

To deploy and start the ECSF server, do the following:

1. Create a Java project in JDeveloper.
2. Add ecsf.jar to its class path.
3. Develop your extensions.
4. Edit web.xml to add the servlet mapping in Example 33-10.
5. To use a custom security service, you must add –
   Doracle.ecsf.security.service=classnameOfSecurityService.
   Otherwise, Oracle Platform Security for Java security service is used.
6. Open ecsf.jar, right-click oracle.ecsf.feed.SearchFeedServlet, and select Run. The ECSF servlet starts, and the system is ready to be crawled.
Example 33-10  SearchFeedServlet Mapping

<servlet>
  <servlet-name>SearchFeedServlet</servlet-name>
  <servlet-class>oracle.ecsf.feed.SearchFeedServlet</servlet-class>
</servlet>

<servlet-mapping>
  <servlet-name>SearchFeedServlet</servlet-name>
  <url-pattern>/searchfeedservlet/*</url-pattern>
</servlet-mapping>

33.4.2.7 Configure Oracle SES to Crawl ECSF

Oracle SES must be installed, then configured to crawl ECSF. Install Oracle SES 11.2.1, then perform the following steps to configure Oracle SES with the necessary information for crawling tree structure-based data sources and identifying items for indexing.

To configure Oracle SES, do the following:

1. In Oracle SES, create a data source of data source type, for example, Oracle Fusion.
   For General, complete the following:
   • Name: your data source name
     Oracle SES supports string values of up to 100 characters.
   • Configuration URL: http://yourhost:port/appname/pathname/searchableObjectName/ConfigFeed
   • Authentication Type: NATIVE
   • User ID: username
   • Password: password
   • Scratch Directory: /tmp or c:\tmp or empty
   • Maximum number of connection attempts: 3
   For Authentication, complete the following:
   • Authorization: ACLs Controlled by the Source
     • User ID: username
     • Password: password
     • Business Component: searchableObjectName
     • Display URL Prefix: prefix of url for Oracle SES UI

2. Create a data source group:
   a. From Search Tab/Source Group, click the Create button.
   b. Provide a name.
c. Select **Fusion Data Type** to filter the data source.

d. Shuttle the data source to the right column.

e. Click **Finish**.

3. Activate the identity extension:

   a. From Global Settings, select **Identity Management Setup**.

   b. Select **Oracle Fusion** from the list.

   c. Click **Activate**. If it is already activated, deactivate it, then reactivate it.

   e. Enter your user name and password.

4. If Oracle SES is needed, create a federated trusted entity:

   a. From Global Settings, select **Federation Trusted Entities**.

   b. For Entity Name, enter your user name.

   c. Select the **Use Identity Plug-in** checkbox for the authentication option.

5. (Optional) Include the Oracle SES client Java archive (JAR) in your class path, as shown in **Example 33-11**, to query Oracle SES through API.

**Example 33-11 Class Path with Oracle SES Client Java Archive**

```java
public SearchHits doSearch(String soName, String query, int pageSize, int page) {
    SearchHits searchHits = null;
    String searchGroupName = GROUP_NAME;
    long engineInstId = -1;
    SearchContext searchContext = ContextFactory.getSearchContext();

    QueryMetaData qmd = new QueryMetaDataImpl();
    qmd.setQueryString(query);
    qmd.setPageSize(pageSize);
    qmd.setCurrentPage(page);

    SearchGroup group = new SearchGroup(searchGroupName, searchGroupName, -1, null, SearchContext.LOCAL);
    SearchGroup[] groups = new SearchGroup[] { group ];
    qmd.setSearchGroups(groups);

    SearchableGroup sg = MetaDataManager.getSearchableGroup(-1, searchGroupName);
    sg.addSearchableObject(soName);

    SearchableObject so = MetaDataManager.getSearchableObject(soName);
    searchContext.setSearchableObject(so);

    SearchEngine engine = SearchEngineManager.getSearchEngine(engineInstId);
    try {
        Searcher searcher = engine.getSearcher(searchContext);
        searchHits = searcher.search(searchContext, qmd);
    } catch (Throwable e)
```
33.4.3 About Integrating Search Functionality for Tree Structures

In the ECSF architecture, search related artifacts can be stored in any persistent storage. The metadata manager obtains these artifacts via configuration store abstraction. For Oracle Fusion Applications, a database-based configuration store is developed that can load configuration from the ECSF tables in the Oracle Fusion Applications database.

If you decide not to use the ECSF database-based configuration store for the metadata, you can implement your own configuration store by implementing the oracle.ecsf.meta.Configuration interface.

The search related artifacts are loaded into memory through VOConfiguration during runtime to be used for crawling, query, and administration. If information is not stored in a database, as in the case of Oracle Business Intelligence that stores its information in a tree structure-based source system, ECSF provides a flexible way to load the runtime objects through an interface (Configuration) placed between MetaDataManager and your configuration storage so that runtime objects are not restricted to being loaded from the database. Figure 33-5 illustrates the runtime architecture that includes the Configuration interface, which provides an alternative mechanism for loading runtime objects.

![Runtime Architecture with Configuration Interface](image)

A system property determines which configuration, VOConfiguration or a custom configuration, to use during runtime. In Figure 33-5, the BIConfiguration class is an example of a custom configuration that extends the existing AbstractConfiguration class.

Integrate search functionality for tree structures by extending the AbstractConfiguration class and using your configuration class.

33.4.3.1 About Setting the Configuration

The MetaDataManager class determines which configuration to call based on how you set the oracle.ecsf.configuration.class system property. For example,

```java
System.setProperty("oracle.ecsf_configuration_class", "oracle.ecsf.meta.impl.BIConfiguration");
```
sets the property to use BIConfiguration. If this property is not set, or an implementation class does not exist for this property, MetaDataManager calls VOConfiguration by default.

33.4.3.2 About Using the Configuration Interface

The Configuration interface, shown in Example 33-12, contains the methods implemented by VOConfiguration or a custom configuration to load runtime objects.

The Configuration interface includes the getEngineParameters() method so you can get and set the search engine parameters needed for ECSF runtime in the absence of a database.

Example 33-12  Configuration Interface

```java
public interface Configuration {
    /**
     * Returns all search engine instances.
     * @return a list of search engine instances available.
     */
    public List<MetaEngineInstance> getEngineInstances();

    /**
     * Returns engine parameters in a hashmap for a given engine instance.
     * @param engineId the engine instance id
     * @return HashMap configuration parameter
     */
    public Map getEngineParameters(long engineId);

    /**
     * Returns a searchable group for a given search engine instance, by name.
     * @param engineId The identification of the engine instance.
     * @param name The name of the searchable group.
     * @return a searchable group. Null if not found.
     */
    public SearchableGroup getSearchableGroup(long engineId, String name);

    /**
     * Returns a searchable object for a given search engine instance by class name.
     * @param engineId The identification of the engine instance.
     * @param name The class name of the searchable object.
     * @return a searchable object, null if not found.
     */
    public SearchableObject getSearchableObject(long engineId, String name);

    /**
     * Returns a list of searchable groups for a given search engine instance.
     * @param engineId The indentification of the engine instance.
     * @return a list of searchable groups, empty if not found.
     */
    public List<SearchableGroup> getSearchableGroups(long engineId);

    /**
     * Requests a reload of the configuration. Implementation should reload the objects from persistent storage.
     */
    public void reload();
}
```
33.4.3.3 About Using the AbstractConfiguration Class

The AbstractConfiguration class implements the necessary functionalities common to all non-database uptakers regardless of where the runtime object information is stored. You must complete the implementation by using your own custom class that extends AbstractConfiguration. For information, see About Extending AbstractConfiguration.

Example 33-13 illustrates the implementation of AbstractConfiguration. In this implementation, getSearchableGroups() loads the available groups from the Oracle SES instance. These groups are treated as external groups, and therefore advanced search and facets are not supported in this scenario.

In this implementation, there is only one engine instance but following MetaDataManager convention, a list of engine instances is returned.

Example 33-13  Sample AbstractConfiguration Implementation

```java
public abstract class AbstractConfiguration implements Configuration {
    public AbstractConfiguration() {
        super();
        MetaEngineInstance engine = new MetaEngineInstance();
        engine.setId(-1L);
        engines.add(engine);
    }

    public List<MetaEngineInstance> getEngineInstances() {
        return engines;
    }

    public List<SearchableGroup> getSearchableGroups(long engineId) {
        if(groups == null) {
            groups = new ArrayList<SearchableGroup>();
            try {
                Map map = SESAdmin.getGroups(ContextFactory.getSearchContext(), engineId);
                for (Object key : map.keySet()) {
                    SearchableGroup sg = new SearchableGroup(key.toString());
                    sg.setDisplayName((String)map.get(key));
                    sg.setIsExternal(true);
                    sg.setEngineInstanceId(engineId);
                    groups.add(sg);
                }
            } catch (SearchException e) {
                e.printStackTrace();
            }
            return groups;
        }

        public SearchableGroup getSearchableGroup(long engineId, String s)
for (SearchableGroup group : getSearchableGroups(engineId))
{
    if (group.getName().equals(s))
    {
        return group;
    }
}
return null;

public SearchableObject getSearchableObject(long engineId, String s)
{
    SearchableObject so = loadSOFromClass(s);
    if (so != null)
    {
        so.setSearchEngineInstanceId(engineId);
    }
    return so;
}

protected SearchableObject loadSOFromClass(String className)
{
    try
    {
        if (className.equals(SearchableObject.class.getName()))
        {
            return null;
        }
        Class cls =
            Thread.currentThread().getContextClassLoader().loadClass(className);
        if (cls != null)
        {
            Object object = null;
            try
            {
                object = cls.newInstance();
            }
            catch (InstantiationException e)
            {
                return null;
            }
            catch (IllegalAccessException e)
            {
                return null;
            }
            if (object instanceof SearchableObject)
            {
                //this is the only path a searchable object will be created
                SearchableObject so = (SearchableObject)object;
                so.setDocument(new VODocumentImpl("root"));
                return so;
            }
        }
        else
        {
            return null;
        }
    }
}
### 33.4.3.4 About Implementing Searchable Object Classes

Since the searchable objects are not stored in the database, you must implement a Java class to define each searchable object. Example 33-14 shows the sample implementation for `EmpView.java`.

Each searchable object is loaded using a class of the same name.

**Example 33-14  Sample Searchable Object Class**

```java
package runtime;  //package where runtime objects reside
import java.util.logging.Logger;
import oracle.ecsf.meta.AbstractDocumentDefinition;
import oracle.ecsf.meta.DocumentDefinition;
import oracle.ecsf.meta.FieldDefinitionImpl;
import oracle.ecsf.meta.SearchableObject;
import oracle.ecsf.util.ECSFLoggerFactory;

public class EmpView extends SearchableObject
{
    private static Logger sLogger =
        ECSFLoggerFactory.getLogger(EmpView.class.getName());

    private static final String DATE_FORMAT = "yyyy-MM-dd'T'HH:mm:ss.SSS'Z'";

    public EmpView()
    {
        super("*");
        setName(getClass().getName());
    }

    public EmpView(String name)
    {
        super(name);
    }

    /**
     * Override to initialize document.
     * @param document
     */
```
public final void setDocument(AbstractDocumentDefinition document) {
    super.setDocument(document);
    initDoc(document);
}

private void initDoc(AbstractDocumentDefinition document)
{
    FieldDefinitionImpl field = new FieldDefinitionImpl("Ename");
    field.setBinding("ENAME");
    field.setPrimaryKey(false);
    field.setStored(true);
    documentDefinition.addField(field);
    field = new FieldDefinitionImpl("Empno");
    field.setBinding("EMPNO");
    field.setPrimaryKey(true);
    field.setStored(true);
    documentDefinition.addField(field);
    field = new FieldDefinitionImpl(DocumentDefinition.ECSF_SO_NAME);
    field.setBinding(DocumentDefinition.ECSF_SO_NAME);
    field.setPrimaryKey(false);
    field.setStored(true);
    documentDefinition.addField(field);
}

33.4.3.5 About Extending AbstractConfiguration

You can extend the AbstractConfiguration class with the BIConfiguration class, as shown in Example 33-15, to define your own way of loading runtime objects that is specific to your environment.

Example 33-15 Sample Implementation for BIConfiguration

package oracle.ecsf.meta.impl;

import java.util.HashMap;
import java.util.Map;

public class BIConfiguration extends AbstractConfiguration {
    public BIConfiguration() {
    }
    public Map getEngineParameters(long engineId) {
        HashMap map = new HashMap();
        map.put("SES_ADMIN_USERNAME", "searchsys");
        map.put("SES_ADMIN_PASSWORD", "welcome1");
        map.put("SES_ADMIN_SESSION_TIMEOUT", "10");
        map.put("SES_ADMIN_SERVICE", "http:// sesserver.com:7777/search/api/admin/AdminService");
        map.put("SES_QUERY_PROXY_USERNAME", "scott");
        map.put("SES_QUERY_PROXY_PASSWORD", "tiger");
        map.put("SES_QUERY_SESSION_TIMEOUT", "10");
        map.put("ECSF_DATA_SERVICE", "http://wlsserver.com:7101/approot/searchfeedservlet/");
    }
}
map.put("ECSF_SECURITY_USERNAME", "scott");
map.put("ECSF_SECURITY_PASSWORD", "tiger");
map.put("ECSF_SECURITY_SERVICE",
"http://wlsserver.com:7101/approot/searchfeedservlet/");
map.put("ECSF_REDIRECT_SERVICE",
"http://wlsserver.com:7101/approot/searchfeedservlet/");

return map;
}

//add search group and search object used for SESAdmin
public List<SearchableGroup> getSearchableGroups(long engineId)
{
    if(searchGroups == null)
    {
        searchGroups = new ArrayList(super.getSearchableGroups(engineId));
        SearchableGroup sgAdmin = new SearchableGroup(GROUP_NAME_ADMIN);
        sgAdmin.setIsExternal(false);
        sgAdmin.setEngineInstanceId(ENGINE_ID);
        SearchableObject so = super.loadSOFromClass(OBJECT_NAME_ADMIN);
        sgAdmin.addSearchableObject(so);
        searchGroups.add(sgAdmin);
    }
    return searchGroups;
}

private List<SearchableGroup> searchGroups = null;

private static final long ENGINE_ID = -1L;
private static final String GROUP_NAME_ADMIN = "runtime.EmpViewAdminTest";
private static final String OBJECT_NAME_ADMIN = "runtime.EmpViewAdminTest";

### 33.5 About Managing Recent Searches

Recent Searches will save the user's top 10 most recent searches. The maximum number of recent searches that are saved can be configured. Recent Searches will display in the UI with the search keywords as their name and the user can use the recent search to requery. Recent Searches can be deleted one at a time, or all Recent Searches for a specified user can be deleted.

The Recent Search feature uses the SaveSearch database table and dataobjects, which already exist. The SEARCH_TYPE column added to the ECSF_SVSEARCH table specifies whether a search is SAVED or RECENT. If necessary, make sure to update the SavedSearchManager so that it handles this column.

Recent Searches uses these components:

- **RecentSearchManager Class**
  
The RecentSearchManager will manage the creation, deletion and retrieval of recent searches from the database.

- **SavedSearchManager Class**
  
  When a Saved Search is created, the SEARCH_TYPE column in the ECSF_SVSEARCH database table will be set to the appropriate value, and the SavedSearchManager will retrieve only searches that are of type SAVED.
33.5.1 About Using the RecentSearchManager API

This class, shown in Example 33-16, manages the Recent Searches.

Example 33-16  RecentSearchManager API

```java
/**
 * Returns a List of recent RecentSearch data objects for the
 * current user defined in the SearchContext
 * @param ctx  the current SearchContext
 * @return List< RecentSearch > list of recent RecentSearches
 * @throws SearchException
 */
public List<RecentSearch> getRecentSearches(SearchContext ctx)
    throws SearchException

/**
 * Returns a List of recent RecentSearch data objects for the
 * current user defined in the SearchContext and the specified
 * caller context
 * @param ctx - the current SearchContext
 * @param callerCtx - the caller context
 * @return List<RecentSearch> - list of recent RecentSearches ordered
 * from most recent to oldest
 * @throws SearchException
 */
public List<RecentSearch> getRecentSearches(SearchContext ctx, String callerCtx)
    throws SearchException

/**
 * Creates a new recent search
 * @param ctx - the SearchContext
 * @param searchDescription - the description of the saved search
 * @param queryDetails - recent saved search query information
 * @return RecentSearch
 * @throws SearchException
 */
public RecentSearch createRecentSearch(SearchContext ctx,
    String searchDescription,
    QueryMetaData queryDetails)
    throws SearchException

/**
 * Creates a new recent search
 * @param ctx - the SearchContext
 * @param searchDescription - the description of the saved search
 * @param queryDetails - recent saved search query information
 * @param callerCtx - the caller context
 * @return RecentSearch
 * @throws SearchException
 */
public RecentSearch createRecentSearch(SearchContext ctx,
    String searchDescription,
    QueryMetaData queryDetails,
### 33.5.2 Understanding How Recent Searches Are Processed

Recent Searches are managed only from the current application container, so the RecentSearchManager only handles recent searches that are found in the local application database, regardless of the ECSF Scope (LOCAL/GLOBAL). RecentSearchManager will not call to other search applications for recent searches.

**Important:** When a RecentSearch query is run, the query is run as usual using the defined Scope and Federation, so a federated query will go across the wire to the search applications if required.

Recent Searches are not implicitly created by ECSF. For a Recent Search to be saved, the `RecentSearchManager.createRecentSearch` API must be called.

The call to get the Recent Searches will return a list ordered from most recent to oldest recent search.

For performance, the list of recent searches returned will not contain the RecentSearchDetails information for the Recent Searches. The fact that this information is not available in the Recent Search dataobject is transparent to the client. When the client wants the details and calls `RecentSearch.getRecentSearchDetails()` on the Recent Search, the dataobject automatically will retrieve the RecentSearchDetails from the database.

By default, the maximum number of Recent Searches for each user is limited to 10. This number can be configured using a Java system property:
oracle.ecsf.recent.search.max.num

This property can be set using the Java -D option or the ecsf.properties file.

---

**Note:**

If the oracle.ecsf.recent.search.max.num property is set to an invalid number or 0, recent searches are disabled and a message is printed to the log.

The isEnabled(SearchContext ctx) API indicates whether Recent Search functionality is enabled. If Recent Search is disabled, calling the other methods in RecentSearchManager will result in an UnsupportedOperationException.

---

When Recent Search records are retrieved from the database, the SQL limits the number of records based on the system property (or the default of 10), so that only the most recent records are returned.

When the RecentSearchManager creates a new Recent Search, it first checks if the user already has the maximum number of Recent Searches stored in the database. If the user does not, a new Recent Search is created. If the user has exceeded the maximum number of Recent Searches allowed, the oldest Recent Search record is deleted and then the new Recent Search is saved into the database.

During the creation of a new Recent Search, at most one older Recent Search record may be deleted. Because the maximum number of Recent Searches is configurable, if this property is changed, there may be more Recent Search records in the database than allowed per user, and the Recent Search records should be manually cleaned from the database to clean up any extra records.

When a new Recent Search is created, due to the ECSF_SVSEARCH database table constraint on the NAME being unique per user, the RecentSearchManager will generate a unique name for the Recent Search using the database RowId for the new record and the queryString input by the user:

```java
String searchName = rowId + ": " + queryDetails.getQueryString();
```

This will maintain the constraint of having a unique name for each recent SavedSearch record. The UI will want to display the keyword string as the Recent Search name. The keyword string can be obtained from the SavedSearch dataobject using its getKeywordSrchStr method:

```java
    String recentSearchDisplayName = recentSearch.getKeywordSrchStr();
```

To run a Recent Search, the RecentSearchDetails can be retrieved from the RecentSearch object and then SearchCtrl.runQuery can be used to run the query on the queryMetaData in the RecentSearchDetails. If the query is federated, it will run as usual using federation. All of the necessary details for this are stored in the queryMetaData object:

```java
    RecentSearchDetails recentSearchDetails = recentSearch.getRecentSearchDetails();
    QueryMetaData qmd = recentSearchDetails.getQueryDetails();
    SearchHits hits = searchCtrl.runQuery(qmd);
```

The callerCtx passed into some of the RecentSearchManager methods is a column used by the UI to tag searches. For example, the Global Search UI will only want to display recent searches that were performed inside the Global Search UI, so the callerCtx will be used when creating and retrieving searches.
Database Schema for Recent Searches

Recent Search uses the ECSF_SVSEARCH and ECSF_SVSEARCH_DETAILS database tables. To support Recent Search, these schema changes have been made:

- SEARCH_TYPE has been added to ECSF_SVSEARCH:
  ```
  SEARCH_TYPE VARCHAR2(20) default 'SAVED' NOT NULL
  ```

- The unique constraint on the ECSF_SVSEARCH table includes the SEARCH_TYPE column.
  ```
  CONSTRAINT ECSF_SVSEARCH_UK1 UNIQUE (NAME, USERID, CALLER_CTX, SEARCH_TYPE)
  ```

- The existing ECSF_SVSEARCH_N1, ECSF_SVSEARCH_N2, and ECSF_SVSEARCH_U2 Indexes for the ECSF_SVSEARCH table include the SEARCH_TYPE column.
  ```
  CREATE INDEX ECSF_SVSEARCH_N1 ON ECSF_SVSEARCH (USERID, SEARCH_TYPE);
  CREATE INDEX ECSF_SVSEARCH_N2 ON ECSF_SVSEARCH (USERID, CALLER_CTX, SEARCH_TYPE);
  CREATE INDEX ECSF_SVSEARCH_U2 ON ECSF_SVSEARCH (NAME, USERID, CALLER_CTX, SEARCH_TYPE);
  ```

- The ECSF_SVSEARCH_DETAILS table is constrained on the Foreign Key to ECSF_SVSEARCH so that corresponding search details are automatically deleted whenever an ECSF_SVSEARCH record is deleted.
  ```
  ALTER TABLE ECSF_SVSEARCH_DETAILS ADD 
  ( CONSTRAINT ECSF_SVSEARCH_DETAILS_FK1 
    FOREIGN KEY (SVSEARCH_ID) REFERENCES ECSF_SVSEARCH (ID) 
    ON DELETE CASCADE 
  )
  ```

RecentSearch Dataobject

The RecentSearch and RecentSearchDetails dataobjects are used. A RecentSearch dataobject is just like SavedSearch except for the details method:

```java
/**
 * Retrieve the RecentSearchDetails for this recent search.
 * @return recent search details
 */
public RecentSearchDetails getRecentSearchDetails()
```

33.6 Set Up Federated Search

ECSF provides the services and federation to enable users to search across Oracle Fusion Applications product families or across multiple Oracle SES instances. For more information, see the "Managing Search with Oracle Enterprise Crawl and Search Framework" chapter in the Administrator's Guide.

Set up ECSF services and federation by:

1. Creating the SearchDB connection on Oracle WebLogic Server
2. Updating the application deployment profile with the Target Directory for Searchable Objects
3. Updating the application to point to the ECSF Service shared library
4. Adding the ECSF Runtime Library
5. Adding searchable objects and their dependencies to the Search application
6. Setting the system parameter for web service
7. Packaging and deploying the Search application
8. Setting up the ECSF client for federation
9. Setting the SearchContext scope to GLOBAL
10. Integrating federation across Oracle Fusion Applications product families

33.6.1 How to Create the SearchDB Connection on Oracle WebLogic Server Instance

The Oracle WebLogic Server instance to which the application is deployed must have a SearchDB connection. The application deployment descriptors are set so that the application does not automatically generate and synchronize weblogic-jdbc.xml descriptors during deployment. This setting prevents you from receiving the deployment error **No credential mapper entry found for password indirection** when you package or deploy from the command line or from Oracle JDeveloper. Because of this, you must manually create the SearchDB connection on Oracle WebLogic Server instance.

To create the SearchDB connection, do the following:

1. In the Domain Structure tree of the Oracle WebLogic Server Administration Console, navigate to Services, then JDBC, then Data Sources.
2. See if there is any data source with Java Naming and Directory Interface (JNDI) value jdbc/SearchDBDS. If not, proceed to the next step.
3. Click the New.
4. On the Connection Properties page, complete the fields with the following values:
   - **JNDI Name**: jdbc/SearchDBDS
   - **Database Type**: Oracle
   - **Database Driver**: Oracle Driver (Thin) 901,92,10,11
5. Click Next, and complete the configuration according to your data source.

33.6.2 How to Update the Application Deployment Profile with the Target Directory for Searchable Objects

All searchable objects and their dependencies must be packaged within the Search application enterprise archive (EAR) file for each product family. You must set the target directory for the Java archive (JAR) files containing the searchable objects and their dependencies in the application deployment descriptor so that they are packaged with the enterprise archive.

To set the target directory, do the following:

1. In the Application Navigator, right-click the application name and navigate to Application Properties, then Deployment.
The deployment descriptor file (for example, Search_Application1.ear, where Search is your application name) appears in the left pane.

2. Click the deployment descriptor file and select Edit.

3. From the Edit EAR Deployment Profile Properties menu navigate to File Groups > VOLib > Contributors, click Add, and set the directory to point to {FULL_PATH_TO_BUILD_FILE}/deploy/lib/, for example, /ade/view_name/fusionapps/crm/deploy/lib.

This directory is empty, but during the pre-enterprise archive step in the build file the directory becomes populated with all of the dependent Java archive (JAR) files. Including this directory in the application deployment descriptor ensures that these dependent Java archive (JAR) files are packaged with the enterprise archive.

4. Click OK.

33.6.3 About Updating the Application to Reference the ECSF Service Shared Library

The ECSF Service shared library eliminates the need for ECSF libraries to be packaged into the Search application for each product family. Instead, applications that depend on ECSF libraries can reference the ECSF shared library that is deployed to the Oracle WebLogic Server instance. The ECSF Service shared library contains the following Java archive (JAR) files:

- ecsf_MiddleTier.war
- ecsf_MiddleTier.jar
- ecsf_Common.jar

You must update the Oracle WebLogic Server deployment descriptor file (weblogic-application.xml) by adding the reference to the ECSF Service shared library (oracle.ecsf.service), as shown in Example 33-17.

Replace REPLACE _CONTEXT_ROOT with the context root that is desired for the Search application’s ECSF Service.

The ECSF Service shared library is automatically deployed to the Integrated WebLogic Server instance by the ECSF extension in JDeveloper through the JDeveloper Application Development Runtime Service (ADRS). However, you must manually deploy the ECSF Service shared library to the standalone Oracle WebLogic Server.

Example 33-17 Reference to the ECSF Service Shared Library

```xml
<library-ref>
  <library-name>oracle.ecsf.service</library-name>
</library-ref>

<library-context-root-override>
  <context-root>searchservice</context-root>
  <override-value>REPLACE _CONTEXT_ROOT</override-value>
</library-context-root-override>
```

33.6.4 How to Add the ECSF Runtime Library

After you update the application deployment profile, update the project by adding the ECSF Runtime Library.

To add the Runtime Library, do the following:
1. Right-click the project and select **Project Properties**.

2. Select the **Libraries and Classpath** category and click the **Add Library** button.

3. In the Add Library dialog, select **ECSF Runtime Server** from the list of available libraries.

4. Click **OK** to save your selection and close the Add Library dialog.

### 33.6.5 About Setting the System Parameter for Web Service

Set the `oracle.ecsf.service.ws.timeout` system parameter to specify the web service timeout value in milliseconds. If no value is specified, then 90,000 milliseconds is used. You can set the system parameter in either the Java system properties or in the `ecsf.properties` file.

#### 33.6.5.1 Set the System Parameter in Java System Properties

Set the `oracle.ecsf.service.ws.timeout` system parameter in Java System Properties to specify the web service timeout value.

To set the system parameter, do the following:

1. In the **Application Navigator**, right-click **ViewController** and select **Project Properties**.

2. In the Project Properties dialog, select **Run/Debug/Profile** in the left panel.

3. Select **Default** in the Run Configurations list, then click the **Edit** button.

4. In the Edit Run Configuration dialog, select **Launch Settings** in the left panel.

5. Enter `-Doracle.ecsf.service.ws.timeout=n` (where `n` is the desired value in milliseconds) in the **Java Options** field, then click **OK**.

6. Click **OK**.

#### 33.6.5.2 About Setting the System Parameter in the `ecsf.properties` File

Set the `oracle.ecsf.service.ws.timeout` system parameter in the `ecsf.properties` file to specify the web service timeout value by adding the following line to the `ecsf.properties` file available in the application classpath:

```
oracle.ecsf.service.ws.timeout=n
```

where `n` is the desired value in milliseconds.

### 33.6.6 About Packaging and Deploying the Search Application

When the application deployment descriptor points to the right directory you can run the **ant** targets to package and deploy the EAR file. You can run the **ant** targets from the command line or from Oracle JDeveloper.

#### 33.6.6.1 About Running the **ant** Targets from the Command Line

Package and deploy the Search application by issuing the following commands in the directory where the build file is located:

```
ant -f build-crmsearch.xml ear
ant -Ddeployenvfile=/scratch/deploy.xml -f build-crmsearch.xml deploy
```
where `build-crmsearch.xml` is the build file for the Search application.

The enterprise archive step in the build file includes the pre-enterprise archive step, so there is no need to manually run the pre-enterprise archive step. The enterprise archive target also runs a post-enterprise archive step that deletes all the files from the `deploy/lib` directory after the enterprise archive is packaged, resulting in a clean folder.

### 33.6.6.2 Run the ant Targets from Oracle JDeveloper

You can use Oracle JDeveloper to package and deploy the Search application.

To package and deploy the Search application, do the following:

**To package and deploy the Search application from Oracle JDeveloper:**

1. Run the pre-enterprise archive steps by opening the build file, right-clicking the open file editor, and selecting `Run ant target > lrg - writeGraph > pre-ear`.

   This step runs the pre-enterprise archive steps that are required for copying required Java archive (JAR) files to the directory specified in the Search application deployment descriptor. All the files in that directory is packaged into the enterprise archive file in the `APP-INF/lib` file where the ECSF WAR can locate them.

2. Package the enterprise archive by right-clicking the application and selecting `Deploy > To ear`.

3. Deploy the enterprise archive by right-clicking the application and selecting `Deploy > To IntegratedWebLogicServer`.

### 33.6.7 About Updating the Search Application with New Searchable Objects or Dependencies

The Search application must be updated if there are new searchable objects to add to the application or if any of the dependencies for existing searchable objects change.

If there are no new searchable objects but dependencies have changed, you only need to run the `dependentJar` ant target and package and deploy the enterprise archive (for information, see About Packaging and Deploying the Search Application).

However, if you are adding new searchable objects to the application, then you must add the new searchable objects to the Search application build file and run the `dependentJar` ant target, then repackage and redeploy the enterprise archive (for information, see About Packaging and Deploying the Search Application).

### 33.6.8 How to Set Up the ECSF Client Application for Federation

To connect to the Search application for each Oracle Fusion Applications product family (collectively called global search applications), you must configure the client application so that when it sends the Search application server a request, it also sends valid encrypted proxy user credentials to the server.

The client that calls the Search application must be configured with information on where to find the global Search applications. This information is stored in the `connections.xml` of the client application. The `connections.xml` file of the client application must contain a reference name element corresponding to each remote ECSF component to which the client application connects.

Set up the ECSF client application by:
1. Adding encryption keys to `cwallet.sso` and `default-keystore.jks`
2. Adding the keystore to `jps-config.xml`
3. Creating the proxy user
4. Updating `connections.xml`

### 33.6.8.1 About Adding Encryption Keys to `cwallet.sso` and `default-keystore.jks`

The security header is encrypted before being sent to the server, so the `cwallet` and `default-keystore` files for both the client and server must be configured for the encryption to function properly. Use the Oracle WebLogic Scripting Tool to create the encryption keys in `cwallet.sso` and `default-keystore.jks`.

The following four new entries appear in `cwallet.sso` and `default-keystore.jks`:

```bash
> createCred(map="oracle.wsm.security", key="keystore-csf-key", user="owsm", password="welcome1", desc="Keystore key")
> createCred(map="oracle.wsm.security", key="enc-csf-key", user="orakey", password="welcome1", desc="Encryption key")
> createCred(map="oracle.wsm.security", key="sign-csf-key", user="orakey", password="welcome1", desc="Signing key")
> createCred(map="oracle.wsm.security", key="basic.credentials", user="weblogic", password="weblogic1", desc="User credentials key")
```

Oracle WebLogic Scripting Tool updates the files directly on the server you specify, so no redeployment is necessary.

### 33.6.8.2 About Adding the Keystore to `jps-config.xml`

In order for the client to be able to use the encryption keystore entries, you must configure the `jps-config.xml` file for the client application.

Add the following entries to `jps-config.xml`:

- **Under serviceProviders:**
  ```xml
  <serviceProvider type="KEY_STORE" name="keystore.provider"
  class="oracle.security.jps.internal.keystore.KeyStoreProvider">
  </serviceProvider>
  ```

- **Under serviceInstances:**
  ```xml
  <serviceInstance name="keystore" provider="keystore.provider" location="/.
default-keystore.jks">
  <description>Default JPS Keystore Service</description>
  <property name="keystore.type" value="JKS"/>
  <property name="keystore.csf.map" value="oracle.wsm.security"/>
  <property name="keystore.pass.csf.key" value="keystore-csf-key"/>
  <property name="keystore.sig.csf.key" value="sign-csf-key"/>
  <property name="keystore.enc.csf.key" value="enc-csf-key"/>
  </serviceInstance>
  ```

- **Under the default jpsContext:**
  ```xml
  <serviceInstanceRef ref="keystore"/>
  ```
33.6.8.3 About Creating the Proxy User

The proxy user must exist on both the client and server. The client's cwallet.sso must also include an entry for the proxy user so that the username and password can be encrypted when they are placed in the security header before being sent to the server. Use Oracle WebLogic Scripting Tool to create an entry for the user in cwallet.sso, as shown in Example 33-18.

The key (in this example, test.user) for the new entry is used in connections.xml.

Example 33-18  Sample Proxy User Entry

createCred(map="oracle.wsm.security", key="test.user", user="weblogic", password="weblogic1", desc="User credentials key")

33.6.8.4 Update connections.xml

The connection between the ECSF client and each of the remote ECSF service components is defined in the connections.xml file in the ECSF client. The connections.xml file contains a list of reference name elements that correspond to each ECSF service component. You must edit the connections.xml file to define the application server connection parameters.

To define the connection parameters, do the following:

1. Expand Application Resources, then Descriptors, then ADF Meta-INF, and open the connections.xml file.
2. Add the reference name elements, as shown in Example 33-19.

Web service security must be enforced by policy at the domain or instance level by configuration.
3. Save.
4. Redeploy the client application.

Example 33-19  Sample Reference Element

<Reference name="\\oracle/ecsf/service/query/common/crm/\}SearchService" className="oracle.adf.model.connection.webservice.impl.WebServiceConnectionImpl" xmlns="">
  <Factory className="oracle.adf.model.connection.webservice.api.WebServiceConnectionFactory"/>
  <RefAddresses>
    <XmlRefAddr addrType="WebServiceConnection">
      <Contents>
          <model name="\\oracle/ecsf/service/query/common\} AppModuleSearchService" xmlns="http://example.com/ws/model">
            <service name="\\oracle/ecsf/service/query/common\} AppModuleSearchService">
              <port name="AppModuleSearchServiceSoapHttpPort" binding="/oracle/ecsf/service/query/common\} AppModuleSearchServiceSoapHttp">
              </port>
            </service>
          </model>
        </wsconnection>
      </Contents>
    </XmlRefAddr>
  </RefAddresses>
</Reference>
33.6.9 About Setting the SearchContext Scope to GLOBAL

ECSF Query APIs can either invoke the ECSF service component internally (GLOBAL) or locally (LOCAL). To set the ECSF calls to be routed to the ECSF service component, you must set the scope of the search context to GLOBAL, as shown in Example 33-20.

When the SearchContext scope is set to GLOBAL, the parameters defined for the remote engine instance in the database are used to access metadata objects and perform query related functions on the remote engine instance. For more information, see the "Managing Search with Oracle Enterprise Crawl and Search Framework" chapter in the Administrator's Guide.
Example 33-20  Client Methods

SearchContext ctx = ContextFactory.getSearchContext();
ctx.setScope("GLOBAL");
ArrayList<SearchEngineInstance> engineInstances =
(ArrayList<SearchEngineInstance>)searchCtrl.getEngineInstances();

33.6.10 About Integrating Federation Across Oracle Fusion Applications Product Families

Use the ECSF API, as shown in Example 33-21, to integrate federation across Oracle Fusion Applications product families.

In the example, ECSF runtime gets the runtime.EmpView search category (search group) from an engine instance.

Example 33-21  Sample API for Implementing Federated Search

SearchCtrl searchCtrl = new SearchCtrl();
SearchHits searchHits = null;
QueryMetaDataImpl queryMetaData = new QueryMetaDataImpl();
queryMetaData.setQueryString("**");
queryMetaData.setPageSize(10);
queryMetaData.setCurrentPage(1);
ctx.setScope(SearchContext.GLOBAL);
ctx.setCurrLocale(Locale.US);

ArrayList<SearchGroup> allGroups = new ArrayList<SearchGroup>();
ArrayList<SearchGroup> searchGroups = new ArrayList<SearchGroup>();
ArrayList<SearchEngineInstance> engineInstances =
(ArrayList<SearchEngineInstance>)searchCtrl.getEngineInstances();
for (SearchEngineInstance engineInstance : engineInstances)
{
    allGroups.addAll(engineInstance.getSearchGroups());
}
for (SearchGroup searchGroup : allGroups)
{
    if (searchGroup.getName().equals("runtime.EmpView")
    || searchGroup.getName().equals("Service Request"))
    {
        searchGroups.add(searchGroup);
    }
}
SearchGroup sgs[] = searchGroups.toArray(new SearchGroup[searchGroups.size()]);
queryMetaData.setSearchGroups(sgs);
try
{
    searchHits = searchCtrl.runQuery(ctx, queryMetaData);
}
catch (Exception e)
{
    e.printStackTrace();
}

33.7 About Federating Oracle SES Instances

ECSF supports federation across Oracle SES instances, which allows users to query across multiple Oracle SES instances defined in the client’s own ECSF component. In Figure 33-6, the ECSF client is connected to one ECSF service component, which depends on one database and two Oracle SES instances.
Federation occurs on the client through the Searcher class. For each Oracle SES instance, ECSF runtime groups the search categories belonging to an Oracle SES instance and creates a federation node for it. Separate queries are issued in separate threads for each Oracle SES instance. The results from these queries are merged by ECSF runtime and returned to the user.

**Note:**

You cannot federate both Oracle SES instances and ECSF service components in the same query. ECSF runtime can only create federation nodes for either each Oracle SES instance (for federated Oracle SES) or each ECSF service component (for federated search).

**Example 33-22** illustrates how you can integrate federation across Oracle SES instances.

In the example, two Oracle SES search engine instances are defined.

**Example 33-22  Sample API for Integrating Federated Oracle SES**

```java
SearchContext ctx = ContextFactory.getSearchContext();
ctx.setScope(SearchContext.LOCAL);
SearchGroup[] sgs =
    new SearchGroup[] { new SearchGroup("runtime.EmpView", "runtime.EmpView", 1),
        new SearchGroup("runtime.EmpView", "runtime.EmpView", 17) };

queryMetaData.setSearchGroups(sgs);
try {
    searchHits = searchCtrl.runQuery(ctx, queryMetaData);
} catch (Exception e) {
    bException = true;
}
```
33.8 About Raising Change Events Synchronously

You can use a Java API to raise change events synchronously with `asynch` flag = `false` when searchable object records are modified. Raising events using SQL writes records to the `ECSF_SEARCHABLE_CHANGE_LOG` table of the database.

You can raise change events synchronously by implementing code like the sample code in Example 33-23.

You can use the following `ChangeType` parameters:

- `IndexableDocument.DELETE`
- `IndexableDocument.UPDATE`
- `IndexableDocument.INSERT`

When using the `SearchEventInvocation.raiseEvent(PrimaryKey eventPK, boolean useFabric)` method to create change log records, the keys in the `eventPK` map must be aliases of view object attributes. A view object’s alias can be found by opening the view object in JDeveloper, or by calling the `getBinding()` method of the appropriate `oracle.ecsf.meta.FieldDefinition` instance. Also, the `eventPK` map must contain an entry for every attribute that is part the primary key makeup. Otherwise, the `raiseEvent` method throws an exception.

For more information, see the Javadoc for ECSF.

**Example 33-23   Sample Code for Raising Events Using SQL**

```java
SearchEventInvocation searchEventInvocation = new SearchEventInvocation();
PrimaryKey primaryKey = new PrimaryKey();
primaryKey.put("PartyId", "12322");
SearchChangeLogEvent changeEvent = new SearchChangeLogEvent(pk);
changeEvent.setSearchObjectName("oracle.ecsf.search.demo.EmpVO");
changeEvent.setChangeType(IndexableDocument.INSERT);
searchEventInvocation.raiseEvent(changeEvent, false);
```

33.9 About Using the External ECSF Web Service for Integration

In addition to Java APIs, Oracle Enterprise Crawl and Search Framework (ECSF) provides an external web service for you to integrate ECSF with Oracle Fusion Applications. This web service allows you to build a custom search user interface that enables Oracle Fusion Applications users to search across multiple ECSF service components through a web service client. As an alternative to using Java APIs, you can invoke the external ECSF web service from Oracle Fusion Applications to perform query related functions in both LOCAL and GLOBAL scopes. Using a web service client, users can query across multiple Oracle SES instances in LOCAL scope or across multiple ECSF service components in GLOBAL scope.

33.9.1 About Web Service Methods

The external ECSF web service reuses the web service already provided by an ECSF component and exposes the methods described in Table 33-1.
Table 33-1  ECSF Web Service Methods

<table>
<thead>
<tr>
<th>Method</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>getSavedSearch(String userName, String savedSearchRequest)</td>
<td>Returns a saved search based on the name passed in to the savedSearchRequest parameter.</td>
</tr>
<tr>
<td>getSavedSearches(String userName, String savedSearchRequest)</td>
<td>Returns the saved searches based on the caller context passed in to the savedSearchRequest parameter.</td>
</tr>
<tr>
<td>saveSearch(String userName, String savedSearchRequest)</td>
<td>Saves the search passed in to the savedSearchRequest parameter.</td>
</tr>
<tr>
<td>deleteSearch(String userName, String savedSearchRequest)</td>
<td>Deletes the saved search passed in to the savedSearchRequest parameter.</td>
</tr>
<tr>
<td>getSavedSearchDetails(String userName, String savedSearchRequest)</td>
<td>Returns the saved search details based on the saved search passed in to the savedSearchRequest parameter.</td>
</tr>
<tr>
<td>search(String userName, String queryMetaDataRequest)</td>
<td>Returns search hits based on the request passed in to the QueryMetaData parameter.</td>
</tr>
<tr>
<td>getEngineInstances(String userName, String engineInstanceRequest)</td>
<td>Returns the engine instances based on the engine type ID passed in to the engineInstanceRequest parameter.</td>
</tr>
</tbody>
</table>

33.9.2 About ECSF Web Service WSDL and XSD

The Web Service Description Language (WSDL), shown in Example 33-24, defines the message endpoints and the request and reply messages of the ECSF web service. The XSD, shown in Example 33-25, defines the XML schema of the ECSF web service. Refer to the WSDL and XSD to understand and interact with the ECSF web service.

Example 33-24  ECSF Web Service WSDL

```xml
<wSDL:definitions
    name="AppModuleSearchService"
    targetNamespace="/oracle/ecsf/service/query/common/"
    xmlns:errors="http://xmlns.example.com/adf/svc/errors/"
    xmlns:wsdl="http://schemas.xmlsoap.org/wsdl/
    xmlns:tns="/oracle/ecsf/service/query/common/"
    xmlns:soap="http://schemas.xmlsoap.org/wsdl/soap/
    xmlns:types="/oracle/ecsf/service/query/common/types/">
    <wsdl:import namespace="http://xmlns.example.com/adf/svc/errors/"
        location="classpath:/META-INF/wsdl/ServiceException.wsdl"/>
    <wsdl:types>
        <schema xmlns="http://www.w3.org/2001/XMLSchema">
            <import namespace="/oracle/ecsf/service/query/common/types/" schemaLocation="AppModuleSearchService.xsd"/>
        </schema>
    </wsdl:types>
    <wsdl:message name=" AppModuleSearchService_search">
        <wsdl:part name="parameters" element="types:search"/>
    </wsdl:message>
    <wsdl:message name=" AppModuleSearchService_searchResponse">
        <wsdl:part name="parameters" element="types:searchResponse"/>
    </wsdl:message>
</wSDL:definitions>
```
<wsdl:message name="AppModuleSearchService_saveSearch">
    <wsdl:part name="parameters" element="types:saveSearch"/>
</wsdl:message>

<wsdl:message name="AppModuleSearchService_saveSearchResponse">
    <wsdl:part name="parameters" element="types:saveSearchResponse"/>
</wsdl:message>

<wsdl:message name="AppModuleSearchService_getSavedSearches">
    <wsdl:part name="parameters" element="types:getSavedSearches"/>
</wsdl:message>

<wsdl:message name="AppModuleSearchService_getSavedSearchesResponse">
    <wsdl:part name="parameters" element="types:getSavedSearchesResponse"/>
</wsdl:message>

<wsdl:message name="AppModuleSearchService_getSavedSearchDetails">
    <wsdl:part name="parameters" element="types:getSavedSearchDetails"/>
</wsdl:message>

<wsdl:message name="AppModuleSearchService_getSavedSearchDetailsResponse">
    <wsdl:part name="parameters" element="types:getSavedSearchDetailsResponse"/>
</wsdl:message>

<wsdl:message name="AppModuleSearchService_getSavedSearch">
    <wsdl:part name="parameters" element="types:getSavedSearch"/>
</wsdl:message>

    </sequence>
  </complexType>
</element>
33.9.3 About Web Service Request XSDs and XMLs

Each of the web service methods takes in a username and a request XML. The username is used to bind to the SearchContext. The request XML is passed to the SearchService to perform query related functions.

The request XMLs for the web service methods are based on the following request XSDs:

- SavedSearch Request XSD
- QueryMetaData Request XSD
- engineInstanceRequest Request XSD

33.9.3.1 SavedSearch Request XSD

The request XMLs for the `getSavedSearch()`, `getSavedSearches()`, `saveSearch()`, `deleteSearch()`, and `getSavedSearchDetails()` methods are based on the SavedSearch request XSD, shown in Example 33-26.

The SavedSearch request XSD describes the set of rules that the request XMLs must follow to be valid. Examples of valid request XMLs include the following:

- `getSavedSearch()`

```
<request>
  <name>ECSF_JUNIT_SVSEARCH</name>
  <callerctx>null</callerctx>
```
• getSavedSearches()

  <request>
  <callerctx>%</callerctx>
  <locale>en_us</locale>
  <scope>LOCAL</scope> /*use GLOBAL for global scope*/
  </request>

• saveSearch()

  <request>
  <savedSearch name="ECSF_JUNIT_SVSEARCH" id="1" compid="2">
    <description><![CDATA[Updated Description]]></description>
    <callerctx></callerctx>
    <query></query>
    <ispublic><![CDATA[false]]></ispublic>
    <userid><![CDATA[junit]]></userid>
    <detailsid><![CDATA[1]]></detailsid>
    <queryMetaData>
      <query><![CDATA[%]]></query>
      <page>1</page>
      <lang>en</lang>
      <pageSize>10</pageSize>
      <categories>
        <category name="runtime.EmpView" eid="1" compid="0"></category>
      </categories>
    </queryMetaData>
  </savedSearch>
  </request>

• deleteSearch()

  <request>
  <savedSearch name="DeleteSavedSearch" id="100010033142848" compid="2">
    <description><![CDATA[Junit Saved Search]]></description>
    <callerctx><![CDATA[CRM]]></callerctx>
  </savedSearch>
  </request>
• getSavedSearchDetails()

Example 33-26  SavedSearch Request XSD

<?xml version="1.0" encoding="US-ASCII" ?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema"
33.9.3.2 QueryMetaData Request XSD

The request XML for the `search(String userName, String queryMetaDataRequest)` method is based on the QueryMetaData request XSD, shown in Example 33-27.

The QueryMetaData request XSD describes the set of rules that the request XMLs must follow to be valid. An example of a valid request XML for `search()` is:

```xml
<request>
  <queryMetaData>
    <query><![CDATA[*]]></query>
    <page>1</page>
    <lang>en</lang>
    <pageSize>10</pageSize>
    <categories>
      <category name="runtime.EmpView" eid="1" compid="2"></category>
    </categories>
    <locale>en_us</locale>
    <scope>LOCAL</scope> /*use GLOBAL for global scope*/
  </queryMetaData>
</request>
```
Example 33-27   QueryMetaData Request XSD

<?xml version="1.0" encoding="US-ASCII" ?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema"
  xmlns="http://www.example.com"
  targetNamespace="http://www.example.com"
  elementFormDefault="qualified">
  <xsd:element name="request">
    <xsd:complexType>
      <xsd:sequence>
        <xsd:element ref="queryMetaData"/>
        <xsd:element name="locale" type="xsd:string"/>
        <xsd:element name="scope" type="xsd:string"/>
      </xsd:sequence>
    </xsd:complexType>
  </xsd:element>
  <xsd:element name="queryMetaData">
    <xsd:complexType>
      <xsd:sequence>
        <xsd:element name="query" type="xsd:string"/>
        <xsd:element name="page" type="xsd:integer"/>
        <xsd:element name="lang" type="xsd:string"/>
        <xsd:element name="pageSize" type="xsd:integer"/>
        <xsd:element name="searchCtrl" type="xsd:string" minOccurs="0"/>
        <xsd:element name="soname" type="xsd:string" minOccurs="0"/>
        <xsd:element name="facetPaths" minOccurs="0">  
          <xsd:complexType>
            <xsd:sequence>
              <xsd:element name="facetPath" maxOccurs="unbounded">
                <xsd:complexType>
                  <xsd:sequence>
                    <xsd:element name="value" maxOccurs="unbounded" minOccurs="0">  
                      <xsd:complexType>
                        <xsd:attribute name="name" type="xsd:string" use="required"/>
                        <xsd:attribute name="value" type="xsd:string" use="required"/>
                      </xsd:complexType>
                    </xsd:element>
                  </xsd:sequence>
                </xsd:complexType>
              </xsd:element>
            </xsd:sequence>
          </xsd:complexType>
        </xsd:element>
        <xsd:element name="categories" minOccurs="0">  
          <xsd:complexType>
            <xsd:sequence>
              <xsd:element name="category" maxOccurs="unbounded" minOccurs="0">  
                <xsd:complexType>
                  <xsd:attribute name="name" type="xsd:string" use="required"/>
                  <xsd:attribute name="eid" type="xsd:integer" use="required"/>
                  <xsd:attribute name="compid" type="xsd:integer" use="required"/>
                </xsd:complexType>
              </xsd:element>
            </xsd:sequence>
          </xsd:complexType>
        </xsd:element>
        <xsd:element name="tags" type="xsd:string" minOccurs="0"/>
      </xsd:sequence>
    </xsd:complexType>
  </xsd:element>
</xsd:schema>
<xsd:element name="filters" minOccurs="0">
  <xsd:complexType>
    <xsd:sequence>
      <xsd:element name="filter" maxOccurs="unbounded">
        <xsd:complexType>
          <xsd:simpleContent>
            <xsd:extension base="xsd:string">
              <xsd:attribute name="name" type="xsd:string" use="required"/>
              <xsd:attribute name="operator" type="xsd:string" use="required"/>
              <xsd:attribute name="type" type="xsd:string" use="required"/>
            </xsd:extension>
          </xsd:simpleContent>
        </xsd:complexType>
      </xsd:element>
    </xsd:sequence>
  </xsd:complexType>
</xsd:element>
</xsd:sequence>
</xsd:complexType>
</xsd:element>
</xsd:schema>

33.9.3.3 engineInstanceRequest Request XSD

The request XML for the `getEngineInstances(String userName, String engineInstanceRequest)` method is based on the `engineInstanceRequest request XSD`, shown in Example 33-28.

The `engineInstanceRequest request XSD` describes the set of rules that the request XMLs must follow to be valid. An example of a valid request XML for `getEngineInstances()` is:

```xml
<request>
  <enginetypeid>-1</enginetypeid>
  <locale>en_us</locale>
  <scope>LOCAL</scope> /*use GLOBAL for global scope*/
</request>
```

Example 33-28  engineInstanceRequest Request XSD

```xml
<?xml version="1.0" encoding="US-ASCII" ?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema"
  xmlns="http://www.example.com"
  targetNamespace="http://www.example.com"
  elementFormDefault="qualified">
  <xsd:element name="request">
    <xsd:complexType>
      <xsd:sequence>
        <xsd:element name="enginetypeid"/>
        <xsd:element name="locale" type="xsd:string"/>
        <xsd:element name="scope" type="xsd:string"/>
      </xsd:sequence>
    </xsd:complexType>
  </xsd:element>
</xsd:schema>
```
33.9.4 Understanding Web Service Response XSDs

For each of the web service calls, if the call is successful an XML string is returned. If the web service call results in an error, a service error XML string is returned. The client can then call the ServiceUtil() class to deserialize the XML string into ECSF runtime metadata objects or deserialize the service error XML string into an exception message.

When the query web service requests are successful, a response message is returned. The XML strings for successful web service calls are based on the XSDs for the following methods:

- getSavedSearch()
- getSavedSearches()
- saveSearch()
- deleteSearch()
- getSavedSearchDetails
- search()
- getEngineInstances()

If any of the query web service requests result in an exception, the exception is wrapped in a service error XML response message. The service error XML strings are based on the following XSD:

```xml
<?xml version="1.0" encoding="US-ASCII" ?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema"
    xmlns="http://www.example.com"
    targetNamespace="http://www.example.com"
    elementFormDefault="qualified">
    <xsd:element name="serviceError">
        <xsd:complexType>
            <xsd:sequence>
                <xsd:element name="code" type="xsd:string" minOccurs="0"/>
                <xsd:element name="message" type="xsd:string"/>
                <xsd:element name="stack" type="xsd:string"/>
            </xsd:sequence>
        </xsd:complexType>
    </xsd:element>
</xsd:schema>
```

33.9.4.1 getSavedSearch()

The web service response message for the method String getSavedSearch(String userName, String savedSearchRequest) is based on the following XSD:

```xml
<?xml version="1.0" encoding="US-ASCII" ?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema"
    xmlns="http://www.example.com"
    targetNamespace="http://www.example.com"
    elementFormDefault="qualified">
    <xsd:element name="savedSearch">
        <xsd:complexType>
            <xsd:sequence>
            </xsd:sequence>
        </xsd:complexType>
    </xsd:element>
</xsd:schema>
```
33.9.4.2 getSavedSearches()

The web service response message for the method `String getSavedSearches(String userName, String savedSearchRequest)` is based on the following XSD:

```xml
<?xml version="1.0" encoding="US-ASCII" ?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema"
         xmlns="http://www.example.com"
         targetNamespace="http://www.example.com"
         elementFormDefault="qualified">
    <xsd:include schemaLocation="saved-search.xsd"/>
    <xsd:element name="savedSearches">
        <xsd:complexType>
            <xsd:sequence>
                <xsd:element ref="savedSearch" maxOccurs="unbounded" minOccurs="0"/>
            </xsd:sequence>
        </xsd:complexType>
    </xsd:element>
</xsd:schema>
```

33.9.4.3 saveSearch()

The web service response message for the method `String saveSearch(String userName, String savedSearchRequest)` is the same as the response for `getSavedSearch()`. For information, see `getSavedSearch()`.

33.9.4.4 deleteSearch()

The web service response message for the method `String deleteSearch(String userName, String savedSearchRequest)` is the string `success`.

33.9.4.5 getSavedSearchDetails

The web service response message for the method `String getSavedSearchDetails(String userName, String savedSearchRequest)` is based on the following XSD:

```xml
<?xml version="1.0" encoding="US-ASCII" ?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema"
         xmlns="http://www.example.com"
         targetNamespace="http://www.example.com"
         elementFormDefault="qualified">
    <xsd:include schemaLocation="saved-search.xsd"/>
    <xsd:element name="savedSearchDetails">
        <xsd:complexType>
            <xsd:sequence>
                <xsd:element ref="savedSearch" maxOccurs="unbounded" minOccurs="0"/>
            </xsd:sequence>
        </xsd:complexType>

33.9.5 About Invoking the ECSF Web Service

Invoke the ECSF web service by creating a JAX-WS proxy using the Oracle JDeveloper Web Service Proxy wizard. Then, modify the client Java class named AppModuleSearchServiceSoapHttpPortClient to add calls to the ECSF web service.

Note:
It is assumed that the web service is deployed and running on a remote Oracle WebLogic Server instance.

33.9.5.1 Create a JAX-WS Web Service Proxy

Creating a JAX-WS web service proxy using the Oracle JDeveloper Create Web Service Proxy wizard generates all classes and Java files for the web service enabled methods under the package oracle.ecsf.service.query.common.

To create a JAX-WS web service proxy:

1. In the Application Navigator, right-click the project in which you want to create the web service proxy, and choose New.

2. In the New Gallery, expand Business Tier, select Web Services and then Web Service Proxy, and click OK.

3. On the Select Web Service Description page of the wizard, enter the URL for the WSDL that was generated when the application was deployed on the Oracle WebLogic Server, for example, http://myhost.us.example.com:7101/CrmSearchService/AppModuleSearchService?WSDL, then tab out of the field.

   If the Next button is not enable, click Why Not? to understand what problem JDeveloper encountered when trying to read the WSDL document. If necessary, fix the problem after verifying the URL and repeat this step.

   When the wizard displays an enabled Next button, then Oracle JDeveloper has recognized and validated the WSDL document.

4. For Specify Default Mapping Options, enter or choose a Java package name for the generated web service proxy class.

5. Click Next.

6. Continue through the pages of the wizard to specify details about the web service proxy. For more information about each page of the wizard, press F1 or click Help.

7. Click Finish.

8. Copy the following files from the system11.xxx/DefaultDomain/config/fmwconfig Oracle WebLogic Server directory to the JAX-WS Client application's META-INF directory.
   - jps-config.xml
   - cwallet.sso
About Modifying the AppModuleSearchServiceSoapHttpPortClient Class

After you create the JAX-WS proxy, modify the AppModuleSearchServiceSoapHttpPortClient class to include the calls to web service methods. Example 33-29 shows an example of a modified class.

The sample client class illustrates how each of the methods are called and how the XMLs are deserialized.

Example 33-29  Sample Client Class

```java
import java.io.File;
import java.io.FileInputStream;
import java.io.FileNotFoundException;
import java.io.IOException;
import java.net.URL;
import java.util.ArrayList;
import java.util.Collection;
import java.util.Properties;
import javax.xml.namespace.QName;
import javax.xml.ws.BindingProvider;
import oracle.ecsf.SearchException;
import oracle.ecsf.SearchHits;
import oracle.ecsf.client.SearchGroup;
import oracle.ecsf.client.dataobject.SavedSearch;
import oracle.ecsf.client.dataobject.SavedSearchDetails;
import oracle.ecsf.impl.QueryMetaDataImpl;
import oracle.ecsf.meta.MetaEngineInstance;
import oracle.ecsf.service.query.common.AppModuleSearchService;
import oracle.ecsf.service.query.common.AppModuleSearchService_Service;
import oracle.ecsf.service.query.ws.marshaller.ServiceUtil;
import org.w3c.dom.Document;
import org.w3c.dom.Node;
import org.w3c.dom.NodeList;

### 33.10 About Implementing Coherence Cache for Search

ECSF uses caches for metadata and configurations in support of performance and Coherence cache across servers in a cluster. When an object in the cache is updated, or when the cache is cleared on one server, the caches used by the same applications on all servers in the cluster must reflect these changes. This allows for the use of an administration management console to manage the state of the applications across servers in the cluster without having to restart them.
33.10.1 About Implement Cache Coherence for Search

Set the value in the `oracle.ecsf.cache.type` system property to indicate the type of caching that ECSF should use. The value can be either `local`, in which case ECSF uses a local cache, or `coherence`, in which case ECSF uses a distributed cache that is shared by multiple ECSF servers. Setting the value to `local` causes the `LocalCacheFactory` to be used to instantiate non-Coherence local caches. To enable Coherence caches, specify `coherence` as the value.

By default, the coherence caches are created with the `ecsf-coherence-cache-config.xml` file that is included in `ecsf.jar`. However, you can set the `oracle.ecsf.coherence.cache.config` system property to the path of an alternate coherence configuration file to use. The configuration file must have a mapping for cache names of the format `ecsf-_*`. In the default `ecsf-coherence-cache-config.xml` file, this name maps to a configuration of a Coherence Near Cache. For more information, see Developing Applications with Oracle Coherence. <<Link to COHDG.>>

33.11 About Localizing ECSF Artifacts

When developing applications for international users, it is necessary to customize the display of data by adding locale-specific components and translating text.

Locales identify a specific language and geographic region. You must customize how ECSF presents and formats messages (that is, the data displayed to users) based on their locale. Locale affects:

- Messages that you create during design time (for example, facet display names) and are displayed to the users who perform the queries.
- Messages you create during deployment (for example, searchable object names, search category names, and index schedule names displayed during crawl management).
- Crawlable content.

ECSF must determine the locale to display the messages in the appropriate language for the user.

33.11.1 How to Translate Strings in Groovy Expressions

ECSF provides a way for you to use translated strings to define the `Title`, `Body`, and `Keywords` properties of searchable objects.

The `ECSFFormat` class provides two functions that can be called in Groovy expressions:

- `format(String key, Object param1, Object param 2,...)` takes in a resource bundle key name, as well as up to ten parameters, to be added to the formatted string. This function allows you to use translatable strings in the Groovy expression for the `Title`, `Body`, and `Keywords` properties.
- `getLabel(String attributeName)` takes in an attribute name and gets the translated label for this attribute. This function provides a way for you to get the translated value of an attribute label.

ECSF also reserves a Groovy entity formatter that provides two functions:
formatter.format(String key, Object param1, Object param2,...) allows you to format a string based on a template.

formatter.getLabel(String attributeName) can be used to retrieve the UI label defined for an attribute.

To use translated strings in Groovy expressions, you must:

1. Associate a resource bundle to the view object.
2. Use the format() function in the Groovy expressions for the Title, Body, and Keywords properties.
3. Associate a translated label to the attribute.
4. Use the getLabel() function in the Groovy expressions for the Title, Body, and Keywords properties.

33.11.1.1 Associate Resource Bundles to View Objects

To define translatable strings for use as part of the crawlable search properties, you must associate a resource bundle to the view object and define the translatable strings on the resource bundle.

To add resource bundles, do the following:

1. In the overview editor, select the General navigation tab.
2. Click the Add icon in the Custom Properties table header and select Translatable Property to open the Select Text Resource dialog.
3. Select a resource bundle from the Resource Bundle dropdown menu.

   Note:
   If there is no resource bundle associated with the view object, then an external resource bundle is created in the application. Save the new resource bundle externally.

4. In the Display Value field, enter a string to associate with the key in the page’s resource bundle. For example, enter Identification Number: {0}. {1} {2} {3} {4} {5} {6}.

5. In the Key field, enter a string to uniquely identify a locale-specific object in the resource bundle. For example, enter EMPVIEW_BODY.

6. In the Description field, enter a description of any length for the key and value pair. For example, enter body value for crawling.

7. Click Save and Select.

   A new entry is added to the resource bundle, and the resource bundle is associated to the view object.

33.11.1.2 About Using the format() Function in Groovy Expressions

To use the translatable string in the Groovy expression for Title, Body, and Keywords, you can write a Groovy expression to call the formatter.format() function with
the key to the resource bundle entry as an input parameter. The other input parameters are standard Groovy input parameters.

For example, if the EMPVIEW_BODY translatable string is defined as:

EMPVIEW_BODY=Identification Number: {0}. {1} {2} {3} {4} {5} {6}

then you can use the following Groovy expression for the Body property:

formatter.format("EMPVIEW_BODY", Deptno, Empno ((DeptView.size() > 0) ? "Dept:" : ""), DeptView.Dname, ((StatesEAView.size() > 0) ? "State:" : ""), StatesEAView.Name, TestTransient)

The resource bundle key name, as well as up to ten parameters are added to the formatted string.

For date attributes, you can write a Groovy expression to call formatter.format(String attributeName), without a resource bundle key as an input parameter, to correctly format the date attribute value as part of the Groovy expression.

### 33.11.1.3 Associate Translated Labels to Attributes

In order for an attribute's label to be displayed in the correct locale, you must associate a resource bundle entry to the attribute.

To add labels to attributes, do the following:

1. In the overview editor, select the **Attributes** navigation tab.
2. Select the desired attribute in the Attributes table and click the **Edit selected attribute(s)** icon.
3. In the Edit Attribute dialog, select **Control Hints** to open the Control Hints page.
4. Click the icon next to the **Label Text** field to open and use the Select Text Resource dialog.
5. Select a resource bundle from the **Resource Bundle** dropdown menu.

**Note:**

If there is no resource bundle associated with the view object, then an external resource bundle is created in the application. Save the new resource bundle externally.

6. In the **Display Value** field, enter a string to associate with the key in the page's resource bundle.
7. In the **Key** field, enter a string to uniquely identify a locale-specific object in the resource bundle.
8. In the **Description** field, enter a description of any length for the key and value pair.
9. Click **Save and Select**.

A new entry is added to the resource bundle, and the resource bundle is associated to the view object attribute.
33.11.4 About Using the getLabel() function in Groovy Expressions

In order for the translated value of an attribute label to be crawled in the correct locale, the function `getLabel()` must be called as part of the Groovy expression for Title, Body, and Keywords, as shown in Figure 33-7.

**Figure 33-7  Example of Calling the getLabel() Function**

<table>
<thead>
<tr>
<th>Primary Table</th>
<th>Fusion.Emp.Emp</th>
</tr>
</thead>
<tbody>
<tr>
<td>Title</td>
<td><code>formatter.getLabel(&quot;Ename&quot;) + &quot; - &quot; + Ename + &quot; - &quot; + Sql</code></td>
</tr>
<tr>
<td>Body</td>
<td><code>formatter.format(&quot;EMPLOYEE_GBO&quot;, {Display, Empno ${(Depth*2)} &quot;* Depth:&quot; &quot;&quot;, DepthView Ename, (StakedEAlke...</code></td>
</tr>
<tr>
<td>Keywords</td>
<td><code>*Employee Department Job Salary Data &quot; + curdoc.getChldDoc(&quot;StatesEAView&quot;) + &quot; + &quot; + curdoc.getChldDoc(&quot;State...</code></td>
</tr>
</tbody>
</table>

In the example, `formatter.getLabel("Ename")` retrieves the translated value of the attribute's label from the view object definition.

Calling the `getLabel()` function retrieves the translated value of the attribute's label from the view object definition for crawling.

33.11.2 About Localizing Facet Display Names

If not previously loaded for the current user's locale, facet display values are loaded by querying the list of values (LOV) associated with the facet in the context of the current user at query time. Whatever values or display values returned by querying the LOV in the context of the current user are loaded and returned as part of the facet in the query result for display in the user interface.

There are many ways to configure LOVs for localization. Two of them are described here: using the VL table and using resource bundles.

33.11.2.1 About Configuring LOVs for Localization Using the VL Table

Facets are displayed in a tree.

*Facet Display Name
  *Facet Entry Display Name
  *Facet Entry Display Name
  ...

The facet display name is translated per the resource bundle supported by Oracle Application Development Framework (Oracle ADF). The facet entry display names are translated per the LOV definition with context locale binding.

For example:

*Organization
  *Vision USA
  *Vision Canada

Organization is translated via the Oracle ADF resource bundle with key ORGANIZATION_ID.
To translate Vision USA and Vision Canada, you need to create a view object based on the VL table that supports localization, for example, HR_ALL_ORGANIZATION_UNITS_VL.
After this view object is created and used as the LOV for the BUSINESS_UNIT_ID of the base searchable object, the value for the field name is pulled from the VL table with the correct locale of the current user. For information on how to create facets, see How to Implement Faceted Navigation.

When your facet is localized, Oracle Fusion Applications Search UI requests facet definitions from ECSF when users performs a search. ECSF will load the facet definition, including facet names from the resource bundle based on user's locale. When the user clicks the facet, ECSF will execute the LOV for the facet and retrieve the data from the database based on the current user's language setting. In the example, the organization name will be displayed to the user in his language. When the user clicks on a particular node, such as Vision USA, ECSF will perform a query against the search engine with a filter on Organization ID = 204 where 204 is the organization ID for Vision USA.

33.11.2.2 About Configuring LOVs for Localization Using the Resource Bundles

Facet display names can be localized with Oracle ADF resource bundles. When you create a facet, specify the name of a facet by referring to a resource key. At runtime, when the resource bundle is translated, the correct display name will be retrieved based on the user's locale. Localization of facet entries are supported by view object based LOVs. The view object must be designed to support localization.

**Note:**

Since facets are cached for performance, internationalized messages must be cached with the locale.

If the display name is not available for the current locale, the facet name is used.
ECSF uses LOVs to support facets, and the LOV display values must be translatable. The data sources of the LOVs used for facets can be view objects with static data or view objects with dynamic data (pulled from database through SQL). Display values of LOVs whose data sources are view objects with static data are displayed using the resource file corresponding to the application’s current locale. Display values of LOVs populated with dynamic content can be translated based on the locale in the user’s context.

33.11.2.2.1 How to Translate LOV Display Values

You can translate the LOV display values based on the locale in the user’s context by adding a language code column to the view object. The following instructions are based on the example provided in How to Implement Faceted Navigation. It assumes that you have an EmpView base view object with a working LOV on the StatesView view object already defined.

To translate the LOV display values, do the following

1. Add a **LANG** column (VARCHAR2) to the **STATES** table.

2. Populate the **LANG** column for all rows with a 2-character ISO639 code (for example, **en** or **fr**).

3. Add the **LANG** column to the States entity object and StatesView view object. Alternatively, you can re-create it from scratch.

4. Create a view criteria on StatesView (on the view object, navigate to Query > View Criteria > + and click the Add Criteria button) with the following values:
   - **Attribute**: Lang
   - **Operator**: equal to
   - **Operand**: Bind Variable

5. For Parameter, click **New** to create a bind variable with the following values:
   - **Name**: UserLang
   - **ValueType**: Expression

6. Click OK, and click OK again.

7. Navigate to EmpView > View Accessors, select StatesView1, and click **Edit**.

8. In the Edit View Accessor dialog, select the view accessor (StatesViewCriteria) in the Available list and click the Move icon to add it to the Selected list.

9. Edit the **UserLang** bind variable from StatesView by entering the following Groovy expression that evaluates to the user’s current language:

   ```groovy
   adf.context.locale.getLanguage()
   ```

The view criteria (similar to a defined WHERE clause) on StatesView and a bind variable named **UserLang** are created. The EmpView base view object is configured to use the view criteria when querying StatesView and the value of the bind variable is set to the user’s current language. During runtime, only the
records where LANG matches the locale.getLanguage() of the locale is returned.

### 33.11.3 About Localizing Crawl Management Display Names

Crawl management display names—that is, the searchable object names, search category names, and index schedule names displayed during crawl management—must be translated to the language of the administration tool user. Enabling translation for these display names is handled in the database through the translation table so that it can be shared across runtime, the ECSF Command Line Administration Utility, and Fusion Applications Control.

**Note:**

For Fusion Applications Control, the display name for searchable objects, search categories, and index schedules is in the language of the object created by the administration users.

Deployment to Oracle SES is not based on translated fields.

Localize the crawl management display names by translating the seed data that you create in English. For information see [Initializing Oracle Fusion Application Data Using the Seed Data Loader](#).

### 33.11.4 About Localizing Crawlable Dynamic Content

Content crawled into Oracle SES can support different languages. For searchable objects with dynamic content (content pulled from a database through view objects), ECSF supports one language per business object instance. An example is a sales order created by a customer with a particular language. In other words, ECSF only supports language on a per record or row basis.

While ECSF supports only one language per object instance, each instance can be a different language. ECSF detects the language for a given document. For information, see [About Determining Locale](#).

### 33.11.5 About Localizing Crawlable Template Content

In addition to dynamic content, searchable objects can contain template content. Templates are text formats you create to form the body, title, keywords, action titles, parameters, and so on. In ECSF, you use Groovy scripting language to create expressions for some fields. The language must be identified to translate Groovy-enabled fields into the appropriate language before they are sent to the search engine. Localization for Groovy-enabled fields is supported by formatting functions.

ECSF provides a set of formatting functions based on Java Text Format Function. These formatting functions allow you more flexibility to build your desired formats. [Example 33-30](#) illustrates the use of a Groovy function with Java Text Formatting to form the body for localization.

EMPLOYEE_TEMPLATE and REPORTS_TEMPLATE are keys to two translatable templates that are stored in a resource bundle. The template must be a legal format string for java.text.MessageFormat. (FirstName, LastName, EmailAddress, and ZipCode refer to view object attributes.)
To illustrate how the expression is resolved during runtime, see Table 33-2 for a sample view object, Table 33-3 for a sample child view object, and Example 33-31 for a sample resource bundle.

**Table 33-2 Sample Parent View Object (Employee)**

<table>
<thead>
<tr>
<th>ID</th>
<th>FirstName</th>
<th>LastName</th>
<th>EmailAddress</th>
<th>ZipCode</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>John</td>
<td>Wayne</td>
<td><a href="mailto:john.wayne@example.com">john.wayne@example.com</a></td>
<td>94065</td>
</tr>
<tr>
<td>2</td>
<td>Chris</td>
<td>Smith</td>
<td><a href="mailto:chris.smith@example.com">chris.smith@example.com</a></td>
<td>94066</td>
</tr>
</tbody>
</table>

**Table 33-3 Sample Child View Object (Reports)**

<table>
<thead>
<tr>
<th>ParentID</th>
<th>FIRST_NAME</th>
<th>LAST_NAME</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>John</td>
<td>Doe</td>
</tr>
<tr>
<td>1</td>
<td>Jake</td>
<td>Ray</td>
</tr>
<tr>
<td>2</td>
<td>Bob</td>
<td>Barley</td>
</tr>
<tr>
<td>2</td>
<td>Chris</td>
<td>Carpenter</td>
</tr>
</tbody>
</table>

**Note:**

This example is strictly used to illustrate functionality. Concatenation of words using two resource messages is not translation friendly.

The following shows the resulting data sent to Oracle SES during runtime:

Employee John Wayne with email address john.wayne@example.com works in zipcode 94065
direct report named John Doe has a direct report named Jake Ray

Employee Chris Smith with email address chris.smith@example.com works in zipcode 94066
direct report named Bob Barley has a direct report named Chris Carpenter

Resource bundles are used to store language variations, while translation is the responsibility of Oracle Fusion Applications i18n support infrastructure.

**Example 33-30 Using Groovy Function to Translate the Body**

```groovy
formatter.format("EMPLOYEE_TEMPLATE", FirstName, LastName, EmailAddress, ZipCode)
for (item in doc.getChildDocs("Reports"))
{
    formatter.format("REPORTS_TEMPLATE", item.fields.FIRST_NAME, item.fields.LAST_NAME);
}
```

**Example 33-31 Sample Resource Bundle**

```java
id=EMPLOYEE_MESSAGE,message="Employee {0} {1} with email address {2} works in zipcode {4}"
id=REPORTS_TEMPLATE,message=" direct reports {0} {1}"
```
33.11.6 About Determining Locale

To display messages in the appropriate language for the user, ECSF must determine the locale. How ECSF determines locale varies by module.

33.11.6.1 About the Search Page

The Search page, an extension of Oracle JDeveloper, uses the locale of the Java Virtual Machine (JVM). This locale is set at either the machine level or at JDeveloper level. For information about setting the JVM locale for JDeveloper, see the JDeveloper online help.

33.11.6.2 About the ECSF Command Line Administration Utility

The ECSF Command Line Administration Utility, a standalone and single user application, uses the default locale returned by `Locale.getDefault()`.

33.11.6.3 About Crawl

You can specify the locale of the data to be indexed by using any of the following methods:

- Language field
- Crawler’s language preference
- Java Virtual Machine (JVM) default locale

You can specify a view object attribute as a language field for a searchable object by using the Search page. For information, see Setting Search Property Values for View Objects.

The value of this field for each instance is the language for the instance.

If you do not specify a language field for a given searchable object, ECSF uses the language preference of the crawler user. This implementation is application specific. ECSF obtains a session user through identity manager, and obtains the locale for the user while crawling data. There must be a crawler user with a proper locale profile, including language preference, created for Oracle Fusion Applications. This user’s language preference is used as the default language if a language field does not exist.

If no crawler language is available, JVM's default locale (`Locale.getDefault()`) is used to identify the language, and the JVM default language is used.

33.11.6.4 About Query

The user who calls the ECSF query time API must bind the locale to `SearchContext`. If the locale is not set in the search context, ECSF attempts to get from `ADFContext`. If that fails, the default locale, shown in Example 33-32, is used.

Example 33-32  Default Locale for Searcher

```java
ADFContext adfContext = ADFContext.getCurrent();
Locale mLocale = (adfContext != null && adfContext.getLocale() != null) ? adfContext.getLocale() : Locale.getDefault();
```

33.12 About Using ECSF Diagnostics

This section outlines the use of the diagnostic tests available in the ECSF application. The diagnostic service can be reached in a browser by appending Diagnostics to the
ECSF data service URL. The data service URL will be shown on the Search Engine Instance Parameters tab in the Oracle Enterprise Manager Fusion Applications Control.

All test results will include the number of failures and errors, and the time taken in milliseconds to execute the test.

Tests that are marked as protected require the ECSF_All_Services permission to access.

### 33.12.1 Query Tests

These tests are used to diagnose issues in query functionality.

#### 33.12.1.1 About the Simple Query Test

This test can be used as a sanity check to ensure that queries are returning data. The test queries for all records from the selected category. Table 33-4 lists the parameters.

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Searchable Group</td>
<td>Drop-down</td>
<td>The search category against which to invoke the category. The format of the parameter is &lt;category&gt;@&lt;engine instance&gt;. The selection [All Groups] can be made to search against all of the displayed groups.</td>
</tr>
</tbody>
</table>

Note: The engine instance SES proxy user is used for the search and the search keyword is "*".

**Result**

Indicates if any search hits and facets are returned. The actual data are not displayed due to security reasons.

#### 33.12.1.2 About the Searchable Object Metadata Test

This test provides information about the selected searchable object and validates groovy expressions for the underlying view object. Table 33-5 lists the parameter of this test.

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Searchable Object</td>
<td>Drop-down</td>
<td>The search object to inspect. The format of the parameter is &lt;object&gt;@&lt;engine instance&gt;.</td>
</tr>
</tbody>
</table>

**Results**

- Searchable object configuration, including its display name, view object name, ID, schema name, registered engine instance, associated schedule, and associated categories.

- Searchable object status including if it is deployed, if it is active, and if the latest engine instance parameters have been applied to it. The deployment and crawl statuses of the associated schedule are also displayed, along with the deployment statuses of associated categories.
• View object information, including the driving table, plugin class, if the plugin is ACL enabled, view object SQL select statement, view object fields, and child references.

• Results of the body, title, keywords, and default action title validations.

• Display of top-level facets. Actual data are obfuscated due to security reasons.

• Searchable object actions.

33.12.1.3 About the Searchable Groups Test

This test displays the searchable groups for an engine instance. Table 33-6 lists the parameters of this test.

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Engine Instance Name</td>
<td>Drop-down</td>
<td>Name of the engine instance.</td>
</tr>
</tbody>
</table>

Note: All searchable groups in the search application are displayed.

**Result**

Searchable groups for this engine instance, along with their associated searchable objects.

33.12.1.4 About the Advanced Query (Protected) Test

This test can be used as a more granular check to ensure that queries are returning data. Table 33-7 lists the parameters of this test.

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Searchable Group</td>
<td>Drop-down</td>
<td>The search category to invoke the category against. The format of the parameter is &lt;category&gt;@&lt;engine instance&gt;. The selection [All Groups] can be made to search against all of the displayed groups.</td>
</tr>
<tr>
<td>Query Language (optional)</td>
<td>String</td>
<td>Specify a language for the query (language short code, such as &quot;en&quot;). If no language is specified then the currently configured language will be used.</td>
</tr>
<tr>
<td>User Name</td>
<td>String</td>
<td>The user name to search with. Only data visible to this user will be shown.</td>
</tr>
<tr>
<td>Query String</td>
<td>String</td>
<td>String to search for.</td>
</tr>
</tbody>
</table>

**Results**

• Result hit count: The number of hits for the first page of results (up to 10).

• Estimate hit count: The estimated total hit count will for this query.

• Alternate keywords if any.

• Top-level facets including counts.
• Search results: The title, body, and attribute values for the first page of results (up to 10 records) will be shown.

### 33.12.2 About Crawl Tests

These tests are used to diagnose issues in crawler functionality, including ECSF feed generation.

#### 33.12.2.1 About the Crawl Searchable Object Test

This tests crawling of the object, splitting of its table, and processing of data feeds. Table 33-8 lists the parameters of this test.

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Searchable Object</td>
<td>Drop-down</td>
<td>The search object to crawl. The format of the parameter is <code>&lt;object&gt;@&lt;engine instance&gt;</code>.</td>
</tr>
<tr>
<td>Incremental Crawl</td>
<td>Checkbox</td>
<td>Tests incremental crawl on the Searchable Object, otherwise a full initial crawl will be simulated.</td>
</tr>
<tr>
<td>Number of Batches to test</td>
<td>Input (integer)</td>
<td>Number of data feeds to execute (such as batches). -1 can be specified to process all data feeds/batches (not recommended for large data sets).</td>
</tr>
</tbody>
</table>

Note: The engine instance crawl user is used for this test.

**Results**

• SQL statement for the searchable object.

• Statistics on each work unit (batch) including the number of documents crawled, the time taken, and the rate of documents processed by ECSF.

• Total statistics for all work units processed.

#### 33.12.2.2 About the SES Instance Test

This test displays information about the engine instance, tests proxy login into SES, tests ECSF security service authentication, and displays ECSF metadata as well as SES metadata. Table 33-9 lists the parameter of this test.

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Engine Instance Name</td>
<td>Drop-down</td>
<td>Select the ECSF engine instance to test.</td>
</tr>
</tbody>
</table>

**Results**

• SES admin endpoint.

• ECSF service endpoint.

• Result of proxy login into SES with stored credentials.

• ECSF security service authentication status.
• Search groups in ECSF.
• Source groups in SES.
• Index schedules in ECSF including the statuses in ECSF.
• Index schedules in SES including the statuses in SES.
• Searchable objects in ECSF.
• Data sources in SES.
• Number of configured proxy logins (federated trusted entities) in SES.
• Configured identity plugin URL in SES.

33.12.2.3 About the Control Feed Test
This tests splitting of the table and generates the complete control feed for a searchable object. Table 33-10 lists the parameters of this test.

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Searchable Object</td>
<td>Drop-down</td>
<td>Select the searchable object.</td>
</tr>
<tr>
<td>Incremental Crawl</td>
<td>Checkbox</td>
<td>If checked, it tests incremental crawl on the searchable object; otherwise a full initial crawl will be simulated.</td>
</tr>
</tbody>
</table>

Note: The engine instance crawl user is used for this test.

Result
Complete control feed (including list of data feeds).

33.12.2.4 About the Data Feed (Protected) Test
Tests a data feed for a searchable object. This tests crawling of the object, splitting of its table, and processing of data feeds. Table 33-11 lists the parameters of this test.

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Data Feed URL</td>
<td>Input (String)</td>
<td>Enter a full data feed URL for a searchable object.</td>
</tr>
</tbody>
</table>

Note: The part of the URL that points to the ECSF data service will be ignored. Instead the data feed will be invoked against the data service stored in the database for the object’s associated engine instance.

Result
Complete XML data feed.

33.12.3 About Environment and Configuration Information Tests
These tests provide information about the configuration of the ECSF environment.
33.12.3.1 About the Configuration Parameters Test

This test lists the ECSF search engine instance parameters. Table 33-12 lists the parameter of this test.

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Engine Instance</td>
<td>Drop-down</td>
<td>Specify the engine instance to inspect.</td>
</tr>
</tbody>
</table>

**Result**

Values of the search engine instance parameters. Usernames will be obfuscated for security reasons.

33.12.3.2 About the Environment Information Test

This test retrieves environment information such as ECSF properties and ECSF jar extraction path on the server.

**Results**

- System properties that begin with "oracle.ecsf".
- Location of the Java class for this test on the server.

33.12.3.3 About the Data Source Test

This tests the connection to the SearchDB data source.

**Results**

- Displays if the application was able to obtain the connection successfully.
- If connection is successful displays the connection URL.

33.12.3.4 About the Application Extension/ApplCore Session Locale (Protected) Test

This tests the application extension session for the given user. Table 33-13 lists the parameter of this test.

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>User Name</td>
<td>Input (String)</td>
<td>Specify the user for the test.</td>
</tr>
</tbody>
</table>

**Results**

- Initializes the application extension session for the user.
- Locale for the ApplCore session.

33.12.4 About Security Tests

These tests are used to diagnose issues in the security layer of the ECSF application.
33.12.4.1 About the Security (Protected) Test

This tests various security functionalities for a user. Table 33-14 lists the parameters of this test.

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>User Name</td>
<td>Input (String)</td>
<td>Specify the user to test.</td>
</tr>
<tr>
<td>Permission (optional)</td>
<td>Input (String)</td>
<td>Specify a permission to check for the user. The format of the permission should be TYPE:NAME:ACTIONS.</td>
</tr>
<tr>
<td>Engine Instance Name</td>
<td>Drop-down</td>
<td>The engine instance is used when retrieving credentials for non APPID users.</td>
</tr>
</tbody>
</table>

**Results**

- Checks that the user exists in the system.
- Checks that the user has the given permission.
- Checks that the user has access to the oracle.ecsf credential map.
- Displays if the user has access to all ECSF services.
- Displays if the user has access to the Diagnostics service if it does not have access to all services.
- Checks that the credentials for the user can be obtained from the credential store.

33.12.4.2 About the Credential Store Test

This tests system access to the credential store. Table 33-15 lists the parameters of this test.

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Engine Instance Name</td>
<td>Drop-down</td>
<td>The engine instance determines which map to access in the credential store.</td>
</tr>
</tbody>
</table>

**Result**

Checks that the system can write to the credential store by creating and removing credentials for a dummy user.

33.12.4.3 About the Security Plugin (Protected) Test

This tests the security plugin of a searchable object for a user. Table 33-16 lists the parameters of this test.
Table 33-16  Parameters for Security Plugin (Protected) Test

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Searchable Object</td>
<td>Drop-down</td>
<td>The search object to test against. The format of the parameter is &lt;object&gt;@&lt;engine instance&gt;.</td>
</tr>
<tr>
<td>User Name</td>
<td>Input (String)</td>
<td>Specify the user to test.</td>
</tr>
<tr>
<td>Attribute Name (optional)</td>
<td>Input (String)</td>
<td>The security attribute to use for the test. If no attribute is given then the default security attribute will be used.</td>
</tr>
</tbody>
</table>

Results

- Security attribute values for the user from the plugin.
- Security principals for the user.

33.13 About Troubleshooting ECSF

This section describes common problems that you might encounter when using ECSF and explains how to solve them.

33.13.1 Understand Common Problems and Solutions

The following are common problems you may encounter and solutions that solve them:

- Cannot See Data in Data Feeds
- Configuration or Data Feed Execution Thread Is Busy for Longer than the Configured Warning Timeout
- Class Not Found Errors When Running the ECSF Servlet
- Out of Memory Error when Deploying the ECSF Application to or Running the Application
- Blank /UI Shell Pages
- Memory Leak on ThreadLocal Variable (SearchContext)

33.13.1.1 Cannot Remove the ECSF Runtime Server Library

You remove the ECSF Runtime Server library from the project and save, but the library reappears in your project.

Problem:

The Common-Model.jar file that you added to your project contains a dependency on ECSF Runtime Server.

Solution:

Remove the Common-Model.jar file.

33.13.1.2 Cannot See Data in Data Feeds

Your feed request made through either Oracle SES or the browser returns no data.
Problem:
After you initially crawl the data source, subsequent feed requests result in incremental feeds (that is, feeds that contain only changes in data).

Solution:
Override the incremental feed by performing one of the following tasks:

- Through Oracle SES, start full indexing from the Fusion Applications Control. For information, see the "Starting Full Indexing" section in *Administrator’s Guide*.
- Through the browser, append `?forceInitialCrawl=true` to the config feed.

### 33.13.1.3 Configuration or Data Feed Execution Thread Is Busy for Longer than the Configured Warning Timeout

You receive an error indicating that the execution time of the configuration or data feed execution thread is exceeding the timeout settings, for example:

Error: name has been busy for "elapsedTime" seconds working on the request "curReq", which is more than the configured time (StuckThreadMaxTime) of "maxTime" seconds.

Following are two possible causes and solutions for this issue:

Problem:
A SQL script being executed by ECSF for the configuration feed or data feed is taking a long time to execute.

Solution:
Enable SQL tracing to find long-running SQL processes, and tune the SQL script to reduce the execution time.

Problem:
ECSF is unexpectedly running longer than the configured time.

Solution:
Increase the Oracle WebLogic Server warning timeout setting.

### 33.13.1.4 Class Not Found Errors When Running the ECSF Servlet

You receive Class Not Found errors when you run the ECSF servlet.

Problem:
When you created the ECSF application, you did not select the Fusion Web Application (ADF) template.

Solution:
Add the Fusion Web Application (ADF) template through Application Properties.

### 33.13.1.5 Out of Memory Error when Deploying the ECSF Application to Oracle WebLogic Server or Running the Application

You receive a java.lang.OutOfMemoryError: PermGen space exception when you deploy the ECSF application to Oracle WebLogic Server instance or when you run the application.

Problem:
MaxPermSize is set too low.
Solution:
Increase MaxPermSize by starting the WebLogic JVM using the –XX:MaxPermSize=256m parameter.

If you start the ECSF servlet from within JDeveloper using the Integrated WebLogic Server:

1. Go to the jdev cache directory /.jdeveloper/DefaultDomain/bin.
2. Open setDomainEnv.sh.
3. Locate the line that contains –XX:MaxPermSize=128m, and change it to –XX:MaxPermSize=256m.

33.13.1.6 Blank Oracle ADF/UI Shell Pages
Oracle ADF/UI Shell pages fail to load or a blank page appears. You receive the following exception in the JDeveloper Log window:

java.lang.NoClassDefFoundError: oracle/ecsf/client/SearchCtrl at oracle.apps.fnd.appcore.globalSearch.ui.ecsf.ECSFSearchUtils.getSearchControl(ECSFSearchUtils.java:67)

Problem:
The ECSF Client library is missing from the project class path.

Solution:
Update the project class path with the ECSF Client library.

33.13.1.7 Memory Leak on ThreadLocal Variable (SearchContext)
You encounter memory leaks while using the ECSF query API to define the Oracle Fusion Applications Search user interface.

Problem:
SearchContext is implemented as a ThreadLocal variable, which is created when ContextFactory.getSearchContext() is first called in the current Thread. All subsequent calls to getSearchContext() within the same Thread results in that instance being returned. Since the ThreadLocal variable remains associated with the Thread, memory leaks occur.

Solution:
After the completion of your Oracle Fusion Applications Search UI logic and before results are returned to the UI for rendering, you must call the SearchContext.release method.

When the SearchContext.release method is called on the SearchContext, the instance of the ThreadLocal is removed from the current Thread. A subsequent call to getSearchContext then results in the creation of a new instance of the SearchContext ThreadLocal variable. The SearchContext.release method also implicitly call releaseConnection().
Note:

If you call `SearchContext.release` and then need to call `getSearchContext()` again within the same Thread, then you must set any parameters you need on the `SearchContext` again as it is a brand new instance.

### 33.13.1.8 About Checking the Space Availability for SES Crawls in the Database

The table spaces required are:

- **SEARCH_DATA**
- **SEARCH_INDEX**
- **SEARCH_TEMP**

Verify the details for **SEARCH_DATA** using this SQL statement:

```sql
select FILE_NAME, TABLESPACE_NAME, BYTES, MAXBYTES, BLOCKS, MAXBLOCKS from sys.dba_data_files where TABLESPACE_NAME = 'SEARCH_DATA';
```

Use this command to add additional table space for **SEARCH_DATA**:

```sql
ALTER TABLESPACE SEARCH_DATA ADD DATAFILE '/slot/ems7248/oracle/db/apps_st/data/SEARCH_DATA_3.dbf' SIZE 1052M AUTOEXTEND ON;
```

The DBF filepath will depend on the environment being used. To learn the exact DBF file to be used, use the `select` command shown above. For example: `/slot/ems7248/oracle/db/apps_st/data/SEARCH_DATA_3.dbf`

To delete an additional datafile:

```sql
ALTER TABLESPACE SEARCH_DATA DELETE DATAFILE '/slot/ems7248/oracle/db/apps_st/data/SEARCH_DATA_9.dbf';
```

The same steps can be used to add additional data files for other table spaces.

### 33.13.1.9 About Crawling with a Different User

On a provisioned environment, the crawls will not work for all users. The users will need to be modified.

**Pre-requisite:** Find the application role for which the user must be added.

As an example, take the Application role `ZCA_CRM_FUSION_SEARCH_CRAWL_DUTY` and assign `sales_admin` to this role. `ZCA_CRM_FUSION_SEARCH_CRAWL_DUTY` is the application role that is necessary for a user to access the feeds.

- Login to CRM EM with the required credentials.
- Right-click CRMDomain and select **Security > Application Roles**.
- Select the Stripe as `crm` and in Roles enter `ZCA_CRM_FUSION_SEARCH_CRAWL_DUTY` and search.
- Click the role `ZCA_CRM_FUSION_SEARCH_CRAWL_DUTY` and click Add to add the `sales_admin` user.
- Click **OK**.
The user sales_admin now can be used for crawling.

### 33.13.1.10 "FND-6601 Search categories are not available"

**Problem:**
The endpoints for the search applications are not up and running.

**Solution:**
Set the correct search application endpoints in the `connections.xml` file of the client application. Make sure the `IS_ACTIVE` parameter corresponding to this search engine instance is set to "Y". Make sure the `IS_ACTIVE` parameter corresponding to this search engine instance is set to "Y" in the ECSF_PARAMETER table.

**Problem:**
If your search application only contains one category and the category is secured, the Global Search UI will display this error message if this category does not pass the permission check. In this case, no categories are available for search.

**Solution:**
Usually this is because the permission set on the searchable object is not accessible to the logged-in user, causing the secured category to not be returned by the search application.

**Problem:**
Search_Server1 is not up and running.

**Solution:**
Bounce if required.

**Problem:**
wsm-pm is not up and running. For example, wsm-pm is hosted in the SCM_CommonServer for FSCM.

**Solution:**
Bounce if required.

### 33.13.1.11 "FND-6603 Search is not currently available"

**Problem:**
The identity management setup in SES administration is pointing to an invalid URL combination and the proxy user cannot log into ECSF security service.

**Solution:**
Change the identity management setup to point to the correct url using the correct username and password.

**Problem:**
The response from the Search servers may be very slow and the Search UI is unable to fetch all the results.

**Solution:**
Increase the WS timeout using this parameter in the startup section on the WLS console for the Search Server

```
-Doracle.ecsf.service.ws.timeout=500000
```
33.13.1.12 "FND-6606 An application error occurred with this search"

Problem:
In B16, the category drop-down is not displayed in the main UI page. The Global Search UI does not load categories until an initial search is performed by clicking the Search button. The Global Search UI will show this error if getting categories failed against all the search applications. The endpoints for the search applications are not up and running or the search applications are inactive in the database.

Solution:
Set the correct search application endpoints in the connections.xml file of the client application. Make sure the IS_ACTIVE parameter corresponding to this search engine instance is set to "Y". Make sure the IS_ACTIVE parameter corresponding to this search engine instance is set to "Y" in the ECSF_PARAMETER table.

Cause:
If the search applications are up and running but this error is displayed, all the search applications probably are returning errors.

Look for the following line in the messages logged in the client server log, such as CustomerServer-diagnostics.log:

```java
at oracle.ecsf.service.query.ws.marshaller.ServiceUtil.toError(ServiceUtil.java:1499)
```

33.13.1.13 Query Does Not Return Search Results but No Errors Are Displayed on the UI

Cause:
The crawl for the data sources under this category was not successful.

Solution:
Log into SES administration and check that the schedule for the data source indexed successfully.

33.13.1.14 FUSION_RUNTIME.FND_TABLE_OF_VARCHAR2_4000 Exception on Schedules

Cause:
This exception may occur on the SES when a user tries to run a schedule. This is caused if the administration server and the manager servers are not started from the correct locations. (Console/node manager)

Solution:
The adminserver must be started using nodemanager and all other managed servers must be started by using the Administration console.

33.13.1.15 Where Can I Find the SES-ESS Crawler Logs?

On most of the provisioned environments, the ESS logs will be found in <APPLTOP>/instance/ess/rd. This will contain the crawl records for all the crawls run on the SES installed in that environment. If the location of these logs is changed, log in to the Enterprise Manager farm and update the RequestFileDirectory attribute.
33.13.1.16 My Crawls Are Failing
The SES crawls may fail due to various reasons. Some of the most common issues are listed here.

- Check if the ESS and search_server1 managed servers are running on the Common domain. If these are not running, the crawls will fail.
- Check if the corresponding Search server is in the "RUNNING" state.
- Check if the END points mentioned in the SES Source page are accessible.
- Check if the database has sufficient space to accommodate the crawled data. Check first query to increase the table space.
- Verify the security attributes for the Searchable View Object (SVO). Also verify if the passwords for CRAWL_APPIDs are correct.
- Check that these users are not locked:
  FUSION_APPS_FSCM_SES_CRAWL_APPID,
  FUSION_APPS_CRM_SES_CRAWL_APPID, and
  FUSION_APPS_HCM_SES_CRAWL_APPID.

33.13.1.17 How to Get the Password for the SES Administration Page
The SES Administration page uses "searchsys" as the default user for logging in. The password for SES can be discovered using WebLogic Server Scripting Tools (WLST) commands.

1. Connect to WLST.
2. Run the command:
   ```java
   listCred(map="oracle.apps.security",key="FUSION_APPS_ECSF_SES_ADMIN-KEY")
   ```
   Sample output:
   ```
   Already in Domain Runtime Tree
   [Name : searchsys, Description : null, expiry Date : null]
   PASSWORD:welcome1
   ```

33.13.2 About Diagnosing ECSF Problems
To diagnose ECSF problems in the development environment, you can view the log messages in the Oracle WebLogic Server at `DOMAIN_HOME/servers/SERVER_NAME/logs/SERVER_NAME-diagnostic.log`.

You can configure the log level for ECSF by using Fusion Applications Control or Oracle WebLogic Scripting Tool.

The log level for ECSF can be set to the following values:

- **TRACE** for FINE
- **NOTIFICATION** for INFO (default level)
- **WARNING** for WARNING
- **ERROR** for SEVERE

The following ECSF loggers can be used for logger name:
• oracle.ecsf.AdminLogger
• oracle.ecsf.ClientLogger
• oracle.ecsf.RuntimeLogger

• For more information, see the "Configuring Settings for Log Files" chapter in the
  Administering Oracle Fusion Middleware.
Initiate a SOA Composite from an Oracle ADF Web Application

This chapter describes what a user action or other activity in an Oracle ADF web application needs to do to invoke a SOA composite. The invocation is asynchronous and does not require a response. Inside the SOA composite, an Oracle Mediator component can provide routing and transformation, a BPEL component can provide business process orchestration, a human task service can provide workflows, and a decision service can provide complex business rules based decision making.

**When to implement:** A user action or other activity in an Oracle ADF web application needs to invoke a SOA composite. The invocation is asynchronous and does not require a response. Inside the SOA composite, an Oracle Mediator component can provide routing and transformation, a BPEL component can provide business process orchestration, a human task service can provide workflows, and a decision service can provide complex business rules based decision making.

**Design Pattern Summary:** A business component in the ADF Business Components Framework publishes a business event to execute a SOA composite application. The SOA composite application subscribes to the event using the Oracle Mediator component, and from there it can be routed to any other service component, such as BPEL.

**Involved components:**
- Oracle ADF web application that includes ADF Business Components.
- SOA composite application that includes an Oracle Mediator service component and an additional service component to which the event can be routed (such as a BPEL process service component).

**34.1 Introduction to the Recommended Design Pattern**

Oracle Fusion applications initiate business processes in response to user actions. Oracle ADF provides a change notification framework that is triggered at the end of a transaction involving ADF Business Components. This notification can be declaratively configured to raise business events that conform to an Event Description Language (EDL) definition. When an event is raised, it is published on the Event Delivery Network (EDN).

Process flows are implemented using a BPEL process service component as a bridge from EDN to the BPEL process. Because the events raised by the ADF Business Components are not a native BPEL construct, you use a mediator service component to subscribe to the event and to then invoke the BPEL process service component. The mediator service component acts as a binding between the EDN and the BPEL process service component. Whenever the event is raised by ADF Business Components (whether through a GUI action or programatically), the BPEL process service component is invoked. **Figure 34-1** illustrates how these work together.
This approach is recommended for the following reasons:

- Validation logic can be consolidated in the entity object.
- Multiple user interfaces can invoke the reusable entity object that produces the events.
- Event subscription can be modeled on the mediator service component and not hard wired into the UI.
- The producer of the event (in this case, ADF Business Components) does not need to know who the downstream consumers of the event are. If needed, the SOA back-end service can change, without needing to change anything in the Oracle ADF web application. Decoupling the Oracle ADF and SOA application lifecycles makes development more manageable.

Events raised by ADF Business Components are asynchronous with no return value. The event infrastructure leverages the WLS JMS provider, so any unconsumed events can be de-queued by the SOA platform at some later time if the platform isn’t running, assuming the JMS implementation leverages Oracle Advanced Queuing.

**Related Links**

The following documents provide additional information related to subjects discussed in this section:

- For more information about the EDN, see the chapter “Using Business Events and the Event Delivery Network” in the *Developing SOA Applications with Oracle SOA Suite.*

- For information about integrating Oracle Advanced Queuing with Oracle BPEL Process Manager or Oracle Mediator, see the chapter “Oracle JCA Adapter for AQ” in the *Understanding Technology Adapters.*
34.2 Other Approaches

Instead of using ADF Business Components, and the change notification publisher in entity objects to invoke a BPEL service component, you could use one of the following approaches. Use these development approaches only when the recommended approach cannot be implemented.

- **Using the Java Event API to Publish Events**
- **Using a JAX-WS Proxy to Invoke a Synchronous BPEL Process**

**WARNING:**

The following approaches should not be used:

- A web services data control created using a SOAP web service on the composite to create the view in the web application.
- A custom Java class in the web application using SOAP.
- A direct API call, or some other means to access the SOA composite.

34.3 Example

A web application built using ADF Business Components and Oracle ADF Faces allows users to register bugs found in software. An ADF Business Components entity object is used to create a bug, and contains an event whose payload is the attribute values for the created bug. The event is configured to be raised whenever the Create operation is called on the entity object.

A mediator service component subscribes to the event and accepts the event payload. A routing rule is configured for the mediator service component that routes the payload for the event to a BPEL process service component. This component then sends an email that contains the information from the payload to the bug's creator.

There are some cases in which one might need to propagate the end user ID of the event raiser across the invoked services for auditing purposes. It is recommended to propagate this information in the event payload. When raising events for CUD operations (create, update, delete), include the `last_updated_by` history column in the event definition. As this column exists in every Oracle Fusion Applications table, the user raising the event will always be propagated.

The sample code for this use case can be downloaded from Oracle SOA Suite samples.

34.4 How to Initiate a BPEL Process Service Component from an Oracle ADF Web Application

To initiate a BPEL process service component from a web application, you first need to create the web application using ADF Business Components and Oracle ADF Faces. You then create a SOA composite application that contains a mediator service component to pass the event payload created by ADF Business Components, and execute a BPEL process service component.
To invoke a BPEL process service component from an Oracle ADF web application:

1. In the Oracle ADF web application, define an event on an entity object. When you create the event, ensure the following:
   - Include attributes as needed for the payload.
   - Set the event point to be the database operation (create, update, delete) that will raise the event. You can also create any conditions needed to determine when the event should be raised.

   **Note:**
   - Event points can only be associated with Data Manipulation Language (DML) operations.
   - Personally identifiable information (PII) is any piece of information that can be used to uniquely identify a person. PII is sensitive and must be protected from potential misuse.

   When data is included in events or a BPEL flow, it is potentially exposed. While the transport may be encrypted on the SOA side, the data is not. The data in events, payload and BPEL variables is not secured by the security restrictions for business objects. Consider what data is to be exposed in the payload so as to prevent unauthorized access.

   Defining an event generates an Event Definition Language (.edl) file and XML schema definition (.xsd). The EDL file contains all event definitions for the entity and the XSD file defines the contents of an event’s payload, in addition to other objects needed by the BPEL process service component. These files together define the contract between the Oracle ADF application and the SOA composite application, as for a particular event, they identify the elements the SOA composite expects. Both these files are placed in the *events* directory for the project, and can be found in the Application Navigator as children to the associated entity object.

   In the example bug application, the BugReport entity object contains the BugCreated event. This event carries all the attributes on the entity object as its payload, and is published using the create operation as its event point.

2. Create the page in the view that will invoke the operation defined as the event point for the event (for example, through a command button bound to the commit operation or through the implicit call to the commit operation as a task flow return activity).

   In the example bug application, this is a UI command component bound to the Commit operation on the BugReport entity object. Because this operation commits the data to the database, and the Commit operation’s corresponding DML operation (create) is used to sync the ADF Business Components cache with the database, the ADF Business Components framework raises the event.

3. For verification purposes, you can either run the Oracle ADF web application from the Integrated Oracle WebLogic Server container included with Oracle JDeveloper, or you can deploy the Oracle ADF web application to a standalone container. This step includes procedures for running the Oracle ADF web
application within the embedded container and the SOA composite on a standalone Oracle WebLogic Server container. See Step 4 for procedures on deploying to a standalone container.

a. Make sure that EDN data sources have been configured. Using Oracle WebLogic Server Administration Console, verify that EDNDataSource and EDNLocalTxDataSource have been configured.

Note:
Oracle ADF and SOA data sources for EDN must point to the same schema. The EDN schema cannot be shared by more than one SOA runtime environment (such as outside a cluster).

b. Navigate to Domain Configurations > Services > JDBC > Data Sources to verify the existence of EDN data sources.

c. If the EDN data sources have not been configured, create new EDN data sources. Select EDNDataSource and click New. Enter the following details:
Name: EDNDataSource
JNDI Name: jdbc/EDNDataSource
Database Type: Oracle and Database Driver > Oracle Thin Driver XA: Versions 9.0.1.9.2.0.10.11.
Driver Class Name: oracle.jdbc.xa.client.OracleXADatasource.
Click Next. In the next window, uncheck Supports Global Transactions.
Click Next and configure the following:
Database Name: DB_NAME_FUSION_EDN
Host Name/Port: Enter the host name and port for server running the FUSION_EDN database
Database User Name/Password: Enter a username and password.
Test the data source. Set as DefaultServer and click Finish.

Define EDNLocalTxDataSource as above, but use EDNLocalTxDataSource for the data source and jdbc/EDNLocalTxDataSource for the JNDI name.

d. Map the data source in the web.xml and weblogic.xml files associated with the event publishing application. Add the lines shown in Example 34-1 to the WEB-INF/web.xml file.

e. Create an XML file called weblogic.xml with the following contents, and save it in the WEB-INF directory. This maps the global JMS resources to local JNDI names. The names in this file are the defaults expected by the remote connection factory, so you do not need to specify them. An example is shown in Example 34-2.

4. Add event-related SOA runtime libraries, specifically ADF Business Components uses Event Publishing APIs bundled in fabric-runtime.jar. Add a library reference to oracle.soa.workflow.wc to include the event publishing APIs bundled in the relevant JAR files.
Add the code shown in Example 34-3 to the weblogic-application.xml file.
5. In Oracle JDeveloper, create a SOA composite application project and add a mediator service component.

When you create the project, ensure the following:

- You choose to create a mediator service component on completion.

- Before configuring the mediator service component, manually copy the EDL and XSD files created in Step 1 to the SOA composite application project's source path.

- Open the MPLAN file for the mediator service component and create a new subscription that points to the EDL file moved into the source path. This means the mediator service component will now be subscribed to that event.

In the following sample application, a mediator service component named BugCreatedRouter is subscribed to the BugCreated event, as shown in Figure 34-2.

**Figure 34-2  Mediator Subscription to an Event**

6. Create the BPEL process service component.

When you create the component, ensure the following:

- Use the Create BPEL Process dialog to configure the payload. Use the Input Element finder icon to select the payload from the schema created for the event.

In the sample application, the input element would be the BugCreatedInfo payload under the BugReport.xsd node, as shown in Figure 34-3.
You create an activity that accepts the payload from the input element as its input parameters. In the sample application, an email activity is created that takes various input parameters from the payload as assigns them to the email’s parameters.

7. In the mediator service component, add a routing rule and configure it so that it invokes the BPEL process service and contains a subscription to the ADF Business Components event. Ensure the following:

- You select the initiate operation on the client of the BPEL process service component as the target service, as shown in Figure 34-4.
8. Optionally, use the Transformation map to map the mediator service component’s schema to the input schema of the BPEL process service component. However, this should not be necessary, as you should be using the same schema for both.

9. Deploy the SOA composite application to the SOA infrastructure.

10. Use Oracle Enterprise Manager Fusion Middleware Control Console to view the SOA composite application to ensure it was properly deployed.

- For more information about creating a BPEL process service component, see the chapter "Getting Started with Oracle BPEL Process Manager" in the Developing SOA Applications with Oracle SOA Suite.
• For more information about deploying SOA composites and using Oracle Enterprise Manager Fusion Middleware Control Console, see the chapter "Deploying SOA Composite Applications" in the Developing SOA Applications with Oracle SOA Suite.

Example 34-1  Editing the web.xml File

```xml
<resource-ref>
  <res-ref-name>jdbc/EDNDataSource</res-ref-name>
  <res-type>javax.sql.DataSource</res-type>
  <res-auth>Container</res-auth>
  <res-sharing-scope>Shareable</res-sharing-scope>
</resource-ref>
```

Example 34-2  Mapping Global JMS Resources to Local JNDI Names

```xml
<?xml version="1.0"?>
<resource-description>
  <res-ref-name>jdbc/EDNLocalTxDataSource</res-ref-name>
  <jndi-name>jdbc/EDNLocalTxDataSource</jndi-name>
</resource-description>
<resource-description>
  <res-ref-name>jdbc/EDNDataSource</res-ref-name>
  <jndi-name>jdbc/EDNDataSource</jndi-name>
</resource-description>
```

Example 34-3  Add a Reference to oracle.soa.workflow.wc to the weblogic-application.xml File

```xml
<library-ref>
  <library-name>oracle.soa.workflow.wc</library-name>
</library-ref>
```

### 34.5 Alternative Approaches

Following are alternative approaches to the use case pattern:

- **Using the Java Event API to Publish Events**
- **Using a JAX-WS Proxy to Invoke a Synchronous BPEL Process**

#### 34.5.1 Using the Java Event API to Publish Events

You can programatically raise events following an ADF Business Components CUD operation using the publishEvent API.

**Before you begin:**

1. In Oracle WebLogic Server Console, set up EDN data sources as described in How to Initiate a BPEL Process Service Component from an Web Application.
2. Add a library reference to oracle.soa.workflow.wc.

**To publish events using the Java event API:**

1. Import the required libraries into your application as shown in Example 34-4.
2. Publish events as required. An example is shown in Example 34-5.
Example 34-4  Importing Files into Your Application

import javax.xml.namespace.QName;
import oracle.fabric.blocks.event.BusinessEventConnection;
import oracle.fabric.blocks.event.BusinessEventConnectionFactory;
import oracle.fabric.common.BusinessEvent;
import oracle.integration.platform.blocks.event.BusinessEventBuilder;
import oracle.integration.platform.blocks.event.BusinessEventConnectionFactorySupport;
import oracle.xml.parser.v2.XMLDocument;
import org.w3c.dom.Element;
import oracle.jbo.server.TransactionEvent;
import oracle.jbo.server.JTATransactionHandler;

Example 34-5  Publishing Events Using the Java Event API

private final String eventName = "CreateExpenseReport";
private final String eventNamespace = "/oracle/apps/ta/model/events/edl/ExpenseReportEO";
private final String schemaNamespace = "/oracle/apps/ta/model/events/schema/ExpenseReportEO";

private BusinessEventConnectionFactory cf = null;
private BusinessEventConnection conn = null;

public void eventSetup()
{
    // Get event connection. Set to true for debugging only.
    BusinessEventConnectionFactory cf =
        BusinessEventConnectionFactorySupport.findRelevantBusinessEventConnectionFactory(false);
    BusinessEventConnection conn = cf.createBusinessEventConnection();
}

private XMLDocument getXMLPayload() {
    Element masterElem, childElem1, childElem2;
    XMLDocument document = new XMLDocument();
    masterElem = document.createElementNS(schemaNamespace, "CreateExpenseReportInfo");
    document.appendChild(masterElem);
    childElem1 = document.createElementNS(schemaNamespace, "Id");
    masterElem.appendChild(childElem1);
    childElem2 = document.createElementNS(schemaNamespace, "newValue");
    childElem2.setAttribute("value", ((BigDecimal) this.getAttribute("Id")).toString());
    childElem1.appendChild(childElem2);
    return document;
}

public void beforeCommit(BusinessEventConnection conn, TransactionEvent e) {
    // Determine whether this is a JTA transaction.
    if (this.getDBTransaction() != null &&
        this.getDBTransaction().getTransactionHandler() instanceof
        JTATransactionHandler) {
        // Determine whether the row is newly created.
        if (this.getEntityState() == STATUS_NEW) {
            try {
                // Build the event.
                BusinessEventBuilder builder = BusinessEventBuilder.newInstance();
                // Specify the event name and namespace. In this example,
they are constants: eventNamespace and eventName.

builder.setEventName(new QName(eventNamespace, eventName));

// Specify the event payload. In this example, the custom
// method getXMLPayload constructs the payload.
builder.setBody(getXMLPayload().getDocumentElement());
BusinessEvent event = builder.createEvent();

// Publish the event.
conn.publishEvent(event, 5);
conn.close();

// For debugging and testing purposes, print the result.
System.out.println("Event was sent sucessfully");
} catch (Exception exp) {
    System.out.println("Failed sending event: " + exp.getMessage());
    exp.printStackTrace();
}
}

super.beforeCommit(e);

34.5.2 Using a JAX-WS Proxy to Invoke a Synchronous BPEL Process

Another way to invoke a SOA composite as a web service from an Oracle ADF web
application is to use a JAX-WS proxy.

Use this pattern only for synchronously invoking BPEL processes where the calling
application waits for a response. As such, any BPEL processes called using this pattern
must be synchronous and brief so as to avoid any time out issues.

---

Caution:

- Do not use this pattern for a long running or asynchronous BPEL process.
- Make sure that synchronous services return immediately. Synchronous
  services should be simple input/output payloads.
- Do not use multi-record or N record services in which processing time
  varies from seconds to minutes or longer.

---

In this pattern, SOA composite services are exposed as web services. You generate a
JAX-WS proxy client to invoke the SOA composite exposed as a web service from your
ADF Business Components application module.

You use the web services wizard to generate a web service proxy, and then call the
web service using method calls.

An indirection for the web service proxy node enables retrieving the location of the
web service WSDL, username and password from connections.xml. To use the
indirection, access the proxy via
oracle.adf.model.connections.webservice.WebServiceConnection.

An example is shown in Example 34-6.
Use the username or SAML token policies for identity propagation and security.

**Related Links**
The following documents provide additional information related to subjects discussed in this section:

- For more information about this approach, see the chapter "Integrating Web Services Into a Fusion Web Application" in *Developing Fusion Web Applications with Oracle Application Development Framework*.

- For more information about securing the use case, see *Securing Web Services Use Cases*.

**Example 34-6  Using WebServiceConnection**

```java
WebServiceConnection wsc = (WebServiceConnection)ADFContext.getCurrent().getConnectionsContext().lookup(connectonName);
Hello hello = wsc.getJaxWSPort(Hello.class);
```

### 34.5.3 Invoking Third-Party Web Services in the Cloud

The typical design pattern described here works for developers and implementers who subscribe to a business event and invoke third-party services in BPEL via partner links. However, when using Software as a Service (SaaS), it is not always possible to simply deploy composites with custom-built BPEL processes. In these cases, the following recommendations may be useful.

- Invoke a SOA composite with a seeded web service callout to the registered URL with a pre-determined WSDL file one way notification. You can implement this pattern using Oracle Java Cloud Service.

- Invoke a SOA composite with a seeded w service callout to a registered URL with a pre-determined WSDL file request response. You can implement this pattern using Oracle Java Cloud Service.

- Invoke SOA composite with a seeded web service callout to a registered Oracle Business Process Management process. You can implement this pattern using Oracle Business Process Management Composer and then create the third-party service using Oracle Business Process Management Business Catalog.

### 34.6 Secure the Design Pattern

To secure this pattern, it is recommended that you secure the Oracle ADF web application. For more information about securing the pattern, see *Securing Web Services Use Cases*.

#### 34.6.1 Run the Mediator as an Event Publisher

To make the mediator run as an event publisher:

1. Open the composite.xml file for the SOA composite application and manually add the `runAsRoles="$publisher"` attribute to the composite subscriptions. 

   Example 34-7 shows the composite subscription for the sample application.
2. To validate the subject propagation in the SOA composite application, add the following code as shown in Example 34-8 to the BPEL file for the BPEL process flow:

**Example 34-7  runAsRoles Attribute in a Composite Subscription**

```xml
<component name="BugReportMediator">
  <implementation.mediator src="BugReportMediator.mplan" />
  <business-events>
    <subscribe xmlns:sub1="/model/events/edl/BugReport"
              name="sub1:bugCreated"
              consistency="oneAndOnlyOne"
              runAsRoles="$publisher"/>
  </business-events>
</component>
```

**Example 34-8  Using bplex:exec to Print Out Subject Information**

```xml
<bpelix:exec language="java" version="1.5">
  <![CDATA[
    javax.security.auth.Subject
    subject = javax.security.auth.Subject.getSubject
    ( java.security.AccessController.getContext());
    System.out.println("\n\n\n\n\n\n");
    System.out.println("######*****----->
                     subject:  " + subject.toString());
    System.out.println("\n\n\n\n\n\n");
  ]]>}
</bpelix:exec>
```

### 34.6.2 Securing Event-Driven Applications

Events enable event-driven applications and are not related to OWSM. Therefore, OWSM policies do not apply to events.

Events raised by Oracle ADF web applications automatically propagate the event's publisher ID in the event header. No action is required to perform identity propagation. The publisher's ID corresponds to the end-user authenticated in the application.

### 34.7 Verify the Deployment

You can verify the deployment by testing the Oracle ADF web application. Alternatively, you can send EDN events at the command line to verify event-raising functionality.

### 34.7.1 How to Verify the Deployment

To properly verify this design pattern, you should test the Oracle ADF web application and enable logging, use Oracle Enterprise Manager Fusion Middleware Control Console to verify the process instance creation, and check the SOA logs.
To verify this design pattern:

1. Test your Oracle ADF web application. Be sure to enable ADF Business
Components runtime logging by setting the Java VM parameter in the run/debug
profile to \`jbo.debugoutput=console.\` Doing so logs the event and its payload
in the JDeveloper log console.

2. Run the Oracle ADF web application and invoke the method that raises the event.

3. View the ADF Business Components runtime log in the JDeveloper log console to
view the event and payload.

4. Use Fusion Middleware Control Console for tracking composite instances and for a
variety of debugging, monitoring and testing functions.

   Launch Fusion Middleware Control Console using the following URL:

   \http://<hostname>:<port number>/em\n
5. Open Fusion Middleware Control Console to verify the process instance has been
created. Use the Audit tab to verify that the payload is correct.

34.7.2 How to Test EDN Functionality from the Command Line

You can test EDN functionality using SendEvent and edn.debug.event-
connection at the command line.

34.7.2.1 SendEvent

SendEvent is a command line utility for sending an event to a database-based Oracle
Event Delivery Network instance. SendEvent can send an empty event (of a given
queue name) or an entire event from a file. Running the command displays a list of
command line options.

Some examples are shown in Example 34-9 and Example 34-10.

In Example 34-9, an empty event with namespace \`uuid:1111\` and local name
MyEvent is sent to the event bus.

In Example 34-10, the event contained in the file \`AnEvent.xml\` is sent to EDN.

**Example 34-9  Sending an Empty Event**

```bash
oracle.integration.platform.blocks.event.SendEvent -dbconn host.example.com:1521:SID
-dbuser user -dbpass password -eventName {uuid:1111}MyEvent
```

**Example 34-10  Sending an Event to EDN**

```bash
oracle.integration.platform.blocks.event.SendEvent -dbconn host.example.com:1521:SID
-dbuser user -dbpass password -event AnEvent.xml
```

34.7.2.2 BusinessEventConnectionFactorySupport

You can use BusinessEventConnectionFactorySupport in your Oracle ADF
web application to test your event publishing code. Rather than sending an event to a
queue, you can configure your Oracle ADF web application to print the event
information to the log using BusinessEventConnectionFactorySupport.

To do so, set the system property `edn.debug.event-connection` to `true` when
running your application. When the application sends an event, the information for
that event is logged, including the event body in its entirety. This enables you to see
the events that will be sent to EDN when the application runs on a SOA server.
The log name is `oracle.integration.platform.blocks.event.debug`, but in most configurations the information prints to `stdout` by default.

**To set the system property:**

When Oracle WebLogic Server starts up, add the system property shown in Example 34-11 to the `JAVA_OPTIONS` environment variable.

**To access the EDN database log:**

You can use the EDN database log shown in Example 34-12 for diagnostic purposes.

**Example 34-11 Setting the EDN Debug System Property**

```java
-Dedn.debug.event-connection=true
```

**Example 34-12 EDN Database Log**

```
http://HOSTNAME:7001/soa-infra/events/edn-db-log
```

### 34.7.3 Related Links

The following documents provide additional information related to subjects discussed in this section:

- For more information about testing and debugging Oracle ADF web applications, see the chapter "Testing and Debugging ADF Components" in the *Developing Fusion Web Applications with Oracle Application Development Framework*.

### 34.8 Troubleshoot the Use Case

Following are tips that may help resolve common issues that arise when developing or running this use case.

#### 34.8.1 Deployment

If deployment of the SOA composite application fails, then verify the following:

- The `location` element in the EDL file located in the directory is relative to the directory that contains the EDL file.
- If you get an invalid XPath expression exception, use a static value instead of a value from the payload.

#### 34.8.2 Runtime Errors

If your Oracle ADF web application encounters a runtime class load error for `EventConnectionFactory`, you need to add a library reference to `oracle.soa.workflow.wc`.

### 34.9 What You May Need to Know About Initiating a SOA Composite from an Oracle ADF Web Application

Before you implement these design patterns, you should be aware of the following:

- If you change the event name or event payload, the mediator will not respond to the raising of the event. If you need to make changes, you should create a new event. During development, you need to change the mediator (if the name of the event changes) and/or the BPEL process being invoked (if the payload changes).
34.10 Known Issues and Workarounds

Following are known issues:

- You must add a library reference to `oracle.soa.workflow.wc` to raise events successfully.
- You can only specify `$publisher` as the `runAsRole` for an event subscription.
Initiate a SOA Composite from a PL/SQL Stored Procedure

This chapter describes what a PL/SQL stored procedure needs to do to initiate a SOA composite application.

**When to implement:** When a PL/SQL stored procedure needs to initiate a SOA composite application.

**Design Pattern Summary:** A PL/SQL stored procedure raises an event through the Event Delivery Network within the database. A mediator in the SOA composite application subscribes to the event and routes it as appropriate.

**Involved components:**
- PL/SQL stored procedures
- Event Delivery Network database
- SOA composite application that includes Oracle Mediator and other components as needed.

### 35.1 Introduction to the Recommended Design Pattern

Oracle Fusion applications may contain stored procedures that need to invoke a component within a SOA composite application, such as a BPEL process service component. A stored procedure can use the Event Delivery Network database API to publish an event whose payload is `xmltype`. An Oracle Mediator service component subscribes to the event by event name or by using a XPath expression on the event payload. The .edl file (*event definition file*) for the event can be supplied in the composite or deployed separately in a MAR (*metadata archive*). When the stored procedure publishes the event, the subscribed Oracle Mediator service component forwards the payload to the BPEL process service component.

This chapter explains how to implement the recommended approach.

### 35.2 Example

The sample code for this use case can be downloaded from Oracle SOA Suite samples.

### 35.3 How to Invoke a SOA Composite Application Component Using PL/SQL

To invoke a SOA composite application component from a stored procedure, you must first create the event within the SOA composite application. The stored procedure must then raise the event and pass any required data via the EDN database API.
To invoke a SOA composite application component using PL/SQL:

1. Create a SOA composite application with an Oracle Mediator component.

2. Configure Oracle Mediator to subscribe to a new event (with a name of your choosing).

   The event filter can be by event name or using an XPath expression on the event payload and the EDL for the event can either be supplied in the composite.xml or deployed separately in a MAR.

3. Create the SOA composite application component that will be invoked (for example, a BPEL process service component), and create a wire between the Oracle Mediator component reference and the component service.

4. From a PL/SQL stored procedure, call the EDN-DB API method publish_event with the event namespace and the event payload as a CLOB type. An example is shown in Example 35-1.

Example 35-1  Calling the publish_event Method

```sql
DECLARE
  NAMESPACE VARCHAR2(200);
  LOCAL_NAME VARCHAR2(200);
  PAYLOAD CLOB;
BEGIN
  NAMESPACE := 'http://xmlns.oracle.com/SubEventMediator/EventDefinition1';
  LOCAL_NAME := 'CustomerEvent';
  PAYLOAD := to_clob('<eb:business-event xmlns:eb=
xmlns:ob="http://xmlns.oracle.com/SubEventMediator/EventDefinition1">
  <eb:name>ob:CustomerEvent</eb:name><eb:content><CU:CustomerData
xmlns:CU="http://xmlns.oracle.com/Esb/CustomerData
xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
  <CustomerId>A22-9AXC2</CustomerId><CustomerName>Deserae International</CustomerName><Type>Gold</Type><Description>Accounting Outsourcing Partner</Description><Address>3228 Massilon Blvd</Address><City>Juniper</City><State>Massachusetts</State><Zip>01854</Zip><Country>US</Country><Phone>877-555-9876</Phone><Status>Active</Status><CreditRating>5</CreditRating><Discount>0</Discount><Terms>30n4</Terms><EnrollDate>01/1/01</EnrollDate><LastOrderDate>05/05/05</LastOrderDate><Currency>USD</Currency><ContactName>Jan Forester</ContactName><ContactTitle>VP Finance</ContactTitle><ContactPhone>877-555-9000</ContactPhone><AccountRep>Geoff Seattle</AccountRep><CampaignRating>2</CampaignRating><ReferredBy>Houston America Taxco</ReferredBy><ContactName></CU:CustomerData></eb:content></eb:business-event>);
  EDN_PUBLISH_EVENT( NAMESPACE => NAMESPACE, LOCAL_NAME => LOCAL_NAME, PAYLOAD => PAYLOAD);
END;
```

35.4 Securing the Design Pattern

Secure Oracle Mediator by configuring the property runAsRoles=$publisher.

When the database connection is established from the middle tier so as to invoke the PL/SQL stored procedure, a session is established with the appropriate identity. This identity is propagated through EDN back to the middle tier for the subscription. The subscription runs as the identity of the publisher.
Related Links
The following documents provide additional information related to subjects discussed in this section:

- For details on securing the Oracle Mediator, see Securing the Design Pattern.
- For more information about securing this pattern, see Securing Web Services Use Cases.

35.5 Verify the Deployment
Verifying the deployment involves the following:

- Testing and Deploying the Use Case
- Verifying the SOA Composite Deployment Using Oracle Enterprise Manager Fusion Middleware Control Console

35.5.1 Test and Deploy the Use Case
Testing and deploying the use case involves the following main steps:

1. Test your Oracle ADF application.

2. Deploy the SOA composite application to the standalone WLS where the SOA infrastructure has been installed. Because you created a published event from the SOA composite application to the ADF Business Components service, the ADF Business Components service need not to also be deployed to the SOA infrastructure.

3. Test the deployed SOA composite service using Oracle Enterprise Manager Fusion Middleware Control Console. Every deployed service has its own test page, so you can quickly test that the service functions as you expect.

35.5.2 Verifying the SOA Composite Deployment Using Oracle Enterprise Manager Fusion Middleware Control Console
You can use Oracle Enterprise Manager Fusion Middleware Control Console to verify that the SOA composite was successfully deployed. In Oracle Enterprise Manager Fusion Middleware Control Console, you can select the SOA composite instance and display the result of the event.

Using Oracle Enterprise Manager Fusion Middleware Control Console, you can:

- Verify the deployment of the SOA composite.
- Test the SOA composite.
- Verify the SOA composite test results.

To verify that the SOA composite was successfully deployed and the event was received:

1. Using a web browser, access the Oracle Enterprise Manager Fusion Middleware Control Console using a URL such as the following:

   http://<host name>:<port number>/em
2. From the list of applications, expand the PLSQLEvent composite.

3. In the Last 5 Instances pane, click the most recent instance as shown in Figure 35-1.

Figure 35-1  Finding the Latest PLSQLEvent Composite Instance

4. In the Flow Trace window that displays, click the Oracle Mediator component, as shown in Figure 35-2.

Figure 35-2  The Flow Trace Window

A window displays, showing the event results, as shown in Figure 35-3.
35.5.3 Check the Output Log File to Verify that the Event was Received

You can check the output log file to verify that the Mediator received the event.

To verify that the event was received using the output log file:

1. Navigate to the `/tmp/output` directory.

2. Open the `p_n.xml` file, where `n` is a sequential number indicating the application instance. For example, running the application twice results in two files under the `/tmp/output` directory: `p_1.xml` and `p_2.xml`.

3. Examine the file in order to verify that the event was received.

For example, the payload log file in Example 35-2 indicates that the event was received (as shown in the bold text):

Example 35-2  Example p_n.xml file

```
2007-07-25 13:16:02.062 NOTIFICATION Immediate case {WriteCustomer.Write} will be executed

- For more information about testing and debugging your Oracle ADF application, see the chapter "Testing and Debugging ADF Components" of the Developing Fusion Web Applications with Oracle Application Development Framework.

- For information about testing the ADF Business Components service, see the chapter "Integrating Web Services Into a Fusion Web Application" in the Developing Fusion Web Applications with Oracle Application Development Framework.

- For more information about using the Fusion Middleware Control Console to test deployed SOA composite applications, see the chapter "Automating Testing of SOA Composite Applications" in the Developing SOA Applications with Oracle SOA Suite.

35.6 Troubleshooting the Use Case

Following are tips that may help resolve common issues that arise when developing or running this use case.

- Enable logging for Oracle Mediator using logging.xml.

- For the events functionality, use the Event Delivery Network database log page at http://host:port/soa-infra/events/edn-db-log. The EDN schema name is FUSION_EDN.

Related Links

See the troubleshooting section in the chapter "Deploying SOA Composite Applications" of the Oracle SOA Suite Developer’s Guide for more information.

35.7 What You May Need to Know About Initiating a SOA Composite from a PL/SQL Stored Procedure

Before you implement these design patterns, be aware of the following:
Run the sample provided before implementing your own version of this use case. Running the sample ensures that the EDN database queue works as expected.

### 35.8 Known Issues and Workarounds

Following are known issues:

- Event publishing is an asynchronous action, there is no support for synchronous event publishing.
Orchestrate ADF Business Components Services

This chapter describes how to use a SOA composite application to invoke business methods within an Oracle ADF web application. In this pattern, the Oracle ADF web application business methods make changes to data, whereas the SOA composite does not.

**When to implement:** This pattern describes how to use a SOA composite application to invoke business methods within an Oracle ADF web application. In this pattern, the Oracle ADF web application business methods make changes to data, whereas the SOA composite does not. For example:

- A BPEL process service component must retrieve data from a database using an ADF Business Components service. However, the BPEL process service component will not post any changes back to the database.

- A BPEL process service component must access an exposed service method on an ADF Business Components service, and that method contains only business logic and does not update data.

- A BPEL process service component must access an exposed service method on an ADF Business Components service. The exposed service method on the business component service does not require a conversational callback style of interaction. Instead, it provides a single invocation, wrapping all of the business logic and view object manipulation. An example of this is a service method that deletes an order and all line items, given an order ID as a parameter.

**Related Links**

The following document provides additional information related to subjects discussed in this section:

See [Manipulating Back-End Data from a SOA Composite](#) for information regarding patterns in which both the Oracle ADF web application and SOA composite must update data without conflicting.

**Design Pattern Summary:** A BPEL process service component uses an invoke activity to invoke a partner link that accesses a SOAP service created for a business component.

**Involved components:**

- SOA composite application that includes a BPEL process service component
- Oracle ADF web application that includes ADF Business Components
36.1 Introduction to the Recommended Design Pattern

Oracle Fusion applications may require that a BPEL process service component access data values from ADF Business Components in an Oracle ADF web application. Oracle Fusion applications may also require that a BPEL process service component invoke a method contained in ADF Business Components. Instead of directly accessing the ADF Business Components, you can publish the component as a web service. The composite then accesses the published component over SOAP using an invoke activity and partner link in the BPEL process service component. Figure 36-1 shows a high-level overview of this design pattern.

![Figure 36-1 SOA Composite Application Accesses ADF Business Components Using SOAP](image)

This approach is recommended because SOAP bindings do not require that the Oracle ADF web application and the SOA components be co-located in the same container.

36.2 Other Approaches

There are no other approaches to implementing this use case. The only supported way to invoke ADF Business Components services is to use a web service SOAP binding.

**WARNING:**

Using the Oracle ADF binding to invoke ADF Business Components services is prohibited due to topology and security requirements. (Oracle ADF services and SOA composites must be collocated; there are no application roles and privileges cannot be escalated.)

36.3 Example

The sample code for this use case can be downloaded from *Oracle SOA Suite samples*.
36.4 How to Invoke an ADF Business Components Service from a BPEL Process Service Component

To invoke ADF Business Components using a SOAP binding, you first publish the business component as a web service. You then create a BPEL process service component that contains a partner link to the ADF Business Components service. The partner link is accessed from an invoke activity. An assign activity is used to populate data into a variable used to pass data to the ADF Business Components service.

To invoke ADF Business Components from a BPEL process service component:

1. Create ADF Business Components, including an application module.

2. Optionally, create any SDO classes for view objects.
   Any top-level view objects referenced in a service interface created from an application module will automatically be service-enabled. However, creating the SDO classes for individual view and entity objects allows you to configure the SDO name or namespace, or selectively service-enable child view objects.

3. Configure the service interface for the application module.
   You can elect to include in your service interface custom methods, top-level service view instances, and any find operations based on view criteria.
   At the end of this step, Oracle JDeveloper creates the WSDL files that will be used by the BPEL process service component to access any required methods or data. Figure 36-2 shows the WSDL created for StoreFrontService in the sample application. This service accesses the customer and order information needed by the SOA composite application.

4. Implement the security as described in Securing the Design Pattern.

5. For verification purposes, you can either run the Oracle ADF web application from the Integrated Weblogic Server container included with Oracle JDeveloper, or you can deploy the Oracle ADF web application to a standalone container. To deploy to a standalone container:
   a. Create a deployment profile for the web application.
b. Make an Oracle WebLogic Server connection to the container.

c. Deploy the profile to the container.

d. Add a library reference to oracle.soa.workflow.wc. Add the following entry to the file in MW_HOME/user_projects/domains/<domain name>/config/config.xml directory, and add the line shown in Example 36-1 to oracle.adf.domain.loader.

Note:
Skip this step if deploying the profile to the WLS container included in the SOA installation.

6. Add the WSDL file for the ADF Business Components service to the Resource Palette of Oracle JDeveloper. If you are using the embedded server, you first need to run your application. You then create a new URL connection in the Resource Palette to the embedded server. The URL is:

http://host:7101/ApplicationName-ProjectName-context-root/AppModuleService Name

The URL for the embedded server is generated at the bottom of the WSDL file. Alternatively, you can open the file and copy the soap:address URI.

If you have deployed the Oracle ADF web application to a standalone server, then create a new Application Server connection in the Resource Palette. For more information about using the Resource Palette, see the Oracle JDeveloper Online Help.

7. Create a SOA composite application that includes a BPEL process service component.

8. In the SOA composite application, create the reference web service binding to the WSDL file for the ADF Business Components service. When creating the binding, be sure to select the WSDL from the Resource Palette.

Note:
The ADF Business Components service must be running in order for it to be discoverable.

Figure 36-3 shows the composite.xml file for the sample application.
A Partner Link for the ADF Business Components is automatically created when the reference is wired to the BPEL process.

9. Wire the BPEL component to the Oracle ADF web service
   Use a web service binding so that the ADF Business Components service can be remotely deployed.

10. Create an Invoke activity that invokes the partner link for the ADF Business Components.

11. Create an Assign activity to assign any values (for example, a static XML fragment) to variables for the BPEL process service component. These can then be passed to the ADF Business Components service.

12. Repeat adding assign and invoke activities as needed. Figure 36-4 shows the BPEL flow for the sample application.
13. Implement the security as described in Securing the Design Pattern.

Related Links
The following documents provide additional information related to subjects discussed in this section:

- For more information about creating ADF Business Components, see Part II: Building Your Business Services in the Developing Fusion Web Applications with Oracle Application Development Framework.
• For more information about configuring a service interface for an application module and creating SDO classes for view objects, see the chapter Integrating Service-Enabled Application Modules in the Developing Fusion Web Applications with Oracle Application Development Framework.

• For more information about creating a deployment profile for a web application, see the chapter Deploying Fusion Web Applications of the Developing Fusion Web Applications with Oracle Application Development Framework.

• For more information about creating SOA composite applications, as well as bindings and wiring references, see the chapter Developing SOA Composite Applications with Oracle SOA Suite in the Developing SOA Applications with Oracle SOA Suite.

• For more information about creating Assign and Invoke activities, see the chapter Getting Started with Oracle BPEL Process Manager in the Developing SOA Applications with Oracle SOA Suite.

Example 36-1 Shared Library Name

```xml
<shared-library name="adf.oracle.domain" version="11.1.1" library-compatible="true">
...
</import-shared-library name="oracle.soa.workflow.wc"/>
```

36.5 Securing the Design Pattern

You need to secure the following:

• Secure the ADF Business Components web service data control and the SOA composite using SAML policies.

• Secure the ADF Business Components web service and the SOA composite with username token policies.

For information about securing the design pattern, see Securing Web Services Use Cases.

36.6 Verifying the Deployment

To properly verify this design pattern, you should test your ADF Business Components, then deploy and verify the SOA composite application.

To verify this design pattern:

1. Test your Oracle ADF web application.

2. Deploy the SOA composite application to the standalone WLS where the SOA infrastructure has been installed. Because you created a web service binding from the SOA composite application to the ADF Business Components web service, the ADF Business Components web service need not be deployed to the SOA infrastructure.

3. Test the deployed SOA composite service using Fusion Middleware Control Console. Every deployed service has its own test page, so you can quickly test that the service functions as you expect.

### 36.7 Troubleshooting the Use Case

Following are tips that may help resolve common issues that arise when developing or running this use case.

Use Oracle Enterprise Manager Fusion Middleware Control Console to troubleshoot the use case:

http://localhost:8888/em

You can test your SOA composite using Fusion Middleware Control Console.

### 36.8 What You May Need to Know About Orchestrating ADF Business Components Services

Before you implement these design patterns, you should be aware of the following:

Any time you invoke an ADF Business Components service, the database transaction for that operation is committed when it completes.

There is no session propagation between the BPEL process and Oracle ADF. While the identity is passed in when security policies are in place, a new Oracle Fusion Data Security session is created with each invocation of the ADF Business Components service operations.

If you invoke ADF Business Components service operations that use event-raising entities, those events are not raised.
This chapter describes what updates created in a SOA composite application need to do to perform create, read, update, or delete (CRUD) operations on back-end data stored in a database.

**When to implement:** When updates created in a SOA composite application need to perform create, read, update, or delete (CRUD) operations on back-end data stored in a database.

**Design Pattern Summary:** Entity variables within a BPEL process service component access ADF Business Components view objects through a service to fetch data on the back end. The BPEL process service component then manipulates the data, and the changes synchronize with the ADF Business Components service when the BPEL service dehydrates. This is also known as master detail with indexing.

An example of master detail with indexing is entity variables created on master detail records such as an order header with lines, accessing the lines individually with array subscripting.

**Involved components:**

- SOA Composite with a BPEL process service component and a SOAP binding.
- ADF Business Components, including view objects, with a published web service interface.

### 37.1 Introduction to the Recommended Design Pattern

When a BPEL process service component needs to perform CRUD operations on back-end data stored in a database, you use BPEL entity variables. Entity variables can fetch data from an ADF Business Components view object through a web service interface, and manipulate the data using common BPEL assign and XPath constructs. These changes automatically synchronize with the ADF Business Components service when the BPEL instance dehydrates. Using entity variables provides the following:

- Ease-of-use by abstracting data manipulation
- Performance gains from the use of SDO change summaries
- Strongly typed XML document to back XML element manipulations

The transaction locking strategy for SDO is optimistic. If the BPEL engine tries to update an SDO or entity variable and the current revision number is out of date, an exception will be thrown by the ADF Business Components service.
37.2 Example

The sample code for this use case can be downloaded from Oracle SOA Suite sample.

37.3 How to Manipulate Data from a BPEL Process Service Component

To manipulate data, first you create an ADF Business Components entity object that accesses and updates the data. You then publish the business component as a web service. Next, you create a SOA composite application that includes a BPEL service component to which you add entity variables that can manipulate the data.

To manipulate data from a BPEL process service component:

1. Create ADF Business Components, including an application module.

2. Optionally create any SDO classes for view objects.

   When modeling your view objects, it is important to determine which may need to be available for binding to SOA composite entities. It is possible to automatically enable services in top-level view objects referenced in a service interface create from an application module. However, you must create the SDO classes for individual view objects so as to configure the SDO name or namespace, or selectively service-enable child view objects.

3. Configure the service interface for the application module.

   You can elect to include in your service interface custom methods, top-level service view instances, and any find operations based on view criteria.

   At the end of this step, JDeveloper creates the WSDL files that will be used by the BPEL process service component to access any required methods or data.

4. Deploy the services to the Integrated Oracle WebLogic Server by right-clicking the nameServiceImpl class and selecting Run. Alternatively, define an ADF Business Components service interface profile and deploy it to the standalone Oracle WebLogic Server.

5. Add the WSDL file for the ADF Business Components service to the Resource Palette. If you are using the integrated server, you must first run your application. In the Resource Palette, create a new URL connection to the integrated server. The URL is:

   http://localhost:7001/ApplicationName-ProjectName-context-root/AppModuleService Name

   The URL for the embedded server is generated at the bottom of the WSDL file. Alternatively, you can open the file and copy the soap:address URI.

   If you have deployed the Oracle ADF web application to a standalone server, then create a new Application Server connection in the Resource Palette. For more information about using the Resource Palette, see JDeveloper Online Help.

**Note:**

The ADF Business Components service must be running in order for it to be discoverable.
6. Create a SOA composite application that includes a BPEL process service component.

7. In the SOA composite application, create a reference binding from the BPEL process to the WSDL file for the ADF Business Components service. When creating the reference binding, be sure to select the WSDL from the Resource Palette.

Note: The ADF Business Components service must be running in order for it to be discoverable.

8. In the BPEL process service component, create an entity variable. This type of variable delegates BPEL data manipulation operations to an underlying data provider implementation, in this case the business component.

When you create the entity variable, ensure that you select the business component as the Partner Link.

9. Add a Bind activity to the BPEL process service component. This activity establishes the key to pass to the ADF Business Components service when the SDO will be fetched from the database.

Example 37-1 shows the XML for a bind activity that establishes OrderId as the key that will be passed to retrieve orders.

10. Add an Assign activity to the BPEL process service component that will manipulate the data.

Example 37-2 shows the XML for an assign activity that first assigns the value from the entity variable to another variable, then takes the value of the entity variable and manipulates it using an XPath expression. The change operations are mapped back to the SDO automatically. For more information about using XPath operations, see Support for XPath Operations.

When the BPEL process service component hits a breakpoint activity (receive, onMessage, wait, onAlarm) the instance is dehydrated. When dehydration happens, or the scope where entity variables are declared completes, all related entity variables that have been loaded flush their changes back to the business component, and from there to the database. For more information, see When Entity Variables Flush Changes Back to ADF Business Components.

You can use sensor variables to monitor the service data object. For more information, see the following links:

11. Deploy the ADF Business Components web service to the Integrated Oracle WebLogic Server with SOA infrastructure. Then deploy the SOA composite application.

Example 37-1 Bind Activity Establishes the Key

```
<bpelx:bindEntity name="BindEntity_1" variable="orderEntityVar">
  <bipelx:key keyname="ns4:OrderId">bpws:getVariableData('inputVariable', 'payload', '/client:BPELEntityVarADFBCProcessRequest/client:orderID')
  </bipelx:key>
</bipelx:bindEntity>
```
Example 37-2  Assign Activity Manipulates an Entity Variable Value

<assign>
  <copy>
    <from expression="$orderEVar/fdsm:OrderTotal + 1" />
    <to variable="orderEVar" query="fdsm:OrderTotal" />
  </copy>
</assign>

37.4 Securing the Design Pattern

To secure this pattern, it is recommended that you follow the same steps as described in Securing the Design Pattern.

37.5 Verifying the Deployment

To properly verify this design pattern, you should test your ADF Business Components service, then deploy and test the SOA composite application.

To verify this design pattern:

1. Test your Oracle ADF web application.

2. Deploy the SOA composite application to the standalone WLS where the SOA infrastructure has been installed. Because you created a web service binding from the SOA composite application to the ADF Business Components web service, the ADF Business Components web service need not be deployed to the SOA infrastructure.

3. Test the deployed SOA composite service using Fusion Middleware Control Console. Every deployed service has its own test page, so you can quickly test that the service functions as you expect.

Tip:

The use of entity variables greatly affects the ability to unit test the process in an isolated environment. Unit tests of processes that use entity variables usually require managing the backend database state.

37.6 Troubleshooting the Use Case

Following are tips that may help resolve common issues that arise when developing or running this use case.

To get more logging information, add logger reference oracle.soa.bpel.entity.
### 37.7 What You May Need to Know About Manipulating Back-end Data from a SOA Composite

Before you implement these design patterns, you may want to know more about when variables flush changes back to the business component, how to test variables without invoking ADF Business Components, support for XPath operations, and how to invoke multiple services.

#### 37.7.1 When Entity Variables Flush Changes Back to ADF Business Components

There are three points within the flow when an entity variable flushes its changes back to the ADF Business Components service:

- When the BPEL instance dehydrates. This happens whenever a breakpoint activity is reached (for example receive, onMessage, wait, onAlarm) or execution reaches the end of the flow definition.

- When the BPEL instance dehydrates due to reaching its activity processing threshold. By default, the threshold is set to 600 activities. The property dspMaxRequestDepth in the file bpel-config.xml sets the threshold.

- When execution reaches the end of the scope, if the entity variable has been declared locally (for example within a scope). If the entity variable is declared globally, it flushes changes when the instance completes.

To illustrate, Example 37-3 includes a locally declared entity variable.

Because the variable was defined locally within the scope myScope, after that scope completes, the variable declaration is no longer accessible from the outer enclosing scope. At this point, changes made to the variable from the Assign activity will be flushed to the ADF Business Components service.

Example 37-4 shows an entity variable defined globally, hence its scope will complete when the instance completes.

**Example 37-3  Local Entity Variable**

```xml
<scope name="myScope">
  <variables>
    <variable name="orderEVar" element="fdsm:orderInfo2SDO"
      bpelx:entity.si="OrderService" />
  </variables>
  <bpelx:bindEntity name="BindEntity_1" variable="orderEntityVar">
    <bpelx:key keyname="ns4:OrderId">bpws:getVariableData('inputVariable','payload','/client:BPELEntityVarADFBCProcessRequest/client:orderID')</bpelx:key>
  </bpelx:bindEntity>
  <assign> ... </assign>
</scope>
```

**Example 37-4  Global Entity Variable**

```xml
<process ...
  <variables>
    <variable name="orderEVar" element="fdsm:orderInfo2SDO"
      bpelx:entity.si="OrderService" />
  </variables>
  <sequence>
    <receive ...>
```
37.7.2 Support for XPath Operations

XPath operations can be used in Assign activities to manipulate data. Most XPath operations are supported. Following are noted limitations:

- Nested predicates, such as `-nameStep1[x1[y1>3]]` are not supported.
- Multiple steps within a predicate, such as `-nameStep1[x1/y1>3]` are not supported.
- There are limitations present in the ADF Business Components SDO binding layer, such as numeric computation and function. However, BPEL’s XPath layer will rewrite the expression into a form supported by ADF Business Components. For example:

  - `nameStep1[x1 > 23 + 45 and y1 = concatenate('a', 'b')]`

All entity variables are stored in the BPEL dehydration store. However, BPEL only stores the key data required for the variable and not the variable in its entirety. When loading these variables upon re-hydration, BPEL runs a find request on the variable to reload the variable data. However, the Oracle ADF web application may have changed the variable, leading to potential loss of data integrity.

You can check the variable for data integrity by running `bpelx:entity.doVersionCheck = "true"`. `doVersionCheck` checks for `ObjectVersionId`. If this returns a different value from that in the BPEL store, a fault is raised.

**Example 37-5** illustrates the verification of variable data integrity.

---

**Note:**

The version fields must exist in the data object returned. If the Xpath query fails, an exception is thrown. Make sure the custom version fields are defined in the XSD and that the names match.

---

**Example 37-5  Checking Variable Data Integrity**

// Checks the variable version.
<variable name="Variable_1" element="ns1:emp" bpelx:entity.si="Service1"
bpelx:entity.doVersionCheck="false"/>

// Enables doing a custom version check on custom fields Sal and Deptno.
<variable name="Variable_1" element="ns1:emp" bpelx:entity.si="Service1"
bpelx:entity.customVersionCheck="ns1:Sal ns10:Deptno "/>
37.7.3 Invoking an ADF Business Components Service and Entity Variables in the Same BPEL Process Service Component

The pattern described in this chapter and the pattern described in Orchestrating ADF Business Components Services can be easily combined.
This chapter describes what a SOA composite application needs to do to access logic implemented as PL/SQL in the database.

When to implement: A SOA composite application needs to access logic implemented as PL/SQL in the database.

Design Pattern Summary: The SOA composite application accesses an ADF Business Components service, which in turn accesses the PL/SQL stored procedure.

Involved components:

- Business component that accesses a PL/SQL stored procedure, and is published as a service.
- SOA composite application which includes a BPEL process service component that accesses the ADF Business Components service.

38.1 Introduction to the Recommended Design Pattern

Oracle Fusion applications may contain stored procedures in the database that a SOA composite application needs to access. The stored procedure must be wrapped by an ADF Business Components service; the BPEL process then accesses the ADF Business Components service.

38.2 Other Approaches

Instead of accessing the stored procedure through an ADF Business Components service, you could use a SOA database binding component. However, this is not allowed because the SOA database binding component does not handle data changes or database schema changes gracefully. In addition, a PL/SQL stored procedure definition cannot be considered a service contract, as there is often some needed extrapolation.

Another alternative is to create a Web service directly on top of PL/SQL. This is not allowed because of security issues in the PL/SQL Web service.

38.3 Example

The sample code for this use case can be downloaded from Oracle SOA Suite samples.
38.4 How to Invoke a PL/SQL Stored Procedure from a SOA Composite Application

Instead of directly accessing the stored procedure, you create a business component that accesses the procedure, you then publish the business component as a SOAP service. The SOA composite application component accesses the ADF Business Components service, which in turn invokes the stored procedure.

**To invoke a PL/SQL stored procedure from a SOA composite application:**

1. Create a business component, including an application module.
2. Write a method in your application module that accesses the PL/SQL stored procedure.
3. Generate the service interface for the business component.
4. Invoke it through a SOAP binding, as described in Orchestrating ADF Business Components Services.

**Related Links**

The following documents provide additional information related to subjects discussed in this section:

- For more information about creating a business component with an application module, see the section "Part II: Building Your Business Services" of the Developing Fusion Web Applications with Oracle Application Development Framework.

- For more information about accessing PL/SQL stored procedures, see the section "Invoking Stored Procedures and Functions" in the chapter "Advanced Business Components Techniques" of the Developing Fusion Web Applications with Oracle Application Development Framework.

- For more information about generating a service interface for a business component, see the chapter "Integrating Web Services Into a Fusion Web Application" in Developing Fusion Web Applications with Oracle Application Development Framework.

38.5 Securing the Design Pattern

You secure this design pattern in the same way you secure a pattern with an ADF Business Components service invoked from a SOA composite application. For details, see Securing the Design Pattern.

Identity propagation is enabled using Application User Sessions. When the application module initializes, an Application User Session is created with the user who is currently logged in (assuming no such Application User Session yet exists). The Application User Session is pushed to the database, making it accessible from PL/SQL.

For information about accessing the Application User Session, see Implementing Application User Sessions.

For information about securing the design pattern, see Securing Web Services Use Cases.
38.6 Verifying the Deployment

To properly verify this design pattern, test your business component, then deploy and test the SOA composite application.

**To verify this design pattern:**

1. Test your Oracle ADF application.

2. Deploy the SOA composite application to the standalone WLS where the SOA infrastructure has been installed. Because you created a published event from the SOA composite application to the ADF Business Components service, the ADF Business Components service need not to also be deployed to the SOA infrastructure.

3. Test the deployed SOA composite service using Oracle Enterprise Manager Fusion Middleware Control Console. Every deployed service has its own test page, so you can quickly test that the service functions as you expect. For more information about using the Fusion Middleware Control Console to test deployed SOA composite applications, see the following chapter:

Access a PL/SQL Service from a SOA Composite 38-3
This chapter describes what a SOA composite application needs to do to invoke logic implemented by a Java class.

**When to implement:** A SOA composite application needs to invoke logic implemented by a Java class.

**Design Pattern Summary:** The logic is accessed using a web service that the SOA composite component accesses directly. The logic can be placed within an existing ADF Business Components service, or the Java class can be published as a web service.

**Involved components:**

- Business component that contains a service method, and is published as a service; or a Java class published as a web service.
- SOA composite application that includes a BPEL process service component that accesses the ADF Business Components service or the Java class web service.

### 39.1 Introduction to the Recommended Design Pattern

While the most common implementation of business logic will either be inside the application module of a business component or in a SOA composite application, Oracle Fusion applications may contain business logic implemented in a separate Java class. A SOA composite component within the application may need to access this logic. When the logic has some relation to the entity or view objects defined in a business component, it is best to implement the logic as another service method on the component. You can publish the business component as a service, and the SOA component can access the logic through that service.

In some cases, the application does not contain a business component that accesses the same data as the logic in the Java class. In this case, you can publish the class as a web service, allowing the SOA component to directly access the logic through the service.

### 39.2 Other Approaches

Instead of accessing the logic through a SOAP binding, you could use a BPEL component with a Java activity to invoke some custom Java code.

An alternative is to use the `bpelx:exec` command to programmatically call Java methods. This is the same as using a Java activity, only without a UI. It is recommended to use the `bpelx:exec` command to complete light tasks such as the following:

- Manipulating data.
• Calling self-contained Java classes that do not have dependencies on other system resources.

• Calling functions provided by the BPEL service engine, such as adding an auditTrail component, and so on.

• Calling Enterprise JavaBeans.

WARNING:
Do not use the \texttt{bpelx:exec} command to access the application database or a SOAP service.

To access the application database, use a JCA database adapter. To access a SOAP service, use a BPEL Invoke activity.

Another alternative is to call custom Java classes using custom XPath functions.

Related Links
The following documents provide additional information related to subjects discussed in this section:

• For more information about using the \texttt{bpelx:exec} command, see the chapter "Incorporating Java and Java EE Code in a BPEL Process" in the Developing SOA Applications with Oracle SOA Suite.

• For more information about using XPath functions to call a Java class, see the subsection "Creating User-Defined XPath Extension Functions" in the appendix "XPath Extension Functions" in the Developing SOA Applications with Oracle SOA Suite.

39.3 Example
Download the sample code for this use case from the Oracle SOA Suite samples.

39.4 How to Invoke a Java Class from a SOA Composite Application
Instead of directly accessing the Java class, you can add the logic to a business component and then publish the business component as a SOAP service. The SOA composite application component accesses the ADF Business Components service, which in turn invokes the Java code.

To use a business component:

1. Create a business component, including the required logic as a method on an application module,

2. Generate the service interface for the business component and from the SOA component, invoke the service through a SOAP binding, as described in Orchestrating ADF Business Components Services.

Related Links
For more information about creating a business components, see "Part II: Building Your Business Services" in the Developing Fusion Web Applications with Oracle Application Development Framework.
39.5 Securing the Design Pattern

You secure this design pattern in the same way as you secure a pattern that has an ADF Business Components service invoked from a SOA composite application. For details, see Securing the Design Pattern.

39.6 Verifying the Deployment

To properly verify this design pattern, you should test your business component, then deploy and test the SOA composite application.

To verify this design pattern:
1. Test your Oracle ADF application.

2. Deploy the SOA composite application to the standalone WLS where the SOA infrastructure has been installed. Because you created a published event from the SOA composite application to the ADF Business Components service, the ADF Business Components service need not to also be deployed to the SOA infrastructure.

3. Test the deployed SOA composite service using Oracle Enterprise Manager Fusion Middleware Control Console. Every deployed service has its own test page, so you can quickly test that the service functions as you expect.

Related Links
The following documents provide additional information related to subjects discussed in this section:

- For more information about testing and debugging Oracle ADF applications, see the chapter “Testing and Debugging ADF Components” of the Developing Fusion Web Applications with Oracle Application Development Framework.
- For information about testing the ADF Business Components service, see the chapter ”Integrating Web Services Into a Fusion Web Application” in the Developing Fusion Web Applications with Oracle Application Development Framework.

39.7 Troubleshooting the Use Case

Following are tips that may help resolve common issues that arise when developing or running this use case.

When writing custom Java code, you may need to use logging messages for debugging. You can then monitor the log files for troubleshooting information.

39.8 What You May Need to Know About Invoking Custom Java Code from a SOA Composite

If you have already created a business component and the method semantics of the needed logic fit with the other service methods already implemented in the
application module, you should add another method for the needed logic to the application module. If the method relies on entity and or view objects on the business component, then adding the method to the business component is the only approach available.

If you have not created a business component or the method semantics do not fit with the other service methods already implemented in the application module, you may want to create a Java web service instead.
This chapter describes what your ADF application needs to do to assign tasks to users or groups.

**When to implement:** When your ADF application needs to assign tasks to users or groups.

**Design Pattern Summary:** An ADF task flow in a web application contains a page where a user action invokes an ADF Business Components object that performs some logic. Because of this user action, a task must be assigned to another user. For example, an employee uses an ADF web application to submit an expense report. The page used to create the expense report is within an ADF task flow. When the expense report is submitted, a task must be raised to the employee's manager so that they can approve or reject the expense report. To make this happen, when the ADF Business Components object is invoked, it invokes a BPEL process service component that uses a human task service component to assign the task to the manager. After the human task service component is invoked, the manager uses the Worklist application to complete the task, in this case the approval or rejection of the expense report. The Worklist application also uses an ADF task flow to present those pages to the manager.

This design pattern uses BPEL so as to enable orchestration after the task is submitted.

**Involved components:**

- ADF web application that includes an ADF Business Components object and an ADF task flow that contains the UI pages where the end user submits data.
- SOA composite with a mediator component that listens for events raised by the ADF application. The mediator invokes a BPEL service component that uses an included human task component.

**Note:**

BPEL is not a requirement for working with human tasks. However, BPEL is used when orchestrating tasks after the end-user submits the human task, for example to approve or reject forms filled out by the end-user.

Instead of using the worklist application, you could use a custom task application or APIs.

### 40.1 Introduction to the Recommended Pattern

Oracle Fusion applications may need to assign users tasks that they need to complete. The application needs to notify users of assigned tasks, then provide a way for them to
complete the tasks. The SOA composite project may include a BPEL process that assigns tasks to users as part of the process flow. The human workflow service can be used to accomplish this. The workflow component also includes an out-of-the-box worklist application displaying all the tasks assigned to a particular user or group. You can use the ADF task flow to create UI pages listing pending tasks. These are displayed upon logging in to the worklist application.

To develop this pattern, an ADF application can invoke an SOA composite application, as described in Initiating a SOA Composite from an Web Application. A human task service component can be included in the composite that assigns tasks to users or roles. This component includes a task editor used to design the metadata for the task, an ADF task flow for creating task forms for the human interaction, and the out-of-the-box Worklist application for users to access tasks and act on them. The Worklist application can use an ADF task flow to manage the pages needed to complete the tasks.

This pattern is recommended for the following reasons:

- You can do any required validation of the data in the ADF Business Components layer as opposed to the process.

- You can pass only minimal data from the ADF web application into the process. Using this approach, you can pass just header level information required to route the task, (for example an expense ID, amount, requester). All other information remains in the database and is accessed in the task form by reference. The task form is used to display relevant details to the user. The data is therefore not carried through the process.

Figure 40-1 shows the recommended pattern.
This chapter explains how to implement the recommended pattern.

**40.2 Other Approaches**

There are no other supported approaches to this use case.

**40.3 Example**

Following is an example that illustrates the design pattern.

An Expense application contains an ADF task flow used to create an expense report and submit it for approval. When the user submits the expense report, a BPEL process service component is invoked that contains a human task service component, which assigns the task of approving expense report to the user’s supervisor. The human task service component notifies the supervisor that an expense report must be approved. When the supervisor logs into the Worklist application, he sees notification of an expense report that requires approval. The Worklist application contains an ADF task flow that allows the supervisor to either approve or reject the expense report.

The sample code for this use case can be downloaded from Oracle SOA Suite samples.

**40.4 How to Manage a Human Task Flow from an ADF Application**

There are three high-level steps needed to invoke a human task flow from an ADF web application:
1. Create and deploy the ADF web application that contains the UI necessary to invoke the SOA composite that contains the human work flow.

2. Create the SOA composite that contains a mediator, BPEL process service component, and human task component that will assign the task to the user.

3. Create the ADF task flow based on the human task component. This will provide the UI necessary for the user to resolve the task.

These procedures are detailed in the remainder of this section.

To invoke a human work flow from an ADF application:

1. Create an ADF application that contains a page that will raise an event, as described in How to Initiate a BPEL Process Service Component from an Web Application.

2. Create an SOA composite application component that includes a mediator service component, along with a BPEL process service component that the mediator service component invokes when the ADF Business Components event is raised. Follow the procedures as documented in How to Initiate a BPEL Process Service Component from an Web Application.

3. In the SOA composite application, create a human task service component that uses the payload of the message received from the mediator service component to provide any parameters needed to create the task in the workflow.

When creating the human task service, note the following:

- The task will require details about the assignee, task parameters, and so on. However, you do not need to capture the entire object used to create the task in the task parameters. You only need to include enough information to make the assignment decision and to then query the object using the service interfaces for the ADF Business Components application module.

  For example, in the expense report sample application, you might create parameters for the expense report number, the "submitted by" value, and optionally the amount. This would be the only information needed to dynamically assign the task to the submitter’s manager.

- You can assign tasks statically or dynamically. Make sure that any user to whom the task is assigned is seeded in the identity management store (for more information, see Securing the Design Pattern).

- You should model any email or other notifications as part of the task metadata. For example, you may want to model an email to the supervisor when the task is assigned to them and an email to the initiator when the task is completed.

4. In the BPEL process, add a human task activity and wire it to the human task service component. In the human task activity, specify which BPEL variables map to the data required for the task.

After you create the human task activity, a switch statement is automatically inserted that contains various branches based on the previously specified outcome of the human task. Based on how the outcome impacts the specific use case, additional business logic should be inserted inside the branches.

For example, in the expense report example, you might include a branch that calls the ADF Business Components object to update the state of the expense report to
Approved. This can be done by exposing the ADF Business Components application module as a service and then invoking it from BPEL as a SOAP service. For more information, see Manipulating Back-End Data from a SOA Composite.

5. Create an ADF task flow based on the human task service component. This will be the flow used in the worklist application that displays the pages the user views to complete the task.

Note the following:

- When creating the task flow, select the .task file created in Step 3. This automatically generates a task data control that can access the task parameters and perform actions on the task such as Approve and Reject.

- On the JSP pages, use the drop handlers on the task data control to insert sections such as Task Header, Comments and Attachments, Approval History, and so on.

- Use the ADF Business Components data control to pull in any transactional data, such as line items. You can use the object id (available in task parameters) in the query API for the ADF Business Components.

- Drag and drop any custom actions (for example, approve or reject) on the form. You can also include system actions (for example, escalate, reassign, delegate) on the form.

- Note that by default, the first page in the task flow is sent in email notifications. The buttons on the page are replaced with ReplyTo links for actions such as Approve and Reject, allowing the user to approve or reject the object in the task from the email. You can also model a different page for email approval.

6. Deploy the SOA composite and the ADF task flow for the human task service to the standalone WLS where the SOA infrastructure has been installed.

Deploy the task from the application menu and the SOA composite from the project menu.

The following documents provide additional information related to subjects discussed in this section:

- For detailed procedures on creating a human task service, see the chapter "Creating Human Tasks" in the Developing SOA Applications with Oracle SOA Suite.

- For more information about notifying users of changes to task status, see the chapter "Creating Human Tasks" in the Developing SOA Applications with Oracle SOA Suite.

- For more information about creating an ADF task flow based on the human task service component, see the chapter "Creating Human Tasks" in the Developing SOA Applications with Oracle SOA Suite.

40.5 Other Approaches

You can deploy the human task flow to a remote server without SOA infrastructure.
**Related Links**

For more information about deploying human task flows to remote servers without SOA infrastructure, see the section "How To Deploy a Task Display Form to a non-SOA Oracle WebLogic Server" in the chapter "Designing Task Forms for Human Tasks" in the *Developing SOA Applications with Oracle SOA Suite*.

### 40.6 Securing the Design Pattern

**Note:**

To use the ADF Security Wizard, developers must start up JDeveloper with a role profile that supports JAAS-XS security, such as the Oracle CRM Application Developer Role. To deploy an SOA composite to a WLS container, the application deployer must start up JDeveloper using the default role.

The human task service uses Java platform security (JPS) for accessing user/role profile information. JPS supports multiple providers, such as XML and XS.

The default authentication provider in Oracle WebLogic Server is *WLSAuthenticator*, while the authorization provider is based on the JPS policy store.

The default security configuration uses the Oracle WebLogic Server embedded LDAP as the identity store and *system-jazn-data.xml* as the policy store. This configuration is held in the *workflow-identity-config.xml* file, as shown in Example 40-1.

**Note:**

As other applications plan to use XS database as a repository, XML-based providers must synchronize with the XS database whenever changes occur to user or role related data.

**Related Links**

The following documents provide additional information related to subjects discussed in this section:

- For more information about configuring or updating the human workflow Identity Service, see the section "Configuring the Identity Service" in the chapter "Configuring Human Workflow Service Components and Engines" in the *Administering Oracle SOA Suite and Oracle Business Process Management Suite*.

- For more information, see the chapter "Configuring the OPSS Security Store" in the *Oracle Fusion Middleware Applications Security Guide*.

**Example 40-1  Identity Service Configuration**

```xml
<ISConfiguration xmlns="http://www.oracle.com/pcbpel/identityservice/isconfig" >
  <configurations>
    <configuration realmName="jazn.com">
      <provider providerType="JPS" name="JpsProvider" service="Identity">
        <property name="jpsContextName" value="default" />
      </provider>
    </configuration>
  </configurations>
</ISConfiguration>
```
40.7 Verifying the Deployment

To properly verify this design pattern, you should test and deploy your ADF application, deploy the SOA composite application and the ADF task from the Worklist application, and then run the ADF application.

To verify this design pattern:

1. Test your Oracle ADF web application. Be sure to enable the ADF Business Components runtime logging by setting the Java VM parameter `jbo.debugoutput=console`. Doing so logs the event and its payload in the JDeveloper log console.

2. Use Oracle Enterprise Manager Fusion Middleware Control Console to view the SOA composite application and ensure it was properly deployed.

3. Run the ADF application and invoke the method that raises the event.

   Alternatively, you can use the Composite initiate page in Enterprise Manager to send a test message to the BPEL process service component. Note that this bypasses the mediator service component and directly calls the BPEL process service component which in turn invokes the human task service component.

   The web service ending point for each of the services in the composite is

   
   http://HOST_NAME:PORT/fabric/application name/composite_name/service_name

   For example:

4. View the ADF Business Components runtime log to view the event and payload.

5. Use Oracle Enterprise Manager Fusion Middleware Control Console to check if an instance of the SOA composite application has been created. The process should be in running state and waiting at the human task step.

6. Log in to the worklist application to view the task created for the supervisor. The worklist application is located at http://hostname/integration/worklistapp/

   Click Approve or Reject to complete this task.

   If successful, the status of the task will be updated on the home page the Worklist application.

7. In Fusion Middleware Control Console, check that the human task has completed. This ensures that the waiting BPEL process can proceed with the subsequent steps.

40.8 Troubleshoot the Use Case

Following are tips that may help resolve common issues that arise when developing or running this use case.

40.8.1 Worklist Notification Locale Does Not Honor the Regional Applications Session Setting

When logging into the worklist application, both the worklist and human task details honor the regional setting in the Applications Core session. However, the notification locale does not honor the regional setting of the Applications Core session.

Notifications cannot consider the Applications Core sessions of the worklist application.

Consider a task being assigned to user jcooper. The user jcooper may not be logged into the worklist at the time, but notifications must be sent to jcooper when the task is assigned.

To do so, implement oracle.bpel.services.workflow.task.INotificationCallback. You can add print statements to the implementation and verify the values that are returned.

40.8.2 Task Does Not Display in Worklist Application

If you are not able to find the task in the worklist application, try the following:

• Login to the worklist application with weblogic as the user. Navigate to the Administration Tasks tab. This will list all the tasks in the system. Locate the task that was created and validate the state (it should be ASSIGNED) and the assignees.

• Alternatively, log in to Oracle Enterprise Manager Fusion Middleware Control Console at http://HOST_NAME:PORT/em and click the instance ID to display an audit track window. In the audit track view, click the BPEL instance and select the Flow-Debug tab to display the BPEL audit trail. Check the following values in the initiateTaskResponse:

  – task:task/task:systemAttributes/task:state: This should be ASSIGNED

  – task:task/task:systemAttributes/task:assignees: This displays the assignees of the task

• Check the following log files and the shell where the server was started to make sure that there are no errors (for information about logging, see Logging).
• Use the web services page http://HOST_NAME:PORT/integration/services/IdentityService/identity to check user and group properties. Users and groups may be seeded differently from what is assumed and may therefore cause unexpected results.

40.8.3 Task Details Do Not Display in the ADF Task Flow

If you are not able to see the human task details when you click on the task in the worklist application, try the following:

• For design time issues, make sure you start JDeveloper using jdev.exe instead of jdevw.exe in a Windows environment. This brings up a console window in the background that shows any error messages or stack traces.

• If you see any errors during deployment of the ADF task flow, check the following:
  – The ADF task flow for the human task service is deployed on the same instance as the SOA server. If it is deployed to a server without SOA infrastructure, make sure to correctly follow the steps for deploying task flows.
  – Check if the taskflow.properties file exists in your project and has the following settings:

```
human.task.lookup.type=LOCAL
```

  – Check that all shared libraries are installed to the WLS instance where the task flow is deployed, including adf.oracle.domain, adf.oracle.domain.webapp, JSF, JSTL and oracle.soa.workflow or any shared library specified in weblogic-application.xml. You can verify this by logging into Oracle WebLogic Server Console as an administrator, and clicking Deployments.

• If you see the task in the task list but you get an error when clicking on the task title, try the following:
  – Determine if there were any deployment errors.
  – Enable logging for ADF as described in Logging. Set the log level to FINE and deploy the task flow again. After you do this, you should see error messages in the log file. $OC4J_HOME/j2ee/home/log/oc4j/log.xml file
  – If you get any errors on the task details screen when performing any operations, check the following log files:
40.8.4 Logging

You can set logging for the Workflow application and for the ADF task flow.

40.8.4.1 Workflow Logging

To enable debug logging for the workflow service, add a new log_handler and logger for oracle.bpel.services in ORACLE_HOME/j2ee/home/config/j2ee-logging.xml as shown in Example 40-2. After these changes are made, you must restart the server. When this logger is added, the logs will be found in MW_HOME/user_projects/domains/<domain name>/config/config.xml.

Example 40-2 Adding a New Log Handler

```xml
<?xml version="1.0" encoding="iso-8859-1"?>

<logging_configuration>
  <log_handlers>
    ...
    <log_handler name="oracle-bpel-services-handler" class="oracle.core.ojdl.logging.ODLHandlerFactory">
      <property name="path" value="../log/wls/bpel/services"/>
      <property name="maxFileSize" value="10485760"/>
      <property name="maxLogSize" value="104857600"/>
      <property name="encoding" value="UTF-8"/>
      <property name="supplementalAttributes" value="J2EE_APP.name,J2EE_MODULE.name,WEBSERVICE.name,WEBSERVICE_PORT.name"/>
    </log_handler>
    ...
  </log_handlers>
  <loggers>
    ...
    <logger name="oracle.bpel.services" level="FINEST" useParentHandlers="false">
      <handler name="oracle-bpel-services-handler"/>
    </logger>
    ...
  </loggers>
</logging_configuration>
```

40.8.4.2 ADF Task Flow Logging

To enable ADF logging for the task flow, add fragments shown in Example 40-3 to MW_HOME/user_projects/domains/DOMAIN/soainfra/config/fmwconfig/servers/AdminServer/logging.xml and restart the server.

MW_HOME/user_projects/DOMAIN/domains/<domain name>/config/config.xml
Example 40-3 Adding Fragments to the Logging File

```xml
<logger name='oracle.adf' level='FINE' useParentHandlers='false'>
    <handler name='wls-domain'/>
    <handler name='console-handler'/>
</logger>

<logger name='oracle.adfinternal' level='FINE' useParentHandlers='false'>
    <handler name='wls-domain'/>
    <handler name='console-handler'/>
</logger>

<logger name='oracle.jbo' level='FINE' useParentHandlers='false'>
    <handler name='wls-domain'/>
    <handler name='console-handler'/>
</logger>
```

40.9 What You May Need to Know About Managing Tasks from an ADF Application

Tasks are linked to the composite instance that created them. When a new version of the BPEL process service component or workflow service component is deployed, any existing composite and associated task instances are marked stale. You can clean up stale composites using Oracle Enterprise Manager Fusion Middleware Control Console. Cleaning up stale composite instances automatically deletes the associated task instances as well.

Related Links

For more information about managing tasks from an ADF application, see the chapter "Managing SOA Composite Application Instances" in the *Administering Oracle SOA Suite and Oracle Business Process Management Suite*.
This chapter describes what to do when you need to work with data from a remote Oracle ADF Fusion Business Service in the format of an ADF Business Components component, such as rendering the data in a UI table, or creating a view link to it.

**When to implement:** When you need to work with data from a remote Oracle ADF Fusion Business Service in the format of an ADF Business Components component, such as rendering the data in a UI table, or creating a view link to it.

**Design Pattern Summary:** Create service-based entity objects and view objects and use these entity objects and view objects as normal ADF Business Components either in your business logic or for rendering on UI pages to simplify the task.

**Involved components:**
- ADF Business Components service that accesses data from a different pillar.
- Entity object based on the ADF Business Components service, and view object on top of the entity object.

### 41.1 Introduction to the Recommended Design Pattern

When you want to work with data from a remote ADF Business Components service, you can create service-based entity objects and view objects to simplify the task. A service-based entity object is an entity object that encapsulates the details of accessing and modifying a row of data from a remote ADF Business Components service. The service-based entity object then can be used in the same way as a normal database-table-based entity object.

### 41.2 Potential Approaches

If the data that you need to work with is always local to you, that is, available in the same database, then use a table-based entity object instead. The service-based entity object or view object will have additional performance overhead since each has an extra service layer.

Instead of wrapping with a service-based entity object or view object, you always can invoke the ADF Business Components service directly. For more information, see [Synchronously Invoking an ADF Business Components Service from an Application](#). As UI components cannot be bound to Service Data Objects (SDOs) directly and an ADF Business Components service only accesses SDOs, using service-based entity objects and view objects is a simpler approach, especially if you just need to invoke a method as part of your business logic and you do not need to bind the input/output of the method to UI components.
41.3 Example

Currently, no example is available.

41.4 How to Create Service-Based Entity Objects and View Objects

Instead of creating an entity object on top of a database schema, you create it based on a WSDL.

To create service-based entity objects and view objects:

1. Ensure that the WSDL file of the targeted ADF Business Components service is available, either from your file system or from a URL.

2. Create a new entity object using the Create Entity Object wizard.

   **Note:**
   Instead of using a database schema object for the entity’s data source, select Service Interface.

3. Create a view object on top of the entity object that you created in the previous step. This step is the same as creating a normal entity object-based view object.

4. Register the targeted service in your connections.xml file (found in Application Resources > Descriptors > ADF META-INF). This entry is needed during runtime to invoke the service. Note that this also requires that the targeted service be hosted and running, since the registration requires the URL of where the service is deployed. Example 41-1 shows sample code used in the connections.xml file.

5. Get the service interface common.jar file from the service provider, and add the file to your library. This is also required during runtime. The common.jar file is generated when the service provider uses an ADF Business Component Service Interface deployment profile to deploy.

**Example 41-1 Sample connections.xml Code**

```xml
<Reference name="[http://xmlns.oracle.com/apps/adfsvc/deptempService/]DeptEmpService" className="oracle.jbo.client.svc.Service" xmlns="">
  <Factory className="oracle.jbo.client.svc.ServiceFactory"/>
  <RefAddresses>
    <StringRefAddr addrType="serviceInterfaceName">
      <Contents>oracle.apps.adfsvc.deptempService.DeptEmpService</Contents>
    </StringRefAddr>
    <StringRefAddr addrType="serviceEndpointProvider">
      <Contents>ADFBC</Contents>
    </StringRefAddr>
    <StringRefAddr addrType="jndiName">
      <Contents>DeptEmpServiceBean#oracle.apps.adfsvc.deptempService.DeptEmpService</Contents>
    </StringRefAddr>
    <StringRefAddr addrType="serviceSchemaName">
      <Contents>DeptEmpService.xsd</Contents>
    </StringRefAddr>
    <StringRefAddr addrType="serviceSchemaLocation">
      <Contents>oracle/apps/adfsvc/deptempService</Contents>
    </StringRefAddr>
  </RefAddresses>
</Reference>
```

The following documents provide additional information related to subjects discussed in this section:

- For more information about creating service-based entity objects and view objects, see the section "Accessing Remote Data Over the Service-Enabled Application Module" in the chapter "Integrating Service-Enabled Application Modules" in Developing Fusion Web Applications with Oracle Application Development Framework.

- For more information, see the chapter "Defining SQL Queries Using View Objects" in Developing Fusion Web Applications with Oracle Application Development Framework.

41.5 Securing the Design Pattern

For more information about securing the use case, see Securing Web Services Use Cases.

41.6 Verifying the Deployment

To properly verify this design pattern, test your service-based view object in an application module tester, then deploy and test the application that uses the service-based entity object and view object.

To verify this design pattern:
Test your Oracle ADF application.

Related Links

For more information about testing and debugging Oracle ADF applications, see the chapter "Testing and Debugging ADF Components" in the Developing Fusion Web Applications with Oracle Application Development Framework.

41.7 Troubleshooting the Use Case

Currently, there are no tips for troubleshooting the use case.

41.8 Understanding the Transactional Behavior of Service-Based Entity Objects and View Objects

Note that the underlying data source for service-based entity objects and view objects is an ADF Business Components service, which is stateless and in a different transaction. When you commit your transaction of your local application module, a service call will be made if there is any change in the service-based entity object that is not part of your local transaction. If the service invocation fails, then the local transaction also will fail. However, if the service invocation succeeds and then later your local transaction fails, it is your error handling code that must perform a
compensating transaction against the remote service to "undo" the previous change made.

41.9 Known Issues and Workarounds

Known limitations are the following:

- A service-based entity object cannot be referenced as a secondary entity usage in a view object.
- A service-based view object cannot have secondary entity usages.

These limitations mean that you cannot create a flattened join of multiple entities if one of them is a service-based entity object. The workaround is to use a view link to traverse from one view object to another.
This chapter describes what a SOA composite application needs to do to invoke an asynchronous service such as an Oracle ADF service or another SOA composite application.

When to implement: A SOA composite application needs to invoke an asynchronous service such as an Oracle ADF service or another SOA composite application.

Design Pattern Summary: A SOA composite is designed with a Mediator or BPEL component that invokes an asynchronous service endpoint, after which goes into a state of rest until the asynchronous endpoint calls back with the response payload.

Involved components:

- One SOA composite (Consumer role).
- One or more (Producer role) SOA Composites or Oracle ADF Services.

42.1 Introduction to the Recommended Design Pattern

Oracle Fusion web applications often include services with long-running computation that are exposed through service interfaces. When invoking services through a synchronous service interface, the service may not execute as desired due to time outs or lack of resources caused by blocked, waiting threads. To solve this problem, services are exposed through asynchronous interfaces that wait for a response when invoking long-running services.

The recommended approach to asynchronous invocation is to create an asynchronous SOA composite with a BPEL process that invokes the asynchronous service.

Note:

Per Oracle Fusion Applications standards, a composite that exposes a synchronous interface must not invoke an asynchronous service.

Figure 42-1 illustrates the process flow of BPEL process invoking an asynchronous service.
The client BPEL process invokes an asynchronous service through the WSDL partner link. The service runs as required, and returns a response to the waiting client BPEL process.

### 42.2 Other Approaches

Following are alternative, unsupported approaches to the use case.

- Invoke services synchronously. This approach is not supported due to time out issues.
- Invoke services asynchronously, without registering a callback handler service. This approach is not supported, as a callback handler is required when asynchronously invoking a service.
- Invoke a one-way service. This approach is not supported for Oracle ADF services.
- Invoke a service asynchronously, registering another service as the callback handler. This approach is not supported. Use business events instead.

**Caution:**

These approaches are not supported and should not be implemented.

### 42.3 Example

An interface table is populated by third-party entities using legacy interfaces, such as FTP and files. After the interface table is populated, a periodic Oracle Enterprise Scheduler job runs, checking for new interface table rows. If the job finds new table rows, it raises a business event that initiates a BPEL process. The BPEL process orchestrates any required services such as those used to import and notify users, obtain necessary approvals, and so on.

In this scenario, one or more services or tasks require several minutes or even hours to complete, as is typical among asynchronous service interfaces. The BPEL process invokes the service and enters a dormant state in which the process progress and variable data are stored in the database, which frees memory and thread resources for other BPEL processes. When the long-running service completes, the asynchronous callback revives the process. The BPEL process continues from where it left off.

You can find the sample code for this use case in the *Oracle SOA Suite samples*. 
42.4 How to Invoke a SOA Composite Application from Within a SOA Composite Application

To initiate an asynchronous service from a BPEL process, do the following:

1. Create a SOA composite with a BPEL process.
2. Create the service reference to the asynchronous web service you want to invoke.
3. Populate the BPEL process with scope, invoke, receive, assign and fault-handling activities.

Before defining the service reference, create your composite and BPEL process with the requisite input and output payload types. Figure 42-2 shows an example of a minimalist composite with a new BPEL process.

Figure 42-2 Composite Before Web Service Reference Definition

Defining the service reference to the asynchronous web service endpoint involves the following tasks:

1. Define the new web service reference.
2. Wire the BPEL process to the new service reference.
3. Invoke the asynchronous web service from the BPEL flow.
4. Deploying and testing the composite.

42.4.1 Define a New Web Service Reference

Define the service that the composite is to invoke.

To define the new web service reference, do the following:

1. In the composite, define the asynchronous service reference by dragging a Web Service component to the right-hand swim lane of the composite.

   The Create Web Service dialog opens.

2. In the Create Web Service dialog, enter the following information:
   - Name: Enter the name of the web service reference for this composite.
• **Type:** Select Reference. A Reference is a service that this composite will be invoking.

• **WSDL URL:** Select the full URL to the WSDL of the asynchronous web service to be invoked. Use the service explorer to navigate to and select the WSDL.

• **Port Type:** Select the execute port type of the end point service. This value is often automatically defaulted by the UI. This is the port type invoked by the composite.

• **Callback Port Type:** Select the callback port type of the end point service. This value is often defaulted automatically by the UI. This is the port type used to call back the composite.

Figure 42-3 shows an example of a filled in Create Web Service dialog.

**Figure 42-3 Create Web Service Dialog**

![Create Web Service Dialog](image)

### 42.4.2 Wiring the BPEL Process to the New Web Service Reference

To invoke a web service, a BPEL process must include a local partner link definition. You can define a partner link in one of two ways.

- Define a partner link in the BPEL process editor.
- Drag the interface pin from the BPEL process to the service reference.

Defining a partner link involves additional work as compared to the alternative approach of dragging the interface pins. However, when creating a partner link for a web service that has not yet been defined as a service reference in the composite, Oracle JDeveloper automatically creates the composite service reference and wires the BPEL process to that service.

Dragging the interface pin from a component to a service is a quick and easy way to automatically create partner links and other service component integrations, such as wiring a Mediator to a Business Rule component. Wiring components by clicking and dragging automatically generates the metadata files and entries used to support the interaction between the components.
To define a partner link in the BPEL process editor:

1. In the Composite Editor, double-click the BPEL process component.

2. In the right-hand swim lane of the BPEL process, right-click the area under Partner Links.
   The Create Partner Link dialog is displayed, as shown in Figure 42-4.

   **Figure 42-4  Create Partner Link Dialog**

   ![Create Partner Link Dialog](image)

3. In the Create Partner Link dialog, enter the following information:
   - **Name**: Enter the name of the partner link. This defaults to the service name.
   - **WSDL URL**: Enter the full URL for the WSDL file of the asynchronous web service to be invoked.
   - **Partner Link Type**: Enter the service partner link type. This value is automatically filled in using the service name, as derived from the WSDL referenced in the WSDL URL field.
   - **Partner Role**: From the dropdown list, select the `ServiceNameProvider` role. This is the role of the producer service for which you entered the WSDL.
   - **My Role**: From the dropdown list, select the `ServiceNameRequester` role. This is the role of the BPEL process as the consumer of the asynchronous service.

4. Alternatively, click and drag the pin from the BPEL component to the service reference.
   a. Hover the mouse over the BPEL component and the input and output icons.
   b. Drag the input and output icons to the matching icons on the service reference component, as shown in Figure 42-5.

   ![Drag and Drop Partner Link](image)
42.4.3 Invoke the Asynchronous Web Service from the BPEL Flow

By default, an asynchronous BPEL flow contains two activities: the receive activity that starts the process and the invoke activity that initiates the callback response.

Asynchronous services do not throw faults, such that they must always return a valid payload whenever possible. In the event of a business failure at the endpoint service, services should return a payload that contains a failed status.

Invoking the asynchronous web service from the BPEL flow involves the following steps:

1. Add required resilience and logging.

2. Add a scope activity to include the asynchronous service invocation and variable assignment activities.

3. Add fault handlers to trap any system failures that may occur during any activities within a scope, so as to permit logging, incident creation and error management as required by the use case. Asynchronous services do not throw WSDL-defined faults, necessitating a fault handler.

4. Add logging. All BPEL processes within Oracle Fusion web applications are required to implement translatable, tokenized, message-level logging for fault-handling scenarios.

5. Invoke the service.

6. Add invoke, receive and assign activities.

   a. Invoke: This activity defines the partner link and invoke operation, and defines the BPEL variable containing the payload to be submitted.

   b. Receive: This activity defines the partner link and operation to be invoked, and defines the variable to store the response payload when the asynchronous callback is made.

   c. Assign (1): The first assign activity copies BPEL process input data, XML fragments and XPath expression results to the payload that is sent to the asynchronous service.

   d. Assign (2): The second assign activity copies the contents of the asynchronous response payload to the BPEL output variable, which is then sent back to the calling process.
To invoke the asynchronous web service from the BPEL flow:

1. To adhere to Oracle Fusion Applications fault handling and logging standards, add the following activities:
   - **Scope:** By default, the main BPEL flow is the top-level scope of the process. However, should any of the activities generate a fault within that scope, compensation or recovery options are limited. Leverage nested scopes to contain errors and implement resilient functionality.
   - **Fault Handlers:** Each nested and top-level scope should have qualified and catch-all fault handlers to catch business- or system-level faults and respond accordingly to the use case.
   - **Logging:** Add assign activities as needed. Alternatively, add copy operations to pre-existing assign activities to implement logging.

2. Add a scope activity.
   a. In the Composite Editor, double-click the BPEL component to open the BPEL process editor.
   b. Drag a new scope activity onto the process and name according to the activities it will contain, for example, `InvokeAsyncServiceName`.
   c. To the scope activity, add the service invocation and variable assignment activities.

3. Add a catch-all fault handler to trap any errors that may occur during assign, invoke, receive or dehydration activities that may occur within the scope. Use either of the following:
   - **Reply Normally:** Returns a payload with an error status and completes in all cases.
   - **Wait State:** Sends the asynchronous response, which then sends a user notification or updates an Oracle ADF record, and enters a correlated wait state. The wait state allows another entity to invoke the in-flight process that provides additional instructions.

4. Implement translatable, tokenized, message-level logging for fault-handling scenarios. Optionally, implement bread crumb logging and incident creation, where applicable to the use case.

5. Define an invoke activity for the asynchronous web service. In the scope previously defined, drag an **Invoke** activity to the flow.

6. Double-click the activity. In the Invoke Activity dialog, enter the following information.
   - **Name:** The name of the invoke activity, such as `Invoke<ServiceName>`.
   - **Interaction Type:** Select **Partner Link**.
   - **Partner Link:** Select a partner link from the list of partner links that were previously defined in the BPEL process metadata. To select a partner link, browse through the expanded list of partner links for the asynchronous service defined earlier.
• **Operation:** Select an operation from the list of all the available synchronous and asynchronous operations defined on the web service of the partner link. Be sure to select the relevant asynchronous operation.

**Note:**
For Oracle ADF Services, the operation names end with `Async`.

• **Input:** Click the **Add** button to create a scope-local variable to contain the payload intended for the asynchronous service invocation. **Figure 42-6** shows a completed Invoke Activity dialog.

**Figure 42-6  Invoke Activity Dialog**

![Invoke Activity Dialog](image)

7. Define a receive activity to handle the asynchronous callback from the endpoint service, and store the response payload in a variable for use by the process. Drag a receive activity immediately following the invoke activity.

8. In the Receive Activity dialog, enter the following information.
   - **Name:** Enter a name for the invoke activity, such as `Invoke<ServiceName>`.
   - **Interaction Type:** Select **Partner Link**.
   - **Partner Link:** Select a partner link from the list of partner links that were previously defined in the BPEL process metadata. To select a partner link, click the **Browse** button and browse through the expanded list of partner links for the asynchronous service defined earlier.
   - **Operation:** Select an operation from the list of all the available synchronous and asynchronous operations defined on the partner link’s web service. Be sure to select the appropriate asynchronous callback operation.
• **Variable:** Click the **Add** button to define a scope-local variable to contain the payload received from the asynchronous service invocation.

**Figure 42-7** shows a completed Receive Activity dialog.

**Figure 42-7 Receive Activity Dialog**

9. Drag an assign activity onto the flow (within the scope) just above the invoke activity you created earlier. Drag a second assign activity onto the flow just below the receive activity you created earlier.

10. Name each assign activity.

   Double-click the activity, click the **General** tab and enter a meaningful name such as `AssignInputForAsync<ServiceName>` or `CopyOutputFrom<ServiceName>`.

11. Select the **Copy Operation** tab and click the **Add** button to open the Create Copy Operation dialog.

   In the Create Copy Operation dialog, select **Copy Operation**.

12. Depending on the type of data you want to assign to the invoke input variable, configure the following.

   • **Variable:** Select the contents of an element from the source variable, such as the default BPEL `inputVariable`, as shown in **Figure 42-8**.
**Figure 42-8  Variable Copy Operation**

- **XPath Expression**: Enter an XPath expression as required, such as `concat($variable1, '-', $variable2)`, as shown in Figure 42-9.

**Figure 42-9  XPath Expression Copy Operation**
• **XML Fragment**: A fully namespace-qualified XML document that matches the XML schema structure of the target variable or variable element, as shown in Figure 42-10.

**Note:**
If you receive an "Invalid XML" error message, ensure that all elements are namespace qualified within the context of the fragment as BPEL process namespaces are not scoped into fragments.

*Figure 42-10  XML Fragment Copy Operation*

• **Partner Link**: The contents and properties of a Partner Link (useful for dynamic partner links).

13. Save your files.
14. Deploy the SOA composite application to the SOA infrastructure.
15. Test the application.

**Related Links**
The following documents provide additional information related to subjects discussed in this section:

- For more information about deploying SOA composite applications, see *Deploying SOA Composite Applications* in *Developing SOA Applications with Oracle SOA Suite*.
- For more information about testing your SOA composite application, see the chapter *Automating Testing of SOA Composite Applications* in *Developing SOA Applications with Oracle SOA Suite*.
42.4.4 What Happens When You Invoke an Asynchronous Service from within a SOA Composite Application

Defining the web service reference generates a local, abstract WSDL (.wsdl) file named after the service for which it was created. This WSDL file contains partner link information used by BPEL, as well as a reference to the asynchronous web service WSDL URL for looking up message type and schema information. Typically, the WSDL file name is the same as the service name, with the suffix .wsdl appended at the end.

42.4.5 What Happens at Runtime: How an Asynchronous Service is Invoked from within a SOA Composite Application

At runtime, the following occurs within the BPEL process:

- The invoke activity initiates the remote service.
- The BPEL process is dehydrated (session and variable data is serialized) to the database.
- The process thread is freed such that other potential processes may use it while waiting for the asynchronous service to complete and respond.

42.5 Securing the Design Pattern

To secure this pattern, add the Oracle Web Services Manager policies to both the service endpoint and service reference components in the composite.

For more information, see Securing Web Services Use Cases.

42.6 Verifying the Deployment

To properly test this pattern, deploy this SOA composite to the SOA domain and initiate the composite through the service test client page.

To verify the deployment:

1. Open a web browser and navigate to the following URL format.
   
   http://host:port/em

   Note:

   Use the HTTPS protocol instead of HTTP if your server is configured to use SSL.

   You will see a list of all successfully deployed composites in this SOA environment.

2. Click the service endpoint link beneath the name of the deployed composite. This renders the service test client page, which then can be used to enter payload data and invoke the composite.

3. Enter the payload fields as needed and click Initiate.
4. Navigate to Oracle Enterprise Manager Fusion Middleware Control Console using the following URL format.
   
   http://host:port/em

5. Login to Oracle Enterprise Manager Fusion Middleware Control Console and take the following actions.
   
   a. On the left side of Oracle Enterprise Manager Fusion Middleware Control Console, expand the SOA tree node.
   
   b. Expand the **soa-infra** node for the correct SOA server and select the name of the deployed composite.
   
   c. Click the instance ID link for the most recent instance of this composite. The Flow Trace window displays.
   
   d. In the Flow Trace window, find the entry for your BPEL process component. Click the BPEL process component to open the Audit Flow view.

   The Audit Flow view displays the activities that were executed in the BPEL process, along with payload details that you can view by clicking the activity.

42.7 Troubleshoot the Use Case

Following are tips that may help resolve common issues that arise when deploying or running this use case.

42.7.1 Deployment

If failures occur during compilation or deployment, observe the Oracle JDeveloper console and compiler output to resolve any issues.

If deployment is successful but the composite does not display in the soa-infra composites list, check the server's diagnostic log and console output for any exceptions and resolve them.

42.7.2 Runtime

If faults occur when invoking the composite, the logging activities and fault-handling branches should provide meaningful content in the applications diagnostic log (defined in **logging.xml**) or be present in the callback payload.

Use the Audit Flow view to diagnose the problem and correct your BPEL process, then redeploy. For more information about using the Audit Flow view, see the deployment steps in Verifying the Deployment.

42.8 What You May Need to Know About Invoking an Asynchronous Service from Another SOA Composite

Make sure to finalize the XML schemas before implementing the design pattern and defining payload types and variables.
Synchronously Invoking an ADF Business Components Service from an Oracle ADF Application

This chapter describes what to do when you need to invoke an ADF Business Components service either from an ADF Business Components object or from a UI. Use only with synchronous processes with an immediate response.

**When to implement:** When you need to invoke an ADF Business Components service either from an ADF Business Components object or from a UI. Use only with synchronous processes with an immediate response.

**Design Pattern Summary:** Use `ServiceFactory` to generate a dynamic proxy to the target ADF Business Components service, then use the proxy to invoke the desired service method.

**Involved components:**
- ADF Business Components service
- A local ADF Business Components object (such as an application module or an entity object), or from a UI via either a local ADF Business Components object or a managed JavaBean

### 43.1 Introduction to the Recommended Design Pattern

When you need to invoke an ADF Business Components service from an Oracle ADF application, use `oracle.jbo.client.svc.ServiceFactory` to invoke the service.

### 43.2 Potential Approaches

One alternative is to use JAX-WS to generate static proxy classes. This is prohibited for ADF Business Components services because:

- Using JAX-WS generates many proxy classes that you need to maintain, which increases maintenance costs.
- `oracle.jbo.client.svc.ServiceFactory` uses a local Java call if the service is co-located, which offers performance benefits.

The other alternative is to use a dynamic invocation interface. This is not recommended as it requires much more coding.

If you need to bind the input or output of the service to UI components, consider using service-based entity objects and view objects. For more information, see *Working with Data from a Remote ADF Business Components Service.*
43.3 Example

Currently, no example is available.

43.4 How to Invoke an ADF Business Components Service from an Oracle ADF Application

On the service provider side, you must create an ADF Business Components service interface deployment profile. This profile generates two JAR files: one common JAR file that contains only the service interface, and another file that contains the implementation.

To invoke an ADF Business Components service from an Oracle ADF application:

1. Navigate to Application Resources > Descriptors > ADF META-INF and open the connections.xml file.

   This entry is needed to invoke the service during runtime.

   **Note:**

   The targeted service must be hosted and running, as registration requires the URL of the service deployment location.

2. Register the targeted service in connections.xml, as shown in Example 43-1.

3. Get the service interface common JAR file from the service provider and add it to your library.

   This file is required during runtime. The common JAR file is generated when the service provider uses a ADF Business Components service interface deployment profile for deployment.

4. In your ADF Business Components service or managed Java bean class, invoke the desired service using ServiceFactory, as shown in Example 43-2.

   Sample queries are shown in Example 43-3.

   **Example 43-1  Sample Code for the File connections.xml**

   ```xml
   <Reference name="{http://xmlns.oracle.com/apps/adfsvc/deptempService/}DeptEmpService" className="oracle.jbo.client.svc.Service" xmlns="">
   <Factory className="oracle.jbo.client.svc.ServiceFactory"/>
   <RefAddresses>
     <StringRefAddr addrType="serviceInterfaceName">
       <Contents>oracle.apps.adfsvc.deptempService.DeptEmpService</Contents>
     </StringRefAddr>
     <StringRefAddr addrType="serviceEndpointProvider">
       <Contents>ADFBC</Contents>
     </StringRefAddr>
     <StringRefAddr addrType="jndiName">
       <Contents>DeptEmpServiceBean#oracle.apps.adfsvc.deptempService.DeptEmpService</Contents>
     </StringRefAddr>
   </RefAddresses>
   </Reference>
   ```

43-2 Oracle Fusion Applications Developer's Guide
Example 43-2  ServiceFactory Code

```java
OrganizationService svc = (OrganizationService)ServiceFactory.getServiceProxy(OrganizationService.NAME);
List orgs = new ArrayList(2);
Org org1 = (Org)DataFactory.INSTANCE.create(Org.class);
org1.setOrganizationId(new Long(10000));
org1.setOrgName("OrgName");
org1.setName("TranslatedName"); //... and set more attributes
orgs.add(org1);
svc.processOrganization("Merge", orgs, null);
```

Example 43-3  Query Samples

```java
// Retrieve only Dname, Loc from Dept and exclude Empno from Emp.
DeptEmpService mSvc = (DeptEmpService)ServiceFactory.getServiceProxy(DeptEmpService.NAME);
FindCriteria fc = (FindCriteria)DataFactory.INSTANCE.create(FindCriteria.class);
List l = new ArrayList();
l.add("Dname");
l.add("Loc");
l.add("Emp");
fc.setFindAttribute(l);
List cfcl = new ArrayList();
ChildFindCriteria cfc =
(ChildFindCriteria)DataFactory.INSTANCE.create(ChildFindCriteria.class);
cfc.setChildAttrName("Emp");
List cl = new ArrayList();
cl.add("Empno");
cfc.setFindAttribute(cl);
cfc.setExcludeAttribute(true);
cfcl.add(cfc);
fcc.setChildFindCriteria(cfcl);
DeptResult res = mSvc.findDept(fc, null);

// Exclude PurchaseOrderLine from PurchaseOrder.
PurchaseOrderService svc =
(PurchaseOrderService)ServiceFactory.getServiceProxy(PurchaseOrderService.NAME);
FindCriteria fc = (FindCriteria)DataFactory.INSTANCE.create(FindCriteria.class);
List l = new ArrayList();
fcc.setExcludeAttribute(true);
l.add("PurchaseOrderLine");
fcc.setFindAttribute(l);
PurchaseOrderResult res = svc.findPurchaseOrder(fc, null);

// Retrieve only the 2nd Emp along with Dept with Deptno=10.
FindCriteria fc = (FindCriteria)DataFactory.INSTANCE.create(FindCriteria.class);
```
// Create the view criteria item.
List value = new ArrayList();
value.add(new Integer(10));
ViewCriteriaItem vci =
    (ViewCriteriaItem)DataFactory.INSTANCE.create(ViewCriteriaItem.class);
vci.setValue(value);
vci.setAttribute("Deptno");
List<ViewCriteriaItem> items = new ArrayList(1);
items.add(vci);
// Create view criteria row.
ViewCriteriaRow vcr = (ViewCriteriaRow) DataFactory.INSTANCE.create(ViewCriteriaRow.class);
vcr.setItem(items);
// Create the view criteria.
List group = new ArrayList();
group.add(vcr);
ViewCriteria vc = (ViewCriteria)DataFactory.INSTANCE.create(ViewCriteria.class);
vc.setGroup(group);
// Set filter.
fILTER(vc);

List cfcl = new ArrayList();
ChildFindCriteria cfc =
    (ChildFindCriteria)DataFactory.INSTANCE.create(ChildFindCriteria.class);
cfc.setChildAttrName("Emp");
cfc.setFetchStart(1);
cfc.setFetchSize(1);
cfcl.add(cfc);
fc.setChildFindCriteria(cfcl);
DeptResult dres = svc.findDept(fc, null);
pw.println("### Dept 10 and 2nd Emp ###");

Implement an Asynchronous Service Initiation with Dynamic UI Update

This chapter describes what to do when initiating asynchronous or long-running functionality from an Oracle ADF UI and, on completion, notifying users of the completion of that process by dynamically updating the UI. This provides a more dynamic experience for the end user and eliminates the need to constantly click a refresh button.

Note:

- To date, the only supported Oracle ADF UI components for Active Data Service (ADS) update are outputText and image.
- This pattern is in the process of being re-written for conformance to Oracle WebLogic Server and Oracle Java Messaging Service (JMS) guidance and, in the interim, should be implemented with the understanding that a re-write is pending.

When to implement: When initiating asynchronous or long-running functionality from an Oracle ADF UI and, on completion, notifying users of the completion of that process by dynamically updating the UI. This provides a more dynamic experience for the end user and eliminates the need to constantly click a refresh button.

Design Pattern Summary: Oracle ADF UI registers an Active Data control subscriber on top of a JMS queue. The Oracle ADF UI then raises a business event either via the default CRUD operations on the entity or programmatically via Java. This event initiates a BPEL process that performs work and, when completed, invokes a synchronous ADF Business Components service method to trigger pushing the message on the JMS queue, which then causes the Active Data Service control to refresh the component or area of the component.

Involved components:

- Oracle ADF UI
- ADS
- JMS
- Business Events (programmatic)
- SOA Mediator
- SOA BPEL
• ADF Business Components services

44.1 Introduction to the Recommended Design Pattern

Asynchronous services cannot be invoked from Java code in Oracle Fusion applications. When notification of completion of asynchronous, long-running functionality is required in a UI, business events can be used for asynchrony. In addition, ADS triggered over JMS will cause the UI update when the BPEL process completes and invokes the ADF Business Components service to signal its completion.

This approach is recommended because supported technology is used. The approach also supports dynamic page updates if the user navigates away and later returns.

44.2 Potential Approaches

Other than the Oracle ADF UI > Event > BPEL > ADF Business Components > ADS approach, following are the potential approaches:

- Invoke asynchronous service and wait for an asynchronous callback. Unsupported due to thread blocking, pooled resources checked out until functionality completes and returns, potentially hours and days.
- Invoke asynchronous functionality through synchronous interface. Potential time out issues and thread blocking caveats.
- JAX-WS proxy to synchronously invoke the one-way initiate operation, register an ADF Business Components service as the callback service. This is a bit of a hack, not extendible as an integration point, and it doesn't dynamically update the UI.

44.3 Example

The following is an example that illustrates the design pattern.

In an order workbench, an end user selects an order and submits it to a scheduling system for fulfillment. The scheduling system services take several seconds to several minutes to acknowledge scheduling and when the user clicks the button to initiate the scheduling process, must be notified in the UI upon successful scheduling for fulfillment without the need to repeatedly refresh the page by hand.

In this implementation, entering the UI data and clicking Schedule programmatically raises a business event, initiates a BPEL process which goes through processing and approvals as needed, then finally invokes an order ADF Business Components service to complete the process and publish the JMS message to trigger the ADS UI update.

44.4 How to Implement an Asynchronous Service Initiation with Dynamic UI Update

To enable the UI for dynamic update via ADS, you must first create the ADS handler, which uses a common set of JMS Queue handlers to broker the updates coming from the call to ADF Business Components services.

The main steps are as follows, as shown in Figure 44-1:

1. A business event is raised to initiate BPEL, which can perform work asynchronously.
2. The BPEL process updates the database and submits Oracle Enterprise Scheduler jobs.
3. At the end of the BPEL process, a web service is invoked to publish the message.
4. The web service publishes the message to JMS.
5. JMS delivers the message to the ActiveDataCollectionModel.
6. The ActiveDataCollectionModel decodes the message and updates the UI.

Figure 44-1 Technology Flow Diagram (with Optional Oracle Enterprise Scheduler Job Submission)

Prerequisites (for Prototyping Only)
Create the JMS queue in your development environment. Use the prototype common library to build this functionality into your application with minimal changes after the dependent functionality is consumed by the infrastructure.

For prototyping only, take the following steps to set up JMS using Oracle WebLogic Server Console:

---

**Note:**
This procedure assumes that the JMS Module does not already exist.

1. In the Oracle WebLogic Server Console, navigate to **Messaging > JMS Modules**.
2. Click **New** to create the JMS Module.
3. Name the module "FusionAppsADSJMSModule" and click **Next**.
4. In the Targets panel, choose the **AdminServer** target and click **Next**.
5. Choose "Would you like to add resources to this JMS system module?" and click **Finish**.
6. In the Summary of Resources table, click **New**.
7. Choose **Connection Factory** and click **Next**.
8. Name the connection factory **FusionAppsADSJMSConnectionFactory**, provide the JNDI name **jms/Prototype/MyQueueConnFactory**, and click **Next**.
9. Click **Finish**.
10. Verify the new connection factory in the Summary of Resources table and click New.

11. Choose Queue and click Next.

12. Name the queue FusionAppsADSJMSQueue, provide the JNDI name jms/Prototype/MyQueue and click Finish.

44.4.1 Writing the Active Data Handler

The classes shown in Example 44-1, Example 44-2, and Example 44-3 are common to every implementation of this pattern, and are responsible for handling JMS integration with ADS supported events.

**To implement the Active Data Collection Model:**

The Active Data Collection Model, driven by the ADS infrastructure, manages the messages coming from the queue and propagates them to the UI as Oracle ADF Rich Events. Implement the Active Data Collection Model by extending the CollectionModel class in the org.apache.myfaces.trinidad.model package and overriding the `startActiveData, stopActiveData` and `onMessage` methods. The class must implement `ActiveDataModel` and `MessageListener` as the `onMessage` method accepts JMS messages (which is a list of update events) and runs them through the active data listener.

---

**Note:**

Instead of implementing all the logic for CollectionModel, delegate to the collection model returned by the tree binding.

---

What you need to know before you begin:

- The following methods must be implemented for `ActiveDataModel`:
  - `getActiveDataPolicy()` always returns `ActiveDataPolicy.ACTIVE`;
  - `startActiveData(Collection<Object> rowKeys, int startChangeCount, ActiveDataListener listener)` is where you create a queue receiver of the topic subscriber in JMS. If you are not using JMS, this is where you register yourself with the event source as listener.
  - `stopActiveDate(Collection<Object> rowKeys, ActiveDataListener listener)` removes the queue receiver of the topic subscriber in JMS.
  - `getCurrentChangeCount()`: ADS expects the events to arrive in order. Keep a counter in the JavaBean, so that the counter increments when a new event is pushed.

- For `ActiveDataCollectionModel` to be the queue receiver or topic subscriber, `ActiveDataCollectionModel` must implement the `MessageListener` interface using the `onMessage` method. Do the following:
  1. Get the payload from the message. It should be `DataUpdateEvent`. 

---

44-4 Oracle Fusion Applications Developer’s Guide
2. Convert `DataUpdateEvent` to `ActiveDataEvent` so that ADS can process the event.

3. Deliver `ActiveDataEvent` to ADS.

Example 44-4 shows a collection model returned by a tree binding.

There are two reasons for implementing the `getModel()` method this way:

- It is necessary to delegate all collection model-related logic to the model returned by the tree binding. Inside the collection handler, you must get a handle to the collection model returned by the tree binding by looking up the binding container. As you reference the collection model often, store it somewhere for optimal performance. Make sure the managed JavaBean has a view scope while the binding container, tree binding or collection model has a request scope. You cannot store the collection model on the JavaBean. Instead, store the collection model in the request scope. When accessing the collection model, look it up first in the request scope. If the value is null—for example, at the beginning of the request—retrieve the value from the binding container.

- When pushing the `ActiveDataEvent` through ADS, only the UI is updated with the new value. The binding layer is not aware that the underlying data source has changed. If the page is refreshed now, the UI displays the old data from the binding layer. A workaround is to keep a `refreshBinding` flag on the `ActiveDataCollectionModel` to indicate whether the binding requires refreshing. The flag is initially set to false. When an event is received, the flag is set to true. When getting the collection model, check for this flag first. If the flag is set to true, programmatically refresh the related binding before returning the collection model. Example 44-5 shows sample `ActiveDataCollectionHandler` code.

**Example 44-1  DemoDataChangeEntry.java**

```java
package ads.demo.common;

import java.io.Serializable;

public class DemoDataChangeEntry implements Serializable {
    public enum ChangeType {
        /**
         * Indicates the change is row value updates
         */
        UPDATE,

        /**
         * Indicates the change is a new row insertion
         */
        INSERT,

        /**
         * Indicates the change is a new row insertion before a row
         */
        INSERT_BEFORE,

        /**
         * Indicates the change is a new row insertion after a row
         */
        INSERT_AFTER,
    }
}
```

Implement an Asynchronous Service Initiation with Dynamic UI Update 44-5
/**
 * Indicates the change is a new row insertion inside a parent
 */
INSERT_INSIDE,

/**
 * Indicates the change is row deletion
 */
REMOVE,

/**
 * Indicates the change is range refresh
 */
REFRESH

public DemoDataChangeEntry() {
    super();
}

public DemoDataChangeEntry(Object[] pk, ChangeType type,
        String[] attributes, Object[] values) {
    _pk = pk;
    _type = type;
    _attributes = attributes;
    _values = values;
}

private Object[] _pk;
private ChangeType _type;
private String[] _attributes;
private Object[] _values;

public Object[] getPk() {
    return _pk;
}

public ChangeType getType() {
    return _type;
}

public String[] getAttributes() {
    return _attributes;
}

public Object[] getValues() {
    return _values;
}

public void setPk(Object[] _pk) {
    this._pk = _pk;
}

public void setType(ChangeType _type) {
    this._type = _type;
}

public void setAttributes(String[] _attributes) {
    this._attributes = _attributes;
}

public void setValues(Object[] _values) {
Example 44-2  DemoDataUpdateEvent.java

```java
package ads.demo.common;
import java.io.Serializable;
import java.util.List;
public class DemoDataUpdateEvent implements Serializable {
    public DemoDataUpdateEvent() {
    }
    public DemoDataUpdateEvent(List<DemoDataChangeEntry> entries) {
        _entries = entries;
    }
    private List<DemoDataChangeEntry> _entries;
    public List<DemoDataChangeEntry> getEntries() {
        return _entries;
    }
    public void setEntries(List<DemoDataChangeEntry> _entries) {
        this._entries = _entries;
    }
}
```

Example 44-3  JMSHelper.java

```java
package ads.demo.common;
import java.util.Hashtable;
import javax.jms.JMSException;
import javax.jms.MessageListener;
import javax.jms.ObjectMessage;
import javax.jms.Queue;
import javax.jms.QueueConnection;
import javax.jms.QueueConnectionFactory;
import javax.jms.QueueReceiver;
import javax.jms.QueueSender;
import javax.jms.QueueSession;
import javax.jms.Session;
import javax.naming.Context;
import javax.naming.InitialContext;
import javax.naming.NamingException;
public final class JMSHelper {
    private static JMSHelper _instance = new JMSHelper();
    public static JMSHelper getInstance() {
        return _instance;
    }
    public ObjectMessage createObjectMessage() throws JMSException {
        return qsession.createObjectMessage();
    }
}
```

Implement an Asynchronous Service Initiation with Dynamic UI Update 44-7
public void sendMessage(ObjectMessage message) throws JMSException {
    qsender.send(message);
}

public QueueReceiver createQueueReceiver(MessageListener listener,
    String messageFilter) throws JMSException {
    QueueReceiver qreceiver = qsession.createReceiver(queue, messageFilter);
    qreceiver.setMessageListener(listener);
    return qreceiver;
}

private JMSHelper() {
    try {
        init();
    } catch (Exception e) {
        e.printStackTrace();
    }
}

// Defines the JMS context factory.
private final static String JMS_QUEUE_FACTORY =
    "jms/Prototype/MyQueueConnFactory";

// Defines the queue.
private final static String ADS_QUEUE = "jms/Prototype/MyQueue";

private QueueConnectionFactory qconFactory;
private QueueConnection qcon;
private QueueSession qsession;
private QueueSender qsender;
private Queue queue;

/**
 * Creates all the necessary objects for sending
 * messages to a JMS queue.
 * @param ctx JNDI initial context
 * @param queueName name of queue
 * @exception NamingException if operation cannot be performed
 * @exception JMSException if JMS fails to initialize due to internal error
 */
private void init() throws NamingException, JMSException {
    InitialContext ctx = new InitialContext();
    qconFactory = (QueueConnectionFactory) ctx.lookup(JMS_QUEUE_FACTORY);
    qcon = qconFactory.createQueueConnection();
    qsession = qcon.createQueueSession(false, Session.AUTO_ACKNOWLEDGE);
    queue = (Queue) ctx.lookup(ADS_QUEUE);
    qsender = qsession.createSender(queue);
    qcon.start();
}

/**
 * Closes JMS objects.
 * @exception JMSException if JMS fails to close objects due to internal error
 */
private void close() throws JMSException {
    qsender.close();
Example 44-4  Collection Model Returned by Tree Binding

package ads.demo.view;
import ads.demo.common.DemoDataChangeEntry;
import ads.demo.common.DemoDataUpdateEvent;
import ads.demo.common.JMSHelper;
import javax.jms.JMSException;
import javax.jms.Message;
import javax.jms.MessageListener;
import javax.jms.ObjectMessage;

      FacesCtrlHierBinding hierBinding =
         (FacesCtrlHierBinding)bindings.findCtrlBinding(_treeBindingName);
      cm = hierBinding.getCollectionModel();
      ADFContext.getCurrent().getRequestScope().put("collectionModel_" +
         this.hashCode(), cm);
   }
   return cm;
}
```

### 44.4.2 Building the Supporting Active Data Entry Classes

The [ActiveDataCollectionHandler](#) uses Oracle ADF Rich Events to propagate the data updates and UI refresh in response to JMS queue updates. You must implement these event classes and register them as events from the [CollectionHandler](#).

**To create the Active Data Entry implementation:**

The class shown in **Example 44-6** extends the Oracle ADF class `oracle.adf.view.rich.event.ActiveDataEntry` and implements several methods in that interface.

**To implement the Active Data Update Event:**

The Active Data update event takes a list of Active Data entry events and performs them at once. The class extends from
oracle.adf.view.rich.event.ActiveDataUpdateEvent and implements several methods, as shown in Example 44-7.

**Example 44-6  Active Data Entry Class**

```java
package ads.demo.view;

import java.util.HashMap;
import java.util.Map;
import oracle.adf.view.rich.event.ActiveDataEntry;

public class DemoActiveDataEntry extends ActiveDataEntry {
    public DemoActiveDataEntry(ActiveDataEntry.ChangeType change,
            Object[] path, Object[] insertKeyPath,
            String[] names, Object[] values) {
        super();

        if (names != null) {
            for (int i = 0; i < names.length; i++) {
                String attribute = names[i];
                Object value = values[i];
                _valuesMap.put(attribute, value);
            }
        }

        _attributes = names;
        _values = values;
        _changeType = change;
        _path = path;
        _insertPath = insertKeyPath;
    }

    public ActiveDataEntry.ChangeType getChangeType() {
        return _changeType;
    }

    public Object[] getKeyPath() {
        return _path;
    }

    public Object[] getInsertKeyPath() {
        return _insertPath;
    }

    public String[] getAttributeNames() {
        return _attributes;
    }

    public Object getAttributeValue(String name) {
        return _valuesMap.get(name);
    }

    public Object getFormattedAttributeValue(String name) {
        return getAttributeValue(name);
    }

    private final Map<String, Object> _valuesMap =
            new HashMap<String, Object>();
```
private String[] _attributes = null;
private Object[] _values = null;
private Change _changeType = null;
private Object[] _path = null;
private Object[] _insertPath = null;
}

Example 44-7   Active Data Update Event

package ads.demo.view;
import java.util.Collections;
import java.util.List;
import oracle.adf.view.rich.event.ActiveDataEntry;
import oracle.adf.view.rich.event.ActiveDataUpdateEvent;

public class DemoActiveDataUpdateEvent extends ActiveDataUpdateEvent {
    public DemoActiveDataUpdateEvent(Object object) {
        super(object);
    }

    public DemoActiveDataUpdateEvent(Object source, int eventId,
            List<ActiveDataEntry> changeList) {
        super(source);
        _changeList = changeList;
        _eventId = eventId;
    }

    /**
     * Get the change list of this event
     * @return the change list of this event
     */
    public List<ActiveDataEntry> getChangeList() {
        return _changeList;
    }

    /**
     * Get the event ID
     * @return the event ID
     */
    public int getEventId() {
        return _eventId;
    }

    public long getEventTime() {
        return System.currentTimeMillis();
    }

    public String toString() {
        return super.toString() + " eventId:" + _eventId + " changeList:" +
            _changeList;
    }
}
44.4.3 Register the Active Data Collection Model with the Oracle ADF UI Page

To enable the active data feature and "hook" your collection model, you need to register the class as a managed JavaBean.

ADS requires UI components to have the same model across requests. Therefore, register the `ActiveDataCollectionModel` as a view scoped managed JavaBean. If you stay on the same page, the table is based on the same model.

To register your collection model as a managed JavaBean:

1. Open `adfc-config.xml`.
2. Add the managed JavaBean named `adsBean` and provide the package to your collection model class, as shown in Example 44-8.

**Example 44-8   adsBean Managed JavaBean**

```xml
<managed-bean>
  <managed-bean-name>adsBean</managed-bean-name>
  <managed-bean-class>ads.demo.view.ActiveDataCollectionModel</managed-bean-class>
  <managed-bean-scope>view</managed-bean-scope>
  <managed-property>
    <property-name>treeBindingName</property-name>
    <property-class>java.lang.String</property-class>
    <value>EmpView1</value>
  </managed-property>
  <managed-property>
    <property-name>iterBindingName</property-name>
    <property-class>java.lang.String</property-class>
    <value>EmpView1Iterator</value>
  </managed-property>
</managed-bean>
```

44.4.4 Register the Component Managed JavaBean for Supporting Method Actions

To trigger the synchronous functionality of the use case pattern, raise a business event in response to the click of an Oracle ADF button. To support a response to the click of a button, create a managed JavaBean with which you can associate methods as the action for these buttons.

To build your Oracle ADF component managed JavaBean:

In the prototype use case, there is a table that contains a list of employees and their entity object attributes. Add two buttons at the top of the table in a panel collection toolbar which, when clicked, uses the selected employee to initiate an approval process. When completed, the approval process dynamically updates the table, as shown in Figure 44-2.
The table component requires the managed JavaBean shown in Example 44-9.

To register the component managed JavaBean:
As with the collection model, register the component managed JavaBean by adding an entry to adfc-config.xml, as shown in Example 44-10.

**Example 44-9 Table Component Managed JavaBean**

```java
package ads.demo.view;

import java.util.ArrayList;
import java.util.Collection;
import java.util.Map;
import javax.faces.application.FacesMessage;
import javax.faces.context.FacesContext;
import javax.faces.event.ActionEvent;
import oracle.adf.model.OperationBinding;
import oracle.adf.model.binding.DCBindingContainer;
import oracle.adf.share.ADFContext;
import oracle.adf.view.rich.component.rich.data.RichTable;
import oracle.jbo.Key;
import org.apache.myfaces.trinidad.model.RowKeySet;

public class TableHandlerBean {
    private RichTable _table;

    public TableHandlerBean() {
        super();
    }

    public void setTable(RichTable _table) {
        this._table = _table;
    }
}
```
public RichTable getTable() {
    return _table;
}

public void handleRaise(ActionEvent event) {
    String correlationId = ((ActiveDataCollectionModel)ADFContext.getCurrent().getViewScope().get("adsBean")).getUuid();
    RowKeySet selectedRowKeys = getTable().getSelectedRowKeys();
    ArrayList<String> selectedEmp = new ArrayList<String>(selectedRowKeys.size());
    for (Object rowKey : selectedRowKeys) {
        Key jboKey = ((Collection<Key>)rowKey).iterator().next();
        String rowKeyString = ((Integer)jboKey.getKeyValues()[0]).toString();
        selectedEmp.add(rowKeyString);

        // Publish event
        try {
            DCBindingContainer bindings = (DCBindingContainer)ADFContext.getCurrent().getRequestScope().get("bindings");
            OperationBinding action = (OperationBinding)bindings.findCtrlBinding("publishEvent");
            Map params = action.getParamsMap();
            params.put("correlationId", correlationId);
            params.put("key", rowKeyString);
            params.put("eventType", "payRaise");
            action.execute();
        } catch ( Exception e ) {
            log.severe("ASM: Failed to raise commission event for key: " + rowKeyString);
        }
    }
}

// Invoke BPEL from here.

public void handleCommission(ActionEvent event) {
    String correlationId = ((ActiveDataCollectionModel)ADFContext.getCurrent().getViewScope().get("adsBean")).getUuid();
    RowKeySet selectedRowKeys = getTable().getSelectedRowKeys();
    ArrayList<String> selectedEmp = new ArrayList<String>(selectedRowKeys.size());
    for (Object rowKey : selectedRowKeys) {
        Key jboKey = ((Collection<Key>)rowKey).iterator().next();
        String rowKeyString = ((Integer)jboKey.getKeyValues()[0]).toString();
        selectedEmp.add(rowKeyString);

        // Publish event
        try {
            DCBindingContainer bindings = (DCBindingContainer)ADFContext.getCurrent().getRequestScope().get("bindings");
            OperationBinding action = (OperationBinding)bindings.findCtrlBinding("publishEvent");
            Map params = action.getParamsMap();
            params.put("correlationId", correlationId);
            params.put("key", rowKeyString);
            params.put("eventType", "payCommission");
            action.execute();
        } catch ( Exception e ) {
            log.severe("ASM: Failed to raise commission event for key: " + rowKeyString);
        }
    }
}

// Invoke BPEL from here.
private void addConfirmationMessage() {
    FacesMessage msg = new FacesMessage("You request is submitted for approval.");
    FacesContext.getCurrentInstance().addMessage(null, msg);
}

Example 44-10  adfc-config.xml Registration Code

<managed-bean>
    <managed-bean-name>tableBean</managed-bean-name>
    <managed-bean-class>ads.demo.view.TableHandlerBean</managed-bean-class>
    <managed-bean-scope>request</managed-bean-scope>
</managed-bean>

44.4.5 Reference the Managed JavaBean in the Page UI

Modify the page component to reference the managed JavaBean from the earlier steps, as shown in Example 44-11.

Note:
You may notice that selectedRowKeys is not bound to any method. By default, it is bound to #{bindings.treeBinding.collectionModel.selectedRowKeys}. It will no longer work after using ActiveDataCollectionModel.

Example 44-11  Referencing the Managed JavaBean

<af:table value="#{viewScope.adsBean}" var="row"
    rows="#{bindings.EmpView1.rangeSize}"
    fetchSize="#{bindings.EmpView1.rangeSize}"
    rowBandingInterval="0"
    filterModel="#{bindings.EmpView1Query.queryDescriptor}"
    queryListener="#{bindings.EmpView1Query.processQuery}"
    filterVisible="true" varStatus="vs"
    selectionListener="#{bindings.EmpView1.collectionModel.makeCurrent}"
    rowSelection="multiple" id="t1" width="100%"
    binding="#{tableBean.table}"

44.4.6 Create the Data Model and Add Application Module Methods

The data model should exist before the page is built to simplify laying out the components required to display the data contained in that model. The application module needs additional methods to support incoming service methods and, optionally, the methods for raising the business event.

To extend the methods of your application module for the service interface:

Make sure to expose one or more application module methods in the application module service. This facilitates the callback from BPEL upon completion of the process, triggering the ADS UI update. These methods publish the message to the JMS queue following the message structure shown here.

The message payload should take the format of DataUpdateEvent, which comprises one or more DataChangeEntry items.
• changeType: enum (UPDATE, REFRESH). Currently, there is no use case for INSERT.

• key: Object[]

• insertKey: Object[]

• attributeNames: String[], a list of names of changed attributes

• attributeValues: Object[], a list of new values for the changed attributes

In this pattern, payRaise and payCommission are supported for one or more selected employees. Use methods with simple string interfaces invoked by BPEL to complete the payRaise or payCommission event for each particular employee. Call the sendMessage method to publish the JMS message to notify ADS of the UI update. Sample BPEL methods are shown in Example 44-12.

To define structure and compose event metadata:

The code that programmatically creates business event payloads and raises them through the business event APIs should be deliberately built around the namespace and event attributes defined in the appropriate EDL and XSD files.

For this pattern, a single event is used that supports multiple event types through an attribute value such as payRaise and payCommission. However, support for additional event types only requires adding the UI facet, the programmatic method to raise that new event type and a conditional branch in BPEL. If the pattern requires completely separate event definitions, the code becomes more complex, the number of managed metadata source files increases, and the composite becomes more complex as well.

While this is a simpler approach, it is not as flexible from an integration perspective. Define your event types such that they support your current use case and potentially support additional integration in the future. Example 44-13 shows a simplified event definition, while Example 44-14 shows an event schema definition.

To extend the application module with publishEvent and supporting methods:

In the page bindings, add the method publishEvent that binds to the application module method of the same name. Use this binding in the handleRaise and handleCommission methods of the TableHandlerBean to publish the event for each employee to be updated.

For more information about extending the application module with the publishEvent method, see Using the Java Event API to Publish Events.

Note:

It is critical that the event name and namespace are consistent throughout the code and metadata definitions in the subscribing SOA composite.

Example 44-12  BPEL Methods

// Simplified interface method for service call per employee

    public void performSingleRaise(String correlationId, String key) {
        ArrayList thelist = new ArrayList<String>();
        thelist.add(key);
        performRaise(correlationId, thelist);
    }

// List interface for call from UI and by Simplified Service Method

    public void performRaise(String correlationId, List<String> keyValues) {
        List<DemoDataChangeEntry> dces = new ArrayList<DemoDataChangeEntry>(keyValues.size());
        ViewObject empVO = getEmpView1();
        for (String keyVal : keyValues) {
            Key key = new Key(new Object[] { keyVal });
            Row row = empVO.findByKey(key, 1)[0];
            BigDecimal newSal = new BigDecimal(Math.round(((BigDecimal)row.getAttribute("Sal")).doubleValue()*(1+(new Random()).nextDouble()/10)));
            row.setAttribute("Sal", newSal);
            DemoDataChangeEntry dce = new DemoDataChangeEntry(new Object[] { new Integer(keyVal) }, DemoDataChangeEntry.ChangeType.UPDATE, new String[] { "Sal" }, new Object[] { newSal.toString() });
            dces.add(dce);
            this.getDBTransaction().commit();
            DemoDataUpdateEvent event = new DemoDataUpdateEvent(dces);
            // Send a message
            sendMessage(correlationId, event);
        }
    }

// Simplified interface for Service method

    public void paySingleCommission(String correlationId, String key) {
        ArrayList<String> thelist = new ArrayList<String>();
        thelist.add(key);
        payCommission(correlationId, thelist);
    }

// List interface for calling from UI and by Simplified Service Method

    public void payCommission(String correlationId, List<String> keyValues) {
        List<DemoDataChangeEntry> dces = new ArrayList<DemoDataChangeEntry>(keyValues.size());
        ViewObject empVO = getEmpView1();
        for (String keyVal : keyValues) {
            Key key = new Key(new Object[] { keyVal });
            Row row = empVO.findByKey(key, 1)[0];
            BigDecimal newComm = new BigDecimal((new Random()).nextInt(10000));
            row.setAttribute("Comm", newComm);
            DemoDataChangeEntry dce = new DemoDataChangeEntry(new Object[] { new Integer(keyVal) }, DemoDataChangeEntry.ChangeType.REFRESH,
new String[] { "Comm" },
new Object[] { newComm.toString() });

dces.add(dce);
} this.getDBTransaction().commit();

DemoDataUpdateEvent event = new DemoDataUpdateEvent(dces);
// send message
sendMessage(correlationId, event);
}

// Private method to push ADS update to JMS queue
private void sendMessage(String correlationId, DemoDataUpdateEvent event) {
    try {
        JMSHelper helper = JMSHelper.getInstance();
        ObjectMessage message = helper.createObjectMessage();
        message.setObject(event);
        message.setJMSCorrelationID(correlationId);
        helper.sendMessage(message);
    } catch (JMSException e) { e.printStackTrace();
    } // try
} // sendMessage

**Example 44-13 Simplified Event Definition**

```xml
<?xml version="1.0" encoding="UTF-8" standalone="yes"?>
<definitions xmlns="http://schemas.oracle.com/events/edl"
    targetNamespace="http://xmlns.oracle.com/apps/ta/adsdemo/events/edl">
    <schema-import namespace="http://xmlns.oracle.com/apps/ta/adsdemo/events/schema"
        location="xsd/ADSDemoEventSchema.xsd"/>
    <event-definition name="ADSDemoEvent">
        <content xmlns:ns0="http://xmlns.oracle.com/apps/ta/adsdemo/events/schema"
            element="ns0:ADSDemoEventElement"/>
    </event-definition>
</definitions>
```

**Example 44-14 Event Schema Definition**

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema"
    xmlns="http://xmlns.oracle.com/apps/ta/adsdemo/events/schema"
    targetNamespace="http://xmlns.oracle.com/apps/ta/adsdemo/events/schema"
    attributeFormDefault="unqualified"
    elementFormDefault="qualified">
    <xsd:element name="ADSDemoEventElement" type="ADSDemoEventElementType"/>
    <xsd:complexType name="ADSDemoEventElementType">
        <xsd:sequence>
            <xsd:element name="correlationId" type="xsd:long"/>
            <xsd:element name="key" type="xsd:long"/>
            <xsd:element name="eventType" type="xsd:string"/>
        </xsd:sequence>
    </xsd:complexType>
</xsd:schema>
```
44.4.7 Create a SOA Composite that Subscribes to the Published Event

The creation of a SOA composite that subscribes to an event is covered in \textit{Initiating a SOA Composite from an Web Application}. A sample pattern composite is shown in Figure 44-3.

\textit{Figure 44-3} \hspace{1em} \textit{Pattern Composite}

\begin{center}

\end{center}

44.4.8 Construct a BPEL Process to Perform Asynchronous Work

The creation of a BPEL process and human task activities is described in other sections. For more information, see \textit{Managing Tasks from an Application}. A sample BPEL process is shown in Figure 44-4.

\begin{center}
\includegraphics[width=\textwidth]{bpel_process.png}
\end{center}
44.4.9 Invoking the ADF Business Components Service

Invoking an ADF Business Components service from a BPEL process is covered in another section. For more information, see Orchestrating ADF Business Components Services.

44.5 Securing the Design Pattern

The process of securing this design pattern is the same as that of securing an Oracle ADF UI application.

For more information, see Securing Web Services Use Cases.

44.6 Verifying the Deployment

Do the following to test functionality:

1. Turn on the EDN-DB-LOG page by navigating to http://host:port/soa-infra/events/edn-db-log and ensure it reads "Log is Enabled." If it is not, click Enable.

2. Open the UI page and interact with the UI components that you designed to trigger the event.
   The event should immediately display in the EDN-DB-LOG page.

3. Check for the event payload shown in Example 44-15.

4. Check the console ($DOMAIN_HOME/as.log) or soa-diagnostic logs ($DOMAIN_HOME/servers/<servername>logs/<servername>.log) to see any Mediator activity that results from your event.
INFO: MediatorServiceEngine received an event = {http://xmlns.oracle.com/apps/ta/adsdemo/events/edl}ADSDemoEvent

id :{(5852BA028921DEAF6403EF6E2FB21D) will be executed
Apr 17, 2009 1:57:26 PM oracle.tip.mediator.service.filter.FilterFactory
createFilterHandler
INFO: No Condition defined

5. Check Oracle Enterprise Manager at http://host:port/em for an instance
of your SOA composite, and check for errors.

6. If your process has no errors and is expecting a response from the human
workflow notification, do the following:
   a. Navigate to the worklist at http://host:port/integration/
      worklistapp.
   b. Log in as the assigned approver.
   c. Approve or reject the notification per your design requirements.

At this point, the BPEL process should complete and invoke the ADF Business
Components service to trigger the ADS push. The UI should promptly update. Check
the Oracle ADF UI runtime console and diagnostic logs for stack traces and log
messages.

**Example 44-15  Event Payload**

Enqueing event: http://xmlns.oracle.com/apps/ta/adsdemo/events/edl:ADSDemoEvent from J
xmlns="http://oracle.com/fabric/businessEvent">
  <name>ns:ADSDemoEvent</name>
  <id>494ae921-4667-4a42-8190-5a5aaa428f7e</id>

44.7 Troubleshooting the Use Case

For the Oracle ADF UI functionality, use Fusion Middleware Control, Oracle Fusion Applications Logger, and server diagnostic logs for information about what is failing.

For the events functionality, use the Event Delivery Network database log page at http://host:port/soa-infra/events/edn-db-log.

For the SOA functionality, use the Oracle Enterprise Manager console for diagnostics and Oracle Fusion Applications Logger sensor variables for logging.

For the ADF Business Components service functionality, use BPEL fault handling and logging via Oracle Fusion Applications Logger sensor variables as well as the console, Oracle Fusion Applications Logger and server diagnostic logs for more detailed error messages.

44.8 What You May Need to Know About Initiating an Asynchronous Service with Dynamic UI Update

- Oracle ADF UI
- ADS
- JMS
- Business Events (programmatic)
- SOA Mediator
- SOA BPEL
- ADF Business Components services

44.9 Known Issues and Workarounds

Known issues are as follows:

- Sparkle does not occur on selected rows.
Manage Tasks Programmatically

This chapter describes what to do when you need to programmatically create, set an outcome for, or query task information that resides in one or more SOA domains.

**When to implement:** When you need to programmatically create, set an outcome for, or query task information that resides in one or more SOA domains.

**Design Pattern Summary:** The design pattern involves programmatic interaction with human task client services by an application with the following requirements: displaying task status information, providing UI facets to enable setting task outcomes without navigating through the worklist, and submitting new tasks without initiating a BPEL process.

In addition, the human task services support federated task queries across several SOA domains so as to obtain an aggregated task list across several product families.

**Involved components:**

- Java code, such as an Oracle ADF application module or Oracle Enterprise Scheduler Java job
- SOA Domain with deployed human task

**45.1 Introduction to the Recommended Design Pattern**

Some Oracle Fusion web applications have use cases that require programmatically interacting with the human workflow layer to approve, reject and display lists of tasks using specific search criteria. All SOA runtime environments that are configured as part of the topology are stored in the Oracle Fusion Middleware Extensions for Applications taxonomy schema and accessed at runtime using APIs. In the taxonomy schema, each SOA runtime environment has an entry with a unique identifying name that maps to a corresponding endpoint URL. For example, a SOA runtime environment called `FIN_SOA_RMI` has a corresponding endpoint URL `t3://fpp-02.mycompany.com:7001/`.

At runtime, the taxonomy schema is queried to construct a list of servers and their respective endpoints. This list of servers and endpoints passes to the human workflow client service APIs as a JAXB object. In the context of the federated task query service, some or all of these servers can be referenced. One of these servers is set as the default, and is used in the context of non-federated task services such as the task and task query services.

Alternatively, servers can be excluded from the list of federated servers, and exist only in the JAXB object. This allows servers to be used only when named explicitly in the list of requested servers. In this case, the excluded servers will not be used when the list of requested servers is empty.
Oracle Fusion Middleware Extensions for Applications maintains the list of servers in the taxonomy tables. An API enables building the JAXB object based on the list of SOA domains in the Oracle Fusion Applications topology.

This pattern is recommended as it provides the following features:

- Federated query support,
- Programmatic access supports custom UI requirements and ADF Business Components services and Oracle Enterprise Scheduler job integration.

### 45.2 Potential Approaches

- Supported approach: Managing Tasks from an Oracle ADF application.
- Unsupported approach: Direct invoking a service using JAX-WS proxies.

### 45.3 Example

The Expenses team has an Expenses Manager role with administrator privileges to approve or reject expenses that belong to other users. The Expenses team must provide a workbench that collectively scans all SOA domains for open expense notifications and provide a consolidated UI to set their outcome, potentially all at once. This UI would comprise a table listing notifications matching certain filter criteria with buttons to select and set the appropriate outcome of the expense. This is done through RMI interaction with the appropriate SOA domain.

### 45.4 Manage Human Workflow Tasks from a Java Application

These are two main high-level steps involved in this process:

- Create and deploy a human task definition using a SOA composite that contains the human task.
- Develop code to do the following:
  - Connect to the task services.
  - Query or lookup the tasks.
  - Display the task summary.
  - Set the desired task outcome.

#### 45.4.1 How to Connect to the Task Service/Task Query Service

The human workflow APIs provide three types of task services: single, query and federated query. The type of service you use depends on the product use case. The RMI endpoint for these services must be derived at runtime and compiled into a server list. The server list is contained by a JAXB object, which can be passed to the human workflow client service APIs. To support this runtime lookup, the Oracle Fusion Middleware Extensions for Applications taxonomy schema and APIs must be seeded during provisioning. You need only provide an `ArrayList` (`java.util.ArrayList`) of server names to be used in the federated query.
Note:
Consider performance requirements when using the query or federated query service APIs. It is recommended to page the result sets in batches, for example, in sets of 10-25.

Services are as follows:

- **Task Service**: The task service programmatically sets a task outcome, such as approve or reject for a single, particular task using a single, particular SOA runtime.

- **Task Query Service**: The task query service programmatically queries tasks for a particular task type. Use the portlet to render a worklist and relevant tasks in your dashboard. Alternatively, you may manually build the worklist instead.

- **Federated Task Query Service**: The federated task query service programmatically executes a federated query of tasks for a particular task type. Use the portlet to render a worklist and relevant tasks in your dashboard. Alternatively, you may manually build the worklist instead.

Use the following guidelines to determine the type of task or query service to use.

- **Single server task service API**: Use this API to obtain a single task object using the task number or task ID from a single, specific SOA runtime.

- **Single server task query service API**: Use this API to query for tasks from a single, specific SOA runtime.

- **Federated task query service API**: Use this API to query tasks based on namespace or task name from one or more SOA runtime domains.

### 45.4.2 How to Use the Single Server Task Service API

If your use case requires connecting to one SOA domain and obtaining the details of a single task via a primary key such as task number or task ID, take the following steps. After it is obtained, configure the task detail display or set the task outcome.

- Import libraries into the Java project.
- Import code packages into the Java project.
- Declare and obtain task service object references.

#### 45.4.2.1 Import Libraries into the Java Project

Add the following libraries to the Oracle JDeveloper project:

- **Applications Core**: Add this library to enable using Oracle Fusion Middleware Extensions for Applications taxonomy APIs to obtain the necessary JAXB object containing the RMI endpoint information for the desired server.
- **SOA Runtime**: Add this library to enable using the human workflow task query APIs.

#### 45.4.2.2 Import Code Packages into the Java Project

Import the code packages shown in Example 45-1 into the Java source.
**Example 45-1 Importing Code Packages to Enable Using the Single Server Task Service API**

```java
import java.util.ArrayList;
import java.util.List;
import java.util.logging.Logger;
import javax.jws.WebService;
import oracle.bpel.services.workflow.verification.IWorkflowContext;
import oracle.bpel.services.workflow.client.IWorkflowServiceClient;
import oracle.bpel.services.workflow.task.model.Task;
import oracle.bpel.services.workflow.IWorkflowConstants;
import oracle.bpel.services.workflow.client.WorkflowServiceClientFactory;
import oracle.bpel.services.workflow.query.ITaskQueryService;
import oracle.bpel.services.workflow.repos.Ordering;
import oracle.bpel.services.workflow.repos.Predicate;
import oracle.bpel.services.workflow.repos.TableConstants;
import oracle.bpel.services.workflow.task.IInitiateTaskResponse;
import oracle.bpel.services.workflow.task.ITaskService;
import oracle.bpel.services.workflow.task.model.ObjectFactory;
import oracle.apps.fnd.applcore.common.DeploymentsUtil;
import oracle.bpel.services.workflow.client.config.RemoteClientType;
import oracle.bpel.services.workflow.client.config.ServerType;
import oracle.bpel.services.workflow.client.config.WorkflowServicesClientConfigurationType;
```

45.4.2.3 Declare and Obtain Task Service Object References

Create the query and task service references by invoking the `WorkflowServiceClientFactory` API `getWorkflowServiceClient` method, which provides the JAXB object containing the server list and a logger object reference. The human workflow task service connects to the server marked as the default in the JAXB object. When calling the APIs to craft the JAXB object, be sure to specify the name of the server you want to call. Example 45-2 shows sample code used to declare and obtain task service object references.

**Note:**

Previously, developers would populate the properties for `EJB_PROVIDER` and `EJB_SECURITY` to provide the RMI endpoint and credentials. Instead, RMI identity propagation uses the current user context for authentication. In Oracle Fusion Applications, most UI and services require authentication that provides the appropriate user context. If no current user context exists, create one.

**Example 45-2 Declaring and Obtaining Task Service Object References**

```java
ITaskService taskSvc = null;
ITaskQueryService querySvc = null;
IWorkflowContext wfCtx = null;
java.util.logging.Logger logger = Logger.getLogger("oracle.apps");
try {
    WorkflowServicesClientConfigurationType wscct =
    getWorkflowClientConfigObject("FIN_SOA_RMI");
    if ( wscct == null ) {  //Log incident
        return "FAILED!";
    }
```
} // if

IWorkflowServiceClient wfSvcClient = WorkflowServiceClientFactory.getWorkflowServiceClient(wscct, logger);
taskSvc = wfSvcClient.getTaskService();
querySvc = wfSvcClient.getTaskQueryService();

### 45.4.2.4 Obtain the Workflow Service Context Object

To sustain performance in all interactions to the workflow client service APIs, pass the workflow service context object to any applicable APIs. To obtain the context using the current user's identity, call the `getWorkflowContextForAuthenticatedUser()` method, as shown in Example 45-3.

**Note:**

For performance reasons, be sure to pass this context to all subsequent calls to the APIs.

---

**Example 45-3   Getting the Workflow Service Context Object**

```java
// Get the workflow task service context for use in later calls for performance improvement
wfCtx = querySvc.getWorkflowContextForAuthenticatedUser();
```

### 45.4.2.5 Obtain the Single Task Object and Set Task Outcome

When interacting with the task service, you must first obtain the task number or ID for the task to retrieve the task details. Use the task number or task ID to invoke the `getTaskDetailsById` or `getTaskDetailsByNumber` methods of the task query service object.

**Note:**

This approach assumes that you have obtained the task number or task ID (either through the task query service or otherwise).

---

**Example 45-4** shows the approval of a task with the ID 0a6d287a-9849-4e5e-914b-805706d6b9d9.

**Example 45-5** shows how to use STDOUT calls to display the various task attributes through the task API.

**Example 45-4   Getting the Single Task Object with the Task ID**

```java
Task t = querySvc.getTaskDetailsById(wfCtx, "0a6d287a-9849-4e5e-914b-805706d6b9d9");
taskSvc.updateTaskOutcome(wfCtx, t, "APPROVE");
// Another example, using the task number to reject a task.
Task t = querySvc.getTaskDetailsByNumber(wfCtx, 200140 );
taskSvc.updateTaskOutcome(wfCtx, t, "REJECT");
```

**Example 45-5   Using STDOUT Calls to Display Task Attributes**

```java
System.out.println("Task Number: " + task.getSystemAttributes().getTaskNumber());
System.out.println("Task Id: " + task.getSystemAttributes().getTaskId());
System.out.println("Title: " + task.getTitle());
System.out.println("Priority: " + task.getPriority());
System.out.println("State: " + task.getSystemAttributes().getState());
```
45.4.3 How to Use the Single Server Task Query Service API

If your use case involves connecting to a single SOA domain and querying for all tasks that match certain criteria, take the following steps. After you have queried for the relevant tasks, you can display them in an ordered list in the UI or programmatically set task outcome all at once.

- Import libraries into the Java project.
- Import code packages into the Java project.
- Declare and obtain task query service object references.
- Manage query and task outcome states.

45.4.3.1 Import Libraries into the Java Project

Import the libraries described in Import Libraries into the Java Project.

45.4.3.2 Import Code Packages into the Java Project

Import the code packages described in Import Code Packages into the Java Project.

45.4.3.3 Declare and Obtain Task Query Service Object References

Create the query and task service references by invoking the `WorkflowServiceClientFactory` API `getWorkflowServiceClient` method, which provides the JAXB object containing the server list and a logger object reference. The human workflow task service connects to the server marked as the default in the JAXB object. When calling the APIs to craft the JAXB object, be sure to specify the name of the server you want to call.

Example 45-6 shows sample code in which task query service object references are declared and obtained.

Note:

Previously, developers would populate the properties for `EJB_PROVIDER` and `EJB_SECURITY` to provide the RMI endpoint and credentials. Instead, RMI identity propagation uses the current user context for authentication. In Oracle Fusion Applications, most UI and services require authentication that provides the appropriate user context. If no current user context exists, create one.

---

Example 45-6 Declaring and Obtaining Task Query Service Object References

```java
ITaskService taskSvc = null;
ITaskQueryService querySvc = null;
IWorkflowContext wfCtx = null;
try {
    java.util.logging.Logger logger = Logger.getLogger("oracle.apps");
    WorkflowServicesClientConfigurationType wscct =
        getWorkflowClientConfigObject("FIN_SOA_RMI");
    if ( wscct == null )   {               // Log incident
        return "FAILED!";
    }
    // Log incident
    return "FAILED!";
}
```
IWorkflowServiceClient wfSvcClient = WorkflowServiceClientFactory.getWorkflowServiceClient(wscct, logger);
taskSvc = wfSvcClient.getTaskService();
querySvc = wfSvcClient.getTaskQueryService();

45.4.3.4 Manage Query and Task Outcome States
Performing queries and interacting with the task result set is similar for both the federated and non-federated task query services. For more information about this process, see How to Query and Traverse Federated and Non-federated Query Result Sets.

45.4.4 How to Use the Federated Server Task Query Service API
Using the federated server task query service API involves the following main steps:

- Import libraries into the Java project.
- Import code packages into the Java project.
- Create a list of servers for a parallel federated query.
- Declare task and query service references, and create the workflow client service object.
- Obtain the workflow service client.
- Implement exception handling for federated queries.
- Manage query and task outcome states.

45.4.4.1 Import Libraries into the Java Project
Import the libraries described in Import Libraries into the Java Project.

45.4.4.2 Import Code Packages into the Java Project
Import the code packages described in Import Code Packages into the Java Project.

In addition, import the code package shown in Example 45-7.

Example 45-7    Importing the Code Package IFederatedWorkflowContext
import oracle.bpel.services.workflow.fws.client.IFederatedWorkflowContext;

45.4.4.3 Create a List of Servers for a Parallel Federated Query
To leverage the federated query service, decide whether to query all human workflow services in Oracle Fusion Applications or just a subset of those services. The servers are named according to standards and are populated in a JAXB object which contain the service endpoints for lookup at runtime. You need only know the name or names of the product services you want to poll or provide a list.

To use a subset of the human workflow services, construct a Java list of those service names and pass that list to getFederatedTaskQueryService.
Note:

Be sure to provide a list of requested servers, as all servers in the list are polled. Failing to provide a list of servers results in all the servers being polled, which has significant performance implications.

Example 45-8 shows sample code in which a list of servers is created for a parallel federated query.

Example 45-8 Creating a List of Servers for a Parallel Federated Query

// Create the human workflow server subset list.
List<String> requestedServers = new ArrayList<String>();
requestedServers.add("FIN_SOA_RMI");
requestedServers.add("CRM_SOA_RMI");
requestedServers.add("PRJ_SOA_RMI");

45.4.4.4 Declare Task and Query Service References and Create the Workflow Client Service Object

After constructing the server list, obtain the query service object reference by invoking the `getFederatedTaskQueryService` API of the `WorkflowServiceClientFactory`, as shown in Example 45-9.

Note:

Previously, developers would populate the properties for `EJB_PROVIDER` and `EJB_SECURITY` to provide the RMI endpoint and credentials. Instead, RMI identity propagation uses the current user context for authentication. In Oracle Fusion Applications, most UI and services require authentication that provides the appropriate user context. If no current user context exists, create one.

Example 45-9 Declaring Task and Query Service References and Creating the Workflow Client Service Object

java.util.logging.Logger logger = Logger.getLogger("oracle.apps");
WorkflowServicesClientConfigurationType wscct =
    getWorkflowClientConfigObject("FIN_SOA_RMI");
if ( wscct == null ) {    // Log Incident
    return "FAILED!";
} // if
querySvc = WorkflowServiceClientFactory.getFederatedTaskQueryService(wscct,
    requestedServers, logger);

45.4.4.5 Obtain the Workflow Service Context

Obtain the workflow service context from the query service, as shown in Example 45-10. This improves performance with all workflow client service API interactions.

Note:

This context is cast as `IFederatedWorkflowContext`. For performance reasons, the context must be passed to all subsequent API calls.
45.4.4.6 Implement Exception Handling for Federated Queries

When performing queries on federated task query services, exceptions in communicating with any servers in the list of servers do not cause the query to fail. Instead, the context has a boolean isFailed() operation which can be interrogated to determine whether any failures occurred. Exceptions can be obtained from the context's getExceptionMap() method as shown in Example 45-11.

Example 45-11 Implementing Exception Handling

```java
// Partial success does not throw exceptions, instead check for isFailed and inspect the Exception and Context maps.
if (fedWFCtx.isFailed()) {
    // Log Messages
    logger.warning("Exception map: " + fedWFCtx.getExceptionMap());
    logger.warning("Context map: " + fedWFCtx.getWorkflowContextMap());
} // if
```

45.4.4.7 Manage Query and Task Outcome States

Performing queries and interacting with the task result set is similar for both the federated and non-federated task query services. For more information about this process, see How to Query and Traverse Federated and Non-federated Query Result Sets.

45.4.5 How to Query and Traverse Federated and Non-federated Query Result Sets

Querying and traversing federated and non-federated query result sets involves the following main steps:

- Determine query service search criteria.
- Construct the predicate for the queryTasks() method.
- Arrange the order of results returned by the queryTasks() method.
- Construct the list of display columns for the queryTasks() method.
- Construct a list of OptionalInfo items for the results of the queryTasks() method.
- Invoke the queryTasks() method with the attribute lists.
- Iterate through the result set.
- Programatically set the task outcome.

45.4.5.1 Determine Query Service Search Criteria

This section assumes you have implemented the task query service for either single or federated queries by following the instructions in How to Use the Single Server Task Query Service API and How to Use the Federated Server Task Query Service API.

For example, creating a human task in a composite produces a TASK file containing the metadata that defines the task behavior for approval hierarchy as well as possible outcomes. Examining the source of this TASK file reveals the task name, target namespace, possible outcomes, and so on. When deploying the composite containing
this task, the WFTASK tables are updated with task-related data that supports the human workflow infrastructure, as shown in Example 45-12.

The task metadata includes a value for targetNamespace, in this case http://xmlns.oracle.com/WFClientPatternSOAApp/WFClientPatternTaskComposite/Humantask1.

If you can access the SOAInfra schema of your runtime environment, you can query the details of this task with the query shown in Example 45-13.

This query results in the WFTASKMETADATA row, shown in Table 45-1 and Table 45-2.

### Table 45-1 WFTASKMETADATA Row Part One

<table>
<thead>
<tr>
<th>ID</th>
<th>URI</th>
<th>Name</th>
<th>Title</th>
<th>Component Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>default/SOAComposite1!1.0*2008-12-02_08-32-41_642/Humantask1</td>
<td>default/SOAComposite1!1.0*2008-12-02_08-32-41_642/Humantask1</td>
<td>Humantask1</td>
<td>string('Task Title')</td>
<td>Humantask1</td>
</tr>
</tbody>
</table>

### Table 45-2 WFTASKMETADATA Row Part Two

<table>
<thead>
<tr>
<th>CompositeDN</th>
<th>Composite Name</th>
<th>Composite Version</th>
<th>Namespace</th>
</tr>
</thead>
<tbody>
<tr>
<td>default/SOAComposite1!1.0*2008-12-02_08-32-41_642</td>
<td>SOAComposite</td>
<td>1.0</td>
<td><a href="http://xmlns.oracle.com/WFClientPatternSOAApp/WFClientPatternTaskComposite/Humantask1">http://xmlns.oracle.com/WFClientPatternSOAApp/WFClientPatternTaskComposite/Humantask1</a></td>
</tr>
</tbody>
</table>

You can then query the WFTASK table using the task ID shown in the first column of Table 45-1, as shown in Example 45-14.

The results of the entire table are too large to print, but the selected columns shown in Table 45-3 may be useful.

### Table 45-3 Useful Columns

<table>
<thead>
<tr>
<th>Column Name</th>
<th>Column Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>State</td>
<td>ASSIGNED</td>
</tr>
<tr>
<td>TaskID</td>
<td>0a6d287a-9849-4e5e-914b-805706d6b9d9</td>
</tr>
<tr>
<td>TaskNumber</td>
<td>200140</td>
</tr>
<tr>
<td>WorkflowDescriptorURI</td>
<td>default/SOAComposite1!1.0*2008-12-02_08-32-41_642/Humantask1</td>
</tr>
<tr>
<td>TaskDefinitionID</td>
<td>default/SOAComposite1!1.0*2008-12-02_08-32-41_642/Humantask1</td>
</tr>
<tr>
<td>TaskDefinitionName</td>
<td>Humantask1</td>
</tr>
</tbody>
</table>
This example focuses on tasks belonging to the current user identity, obtained automatically from the session context and passed using a SAML token in the SOAP header. These tasks that bear the ASSIGNED state and match the namespace http://xmlns.oracle.com/WFClientPatternSOAApp/WFClientPatternTaskComposite/Humantask1.

Example 45-12  Sample `.task File Snippet`

```xml
<?xml version = '1.0' encoding = 'UTF-8'?>
<taskDefinition targetNamespace="http://xmlns.oracle.com/WFClientPatternSOAApp/WFClientPatternTaskComposite/Humantask1"
xmns:ora="http://schemas.oracle.com/xpath/extension"
xmns:task="http://xmlns.oracle.com/bpel/workflow/task"
xmns:xsd="http://www.w3.org/2001/XMLSchema"
xmns="http://xmlns.oracle.com/bpel/workflow/taskDefinition"

xmns:dvmm="http://www.oracle.com/XSL/Transform/java/oracle.tip.dvm.LookupValue"
xmns:ns0="http://xmlns.oracle.com/bpel/workflow/common"
xmns:hwf="http://xmlns.oracle.com/bpel/workflow/xpath"
xmns:tsc="http://xmlns.oracle.com/bpel/workflow/common/tsc"
xmns:xref="http://www.oracle.com/XSL/Transform/java/oracle.tip.xref.xpath.XRefXPathFunctions"
xmns:ids="http://xmlns.oracle.com/bpel/services/IdentityService/xpath"
  <name>Humantask1</name>
  ...
</taskDefinition>
```

Example 45-13  Query task details

```
select * from wftaskmetadata where namespace = 'http://xmlns.oracle.com/WFClientPatternSOAApp/WFClientPatternTaskComposite/Humantask1';
```

Example 45-14  Query the WFTASK table using the task ID

```sql
task:select * from wftask where taskdefinitionid = 'default/SOAComposite1!1.0*2008-12-02_08-32-41_642/Humantask1';
```

45.4.5.2 Construct the Predicate for queryTasks()

Predicate construction is the instantiation of objects which define an expression to model the conditional part of the underlying where clause. For example, a conditional statement such as TASKNUMBER = 200140 equates to the predicate constructor shown in Example 45-15.

For this case, a predicate is required to match the WFTASKMETA_NAMESPACE_COLUMN and the WFTASK_STATE_COLUMN columns to the appropriate values. First create the namespace column predicate, then the state column predicate, followed by a predicate combining these two predicates with a conditional, as shown in Example 45-16.
An additional way to construct a predicate is shown in Example 45-17, as specified in the ITaskQueryService documentation.

**Example 45-15  Constructing the Predicate**

```java
new Predicate(TableConstants.WFTASK_TASKNUMBER_COLUMN, Predicate.OP_EQ, 200140);
```

**Example 45-16  Creating Namespace, State and Combination Predicates**

```java
Predicate predicate1 = new Predicate(TableConstants.WFTASK_STATE_COLUMN, Predicate.OP_EQ, IWorkflowConstants.TASK_STATE_ASSIGNED);
Predicate predicate2 = new Predicate(TableConstants.WFTASKMETADATA_NAMESPACE_COLUMN, Predicate.OP_EQ, TASK_TARGET_NAMESPACE);
Predicate predicate = new Predicate(predicate1, Predicate.AND, predicate2);
```

**Example 45-17  Another Way to Construct a Predicate**

```java
Predicate statePredicate = new Predicate(TableConstants.WFTASK_STATE_COLUMN, Predicate.OP_NEQ, IWorkflowConstants.TASK_STATE_ASSIGNED);
statePredicate.addClause(Predicate.AND, TableConstants.WFTASK_NUMBERATTRIBUTE1_COLUMN, Predicate.OP_IS_NULL, nullParam);
Predicate datePredicate = new Predicate(TableConstants.WFTASK_ENDDATE_COLUMN, Predicate.OP_ON, new Date());
Predicate predicate = new Predicate(statePredicate, Predicate.AND, datePredicate);
```

**45.4.5.3 Arrange the Order of Results Returned by the queryTasks() Method**

This step is optional.

The Ordering parameter facilitates implementing an ORDER_BY clause in the task list query.

In Example 45-18, the TITLE_COLUMN and PRIORITY_COLUMN properties are added to the ORDER_BY clause.

**Example 45-18  Constructing the Ordering of queryTasks()**

```java
// Create the ordering
Ordering ordering = new Ordering(TableConstants.WFTASK_TITLE_COLUMN, true, true);
ordering.addClause(TableConstants.WFTASK_PRIORITY_COLUMN, true, true);
```

**45.4.5.4 Construct the List of Display Columns for the queryTasks() Method**

By default, the queryTasks() method returns only a list of tasks with their TASKID value. If you require additional columns, such as TASKNUMBER, TITLE, PRIORITY, STATE, ENDDATE, ASSIGNEE, COMPOSITEINSTANCEID, ROOTTASKID, and so on, construct an ArrayList of String objects containing the names of the additional columns you want returned in the result set. Example 45-19 shows sample code that constructs a list of display columns for queryTasks().

**Example 45-19  Constructing the List of Display Columns for queryTasks()**

```java
List queryColumns = new ArrayList();
queryColumns.add("TASKNUMBER");
```
queryColumns.add("TITLE");
queryColumns.add("PRIORITY");
queryColumns.add("STATE");
queryColumns.add("ENDDATE");
queryColumns.add("NUMBERATTRIBUTE1");
queryColumns.add("TEXTATTRIBUTE1");

45.4.5.5 Construct a List of OptionalInfo Items to be Returned from queryTasks()

This step is optional.

Per the API documentation, the OptionalInfo enumeration consists of additional, optional values that can be obtained with the task in the result set. These optional values include the available actions for a task, attachments, user comments, and so on. An example is shown in Example 45-20.

Example 45-20   Constructing a List of OptionalInfo Items

```
// List of optional info
// You can fetch any specified optionalInfo items from the Task object.
// For example: if you have specified "CustomActions", you can retrieve
// it using task.getSystemAttributes().getCustomActions();
// "Actions" (All Actions) - task.getSystemAttributes().getSystemActions()
// "GroupActions" (Only group Actions: Actions that can be permuted by the user
// as a member of a group).
// "ShortHistory" - task.getSystemAttributes().getShortHistory()
List optionalInfo = new ArrayList();
optionalInfo.add("Actions");
```

45.4.5.6 Invoke queryTasks() with the Attribute Lists

Now that the attribute classes have been constructed to constrain, order and specify the attributes returned in the query, invoke the queryTasks() method.

The query service API has the method signature shown in Example 45-21.

The queryTasks() method returns a list of tasks that match the predicate and ordering criterion.

Example 45-22 shows how to invoke queryTasks() using the previously constructed attribute lists.

More information on paging is available in the API documentation. (Look for the text "How to use paging.")

Example 45-21   Query Service API

```java
queryTasks(IWorkflowContext ctx, java.util.List displayColumns,
        java.util.List<ITaskQueryService.OptionalInfo> optionalInformation,
        ITaskQueryService.AssignmentFilter assignmentFilter,
        java.lang.String keywords,
        Predicate predicate,
        Ordering ordering,
        int startRow,
        int endRow)
```

Example 45-22   Invoking queryTasks() with the Previously Constructed Attribute Lists

```
List tasksList = querySvc.queryTasks(wfCtx,
        queryColumns,
        optionalInfo,
        ITaskQueryService.ASSIGNMENT_FILTER_MY_AND_GROUP,
        keyword,
```
**45.4.5.7 Iterate through the Result Set**

The method `queryTasks` returns a list of task objects. Use standard Java iteration to iterate through the list. Then, invoke various accessors to obtain the attributes specified in the query column list. Example 45-23 shows how to iterate through the result set.

**Example 45-23  Iterating through the Result Set**

```java
if (tasksList != null) { // There are tasks
    str = str + tasksList.size() + ":";
    Task task = null;
    for (int i = 0; i < tasksList.size(); i++) {
        task = (Task) tasksList.get(i);
        str = str + task.getSystemAttributes().getTaskNumber() + "/" +
        task.getSystemAttributes().getTaskId();
        System.out.println("Task Number: "+
        task.getSystemAttributes().getTaskNumber());
        System.out.println("Task Id: " + task.getTaskId());
        System.out.println("Title: "+ task.getTitle());
        System.out.println("Priority: " + task.getPriority());
        System.out.println("State: "+ task.getSystemAttributes().getState());
        // Retrive any Optional Info specified
        // Use task service, to perform operations on the task
        str = str + ":";
    }
}
```

**45.4.5.8 Programmatically Set the Task Outcome**

After you have obtained one or more task objects through the query service, approve or reject the tasks by calling the task service `updateTaskOutcome` method from the `ITaskService` API, as shown in the following examples:

- **Example 45-24**
- **Example 45-25**
- **Example 45-26**
- **Example 45-27**
- **Example 45-28**
- **Example 45-29**

**Example 45-24  Programmatically Setting the Task Outcome**

```java
updateTaskOutcome(IWorkflowContext context, Task task, java.lang.String outcome)
// Set the outcome of the task.
```

**Example 45-25  Setting the Outcome of the Task Reference on the Single Server Task Service**

```java
'APPROVE'.taskSvc.updateTaskOutcome(wfCtxt, t, "APPROVE");
```
Example 45-26  Setting the Outcome of the Task Reference on the Single Server Task Service

'REJECT'.taskSvc.updateTaskOutcome(wfCtxt, t, "REJECT");

Example 45-27  Obtaining a Single Task Reference Using the Non-Federated Query Service

getTaskDetailsById, then setting the outcome to 'APPROVE'.Task t =
querySvc.getTaskDetailsById(wfCtxt, "0a6d287a-9849-4e5e-914b-805706d6b9d9");
taskSvc.updateTaskOutcome(wfCtxt, t, "APPROVE");

Example 45-28  Obtaining a Single Task Reference Using the Non-Federated Query Service

getTaskDetailsByNumber, then setting the outcome to 'REJECT'.Task t =
querySvc.getTaskDetailsByNumber(wfCtxt, 200140 );
taskSvc.updateTaskOutcome(wfCtxt, t, "REJECT");

Example 45-29  Updating a Single Task Outcome on the Federated Query Service

Map<String, IWorklowContext> ctxMap = fedWFCtx.getWorkflowContextMap()
String serverName = task.getServerName();
IWorkflowContext taskWfCtx = ctxMap.get(serverName);
if (taskWfCtx !=null)

45.5 Other Approaches

Programmatically, it is possible to use a SOAP-based client interface and manually set
endpoint and credential information in the code from a product-specific table. This
approach is not recommended as the SOAP interface may negatively affect
performance liability. Furthermore, managing endpoint or credential information
yourself is not recommended. Endpoint implementation and credential provisioning
are best facilitated by centralized endpoint management and identity propagation.

45.6 Securing the Design Pattern

Secure your human workflow client service in the manner appropriate for the type of
code you are developing. For more information about securing your application, see
Securing Web Services Use Cases .

45.7 Verify the Deployment

Validating your implementation involves deploying human tasks to a SOA domain, in
the following steps.

- Deploying the Human Task
- Deploying Programmatic Task Functionality
- Invoking Programmatic Task Functionality

45.7.1 Deploy the Human Task

Upon deployment of the SOA composite containing the human task metadata, the
human workflow infrastructure registers the task by name and namespace. After the
task is deployed and registered, your code or BPEL can initiate the task and facilitate
task resolution through the code or worklist.
45.7.2 Deploy Programmatic Task Functionality
Deploy the application containing the task service client code. Make sure to deploy the
SOA composite with a task before deploying the human workflow task client service.
This ensures that the SOA composite has been deployed before creating a task
instance.

45.7.3 Invoke Programmatic Task Functionality
You can use Oracle ADF UI, an ADF Business Components service or an Oracle
Enterprise Scheduler Java job to implement the task client service functionality.
Submit or invoke the task functionality as you normally would, and use the Worklist
application to confirm that tasks have been created and updated. You can access the
Worklist application at the following URL:

45.7.4 Related Links
The following documents provide additional information related to subjects discussed
in this section:

- For more information about deploying human tasks, see "Part V: Using the
  Human Workflow Service Component" in the Developing SOA Applications with
  Oracle SOA Suite.

- For more information about deploying programmatic task functionality, see
  "Deploying and Managing SOA Composite Applications" in the Administering

45.8 Troubleshoot the Use Case
Following are some suggestions for troubleshooting task data and the Java code in the
use case.

45.8.1 Troubleshooting Task Data
In some cases, tasks may have been initiated but the attributes required for the task
have not been set. When this happens, the task may not display in the worklist.
Alternatively, it may be assigned to the wrong user, or to no user at all.
Check the WFTASK table for tasks such as these.

45.8.2 Troubleshooting Java Code
Use Oracle Fusion Middleware Extensions for Applications AppsLogger APIs to
write execution and exception details to the diagnostic logs. You can also use the
Oracle JDeveloper remote debugger to remotely connect to the runtime JVM and step
through your code.

45.9 What You May Need to Know About Implementing Email Notification
for an Oracle ADF Task Flow for a Human Task

- This approach uses the RMI interface to the human workflow task services for
  performance and identity propagation.
• Endpoint information for the RMI URL is stored in the Oracle Fusion Middleware Extensions for Applications taxonomy tables and available in JAXB object form by the taxonomy APIs.

• Use of paging (25 or 50) to limit result set size in task query or federated task query calls is necessary for performance reasons.
This chapter describes what to do if your SOA composite includes a human task, and you need to define an Oracle ADF task flow for a human workflow for users to interact with the task.

**When to implement:** If your SOA composite includes a human task, then you need to define an Oracle ADF task flow for a human workflow for users to interact with the task.

**Design Pattern Summary:** If your SOA composite includes a human task, then you need a way for users to interact with the task. The integrated development environment of Oracle SOA Suite includes Oracle Application Development Framework (Oracle ADF) for this purpose. With Oracle ADF, you can design a task display form that depicts the human task in the SOA composite.

**Involved components:**
- Oracle ADF task flow for human tasks
- Human task service component

### 46.1 Introduction to the Recommended Design Pattern

When invoking a human task from a SOA composite, an interface is required so that end users can interact with the task. You can use Oracle ADF to develop an interface that displays the human task within the SOA composite.

### 46.2 Other Approaches

There are no other supported approaches to this use case.

### 46.3 Example

The sample code for this use case can be downloaded from Oracle SOA Suite samples.

### 46.4 How to Implement an Oracle ADF Task Flow for a Human Task

This section describes the procedure used to invoke an Oracle ADF task flow for a human task. The procedure includes tasks that are detailed in the following sections:

Implementing an Oracle ADF task flow for a human task involves the following tasks:
- Creating an Oracle ADF task flow.
- Creating a user interface.
• Confirming the classpath, libraries and tag libraries.
• Implementing product-specific sections.
• Implementing a task detail with contextual area.
• Implementing email notification.
• Displaying localized translated data.
• Displaying rows in the approval task.
• Configuring a deployment profile.

Before You Begin:
Ensure that you do the following:

• Define your human workflow task definition in SOA workspace. The TASK file
definition and schemas are referenced when creating the Oracle ADF task flow for
human tasks. The TASK file defines the data controls used in your task detail
page.

• Define the UI and uiModel project following the directory structure, package
structure and naming standards. Although the task detail page is associated with
a human task definition in your SOA composite, add to source control the UI
project containing the Oracle ADF task flow for human task definition with the
Oracle ADF workspace, not the SOA workspace.

• If you plan to create other UI and uiModel projects unrelated to Oracle ADF task
flow for human tasks, you can create them in the same LBA directory as the UI
and uiModel projects associated with an Oracle ADF task flow for human tasks.
However, it is recommended to keep the other UI and uiModel projects in
separate projects, using the optional <Context> to differentiate them.

46.4.1 Creating an Oracle ADF Task Flow
The first step in the use case is to create an Oracle ADF task flow.

To create an Oracle ADF task flow:

1. Right-click your UI project and choose New.

2. In the New Gallery window, select Web Tier > JSF > ADF Task Flow Based on
Human Task and click OK.

3. In the SOA Resource Browser dialog, select the TASK file location and target TASK
file.

   This creates the data control definition.

4. Create a bounded task flow. From the Create Task Flow dialog, enter a name for
the task flow and click OK.

Note:
There is no established task flow file-naming standard.
This creates the task flow containing a View component with the default name taskDetails1_jspx, as shown in Figure 46-1. Rename the view activity to something meaningful to you.

Figure 46-1  Task Flow with View Component

5. Double-click the view activity in the task flow. From the Create JSF Page dialog that displays, modify the file name or directory location as needed, and click OK.

6. When placing a bounded task flow on a JSPX page, make sure to handle exceptions in the bounded task flow. If the exception is propagated to the unbounded task flow, the bounded task flow may exit, causing the JSPX page to behave unpredictably.

Use the template with the ID ExceptionHandlerTaskFlowTemplate in the JSPX page to avoid any unpredictable behavior. The template is located in the UIComponents-View.jar, as follows: /oracle/apps/fnd/applcore/patterns/uishell/templates/ExceptionHandlerTaskFlowTemplate.xml.

Note:

Use the Property Inspector to add the template to the page, as shown in Figure 46-2.
46.4.2 Create a User Interface for the Human Task

Use the drop handler template to create a user interface for the human task.

To create a user interface:

1. Create a task detail UI and navigate to Application Navigator > Data Controls > Task Data Control Name > getTaskDetails > Return > Task.

2. Drag and drop the task data control to your JSPX page and select Create > Human Task > Complete Task with Payload, as shown in Figure 46-3.
The Edit Action Binding (getTaskDetails) dialog is displayed.

3. In the Edit Action Binding (getTaskDetails) dialog, click OK.

The Edit Action Binding (UpdateActions) dialog displays, as shown in Figure 46-4.

4. In the Edit Action Binding (UpdateActions) dialog, click OK.

5. In the Source view of the JSPX page, verify that `<af:panelHeader>` displays as the top most component in the `<af:form>` component. Figure 46-5 shows the Source view of a sample JSPX page.
6. Verify that the Applications Core (ViewController) library is included in the UI project class path.

7. Verify that the following distributed libraries are included in the JSP Tag Libraries for the project:
   - Trinidad HTML Components,
   - Workflow Tags 1.0,
   - worklistComponents 1.0,
   - Applications Core (ViewController).

46.4.3 Implement Product-Specific Sections

Product-specific sections include the following:

- Instructions
- Details
- Recommended Actions
- <PLACE APPLICATION SPECIFIC CONTENT HERE>
- Related Links
- Comments and Attachments
- History
46.4.3.1 How to Add Instructions

You can add instructions just before the Details section.

To include instructions in the panelHeader:

Add the component `<af:outputText>` before the Details section, as shown in Example 46-1.

**Example 46-1 Adding instructions above the Details section**

```html
<af:panelGroupLayout layout="vertical" id="pgl3">
  <f:facet name="separator">
    <af:spacer width="15" height="15" id="s6"/>
  </f:facet>
  <af:outputText value="[Instruction text goes here]"/>
  <af:showDetailHeader size="1" text="#{resources.DETAILS}" shortDesc="#{resources.TASK_HEADER}" disclosed="true" id="sdh1"/>
</af:panelGroupLayout>
```

46.4.3.2 How to Modify Details

The Details section, as shown in Figure 46-6, contains the required human task information displayed in the Approvals, Request for Action, and FYI patterns in the first column and displays optional product-specific header information for the task.

**Figure 46-6 Details Section**

![Details Section](image)

Do not modify the code in the first column, which corresponds to the first `<trh:cellFormat>` with id="cf1", as shown in Figure 46-6.

Do any or all of the following:

- If required, change the text attribute for the `<af:showDetailHeader>` component. The default is set to "#{resources.DETAILS}" for example, Details.
- If your page does not display product-specific information in this section, skip this section and continue to the next section.
• If your page displays product-specific information, add it to the third
  <trh:cellFormat> component, which corresponds to the
  <trh:cellFormat> with id="cf6" shown in Example 46-2.

  **Note:**
  Based on the UX specification, the task information displayed in the first
column should only be displayed in the first column and should not wrap into
the third column.

• If your page requires an additional column of product-specific information, take
the following steps.
  Add a column for spacing, <trh:cellFormat id="cf7">. Add a column to
display the product-specific information, <trh:cellFormat id="cf8">.
  Change the width to 33%, for <trh:cellFormat> components with id="cf1",
id="cf6", and id="cf8" as shown in Example 46-3.

**Example 46-2  Modify the third <trh:cellFormat> component**

```xml
<af:showDetailHeader size="1" text="#{resources.DETAILS}" shortDesc="#{resources.TASK_HEADER}" disclosed="true" id="sdh1">
  <f:facet name="toolbar"/>
  <trh:tableLayout width="98%" id="tl1">
    <trh:rowLayout id="rl2">
      <trh:cellFormat width="50%" valign="top" id="cf1">
        ... First column of task-specific fields, do not modify ...
      </trh:cellFormat>
      <trh:cellFormat id="cf5">
        <af:spacer width="15" height="15" id="s3"/>
      </trh:cellFormat>
      <trh:cellFormat width="50%" valign="top" id="cf6">
        ... Second column containing product-specific fields ...
      </trh:cellFormat>
    </trh:rowLayout>
  </trh:tableLayout>
</af:showDetailHeader>
```

**Example 46-3  Adding product-specific information**

```xml
<af:showDetailHeader size="1" text="#{resources.DETAILS}" shortDesc="#{resources.TASK_HEADER}" disclosed="true" id="sdh1">
  <f:facet name="toolbar"/>
  <trh:tableLayout width="98%" id="tl1">
    <trh:rowLayout id="rl2">
      <trh:cellFormat width="33%" valign="top" id="cf1">
        ... First column of task-specific fields, do not modify ...
      </trh:cellFormat>
      <trh:cellFormat id="cf5">
        <af:spacer width="15" height="15" id="s3"/>
      </trh:cellFormat>
      <trh:cellFormat width="33%" valign="top" id="cf6">
        ... Second column containing product-specific fields ...
      </trh:cellFormat>
      <trh:cellFormat id="cf7">
        <af:spacer width="15" height="15" id="s3"/>
      </trh:cellFormat>
      <trh:cellFormat width="33%" valign="top" id="cf8">
```
46.4.3.3 How to Modify Recommended Actions

The Recommended Actions section, as shown in Figure 46-7, is used in the Information Only pattern.

Figure 46-7  Recommended Actions Section

The Oracle ADF code for the Recommended Actions <af:showDetailHeader> component is shown in Example 46-4.

- If your page does not display the Recommended Actions section, remove the <af:showDetailHeader> component with text="#{resources.RECOMMENDED_ACTIONS}" and continue to the next section.
- If your page does display the Recommended Actions section, add the actions and appropriate links to this section.
Note:
Translation and accessibility standards state that individual words should not be implemented as links.

**Example 46-4  Code for Recommended Actions**

```xml
<af:showDetailHeader size="1" id="recommendedActionsHeader"
    text="#{resources.RECOMMENDED_ACTIONS}" disclosed="true">
    <f:facet name="info"/>
    <f:facet name="legend"/>
    <f:facet name="menuBar"/>
    <f:facet name="toolbar"/>
    <f:facet name="context"/>
</af:showDetailHeader>
```

### 46.4.3.4 How to Modify `<PLACE APPLICATION SPECIFIC CONTENT HERE>`

The `<PLACE APPLICATION SPECIFIC CONTENT HERE>` section is a placeholder for product-specific information such as the Purchasing Line section in the Approval Page Details pattern.

The Oracle ADF code for the `<PLACE APPLICATION SPECIFIC CONTENT HERE>` component is shown in **Example 46-5**.

Do any or all of the following:

- If your page does not have an application-specific section, then remove the `<af:showDetailHeader>` component with `text="<PLACE APPLICATION SPECIFIC CONTENT HERE>"` and continue to the next section.

- Modify the text attribute of the `<af:showDetailHeader>` component.

- Modify the body of the `<af:showDetailHeader>` component to meet your requirements.

Note:
The **Complete Task with Payload** drop handler adds an `<af:inputText>` component for each of the task payload fields by default. Remove these fields if they are not required.

- Add links to the bottom of this section, as shown in the pattern. The link implementation instructions are discussed in **How to Implement Links**.

- If additional product-specific sections are required, add them directly below the `<af:showDetailHeader>` section. Ensure that the size of the additional `<af:showDetailHeader>` components is set to 1.

**Example 46-5  Oracle ADF code for the application specific content section**

```xml
<af:showDetailHeader size="1" id="applicationContentHeader" text="<PLACE APPLICATION SPECIFIC CONTENT HERE>" disclosed="true">
    <af:panelGroupLayout id="payload_panel" layout="vertical"
        shortDesc="#{resources.CONTENTS}"
        />
    <af:panelFormLayout id="pfl1">
        <af:inputText value="#{bindings.PayloadInput1.inputValue}"
            label="#{bindings.PayloadInput1.hints.label}"/>
    </af:panelFormLayout>
</af:showDetailHeader>
```
46.4.3.5 How to Implement Links

Use the `af:goLink` component and specify `targetFrame="_blank"` to implement the related link.

To construct the target URL, use the API `oracle.apps.fnd.applcore.patterns.uishell.context.UIShellContext.getURL`. This API can still be used even though the task detail page does not implement the UI Shell. Enter a non-null `webApp` parameter to generate the full URL including the host name and port.

The resulting code should be similar to that displayed in Example 46-6.

**Example 46-6 Code that Results from Implementing Links**

```java
UIShellContext.getURL(java.lang.String viewId,
java.lang.String webApp,
java.lang.String pageParametersList,
java.lang.String navTaskFlowId,
java.lang.String navTaskKeyList,
java.lang.String navTaskParametersList,
java.lang.String navTaskLabel,
FndMethodParameters methodParameters)
```

46.4.3.6 How to Modify Comments and Attachments

The Comments and Attachment sections are used to store comments and attachments associated with the Approval and Request for Action patterns.

Do any of the following:

- If your page requires both comments and attachments, then leave it as is and continue to the next section.

- If your page does not require any comments or attachments, as in the FYI pattern, remove the `<af:switcher>` component with `facetName="#{pageFlowScope.bpmClientType}"` and its facets and continue to the next section.

- If your page requires the comments section only, move the `<af:showDetailHeader>` component with `text=#{resources.COMMENTS}` from the switcher facet with name="notificationClient" so that it is a peer of the switcher with `facetName="#{pageFlowScope.bpmClientType}"`. Then delete the `<af:switcher>` component with `facetName="#{pageFlowScope.bpmClientType}"` and its facets. The resulting code is shown in Example 46-7.

- If you require additional instructions in the Attachments dialog, then add an `<af:outputText>` component after `<af:outputText>` with value="#{resources.UPLOAD_FILE_CAVEAT}"", as shown in Example 46-8.
Example 46-7  Modifying comments and attachments

```xml
<af:showDetailHeader size="1" id="relatedLinksHeader"
  text="#{resources.RELATED_LINKS}"
  disclosed="true">
  ...
</af:showDetailHeader>

<af:showDetailHeader size="1" id="showDetailHeader1"
  text="#{resources.COMMENTS}"
  disclosed="true">
  ...
</af:showDetailHeader>

<af:showDetailHeader size="1" id="historyHeader"
  text="#{resources.HISTORY}"
  disclosed="false">
  ...
</af:showDetailHeader>
```

Example 46-8  Adding additional instructions to the Attachments dialog

```xml
<af:popup id="popupAddAttachmentDialog">
  <af:dialog title="#{resources.ADD_ATTACHMENT}" okVisible="false"
    cancelVisible="false" closeIconVisible="false" id="d2">
    ...
  </af:dialog>
</af:popup>
```

46.4.3.7 How to Modify Related Links

The Related Links section is used in the Information Only pattern.

Example 46-9 shows the Oracle ADF code for the Related Links component.

- If your page does not display the Related Links section, then remove the `af:showDetailHeader` component with text="#{resources.RELATED_LINKS}" and continue to the next section.

- If your page displays the Related Links section, add the appropriate links to this section. The link implementation instructions are described in How to Implement Links.

Example 46-9  Modifying Related Links

```xml
<af:showDetailHeader size="1" id="relatedLinksHeader"
  text="#{resources.RELATED_LINKS}" disclosed="true">
  <f:facet name="info"/>
  <f:facet name="legend"/>
  <f:facet name="menuBar"/>
  <f:facet name="toolbar"/>
```
46.4.3.8 How to Modify History

The History section displays the tabular and graphical displays of the task history. Do any of the following:

- If your page requires the history section, then leave it as is.
- If your page does not require the history section, remove the `<af:showDetailHeader>` component and its facets and child components, as shown in Example 46-10.

**Example 46-10  Modifying task history**

```xml
<af:showDetailHeader size="1" id="historyHeader" text="#{resources.HISTORY}" disclosed="false">
  <f:facet name="info"/>
  <f:facet name="legend"/>
  <f:facet name="menuBar"/>
  <f:facet name="toolbar"/>
  <f:facet name="context"/>
  <af:panelGroupLayout layout="vertical" id="pgl7">
    <wlc:taskHistory initParam="#{aleComponentBean.comp}" showTabularView="true" showGraphicalView="true" id="th1"/>
  </af:panelGroupLayout>
</af:showDetailHeader>
```

46.4.4 Implementing a Task Detail with Contextual Area

If you are implementing a task detail page with a contextual area, do not use the UIShellMainArea template when creating the JSF page. Instead, create the JSF page without a template.

Use `<trh:tableLayout>`, `<trh:rowLayout>` and `<trh:cellFormat>` to configure the layout of the local and contextual areas. For the local area, follow the steps outlined in the following sections:

- Creating an Task Flow
- Creating a User Interface for the Human Task
- Implementing Product-Specific Sections
- Implementing a Task Detail with Contextual Area

46.4.5 Implement Email Notification

The email version of the task details are often called notifications, task notifications or email notifications. Email notifications are viewed in email clients.

The goal in implementing the email version of the task detail page is to use the same Oracle ADF task flow for human tasks definition for both the online and email versions. As both versions are nearly identical, you can implement both as a single page to avoid dual maintenance.
46.4.5.1 Before You Begin

Ensure that the TASK file is configured so that email notifications are actionable and task attachments are added to the email as email attachment, as shown in Figure 46-8.

Figure 46-8 Notification Settings

<table>
<thead>
<tr>
<th>Task Status</th>
<th>Recipient</th>
<th>Notification Header</th>
</tr>
</thead>
<tbody>
<tr>
<td>Assign</td>
<td>Assignees</td>
<td></td>
</tr>
<tr>
<td>Complete</td>
<td>Initiator</td>
<td></td>
</tr>
<tr>
<td>Error</td>
<td>Owner</td>
<td></td>
</tr>
</tbody>
</table>

46.4.5.2 Determine the Implementation Approach

Select an implementation approach from the following:

- If the JSPX page that you defined for your online version contains only the following supported components, then you can use your existing JSPX page for both online and email versions.
  - af:column
  - af:commandLink
  - af:document
  - af:goLink
  - af:image
  - af:inputText
  - af:inputComboBoxListOfValues
  - af:inputDate
  - af:inputListOfValues
  - af:inputNumberSlider
  - af:inputNumberSpinbox
  - af:inputRangeSlider
  - af:outputText
  - af:panelHeader
  - af:panelLabelAndMessage
• If the online version of your JSPX page includes many interactions to be made available in the email notification, then you will need to build a second JSPX page for your email notification.

• Use an If component in the JSPX page to ensure that only supported components are rendered in the email version. For more information, see Using an If Component.

46.4.5.3 Using an If Component

Introduce an If component in your JSPX page when you have components that are not supported in the email notification.

To use an If component in your JSPX page:

1. Move the unsupported components in the <f:facet> with name="online".

2. Add alternative rendering logic using the supported components in <f:facet> where name="notificationClient", as shown in Example 46-11.

3. If it is not a notificationClient, the value of bpmClientType is null. Continue to Fine-Tuning the Emailable Page.

Example 46-11  Using an If component

<af:if defaultFacet="online"
   facetName="#{pageFlowScope.bpmClientType}"
>
   <f:facet name="online">
     ... Place code rendered in online version here ...
   </f:facet>
   <f:facet name="notificationClient">
     ... Place code rendered in email version here ...
   </f:facet>
</af:if>

46.4.5.4 Using a Separate View for Online and Email Versions

You can enable separate views for online and email versions for notifications.
To enable separate views for online and email notifications:

1. In the task flow, add a View Activity for the email version.
   a. Add a new view to the task flow definition and rename it appropriately.
   b. Define a control flow from the newly introduced view to the existing task flow return activity called taskReturn.
   c. Modify the transition value to closeTaskFlow.

2. Add a router.
   a. Add a new router activity and rename it appropriately.
   b. In the property inspector, set the default Outcome attribute to online.
   c. Add two cases, as shown in Example 46-12.
   d. Define a control flow case from the newly introduced router to the view associated with the online version. For the transition value, specify online.
   e. Define a control flow case from the newly introduced router to the view associated with the email version. For the transition value, specify email.

3. Set the newly introduced router as the default activity, as shown in Figure 46-9.

**Figure 46-9 Setting Default Activity**

![Diagram of task flow with router and views]

**Example 46-12 Adding two cases to the switcher**

Expression = "#{pageFlowScope.bpmClientType=="notificationClient"}" and Outcome = "email"

Expression = "#{empty pageFlowScope.bpmClientType}" and Outcome = "online"
46.4.5.5 Fine-Tuning the Emailable Page

To correctly render your JSPX page in email mode, you may need to take any or all of following steps to fine-tune the email page.

- Use an `<af:outputText>` component to render the instruction text, as there is no style class for instruction text based on the `helpTopicId` of `<af:panelHeader>` or `<af:showDetailHeader>`.

- In the `<af:showDetailHeader>` component, if the disclose property is set to false, the disclosure is closed in the page to be emailed. Add an EL expression to the `disclosed` property so that the property is true when in email mode, as shown in Example 46-13.

- Test your page to determine whether the width of `<af:table>` is acceptable. If the table is not wide enough, set the `<af:column>` width attribute.

Example 46-13 Adding an EL expression to the disclosed property

```jsp
<af:showDetailHeader size="1"
    id="histHd"
    text="#{resources.HISTORY}"
    disclosed="#{pageFlowScope.bpmClientType == 'notificationClient'}"
...
```

46.4.6 Displaying Localized Translated Data

If you are adding product-specific code to the template, ensure that your product-specific code adheres to the localization standards for Oracle ADF user interfaces.

If you are displaying a task payload attribute in your JSPX page, you must override the EL expression for the label attribute for each of the payload attributes. For example, in the automatically generated Oracle ADF code shown in Example 46-14, replace the "#{bindings.PayloadInput1.hints.label}" so that it refers to translated text in the Xliff resource bundle associated with your UI project.

Note:

Two strings in the Oracle ADF code template that store their translations in the resource bundle associated with the TASK file (as opposed to the UI project). Do not define the translations in the resource bundle associated with your UI.

- **Title**: Define the title in the task definition using the `Translation` setting. Ensure a translation is provided in a Java resource bundle. Do not use the properties file to store translated text.

- **Custom actions**: Ensure a translation is provided in a Java resource bundle. Do not use the properties file to store translated text.

For more information about translation resource bundles, see the section entitled "How to set up Resource Bundles for Translation of Your Customizations" in Creating Customizable Applications.
46.4.7 Displaying Rows in the Approval Task

If you want to display the rows in the business object that are included in the approval task, use the collection target data in the task data control to determine the rows to be included. Render that information within your product-specific regions.

To use a collection target:

- In Oracle JDeveloper, select Application Navigator > Data Controls > Task Flow Name > getTaskDetails(String, String, String) > Return > Task > System Attributes > Collection Target.

Regardless of whether aggregation is enabled, the collection target contains information on the rows that are being approved or rejected by the approver.

46.4.8 Configure a Deployment Profile

Create a deployment profile as you would for any other Oracle ADF UI project. For more information about configuring a deployment profile, see the section entitled "How to Create Deployment Profiles for Standalone WebLogic Server Deployment" in Setting Up Your JDeveloper Application Workspace and Projects.

To configure a deployment profile:

1. Generate an Oracle ADF library for your UI project containing the Oracle ADF task flow for a human task definition.

2. Add the Oracle ADF library to the SuperWeb project.
   Open the web.xml file for the SuperWeb project and add the code shown in Example 46-15.

3. Under the default source location, create the hwtaskflow.xml file and merge all the notification task flow details. For example, if you are adding a new ADF task flow for a human task to a project defined in a workspace called fusionapps/fin/components/Payables.jws, then you would take the following steps.

   a. In the SuperWeb project of your workspace, manually edit the hwtaskflow.xml file. In this example, the hwtaskflow.xml file is located in the following directory: fusionapps/fin/components/payables/PayablesSuperWeb/afmsrc/hwtaskflow.xml.
b. Under the `<hwTaskFlows>` element, add the relevant `<hwTaskFlow>` elements, as shown in **Example 46-16**.

**Example 46-15   Adding the Oracle ADF library to the SuperWeb project**

```xml
<filter>
  <filter-name>WorkflowFilter</filter-name>
  <filter-class>
    oracle.bpel.services.workflow.client.worklist.util.WorkflowFilter
  </filter-class>
</filter>

<filter-mapping>
  <filter-name>WorkflowFilter</filter-name>
  <url-pattern>/faces/*</url-pattern>
</filter-mapping>

<servlet>
  <servlet-name>IntegrateTaskFlowWithTask</servlet-name>
  <servlet-class>
    oracle.bpel.services.workflow.client.worklist.servlet.IntegrateTaskFlowWithTask
  </servlet-class>
  <load-on-startup>2</load-on-startup>
</servlet>

<servlet>
  <servlet-name>secureNotificationServlet</servlet-name>
  <servlet-class>
    oracle.bpel.services.workflow.client.worklist.servlet.SecureNotificationServlet
  </servlet-class>
</servlet>

<servlet-mapping>
  <servlet-name>IntegrateTaskFlowWithTask</servlet-name>
  <url-pattern>/integratetaskflowwithtask</url-pattern>
</servlet-mapping>

<servlet-mapping>
  <servlet-name>secureNotificationServlet</servlet-name>
  <url-pattern>/notification/secure</url-pattern>
</servlet-mapping>

<context-param>
  <param-name>oracle.adf.view.rich.security.FRAME_BUSTING</param-name>
  <param-value>differentDomain</param-value>
</context-param>

**Example 46-16   Add the `<hwTaskFlow>` elements**

```xml
<xml version='1.0' encoding='UTF-8'>
<hwTaskFlows
  xmlns="http://xmlns.oracle.com/bpel/workflow/hwTaskFlowProperties">
  <ApplicationName>worklist</ApplicationName>
  <LookupType>LOCAL</LookupType>
  <TaskFlowDeploy>false</TaskFlowDeploy>
  <SoaServer>
    <ejbProviderUrl/>
    <aliasKeyName/>
    <keyName/>
    <connectionName/>
  </SoaServer>
</hwTaskFlows>
```
46.5 Securing the Design Pattern

To secure this pattern, follow the instructions described in Securing Web Services Use Cases.

You may want to implement the following security tasks:

- Secure task flows (bounded)
- Secure page fragments
- Secure actions

46.6 Verifying the Deployment

Verifying the deployment involves defining JNDI and foreign JNDI for the non-SOA Oracle WebLogic Server, as well as defining a grant for bpm-services.jar.
In this use case, the Oracle ADF task flow for human tasks is deployed to a non-SOA server as described here, including configuring foreign JNDI providers. Alternatively, you can define a connection to the Oracle SOA Suite server using a deployment script.

You can deploy the Oracle ADF task flow for a human task to a SOA server.

**To verify the deployment:**

1. Deploy the `oracle.soa.workflow` shared library to the non-SOA Oracle WebLogic Server.
   - Navigate to `http://remote_hostname:remote_port/console`, where `remote_hostname` and `remote_port` are the host name and port for the remote non-SOA WebLogic server.
   - Select **Deployments** and click **Install**.
   - In the **Path** field, make sure the following value is specified:
     
     ```
     <jdev_install>/fmwtools/fmwtools_home/jdeveloper/soa/modules/oracle.soa.workflow_11.1.1
     ```
   - Select `oracle.soa.workflow.jar` and click **Finish**.
   - Confirm that the `oracle.soa.workflow(11.1.1,11.1.1)` library is active.

2. Define the foreign JNDI on the non-SOA Oracle WebLogic Server.
   - Navigate to `http://remote_hostname:remote_port/console`, where `remote_hostname` and `remote_port` are the host name and port for the remote non-SOA WebLogic server.
   - Navigate to **Domain Structure > Services > Foreign JNDI Providers** and click **New**.
   - Enter the name `ForeignJNDIProvider-SOA`, and click **OK**.
   - Click **ForeignJNDIProvider-SOA**.
   - Press **Enter** and then click **Save**.
   - Fill in the following for the SOA Oracle WebLogic Server.
     
     **Initial Context Factory**: `weblogic.jndi.WLInitialContextFactory`
     
     **Provider URL**: Enter the URL of the `soa-infra` application, using the following format: `t3://SOA_hostname:SOA_port/soa-infra`
     
     **User/Password**: Enter an administrator username and password for the server.

     **Note:**
     
     The provider URL refers to the `soa-infra` application, not the domain. Do not change `soa-infra`.

3. Define the JNDI links on the non-SOA Oracle WebLogic Server.
a. Navigate to http://remote_hostname:remote_port/console, where remote_hostname and remote_port are the host name and port for the remote non-SOA Oracle WebLogic Server.

b. Navigate to Domain Structure > Services > Foreign JNDI Providers and click ForeignJNDIProvider-SOA.

c. Select the Link tab and click New.

d. Press Enter and click OK. Enter the following values:
   - Name: RuntimeConfigService
   - Local JNDI Name: RuntimeConfigService
   - Remote JNDI Name: RuntimeConfigService
   - Specify ejb/bpel/services/workflow/ for ejb/bpel/services/workflow/TaskServiceBean and ejb/bpel/services/workflow/TaskMetadataServiceBean only.

e. Repeat steps 3.c and 3.d for the following JNDI values:
   - Name/Local JNDI Name/Remote JNDI Name: ejb/bpel/services/workflow/TaskServiceBean
   - Name/Local JNDI Name/Remote JNDI Name: ejb/bpel/services/workflow/TaskMetadataServiceBean
   - Name/Local JNDI Name/Remote JNDI Name: TaskReportServiceBean
   - Name/Local JNDI Name/Remote JNDI Name: TaskEvidenceServiceBean
   - Name/Local JNDI Name/Remote JNDI Name: TaskQueryService
   - Name/Local JNDI Name/Remote JNDI Name: UserMetadataService

4. On the remote non-SOA Oracle WebLogic Server, change jazn-data.xml (not system-jazn-data.xml) to include the grant for bpm-services.jar, as shown in Example 46-17.

5. Restart the remote non-SOA Oracle WebLogic Server.

6. Deploy your application containing the human task detail UI to the remote non-SOA Oracle WebLogic Server.

---

**Tips:**

When accessing the task in the Oracle Business Process Management Worklist, you may get the following message: “Details not available for this task.”

If so, take the following steps:

- Check the WFTASKDISPLAY table in the SOAINFRA schema for entries corresponding to the tasks. The entries should have the host and port number of the non-SOA Oracle WebLogic Server where the task detail page definitions are deployed.

- If there are no entries, check the log files for errors when deploying your task detail pages. Make sure that the grant for the bpm-services.jar is correctly defined.
Related Links
The following documents provide additional information related to subjects discussed in this section:

- For more information about using a deployment script to define a connection to the SOA server, see the section describing the workflow client configuration file (wf_client_config.xml) in the chapter "Introduction to Human Workflow Services" in the Developing SOA Applications with Oracle SOA Suite.

- For more information about deploying the Oracle ADF task flow for human task to a SOA server, see the chapter "Deploying SOA Composite Applications" in Developing SOA Applications with Oracle SOA Suite.

Example 46-17 Grant for bpm-services.jar

```xml
<grant>
  <grantee>
    <codesource>
      <url>file:${oracle.home}/soa/modules/oracle.soa.workflow_11.1.1/-</url>
    </codesource>
  </grantee>
  <permissions>
    <permission>
      <class>oracle.security.jps.JpsPermission</class>
      <name>VerificationService.createInternalWorkflowContext</name>
    </permission>
    <permission>
      <class>oracle.security.jps.service.credstore.CredentialAccessPermission</class>
      <name>context=SYSTEM,mapName=BPM-CRYPTO,keyName=BPM-CRYPTO</name>
      <actions>read,write</actions>
    </permission>
    <permission>
      <class>oracle.security.jps.JpsPermission</class>
      <name>IdentityAssertion</name>
      <actions>*</actions>
    </permission>
  </permissions>
</grant>
```

46.7 Troubleshooting the Use Case

Following are some steps you can take to fix known issues.

- Specify oracle.soa.workflow.wc in weblogic-application.xml.
- Set the FRAME_BUSTING attribute in web.xml.
- Migrate from an earlier version of the drop handler template.
- Override the EL for the create button.

46.7.1 Specify oracle.soa.workflow.wc in weblogic-application.xml

By default, the drop handler generates a reference to the oracle.soa.workflow shared library in weblogic-application.xml. Override the entry in the weblogic-application.xml file so that it references oracle.soa.workflow.wc instead.
Example 46-18 shows a snippet of a sample `weblogic-application.xml` file with the correct reference to `oracle.soa.workflow.wc`.

**Example 46-18  Reference oracle.soa.workflow.wc**

```xml
<?xml version = '1.0' encoding = 'US-ASCII'?>
xmlns="http://www.bea.com/ns/weblogic/weblogic-application">
...
<library-ref>
    <library-name>oracle.soa.workflow.wc</library-name>
</library-ref>
...
</weblogic-application>
```

**46.7.2 Set the FRAME_BUSTING Attribute in web.xml**

If you receive a warning message about frame content not loading, modify `web.xml` to include the code shown in Example 46-19.

**Example 46-19  Set the FRAME_BUSTING attribute in web.xml**

```xml
<context-param>
    <param-name>oracle.adf.view.rich.security.FRAME_BUSTING</param-name>
    <param-value>differentDomain</param-value>
</context-param>
```

If your SOA runtime and task detail UI are running on different domains during development, set the value to `never` for testing purposes only.

**46.7.3 Migrate from an Earlier Version of the Drop Handler Template**

If your page is created using an earlier version of the drop handler template (which used `fnd:applicationPanel` and `af:panelStretchLayout`), take the following steps to migrate `fnd:applicationsPanel` to `af:panelHeader`.

**To migrate from an earlier version of the drop handler template:**

1. Open your JSPX page and, in the Structure pane, locate `af:panelStretchLayout` under `af:form`.

2. When you have found `af:panelStretchLayout`, add `af:panelHeader` above `af:panelStretchLayout` and set the text attribute to `text="#{binding.title.inputValue}"`.

3. In `fnd:applicationsPanel`, find the `actionButtonBar` facet and select the `af:toolbar` below it.
   Move `af:toolbar` under the toolbar facet of `af:panelHeader` added in the previous step.

4. Under the content facet of `fnd:applicationsPanel`, find `af:panelGroupLayout` and move it under `af:panelHeader`.

5. Find `af:panelStretchLayout` and delete it.
6. Save and test your work.

46.7.4 Override the EL for the Create Button

Override shortDesc EL for the Create button in the Comments section:

To override the EL for the Create button:

1. In the JSPX page, locate `<af:commandImageLink>` and find the action property value `#{popupBean.showCommentDialog}`.

2. For `<af:table>`, overwrite the shortDesc property value as follows:

   `shortDesc="#{resources.CREATE}"`.

3. Repeat step 2 for the second `<af:commandImageLink>` with the action property value `#{popupBean.showCommentDialog}`. Example 46-20 shows a sample illustrating `<af:commandImageLink>` after modifying the action property value.

Example 46-20  Modifying the action property value for `<af:commandImageLink>`

```xml
<af:commandImageLink id="adCmtBt" partialSubmit="true"
    actionListener="#{bindings.CreateInsert.execute}"
    action="#{popupBean.showCommentDialog}"
    shortDesc="#{resources.CREATE}"
    hoverIcon="/hw_images/new_ovr.png"
    visible="#{actionAvailable.isCommentUpdatable}"
    icon="/hw_images/new_ena.png"
    disabledIcon="/hw_images/new_dis.png"
    depressedIcon="/hw_images/new_dwn.png"/>
```
This chapter describes what to do when you require your SOA composite to subscribe to a business event published on another Oracle SOA Suite cluster.

**When to implement:** When you require your SOA composite to subscribe to a business event published on another Oracle SOA Suite cluster.

**Design Pattern Summary:** The Event Delivery Network (EDN) infrastructure supports business event publishing and subscription within a single Oracle SOA Suite cluster. To propagate a business event from one Oracle SOA Suite cluster to another, you must build a mediator-to-mediator bridge. The bridge queues the event message in a global queue from the Oracle SOA Suite cluster. The Oracle SOA Suite cluster publishes the event and then dequeues the event message from the Oracle SOA Suite cluster that subscribes to the event.

**Involved components:**
- Oracle Mediator
- Oracle Aqueue Adapter

### 47.1 Introduction to the Recommended Design Pattern

You can use business event publishing and subscription for asynchronous, loosely-coupled integration between two components such as an Oracle ADF UI application and a SOA composite. In most cases, the two components to be integrated are within the same family, and the same Oracle SOA Suite cluster is used to both raise and subscribe to the event. However, in some cases component integration goes across domains. This pattern is used to implement business event propagation from one Oracle SOA Suite cluster to another.

### 47.2 Potential Approaches

There are two other possible approaches to this use case.

- A global EDN queue can be shared across all Oracle Fusion Applications families. Although it supports cross-event subscription, the shared EDN feature is not recommended due to the durability of subscriptions. If any of the Oracle SOA Suite clusters sharing an event queue goes down, then the events will remain in the queue until the cluster goes back up and dequeues the event. If the cluster is offline for a long period, the queue could become quite large. In addition, a large number of events may need to be dequeued by each of the Oracle SOA Suite clusters even if there may no subscribers. This may affect performance.
WARNING:
This approach is not recommended.

- The composite with the event subscription can be deployed to the Oracle SOA Suite cluster which publishes the event.

### 47.3 Example

**CRM Subscribes to Event Published by HCM**

HcmUsersSpmlComposite deployed in the HCM SOA cluster publishes a post-processing event to report the success or failure of the process of creating a new user or assigning roles to a user. In order for CRM to perform additional actions based on the user request, the post-processing event must be propagated from HCM to CRM.

Table 47-1 lists the HCM composite components and values.

<table>
<thead>
<tr>
<th>Composite Components</th>
<th>Values</th>
</tr>
</thead>
<tbody>
<tr>
<td>Publishing Product</td>
<td>Per</td>
</tr>
<tr>
<td>Subscribing Product</td>
<td>Hz</td>
</tr>
<tr>
<td>Owning Product</td>
<td>Hz</td>
</tr>
<tr>
<td>XFAMILYPub composite name</td>
<td>FoundationPartiesPerToHzXFAMILYPubComposite</td>
</tr>
<tr>
<td>XFAMILYSub composite name</td>
<td>FoundationPartiesHzXFAMILYSubComposite</td>
</tr>
<tr>
<td>Recipient/Consumer</td>
<td>FoundationPartiesPerToHz</td>
</tr>
<tr>
<td>SOA workspace</td>
<td>CrmCommonSoa.jws</td>
</tr>
</tbody>
</table>

**Financials Subscribes to CRM Event**

When the ImportPartyData event is raised in the customer or supplier import program in TCA, the Financials PartyImportForTCALocService service must be invoked. The service creates a tax profile for a party which must be involved in financial transactions.

**HCM Subscribes to Event Published by CRM**

The resource directory feature in CRM raises the ActiveLdapRequestEvent event to make an LDAP request for provisioning the abstract role and security roles for newly provisioned user accounts to existing resources. Without processing these requests, resources will not be able to login to the resource directory used to maintain resource information such as phone numbers, email addresses, mail addresses, and so on. The HcmUsersSpmlComposite deployed to the HCM Oracle SOA Suite cluster subscribes to the event and processes the request.

Table 47-2 lists the CRM composite components and values.
### Table 47-2  CRM Composite Components and Values

<table>
<thead>
<tr>
<th>Composite Components</th>
<th>Values</th>
</tr>
</thead>
<tbody>
<tr>
<td>Publishing Product</td>
<td>Hz</td>
</tr>
<tr>
<td>Subscribing Product</td>
<td>Per</td>
</tr>
<tr>
<td>Owning Product</td>
<td>Hz</td>
</tr>
<tr>
<td>XFamilyPub composite name</td>
<td>FoundationPartiesHzToPerXFamilyPubComposite</td>
</tr>
<tr>
<td>XFamilySub composite name</td>
<td>FoundationPartiesPerXFamilySubComposite</td>
</tr>
<tr>
<td>Recipient/Consumer</td>
<td>FoundationPartiesHzToPer</td>
</tr>
<tr>
<td>SOA workspace</td>
<td>CrmCommonSoa.jws</td>
</tr>
</tbody>
</table>

The sample code for this use case can be downloaded from Oracle SOA Suite samples.

#### 47.4 How to Subscribe to a Cross-Family Business Event

To support cross-family event subscriptions, a global aqueue resides in the Oracle Fusion Applications schema to enqueue messages from one Oracle SOA Suite cluster and dequeue to another Oracle SOA Suite cluster. The messages contain information about the event as well as the publisher’s identity and application context information.

In addition to the aqueue, this pattern includes an `XFamilyPub` composite deployed to the Oracle SOA Suite cluster which publishes the cross-family event, and an `XFamilySub` composite deployed to the Oracle SOA Suite cluster which subscribes to the cross-family event. The `XFamilyPub` composite contains a mediator and an Aqueue adapter configured for the enqueue operation. The mediator subscribes to the event, transforms the event information and payload and enqueues a message to the Aqueue with the recipient set to the family subscribing to the event. The `XFamilySub` composite contains an Aqueue adapter configured for the dequeue operation with itself specified as the recipient. The mediator dequeues the message, filters the message based on the `Namespace` and `LocalName` elements in the message, transforms the payload and raises the event locally.

#### 47.4.1 Before You Begin

Your installation of Oracle JDeveloper must include the following database objects, Oracle WebLogic Server configurations and so on:

- Make sure that the database object `ACR_XFAMILY_EVENT_Q` is defined in the FUSION schema. Verify that the database object exists by navigating to the Database Navigator in Oracle JDeveloper, defining a connection to the FUSION schema and double-clicking Queues.

- In Oracle WebLogic Server, define the data source JDBC/ApplicationDBXA. Verify this configuration by running the Oracle WebLogic Server Console and navigating to Data Sources. (See bug 9712616.)

- In Oracle WebLogic Server, define a JDBC/XFamilyEventAqueue AqAdapter connection pool. Verify this configuration by running the Oracle WebLogic Server console and navigating to Domain Configurations > Your Deployment.
47.4.2 Determine the Composites to Be Defined

Following are the components to be defined for the pattern:

- **Publishing product**: The publisher product is the product that publishes the event.
- **Subscribing product**: The subscriber product is the product that subscribes to the event.
- **Owning product**: The owning product is the product that owns the `XFamilyPub` and `XFamilySub` composites.

The product team requiring the cross-family subscription owns both the `XFamilySub` and `XFamilyPub` composites. This pattern assumes the composites are defined at the product level. It is also possible to define the `XFamilySub` and `XFamilyPub` at the family level instead.

Determine whether an `XFamilySub` or `XFamilyPub` composite has been defined for your product. If they have not been defined, then follow these guidelines for naming the `XFamilySub` and `XFamilyPub` composites. The naming guidelines help make cross-family event composites easily identifiable and self-descriptive.

These composites can reside in any LBA in your product.

### Composite Naming Conventions

The composite names must adhere to the following guidelines:

1. **Start with the LBA short name.** You can define the composite in any LBA.
2. **For the subscribing and publishing composites, respectively, do the following:**
   - **Add `<Subscribing product> if not included in LBA short name.** Use the product short name as defined in Oracle Fusion Setup. Use `B2B` if the subscriber is a composite deployed to the Setup SOA cluster for B2B.
   - **Add `<Publisher product>To<Subscriber product>` so that the name is self-descriptive.** Use the product short name as defined in Oracle Fusion Setup.
3. **Identify the purpose of the composite.**
   - For a subscribing composite, add `XFamilySub` to the name.
   - For a publishing composite, add `XFamilyPub` to the name.
4. **End with Composite.**

### `XFamilySub`

A product can have more than one `XFamilyPub` composite.

Using the naming conventions specified in Composite Naming Conventions, the sample composite name is as follows:

- **`FinInfrZxXFamilySubComposite`.** In this example, the LBA short name is `FinInfr` and the `Zx` product subscribes to the cross-family event.
XFamilyPub

A product can have more than one XFamilyPub composite. There should only be one XFamilyPub composite for each publisher product and subscriber product combination.

Using the naming conventions specified in Composite Naming Conventions, sample composite names are as follows:

- **FinInfrHzToZxXFamilyPubComposite**. In this example, the LBA short name is FinInfr and the Zx product subscribes to an event published by the Hz product.
- **FinInfrPerToZxXFamilyPubComposite**. In this example, the LBA short name is FinInfr and the Zx product subscribes to the event published by the Per product.

### 47.4.3 Determining the Aqueue Message Recipient

A recipient or consumer is specified in the Aqueue Adapter defined in the XFamilyPub and XFamilySub composites. The recipient in the XFamilyPub is used to indicate which Aqueue Adapter should receive the enqueued message. The consumer in the XFamilySub is used to identify the Aqueue Adapter. For example, if the XFamilyPub specifies ZX as the recipient for the enqueued message, then the XFamilySub with the consumer set to ZX dequeues the message from the aqueue.

The recipient is the name of the XFamilyPub composite without the suffix XFamilyPubComposite, in the format <LBA short name><Publisher product>to<Subscriber product>.

For example:

- FinInfrHzToZx for FinInfrHzToZxXFamilyPubComposite
- FinInfrPerToZx for FinInfrPerToZxXFamilyPubComposite
- PrcInfrPoToB2B for PrcInfrPoToB2BXFamilyPubComposite

### 47.4.4 Defining an XFamilyPub Composite

This step defines the composite which subscribes to an event on a remote family’s Oracle SOA Suite cluster and enqueues a corresponding message in the ACR_XFAMILY_EVENT_Q aqueue.

1. In the owning team’s SOA workspace, create an empty composite with the name determined in Determining the Composites to Be Defined.

2. Drag and drop an Aqueue Adapter to the right swim lane of your composite and define the adapter as follows.

   a. In the Service Name field, enter a service name for the Aqueue Adapter.

   b. Define a connection for your Oracle Fusion Middleware schema and enter JNDI name eis/AQ/XFamilyEventAqueueInterface. In the Interface field, define the operation and schema.

   c. For the operation type, select the Enqueue radio button. In the Operation Name field, enter Enqueue.

   d. For the queue name, enter FUSION as the database schema and ACR_XFAMILY_EVENT_Q for the queue name.
e. On the Queue Parameters page, enter the recipient as defined in Determining the AQueue Message Recipient.

f. On the Message page, enter `oramds/apps/oracle/apps/common/acr/events/FusionXFamilyEvent.xsd` for the URL and `FusionXFamilyEvent` for the schema element. To access `FusionXFamilyEvent.xsd` from MDS, take the following steps.

   Click the search icon next to the URL field.
   
   In the Type Chooser dialog box, select Import Schema File.

   Click the search icon next to the URL field.

   At the top of the SOA Resource Browser window, select the Resource Palette.

   Under IDE Connections, navigate to `SOA-MDS > SOA-MDS connection Name > oracle > common > acr > events > FusionXFamilyEvent.xsd` and click OK.

   In the Import Schema File window, uncheck Copy to Project and click OK.

   In the Type Chooser window, select `FusionXFamilyEvent` and click OK.

3. Drag and drop a mediator to your composite and name it `EnqueueMediator`. Select Define Interface Later as the template and click OK. Double-click the `EnqueueMediator` component.

4. For each event to which your family subscribes, define a routing rule in the mediator. Click add button next to Event Subscriptions and select the business event to which you want to subscribe on the remote Oracle SOA Suite cluster. Reference the EDL file from MDS, and do not copy the file in your composite.

   a. Add a static routing rule and click the Service button. Select References > EnqueueEventMessage > Enqueue.

   b. Create a transformation XSL file by clicking the transformation icon in the routing rule and selecting Create New Mapper File.

   c. In the column on the right, right-click `msg_out:Namespace`. Select Set Text > Enter Text, and specify the event namespace.

   d. In the column on the right, right-click `msg_out:LocalName`. Select Set Text > Enter Text, and specify the event local name.

   e. In the Component Palette, from XSL Constructs, drag and drop copy-of to the `msg_out:Payload` element on the far right column of the XSL design tab.

      In the Copy-of Type dialog, select Replace the children of the selected node with the results of the copy-of. If an error message displays to the right of the copy-of element, you can ignore it.

   f. In the far left column, select the element just below `<sources>`. Drag-and-drop the element to the copy-of in the far right column in the XSL design tab. After you complete this step, the error icon that displayed in the previous step disappears.

      Example 47-1 shows a sample XSL file.

5. In the routing rule, define an assign statement to copy the context from the `apps.context.header` property into the `ApplicationContext` element in the aqueue message. The Assign Value window is shown in Figure 47-1.
Use the Expression builder to generate an expression for the To region. Select Variables > out > FusionXFamilyEvent > msg_out:FusionXFamilyEvent > msg_out:ApplicationContext, click Insert into Expression and then click OK.

**Figure 47-1  Define an Assign Statement**

The mediator source code is shown in Example 47-2.

6. Open the composite.xml file and search for the following line.

```xml
<binding.jca config="EnqueueEventMessage_aq.jca"/>
```

7. Replace the `binding.jca` element with the code shown in Example 47-3.

8. Add standard fault policies to the composite just above the `<component>` elements in the composite.xml file, as shown in Example 47-4.

**Example 47-1  Sample XSL File**

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<oracle-xsl-mapper
<!-- SPECIFICATION OF MAP SOURCES AND TARGETS, DO NOT MODIFY. -->
<mapSources>
  <source type="XSD">
    <schema location="../xsd/bulkImportEvents.xsd"/>
    <rootElement name="batchInfo"namespace="http://xmlns.oracle.com/apps/crm/hz/bulkImport/FoundationBulkImportEventsComposite"/>
  </source>
</mapSources>
<mapTargets>
  <target type="WSDL">
    <schema location="../EnqueueEventMessage.wsdl"/>
    <rootElement name="FusionXFamilyEvent"namespace="http://xmlns.oracle.com/apps/common/acr/events"/>
  </target>
</mapTargets>
<!-- GENERATED BY oracle XSL MAPPER 11.1.1.2.0(build 100216.1000.2230) AT [MON APR 26 14:00:00 PDT 2010]. -->
```
Example 47-2  Mediator Source Code

<assign>
</assign>

Example 47-3  Replace the JCA Binding

<binding.jca config="EnqueueEventMessage_aq.jca">
<property name="jca.subject.xpath"/>msg_out:FusionXFamilyEvent/msg_out:Subject</property>
<property name="jca.subject.nslist"/>msg_out="http://xmlns.oracle.com/apps/common/acr/events"/>
</binding.jca>
Example 47-4 Add Fault Policies to the composite.xml File

```xml
<property name="oracle.composite.faultPolicyFile">
  oramds:/apps/oracle/apps/fnd/applcore/soa/fault/fault-policies.xml
</property>
<property name="oracle.composite.faultBindingFile">
  oramds:/apps/oracle/apps/fnd/applcore/soa/fault/fault-bindings.xml
</property>
```

47.4.5 Defining an XFamilySub Composite

This step defines the composite which will dequeue messages from ACR_XFAMILY_EVENT_Q and raise the event locally in your family's SOA cluster.

**To define an XFamilySub composite:**

1. In the owning team's SOA workspace, create an empty composite with the XFamilySub composite name determined in Determining the Composites to Be Defined.

2. Drag and drop an Aqueue Adapter onto the left swim lane of your composite and provide the following values in the definition. When specifying the Messages URL, you will be referencing oramds. Ensure you have a SOA-MDS defined which points to fusionapps/soa_shared/soa-infra before proceeding.
   
   a. In the Service Name window, enter the name DequeueEventMessage in the Service Name text field.
   
   b. In the Service Connection window, define a connection for the Oracle Fusion Middleware schema. For the JNDI name, enter eis/AQ/XFamilyEventAqueue. For the XA Data Source, accept the default value.
   
   c. In the Adapter Interface window, accept the default selection Define from operation and schema (this is specified later).
   
   d. In the Operation window, select Dequeue for the operation type. In the Operation Name text field, accept the default value of Dequeue.
   
   e. In the Queue Name window, select the database schema and enter a queue name.
      From the Database Schema dropdown list, select Fusion.
      In the Queue Name field, enter ACR_XFAMILY_EVENT_Q.
   
   f. In the Queue Parameters window, specify the aqueue message recipient as defined in Determining the Aqueue Message Recipient.
   
   g. In the Messages window, select the message schema URL and the relevant schema element.
      In the URL field, browse for the message schema URL.
      From the Schema Element dropdown list, select FusionXFamilyEvent.

3. Drag and drop a mediator component onto your composite using the Define Interface Later template, and name it DequeueMediator.

   Draw a wire between the aqueue adapter and mediator, as shown in Figure 47-2.
4. For each cross family event to which your family subscribes, define a static routing rule in the mediator.

   a. Add a routing rule to raise the event by clicking on the add icon and the Event button. Use oramds to reference the EDL file rather than copying the EDL file into your composite.

   b. Add a filter expression to the rule to select the aqueue messages with the namespace and local name that match the event.

For example, if the namespace of the event is http://xmlns.oracle.com/apps/crm/hz/bulkImport/FoundationBulkImportEventsComposite and the local name is ImportPartyData, then the following filter is defined, as shown in Example 47-5.

   c. Create a transformation XSL file. Click the transformation icon, select Create New Mapper File, and click OK.

   d. In the Component Palette, expand the XSLT Constructs tab. Drag and drop the copy-of construct onto the XSLT file column on the element directly under the <target> element.

   e. In the Copy-of Type dialog, select Replace the selected node with the results of the copy-of.

   f. From the source column, drag and drop the msg_out:Payload onto the copy-of element in the XSLT file column.

   g. In the source tab, add a /child:node() element after <xsl:copy-of select="/msg_out:FusionXFamilyEvent/msg_out:Payload">.

The XSL file should look similar to that shown in Example 47-6.

   h. In the routing rule, define an assign statement to copy the context from the ApplicationContext element in the aqueue message into the apps.context.header property, as shown in Figure 47-3.
5. In the composite.xml file, replace the line `<binding.jca config="EnqueueEventMessage_aq.jca"/>` with the code shown in Example 47-7.

6. Add standard fault policies to the composite, as shown in Example 47-8.

**Example 47-5  A Filter Expression for the Mediator Rule**

```xml
and
($in.FusionXFamilyEvent/msg_out:FusionXFamilyEvent/msg_out:LocalName = "ImportPartyData")
```

**Example 47-6  XSL File**

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<oracle-xsl-mapper
<!-- SPECIFICATION OF MAP SOURCES AND TARGETS, DO NOT MODIFY. -->
<mapSources>
    <source type="WSDL">
        <schema location="../DequeueEventMessage.wsdl"/>
        <rootElement name="FusionXFamilyEvent" namespace="http://xmlns.oracle.com/apps/common/acr/events"/>
    </source>
</mapSources>
<mapTargets>
    <target type="XSD">
        <schema location="../xsd/bulkImportEvents.xsd"/>
        <rootElement name="batchInfo" namespace="http://xmlns.oracle.com/apps/crm/hz/bulkImport/FoundationBulkImportEventsComposite"/>
    </target>
</mapTargets>
<!-- GENERATED BY ORACLE XSL MAPPER 11.1.1.2.0(build 100216.1000.2230) AT [MON APR 26 15:28:04 PDT 2010]. -->
```
Example 47-7  Replacing the binding.jca Element

<binding.jca config="EnqueueEventMessage_aq.jca">
  <property name="jca.subject.xpath">/msg_out:FusionXFamilyEvent/msg_out:Subject</property>
  <property name="jca.subject.nslist">xmlns:msg_out="http://xmlns.oracle.com/apps/common/acr/events"</property>
</binding.jca>

Example 47-8  Adding Standard Fault Policies

<property name="oracle.composite.faultPolicyFile">
  orams://apps/oracle/apps/fnd/applicore/soa/fault/fault-policies.xml</property>
<property name="oracle.composite.faultBindingFile">
  orams://apps/oracle/apps/fnd/applicore/soa/fault/fault-bindings.xml</property>

47.5 Securing the Design Pattern

47.6 Verify the Deployment

You can verify the deployment of the use case by confirming that the event was successfully raised by checking the Event Delivery Network database log.
47.6.1 How to Verify the Deployment of the XFamilyPub Composite

To verify the deployment of XFamilyPub composite:

1. Deploy the XFamilyPub composite to the SOA cluster which receives the cross family business event.

2. Raise the cross family business event. Before integrating with Oracle ADF, you can raise a business event by invoking the following PL/SQL code in the Oracle Fusion Applications schema.
   a. Replace the parameters to initialize_session with the appropriate GUID and user.
   b. Replace hcm_edn_publish_event with the relevant event name, such as fin_edn_publish_event or crm_edn_publish_event, and so on.
   c. Replace the business event content.begin with the relevant business event.

Example 47-9 shows sample PL/SQL code used to raise a business event.

3. Confirm the event was raised on the SOA cluster that raises the cross-family business event by navigating to http://<SOA SERVER>:<SOA PORT>/soa-infra/events/edn-db-log.

4. Confirm the event name space, name, identity, payload and context matches the event raised via the PL/SQL API.
   a. In Fusion Applications Control, verify that an instance of the composite is running.
   b. Verify that a message is being enqueued (ensure the XFamilySub composite is not deployed) by looking at the contents of the FUSION.ACR_XFAMILY_EVENTS_QT table. The body of the message displays in the USER_DATA column. For example:

   ```sql
   select user_data from fusion.acr_xfamily_event_qt;
   ```

Example 47-9    Raise a Business Event by Invoking the PL/SQL Code

```sql
fnd_global.initialize_session('F5867912D280FD03AD1198A55EFC6BF', 'Abraham.Mason');

hcm_edn_publish_event('/oracle/apps/hcm/users/publicModel/entity/events/edl/LdapRequestEO', 'ActiveLdapRequestEvent',
   xmlns:ns="/oracle/apps/hcm/users/publicModel/entity/events/edl/LdapRequestEO">'||
   '<name>ns:ActiveLdapRequestEvent</name>'||
   '<content>'||
   '<ActiveLdapRequestEventInfo xmlns="/oracle/apps/hcm/users/publicModel/ entity/events/schema/LdapRequestEO">'||
   '</ActiveLdapRequestEventInfo>'||
   '</content>'||
   '</business-event>'
```

47.6.2 How to Verify the Deployment of the XFamilySub Composite

You can use Fusion Applications Control to verify that the composite is running.

**To verify the deployment of XFamilySub composite:**

1. Deploy the XFamilySub composite to the SOA cluster that subscribes to the cross-family event.
   
   The composite should pick up the message in the aqueue.

2. In Fusion Applications Control, verify that an instance of the composite is running.

3. Confirm the event was raised on the SOA cluster that subscribes to the cross-family business event by navigating to http://<SOA SERVER>:<SOA PORT>/soa-infra/events/edn-db-log.

4. Confirm the event namespace, name, identity, payload and context matches the event raised via the PL/SQL API.

47.7 Troubleshoot the Use Case

If you encounter any issue with the ACR_XFAMILY_EVENT_Q queue, first run the following select statements in the FUSION schema to confirm the privileges for FUSION_RUNTIME are correct and to confirm that the queue is configured for enqueuing and dequeuing. You can use the FUSION_READ_ONLY user to execute these statements.

### 47.7.1 Privileges to FUSION_RUNTIME

To confirm the necessary privileges are granted to FUSION_RUNTIME, run the statement shown in Example 47-10.

The statement should return the following results. Ensure SELECT, UPDATE, ENQUEUE, and DEQUEUE privileges are returned, as shown in Example 47-11.

If any of these privileges are not defined in your environment, run the appropriate command listed in Example 47-12.
Example 47-10  Confirming Privileges Granted to FUSION_RUNTIME

SELECT GRANTEE, OWNER, GRANTOR, PRIVILEGE, GRANTABLE, TABLE_NAME FROM DBA_TAB_PRIVS
WHERE TABLE_NAME like 'ACR_XFAMILY_EVENT%';

Example 47-11  Results Returned

<table>
<thead>
<tr>
<th>GRANTEE</th>
<th>OWNER</th>
<th>GRANTOR</th>
<th>PRIVILEGE</th>
<th>GRANTABLE</th>
<th>TABLE_NAME</th>
</tr>
</thead>
<tbody>
<tr>
<td>FUSION_RUNTIME</td>
<td>FUSION</td>
<td>FUSION</td>

<td>FUSION</td>
<td>DEQUEUE</td>
<td>NO</td>
<td>ACR_XFAMILY_EVENT_Q</td>
</tr>
</tbody>
</table>

Example 47-12  Granting Relevant Privileges

GRANT SELECT ON FUSION.ACR_XFAMILY_EVENT_QT TO FUSION_RUNTIME;

GRANT UPDATE ON FUSION.ACR_XFAMILY_EVENT_QT TO FUSION_RUNTIME;

execute DBMS_AQADM.GRANT_QUEUE_PRIVILEGE('ENQUEUE', 'ACR_XFAMILY_EVENT_Q', 'FUSION_RUNTIME', FALSE);

execute DBMS_AQADM.GRANT_QUEUE_PRIVILEGE('DEQUEUE', 'ACR_XFAMILY_EVENT_Q', 'FUSION_RUNTIME', FALSE);

47.7.2 Aqueue enabled for Enqueuing and Dequeuing

To confirm ACR_XFAMILY_EVENT_Q is enabled for enqueuing and dequeuing, run the statement shown in Example 47-13.

This statement should return the results shown in Table 47-3. Confirm that the ENQUEUE_ENABLED and DEQUEUE_ENABLED columns are set to YES for ACR_XFAMILY_EVENT_Q.

Table 47-3  Results When Confirming ACR_XFAMILY_EVENT_Q Is Enabled for Enqueuing and Dequeuing

<table>

If the queue is not enabled for enqueue or dequeue, run the command shown in Example 47-14.
Example 47-13  Confirming ACR_XFAMILY_EVENT_Q Is Enabled for Enqueuing and Dequeuing

select * from sys.dba_queues where queue_table like '%ACR_XFAMILY_EVENT%';

Example 47-14  Enabling the Queue for Enqueuing or Dequeuing

dbms_aqadm.start_queue(queue_name => 'ACR_XFAMILY_EVENT_Q');

47.7.3 AQ_INVALID_QUEUE_TYPE

If you encounter the error message, shown in Example 47-15, take the following steps.

This error indicates that FUSION_RUNTIME does not have the appropriate privileges to enqueue messages in the aqueue. Take the steps described in Privileges to FUSION_RUNTIME.

Example 47-15  AQ_INVALID_QUEUE_TYPE Error

{{Error during invoking 1-way operation "Enqueue" on target service "EnqueueEventMessage"
Exception occurred when binding was invoked. Exception occurred during invocation of JCA binding: "JCA Binding execute of Reference operation 'Enqueue' failed due to: AQ_INVALID_QUEUE_TYPE. Unable to obtain the correct queue type. Queue does not exist or not defined correctly. Drop and re-create queue.". The invoked JCA adapter raised a resource exception. Please examine the above error message carefully to determine a resolution.  }}

Troubleshoot the Use Case
Use Oracle Enterprise Scheduler to Invoke an Asynchronous Service

This chapter describes how to invoke an asynchronous web service from an Oracle Enterprise Scheduler asynchronous Java job packaged within an Oracle Enterprise Scheduler hosting application. The scheduled job asynchronously invokes a web service operation, and the web service responds with a callback message to an Oracle Enterprise Scheduler specified endpoint URL.

This chapter includes the following sections:

- Introduction
- Alternative Approaches
- Invoking an Asynchronous ADF Business Components Service from an Java Job
- Securing the Design Pattern
- Verifying the Design Pattern
- Troubleshooting the Use Case
- What You May Need to Know About the Design Pattern

48.1 Introduction

This pattern is recommended for cases in which an asynchronous scheduled Java job executed by a hosting application must invoke an external asynchronous web service operation (such as a SOA composite or Oracle ADF Business Components service operation) using a Java API for XML Web Services (JAX-WS) client.

A Java job is scheduled to be executed by its Oracle Enterprise Scheduler hosting application. Oracle Enterprise Scheduler runs the job, invoking the asynchronous Java job. The job logic uses a JAX-WS client to invoke an external asynchronous web service operation.

The web service operation executes asynchronously in the background. On completion, the web service sends a response to the Oracle Enterprise Scheduler asynchronous callback web service using a callback message.

Involved components:

- Oracle Enterprise Scheduler, which invokes the asynchronous Java job at the scheduled time.
- A Fusion hosting application which executes the asynchronous Java job implementation specified by the scheduled job. The Java job implementation runs when Oracle Enterprise Scheduler executes the scheduled job.
• An external, asynchronous SOAP-based web service (SOA composite or ADF Business Components service).

48.2 Alternative Approaches

Other approaches involve using some form of JAX-WS client or proxy to invoke an external web service operation with custom logic for generating message IDs, correlating callback messages, and so on. Business events can also be used with SOA composites, but not with ADF Business Components or other non-SOA web services.

Following are alternative, unsupported approaches to the use case:

• Invoke services asynchronously, without referencing the Oracle Enterprise Scheduler asynchronous callback web service. This approach is not supported, as using a callback handler external to Oracle Enterprise Scheduler involves using a non-standard job completion notification with Oracle Enterprise Scheduler.

• Invoke a one-way service. This approach is not supported for Oracle ADF Business Components services.

• Using business events to invoke the external web service operation. This approach does not use a direct web service invocation, and will not work for Oracle ADF Business Components web service without using some indirection. This approach is not supported.

WARNING:
These alternative approaches are not supported and should not be implemented.

48.3 Example

You can download a sample asynchronous Java job implementation using a JRF JAX-WS client for invoking asynchronous web service operations here.

48.4 Invoking an Asynchronous ADF Business Components Service from an Oracle Enterprise Scheduler Java Job

This pattern describes how to use web service addressing SOAP headers to ensure message ID generation that allows ESS request id correlation like callback message correlation.

The following code shows how to use a JAX-WS client and WS address SOAP headers to invoke an asynchronous web service operation. This code is part of the job logic of an Oracle Enterprise Scheduler asynchronous Java job.

The invoked asynchronous web service must respond with a callback SOAP message to the endpoint address specified in \texttt{wsa:ReplyTo} SOAP header.

The web service can specify the following URI in the \texttt{wsa:Action} header of the callback message, to indicate that the web service execution resulted in an error: \url{http://xmlns.company.com/oracleas/schema/oracle-fault-11_0/Fault}

Any other URI in the \texttt{wsa:Action} field of the callback message is regarded as success by the Oracle Enterprise Scheduler asynchronous callback web service).
Example 48-1  Invoking an asynchronous ADF Business Components service

...  
// Set up a JAX-WS web service proxy or dispatch.
// The following sample uses a dispatch mode client.
// Similar code can be used for a JAX-WS proxy.
AddressingFeature wsAddressing = new AddressingFeature(true, true);
Dispatch<SOAPMessage> dispatch  = dispatchService.createDispatch(
    portQName, SOAPMessage.class,
    Service.Mode.MESSAGE, wsAddressing);

// Construct SOAP message.
String reqSoapMsg = createSOAPMessageString(wsOp.getRequestMessage());
SOAPMessage dispatchRequest = createSOAPMessage(
    jrfMessageFactory, reqSoapMsg);

// Get RequestContext and set up SOAP headers.
Map<String,object> dispatchRequestContext = dispatch.getRequestContext();

// Initialize SOAPACTION HTTP header.
dispatchRequestContext.put(
    BindingProvider.SOAPACTION_USE_PROPERTY, Boolean.TRUE);
dispatchRequestContext.put(
    BindingProvider.SOAPACTION_URI_PROPERTY, operation);

// Generate message ID from RequestExecutionContext.
String messageId = reqExecContext.toIdString();
saveExternalId(requestId, messageId);

// Initialize the WS message SOAP header: Action, MessageId, To, ReplyTo.
AddressingHelper.setOutgoingAction(
    dispatchRequestContext, operation);
AddressingHelper.setOutgoingMessageId(
    dispatchRequestContext, messageId);
AddressingHelper.setOutgoingToAddress(
    dispatchRequestContext, endpointURLString);
dispatchRequestContext.put(BindingProvider.ENDPOINT_ADDRESS_PROPERTY,
    endpointURLString);

// Configure the wsa:ReplyTo address as the Oracle Enterprise Scheduler Service asynchronous
// callback web service URL.
String callbackAddress = http://essHost:essPort/ess-async/essasynccallback;
AddressingHelper.setOutgoingReplyToAddress(
    dispatchRequestContext, callbackAddress);
AddressingHelper.setOutgoingFaultToAddress(
    dispatchRequestContext, callbackAddress);

// Configure the relatesTo string as the request EXTERNAL_ID system property value,
// only if this is a follow-on operation such as Cancel.
String relatesTo = getExternalId(reqParams);
AddressingHelper.setOutgoingRelatesToMessageId(
    dispatchRequestContext, relatesTo);

// Invoke the proxy or dispatch operation.
dispatch.invokeOneWay(dispatchRequest);
...

// Save the messageId string as an EXTERNAL_ID system property on request using RuntimeService.
protected void saveExternalId(long requestId, String messageId)
    throws ExecutionErrorException  {
    RuntimeService runtime;
Securing the Design Pattern

To secure this pattern, add the Oracle Web Services Manager policies to both the external web service endpoint (ADF Business Components service) and the callback client.

Add corresponding policies to the web service client and service policies subjects associated with the server running Oracle Enterprise Scheduler. The web service client policy is used to invoke the asynchronous web service operation, while the WS-service policy is used by the Oracle Enterprise Scheduler asynchronous callback web service to process callback responses.

For more information, see Securing Web Services Use Cases.

Verifying the Design Pattern

Build and deploy the Oracle Enterprise Scheduler hosting application which invokes the asynchronous Java job definition and job implementation, using Oracle JDeveloper. Ensure that the build and deployment are successful.

Use Oracle Enterprise Manager Fusion Applications Control to verify the job definitions associated with the hosting application. Submit the asynchronous Java job and verify the external asynchronous web service operation invocation.

Troubleshooting the Use Case

The following suggestions help resolve issues that may arise when deploying or running this use case.

Deployment

Compile and deploy the application in JDeveloper, and watch the log at the bottom of the window. If the compilation or deployment fails, the failures and suggestions for resolving issues are displayed in the log.

If deployment succeeds, but the Oracle Enterprise Scheduler hosting application does not display in Fusion Applications Control, check the server's diagnostic log and console output for any exceptions, and resolve them.

Runtime
If faults occur when invoking the job, the Oracle Enterprise Scheduler server log and job log messages include information to help resolve any issues.

For diagnosing invoked SOA composites at runtime, you may use the Audit Flow view to diagnose the problem and correct your BPEL process, then redeploy the process.

48.8 What You May Need to Know About the Design Pattern

Make sure the asynchronous web service and its WSDL is accessible online before scheduling the Oracle Enterprise Scheduler asynchronous Java job which invokes the web service operation.
This chapter describes the components that developers use to secure Oracle Fusion applications and Web services by enforcing authentication and authorization. This chapter includes the following sections:

- Introduction to Securing Oracle Fusion Applications
- Authentication Techniques and Best Practices
- Authorization Techniques and Best Practices
- Learning More About Technologies Used to Secure Oracle Fusion Applications

### 49.1 Introduction to Securing Oracle Fusion Applications

Oracle Fusion Applications security consists of two main components, namely authentication and authorization. Authentication establishes the identity of the user. Authorization ensures that users only have access to resources to which they have been granted access.

When developing an Oracle Fusion application, it is necessary to ensure that authentication and authorization policies are properly enforced throughout the application. The implementation details may vary depending on the technology used in the application.

Additionally, for information about security and extending Oracle Fusion applications, see the *Oracle Fusion Applications Extensibility Guide for Developers*.

### 49.1.1 Architecture

Oracle Fusion applications are built on top of a set of internal and third-party technologies. This set of technologies defines what may be used to develop, build, package, and run Oracle Fusion applications. Each technology and component may have its own specific requirements for security implementation. The following figure depicts the components in the Oracle Fusion Applications security approach and the relationship of these components to the related technologies. For details about the technologies that implement security components, refer to *Services (OPSS) Security Framework* through `c__2798`. 
49.1.1.1 Oracle Platform Security Services (OPSS) Security Framework

OPSS security framework provides security to Oracle Fusion Middleware, including Oracle WebLogic Server, Oracle SOA Suite applications, Oracle WebCenter Portal, Oracle ADF applications, and Oracle Entitlements Server. OPSS is designed to be portable to third-party application servers. Developers can therefore use OPSS as the single security framework for both Oracle and third-party environments, thus decreasing application development, administration, and maintenance costs.

OPSS comprises Oracle WebLogic Server security and Oracle Fusion Middleware security. The following figure illustrates the layered architecture that combines these two security frameworks.
The previous figure depicts the various security components as layers. The uppermost layer includes the Oracle WebLogic Server and the Java applications running on the server; under it, is the layer consisting of APIs for Authentication, Authorization, Credential Store Framework, User and Role, and identity virtualization; the bottom layer includes the Security Service Provider Interface (SSPI) layer and the service providers. The bottom layer interacts with security data repositories, such as LDAP and database servers.

In addition to the list of providers shown in Figure 49-2, other providers include the role mapping and audit providers.

The Security Service Provider Interface (SSPI) layer is accessed through OPSS APIs and provides Java EE container security. It also provides resource-based authorization for the environment, thus allowing customers to choose their security model.

For more information about SSPI, see the Oracle Fusion Middleware Understanding Security for Oracle WebLogic Server guide.

The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For more information about OPSS, see the Understanding Security Concepts section in the Oracle Fusion Middleware Securing Applications with Oracle Platform Security Services, in the Oracle Fusion Middleware Online Documentation Library.

**49.1.1.2 c__2791**

Oracle Web Services Manager (Oracle WSM) provides a policy framework to consistently secure Web services.
Oracle Fusion Applications make use of an Oracle WSM feature called global policy attachments (GPA). Using GPA, web service policies are not attached locally, but are specified at a global level. At runtime, components simply inherit the global policy and Oracle WSM enforces it.

Unlike local policy attachments (LPA), which need to be added at every Web service client and server, global policy attachment can be attached at a domain level. This makes it easy for the system administrator to have a uniform policy for all Web services across the domain.

Because certain scenarios exist in which GPA cannot be used, Oracle Fusion application developers may need to use local policy attachment (LPA) for Web services and Web service clients. Application developers may attach policies locally using JDeveloper to the clients and services.

Authentication and authorization are enforced on the services by Oracle WSM based on the policies attached either at the domain level or locally on the service. The policies determine how the client and service communicate. For the predefined policies the naming convention indicates the behavior of the policy.

For example, given a policy called:

```
oracle/wss11_saml_token_with_message_protection_client_policy
```

- oracle is the path of the policy,
- ws11 indicates the Web services standard,
- saml_token is the authentication token,
- with_message_protection indicates whether message protection is enabled,
- client_policy indicates the type of policy, server or client.

Related Links

The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For more information about Oracle WSM, see the Oracle Fusion Middleware Administering Web Services guide.

How Policies are Executed

When a request is made from a service consumer (also known as a client) to a service provider (also known as a Web service), the request is intercepted by one or more policy interceptors. These interceptors execute policies that are attached to the client and to the Web service. There are five types of interceptors (reliable messaging, management, WS-Addressing, security, and MTOM) that together form a policy interceptor chain. Each interceptor executes policies of the same type. The security interceptor intercepts and executes security policies, the MTOM interceptor intercepts and executes MTOM policies, and so on.

Policies attached to a client or Web service are executed in a specific order via the Policy Interceptor Pipeline, as shown in the following figure.
When the interceptor encounters a policy that deals with authentication or authorization, it delegates the task to OPSS. If the authentication using OPSS is successful, a security subject with the identity is established. Similarly, processing continues only if the authorization using OPSS for the established identity is successful.

For details about the policy interceptor that Web services in Oracle Fusion applications use, see Securing Web Services Use Cases.

49.1.1.3 Oracle ADF Components and ADF Security

Oracle ADF security framework is the provider of authentication and authorization services to Oracle Fusion Applications. Oracle ADF security is built on top of OPSS architecture, and enables declarative, permissions-based security policies that grant users access to ADF bounded task flows and top-level web pages that use ADF bindings.

By default, ADF application resources are protected and thus require the application developer to configure security policies that grant role-based access privileges to enable access by users. A security administrator combines the declarative security policies with the domain-level policy store and configures a domain-level identity store with application users and role memberships.

At runtime, authenticated users are conferred access rights to the ADF resources by a combination of their role membership and the permission grants they inherit from these role memberships.

Oracle ADF security and Oracle JDeveloper provide the tools to interact with the file-based identity and policy store, as well as the architecture to enforce the security policy definitions on ADF application resources.

Related Links

The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

49.1.1.4 Application Context and Application User Sessions

Application user sessions allow applications to store the security and application context for Oracle Fusion Applications. Session attributes contain common information such as the current user and the user's associated roles, current language, date and number formatting, as well as application-specific attributes.

A session is created after the security subject has been established. In the context of Oracle ADF, a session is created using a filter, while a context is created in Oracle SOA Suite using an interceptor. When a session is created, information about the user's associated roles are stored in the session.

Oracle Fusion Data Security relies on the security context in the session when deciding whether a user is allowed to access particular data. If the session is not established, the user cannot access any secured data.

Application user sessions are associated with pillars and, ideally, there should be only one session per pillar. In the case of Web services, if the client and server are on the same pillar then they share the same session. Subsequently, session context is specific to a particular pillar. That is, everything running on that same pillar should see the same context.

For details about application user sessions, see Implementing Application User Sessions.

49.1.1.5 Oracle Fusion Data Security

Oracle Fusion Data Security implementation is a solution specifically for Oracle Fusion Applications. The security policy definitions for who can access what data are stored in the Oracle Fusion Data Security repository in the Oracle Fusion Applications schema. Oracle Fusion application developers who create new business objects can customize these definitions using Oracle Authorization Policy Manager, which can be accessed by the developer through the Setup and Maintenance work area of any Oracle Fusion Setup application.

Additionally, Oracle Fusion application developers must opt into the Oracle Fusion Data Security definitions in their application. In the context of an Oracle Fusion application, developers who want to require users to have sufficient data privileges can do the following:

- Declaratively enforce security on the entity object level
- Declaratively enforce security on the view object level through view criteria
- Programmatically apply security view criteria
- Programmatically call APIs to check whether a user is authorized to access data or obtain a predicate used to retrieve the data the user is authorized to access

The data security implementation relies on the security context defined in the application user session. Even if OPSS authenticates the user and the security subject is established, the user cannot access any data unless the application user session is established.

For details about Oracle Fusion Data Security, see Implementing Oracle Fusion Data Security.
49.1.1.6 c__2796

Oracle Virtual Private Database (VPD) enables controlling access to data on the database level using security policies associated with database objects. VPD controls access to rows and columns by adding a dynamic WHERE clause to a SQL statement issued against a database object to which an VPD security policy has been applied.

VPD can be useful for enforcing security when a development team must enforce security at the database level. Use VPD when securing Personally Identifiable Information (PII) on the database level, for example.

Using VPD affects performance. As such, make sure to evaluate your performance requirements before implementing the VPD solution.

Related Links

The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For more information about VPD, see the "Using Oracle Virtual Private Database to Control Data Access" chapter of the Oracle Database Security Guide, in the Oracle Fusion Middleware Online Documentation Library.

49.1.1.7 c__2798

Oracle Data Integrator (ODI) is used to move and transform data among systems using specific features for authentication and authorization. Authentication is based on Oracle Platform Security Services (OPSS). Following authentication, processing specific to ODI occurs in which OPSS principals are mapped to definitions stored in ODI to determine identity access rights. The security definitions controlling authorization decisions are stored in an ODI master repository.

Related Links

The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For more information about ODI, see the "Understanding Oracle Data Integrator" part in the Oracle Fusion Middleware Developing Integration Projects with Oracle Data Integrator, in the Oracle Fusion Middleware Online Documentation Library.

49.1.2 Authentication

Oracle Fusion applications reside in containers that automatically handle authentication. The container intercepts all requests entering the system and ensures that users are properly authenticated and the security context propagated.

Invoking the ADF Security wizard when developing an application configures the application to enforce security at runtime.

When a request is received with no subject defined, OPSS creates a subject containing the anonymous user principal and the anonymous role role principal. OPSS is configured by the JPSFilter. With this security subject, unauthenticated users can access public resources. When accessing secure resources, the adfAuthentication servlet forces users to authenticate. The security configuration determines the login module to be used for authentication.

By default, Oracle WebLogic Server is the authenticator used when developing applications with Oracle ADF. Different configurations can also be used, such as an Oracle Single Sign-On solution.
Related Links

The following document provides additional information related to Oracle Fusion Middleware topics discussed in this section:

- For more information about ADF Security, see the “Enabling ADF Security in a Fusion Web Application” chapter of the *Developing Fusion Web Applications with Oracle Application Development Framework*, in the Oracle Fusion Middleware Online Documentation Library.

### 49.1.2.1 Oracle Identity Management Repository

Oracle Identity Management Repository stores users, enterprise roles and their relationships. During development the identities exist in two places; the `jazn-data.xml` file in Oracle JDeveloper and the embedded LDAP of JDeveloper’s Integrated WebLogic Server. In staging environments, these definitions reside in LDAP on standalone Oracle WebLogic Server.

#### 49.1.2.1.1 Users

Test users created during development within Oracle JDeveloper enable testing applications in development. These test users are not migrated with the completed application. Rather, they are for testing purposes only. Enterprise users are added by a system administrator who defines users/groups in the enterprise identity store.

#### 49.1.2.1.2 Roles

Users are not assigned permissions directly, rather access is assigned to roles. Roles group particular permissions required to accomplish a task; instead of assigning individual permissions, roles match users with the permissions required to complete their particular task.

There are two main types of roles, enterprise and application. Oracle Identity Management Repository contains enterprise roles that are available across applications. These are created as groups in LDAP, making them available across applications. Application roles are stored in the application-specific policy store.

Functional roles include job, duty, data, abstract and privilege roles. Role are enforced by a role hierarchy. In Oracle Identity Management Repository, these logical roles are translated into technical Oracle Platform Security Services roles.

#### 49.1.2.1.3 Segregation of Duties

Segregation of Duties (SOD) ensures that no single individual has control over two or more phases of a business transaction or operation. The goal of segregation of duties is to prevent information misuse such that the same user cannot both create and approve transactions.

Oracle Applications Access Controls Governor (AACG) is used to manage, remediate and enforce user access policies. AACG ensures effective segregation of duties at the implementation site.

#### 49.1.2.1.4 File-Based Identity Store

The data in the file-based identity store (`jazn-data.xml` file) is used when authenticating within Oracle JDeveloper running Integrated WebLogic Server. The identity data in the `jazn-data.xml` file should not be synchronized with the identities in the LDAP staging server. By default, the deployment configuration disables data synchronization between the `jazn-data.xml` file and the LDAP server. This setting should not be modified.
49.1.2.1.5 File-Based Policy Store

The data in the file-based security policy store (jazn-data.xml file) is used when authorizing within Oracle JDeveloper running Integrated WebLogic Server. Changes to the security policies in the jazn-data.xml file must be migrated to the LDAP staging server by a security administrator. By default, the deployment configuration disables data synchronization between the jazn-data.xml file and the LDAP server. This setting should not be modified.

49.1.2.1.6 ODI

ODI has its own concept of identities such as ODI role and stores in the ODI schema. For authentication, OPSS is used and the OPSS principals are mapped to the ODI identities.

49.1.2.2 Identity Propagation

Identity propagation is a fundamental requirement for securing Oracle Fusion Applications. It provides that the same user identity is visible across different processes and technologies boundaries. While there some cases where the identity is implicitly propagated, in several scenarios explicit configuration is required.

Web Services and SOA

In the case of Web services and SOA applications, you can propagate identities by attaching Oracle Web Services Manager policies to the client and service. When a client sends a request to a service, a policy interceptor intercepts the request. On the client side, the policy interceptor packages the identity to be transported according to the policy attached to the client. On the service side, the interceptor processes the request based on the policy and delegates authentication to Oracle Platform Security Services. If the authentication succeeds, a security subject with the identity is established.

Remote Method Invocation (RMI)

The executing user is automatically propagated when using RMI. If a different identity than the executing user needs to be propagated, it has to be explicitly passed through Java Naming and Directory Interface (JNDI) context.

Oracle WebCenter Portal

Oracle Fusion applications deploy Web Services for Remote Portlets (WSRP). As Web services, they rely on Oracle Web Services Manager for Identity Propagation.

Oracle Data Integrator (ODI)

In a OPSS-enabled environment, ODI authentication happens in two phases.

The following figure depicts the first phase is OPSS authentication, during which time a subject is created using the OPSS framework. The second phase is the ODI authentication itself, which is based on the previously created subject. ODI lists the ODI roles having one or more OPSS principals of the subject as members. Users will need to choose one ODI role from here. ODI will then create an ODI security token based on this role. This ODI security token contains an ODI role and the list of principals associated with the current OPSS subject.
Application Identity

There are several Fusion Web application use cases in which privilege elevation is required. For example, when creating a new employee record, a new Trading Community Architecture (TCA) party record must be created. However, the identity of the user creating the employee has only employee creation privileges. A service must be invoked with temporarily elevated privileges to create the required party and complete the process. To enable privilege elevation, you can switch the identity of the invoker to a common identity with a higher level of access.

Audit Identity

When switching to the application identity, you must propagate the identity to be audited to preserve the submitting identity for auditing purposes.

Auditing is based on who columns, which are populated with session data. When the session is established, it is initialized using the current identity. The session APIs expose a method to manipulate the identity to be used for auditing. This method allows teams to control which identity is stored as the audit identity. The following example illustrates the syntax of this method.

The session is not propagated, rather only the identity is propagated. As the session is initialized using the identity, any application specific values are lost. To prevent this, you must pass the audit identity and override the audit identity on the session.

It is recommended for the service provider to add an extra parameter to the service so as to store the original user ID (historyOverrideUserName, of type String). In order to invoke the service, the service method consumer must fill in the original user ID as part of the payload. Within the service, the value passed is populated on the session as shown in the following example.
Example 49-1  Controlling Which Identity Is Stored as the Audit Identity

ApplSession.setHistoryOverrideUserName()

Example 49-2  Storing the Original Identity

ApplSession session = ApplSessionUtil.getSession();
if (session != null)
  session.setHistoryOverrideUserName(historyOverrideUserName);

49.1.2.3 Application User Session Propagation

Application user sessions are associated with pillars and, ideally, there should be only
one session per pillar. In the case of Web services, if the client and server are on the
same pillar then they share the same session. Subsequently, session context is specific
to a particular pillar. That is, everything running on that same pillar should see the
same context.

49.1.3 Authorization

Authorization ensures that users only have access to the resources to which they have
been granted access. Authorization decisions are based on policies stored in a policy
store. There are two main types of policy stores: OPSS application security repository
and Oracle Fusion Data Security repository. The OPSS repository contains the security
definitions that control access to applications. The Oracle Fusion Data Security
repository contains the security definitions controlling data access.

49.1.3.1 OPSS Application Security Repository

The enterprise security administrator exports the OPSS application security repository
to the jazn-data.xml file policy store. The security definitions in these repositories
control access to application functions. The policies defined in the jazn-data.xml
file are used during development. For testing and implementation, the file-based
policy store content is migrated into LDAP.

Policy Store Content

Enterprise security administrators are responsible for managing application security
policies. Oracle Fusion Applications developers can add new application security
policies, but must not modify existing application security policies.

Roles

The jazn-data.xml file identity store contains the application roles specific to a
given application. These roles are not visible outside the application. The policies are
created against an application role. Permissions are grouped into a permission sets for
administrative purposes. And permission sets are granted to the application roles.
Developers must not allowed to modify role hierarchy or remove privileges defined
by the permission sets granted to existing application roles.

Design Time

During development, you can interact with the jazn-data.xml file policy store
using the tools and user interfaces provided in Oracle JDeveloper.

Runtime

When Oracle ADF security is enabled in an application, the Web container uses the
policies in OPSS application policy store for authorization. Oracle ADF security
enforcement logic checks whether the user, represented by the JAAS subject, has the
correct permissions to access the resource.
The subject contains the user's principals, which include a user principal with the user's name and list of role principals, as well as enterprise roles and application roles obtained from the policy and identity stores. The principal is created to represent all of the user's memberships in application roles defined in the policy store. In turn, each application role may have multiple granted permissions in OPSS application policy store.

At runtime, the page context determines whether the current user has view permissions for the page being accessed. If the page includes an activity of a bounded task flow, the task flow controller determines the permissions. If the page is a top-level page with an associated page definition file, the Oracle ADF model determines the permissions for the page.

The OPSS service provider interface checks whether the subject includes the roles with the relevant permissions required to access the page. If the user is authorized to access the page, then the task flow is initiated. If the user is not authorized, ADF Controller throws an exception and passes control to an exception handler specified by the task flow configuration.

It is also possible to include an API that checks whether the current user has access to a resource.

Developer created additions to the policy store must be migrated to LDAP by a security administrator.

49.1.3.2 Oracle Fusion Data Security Repository

Oracle Fusion Data Security repository is used to control access to data.

Policy Store Content

Enterprise security administrators are responsible for managing data security policies. Oracle Fusion Applications developers can add new data security policies, but must not modify existing data security policies.

For more information about Oracle Fusion Data Security, see Implementing Oracle Fusion Data Security.

Design Time

During development, developers can interact with the Oracle Fusion Data Security repository through the Oracle Authorization Policy Manager.

Runtime

Data security relies on session information for the user identity. When a user session is created at runtime, the user information for that session and the flattened list of roles for the user are propagated to the database. This information is used to identify the user and the user's access level based on the policies in Oracle Fusion Data Security repository.

Data security is not automatically enforced, rather developers must enforce data security either declaratively on the entity object or view object, or programmatically, using API calls.

49.2 Authentication Techniques and Best Practices

There are some cases in which you must implement authentication from an external source or using a different identity. You can implement authentication using APIs, Expression Language or a non-browser based login.
49.2.1 API Support for Authentication

You can implement authentication by using user and role APIs.

**Related Links**
The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For more information, see the Developing with the User and Role API section of the *Oracle Fusion Middleware Securing Applications with Oracle Platform Security Services* guide, in the Oracle Fusion Middleware Online Documentation Library.

49.2.2 Expression Language Support for Authentication

You can use Expression Language (EL) to access security context information for authenticated users. Some useful expressions are as follows:

- `securityContext.userName`
- `securityContext.authenticated`
- `securityContext.userInRole`
- `securityContext.userInAllRoles`
- `securityContext.userGrantedPermission`
- `securityContext.userGrantedResource`
- `securityContext.taskflowViewable`
- `securityContext.regionViewable`

Note that decisions about user’s access rights should not rely on the user’s role information since role definitions may be changed. Instead access should be based on available permissions.

**Related Links**
The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For more information about ADF Security-based EL utility methods, see the "Enabling ADF Security in a Fusion Web Application" chapter of the *Developing Fusion Web Applications with Oracle Application Development Framework*, in the Oracle Fusion Middleware Online Documentation Library.

49.2.3 Non-browser Based Login

For information about using non-browser based security, see the "Securing Your Integrated Excel Workbook" chapter of the *Developing Applications with Oracle ADF Desktop Integration*, in the Oracle Fusion Middleware Online Documentation Library.

49.3 Authorization Techniques and Best Practices

Authorization is implemented using function security policies that control access to application functions. At the most fundamental level, authorization is based on standard JAAS (Java Authentication and Authorization Services) permissions and
OPSS permission sets (also called entitlements) which may be granted to secure specific application artifacts. Oracle ADF defines the JAAS permissions needed to secure certain Oracle ADF application artifacts, including ADF bounded task flows and, in the case of top-level web pages, ADF page definitions files.

49.3.1 Function Security

Security is automatically enforced on all ADF bounded task flows and top-level web pages that use ADF bindings and are not contained in a bounded task flow.

Security is not automatically enforced on Web service methods. You can use API calls to define permissions in the policy store and enforce security based on these permissions.

Implementing function security requires the following main steps:

1. Consult a security administrator to export all predefined function security policies of the application that you are customizing into a jazn-data.xml file.

2. Enable ADF Security for the application by running the Configure ADF Security wizard. This action updates the web.xml file with ADF Security configuration details and generates a temporary jazn-data.xml file.

3. Copy the exported jazn-data.xml file into the application workspace to overwrite the temporary file generated by the Configure ADF Security wizard.

4. Create an entitlement to group one or more ADF resources and their corresponding actions to entitle end users to access the resource.

5. Grant the entitlement to a custom duty role that was added to the Oracle Fusion application policy store.

After running the ADF Security wizard, any web page associated with a bounded ADF task flow will be protected. Therefore before running the application and testing security, developers must first create security policies that grant end users access.

For more information, see Implementing Function Security.

49.3.1.1 Resource Entitlements and Permissions

In general, the JAAS permission determines the allowed operations that the end user may perform on the application resource. However, from the standpoint of Oracle Fusion Applications, end users typically need to interact with multiple resources to complete the duties designated by their provisioned roles. To simplify the task of creating function security policies, developers work with entitlement grants (defined as OPSS permission sets) to grant privileges to access a variety of securable resources, including ADF task flows, Web services, and SOA work flows to a role.

Developers use the Oracle JDeveloper to create the entitlements (with one or more resource-action pairs) and then grant one or more entitlements to the desired application roles (the grantee).

For details about creating entitlement-based security policies, see Implementing Function Security.

Task flow, page definition, and Web service resource permissions are tightly coupled with code artifacts. These permissions are assumed to be associated with concrete code artifacts. In some circumstances, permissions are required, but no code artifacts exist with which the permissions could be associated. For example, suppose the same page is used to view and update tasks. The same code artifact is used for both actions such
that one cannot control access to both view and update tasks separately. Resource permissions enable creating abstract permissions which can be referred to with API calls.

Related Links
The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

• For details about resource permissions and using APIs, see the "Understanding Security Concepts" part in the Oracle Fusion Middleware Applications Security Guide, in the Oracle Fusion Middleware Online Documentation Library.

49.3.1.2 Expression Language Support for Authorization
You can use Expression Language to access security context information to determine the access rights of the authenticated user. Following are some useful expressions:

• securityContext.taskflowViewable
• securityContext.regionViewable
• securityContext.userGrantedPermission

Related Links
The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

• For more information about ADF Security-based EL utility methods, see the "Enabling ADF Security in a Fusion Web Application" chapter of the Developing Fusion Web Applications with Oracle Application Development Framework, in the Oracle Fusion Middleware Online Documentation Library.

49.3.2 Data Security
Implementing data security requires the following main steps:

1. Use Oracle Authorization Policy Manager to create security definitions based on the Oracle Fusion Data Security model. This step is common, regardless of the technology being used.

2. Refer to these security definitions from the code artifacts. This step varies depending on the technology used, as well as the functional requirements of the application.

For more information about implementing Oracle Fusion Data Security, see Implementing Oracle Fusion Data Security.

Related Links
The following document provides additional information related to Oracle Fusion Applications topics discussed in this section:

• For more information about using Oracle Authorization Policy Manager, see the "Using Oracle Authorization Policy Manager" chapter of the Administrator’s Guide.

49.3.2.1 API and Expression Language Support for Data Security
For information about using APIs and Expression Language to secure data, see Implementing Oracle Fusion Data Security.
49.3.2.2 Personally Identifiable Information

PII (Personally Identifiable Information) is any information that can be used to uniquely identify a person. This information is considered sensitive and must be protected from misuse for the purposes of legal regulation, financial liability and personal reputation. For example, only authorized users should be allowed access to the social security numbers of people stored in a system. PII authorization is only implemented on data identified by the PII working group in the data privacy Oracle Fusion uptake document.

PII authorization is implemented using one or more of the following technologies:

- OPSS Keystore APIs for encryption and decryption
- Oracle Fusion Data Security
- Oracle Virtual Private Database for row and column level security

The security requirements for the PII attribute determine the technologies to be used.

Related Links

The following document provides additional information related to Oracle Fusion Applications topics discussed in this section:

- For more information about OPSS encryption/decryption APIs, see the Oracle Fusion Middleware Securing Applications with Oracle Platform Security Services guide, in the Oracle Fusion Middleware Online Documentation Library.
- For more information about using VPD to control data access, see the Oracle Database Security Guide, in the Oracle Database Server Online Documentation Library.

49.3.2.3 Data Role Templates

Installations of Oracle Fusion Applications may require a large number of roles that must be provisioned. For data security purposes, it is often necessary to create the roles as the data security rules are not known at design time.

For more information regarding data role templates, see the product-specific security guides.

49.4 Learning More About Technologies Used to Secure Oracle Fusion Applications

The following resources within this book provide details about implementing Oracle Fusion Data Security and user sessions, and how to secure specific use cases for Oracle ADF application artifacts, Web services, and portlet applications.

- Oracle Fusion application user sessions. For more information, see Implementing Application User Sessions.
- Oracle Fusion Data Security policies for data security. For more information, see Implementing Oracle Fusion Data Security.
- Oracle Fusion Applications security policies for function security. For more information, see Implementing Function Security.
- Oracle WSM policy interceptors. For more information, see Securing Web Services Use Cases.

- Oracle Identify Management. For more information, see:

  Oracle Fusion Middleware Developing and Customizing Applications for Oracle Identity Manager.

- Oracle portlet services. For more information, see Securing End-to-End Portlet Applications.

Additionally, for information about security and extending Oracle Fusion applications, see the Oracle Fusion Applications Extensibility Guide for Developers.

**Related Links**

The following resources provide additional information about Oracle Fusion Middleware key security technologies and features used by Oracle Fusion Applications.

- Application resources including ADF task flows, ADF components, and ADF Business Components. For more information, see:

  Oracle Fusion Middleware Developing Fusion Web Applications with Oracle Application Development Framework, in the Oracle Fusion Middleware Online Documentation Library.

- Oracle Platform Security Services (OPSS) and identity providers (including the LDAP-based provider and the file-based provider (`jazn-data.xml` file)). For more information, see:

Implement Oracle Fusion Data Security

This chapter describes how to use Oracle Fusion Data Security to enforce security authorization for access and modification of specific data records in an Oracle Fusion application.

This chapter includes the following sections:

- Introduction to Oracle Fusion Data Security
- Managing Data Security Artifacts in the Oracle Fusion Data Security Policy Tables
- Integrating with ADF Business Components
- Using Oracle Fusion Data Security to Grant Access to Secured Business Objects
- Getting Security Information from the Application User Session Context
- Understanding Data Security Performance Best Practices
- Validating Data Security with Diagnostic Scripts
- Integrating with Data Security Task Flows

50.1 Introduction to Oracle Fusion Data Security

Oracle Fusion Data Security is the technology that implements data security in Oracle Fusion Applications and is not used by function security (Oracle Platform Security Services (OPSS) is used for function security). Oracle Fusion Data Security integrates with Oracle Platform Security Services (OPSS) by granting actions to an OPSS principal. The grant defines who (the principal) can do what (the actions) on a given resource. A grant in Oracle Fusion Data Security can use any enterprise user or enterprise group as principals. Oracle Fusion Data Security assumes that the connection or session provided to it has been initialized properly with the appropriate user session user context, as described in Implementing Application User Sessions.

Note:

In this chapter, the user session is specifically an application user session (ApplCore). The application user session is the session that Oracle Fusion Data Security expects to see.

The goal of Oracle Fusion Data Security is to authorize a user to perform specified actions on selected data. It can secure rows and attributes of a database object and relies on OPSS to provide the authentication services for OPSS principals (users, groups, or roles). It answers the question "Who can do what on which set of data". 
**Who** refers to the OPSS user or group (or role), **what** is the action, and **which** is the subset of data that can be accessed.

You can use Oracle Fusion Data Security to either restrict the rows that are returned by a given query based on the intended business operation or you can restrict the actions that are available for a given row.

The purpose of data security is to model and enforce security authorization for a specific data record or a set of records. Data security provides access control within Oracle Fusion applications on the data a user can access and the actions a user can perform on that data. Oracle Fusion application rely on data security to restrict access to individual data that is displayed on a page that may display after the user has selected a menu or menu option.

The following are some use cases where Oracle Fusion Data Security can be utilized:

- Grant read action on expense reports to managers of the current employee when the manager is granted Expenses Administrator role.
- Administer the list of documents available to an end user in a Document Management System (DMS) based on Document Categories.
- Show the list of Sales Opportunities available to a Sales Head of an organization based on region.
- Allow a Human resources (HR) Benefits Administrator to only administer the employees whose last name begins with A-F.
- Allow a HR Administrator to only administer the employees in a given region.

In Oracle Fusion Data Security, data that must be secured is identified as resources. These resources are database tables or views. Policies that control which data that a user has access and can perform actions, can be made on a row instance or condition. The following figure illustrates the logical data model implemented by Oracle Fusion Data Security.

**Figure 50-1  Oracle Fusion Data Security — Logical Data Model**

An *instance* is a row of data and is identified by the primary key value of the row in the resource's storage table. A *condition* is a group of row instances whose membership is determined by a rule in the form of a SQL predicate, which must be applicable to the WHERE clause of a single-table query against the resource's storage table.

For example, each row in the Purchase Order table is an instance of the Purchase Order resource. The purchase order number is the primary key that identifies a particular purchase order instance. You can create an condition with the predicate "PO_NUMBER=100", which contains just one row of data. Purchase orders from the
West region can be put into a condition that is defined by the predicate "REGION='WEST'". A condition that contains all the rows of data in the resource's storage table can be defined by the predicate "1=1".

Memberships of a condition are dynamic in many ways, such as:

- Condition membership rules may contain any valid SQL attributes, such as columns of a table. Adding new instances or updating existing instances may affect the membership of a condition. Using the above Purchase Order example, if the predicate is "REGION='WEST'", new purchase orders in the region of West will automatically become a member of the condition.

- When an action is granted to an OPSS application role (also called a duty role by Oracle Fusion Applications) on a condition it can be parameterized. Using the Purchase Order example, the condition may be defined by the predicate "REGION=&PARAM" where the parameter PARAM is associated with different regions. When an action is granted on a condition, it may be done for a particular value of the parameter, such as a sales manager in the West region may have an action granted on a Region condition with the parameter value West.

- The condition rules may not reveal any membership at all. It can just be a WHERE clause to filter rows based on runtime user session variables.

To grant data security actions to a user, you must first identify the resources that you want to secure, define conditions on those resources, and then grant specific actions on these conditions to the application role to which the user belongs.

For additional information about Oracle Fusion Data Security, see the product-specific security guides.

The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For additional information about OPSS, see the Oracle Fusion Middleware Securing Applications with Oracle Platform Security Services guide, in the Oracle Fusion Middleware Online Documentation Library.

50.1.1 Terminology

**Resource**: A resource on which data security is enforced, such as a purchase order. Resources are stored in the Oracle Fusion Applications FND_OBJECTS table. Note that Oracle Fusion Applications database tables are sometimes called FND tables, where FND refers to resources in the "foundation" tables.

**Instance**: A particular item of an resource, such as PO_NUMBER 100. An instance generally corresponds to a row in the database. Row instances have one or more primary key values.

**Condition**: A group of row instances that are determined by a SQL predicate (WHERE clause expression) that queries the attributes of the resource itself. The WHERE clause can reference values from the database context to implement relative conditions where the condition members depend on the security context of the current user. The conditions may also be parameterized, meaning that the WHERE clause references PARAMETER values from the policies for parameterized conditions, as described in How to Use Parameterized Conditions When Securing a Business Object.

Conditions are stored in FND_OBJECT_INSTANCE_SETS table.
**Action:** Secures an action (also called a function, privilege, or permission) that can be performed on a resource. You typically build features using multiple implementation strategies, including various ADF Business Components operations through Java code. These features must be secured to prevent unauthorized execution of the code. These features generally perform events on resources and actions and they are the artifacts used to secure these events. Actions are stored in `FND_FORM_FUNCTIONS` table, and the action names within the table are not unique. Only an action used in combination with a resource is unique.

**Aggregate Action:** A group of actions. Roles specify the combination of actions necessary to perform a particular role on a row instance. For example, a Project Administrator role may include the View, Update, Slip, and Delete actions and a Project Worker role may include only the View and Update actions. Aggregate actions (also called a menu) are stored in `FND_MENU` and `FND_MENU_ENTRIES` tables.

**Principal (Grantee):** A user or a role in Oracle Platform Security Services (OPSS) to which Oracle Fusion Data Security has a reference. The grantee key in the `FND_GRANTS` table holds the GUID of the OPSS user or role.

**User (OPSS User):** Any person or application that accesses information in the database.

**Role (OPSS Role):** Composed of users, groups, and possibly other roles. Roles are used to associate users with actions.

**Policy:** Authorization for the grantee (OPSS user or role) of an aggregate action may be done on the specified row instance, all instances, or condition. The condition for a policy may be static or parameterized. A policy logically joins a principal, aggregate action, and condition. This has the following effects:

- Any action granted on a row instance implies that the Oracle Fusion Data Security runtime system always has the ability to query the instances. This can be used by a standard Virtual Private Database (VPD) policy function to provide default query filtering. However, this does not mean that you have the ability to view or query because the ability to view a row of the resource is secured by an action.

- In the context of a specific row instance, the policies specify the set of actions that can be performed on a data record.

Resource access can be tested using the Oracle Fusion Data Security authorization checking API. Policies are stored in `FND_GRANTS` table.

**VPD - Virtual Private Database:** Provides the ability to dynamically attach a predicate at runtime to all queries issued against a database object (table or view). This feature is available in Oracle RDBMS. For more information about implementing VPD, see Integrating Oracle Fusion Data Security with Virtual Private Database (VPD).

**Security Policy Function:** A PL/SQL function developed to return a predicate added by VPD to a query. This function is bound to a table or view for some or all of DML statement types: SELECT, INSERT, UPDATE, DELETE.

### 50.1.2 Integrating Oracle Fusion Data Security with Oracle Platform Security Services (OPSS)

When integrating Oracle Fusion Data Security with Oracle Platform Security Services (OPSS) to support making policies to OPSS principals, it is important to understand that OPSS principals may be defined in third-party systems and this data does not exist in the database. Only the necessary information (user/user-role mapping) for the
current user session is propagated to the database at runtime during session creation to determine the various actions granted for that user session.

At runtime when a user session is created, the user information for that session and the flattened list of roles (to include role hierarchies) for the user of that session is propagated to the database. The roles available in a user session may be different from all the roles that a user may potentially have based on the authentication mechanism used, such as password vs. biometrics, authentication level of DMZ vs. non-DMZ, and so on. OPSS principal information is not stored in the Oracle Fusion Data Security schema.

50.1.3 Integrating Data Security Task Flows into Oracle Fusion Functional Setup Manager

Every Oracle Fusion application registers ADF task flows for setup activities with a product called Oracle Fusion Functional Setup Manager. These task flows are available from the Fusion Applications Setup and Maintenance work area and enable customers and implementers to set up and configure business processes and products. For more information about data security tasks, see the product-specific security guides.

If data security task flows are used in a web application, that web application must be configured to use ADF Security to enable authentication and authorization so that the correct data security predicates are generated.

Additionally, ADF Security controls access to a specific task flow, and users who do not have the required permission cannot view the task flow. For more information about how to implement function security permissions and roles, see Implementing Function Security.

The following table lists the task flows and their parameters.

<table>
<thead>
<tr>
<th>Task Flow Name</th>
<th>Task Flow XML</th>
<th>Parameters Passed</th>
<th>Behavior</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Manage Database Resource</td>
<td>/WEB-INF/oracle/apps/fnd/appcore/dataSecurity/ui/taskflow/CreateDBResourceTF.xml</td>
<td>mode = edit dbResourceId</td>
<td>Goes to the Conditions tab of the database resource Edit page.</td>
<td>Conditions are a child entity of database resource. There is no Search page for conditions across all database resources; therefore, DB resource ID is mandatory.</td>
</tr>
<tr>
<td>Task Flow Name</td>
<td>Task Flow XML</td>
<td>Parameters Passed</td>
<td>Behavior</td>
<td>Comments</td>
</tr>
<tr>
<td>----------------</td>
<td>---------------</td>
<td>------------------</td>
<td>----------</td>

<tr>
<td>Manage Database Resource Actions</td>
<td>/WEB-INF/oracle/apps/fnd/appcore/dataSecurity/ui/taskflow/CreateDBResourceTF.xml</td>
<td>mode = edit, dbResourceId, panelTab = actions</td>
<td>Goes to the Actions tab of the database resource edit page.</td>
<td>Actions are a child entity of database resource. There is no Search page for actions across all database resources; therefore, DB resource ID is mandatory.</td>
</tr>
<tr>
<td>Manage Policy</td>
<td>/WEB-INF/oracle/apps/fnd/appcore/dataSecurity/ui/taskflow/PolicyTF.xml</td>
<td>grantGuid (optional), dbResourceId (optional), appId (optional), roleName (optional)</td>
<td>This is the Create/Edit Policy page</td>
<td>There is no Search here, except to pick a specific database resource and pick a specific role.</td>
</tr>
</tbody>
</table>

### 50.1.4 Integrating Oracle Fusion Data Security with User Sessions

Oracle Fusion Data Security integrates with user sessions and relies on session context to be implemented properly.

For information about implementing user sessions, see Implementing Application User Sessions.

If a session has been created successfully, you will see the session created in the FND_SESSIONS table and the user session roles in the FND_SESSION_ROLES view.

When making policies to an OPSS principal, the GRANTEE_KEY must be a valid User / Role GUID as identified in the jazn-data.xml file. At runtime, the list of roles available to the user is determined by the roles granted to the user in the jazn-data.xml file and is populated in the FND_SESSION_ROLES view.

### 50.1.5 Integrating Oracle Fusion Data Security with Virtual Private Database (VPD)

Note that integrating with VPD is optional.

The database has a feature called Virtual Private Database (VPD). VPD allows an arbitrary WHERE clause to be appended to a table, view, or synonym. By doing so, the WHERE clause restricts the rows available. A PL/SQL function is written that returns the WHERE clause and a VPD policy is enabled on a particular table, view, or synonym that references that policy function. VPD policy functions based on fnd_data_security.get_security_predicate() are used to enforce data security rules.
Note:
If the base table holds PII data (personally identifiable information), the VPD policy must be created on the table and not on a view or synonym. If the policy is created only on a view or synonym, there is no protection against users accessing PII data from SQL*Plus. Setting the policy on the base table ensures that any PII data cannot be accessed by unauthorized users.

To integrate with VPD:
1. Create an action.
   Use Setup and Maintenance - Manage Data Security Policies UI to create an action on the database resource that you want to secure.

2. When the base table contains no PII data, create a view or synonym.
   If the table contains PII data, you will add the VPD policy directly to the table. Otherwise, create a view or synonym with the exact same name as the action.

3. Add a VPD policy to the table or view.
   Add a VPD policy in the database that will associate the policy function with the table or view.

   At runtime, in LOVs or UIs, wherever you want to display the rows that the user has select access to, they simply select off that view.

50.2 Managing Data Security Artifacts in the Oracle Fusion Data Security Policy Tables
Oracle Fusion Data Security artifacts include resources, row instances, conditions, actions, aggregate actions, and so on. Data security artifacts are stored in the Oracle Fusion Data Security repository and are customized using Oracle Authorization Policy Manager, which can be accessed by the developer through Oracle Fusion Functional Setup Manager, from the Manage Data Security task available in the Setup and Maintenance work area of any Oracle Fusion Setup application.

Note:
After the developer selects the Manage Data Security task in Oracle Fusion Functional Setup Manager, the environment redirects to the data security customization user interface provided by Oracle Authorization Policy Manager. In this document, although the data security customization tool is identified as Oracle Authorization Policy Manager, be aware that the tool must be accessed through Oracle Fusion Functional Setup Manager.

For details about creating and editing policies, see the "Managing Data Security Policies" topic in the Oracle Authorization Policy Manager online help. For supplemental task instructions, see the "Customizing Security for Oracle ADF Application Artifacts" chapter of the Extensibility Guide for Developers.
50.2.1 How to Get Started Managing Data Security

The user who logs in to view and manage database resources and policies must be authorized based on one of the roles described in Table 50-2.

Use cases:

- Application developer must be able to manage database resources for all Oracle Fusion resources.
- Product-family administrator must be able to manage only the database resources for their specific product family.

To use the standard Application Developer role:

The Oracle Fusion reference implementation predefines an Application Developer job role that inherits all the roles described in Table 50-2. You must contact a system administrator for Oracle Fusion Human Content Management (HCM) and request to be provisioned with the Application Developer job role. During the role provisioning process, you will be notified about the details of your account and password.

- Login to Functional Setup Manager with your account user name and password.

Alternatively, to use your own Product Family Administration role:

For example, if you have a CRM product family administration role, you must be able to manage the CRM database resources, but you will not be allowed to access the HCM resources.

If you have your own Product Family Administration role:

1. In Oracle Authorization Policy Manager, login as the user who is assigned to the appropriate duty role for your product family.

2. Inherit the appropriate duty role for your product family from the duty roles listed in Table 50-2.

3. Define the relationship between duty role and enterprise role.

How Oracle Authorization Policy Manager supports managing policies for database resources:

1. Oracle Fusion Applications delivers the duty roles and policies as specified.

2. Oracle Authorization Policy Manager authors enterprise roles and maps the duty roles listed in Table 50-2. A security manager uses Oracle Authorization Policy Manager to define the relationship between a duty role and enterprise roles.

3. A security manager can create their own enterprise roles if required. They can determine which database resources can be managed by specific data security administrators by including the duty roles into their custom enterprise roles. Security managers are expected to use Oracle Authorization Policy Manager to perform enterprise role to duty role mapping.

4. Policies runtime is based on role GUIDs only.

Reasoning:

Data security policies are granted to duty roles as the default approach. This makes it possible for the security manager to quickly assemble the duties to an enterprise role and use the Oracle Fusion reference implementation quickly. Granting them to an
enterprise role means that the security manager must duplicate the policies to any new enterprise roles they create. Enterprise roles are highly guarded and should be created and used only if absolutely needed.

50.2.2 What You May Need to Know About Administering Oracle Fusion Data Security Policy Tables

The data security administration UI is secured so that only administrators are permitted to create and manage security policies.

Note:
You cannot view the database resources or manage policies from the Functional Setup Manager if you have not been granted the appropriate data security manage permissions. Contact your security administrator for details.

The following table lists the duty roles that have been predefined by the Oracle Fusion security reference implementation to allow users to manage data security. These roles are administered at the product family level to manage resources and policies for that specific product family. The security reference implementation provides role-based access control in Oracle Fusion Applications, and is composed of predefined security policies that protect functions, data, and segregation of duties. Note that the table also identifies the duty roles associated with Oracle Authorization Policy Manager (APM) which allow developers to manage product family data security policies using the Manage Data Security Policies task.

Table 50-2 Duty Roles to Manage Data Security Policies

<table>
<thead>
<tr>
<th>#</th>

</table>

50.3 Integrating with ADF Business Components

In Oracle Fusion applications, the data to be secured is typically defined in the application’s data model project by an ADF Business Components entity object. Oracle Fusion Data Security integrates with ADF Business Components so that when you are defining an ADF Business Components entity object you can:

- Identify the actions that are available on a given row
- Have the ability to check at runtime if the user has access to this row based on the policies that are available to that user.
At runtime, authorization check is done automatically by ADF Business Components for standard operations that the Oracle Fusion application developer has declaratively enabled for business components, such as read, update, and removeCurrentRow. To perform a security check on non-standard operations you must call Oracle Fusion Data Security APIs directly.

Developers declaratively enable security for the desired operations on the ADF Business Components entity objects of their data model project. You may not identify operations directly on an ADF Business Components view object; however, when a view object references an entity object whose operations have been secured, the entity security policies also apply to the view object. In this regard, application developers must opt into security for individual business objects.

Oracle Fusion Data Security provides an implementation of a data security provider interface defined by ADF Business Components to perform the authorization check. The ADF Business Components data security provider interface provides a mechanism to filter rows based on a permission and to perform permission checks for certain actions. At runtime, Oracle Fusion Data Security uses an implementation of this interface to secure access to ADF Business Components entity objects and view objects.

50.3.1 How to Configure the ADF Data Model Project

To make the Oracle Fusion Data Security Provider as your data model project's data security provider, you can edit the Oracle Fusion application's adf-config.xml file to define the dataSecurityProviderClass attribute for the sec:JaasSecurityContext element, as shown in the following example.

For example, the adf-config.xml file would contain the sec:JaasSecurityContext element definition shown in the following example.

In Oracle JDeveloper, the design time tools for ADF Business Components are shaped so that the Oracle Fusion Data Security Provider will be automatically registered as the default when you launch JDeveloper with the Oracle Fusion Applications Developer role selected. This occurs when the developer runs the Configure ADF Security wizard for the ADF data model project.

At runtime, the ADF Business Components invocation of Oracle Fusion Data Security Provider happens automatically only for standard operations that have been enabled for entity objects of the data model project. For custom operations that are available on the entity object, you must invoke the Oracle Fusion Data Security authorization checking API manually, as described in How to Perform Authorization Checks for Custom Operations.

There may be other reasons to invoke Oracle Fusion Data Security APIs manually to determine the SQL predicate for a given action or to do an authorization check. For example, you might query VPD policies written based on fnd_data_security.getSecurityPredicate() to enforce data security rules.

Example 50-1 Making the Oracle Fusion Data Security Provider the Data Security Provider

dataSecurityProviderClass="oracle.apps.fnd.appcore.dataSecurity.util.FndDataSecurityProvider"

Example 50-2 sec:JaasSecurityContext Element Example

50.3.2 How to Secure Rows for Read, Update and Delete Access

At design time, you secure the read, update, and delete operations on a given entity object using Security section in the General page of the entity object overview editor. The overview editor exposes a set of standard operations (read, update, removeCurrentRow) as checkboxes that you can select. Until you select these operations, read, update, and delete access will not be enforced and therefore rows queried by entity-based view objects will remain accessible to users. Thus, to secure rows of data, the application developer must opt into security by enabling security for the standard row-level operations on the entity object, as shown in the following figure.

![Entity Object Overview Editor — Security Section](image)

To secure the entity object standard operations:

1. In the Application Navigator, double-click the entity object.
2. In the overview editor for the entity object, click the General navigation tab and expand the Security section.
3. In the Security section, select the operations that you wish to secure: read, update, or removeCurrentRow.

Note that the entity object permission class oracle.adf.share.security.authorization.EntityPermission defines the permissions read, update, and delete, which correspond to the operations read, update, removeCurrentRow, respectively.

50.3.3 How to Secure Rows for Custom Operations and Specific View Objects

Certain situations exist where it is preferable to secure operations at the level of view objects instead of a single entity object which protects access from all view objects derived from the entity object. In this sense, security at the level of view objects...
provides a more granular level of access control. Additionally, in cases where custom action checks needs to be performed, it is necessary to secure the view instance by applying a named view criteria defined for the purpose.

In the case of securing rows at the level of specific view objects, you use the View Criteria section of the General page of the overview editor for the view object to create the named view criteria. The following figure shows a view criteria that has been added in the overview editor for the view object.

**Figure 50-3  View Object Overview Editor — View Criteria Selection**

Once you have defined the view criteria, you must apply it to the view instance that you want the application module data model to filter, as described in the following procedure.

**To secure rows displayed to a user from a view object for a custom action:**

1. In the Application Navigator, double-click the view object that you will use to filter the rows.

2. In the overview editor, click the **Query** navigation tab and expand the View Criteria section, then click **Create New View Criteria** to add a view criteria.

3. In the Create View Criteria dialog, create a named view criteria with no view criteria items and name the view criteria using the following format:

   \[\text{FNDDS__permissionName__objectName__objectAlias}\]

   where:

   - **permissionName** is the permission name that is used to filter the data.
   - **objectName** is the name of the secured database resource in the **FND_OBJECTS** table.
   - **objectAlias** is optional and is the alias for the resource.
Note:
The delimiter is "__" (double underscore characters). This is because no other special character is allowed in a view criteria name.

4. Select **Both** for the **Query Execution Mode**, as shown in the following figure (note that no criteria items are defined).

   The query execution mode for the data security view criteria must be set to **Both**. If you leave the default setting **Database** selected, then the ADF Business Components association consistency feature will not work properly.

   ![Edit View Criteria Dialog](image)

   **Figure 50-4  Edit View Criteria Dialog**

5. In the application module overview editor, select the **Data Model** navigation tab and select the view instance to filter, then click **Edit** to apply the view criteria, as shown in the following figure.

   Alternatively, you can apply the view criteria at runtime in your code by calling the view object's `applyViewCriteria(viewCriteriaName)` API.
50.3.4 What You May Need to Know About Naming Actions

This means that when you define actions in Oracle Fusion Data Security, the actions for those business objects must be named as read, update, or delete to correspond to the entity object security operations that get enabled. Note that the action name corresponding to the removeCurrentRow operation is identified as delete by Oracle Fusion Data Security.

Similarly, when you create custom actions in Oracle Fusion Data Security, the action name that you define must match the custom action specified on the entity object.

50.3.5 What You May Need to Know About Column-Level Security

Oracle Fusion Data Security Provider only implements row-level authorization check. It does not implement a column-level authorization checking API. Even though Oracle Fusion Data Security can be used to perform column-level security using custom actions, it is not integrated with ADF Business Components directly using the data security provider interface. Wherever column-level security is needed, you must use a custom action.

50.3.6 What You May Need to Know About Translatable Entity Objects

The default Oracle Fusion Data Security provider implementation assumes that the object name in FND_OBJECTS for the entity object being secured is the database table/view name backing this entity object. If the entity object is a translatable entity object (MLS entity), then the backing database table/view name is identified by Oracle Fusion Middleware Extensions for Applications custom property fnd:OA_BASE_TABLE.
If the default behavior used to identify the backing database table/view name is not sufficient, one can use the entity object overview editor to set a custom property on the entity object. This custom property will identify the name of the object from the Oracle Fusion Data Security repository that will be used to secure this entity. The custom property OA_DS_BASE_TABLE should be set in the Custom Properties section in the General page of the entity object overview editor to accomplish this.

50.3.7 What Happens at Runtime: How Oracle Fusion Data Security Filters View Instance Rows

Based on standard operations that you enable for entity object security, the appropriate row-level permission checks are done at runtime. To enable these checks to happen automatically, JDeveloper registers the Oracle Fusion Data Security Provider with ADF Business Components in the adf-config.xml file when you secure an operation on the entity object.

At runtime, in the case of standard entity object operations that have been secured, ADF Business Components invokes the Oracle Fusion Data Security Provider in two steps:

1. The security provider first identifies the WHERE clause (if any) that must be added to the SQL statement for the entity object on which the read operation has been secured. This is done before executing the query.

2. After the query has been executed, ADF Business Components then invokes the Oracle Fusion Data Security Provider again to perform the authorization check for the update and removeCurrentRow operations to determine whether user has update and delete access to that row.

The implementation for securing data by applying a view criteria on the view object instance is handled in the Oracle Fusion Middleware Extensions for Applications layer. It requires the use of Oracle Fusion Middleware Extensions for Applications base classes to achieve this behavior. The OAViewCriteriaAdapter class is the default view criteria adapter class set as the ADF Business Components application module in the OAApplicationModuleImpl class. This functionality is provided in the OAViewCriteriaAdapter.getCriteriaClause() method to fetch the security predicate. In this implementation, the method uses the metadata on the view criteria to invoke Oracle Fusion Data Security APIs that fetch the security predicate.

In the case of a custom operation secured by a custom action, multiple data security view criteria can be applied to the view object. When multiple view criteria are applied, the WHERE clause corresponding to each view criteria is AND'ed. This is standard behavior for ADF Business Components. However, when a single data security view criteria for a given permission is applied, the instance sets corresponding to that permission are OR'ed. When multiple permission checks are applied, the instance sets of a permission are AND'ed with the instance sets of another permission. For example, for an object, for permission perm1, the user has instance sets IS1, IS2. For the same object for privilege priv2, the user has instance sets IS3, IS4. If both perm1 and perm2 checks are applied simultaneously (using view criteria), the WHERE clause would be (IS1 OR IS2) AND (IS3 OR IS4).

50.3.8 How to Perform Authorization Checks for Custom Operations

At runtime, the ADF Business Components invocation of Oracle Fusion Data Security Provider happens automatically only for standard operations. For custom operations that are available on the entity object, you must invoke the authorization check API manually as shown in the following example.
Note that the `allowsOperation()` method expects as input the secured operation name rather than the name of the action that secures it. In the case of the standard operations, the operation name for deleting an entity row is `removeCurrentRow` (where `delete` is the action name).

There may be other reasons to invoke Oracle Fusion Data Security APIs manually to determine either the SQL predicate for a given action or to do an authorization check. For example, VPD policies written based on `fnd_data_security.getSecurityPredicate()` to enforce data security rules.

**Example 50-3  Manually Invoking the Authorization Checking API**

```java
if(row.getSecurityHints().allowsOperation("ApprovePO").hasPermission())
    // code for P0 approval
else
    // display error message
```

### 50.3.9 How to Test Permissions Using Expression Language Expressions in the User Interface

You can test data security actions for standard operations (read, update, `removeCurrentRow`) or custom operations on an entity row using Expression Language or Groovy expression exposed on the entity row.

The Expression Language and Groovy expressions described below work by default when the view object is an updateable view object based on an entity object. If the view object is a read-only view object (based on an entity object) or an expert mode view object, then Expression Language or Groovy expression will not work unless you create a transient attribute with a custom Groovy expression that invokes Data Security to check the operation. The transient attribute can be used to control the rendering of some other attribute in the read-only view object on the page.

- The following example shows the Expression Language expression to use on ADF bindings for view object attributes.

  For example, your UI might have a button to control the grant for the `UpdateEmployeeSalary` custom action; the Expression Language expression on the button may be defined as shown in the following example.

  When this expression is invoked, Oracle Fusion Data Security Provider checks to see if the user identified by the `PersonId` attribute has access to the current row for `UpdateEmployeeSalary` operation. Note that even though the attribute name is included in the Expression Language expression, it is really doing a row-level security check.

  **Do not** use the expression shown in the following example as Oracle Fusion Data Security Provider does not implement a column-level security check interface. If you want to perform a column-level security, use the expression shown in the previous example with a custom action.

- The following example shows the expression to use for table iterators:

  **Do not** use the expression shown in the following example as Oracle Fusion Data Security Provider does not implement column-level security check interface. If you want to do column-level security, use the expression shown in the previous example with a custom action.

- When using Expression Language, be careful if you decide to set the expression on the `rendered` attribute. When PPR is enabled, ADF Faces does not handle the `rendered` attribute on a UI component well.
Tip:
PPR is enabled by default in Oracle Fusion Applications.

If you want to use Data Security expressions on the rendered attribute, you must manually identify the partial trigger UI components on the page and then set the partialTriggers attribute on the parent UI component of the UI component that has the data security Expression Language expression. Do not use visible attribute on the UI component as this could potentially be a security hole when the UI component and its data is rendered by the server and sent to the client. The visible attribute is a client-side attribute to show or hide the UI component on the browser.

- When using Groovy expressions, use the expression shown in the following example if the view object is an updateable view object based on an entity object.

- When using Groovy expressions, use the expression shown in the following example if the view object is a read-only view object based on an entity object or an expert mode view object. Create a transient attribute on the view object of type Boolean and Value Type Expression. The transient attribute can be used to control the rendering of some other attribute in the read-only view object on the page.

For example, you have a read-only view object with the attributes PersonId, Name, Gender, and Age and you want to control the rendering of the Gender attribute on the UI. First, you should create a transient attribute by name TransientGenderAttr and set the Groovy expression as mentioned above. The following example shows an EL expression to conditionally render the UI component for the Gender attribute:

You must make sure that the parent UI component of this UI component has the partialTriggers set to the appropriate UI component IDs. Also, in this scenario, make sure to have the binding available for the transient attribute in the view object, and to set the rendered="false" on the UI component for the transient attribute, or comment out the UI component in the JSF page.

**Example 50-4 Using Expression Language on View Object Attributes**

`#{bindings.<attrName>.hints.allows.<operationName>}`

**Example 50-5 Correct Expression Language Expression Example**

`#{bindings.PersonId.hints.allows.UpdateEmployeeSalary}`

**Example 50-6 Incorrect Expression Language Expression Example**

`#{bindings.<attrName>.hints.<attrName>.allows.<operationName>}`

**Example 50-7 Using Expression Language for Table Iterators Example**

`#{row.hints.allows.<operationName>}`

**Example 50-8 Incorrect Expression Language Expression Example**

`#{row.hints.<attrName>.allows.<operationName>}`

**Example 50-9 Groovy Expression Example**

`object.getSecurityHints().allowsOperation("updateCategory").hasPermission()`
Example 50-10  Groovy Expression if View Object is Read-Only Example

```java
testPrivilege("VIEW_PERSON_NAME LIKE_T","PER_EL_TEST_PERSONS", PersonId.toString(),
null,null,null,null,object.getViewObject().getDBTransaction());
```

Example 50-11  Implementing Attribute Security Example

```html
<af:panelFormLayout id="pfl1" partialTriggers="it6 cb3 cb1 cb4 cb5">
  <f:validator binding="#{bindings.Gender.validator}"/>
</af:inputText>

<af:inputText value="#{bindings.TransientGenderAttr.inputValue}" label="#{bindings.TransientGenderAttr.hints.label}" required="#{bindings.TransientGenderAttr.hints.mandatory}" columns="#{bindings.TransientGenderAttr.hints.displayWidth}" maximumLength="#{bindings.TransientGenderAttr.hints.precision}" shortDesc="#{bindings.TransientGenderAttr.hints.tooltip}" rendered="false" id="it1"/>
</af:inputText>

```
</af:panelFormLayout>
```

50.4 Use Oracle Fusion Data Security to Grant Access to Secured Business Objects

To secure the business object in the extended application, where it has been exposed as an ADF entity object, is a multi-step process:
1. A database resource definition must be created in the FND_OBJECTS table to identify the same table or view backing the ADF entity object. The database resource in Oracle Fusion Data Security is the data resource on which data security is enforced.

2. After the business object is defined as an Oracle Fusion Data Security database resource, then a security policy must be created to grant access to the data records. The security policies for the database resource specify access permissions such as read, update, and delete permissions on specific sets of data records exposed by the business object.

3. Finally, to enforce the newly created data security policy, the entity object in the data model project must enforce OPSS authorization checking on the data operations that access the protected data records exposed by the business object, as described Integrating with ADF Business Components.

As an Oracle Fusion Applications security guideline, a new data security policy must be created instead of modifying predefined data security policies of the security reference implementation. For example, a new data security policy is required to expose additional data records or operations for an existing business object. Additionally, a custom duty role must be created as the recipient of the new data security access permissions because granting permissions to a predefined duty role would alter the segregation of duties defined by the security reference implementation.

The general process for defining data security policies to grant access to business objects that you add to your Oracle Fusion application is as follows.

1. Identify the business object that you want to secure:
   a. Register your database view or table that you want to secure with Fusion Oracle Data Security.
   b. Populate the FND_OBJECTS and FND_OBJECTS_TL tables appropriately.

2. Identify the conditions that you want to make available on the registered business object:
   Tip:
   Conditions may be static or parameterized. For details about parameterizing conditions, see How to Use Parameterized Conditions When Securing a Business Object.
   - Populate the FND_OBJECT_INSTANCE SETS and FND_OBJECT_INSTANCE_SETS_TL tables appropriately.

3. Identify the actions that you want to secure this business object:
   - Populate FND_FORM_FUNCTIONS and FND_FORM_FUNCTIONS_TL tables appropriately.

4. Group the actions appropriately to form aggregate actions:
   a. Identify the name of the aggregate action and register it.
   b. Register the various actions that are part of the aggregate action.
   c. Compile the aggregate actions for faster reference.
You must do this to avoid hierarchical queries against the FND_Menu Entries table as aggregate actions may nest other aggregate actions. To compile the menus, invoke fnd_function.fast_compile or fnd_function.compile_all_from_scratch.

Note:
Menu hierarchies, such as sub-menus, are currently not supported. Menus may only include functions. This is because Seed Data Loaders do not support hierarchies now.

However, this step is still required as runtime queries are fired against the fnd_compiled_menu_functions table instead of the fnd_menu_entries table.

d. Populate FND_MENUS, FND_MENUS_TL, and FND_MENU_ENTRIES tables appropriately.

5. Identify the Oracle Platform Security Services (OPSS) principals (OPSS users and roles) for which you want to make policies.

OPSS principals do not exist in the database and are managed by OPSS Policy Store, which may be a third-party system.

6. Make appropriate aggregate action policies on the business resource to OPSS users and roles.

Policies can be made on a row instance, on the resource globally, or for a condition, which may be parameterized.

• Populate the FND_GRANTS table appropriately.

50.4.1 How to Create Data Security Policies for Custom Business Objects

Data security policies are stored in the Oracle Fusion Data Security repository and are defined and edited using Oracle Authorization Policy Manager. You have access to this tool through Oracle Fusion Functional Setup Manager, from the Manage Data Security task available in the Setup and Maintenance work area of any Oracle Fusion Setup application, however, you will need specific permissions. When you have the necessary permissions, Oracle Authorization Policy Manager allows you to access the data security customization user interface.

Note:
For complete details about Oracle Authorization Policy Manager tasks that you can perform with the Manage Data Security Policies user interface, see the "Customizing Security for Oracle ADF Application Artifacts" chapter of the Extensibility Guide for Developers.

Before you begin:
Contact your security administrator to receive the duty role membership that entitles you to perform the Manage Data Security Policies tasks in Oracle Authorization Policy Manager.
You must have configured your user interface project to use application user sessions to support the data security runtime. For more information about implementing application user sessions, see Configuring Your Project to Use Application User Sessions.

You must enable security on your application. For more information about enabling security, see How to Enforce Authorization for Securable ADF Artifacts.

Collect the following information that you will use to define the data security policy in Oracle Authorization Policy Manager:

- The primary key of the database table or view that the custom business object represents
  
  You specified the primary key of the database table or view when you registered the database resource in Oracle Authorization Policy Manager.

- The names of the conditions for which you want the security policy to control access
  
  When you registered the database resource, you may have created named conditions to control access to instance sets composed of multiple rows (Oracle Fusion Data Security does not require that you create a named condition when you want to grant access to instance sets composed either of a single row or of all rows of the database resource).

- The names of the actions for which you want to associate with a particular named condition (or instance set) to control access
  
  When you registered the database resource, you named actions to identify the securable operations of the custom business object. Action names must be identical to the names of the operations the business object supports. For example, the names of actions corresponding to the supported standard operations are view, edit, and delete. However, if your data model project defines custom operations, actions may have names corresponding to operations named, for example, as view_US_ONLY, edit_US_ONLY, or delete_US_ONLY.

- The names of the custom duty roles for which you want to grant access to the conditions and actions of the database resource associated with the custom business object
  
  As an Oracle Fusion Applications security guideline, predefined duty roles defined by the security reference implementation must not be modified. You must use Oracle Authorization Policy Manager to create a new duty role rather than grant data security permissions to predefined duty roles.

In Oracle Authorization Policy Manager, the general steps for defining a data security policy are as follows:

1. Using the Manage Data Security Policies user interface in Oracle Authorization Policy Manager, register the custom business object as a database resource.

2. Define the instance set of data records that you want to associate with specific securable operations of the ADF business component.
   
   The security policy identifies named conditions from the security repository to specify the row instance set available to the end user provisioned to the role with the permission to perform the intended ADF business component operation.

   In Oracle Authorization Policy Manager, a condition you create defines an instance set of multiple rows specified either by simple filters (XML-defined) or
complex SQL queries whose values can be parameterized. No condition definition is needed in the case of a single row instance or all the row instances of the database resource.

3. Define the list of actions that you want to be able to grant to the role.
Actions are database equivalent create, read, update, delete (CRUD) operations and correspond to the names of securable operations of the business object that the end user may invoke. The data security policy you define will associate one or more actions with an instance set.

4. If the custom business object is not supported by a data role template, define the data security policy:
   a. Enter a name and start date for the data security policy.
   b. Select one or more job roles or duty roles to which the policy grants access. The roles you select entitle all end users assigned to those roles with access to the data.
      In Oracle Authorization Policy Manager, duty role names that you enter are identified as OPSS internal roles called application roles. Similarly, job role names are identified as OPSS external roles called enterprise roles.
   c. Specify an instance set on the database resource for which the security policy will control access. This may be a single row, all rows, or multiple rows (specified by a previously defined named condition).
   d. Specify one or more actions to secure on the database resource for the currently specified instance set.
   e. Repeat the steps to grant actions access to additional instance sets for the current data security policy and roles.
      The following figure illustrates the Actions tab in the Edit Data Security page after several actions have been selected. Available actions will be limited to the actions that had been defined for the database resource.
Example: Securing a document categories business object

The following scenario describes the general steps that you would follow using Oracle Authorization Policy Manager to secure a document categories business object. For detailed information about the data security management tasks you can perform in Oracle Authorization Policy Manager, see the "Customizing Security for Oracle ADF Application Artifacts" chapter of the Extensibility Guide for Developers.

The document categories business data is stored in the `FND_DEMO_DOC_CATEGORIES` table. The following table lists the document category definitions for the table.

<table>
<thead>
<tr>
<th>Name</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>CATEGORY_ID</td>
<td>NOT NULL NUMBER</td>
</tr>
<tr>
<td>APPLICATION_ID</td>
<td>NUMBER</td>
</tr>
<tr>
<td>CREATION_DATE</td>
<td>NOT NULL DATE</td>
</tr>
<tr>
<td>CREATED_BY</td>
<td>NOT NULL NUMBER</td>
</tr>
<tr>
<td>LAST_UPDATE_DATE</td>
<td>NOT NULL DATE</td>
</tr>
<tr>
<td>LAST_UPDATED_BY</td>
<td>NOT NULL NUMBER</td>
</tr>
<tr>
<td>LAST_UPDATE_LOGIN</td>
<td>NUMBER</td>
</tr>
<tr>
<td>NAME</td>
<td>NOT NULL VARCHAR2(30)</td>
</tr>
<tr>
<td>START_DATE_ACTIVE</td>
<td>DATE</td>
</tr>
<tr>
<td>END_DATE_ACTIVE</td>
<td>DATE</td>
</tr>
</tbody>
</table>
The following example assumes that you have the necessary permission to perform the **Manage Data Security Policies** task in Oracle Authorization Policy Manager.

To secure a document categories business object in Oracle Authorization Policy Manager:

1. Create a resource named `FND_DEMO_DOC_CATEGORIES` and identify its primary key as `category_id`.

2. Create a static condition named `DMS_STATIC_INSTANCE_SET`, which secures categories 33, 34, and 35.
   
   The predicate for this condition is `'category_id in (33, 34, 35)'`.

3. Create a dynamic condition named `DMS_PARAMETERIZED_IS` to secure categories, which can be identified at grant time.
   
   The predicate for this condition is `'category_id in (%GRANT_ALIAS.PARAMETER1, %GRANT_ALIAS.PARAMETER2)'`, where `&GRANT_ALIAS` refers to the Policies table.

4. Identify the actions securing this entity object for *read*, *update*, and *delete* operations as read, update, delete. Additionally, custom actions with the names `FND_DEMO_ATTACHMENT_VIEW`, `FND_DEMO_ATTACHMENT_UPD`, and `FND_DEMO_ATTACHMENT_DEL` may be created for testing.

5. Identify aggregate actions for which policies are made for this entity:

   - Create an aggregate action named `FND_DEMO_ATTACHMENT_VIEW` for the *read* operation, which contains actions named read and `FND_DEMO_ATTACHMENT_VIEW`.

   - Create an aggregate action named `FND_DEMO_ATTACHMENT_ADMIN`, which allows a user to administer this resource. It has *read*, *update*, and *delete* actions. This aggregate action contains read, update, delete, `FND_DEMO_ATTACHMENT_VIEW`, `FND_DEMO_ATTACHMENT_UPD`, and `FND_DEMO_ATTACHMENT_DEL` actions.

6. Compile the menus in the database by executing:

   ```
fnd_function.compile_all_from_scratch;
   ```

7. Create OPSS principals.

   For this example the user names created are `joeUser` and `admin`. The role names created are `regularUserRole` and `admin`.

8. Make policies to OPSS principals `admin` and `regularUserRole` for the `FND_DEMO_DOC_CATEGORIES` business resource.

---

**Table 50-3 (Cont.) FND_DEMO_DOC_CATEGORIES Table Definition**

<table>
<thead>
<tr>
<th>Name</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>ATTRIBUTE_CATEGORY</td>
<td>VARCHAR2(30)</td>
</tr>
<tr>
<td>ATTRIBUTE1 thru ATTRIBUTE15</td>
<td>VARCHAR2(150)</td>
</tr>
<tr>
<td>DEFAULT_DATATYPE_ID</td>
<td>NUMBER</td>
</tr>
</tbody>
</table>

---

*Use Oracle Fusion Data Security to Grant Access to Secured Business Objects*
• Grant FND_DEMO_ATTACHMENT_ADMIN aggregate action on the resource globally to OPSS admin role.

• Grant FND_DEMO_ATTACHMENT_VIEW aggregate action to regularUserRole for static DMS_STATIC_INSTANCE_SET and dynamic (DMS_PARAMAETERIZED_IS with parameters 37 and 38) conditions.

50.4.2 How to Use Parameterized Conditions When Securing a Business Object

Parameterized conditions allow conditions to be specified generally but granted specifically. Parameterized conditions are useful because they reduce the number of predicates that the database must parse, as well as reducing the number of conditions that the administrator needs to manage.

The following example shows how a parameterized condition can be reused.

An administrator can reuse the first condition for several different policies granted to different locations and the second condition can be reused for policies granted to different titles. For example, one policy might use OIS1 to grant to 'WEST' by putting 'WEST' in FND_GRANTS.PARAMETER1, while another policy would reuse the same OIS1 to grant to 'EAST'. At runtime, the FND_DATA_SECURITY package substitutes the PARAMETER values from the FND_GRANTS table to the OISs granted.

When the data security system runs the predicates that have been defined in the conditions, it does a simple replace-style parsing of the predicate. For example, &TABLE_ALIAS is replaced by the table alias of the resource table, if it was passed to the get_security_predicate() call, and &GRANT_ALIAS is replaced by the policy table alias.

Caution:

The &TABLE_ALIAS and &GRANT_ALIAS column qualifiers must be included in the predicates of all conditions to keep possible duplicate column names from causing collisions.

Example 50-12 Reusing Parameterized Conditions

Condition. Employees in a particular region.
Predicate: "&TABLE_ALIAS.REGION = &GRANT_ALIAS.PARAMETER1"

50.4.2.1 Converting Non-String Parameter Values Into Character Values

The policy parameters hold only string values so you must convert non-string values into character values.

To convert non-string values into character values:

• integer- NUMBER with no decimal point. For example, 123.
  To store the number in the policy PARAMETER column, use to_char() without a format mask.

• float- NUMBER that can have a decimal point. For example, 123.456.
  This should be stored in the canonical format, using
  FND_NUMBER.NUMBER_TO_CANONICAL(). (The canonical format is based on the
  FND_NUMBER package
  'FM999999999999999999999.99999999999999999999'.)
You should use canonical format because the string must be stored in a format that doesn't need to be converted if the data is passed between systems that use different decimal characters or other number formatting.

- **date-** DATE calendar date, optional time. For example, 2009/04/30 11:32:32.
  
  This should be stored in canonical format, using FND_DATE.DATE_TO_CANONICAL(). (The canonical format is based on the FND_DATE package, 'YYYY/MM/DD HH24:MI:SS'.
  
  You should use canonical format because the string must be stored in a format that doesn't need to be converted if the data is passed between systems that use different date formats.

- **varchar2-** VARCHAR2 character string. For example, FND_THING_NAME.
  
  This can be stored without any conversion.
  
  However, translated values should not be stored here. This is for internal developer key values. There is no facility for having different multilingual values in different languages because predicates should not be comparing translated values.

### 50.4.2.2 Writing Performance Type Conversions in Predicates

Use the following rules when writing performance type conversions in your predicates.

**Integer Equality:**

The following example shows the correct Integer equality format to use.

The following example shows Integer equality formats that you should NOT use.

You must use to_char() as it is built-in and performs much faster than fnd_data_security.to_init().

When used with data security parameters, to_number() causes Invalid Number exceptions. This in turn, will make SQL statements abort if the to_number() gets run on policy parameters, which store non-numeric data such as DATE or VARCHAR2 data. The policies table will almost certainly contain some non-numeric data in a policy.

It may be decided to run a to_number(&GRANT_ALIAS.PARAMETER1) in a big statement on more policy rows than intended, and filter the rest of the rows later in the execution. This will definitely cause your SQL statement to fail so therefore, you must not have to_number() around any of the policy parameters in your predicate.

**Tip:**

The routine fnd_data_security.to_init() was written to avoid this problem; it is basically a wrapper over to_number(), which traps the Invalid Number exception. Therefore, if the execution plan involves operating against policies that don’t apply, they won’t cause the whole statement to fail. However, because of performance issues, to_char() is the preferred solution.

**Integer Range:**

The following example shows the correct Integer range format to use.

The following example shows Integer range formats that you should NOT use.
As explained previously, `to_number()` can fail with an *Invalid Number* exception if other policy rows are processed that have non-numeric parameters. `to_char()` does not produce the correct ordering. For example, '3' > '25'.

**Float Equality:**

The following example shows the correct Float equality format to use.

The following example shows Float equality formats that you should NOT use.

Using `to_number()` without a format could fail if the environment is set up to use comma as the decimal character and the parameter is stored with a period as the decimal character. Using `to_char()` without an explicit format could convert to a comma-format number, which would not match the period-format number. Because of these potential problems, you must explicitly provide the canonical format.

**Float Range:**

The following example shows the correct Float range format to use.

The following example shows Float range formats that you should NOT use.

You should not use `to_char()` because it does not order correctly.

You should use `fnd_data_security.to_decimal()` instead of `fnd_data_security.to_init()` because the data may contain decimals, which `to_init()` cannot handle.

**Date Equality:**

The following example shows the correct Date equality format to use.

The following example shows Date equality formats that you should NOT use.

As mentioned previously, `to_char()` performs best because it is built-in. The format mask is also required to make sure the canonical format is used.

**Date Range:**

The following example shows the correct Date range format to use.

The following example shows Date range formats that you should NOT use.

In this case, you can use `to_char()` with a format mask because the canonical format maintains proper ordering of the character domain.

**Example 50-13  Integer Equality Format**

```
      to_char(&TABLE_ALIAS.ITEM_ID) = &GRANT_ALIAS.PARAMETER1
```

**Example 50-14  Incorrect Integer Equality Formats**

```
&TABLE_ALIAS.ITEM_ID = to_number(&GRANT_ALIAS.PARAMETER1)
&TABLE_ALIAS.ITEM_ID = fnd_data_security.to_decimal(&GRANT_ALIAS.PARAMETER1)
```

**Example 50-15  Integer Range Format**

```
&TABLE_ALIAS.LEVEL >= fnd_data_security.to_init(&GRANT_ALIAS.PARAMETER1)
```

**Example 50-16  Incorrect Integer Range Formats**

```
&TABLE_ALIAS.LEVEL >= to_number(&GRANT_ALIAS.PARAMETER1)
to_char(&TABLE_ALIAS.LEVEL) >= &GRANT_ALIAS.PARAMETER1
```
Example 50-17  Float Equality Format

to_char(&TABLE_ALIAS.TEMP,'FM999999999999999999999.99999999999999999999') = &GRANT_ALIAS.PARAMETER1

Example 50-18  Incorrect Float Equality Formats

to_char(&TABLE_ALIAS.TEMP) = &GRANT_ALIAS.PARAMETER1
&TABLE_ALIAS.TEMP = to_number(&GRANT_ALIAS.PARAMETER1)
&TABLE_ALIAS.TEMP = fnd_data_security.to_decimal(&GRANT_ALIAS.PARAMETER1)

Example 50-19  Float Range Format

&TABLE_ALIAS.TEMP > fnd_data_security.to_decimal(&GRANT_ALIAS.PARAMETER1)

Example 50-20  Incorrect Float Range Formats

to_char(&TABLE_ALIAS.TEMP,'FM999999999999999999999.99999999999999999999') > &GRANT_ALIAS.PARAMETER1
&TABLE_ALIAS.TEMP > to_number(&GRANT_ALIAS.PARAMETER1)
&TABLE_ALIAS.TEMP > fnd_data_security.to_init(&GRANT_ALIAS.PARAMETER1)

Example 50-21  Date Equality Format

&TABLE_ALIAS.ACTION_DATE = fnd_data_security.to_date(&GRANT_ALIAS.PARAMETER1)

Example 50-22  Incorrect Date Equality Formats

to_char(&TABLE_ALIAS.ACTION_DATE) = (GRANT_ALIAS.PARAMETER1)
&TABLE_ALIAS.ACTION_DATE = to_date(&GRANT_ALIAS.PARAMETER1)
&TABLE_ALIAS.ACTION_DATE = to_date(&GRANT_ALIAS.PARAMETER1)

Example 50-23  Date Range Format

&TABLE_ALIAS.HIRE_DATE > fnd_data_security.to_date(&GRANT_ALIAS.PARAMETER1)

Example 50-24  Incorrect Date Range Formats

&TABLE_ALIAS.HIRE_DATE = fnd_data_security.to_date(&GRANT_ALIAS.PARAMETER1)
&TABLE_ALIAS.HIRE_DATE = to_date(&GRANT_ALIAS.PARAMETER1)

50.4.3 How to Create Test Users in JDeveloper

For development purposes, you can use the OPSS jazn-data.xml flat file to create users and roles for testing.

For an example of the identity store in the flat file used by JDeveloper, see the Enabling ADF Security in a Fusion Web Application chapter of the Developing Fusion Web Applications with Oracle Application Development Framework, in the Oracle Fusion Middleware Online Documentation Library.

50.4.4 What You May Need to Know About Creating Application Roles

Before testing the application in the staging environment, any custom application roles that you created will need to be created in the LDAP application policy store. These new application roles will receive new GUIDs and any data security policies defined for application roles of the same name must have their GUIDs reconciled. For details about reconciling GUIDs in the data security repository, see the Reconciling GUIDs section in the Administrator’s Guide.
50.5 Getting Security Information from the Application User Session Context

Oracle Fusion Data Security is a layer that interacts with Oracle Platform Security Services. Hence data security information can be obtained from security context as required while developing the application.

50.5.1 How to Use the DataSecurityAM API to Get Session Context Information

The DataSecurityAMImpl class is in the oracle.apps.fnd.applcore.dataSecurity.dataSecurityService.applicationModule package. It is the container for all data security resources provided by Oracle Fusion Middleware Extensions for Applications. This class contains core methods to:

- Check action for the current user, as shown in the following example.
  
  Where DataContext is a container class that represents the resource and optionally the primary keys of that resource for which data security check must be done. It has the following attributes: ObjectName, PK1, PK2, PK3, PK4, PK5.

```
Note:
Privilege and DataContext classes are in the oracle.apps.fnd.applcore.dataSecurity.util package.
```

If the action is granted to an Oracle Platform Security Services (OPSS) role in FND_GRANTS table, then the system retrieves all the OPSS roles that the user has access to, and checks if one of them matches with the OPSS role to which the action has been granted.

- Get the security predicate associated with a given action on a given resource for the current user, as shown in the following example.

- Get all the actions available on a given row instance for the current user, as shown in the following example.

- Get all the aggregate actions available on a given row instance for the current user, as shown in the following example.

As shown in the following example, static APIs are also provided in the DataSecurityAMImpl class for the above core methods that take in a DBTransaction object.

**Example 50-25 Check Action Method**

```java
/**
  * Test if an action is accessible for a given data context for the user
  * in the current session context.
  * @param privilege the privilege to test
  * @param dataContext data context (object and primary key) to use for
  * testing the privilege.
  * @return true if privilege is accessible, false otherwise.
  */
  public boolean testPrivilege(Privilege privilege, DataContext context)
```
Example 50-26  Get Security Predicate Method

/**
 * Return the security predicate for a given action on a resource
 * for the user in the current session context.
 * @param privilege privilege to use to determine the predicate.
 * @param dataContext the data context, which provides the object name.
 * @param grantInstanceType the grant instance type, (such as "UNIVERSAL").
 * @param statementType the statement type, (such as "OTHER").
 * @param tableAlias alias for the table.
 * @return the security predicate.
 */
public String getSecurityPredicate(Privilege privilege, DataContext dataContext,
        grantInstanceType, String statementType, String tableAlias)

Example 50-27  Get All Actions Available Method

/**
 * Provides the list of action names granted to the user for
 * the specified dataContext (Object/PK) in the current session context.
 * @param dataContext data context (object and primary key) to use for
 * identifying the granted actions.
 * @return list of action names.
 */
public String[] getPrivileges(DataContext dataContext)

Example 50-28  Get All Aggregate Actions Method

/**
 * Provides the list of aggregate action names granted to the user for
 * the specified dataContext (Object/PK) in the current session context.
 * @param dataContext data context (object and primary key) to use for
 * identifying the granted aggregate actions.
 * @return list of aggregate action names.
 */
public String[] getAggregatePrivileges(DataContext dataContext)

Example 50-29  Static API Examples

public static boolean testPrivilege(Privilege privilege, DataContext context,
        DBTransaction dbTxn)

public static String getSecurityPredicate(Privilege privilege, DataContext dataContext,
        grantInstanceType, String statementType, String tableAlias, DBTransaction dbTxn)

public static String[] getAggregatePrivileges(DataContext dataContext, DBTransaction dbTxn)

public static String[] getPrivileges(DataContext dataContext, DBTransaction dbTxn)

50.5.2 How to Use the PL/SQL Data Security API to Check User Privileges

Oracle Fusion Middleware Extensions for Applications provides the FND_DATA_SECURITY PL/SQL package for the data security system.

FUNCTION check_privilege determines whether the user is granted a particular action for a particular row instance, as shown in the following example. The user is determined from the user session context.

This API returns a 1 byte result code:

T - Action is granted.
F - Action is not granted.
E - Error
U - Unexpected error.

PROCEDURE get_security_predicate gets the union of all predicates for the user on an action, as shown in the following example. The user is determined from the user session context.

p_grant_instance_type can take on one of the following values:

INSTANCE - Returns predicate for policies with instance_type = 'INSTANCE' or 'GLOBAL'.
SET - Returns predicate for policies with instance_type = 'SET'.

Note:
'SET' mode does not support aliases.

UNIVERSAL - (Default) Returns predicate for policies with any instance_type.

p_table_alias is appended in front of the column references in the returned x_predicate. It is normally used when two security predicates are going to be ANDed together to use with a select that joins two secured tables. The value passed here should correspond to the table alias that the statement uses for the p_object_name passed to this routine. The default, NULL, means there is no table alias so none is appended.

p_statement_type can take on one of the following values:

OTHER - (Default). The predicate returned is not attached by policy to the base table as is done for VPD. In practice, this allows the predicate to have a sub select against the base table, which allows aliases and may improve performance.

VPD - Pass this type if the predicate is attached by policy to the base table. Use this when VPD uses the returned predicate to control access. In practice, this means the predicate cannot have sub selects against the base table, prevents aliases and may lower performance.

EXISTS - Pass this type if the predicate is simply used to determine if there are any rows at all that are available. The predicate returned is in the format like 'EXISTS...'.

x_return_status is the result of all the operations:
T - Successfully got predicate
E - Error
U - Unexpected error
L - Value too long - predicate too large for database VPD

The return value is all the available predicates from the policies on this action for this user. They are OR'ed together to form a SQL predicate that can be dropped into the WHERE clause to limit rows returned to those that are allowed by the security. Does not include WHERE.

Example 50-30  FUNCTION check_privilege API

FUNCTION check_privilege

p_api_version          IN NUMBER,
/* API Version of this procedure - currently 1.0 (Required) */
p_privilege            IN VARCHAR2,
/* Name of the action (Required) */
p_object_name          IN VARCHAR2,
/* Resource on which the policy should be checked from FND_Objects table (Required) */
p_instance_pk1_value   IN VARCHAR2 DEFAULT NULL,
/* p_instance_pk(1...5)_value (Required) 
Primary key values for the row instance, with order corresponding to the order of the PKs in the FND_Objects table. Most resources have only a few primary key columns so let the higher, unused columns default to NULL. 
NOTE: The caller must pass an actual primary key and it must be the primary key of an actual instance (row). */
p_instance_pk2_value   IN VARCHAR2 DEFAULT NULL,
p_instance_pk3_value   IN VARCHAR2 DEFAULT NULL,
p_instance_pk4_value   IN VARCHAR2 DEFAULT NULL,
p_instance_pk5_value   IN VARCHAR2 DEFAULT NULL
)RETURN VARCHAR2;

Example 50-31  PROCEDURE get_security_predicate

PROCEDURE get_security_predicate
(
    p_api_version          IN NUMBER,
/* API version of this procedure - Currently 1.0 (Required) */
    p_privilege            IN VARCHAR2 DEFAULT NULL,
/* NULL represents all actions so the predicate will not take the action into account. */
    p_object_name          IN VARCHAR2,
/* Object on which the predicate should be checked from FND_Objects table. */
    p_grant_instance_type  IN VARCHAR2 DEFAULT 'UNIVERSAL',
/* SET, INSTANCE (Optional) */
    p_statement)_type      IN VARCHAR2 DEFAULT 'OTHER',
/* (Optional) statement type: 'OTHER', 'VPD', 'EXISTS' = to check existence. */
    x_predicate            OUT NOCOPY VARCHAR2,
    x_return_status        OUT NOCOPY VARCHAR2,
    p_table_alias          IN VARCHAR2 DEFAULT NULL
/* (Optional) */
);
Note:
Data security is not designed as a means to limit the number of rows returned; there must always be another selective WHERE clause before the data security predicate.

Condition predicates must be as fast as possible. All predicates that apply to a particular context must go into the SQL statement that gets executed; therefore, all predicates need to be efficient, whether they reject no rows, a few rows, or many rows. Any sub selects in predicates should be on well-indexed columns. Predicates must execute in linear time, doing simply indexed selects. Predicates that involve connect-by or other network, hierarchical operations are not supported. The suggested approach to hierarchical data representations is building and selecting against a compiled representation of the data.

You should use conditions rather than row instance policies. Row instance policies are policies where each policy maps to exactly one row in the resource table. They generally don’t scale well because they require one policy row for every resource table row. Performance is best when the number of policies that apply in any particular context is low. Condition policies involve just one policy, which specifies an unlimited number of rows. If the normal use case would involve more than a few row instance policies, then you probably need to be change the design to use conditions.

Note:
There are no plans to provide any APIs to answer the question “What users have access to a particular function on a particular row instance?” The reason being is that the condition predicates can reference context that can be driven by the user, like profiles. The only way to answer that question would be to loop through every user and set up their context (including profiles, and so on), and then see if they had access. That is not practical given the large number of users that are possible. For the same reason, data security does not try to answer the question “Does a particular user have access to a particular function?”

50.7 Validating Data Security with Diagnostic Scripts

Oracle Fusion Applications provides WLST (Oracle WebLogic Scripting Tool) scripts written in the Python programming language to help administrators verify that data security setup and configuration definitions are correct for a newly deployed application. Other WLST scripts help administrators verify that applications context setup and configuration definitions are correct for a newly deployed application and that the applications context is created for a logged-in user.

The data security diagnostic scripts may be run in the WLST scripting environment or from the Diagnostic Dashboard application of any Oracle Fusion application. The Diagnostic Dashboard provides administrators with a graphical user interface to execute and monitor diagnostic tests.

For more information about the Diagnostic Dashboard, see the “Running and Working with Diagnostic Tests Manually” section in the Administrator’s Guide.
50.7.1 How to Validate Data Security Configuration with Diagnostic Scripts

The WLST script `datasecurityDiagnostics.py` is provided to help administrators verify that data security setup and configuration definitions are correct for a newly deployed application. Additionally, the script generates a report that system integrators, developers and security managers can further use to diagnose runtime issues related to a logged-in user's ability to access data.

To accomplish these tasks, the script performs these specific functions:

- Validates data security configuration in the `adf-config.xml` file, which is archived in the application EAR file. The script checks the configuration values of the `<sec:JaasSecurityContext>` element to verify that the data security provider is properly configured and outputs the result to the output file `DataSecurityDiagResults.out`.

- Validates that GUID consistency is enabled in the `weblogic-application.xml` file. The script checks the value of the `jps.approle.preserveguid` application parameter and outputs the result to the output file `DataSecurityDiagResults.out`. The application parameter must be set to `TRUE` to support deploying the policy store from a test to a production environment. This ensures the GUID for each application role remain the same when migrated from XML to LDAP or LDAP to LDAP.

- Optionally, takes the running application's session cookie value as an input parameter and, using this session cookie, the script gets the corresponding session object from the data source, inspects the session attributes and outputs the session information to the output file `DataSecurityDiagResults.out`. Using the session cookie, the script gets role information corresponding to the session's logged-in user, along with their access privileges to various database objects and outputs it to the output file `DataSecurityDiagResults.out`.

  Note: If you only want the script to perform the application configuration validation checks, you can skip this step by pressing Enter when prompted to enter the value for session cookie.

Important Note

Before invoking a WLST script you must run the following `wlst.sh` script on Oracle WebLogic Server to ensure that the required JARs are added to the class path.

```bash
>sh $ORACLE_HOME/common/bin/wlst.sh
```

After you invoke the `wlst.sh` script, you can connect to Oracle WebLogic Server in offline mode, that is, the data security script does not require a connection to a running server to operate.

To invoke the data security diagnostic script:

At the offline prompt, enter the following command:

```bash
>ws:/offline> execfile('datasecurityDiagnostics.py')
```

The script prompts you for the following information before outputting the results:

- Output file's directory path where you want the script's output file to be saved.
- Application name for which you want to run the script. The application name is the deployment name in Oracle WebLogic Server. For example, `SalesApp#V3.0`. 
Note that the version part of the application name is specified with a # symbol: for example, #V3.0 in SalesApp#V3.0.

- Application source path of the deployed application. For example, /scratch/myself/view_storage/myself_main_gene_testing/system11.1.4.37.56.69/DefaultDomain/servers/DefaultServer/upload/DemoSecurity/V2.0/app/DemoSecurity.ear. The source path can be obtained from Oracle WebLogic Server Administration Console, under the Deployments section for the application.

- Session cookie value created for the logged-in user for whom you want to validate data security roles and privileges. Optional (you can press Enter to skip). To obtain the session cookie, you must log into the application as the user whose roles and privileges you want to examine. After logging into the application, from the browser, open the cookies window (for example, in Internet Explorer, you can display cookies from the Temporary Internet Files and History Settings dialog). Under the site oracle.com, locate the cookie named <DATABASE_SID>_FND_SESSION and copy the value, which is the required session cookie. If you do not find this named session cookie, it means that the applications context is not created for your application.

Tip:
You can run the application context diagnostic script by pressing Enter when the data security script prompt you to enter the value for session cookie for your application. This will invoke the applications context script and validate the applications context configuration. For details about the applications context script, see How to Validate Applications Context.

### 50.7.2 How to Validate Applications Context

The WLST script applsessionDiagnostics.py is provided to help administrators verify that applications context setup and configuration definitions are correct for a newly deployed application and that the applications context is created for a logged-in user. Additionally, the script generates a report that system integrators, developers and security managers can further use to diagnose the runtime issues related to an Application Session.

To accomplish these tasks, the script performs these specific functions:

- Validates the session filters and filter mapping definitions in the web.xml file, which is archived in the application EAR file. The scripts checks for the presence of the <filter-name>ApplSessionFilter</filter-name> element and verifies that the ApplSessionFilter mapping definition appears immediately after the JpsFilter mapping definition, and then outputs the result to the output file ApplsessionDiagResults.out.

- Connects to the database and gets the Oracle Fusion Applications FND table metadata for the application context. The script checks the value of the Name, Datatype, Precision, and isNullable attributes for each column in the tables, validates the database schema for each table, and then outputs the result to the output file ApplsessionDiagResults.out.

- Optionally, takes the running application’s session cookie value as an input parameter and, using this session cookie, the script gets the corresponding session object from the data source, inspects the session attributes and outputs the applications context session properties to the output file.
ApplsessionDiagResults.out. Using the session cookie, the script gets the applications context properties corresponding to the session's logged-in user, determines whether ApplSession is created properly, and outputs the result to the output file ApplsessionDiagResults.out.

Note: If you only want the script to perform the application configuration validation and the database metadata validation checks, you can skip this step by pressing Enter when prompted to enter the value for session cookie.

- Connects to the database and validates the FUSION.FND_SESSION_MGMT PL/SQL package to check for its consistency. The script checks whether a valid package header and package body is defined for the package and outputs the result to the output file ApplsessionDiagResults.out.

Before you begin:

Before invoking a WLST script you must run the following wlst.sh script on Oracle WebLogic Server to ensure that the required JARs are added to the class path. Use the following command:

>sh $ORACLE_HOME/common/bin/wlst.sh

After you invoke the wlst.sh script, you can connect to Oracle WebLogic Server in offline mode, that is, the data security script does not require a connection to a running server to operate.

To invoke the application context diagnostic script:

At the offline prompt, enter the following command:

>wls:/offline> execfile('applsessionDiagnostics.py')

The script prompts you for the following information before outputting the results:

- Output file's directory path where you want the script's output file to be saved.
- Application name for which you want to run the script. The application name is the deployment name in Oracle WebLogic Server. For example, SalesApp#V3.0. Note that the version part of the application name is specified with a # symbol: for example, #V3.0 in SalesApp#V3.0.
- Application source path of the deployed application. For example, /scratch/ myself/view_storage/myself_main_gene_testing/ system11.1.1.4.37.56.69/DefaultDomain/servers/DefaultServer/ upload/DemoSecurity/V2.0/app/DemoSecurity.ear. The source path can be obtained from Oracle WebLogic Server Administration Console, under the Deployments section for the application.
- Session cookie value created for the logged-in user for whom you want to validate data security roles and privileges. Optional (press Enter to skip). To obtain the session cookie, you must log into the application as the user whose roles and privileges you want to examine. After logging into the application, from the browser, open the cookies window (for example, in Internet Explorer, you can display cookies from the Temporary Internet Files and History Settings dialog). Under the site oracle.com, locate the cookie named <DATABASE_SID>_FND_SESSION and copy the value, which is the required session cookie. If you do not find this named session cookie, it means that the applications context is not created for your application.
50.8 Integrating with Data Security Task Flows

The Oracle Fusion Middleware Extensions for Applications data security task flows are a set of four task flows that provide a simplified user interface for implementing role-based security in Fusion applications. Consider integrating data security task flows into an Oracle Fusion application when your application needs to support an authorized end user's ability to secure business objects in their business domain. For example, these task flows can give Human Resources managers the ability to secure employee records to grant HR representatives access to defined groups of employee records.

Oracle Fusion Middleware Extensions for Applications data security task flows use Oracle Fusion Applications security technology to implement data security policies in Oracle Fusion Applications FND tables and function security policies in the LDAP policy store. At runtime, the task flows implementation performs the necessary backend operations to both secure data exposed by a business object (data security) and to secure the user interface (function security) that displays the business objects.

The following task flows are available and may be integrated using Oracle JDeveloper:

- **Object-centric task flow** lets the end user display and secure a single business object. The flow displays the end user's business object selection and then displays all the application roles that may be granted access to that object. This task flow simplifies the task of securing a business object across the organization.

- **Role-centric task flow** (also called the Profile task flow) lets the end user select an application role profile and secure multiple business objects pertaining to that profile. The flow displays the end user's application role profile selection and displays all the securable business objects that the profile may access. This task flow is also called the profile task flow since every end user is assigned to a profile that corresponds to an enterprise role mapped to a hierarchy of application roles. Note that the role-centric task flow and the object-centric task flow present the end user with different views of the same security functionality. Both enable data security and functionality security policies for permissions that the end user selects across business objects.

- **Instance-level task flow** lets the end user select an instance of a securable business object (one row) for which they have access and then confer access rights to another user or group of users. This task flow provides a way for end users to share access rights with other members of their organization. The scope of this task flow is different from the role-centric and object-centric task flows in that security is limited to the business object instance. The business object itself must already have grants made to the end user who wishes to share access.

- **Role management task flow** lets the end user create and edit application roles. This task flow is particularly useful when the user creates custom business objects and wishes to grant permission to that object for a custom application role.

50.8.1 About Integrating the Data Security Task Flows into Your Application

The process of integrating the data security task flows into an Oracle Fusion application involves understanding the input parameters of the task flow. Your application will use a managed bean to initialize the task flow’s parameters before the application displays the task flow to the end user. The way your application references the values of the input parameters on the bean depends on how you want to display
the task flow. Your application can display the data security task flow one of two ways:

- You can display the task flow in the application's primary browser window.
- You can display the task flow in the application's secondary browser window that displays a new web page and allows the user to view the primary window while working in the task flow.

For example, the object instance task flow user interface is well-suited to run in a dialog. When you run this task flow in a dialog, the user can select an object in the primary browser window, make grants on the selection in the secondary window, and repeat for other objects without needing to reopen the primary window. The other task flows, including the object-centric task flow, profile (role-centric) task flow, and role management task flow, are large enough that you may want to display them in the primary window.

The steps to integrate the data security task flows into your application will depend on the method you choose to display the task flow. However, review the following general steps for an overview of the process.

Before you begin:

Add the data security task flows to your project. Decide whether you want your application to display the task flow in the primary window or in a popup dialog.

To integrate the data security task flows, follow these general steps.

1. Decide whether you want your application to display the task flow in the primary window or in a popup dialog.

2. Create a task flow reference in your application to bind the data security task flow to the ADF Model layer.

   In JDeveloper, the reference will be generated for you when you drag and drop the data security task flow. The way you drag and drop the data security task flow depends on the way your application displays the task flow:

   - How to Configure Data Security Task Flows to Display in the Primary Window
   - How to Configure the Object Instance Task Flow to Display in a Dialog

a. Define the data security task flow’s input parameters so they have page flow scope.

   Page flow scope will allow the values to be passed into the task flow from a managed bean. The ADF Model layer component that you use to define the parameters depends on the way your application displays the task flow:

   - How to Configure Data Security Task Flows to Display in the Primary Window
   - How to Configure the Object Instance Task Flow to Display in a Dialog

b. Create a managed bean and define an initialization method to populate the input parameters for the data security task flows, as shown in Table 50-4.

   The method you define will initialize the values before your application displays the task flow. When displaying the page inside your application’s primary window, the initialization method must also return the value of the flow control outcome you configure in your application’s task flow to invoke the data security task flow. The outcome return value is not needed when displaying a dialog, since the dialog is not invoked the same way.
**c.** Create a navigation button that invokes the initialization method in your method bean.

The ADF Faces component you use to create the button depends on how you want the data security task flow to display:

3. Authorize the data security task flows to make grants in the LDAP policy store. For details see How to Grant the Data Security Task Flows Access to the Application Policy Store.

4. Authorize end user to access the task flow. For details see How to Grant the End User Access to the Data Security Task Flows.

5. Configure the application to access the domain LDAP policy store. For details see How to Map the Application to an Existing Application Stripe.

The following table describes the input parameters that your managed bean must initialize for each task flow.

<table>
<thead>
<tr>
<th>Task Flow Name</th>
<th>Task Flow XML</th>
<th>Parameters Passed</th>
<th>Behavior</th>
</tr>
</thead>
<tbody>
<tr>
<td>Object-centric task flow (also referred to as ObjectLevelTF)</td>
<td>/WEB-INF/oracle/apps/fnd/applcore/dataSecurity/ui/taskflow/ObjectLevelTF.xml</td>
<td>Specify the name of the object for which the grant will be managed: objectName Specify the list of role categories from which the available application roles will be fetched: roleCategories Specify the list of securable actions to be displayed in the UI for the object: actions Specify true/false to determine whether the View All column (supports global grants) should appear in the task flow UI: disableViewAll Specify true/false to determine whether the Update All column (supports global grants) should appear in the task flow UI: disableUpdateAll</td>
<td>Create and manage grants to multiple application roles for a single business object.</td>
</tr>
</tbody>
</table>
### Table 50-4  (Cont.) Data Security Task Flows and Their Input Parameters

<table>
<thead>
<tr>
<th>Task Flow Name</th>
<th>Task Flow XML</th>
<th>Parameters Passed</th>
<th>Behavior</th>
</tr>
</thead>
<tbody>
<tr>
<td>Role-centric task flow (also referred to as ProfileTF)</td>

<td>Specify the list of role categories from which the available application roles will be fetched: roleCategories Specify the title of the task flow UI: title</td>
<td>Create and edit custom application roles.</td>
</tr>
</tbody>
</table>

50.8.2 How to Configure Data Security Task Flows to Display in the Primary Window

When you integrate the task flow as a primary window, your application's task flow invokes the data security task flow using a task flow call activity. A control flow case defines the transition (identified with a particular outcome value) between your application's view activity (for the calling web page) and the call activity. A navigation button in the calling web page invokes a method on the managed bean that initializes the task flow's input parameters and returns the expected value of the control flow case outcome. Your application's task flow invokes the data security task flow through the call activity reference that matches the returned outcome.

To integrate a data security task flow with your application so it appears in the primary browser window of the application:

1. In your application's task flow, create a call activity and specify a control flow case from the calling web page's view activity.

   The calling web page is the page in your application where you want the end user to launch the data security UI. This is the page that will be replaced in the browser window when the data security UI is displayed.

2. Drop the desired data security task flow onto the task flow call activity.

3. Edit your application's task flow configuration file to specify the data security task flow's input parameter values on the call activity.

4. Create a managed bean that initializes the data security task flow's input parameters and returns the value of the outcome for the control flow case you specified.

5. Register the managed bean in your application's task flow configuration file.

6. In the web page associated with the view activity, drop an ADF command button and configure the button to invoke the managed bean's initialization method.

50.8.2.1 Create a Task Flow Call Activity in Your Application's Task Flow

You can use a task flow call activity to call any one of the data security task flows from your application's unbounded or bounded task flow. The task flow call activity allows you to call the data security task flows located within the same or a different application. To pass parameters into the data security task flow, you specify input parameter values on the task flow call activity. These values must correspond to the input parameter definitions on the called data security task flow.
The following example shows the task flow call activity definition with a reference to the object-centric data security task flow. The task flow call activity also defines the input parameter values required by the object-centric task flow.

The following example shows the task flow call activity definition with a reference to the role-centric data security task flow. The task flow call activity also defines the input parameter values required by the role-centric task flow.

The following example shows task flow call activity definition with a reference to the role management data security task flow. The task flow call activity also defines the input parameter values required by the role management task flow.

To create the task flow call activity:

1. Open your application's task flow (the calling task flow) in the diagram editor.

2. In the ADF Task Flow page of the Component Palette, drag a Task Flow Call activity and drop it on the calling task flow.

3. In the ADF Task Flow page of the Component Palette, select Control Flow Case and create the control flow case between the source activity (in your calling task flow) and the call activity.

4. In the task flow diagram, enter the outcome value for the control flow case.

   The value of the outcome must match the return value of the task flow initialization method you create in the managed bean. For details about the managed bean, see Initializing the Data Security Task Flow Using a Managed Bean.

5. In the Application Navigator, drag the desired data security task flow and drop it on top of the task flow call activity that is located on the calling task flow.

   This action references the data security task flow as the called task flow in the <task-flow-call> definition. JDeveloper adds the task flow reference to the calling task flow's configuration file.

6. In the editor for the calling task flow, click the Source tab to view the new task flow reference.

7. In the source for the calling task flow, locate the <task-flow-call> element and create the input parameter definitions by copying and pasting from the sample code:

   - If you dropped the object-centric task flow (the activity references task flow <id>ObjectLevelTF</id>), add the input parameter values from Example 50-32.
   - If you dropped the role-centric task flow (the activity references task flow <id>ProfileTF</id>), add the input parameter values from Example 50-33.
   - If you dropped the role management task flow (the activity references task flow <id>RoleManagementTF</id>), add the input parameter values from Example 50-34.

Instead of copying and pasting the input parameter values from the samples, you can also use the Property Inspector to define each input parameter value. However, it is important that the input parameter values you create match the parameter names specified by the called task flow. Copying from the samples ensures the names match exactly.
Example 50-32  ObjectLevelTF Reference in Calling Task Flow Configuration File

```xml
<task-flow-call id="ObjectLevelTF">
  <task-flow-reference>
    <id>ObjectLevelTF</id>
  </task-flow-reference>
  <input-parameter>
    <name>objectName</name>
    <value>${pageFlowScope.objectName}</value>
  </input-parameter>
  <input-parameter>
    <name>roleCategories</name>
    <value>${pageFlowScope.roleCategories}</value>
  </input-parameter>
  <input-parameter>
    <name>actions</name>
    <value>${pageFlowScope.actions}</value>
  </input-parameter>
  <input-parameter>
    <name>disableViewAll</name>
    <value>${pageFlowScope.disableViewAll}</value>
  </input-parameter>
  <input-parameter>
    <name>disableUpdateAll</name>
    <value>${pageFlowScope.disableUpdateAll}</value>
  </input-parameter>
</task-flow-call>
```

Example 50-33  ProfileTF Reference in Calling Task Flow Configuration File

```xml
<task-flow-call id="ProfileTF">
  <task-flow-reference>
    <document>/WEB-INF/oracle/apps/fnd/applcore/dataSecurity/ui/taskflow/ProfileTF.xml</document>
    <id>ProfileTF</id>
  </task-flow-reference>
  <input-parameter>
    <name>roleCategories</name>
    <value>${pageFlowScope.roleCategories}</value>
  </input-parameter>
  <input-parameter>
    <name>actions</name>
    <value>${pageFlowScope.actions}</value>
  </input-parameter>
  <input-parameter>
    <name>disableViewAll</name>
    <value>${pageFlowScope.disableViewAll}</value>
  </input-parameter>
  <input-parameter>
    <name>disableUpdateAll</name>
    <value>${pageFlowScope.disableUpdateAll}</value>
  </input-parameter>
</task-flow-call>
```

Example 50-34  RoleManagementTF Reference in Calling Task Flow Configuration File

```xml
<task-flow-call id="RoleManagementTF">
  <task-flow-reference>
  </task-flow-reference>
</task-flow-call>
```
50.8.2.2 Initialize the Data Security Task Flow Using a Managed Bean

Managed beans are Java classes that you register with the application in your calling task flow’s configuration file. You will create a method on a managed bean to:

- Initialize the input parameters of the data security task flows.
- Return a value that matches the outcome of the calling task flow.

When your application runs, and the end user clicks the button in the calling web page, the method is invoked and the properties are declared, allowing the called data security task flow input parameters to be populated with the declared values.

The following example shows the additional source code that your managed bean must include to initialize the object-centric (ObjectLevelTF) task flow.

The following example shows the additional source code that your managed bean must include to initialize the role-centric (ProfileTF) task flow.

The following example shows the additional source code that your managed bean must include to initialize the role management (RoleManagementTF) task flow.

To populate task flow input parameters with a managed bean:

1. Use the New Gallery to create the managed bean class and name it for the called task flow.

   For example, you might create a bean named DSRoleManage.java for the RoleManagementTF task flow.

2. In the class editor, create a method that you want to use to initialize the task flow input parameters.

   For example, you might create a method for the RoleManagementTF task flow, initializeRoleManagement().

3. In the method definition, create the input parameter property definitions by copying and pasting from the sample code into the method definition:

   - If you want to initialize the object-centric task flow, add the input parameter property declarations from Example 50-35.

   - If you want to initialize the role-centric task flow (also called the Profile task flow), add the input parameter property declarations from Example 50-36.

   - If you want to initialize the role management task flow, add the input parameter property declarations from Example 50-37.
Copying from the samples ensures the input parameters names match those defined by the data security task flow.

4. In the source you pasted, edit the input parameter property definitions to specify the default values for your application.

5. Enter a return value for the initialization method that matches the outcome of the control flow case you specified in your calling task flow.

For example, for the outcome value "start", your method should show:

```
return "start";
```

For details about creating the control flow case in your application’s task flow, see Creating a Task Flow Call Activity in Your Application’s Task Flow.

**Example 50-35  Source for Populating the ObjectLevelTF Input Parameters**

```
//Source for managed bean method to populate and pass ObjectLevelTF parameters
String objectName = "TEST_DS_EMP";
List actions = new ArrayList<ActionMap>();

//for action 1
List<String> instanceSets1 = new ArrayList<String>();
instanceSets1.add("TEST_EMP_IS1");
instanceSets1.add("TEST_EMP_IS2");
instanceSets1.add("TEST_EMP_IS3");

ActionMap action1 = ActionMap.getActionMapForObjectUI("View", "VIEW_M",
    "ViewPermSet", false, instanceSets1);
actions.add(action1);

//for action 2
List<String> instanceSets2 = new ArrayList<String>();
instanceSets2.add("TEST_EMP_IS2");
instanceSets2.add("TEST_EMP_IS3");
instanceSets2.add("TEST_EMP_IS4");

ActionMap action2 = ActionMap.getActionMapForObjectUI("Update", "UPDATE_M",
    "UpdatePermSet", false, instanceSets2);
actions.add(action2);

//populate role categories
List roleCategories = new ArrayList<String>();
roleCategories.add("Category1");
roleCategories.add("Category2");
roleCategories.add("Category3");

//set the parameters in pageflow scope
AdfFacesContext context = AdfFacesContext.getCurrentInstance();
Map pageFlowScope = context.getPageFlowScope();
pageFlowScope.put("objectName", objectName);
pageFlowScope.put("roleCategories", roleCategories);
pageFlowScope.put("actions", actions);
```

**Example 50-36  Source for Populating the ProfileTF Input Parameters**

```
//Source for managed bean method to populate and pass ProfileTF parameters
List roleCategories = new ArrayList<String>();
roleCategories.add("Category1");
```
roleCategories.add("Category2");

List actions = new ArrayList<ActionMap>();

// for action 1
List<ProfileActionObject> profileObjects1 = new ArrayList<ProfileActionObject>();
profileObjects1.add(ProfileActionObject.getProfileActionObject("View", "TEST_DS_EMP", "VIEW_EMP_M","ViewEmpPermSet"));
profileObjects1.add(ProfileActionObject.getProfileActionObject("View", "TEST_DS_EMP1", "VIEW_EMP1_M","ViewEmp1PermSet"));
profileObjects1.add(ProfileActionObject.getProfileActionObject("View", "TEST_DS_EMP2", "VIEW_EMP2_M","ViewEmp2PermSet"));
ActionMap action1 = ActionMap.getActionMapForProfileUI("View", profileObjects1);
actions.add(action1);

// for action 2
List<ProfileActionObject> profileObjects2 = new ArrayList<ProfileActionObject>();
profileObjects2.add(ProfileActionObject.getProfileActionObject("Update", "TEST_DS_EMP1", "UPDATE_EMP1_M","UpdateEmp1PermSet"));
profileObjects2.add(ProfileActionObject.getProfileActionObject("Update", "TEST_DS_EMP2", "UPDATE_EMP2_M","UpdateEmp2PermSet"));
ActionMap action2 = ActionMap.getActionMapForProfileUI("Update", profileObjects2);
actions.add(action2);

AdfFacesContext context = AdfFacesContext.getCurrentInstance();
Map pageFlowScope = context.getPageFlowScope();
pageFlowScope.clear();
pageFlowScope.put("roleCategories", roleCategories);
pageFlowScope.put("actions", actions);
pageFlowScope.put("disableViewAll", false);
pageFlowScope.put("disableUpdateAll", false);

Example 50-37 Source for Populating the RoleManagementTF Input Parameters

// Source for managed bean method to populate & pass RoleManagementTF parameters
AdfFacesContext context = AdfFacesContext.getCurrentInstance();
Map pageFlowScope = context.getPageFlowScope();
pageFlowScope.clear();
List roleCategories = new ArrayList<String>();
roleCategories.add("Category1");
roleCategories.add("Category2");
roleCategories.add("Category3");
pageFlowScope.put("roleCategories", roleCategories);
pageFlowScope.put("title", "Role Management");

50.8.2.3 Register the Managed Bean with Your Application's Task Flow

To declare the manage bean in the calling task flow's configuration file, you must enter a bean identifier name, the class path for the bean, and you must specify backing bean scope. The following example uses the bean identifier roleManageBean to match the Action attribute definition specified on the button component shown in Example 50-39.

To register the managed bean with the calling task flow:

1. Open your application's task flow (the calling task flow) in the diagram editor.
2. In the editor for the task flow, click the Source tab.
3. In the source for the calling task flow, declare the managed bean by creating the `<managed-bean>` element similar to the sample shown in the previous example.

**Example 50-38 Managed Bean Declaration in Calling Task Flow Configuration File**

```xml
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <task-flow-definition id="MyCallingTaskFlow">
    <default-activity id="__1">CallRoleManageTF</default-activity>
    <managed-bean id="__4">
      <managed-bean-name id="__5">roleManageBean</managed-bean-name>
      <managed-bean-class id="__2">oracle.apps.fnd.applcore.dataSecurity.view.RoleManage</managed-bean-class>
      <managed-bean-scope id="__3">backingBean</managed-bean-scope>
    </managed-bean>
  </task-flow-definition>
  ...
</adfc-config>
```

50.8.2.4 Creating a Command Button to Invoke the Task Flow in the Primary Window

Create an ADF command button component in the web page associated with the source activity of the control flow case you create in the calling task flow. When the end user clicks the button, the button will cause the data security task flow to display. You will need to configure the Action attribute of the button so a click by the end user invokes the initialization method of your managed bean.

The following example shows a command button component with an Action attribute that invokes the method `initializeRoleManagement()` on the bean referenced by the bean identifier `roleManageBean`. The name of the identifier corresponds to the managed bean declaration you create when you edit the calling task flow configuration file, as described in Registering the Managed Bean with Your Application's Task Flow.

**Example 50-39 Button Component with Action Attribute to Invoke Bean Method**

```xml
<af:commandButton text="Manage Roles" id="cb1"
  action="#{backingBeanScope.roleManageBean.initializeRoleManagement}"/>
```

50.8.3 How to Configure the Object Instance Task Flow to Display in a Dialog

When you integrate a data security task flow as a dialog, your application’s task flow invokes the task flow using an executable in the ADF Model layer. This executable is defined by JDeveloper when you drop the data security task flow as region onto a dialog component that you add to your application’s calling web page. The web page the defines the region is associated with a view activity in your application task flow; no task flow control flow case is needed to invoke the data security task flow.

A popup button in the calling web page defines a listener that invokes a method on the managed bean to initialize the task flow’s input parameters. The button then displays the dialog with a region that invokes the task flow using the executable defined on the calling page’s definition. When the user clicks the dialog close button, a listener (for the dialog’s close button) saves the end user’s sections from data security UI.

To integrate the object instance task flow (ObjectInstTF) with your application so it appears in a dialog (as a secondary browser window):

1. In your application’s task flow, double-click the view activity associated with the web page that end users will use to open the dialog.
2. In the web page, drop an ADF command button component.

3. Drop an ADF popup component onto the button and configure a popup fetch listener to invoke an initialization method on a managed bean.

4. Drop an ADF dialog inside the popup component and configure a dialog listener to invoke a method to save grants made by the user.

5. Drop the object instance task flow as a region onto the dialog component.

6. Edit the page definition file for the calling page to specify the data security task flow’s input parameter values on the task flow executable.

7. Create a managed bean and define a method to initialize the task flow parameters before the dialog displays.

8. Define another method on the managed bean to trigger the task flow save action and save the grants into the database.

9. Register the managed bean in your application's task flow configuration file.

50.8.3.1 Create the Task Flow Executable in the Region Page Definition File

When you drop a data security task flow onto a web page to create an ADF region, JDeveloper adds an af:region tag to the page. The af:region tag references an object that implements RegionModel, as shown in #unique_1712/unique_1712_Connect_42_BABGFDE. JDeveloper also adds a task flow binding to the <executables> element of the page definition file for the page that defines the ADF region. The task flow binding provides a bridge between the ADF region and the data security task flow. It binds a specific instance of an ADF region to the data security task flow and maintains all information specific to the task flow. The taskFlowId attribute specifies the directory path and the name of the source file for the bounded task flow. To pass parameters into the data security task flow, you must specify input parameter values on the task flow binding. These values must correspond to the input parameter definitions on the called data security task flow.

The following example shows task flow binding in the page definition file with a reference to the object-instance data security task flow. The task flow binding also defines the input parameter values required by the object-instance task flow.

To create the task flow binding definition:

1. Open your application's task flow (the calling task flow) in the diagram editor.

2. In the ADF Task Flow page of the Component Palette, drag a View activity and drop it on the calling task flow.

3. In the ADF Task Flow page of the Component Palette, select Control Flow Case and create the control flow case between the source activity (in your calling task flow) and the view activity.

4. In the task flow diagram, enter the outcome value.

   The value of the outcome should match the return value of the initialization method you create in the managed bean used to populate the data security input parameters. For details about the managed bean, see Initializing the Data Security Task Flow Using a Managed Bean.

5. In the Application Navigator, drag the object instance task flow and drop it on top of the task flow call activity that is located on the calling task flow.
This action defines the data security task flow as the called task flow using a `<task-flow-call>` definition. The task flow call definition appears in the calling task flow configuration file.

6. In the editor for the task flow, click the **Source** tab to view the new task flow reference.

7. In the source for the calling task flow, locate the `<task-flow-call>` element and create the input parameter definitions by copying and pasting from the sample code:

   - If you dropped the object-centric task flow (activity will show task flow reference `<id>ObjectLevelTF</id>`), add the input parameter values from Example 50-32.
   - If you dropped the role-centric task flow (activity will show task flow reference `<id>ProfileTK</id>`), add the input parameter values from Example 50-33.
   - If you dropped the role management task flow (activity will show task flow reference `<id>RoleManagementTF</id>`), add the input parameter values from Example 50-34.

Instead of copying and pasting the input parameter definitions from the samples, you could also use the Property Inspector to define each input parameter. However, it is important that the input parameter definitions you create match the parameter names specified by the called task flow. Copying from the samples ensures the names match exactly.

**Example 50-40  **ObjectInstTF Call Entry in Page Definition File**

```
<taskFlow id="ObjectInstTF1"
  taskFlowId="/WEB-INF/oracle/apps/fnd/applcore/dataSecurity/ui/
   taskflow/ObjectInstTF.xml#ObjectInstTF"
  Refresh="ifNeeded"
  xmlns="http://xmlns.oracle.com/adf/controller/binding">
  <parameters>
    <parameter id="objectName" value="#{pageFlowScope.objectName}" xmlns="http://xmlns.oracle.com/adfm/uimodel" />
    <parameter id="actions" value="#{pageFlowScope.actions}" xmlns="http://xmlns.oracle.com/adfm/uimodel" />
    <parameter id="instancePK1" value="#{pageFlowScope.instancePK1}" xmlns="http://xmlns.oracle.com/adfm/uimodel" />
    <parameter id="instancePK2" value="#{pageFlowScope.instancePK2}" xmlns="http://xmlns.oracle.com/adfm/uimodel" />
    <parameter id="instancePK3" value="#{pageFlowScope.instancePK3}" xmlns="http://xmlns.oracle.com/adfm/uimodel" />
    <parameter id="instancePK4" value="#{pageFlowScope.instancePK4}" xmlns="http://xmlns.oracle.com/adfm/uimodel" />
    <parameter id="instancePK5" value="#{pageFlowScope.instancePK5}" xmlns="http://xmlns.oracle.com/adfm/uimodel" />
    <parameter id="taskflowId" value="#{pageFlowScope.taskflowId}" xmlns="http://xmlns.oracle.com/adfm/uimodel" />
    <parameter id="parameterMap" value="#{pageFlowScope.parameterMap}" xmlns="http://xmlns.oracle.com/adfm/uimodel" />
  </parameters>
</taskFlow>
```

### 50.8.3.2 Creating a Command Button to Invoke the Popup Dialog

Your web page should display a button that will invoke the popup operation.
Create an ADF command button component in the web page associated with the view activity of the calling task flow. Then drop an ADF popup component in the panel that contains the button. Then drop an ADF `showPopupBehavior` operation onto the button and set it to the ID of the popup component. Finally, drag a dialog onto the popup component.

You will also need to specify a listener for both the popup component and the dialog component. These listeners invoke methods on the managed bean to initialize the input parameters and save the user selections.

The following example shows a command button component with the `showPopupBehavior` operation nested on the button. The popup component appears in the same panel as the button and defines the `popupFetchListener` property to identify the `launchPolicy()` method on the bean referenced by the bean identifier `objectInstanceBean`. The dialog component defines the `dialogListener` property to identify the `okCreatePolicy()` method on the bean referenced by the same bean identifier. The name of the identifier corresponds to the managed bean declaration you create when you edit the calling task flow configuration file.

Note that the ADF region component element shown in the example will be created when you drop the data security object instance task flow as a region.

**Button Component with Show Popup Operation to Invoke Dialog**

```html
<af:panelHeader id="phl12" text="Test Instance UI">
  <af:panelGroupLayout id="pgl13" layout="horizontal">
    <af:commandButton id="cb6" text="Launch Object Instance Popup"
      partialSubmit="true">
      <af:showPopupBehavior popupId="objInst"/>
    </af:commandButton>
    <af:popup id="objInst" contentDelivery="lazyUncached"
      popupFetchListener="#{backingBeanScope.objectInstanceBean.launchPolicy}"
      childCreation="deferred">
      <af:dialog id="polDiag" modal="true" title="Object Instance UI"
        affirmativeTextAndAccessKey="Save and Close" resize="on"
        contentWidth="600" contentHeight="330"
        stretchChildren="first"
        dialogListener="#{backingBeanScope.objectInstanceBean.okCreatePolicy}"
      >
        <af:region value="#{bindings.ObjectInstTF1.regionModel}" id="r1"/>
      </af:dialog>
    </af:popup>
  </af:panelGroupLayout>
</af:panelHeader>
```

### 50.8.3.3 Initialize the Object-Instance Task Flow Using a Managed Bean

Managed beans are Java classes that you register with the application in your calling task flow’s configuration file. You will define two methods on a managed bean:

- A popup fetch listener method to add properties to the managed bean that will initialize the input parameters of the data security task flows.
- A dialog listener method to save the grants made by the end user to the database when the user closes the dialog.

When your application runs, and the end user clicks the button in the calling web page, the popup fetch listener method is invoked and the properties are declared, allowing the called data security task flow input parameters to be populated with the declared values.
The following example shows additional source code that your managed bean must include to initialize the object-instance (ObjectInstTF) task flow.

The following example shows the source code you must add for the method your dialog listener invokes. In this case, the method is named `okCreatePolicy()` to match the method invoked by the dialog listener in `#unique_1712/unique_1712_Connect_42_BABGFDGE`.

To populate task flow input parameters with a managed bean:

1. Use the New Gallery to create the managed bean class and name it for the called task flow.

   For example, you might create a bean named `DSObjectInstance.java` for the object instance task flow.

2. In the class editor, create a method that you want the popup listener to invoke to initialize the task flow input parameters.

   For example, you might create a method `launchPolicy()` named for the method invoked by the popup listener (shown in `#unique_1712/unique_1712_Connect_42_BABGFDGE`).

3. In the method definition, create the input parameter property definitions by copying and pasting from Example 50-41 into the new initialization method definition.

   Copying from the sample ensures the input parameters names match those defined by the object instance task flow.

4. In the source you pasted, edit the input parameter property definitions to specify the default values for your application.

5. In the class editor, create a method that you want the dialog listener to invoke to save the grants after the user closes the dialog.

   For example, you might create a method `okCreatePolicies()` named for the method invoked by the dialog listener (shown in `#unique_1712/unique_1712_Connect_42_BABGFDGE`).

6. In the method definition, create the save operation by copying and pasting from Example 50-42 into the new save grants method definition.

   Copying from the sample ensures the method `saveInstanceGrants()` is called exactly as shown.

**Example 50-41 Source for Populating the ObjectInstTF Input Parameters**

```java
//Source for managed bean to populate and pass ObjectInstTF parameters
public void launchPolicy(PopupFetchEvent popupFetchEvent) {
    List actions = new ArrayList<ActionMap>();

    ActionMap action1 = ActionMap.getActionMapForInstanceUI("View", "VIEW_EMP_M");
    actions.add(action1);

    ActionMap action2 = ActionMap.getActionMapForInstanceUI("Update", "UPDATE_EMP_M");
    actions.add(action2);

    ActionMap action3 = ActionMap.getActionMapForInstanceUI("Create", "CREATE_EMP_M");
}
```

Implement Oracle Fusion Data Security 50-51
actions.add(action3);
ActionMap action4 =
ActionMap.getActionMapForInstanceUI("Delete", "DELETE_EMP_M");
actions.add(action4);
ActionMap action5 =
ActionMap.getActionMapForInstanceUI("CustomFSOnlyAction",
"CUSTOMFSONLYACTION_EMP_M");
actions.add(action5);

AdfFacesContext context = AdfFacesContext.getCurrentInstance();
Map pageFlowScope = context.getPageFlowScope();
pageFlowScope.clear();
pageFlowScope.put("actions", actions);
pageFlowScope.put("objectName", "TEST_DS_EMP");
pageFlowScope.put("instancePK1", "2");
pageFlowScope.put("instancePK2", null);
pageFlowScope.put("instancePK3", null);
pageFlowScope.put("instancePK4", null);
pageFlowScope.put("instancePK5", null);

// If you want to use a customized task flow instead of people picker to select
// users, you need specify values for the taskflowId and parameterMap.
// Map<String, Object> paraMap = new HashMap<String, Object>();
// paraMap.put("pageTitle", "Custom User Selection");
// pageFlowScope.put("parameterMap", paraMap);
// Taskflow name
// pageFlowScope.put("taskflowId", "/WEB-INF/CustomDSUserTF.xml#CustomDSUserTF");

Example 50-42  Source for Saving the ObjectInstTF Grants

//Source for managed bean to save end user grant
public void okCreatePolicy(DialogEvent dialogEvent)
{
   DataSecurityUIUtils.saveInstanceGrants(dialogEvent);
   //Add your custom code if needed
}

50.8.3.4 Register the Managed Bean with Your Application's Task Flow

To declare the managed bean in the calling task flow's configuration file, you must enter
a bean identifier name, the class path for the bean, and you must specify backing bean
scope. The following example uses the bean identifier objectInstanceBean to
match the bean references specified in the listener properties shown in #unique_1712/
unique_1712_Connect_42_BABGFDE.

To register the managed bean with the calling task flow:

1. Open your application's task flow (the calling task flow) in the diagram editor.
2. In the editor for the task flow, click the Source tab.
3. In the source for the calling task flow, declare the managed bean by creating the
   <managed-bean> element similar to the sample shown in the previous example.

Example 50-43  Managed Bean Definition in Calling Task Flow Configuration File

<adf-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">  
<task-flow-definition id="MyCallingTaskFlow">
50.8.4 How to Grant the Data Security Task Flows Access to the Application Policy Store

A grant must be added to the jazn-data.xml policy store to allow your application to provision the LDAP policy store. The LDAP policy store is secured so that only authorized applications can make API calls needed to create and update grants in the store. For this purpose, a code source grant must be made to authorize the implementation code of the data security task flows to make credential store and policy store API calls. The following example shows the code source grant where <application-name> is the application name specified in the jazn-data.xml policy store.

To enable the application to access and update the domain policy store:

1. In JDeveloper, open the jazn-data.xml file in the overview editor.
2. In the source for the jazn-data.xml file, add the code source grant shown in the previous example to the policy store and enter the name of your application in the <url> and <name> definitions.
   
   The application name you enter must match the application name identified in the policy store definition.

Example 50-44 Grant to Enable Policy Store Provisioning by Data Security Task Flow Source Code

50.8.5 How to Grant the End User Access to the Data Security Task Flows

The data security task flows, when integrated into your application, behave like other web application resources secured by ADF Security. By default, ADF Security locks down application resources and therefore requires that you grant access rights to the members of the application roles for the task flows.
To grant view access to the task flows, you define a OPSS permission grant defined by the `oracle.adf.controller.security.TaskFlowPermission` class. The following example shows the permission definition that grants the users (identified by `<grantee>` in your application) view access rights to the task flows.

Note that the resources in the permission grant are identified by regular expression metacharacters `.*` (dot followed by an asterisk). This expression denote any number of arbitrary characters and effectively grants view rights on all task flows in the Oracle Fusion Applications data security path `/WEB-INF/oracle/apps/fnd/appcore/dataSecurity/ui/taskflow/`.

The grantee of the permission are the application roles that your application specifies. If you are using custom application roles not defined by Oracle Fusion Applications, a security manager will need to configure these application roles using Oracle Authorization Policy Manager. For example, an application role requires a role category definition.

To enable function security for the data security task flows:

1. In JDeveloper, open the `jazn-data.xml` file in the overview editor.
2. In the source for the `jazn-data.xml` file, add the permission definition shown in the previous example to the policy store and define the grantee.

   Grantee are typically application roles that your application defines. A grant is always made to a single grantee. When you need to grant view permission to more than one grantee, create duplicate grants and name the grantee in each.

Example 50-45  Grant to View Data Security Task Flows

```xml
<grant>
  <grantee>
    ...
  </grantee>
  <permissions>
    <permission>
      <class>oracle.adf.controller.security.TaskFlowPermission</class>
      <name>/WEB-INF/oracle/apps/fnd/appcore/dataSecurity/ui/taskflow/.*</name>
      <actions>view</actions>
    </permission>
  </permissions>
</grant>
```

50.8.6 How to Map the Application to an Existing Application Stripe

Before you deploy the application, you need to identify the application stripe in the production environment. When deployed, the application will make use of the application roles and security policies defined by the application stripe. The following example shows the `web.xml` entry to identify the existing application stripe.

To map the application to the deployed application stripe:

1. In JDeveloper, open the `web.xml` file in the overview editor.
2. In the source for the `web.xml` file, add the web application initialization parameter shown in the previous example beneath the JPS filter.

   The application name you enter must match the application name identified in the policy store definition.

**Example 50-46  `web.xml` Parameter Identifies Deployed Application Stripe**

```xml
<init-param>
    <param-name>application.name</param-name>
    <param-value><application-name></param-value>
</init-param>
```
This chapter describes how to implement application user sessions in an Oracle Fusion application to allow applications to store security and application context on the user session.

This chapter includes the following sections:

- Introduction to Application User Sessions
- Configuring Your Project to Use Application User Sessions
- Accessing Properties of the Applications Context

### 51.1 Introduction to Application User Sessions

Configuring your user interface project for an application user session is a requirement whenever you want to secure data and interact with Oracle Fusion Data Security. Additionally, before you can run and test your application from a task flow or web page, you should configure your user interface project to use an application user session.

The application user session is used to store user and application context from the time the user logs in until log out. When the application user session is implemented, the Oracle Fusion application can easily reconnect to the same user session for each request, maintaining the user context over the duration of the user's session without the overhead of having to obtain and initiate a database connection each time. The actual connection used is not guaranteed to be the same between requests. Application user session roles can be enabled for a user, which can dictate what data is available to the user based strictly on existing data security policies.

The application user session stores common information used in Oracle Fusion Applications as session attributes and includes basic information about user identity and language preferences, as well as context important to particular applications. Specifically, session information includes the session ID, current user information, current language, date and number formatting, and other similar properties. Session attributes can also be used to track application specific information such as, the current user's shopping cart, the country selection, or the currently selected operating unit.

Application user session namespaces are where attributes on the session are stored. These attributes are then available over multiple requests whenever the session is attached.

Oracle Fusion Applications maintains its own namespaces - one for tracking security information, and another that developers can use to store attributes that they need to track over the life of a session.

Additionally, developers can create their own namespaces for any product specific attributes that they need to track over the life of a session. For example, when a large
number of attributes exists, developers may want to create their own namespaces to group the attributes together more cleanly.

Oracle Fusion Middleware Extensions for Applications provides covers on top of the routines for getting attributes. To access the attributes of the application context, APIs exist in both PL/SQL and Java, as described in Accessing Properties of the Applications Context.

51.2 Configuring Your Project to Use Application User Sessions

When you create a user interface project to test or run a task flow (anything that contains a .jspx file) you need to enable application user sessions for any JSPX pages or task flows that you have created in your user interface project.

If the user interface project provides task flows that are only called from a page in another project, then there is no need to configure your project to use sessions.

51.2.1 How to Configure Your Project to Use Application User Sessions

By default, application user sessions are not enabled for your project. If you wish to access this functionality, you must configure your project.

Before you begin:

It may be helpful to have an understanding of application user sessions. For more information, see Implementing Application User Sessions.

You may need to complete these tasks:

- If you have any web services projects, you must configure them to maintain the application user session across the web service request. For more information, see Maintaining Application Session Context Across Web Service Requests.

- If you have any portlet projects, you must configure them to maintain the application user session across the web service request. For more information, see Maintaining Application Session Context Across Web Service Requests.

To configure your project to use application user sessions:

1. In your Application Navigator, select your data model project and then right-click and choose Project Properties. In the Categories tree, select Libraries and Classpath and verify that the Applications Core and Web Services Data Control libraries have been added.

2. In your Application Navigator, select the web.xml file in the WEB-INF folder of your user interface project. Double-click to open the file. In the Categories tree, select Filters to create a new filter. Enter the following information:

   Filter Name: Enter ApplSessionFilter

   Filter Class: Enter oracle.apps.fnd.applcore.common.ApplSessionFilter

3. Select the Source view to manually modify the web.xml source to add the ApplSessionFilter mapping definition into the same section where other filters are defined—immediately after the JpsFilter mapping definition and before any other definitions.

   The following example shows the ApplSessionFilter mapping definition to add.
It is important that you add this filter mapping immediately after the JpsFilter mapping definition and before any other definitions. This is to ensure that the ApplSessionFilter servlet filter executes immediately after the JpsFilter servlet handles authentication. Normally, this does not make a difference, however there are cases, such as customization code, where this is required.

You can create the above through the Filter Mappings tab (with Mapping Type set to Servlet, and Mapping set to Faces Servlet, and Dispatcher Type set to Forward, Request) but to change the ordering of the filter mapping, you must modify the web.xml file directly.

4. Save all changes.

**Example 51-1 Creating a New Filter Mapping Definition**

```xml
<filter-mapping>
  <filter-name>ApplSessionFilter</filter-name>
  <servlet-name>Faces Servlet</servlet-name>
  <dispatcher>FORWARD</dispatcher>
  <dispatcher>REQUEST</dispatcher>
</filter-mapping>
```

You should also stop and restart any server processes that you have running to make sure JDeveloper notices this new change. At this point you can run your page with application user sessions enabled, but you will always be running as the anonymous user. If you wish to require that users to authenticate, you will need to enable authentication and define some users and roles, as described in Adding Function Security to the Application.

### 51.2.2 How to Configure the ADF Business Component Browser

The steps in How to Configure Your Project to Use Application User Sessions can be used to configure the ADF Business Component Browser to run in a mode that supports application user sessions.

If you are running a standalone Java program or a JUnit test, you must explicitly call the ApplSessionUtil.initializeSession API at the beginning of your program to create an applications context object. For more information about how to call the ApplSession.initializeSession API, see Initializing Sessions.

### 51.2.3 How to Use the ApplSession Logger for Troubleshooting

One of the most useful diagnostic tools for applications configured for application user sessions is the ApplSession logger. The specific logger for application users sessions logging is named oracle.apps.fnd.appcore.common.session (also called the ApplSession logger). You use this logger to capture runtime traces messages that are specific to application user sessions. By default, the logger records messages at the WARNING level. If you need to log additional details as part of troubleshooting, you can increase the ApplSession log level to adjust the amount of information that is recorded. For example, more detailed information may help you to quickly identify the origin of an application user sessions error.

In JDeveloper, when you configure a logger and run the application, JDeveloper displays runtime messages recorded by the logger in the Log window and a system log file. You configure logging in JDeveloper using the editor for Oracle Diagnostic Logging Configuration. After you have created a log, you can view and filter the log
messages with Oracle Diagnostic Log Analyzer. This tool allows you to set filters for
different log levels, define message time frames, and search on message text.

After the application is deployed to standalone Oracle WebLogic Server, a system
administrator uses Oracle Enterprise Manager Fusion Applications Control to adjust
the log level and to view the logger’s recorded messages. The system administrator
may increase the ApplSession log level to gather detailed information for a particular
managed server.

For more information about adjusting log levels for the ApplSession logger, using
Fusion Applications Control, see the "Configuring ApplSession Log Levels" section in
the Administrator’s Guide.

  Fusion Middleware, in the Oracle Fusion Middleware Online Documentation
  Library.

51.2.4 What Happens at Runtime: How the Application User Session is Used

When you run your page, the OPSS layer checks if authentication is required. When
access to the page requires authentication of the user, an authentication dialog
prompts the user to log in. After the user completes login, the ApplSessionFilter
is triggered and establishes an applications user session for the user based on the
Subject asserted by the OPSS layer. For example, if you login as OPERATIONS/
welcome, an application user session for the OPERATIONS user is created and set as
the current session. Your page can access this session through the ApplSessionUtil
class, as described in Accessing Properties of the Applications Context.

For details about enforcing security and granting access to application resources while
testing the applications, see Adding Function Security to the Application.

51.3 Accessing Properties of the Applications Context

The applications context is a set of properties relevant to applications that is stored on
the application user session as a series of name-value pairs. You can access the core
application security context in one of two ways:

• Through the ApplSession.java class in the
  oracle.apps.fnd.applicore.common package

• Through the FND_GLOBAL package in PLSQL

The list of context attributes includes information such as current user name and the
current language. The core attributes that are now supported were derived from the
following:

• Customization layer hierarchy.
The following is the list of context attributes that are automatically captured and maintained in the ApplSession context. The values listed are the exact names of the attributes as they are defined in the session context. Note that developers can add their own custom attributes as well.

**Security and Customization attributes:**

- **USER_GUID** - The unique GUID that identifies the currently logged in user.
- **USER_NAME** - The name of the currently logged in user.
- **PRODUCT_FAMILY** - The current active product family.
- **PRODUCT** - The current active product.
- **INDUSTRY** - The current active industry.
- **TERRITORY** - The current active territory.
- **SITE** - Returns the constant value SITE.
- **GLOBAL** - Returns the constant value GLOBAL.
- **ADDTL_CUSTOM_LEVEL** - Additional customization level is a context property that can be customized by developers.
- **INDUSTRY_IN_TERRITORY** - The current active industry in a particular territory.
- **ROLES** - A list of roles (both enterprise roles and OPSS application roles) that are currently active. (Assigned to the currently logged in user). If the application session changes, then the roles associated with the new application will be appended onto the session list.

**Language attributes:**

- **LANGUAGE** - The language tag representing the current language.
- **NLS_LANG** - The two-letter database language code. Derived from the language.
- **NLS_LANGUAGE** - The database language. Derived from the language.
- **NLS_SORT** - String sorting logic in database. This is from linguistic sorting support project.
- **TERRITORY** - Listed above as part of the customization context.
- **DATE_FORMAT** - Format mask pattern for date parsing and formatting.
- **TIME_FORMAT** - Format mask pattern for time parsing and formatting. This includes time zone formatting.
- **GROUPING_SEPARATOR** - Grouping separator for number formatting.
- **DECIMAL_SEPARATOR** - Decimal separator for number formatting.
- **TIME_ZONE** - User’s preferred time zone in Oracle E-Business Suite (EBS) R12.
- **CURRENCY** - The current currency code.
• **CLIENT_ENCODING** - Client native encoding used for file uploading, downloading, export, and attachment.

**Note:**
All language context attributes are handled using Java conventions, except for those that are explicitly prefixed with NLS. For example, `getLanguage()` returns en-US (corresponding to "AMERICAN" in the database) and `getDateFormat()` returns dd-MMM-yy (corresponding to DD-MON-RR in the database).

**Miscellaneous attributes:**
- **TRACE_LEVEL** - The current tracing level when tracing is turned on.
- **MODULE** - Stores the current module for tracing purposes.
- **ACTION** - Stores the current action, such as page, being taken for tracing.
- **ACCESSIBILITY_MODE** - The current accessibility mode.

The stored name-value pairs are partitioned into separate namespaces. Oracle Fusion Applications creates namespaces to store the context attributes.

**Note:**
The actual names of these namespaces and which attributes are used in which namespace is an implementation detail that you do not need to be aware of.

Developers can access the attribute-storage namespaces through the standard APIs that are detailed below.

Developers may also choose to define their own namespaces, especially if they have several attributes they wish to store on the session. Developers may currently choose among the following APIs for initializing namespaces:

- **Java:** `ApplSession.initializeNamespace(String namespaceName)`
- **PL/SQL:** `fnd_global.initialize_namespace (namespace_name IN VARCHAR2);`

The Java and PL/SQL initializeNamespace routines are identical, just invoked from different layers—these will dynamically create a new namespace associated with the currently attached session, which you can then access and retrieve session attributes from for the duration of that session.

### 51.3.1 How to Access Sessions Using Java APIs

In Java, the applications context is accessed through the `ApplSession.java` and `ApplSessionUtil.java` classes, which can be found in the `oracle.apps.fndapplcore.common` package. Each of the attributes listed above have corresponding APIs in the `ApplSession` class, along with a corresponding static API in the `ApplSessionUtil` class for easier access.

For more information, see the javadoc included with Oracle Fusion Middleware Extensions for Applications libraries.
51.3.1.1 Initializing Sessions

Because it is not possible to authenticate users in the PLSQL layer, the API to initialize a session in PS/SQL is only expected to be called for testing. To use sessions, you must first configure your project to use application user sessions. For more information about configuring your project, see Configuring Your Project to Use Application User Sessions.

After you have configured your project to use application user sessions, you should be able to access sessions automatically if you are running a Java EE page.

For J2SE programs, such as JUnit tests, you must call an explicit API to initialize your session. As the following example shows, for JUnit tests in particular, this is most likely your setUp() or setUpBeforeClass() method along with a terminateSession call in the corresponding tearDown() or tearDownAfterClass() method.

Caution:

Remember, every call to initializeSession should have a corresponding terminateSession invoked after the code completes to prevent memory leaks.

Example 51-2 Initializing Your Session

```java
@BeforeClass
public static void setUpBeforeClass() throws exception {
    // Create a session for the OPERATIONS user
    List<String> roleGuids = new ArrayList<String>(1);
    List<String> roleNames = new ArrayList<String>(1);
    roleGuids.add("1807EDD02DBB11DDBFDC91643D402C34");
    roleNames.add("operationsRole");
    ApplSession session = ApplSessionUtil.initializeSession("43B84790D5F011DCAF4F5FFD8462C8E7", "OPERATIONS", roleGuids, roleNames, null);
}

@AfterClass
public static void tearDownAfterClass() throws exception {
    // note that if a connection to the 'initializeSession' call had been passed
    // in, it would would have to be freed here. Since null is passed in, the
    // connection that was obtained in that call will be freed automatically.
    ApplSessionUtil.terminateSession();
}
```

51.3.1.2 Getting Context Attributes

Accessing a context attribute is simple. First, make sure your project is configured to use application user sessions and then import the ApplSession and ApplSessionUtil classes. As the following example shows, after you complete
those tasks you can access the session and its properties using the static APIs that are provided.

Using the example, guid1 and guid2 should both return the same value. The ApplSessionUtil API is a convenience method that essentially calls the same code as the first two lines. One difference is that ApplSessionUtil.getUserGuid() raises an exception if the session is not available. This is true for all the ApplSessionUtil get methods, except for getSession(), which just returns null if there is no session.

All of the centrally maintained attributes listed above have corresponding get APIs available. The following example shows a mechanism for getting generic attributes. The following example shows the API you use to fetch attributes from a particular namespace.

**Example 51-3   Accessing the Session**

```java
ApplSession session = ApplSessionUtil.getSession();
String guid1 = session.getUserGuid();

String guid2 = ApplSessionUtil.getUserGuid();
```

**Example 51-4   Getting Generic Attributes**

```java
String attr1 = ApplSessionUtil.getSessionAttribute("ATTRIBUTE1");
```

**Example 51-5   Fetching Attributes From A Particular Namespace**

```java
String attr1 = ApplSessionUtil.getNamespaceAttribute("MY$NAMESPACE", "ATTRIBUTE1");
```

### 51.3.1.3 Setting Context Attributes

In addition to providing getters for all of the context attributes listed above, there are corresponding set APIs directly available in the ApplSession class. Attributes like the user name or the language are set automatically on the context at creation time, but the set APIs can also be called if an attribute must be changed in the middle of the request.

The following example sets the PRODUCT_FAMILY attribute to FND and also sets a generic attribute called ATTRIBUTE1 to VALUE1 on both the session and a private namespace using the Java APIs.

**Caution:**

Sets of ApplSession attributes get cached in the middle tier, and only written to the database when the session is detached or the ApplSession.synchronize() method is explicitly called. If the set operation takes place from within a request, synchronization will happen automatically. However, if you are running standalone java or need the attributes to get written to the database immediately, you should add a call to session.synchronize().

**Example 51-6   Setting Context Attributes**

```java
ApplSession session = ApplSessionUtil.getSession();
if (session != null)
{
    session.setProductFamily("FND");
    session.setSessionAttribute("ATTRIBUTE1", "VALUE1");
```
session.setNamespaceAttribute("MY$NAMESPACE", "ATTRIBUTE1", "VALUE1");
}

### 51.3.1.4 Accessing the Connection

The applications context does not hold onto connections, instead it obtains and releases them as needed. As the following example shows, if your application explicitly obtains a connection via the `ApplSession.getConnection()` API, you will need to add a `finally` block that releases that connection. It is recommended that you call the newly provided `ApplSession.releaseConnection(Connection conn)` API as it takes care of clearing out session-specific PL/SQL state in the connection before closing it.

**Example 51-7  Accessing the Connection of the Current ApplSession**

```java
Connection conn = null;
ApplSession session = ApplSessionUtil.getSession();
if (session != null)
{
  try
  {
    conn = session.getConnection();
    ...
  }
  finally
  {
    if (conn != null)
    {
      session.releaseConnection(conn);
    }
  }
}
```

### 51.3.1.5 Access Session Context Using the Java API

To access the context in your Java code, just call any of the static methods in the `ApplSessionUtil` class. If you are running from an environment where application user sessions are enabled, there should not be anything else you must do aside from importing the `ApplSessionUtil` class.

**Tip:**

If you are running without application user sessions enabled, an exception will be thrown when any of the above calls are made except the `getSession()` API. This API returns a `null` if sessions are not enabled.

The following is a more complex example of how you might use this:

You have a view object (`TestVO`) where you want to always display the current user name as one of the fields.

**To always display the current user name as one of the fields:**

1. Add a non-column based `UserName` attribute to the `TestVO` object.
2. Generate the View Row Class for the view object.
3. Look for the definition of `getUserName()`. As shown in the following example, change it to return the value of the call to `ApplSessionUtil.getUserName()` in the `TestVORowImpl.java` that gets autogenerated.
Whenever the TestVO view object is displayed, by default it will include the current user name field.

**Example 51-8 Changing the getUserName() Value**

```java
public String getUserName()
{
    return ApplSessionUtil.getUserName();
}
```

**Example 51-9 TestVO Example**

```java
public String getSysAdminInfo()
{
    String productName = ApplSessionUtil.getProduct();
    if ("FND".equals(productName))
    {
        return (String) getAttributeInternal(SYSADMININFO);
    }
    else
    {
        return null;
    }
}
```

The following example uses the SysadminInfo field that was added to the TestVO view object to display a value when running the FND product.

### 51.3.2 How to Access Sessions Using PL/SQL APIs

The applications context can also be accessed through APIs that are provided in the FND_GLOBAL package. As in Java, functions exist to get and to set each of the core attributes listed in Accessing Properties of the Applications Context, assuming you have initialized the connection to use sessions properly. For detailed information about the FND_GLOBAL package, see the javadoc.

#### 51.3.2.1 Initializing Sessions

The FND_GLOBAL.INITIALIZE_SESSION takes in the user GUID, the user name, and two lists of roles. The first represents the list of role GUIDs, and the second represents the list of corresponding role names. As the following example shows, the lists must be of the same length.

**Example 51-10 Initializing Sessions**

```sql
DECLARE
    l_roleguids FND_TABLE_OF_VARCHAR2_4000 := FND_TABLE_OF_VARCHAR2_4000();
    l ролenames FND_TABLE_OF_VARCHAR2_4000 := FND_TABLE_OF_VARCHAR2_4000();
BEGIN
    l_roleguids.extend(1);
    l ролenames.extend(1);
    l_roleguids(1) := '1807EDD02DBB11DDBFDC91643D402C34';
    l ролenames(1) := 'operationsRole';
    fnd_global.initialize_session('43B84790D5F011DCAF4F5FFD8462C8E7','OPERATIONS',
    l_roleguids,  l ролenames);
    <your code here>
    fnd_global.terminate_session;
END;
```
51.3.2.2 Getting Context Attributes
As an example, you can retrieve the current user by calling FND_GLOBAL.USER_NAME, and you can get a generic attribute by calling FND_GLOBAL.GET_SESSION_ATTRIBUTE.

51.3.2.3 Setting Context Attributes
As an example, you can set the language by calling FND_GLOBAL.SET_LANGUAGE, and you can set a generic attribute by calling FND_GLOBAL.SET_SESSION_ATTRIBUTE.
This chapter describes how to enforce security to authorize access to securable application artifacts created using Oracle Application Development Framework (Oracle ADF) in Oracle Fusion applications.

This chapter contains the following sections:

- Introduction to Function Security
- Function Security Implementation Process Overview
- Adding Function Security to the Application
- Learning More About Function Security in Oracle Fusion Applications

### 52.1 Introduction to Function Security

An important principle of Oracle Fusion function security ensures that end users do not have unintended access to web pages and application resources in an application that is created using Oracle Application Development Framework (Oracle ADF).

To enable access to application resources, you can use JDeveloper to create security policies to specify “who can perform what operations on what specific application artifacts.”

To create the security policy, you must consider the additional duties the end users of the application will perform and then grant the desired roles specific rights to:

- Access application resources, such as a custom ADF task flow that supports the duty
- Initiate only those operations on the data required by the duty

---

**Note:**

Securing the data of the application requires creating data security policies. For details about creating data security policies, see Implementing Oracle Fusion Data Security.

Function security controls access to securable ADF artifacts including ADF task flows and top-level web pages backed by ADF page definition files. Function security may also control the visibility of UI components within the web pages. Users who do not have the required privilege cannot view the task flow or view buttons that initiate create, update, and delete operations. For example, in a sales organization, duties such as Manage_Accounts and Manage_Invoices exist for roles, such as Sales_Manager or Sales_Associate. A function security policy might give end users who belong to the Sales_Manager role the ability to view and edit customer
invoices. Whereas, end users who do not belong to the Sales_Manager role, may enter the task flow to view customer invoices but not edit them.

52.1.1 Function Security Development Environment

Before you can implement function security for custom application resources, a security administrator must export the function security definitions from an LDAP-based policy store (typically from a staging environment) into a file-based policy store that you can work with in JDeveloper. The exported file will contain the function security artifacts that will enable you to run your application and access the resources that may otherwise have been secured by predefined function security policies.

The file you receive is formatted as XML and named jazn-data.xml. The XML definitions of the exported file comprise two major sections: an identity store to define valid end users of the application and a policy store to define the security policies that are specific to the application. Initially, only the policy store will be populated with security artifacts from the LDAP stores. The exported jazn-data.xml file will not contain the end user identities of the enterprise, thus the identity store section will initially appear empty.

Note:

As an Oracle Fusion security guideline, do not modify the predefined function security definitions contained in the jazn-data.xml file. Predefined security definitions include the security definitions of the Oracle security reference implementation and must not be modified. The security reference implementation provides role-based access control in Oracle Fusion Applications, and is composed of predefined security policies that protect functions, data, and segregation of duties. You should always add custom application roles to grant access rights. For details about restrictions when working with the file-based policy store, see What You May Need to Know About Actions That Developers Must Not Perform.

When you define security policies for custom Oracle ADF application artifacts, you should only use Oracle JDeveloper tools to work on the exported file-based policy store, and you should not edit the security definitions directly. JDeveloper supports iterative development of security so you can easily create, test, and edit security policies that you define.

After you customize security, you use JDeveloper to add end user identities to the identity store of the exported file before running and testing the application in JDeveloper's Integrated WebLogic Server. You provision a few test end user identities by defining user groups and then assign those groups to application roles to simulate how the actual end users of the enterprise will access the secured application artifacts. When you deploy the application in your development environment, JDeveloper migrates the identity store you created to the embedded LDAP of Integrated WebLogic Server. The application policy store is migrated to a system-jazn-data.xml file that aggregates the security policies definitions of all applications in your workspace.

After testing in JDeveloper, you must consult with the security administrator to merge the LDAP-based application policy store in the staging environment with the security policies that you added to the exported jazn-data.xml file. The staging environment is an LDAP-based Oracle WebLogic Server configured to use Oracle Internet Directory (OID) for the enterprise's application policy store and identity store.
(note that the stores of the staging server are LDAP-based and not file-based). Initially, the staging environment allows further testing using that server’s identity store before deploying to the production environment. Thus, end user identities created in JDeveloper are not migrated to standalone Oracle WebLogic Server and are used only in Integrated WebLogic Server to test the extended application.

52.1.2 Function Security Implementation Scenarios

As an Oracle Fusion security guideline, when you secure the functions of your application, you should not modify the predefined security definitions specified by the Oracle Fusion security reference implementation. When you modify the file-based policy store, always create new security definitions.

---

**Note:**

The term *protected* in this chapter refers to the default Oracle Fusion application condition that denies end users access to database resources and application artifacts. In contrast, the term *secured* refers to resources that have been made accessible to end users through security policies created for this purpose. Therefore, a security policy specifically *enables access* to the resource based on the access rights it confers to the end user.

---

The following table summarizes the function security scenarios that Oracle Fusion security supports. The "Application Developer Tasks" column of the table provides a brief description of the security artifacts involved in each scenario.

**Table 52-1  Oracle Fusion Function Security Use Cases**

<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Control whether the end user associated with a particular role may access a new task flow and view all the web pages of the flow.</td>
<td>Create a new entitlement grant. The new task flow will be inaccessible by default (also called <em>protected</em>) and will require a new function security policy to grant end users access. Because the end user duty being secured is rarely addressed by grants to a single resource, the Oracle Fusion security best practice is to create entitlement grants. Entitlement grants provide the means to aggregate multiple securable resources into a named security group so that privileges for the entire group can be granted to application roles through a single statement.</td>
<td>Enable ADF Security on the user interface project to protect all task flows (and the web pages they contain). Then, in the file-based policy store, create a resource definition for the task flow and assign the definition as a member of an entitlement (defined in the policy store as a <em>permission set</em>) that you name. Then, create the security policy by granting the entitlement to a custom application role that you either created or consulted with a security administrator to create for you. For more information, see How to Create Entitlement Grants for Custom Application Roles.</td>
</tr>
<tr>
<td>---------------</td>
<td>-----------------------------</td>
<td>-----------------------------</td>
</tr>
<tr>
<td>Control whether the end user associated with a particular role may access a new top-level web page. In Oracle Fusion applications, a top-level web page is one that is not contained by a task flow.</td>
<td>Create a new entitlement grant. The new top-level web page will be inaccessible by default (also called protected) and will require a new function security policy to grant end users access. The ability to secure individual web pages in Oracle Fusion applications is reserved for top-level web pages backed by an ADF page definition file only.</td>
<td>Enable ADF Security on the user interface project to protect all top-level web pages backed by ADF page definition files. Then, in the file-based policy store, create a resource definition for the web page and assign the definition as a member of an entitlement (defined in the policy store as a permission set) that you name. Then, create the security policy by granting the entitlement to a custom application role that you either created or consulted with a security administrator to create for you. For more information, see How to Create Entitlement Grants for Custom Application Roles.</td>
</tr>
<tr>
<td>Control whether a new task flow or a new top-level web page is publicly accessible.</td>
<td>Create a new resource grant. The new ADF artifact will be inaccessible by default (also called protected) and will require a new function security policy to grant end users access. Because the publicly accessible artifact is a single resource, the Oracle Fusion security best practice is to create resource grants (rather than entitlement grants) for publicly accessible artifacts.</td>
<td>Enable ADF Security on the user interface project to protect all ADF-backed application artifacts. Then, in the file-based policy store, grant an action (defined in the policy store as a permission) directly to the artifact. Then, create the security policy by granting the permission to a built-in OPSS application role. For more information, see How to Define Resource Grants for OPSS Built-In Roles.</td>
</tr>
<tr>
<td>Determine whether the end user associated with a particular role has the right to view UI components, such as buttons that initiate create, update, or delete operations in the displayed web page.</td>
<td>Create a grant. Access to user interface components, such as buttons can be controlled by rendering the button in the user interface based on a permission check.</td>
<td>Conditionally render the component by entering ADF Security Expression Language (EL) utility methods on the rendered attribute of the button to test whether the end user has the necessary permission grant. For more information about rendering components using EL utility methods, see the &quot;Enabling ADF Security in a Fusion Web Application&quot; chapter of the Developing Fusion Web Applications with Oracle Application Development Framework.</td>
</tr>
</tbody>
</table>

For more information about how data security and function security work together to control access to the data and functions of the application, see the "Customizing Security for Oracle ADF Application Artifacts" chapter in the Extensibility Guide for Developers.

### 52.1.3 Function Security-Related Application Files

When you create a Fusion web application, JDeveloper creates specific files that are needed to secure the application. Additionally, when you run the Configure ADF
Security wizard, JDeveloper updates these files to reflect the selections you make in the wizard.

For details about the created files, see the "What Happens When You Enable ADF Security" section in the Developing Fusion Web Applications with Oracle Application Development Framework.

52.2 Function Security Implementation Process Overview

An ADF bounded task flow that you add to your application is one of the main ADF artifacts that you can secure. You can also directly secure top-level web pages that are backed by ADF page definitions to specify data bindings. Although you can secure a variety of application resources, implementing function security follows a similar pattern.

Before You Begin

You will need to complete these tasks:

1. Decide the names of custom application roles that your application will specify as the grantee of security privileges.

2. Optionally, ask the security administrator to create custom application roles with the names you supply.

   If a security administrator creates the application roles you identify, then those custom application roles will already appear in the policy store section of the exported jazn-data.xml file.

   If you do not ask the security administrator to create custom application roles, then you must create them in JDeveloper before you define security policies.

3. Consult a security administrator to export all predefined function security policies of the application that you are customizing into a jazn-data.xml file.

   For details about extracting data from an OID store to a file, see the "Security Store Management" section of the Administrator’s Guide.

To implement function security:

1. Copy the exported jazn-data.xml file into your application workspace.

   This is the file that JDeveloper will update when you create function security policies. In order for JDeveloper to use the file, copy the file to your application workspace in the <JDevAppHome>/src/META-INF folder.

2. Determine which ADF artifacts should be secured and grant entitlement privileges to custom application roles to specify the access rights of end users.

   Although ADF Security permits you to define function security policies for ADF artifacts using only resource privilege grants, an Oracle Fusion security best practice is to define access policies using entitlement grants except for publicly accessible application artifacts.

   For details about securing application functions, see How to Create Entitlement Grants for Custom Application Roles.

3. Determine which ADF artifacts should be public and grant resource privileges to an appropriate OPSS built-in application role.

   For details about making application functions public, see How to Define Resource Grants for OPSS Built-In Roles.
4. Opt into the previously defined function security policies by running the Configure ADF Security wizard to enforce OPSS authorization checking.

   For details about enabling security on the user interface project, see How to Enforce Authorization for Securable ADF Artifacts.

5. Determine which user interface components you want to associate with user entitlements, and enter ADF Security-based EL utility methods on the component to make it logically consistent with its target.

   ADF does not enforce security on user interface components, such as buttons or links that navigate to securable artifacts (pages and task flows).

6. Define test user identities and run the application in JDeveloper to simulate the privileges of the enterprise users who will eventually interact with the application.

   For details about adding test user in JDeveloper, see How to Enable Authentication and Test the Application in JDeveloper.

To migrate security policies to the domain policy store:

1. After testing is complete, remove the test users from the jazn-data.xml file and provide the updated jazn-data.xml file to the security administrator to merge the file-based policy store with the application policy store in the staging environment.

   JDeveloper must not be used as an identity store provisioning tool, and you must be careful not to deploy the application with user identities that you create for testing purposes. Deploying user identities with the application introduces the risk that malicious users may gain unintended access.

2. The security administrator provisions enterprise users by mapping enterprise roles defined in the staging environment identity store to the custom application roles.

   For information about how the security administrator provisions enterprise users using Oracle Authorization Policy Manager, see the product-specific security guides.

3. Before running the application in the staging environment, the security administrator must reconcile the application roles GUIDs of any data security policies that were created based on new custom application roles.

   When the file-based policy store is merged, the GUIDs of application roles are not preserved.

4. Continue testing the application in the staging environment before deploying the application to production and merging the policies into the production environment application policy store.

   For details about how to modify the application to use the identity store and policy store of the staging environment, see What You May Need to Know About Testing.

52.3 Add Function Security to the Application

You implement function security by identifying the type of resource that corresponds to the ADF artifact whose function you intend to secure. You then select a resource instance of that type and select the action that corresponds to the artifact function you intend to grant to end users. Function security aggregates these resource / action pairs as an entitlement that serves as the grantable entity. Each entitlement can include as
many resource / action pairs as needed to describe a particular duty to be performed by the end user. To support this goal, entitlements can include resources of different types. To create a function security policy, you then grant the entitlement to a custom application role, also called a duty role in Oracle Fusion applications.

In cases where a resource should be publicly accessible, you will not need to aggregate multiple resources to define a particular duty. Instead, you can create a resource-based function security policy with a single resource /action pair defined as the grantable entity.

---

**Note:**

Although ADF Security permits you to define function security policies for ADF artifacts using only resource privilege grants, an Oracle Fusion security best practice is to define access policies using entitlement grants except for publicly accessible application artifacts.

---

To simplify the task of securing the functions of your application, ADF provides the ADF Security framework. ADF Security defines a containment hierarchy that lets you define a single security policy for the ADF bounded task flow and its contains web pages. In other words, the security policy defined at the level of the bounded task flow, secures the flow’s entry point and then all pages within that flow are secured by the same policy. For example, a series of web pages may guide new end users through a registration process and the bounded task flow controls page navigation for the process.

Specifically, ADF artifacts that are automatically protected by ADF Security and require function security policies to grant users access are:

- ADF bounded task flow protects the entry point to the task flow, which in turn controls the end user’s access to the pages contained by the flow

  The ADF unbounded task flow is not a securable application artifact and thus does not participate in OPSS authorization checks. When you need to secure the constituent pages of an unbounded task flow, you define policies for the page definition files associated with the pages instead.

- ADF page definition files associated with top-level web pages and regions

  For example, a page may display a summary of products with data coordinated by the ADF bindings of the page’s associated ADF page definition file.

---

**Best Practice:**

Do not create entitlement grants for the individual web pages of an ADF bounded task flow. When the end user accesses the bounded task flow, security for all pages will be managed by the entitlements you create for the task flow. This supports a well-defined security model for task flows that enforces a single entry point for all end users. For additional best practice information about ADF and function security, see What You May Need to Know About ADF Security Guidelines.

---

To add function security to the application:
1. Determine which ADF task flows and top-level web pages should be secured and grant entitlement privileges to custom application roles to define the duties of end users.

2. Determine which ADF task flows and top-level web pages should be public and grant resource privileges to an appropriate OPSS built-in application role.

3. Determine which user interface components should be secured and create a resource permission and grant the view action in the entitlement grant to a custom application role.

ADF does not automatically enforce security on user interface components, such as buttons or links that navigate to securable artifacts (pages and task flows). To secure these application artifacts, you must create a resource permission that the application can test by entering ADF Security-based EL utility methods on the component to make it logically consistent with its target.

4. Opt into the previously defined function security policies by running the Configure ADF Security wizard to enforce OPSS authorization checking.

5. Define test user identities and run the application in JDeveloper to simulate the privileges of the enterprise users who will eventually interact with the application.

### 52.3.1 How to Create Entitlement Grants for Custom Application Roles

Because the particular end user duty you want to secure is rarely addressed by grants to a single resource, you define the access policy for securable ADF artifacts by creating entitlement grants. Resource grants are only necessary to define publicly accessible application artifacts, as described in How to Define Resource Grants for OPSS Built-In Roles.

You create entitlement grants in the Entitlements Grants page of the jazn-data.xml file overview editor. The grants you create will appear as metadata in the policy store section of the jazn-data.xml file. This metadata defines an entitlement (identified in the XML definition as `<permission-set>`) comprised of resource instance / action pairs that you select. This entitlement is a grantable entity that you then grant to a custom application role.

**Note:**

Note that, in Oracle Fusion Applications, application roles are called duty roles. You must not modify predefined duty roles, and you must always add custom application roles (duty roles) to grant access permissions.

The list of resource types appears in the security policy overview editor. The resource type you select filters the resource instances defined within the projects of your application’s workspace. The resource type selection also determines the list of available actions displayed by the overview editor. For example, when you select the Task Flow resource type, the overview editor will display all of the task flows in the user interface projects that you select and also displays the view action that you can associate with the available ADF bounded task flow resources.

The following table lists the resource types displayed in JDeveloper and identifies the associated resource and actions.
Table 52-2  Resource Types of Securable ADF Artifacts

<table>
<thead>
<tr>
<th>Resource Type</th>
<th>Supports These Resources and Actions</th>
</tr>
</thead>
<tbody>
<tr>
<td>ADF Task Flow</td>
<td>Defines personalize, customize, grant, edit, and view actions on ADF bounded task flows in a Fusion Web application.</td>
</tr>
<tr>
<td>ADF Region</td>
<td>Defines personalize, customize, grant, edit, and view actions on regions and web pages backed by an ADF page definition file in a Fusion Web application.</td>
</tr>
<tr>
<td>ADF Entity</td>
<td>Not used by Oracle Fusion Applications. Data security is provided by Oracle Fusion Data Security, as described in Implementing Oracle Fusion Data Security.</td>
</tr>
<tr>
<td>ADF Method</td>
<td>Defines execute, invoke, and view actions on ADF methods in a Fusion web application.</td>
</tr>
<tr>
<td>Resource</td>
<td>Defines custom actions on any functional artifact in a Fusion web application. Resource permissions are useful to create grants for UI components, as described in How to Protect UI Components.</td>
</tr>
<tr>
<td>Webservice</td>
<td>Defines invoke actions on Fusion Web services. For more details about securing Web services, see Authorizing the Web Service with Entitlement Grants.</td>
</tr>
</tbody>
</table>

To define an entitlement grant for a securable ADF artifact, use the Entitlement Grants page of the overview editor for the jazn-data.xml file. This editor is also called the security policy overview editor.

Before you begin:

It may be helpful to understand the details of the ADF Security containment model. For more information, see What You May Need to Know About ADF Security Guidelines.

You will need to complete these tasks:

- Consult the security administrator for the enterprise to obtain the jazn-data.xml file that contains the predefined function security policies for your application. You must add the file to your application workspace, as explained in Function Security Implementation Process Overview.

To define an entitlement grant for an ADF artifact:

1. In the main menu, choose Application and then Secure > Entitlement Grants.

2. In the Entitlement Grants page of security policy overview editor, click the Add Entitlements icon in the Entitlements list.

The overview editor displays all the resources that your application defines.
3. In the Resources section, click the Add Member Resource icon to add a member resource to the entitlement.

4. In the Select Resources dialog, select the resource from the Resource Type dropdown and then select the desired project in the Source Projects list.

   The dialog displays all the projects in your application workspace.

5. In the Available Resources list, select the resource from and click the Add icon.

   The dialog displays all the resources defined by your selected project.

6. In the Actions lists, select the desired action for the selected resource.

   The following figure shows the overview editor with the View action selected for the task flow and added to MyEntitlement.

   Figure 52-1 Adding a Bounded Task Flow as a Resource in an Entitlement Grant

7. Add other desired resources to the list.

8. In the Grants section of the security policy overview editor, click the Add Role Grants icon to grant the entitlement to an application role.

9. In the Select Application Roles dialog, select one or more custom application roles.

   The dialog displays all the application roles from the jazn-data.xml file. You must not add a grant to a predefined application role (also called duty roles in the terminology of Oracle Fusion Applications). Only select custom application roles that either you created in JDeveloper or that were created by a security administrator for this purpose.

10. Click OK.

11. You can repeat these steps to add other resources and make grants on those resources to the same entitlement for the same custom application role.
52.3.2 What Happens After You Create an Entitlement Grant

When you use the security policy editor in JDeveloper to create an entitlement grant, JDeveloper modifies the source for the application policy store in the jazn-data.xml file. The policy store section of the file contains a <resource-type> definition (that identifies the actions supported for resources of the selected type), a <resource> definition (to identify the resource instance that you selected from your application and mapped to a resource type), a <permission-set> definition (to define the resources and actions to be granted as an entitlement), and a <grant> definition with one or more entitlements (defined in the XML as a permission set) granted to the desired application roles (the grantee).

As the following example shows, entitlement-based security policies in the Oracle Fusion application are defined in the <jazn-policies> element and consist of one or more entitlements granted to a single application role.

Example 52-1 Entitlement-Based Policy Definition in the jazn-data.xml File

```xml
<?xml version="1.0" ?>
<jazn-data>
  <policy-store>
    <applications>
      <application>
        <name>MyApp</name>
        <app-roles>
          <app-role>
            <name>AppRole</name>
            <display-name>AppRole display name</display-name>
            <description>AppRole description</description>
            <guid>F5494E409CFB11DEBFEBC11296284F58</guid>
            <class>oracle.security.jps.service.policystore.ApplicationRole</class>
          </app-role>
        </app-roles>
        <role-categories>
          <role-category>
            <name>MyAppRoleCategory</name>
            <display-name>MyAppRoleCategory display name</display-name>
            <description>MyAppRoleCategory description</description>
          </role-category>
        </role-categories>
        <!-- resource-specific OPSS permission class definition -->
        <resource-types>
          <resource-type>
            <name>APredefinedResourceType</name>
            <display-name>APredefinedResourceType display name</display-name>
            <description>APredefinedResourceType description</description>
            <provider-name>APredefinedResourceType provider</provider-name>
            <matcher-class>oracle.security.jps.ResourcePermission</matcher-class>
            <actions-delimiter>,</actions-delimiter>
            <actions>write,read</actions>
          </resource-type>
        </resource-types>
        <resources>
          <resource>
            <name>MyResource</name>
            <display-name>MyResource display name</display-name>
          </resource>
        </resources>
    </application>
  </applications>
</jazn-data>
```
52.3.3 How to Define Resource Grants for OPSS Built-In Roles

A common requirement of the application is that some web pages be available to all end users, regardless of their specific access privileges. For example, the home page should be seen by all visitors to the site, while a corporate site should be available only to those who have identified themselves through authentication.

In both cases, the page may be considered public, because the ability to view the page is not defined by the end users’ specific privileges. Rather, the difference is whether the end user is anonymous or a known identity.
In the OPSS security model, you differentiate between the absence of security and public access to content by granting access privileges to the anonymous-role principal. The anonymous-role allows access to a resource by unauthenticated users, for example, guest users. To provide access to authenticated users only, the policy must be defined for the authenticated-role principal.

The built-in OPSS role authenticated-role stands for any authenticated user and is useful to implement authorization checks for end users who do not need to be explicitly assigned to specific custom application roles to get access to a resource. The authenticated-role can be directly granted any resource grants.

Before you begin:

It may be helpful to have an understanding of OPSS support for public, unprotected resources. For more information, see the “Understanding Users and Roles” chapter of the Oracle Fusion Middleware Applications Security Guide, in the Oracle Fusion Middleware Online Documentation Library.

It may also be helpful to understand the details of the ADF Security containment model. For more information, see What You May Need to Know About ADF Security Guidelines.

You will need to complete this task:

- Consult the security administrator for the enterprise to obtain the jazn-data.xml file that contains the predefined function security policies for your application. You must add the file to your application workspace, as explained in Function Security Implementation Process Overview.

To grant public access to securable ADF artifact:

1. In the main menu, choose Application and then Secure > Resource Grants.

2. In the Resource Grants page of security policy overview editor, select the resource from the Resource Type dropdown and then select the desired project in the Source Projects list.

   The overview editor displays all the projects in your application workspace.

3. In the Resources column, select the ADF artifact for which you want to grant access rights.

   Tip: Click the lock icon to show only those resources that do not yet have grants.

4. In the Granted to column, click the Add Grantee icon and choose Add Application Role.

5. In the Select Application Roles dialog, select one of these built-in application roles:

   - **anonymous-role** means the resource will be accessible to anyone who visits the site. A grant to this role is necessary if you want to make web pages backed by securable ADF artifacts accessible before an end user logs in. For example, you would grant to anonymous-role for an ADF bounded task flow that manages customer registration.

   - **authenticated-role** means the resource will be accessible only to authenticated users (ones who visit the site and log in). For example, you would grant to authenticated-role for an ADF bounded task flow that manages employee registration.
6. In the Select Application Roles dialog, click **OK**.

7. In the Resource Grants page of the overview editor, in the **Actions** column, select the desired action.

The following figure shows the overview editor with the View action selected for the task flow and granted to **authenticated-role**.

**Figure 52-2  Granting to authenticated-role in the Overview Editor**

---

52.3.4 What Happens When You Make an ADF Resource Public

When you use the security policy editor in JDeveloper to create a resource grant, JDeveloper modifies the source for the application policy store in the **jazn-data.xml** file.

The following example shows a resource-based security policy in the **jazn-data.xml** file that makes a customer registration task flow public to all authenticated users. The grant to the OPSS built-in role **authenticated-role** contains a single view permission for a bounded task flow, **customer-registration-task-flow**. With this grant, any authenticated user will be able to enter the employee registration task flow.

**Example 52-2  Resource-Based Policy Definition in the jazn-data.xml File**

```xml
<policy-store>
  ...
  <jazn-policy>
    <grant>
      <grantee>
        <principals>
          <principal>
            <class>oracle.security.jps.internal.core.principals.JpsAuthenticatedRoleImpl</class>
            <name>authenticated-role</name>
          </principal>
          ...
        </principals>
      </grantee>
      <permissions>
        <permission>
          <name>view</name>
          <resource>customer-registration-task-flow</resource>
        </permission>
      </permissions>
    </grant>
  ...
</jazn-policy>
</policy-store>
```
52.3.5 How to Protect UI Components

Security expressions in the ADF Security EL namespace let you check the user permission, authentication and role membership status before displaying UI components in your page. When you need fine-grained protection over UI components to secure functional parts of the application that are not part of task flow security or web page security, you use the EL value userGrantedResource and a resource grant that you define for a custom resource type. For instance, through a resource grant that you create for a menu item, the application may either enable or disable a Cancel Shipment menu item to limit who may perform customer order updates.

Resource grants for custom resources types rely on the ResourcePermission class, which is provided by Oracle Platform Security Services (OPSS) and packaged with the application.

You use the overview editor for security policies to create a security policy for the custom resource type. And, in your web page, you use the security expression to evaluate the user’s access rights to the UI component projected by the resource grant.

To grant resource policies for a custom resource type:

1. Create the custom resource type for the UI component you want to protect.
2. Create the resource grant for the custom resource.
3. Associate the rendering of a UI component with a role’s granted resource permission.

For complete details about protecting UI components, see the "How to Protect UI Components Using OPSS Resource Permissions and EL" section in the Developing Fusion Web Applications with Oracle Application Development Framework.

52.3.6 How to Enforce Authorization for Securable ADF Artifacts

You run the Configure ADF Security wizard to enable authorization and make the function security policies you define effective. When you run the Configure ADF Security wizard, it has the following affect:

- It configures your application to enable OPSS security when running in the JDeveloper test environment.
- It allows the Integrated WebLogic Server to use the file-based security policies to authorize access to application resources by the end user (where OPSS determines at runtime whether the end user (represented by the JAAS subject) has the privileges necessary to access the resources they intend.
When you run the wizard, you are effectively enforcing authorization checking for all securable ADF artifacts. The wizard also enables the ADF authentication servlet to require the end user to log in the first time a page in the application is accessed.

This configuration requires a valid user to access the pages of your application. This assumes that you will define custom application roles and assign explicit grants to those roles to manage access to securable ADF artifacts, as described in How to Create Entitlement Grants for Custom Application Roles. Alternatively, when you want to make a page public and accessible by unauthenticated user, you must explicitly grant to a built-in OPSS role, as described in How to Define Resource Grants for OPSS Built-In Roles.

Before you begin:

It may be helpful to have an understanding of the configuration changes made by the Configure ADF Security wizard. For more information, see the "Enabling ADF Security in a Fusion Web Application' chapter of the Developing Fusion Web Applications with Oracle Application Development Framework, in the Oracle Fusion Middleware Online Documentation Library.

It may also be helpful to have an understanding of the test-all role when you want to test the application without restricted access. For more information, see the "Enabling ADF Security in a Fusion Web Application’ chapter of the Developing Fusion Web Applications with Oracle Application Development Framework, in the Oracle Fusion Middleware Online Documentation Library.

To enforce authorization:

1. In the main menu, choose Application and then Secure > Configure ADF Security.
2. Complete the Configure ADF Security wizard pages.

For complete details about running the wizard, see the "Enabling ADF Security' section in the Developing Fusion Web Applications with Oracle Application Development Framework.

52.3.7 How to Enable Authentication and Test the Application in JDeveloper

Authentication is enabled when you run the Configure ADF Security wizard, as described in How to Enforce Authorization for Securable ADF Artifacts. This means you when you run your application, you will be prompted to log in upon accessing any page backed by securable ADF artifacts.

To test your application, you will need to create test user identities and provision them with the custom application roles that you defined. The end user’s membership in an application role defines their access privileges to the resources. If you prefer to be consistent with the Oracle Fusion standard for provisioning users and simulate how the actual end users of the enterprise access resources, you can optionally provision test users by defining enterprise roles consisting of groups of users (called job roles in Oracle Fusion applications) and then assign those groups to application roles (called duty roles in Oracle Fusion applications).

Note that if you enabled the option to grant to a test role when you run the Configure ADF Security wizard, your grants may be of the following two types:

- For the task flows that you create before running the Configure ADF Security wizard, the wizard automatically assigns them to the test-all role. You will need to remove these grants and create valid grants to your custom application
roles. For each entitlement granted to a specific role, the equivalent grant to the test-all role must be removed.

- The new task flows you create after running the Configure ADF Security wizard are not granted to the test-all role automatically. You need to manually grant the entitlements for the new task flows to your custom application roles.

The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For details about creating test users, see the "Enabling ADF Security in a Fusion Web Application" chapter of the Developing Fusion Web Applications with Oracle Application Development Framework, in the Oracle Fusion Middleware Online Documentation Library.

52.3.8 What You May Need to Know About Actions That Developers Must Not Perform

Security definitions that are predefined in the Oracle Fusion security reference implementation must not be changed by developers. When modifying the file-based policy store, always create custom application roles and define new entitlement grants.

Specifically, developers must not make the following changes to the predefined security definitions of the Oracle Fusion security reference implementation.

- Add or remove entitlement grants on predefined application roles (those supplied by Oracle).
- Add or remove resources on predefined entitlements (those supplied by Oracle).
- Add or remove actions on resources on predefined entitlements (those supplied by Oracle).

For more information about the Oracle Fusion security reference implementation, see the product-specific security guides.

52.3.9 What You May Need to Know About Testing

When the application needs to undergo testing either in your local environment or on a staging server, the following changes will ensure that the application uses the LDAP-based identity and policy stores configured on the staging server.

To configure the deployed application to use the security repositories on the target server:

1. Set the application name in the web.xml file to point to the application stripe on the target server.

   The domain policy store is logically partitioned in stripes, one for each application name specified in the file system-jazn-data.xml under the element <applications>. Each stripe identifies the subset of domain policies pertaining to a particular application. For more details about application stripes, see the "Managing the Policy Store" chapter in the Oracle Fusion Middleware Applications Security Guide.

2. Set the jps.policystore.applicationid in the weblogic-application.xml file to point to the application stripe on the target server.
3. If you want the policies to persist on the staging server after the application is undeployed, then set the `jps.policystore.removal` flag in the `weblogic-application.xml` file.

4. Note that the `jps-config.xml` file in the application does not need to be modified. When the application is deployed, the staging server will have its own instance of the `jps-config.xml` file which is configured through a WLST command (the `reassociateSecurityStore` command). Therefore, the application `jps-config.xml` file can remain unchanged.

If you use JDeveloper to deploy to the application to standalone Oracle WebLogic Server, then you must ensure the Users and Groups checkbox is not selected in the application deployment properties (Menu Application > Secure > Configure Security Deployment...), as shown in the following figure.

**Figure 52-3  Application Deployment Properties Related to Security**

![Application Deployment Properties](image)

As a security best practice, you should not migrate users and groups that you create in JDeveloper. If the Users and Groups checkbox is selected, test users and groups in `jazn-data.xml` will be merged into the target server with different GUIDs than those used to grant data security privileges.

**Note:**

JDeveloper must not be used as an identity store provisioning tool, and you must be careful not to deploy the application with user identities that you create for testing purposes. Deploying user identities with the application introduces the risk that malicious users may gain unintended access. Instead, rely on the system administrator to configure user identities through the tools provided by the domain-level identity management system.

Before testing the application in the staging environment, any custom application roles that you created will need to be created in the LDAP application policy store. These
new application roles will receive new GUIDs and any data security policies defined for application roles of the same name must have their GUIDs reconciled.

Related Links
The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For details about the LDAP identity and policy store configuration, see the "OPSS Services" part of the Oracle Fusion Middleware Applications Security Guide, in the Oracle Fusion Middleware Online Documentation Library.
- For details about how security administrators reconcile GUIDs in the data security repository, see the "Reconciling GUIDs" section in the Administrator's Guide.

52.3.10 What You May Need to Know About ADF Security Guidelines

ADF implements a particular security model. Follow these rules to address problems you encounter when adding security to the application:

- Bounded task flows are secured by default. Secured by default means OPSS will check authorization on all bounded task flows when ADF Security has been enabled.
- Pages and page fragments backed by an ADF page definition file are also secured by default when not embedded in a bounded task flow. Keep in mind that OPSS will not check authorization for pages or page fragments that do not have a corresponding ADF page definition file.
- Pages and page fragments embedded in bounded task flows will not be checked by OPSS for authorization. Instead, they are granted or denied as a unit depending on the entitlement granted to the bounded task flow. That means those pages and page fragments do not need to be explicitly granted in the policy store.
- Bounded task flows embedded in bounded task flows will be checked by OPSS for authorization.
- ADF does not enforce security on user interface components, such as buttons or links) that navigate to securable artifacts (pages and task flows). An explicit EL expression must be attached to the component to make it logically consistent with its target.
- The test-all role is just a means of not breaking the application when ADF Security is enabled. Therefore, it should never be deployed, since it grants access to the application for non-authenticated users.

This chapter describes the best practices for securing Web services in an Oracle Fusion application using an Oracle Web Services Manager (Oracle WSM) feature called global policy attachments (GPA).

This chapter contains the following sections:

- Introduction to Securing Web Services Use Cases
- Understanding Best Practices
- Attaching Policies Globally
- Attaching Policies Locally
- Authorizing the Web Service with Entitlement Grants
- What Happens At Runtime: How Policies Are Enforced
- Maintaining Application Session Context Across Web Service Requests

### 53.1 Introduction to Securing Web Services Use Cases

The service use case patterns described in Common Service Use Cases and Design Patterns must be secured. Security requirements vary depending on service and client implementations.

The following Web service integration scenario represents a typical integration pattern. The scenario highlights the security implementation requirements of each service component, as illustrated in the accompanying figure below.

**An example Web service integration scenario that relies on Oracle Mediator:**

1. A user logs into an ADF web application.
2. The application raises a business event.
3. The business event triggers an SOA composite through an Oracle Mediator service component.
4. The Mediator component invokes a Business Process Execution Language (BPEL) process.
   - The Mediator can invoke various BPEL processes based on the incoming event. It can also transform the event to the payload that BPEL process takes.
5. The BPEL process interacts with ADF Business Components Web services so as to execute the business logic of the use case.

While event generation typically begins with ADF Business Components, as an alternative, you can also trigger or call a SOA composite and either directly or
indirectly invoke the ADF Business Components Web service by any one of the following:

- Another SOA composite through a business event.
- Java or PL/SQL code through a business event.
- Synchronously calling the SOA composite through a JAX-WS proxy.
- An ADF Web service data control.

These alternative flow patterns require different security implementations. For example, both JAX-WS proxy and ADF Web service data control can access the client security policy references in the `connections.xml` file of the application to propagate the current user. However, when the event is triggered from the user interface and ADF Business Components, the ADF Business Components Web service can be invoked synchronously using the `ServiceFactory` interface (using either RMI or SOAP).

The following figure illustrates the possible event generation scenarios for Oracle Fusion applications. The main scenario flow—ADF Business Components-generated events—is illustrated in the center, along with numbers (enclosed in circles) illustrating the corresponding steps of the above integration scenario. Possible alternative flows are represented by dashed lines and numbers.

**Figure 53-1  Sample Web Service Integration Scenario**

Oracle Fusion applications typically use SOAP services. Use Oracle Web Services Manager (Oracle WSM) to secure these services. Following are the main recommendations when using Oracle WSM with Oracle Fusion Applications.
• Attach Oracle WSM authentication service policies to Web services and BPEL process Web service bindings only when it is not possible to globally attach policies at the domain level.

• Attach Oracle WSM client policies to Web services references in BPEL Partner links, proxies and ADF Web services data controls.

• It is a requirement to enforce authentication on all ADF Business Components Web services and exposed BPEL processes. Global policy attachment automatically satisfied this requirement.

• It is a requirement to enforce authorization on all ADF Business Components Web services.

• No authorization is required for SOA components, although it is possible to implement authorization checks for users and enterprise roles. You can enable authorization checks in ADF Business Components Web services.

• All request and response messages must be protected for integrity and confidentiality using either message protection security policies or message protection and authentication with SSL security policies. Oracle WSM transparently handles this.

• Oracle WSM policies do not apply to events.

53.2 Understanding Oracle Web Services Manager Best Practices

You can secure Web services and clients used in your Oracle Fusion application with Oracle Web Services Manager (Oracle WSM). A component of Oracle SOA Suite, Oracle Web Services Manager provides security policies that you can declaratively attach to SOAP services and clients.

Oracle Fusion Applications make use of an Oracle WSM feature called global policy attachments (GPA). Using GPA, policies are not attached locally, but are specified at a global level. At runtime, components simply inherit the global policy and Oracle WSM enforces it.

Unlike local policy attachments (LPA), which need to be added at every Web service client and server, global policy attachment (GPA) can be attached at a domain level. This makes it easy for the system administrator to have a uniform policy for all Web services across the domain.

Note:

All Oracle Fusion application Web services should use global policy attachment wherever possible.

Certain scenarios exist in which GPA cannot be used:

• Public Web services (those that do not need any user authentication) should use LPA to locally attach a "no authentication" policy on both the client side and the service side.

• When a Web service client needs to connect to a service using a particular user name and password, you need to specify the user name and password using a configuration override.
But GPA policies do not allow configuration overrides, which means you must use LPA to attach a username password policy on the client side. Note that even though configuration overrides require that you implement LPA on the client side, you still can allow the system administrator to define GPA on the server side for username password policies. Unlike the client side, the server side need not specify a particular username and password, instead it will accept any username and password.

- When a Web service requires additional security hardening, because, for example, they want to use a key that is different from the domain key generated for Oracle Fusion Applications, then you must use LPA and specify this key using a configuration override.

The Oracle Fusion Applications provisioning script generates a single keypair (public key and self signed certificate) with the alias orakey and stores the keypair in all Oracle Fusion Applications domains. All GPA policies will use this key by default unless you use LPA and specify a different key.

- When a Web service exists that must be invoked outside of an Oracle Fusion application that external service will be secured either with message protection or it must go through SSL to ensure protection. The default GPA for Oracle Fusion Applications is no message protection, which is not sufficient for external services that can be invoked outside Oracle Fusion applications. For external Web services, you must use LPA to use a message protection policy, for example to secure the external service to make it more secure or less secure.

- When a Fusion Web service can be invoked by an application outside of Oracle Fusion applications (because an Oracle Fusion application is integrated with the calling application) that service will most likely need to use policies to provide additional hardening. In this case, these clients should use LPA.

- Fusion Web service clients that need to connect to external non Fusion Web services will most likely need to use policies that are different from the globally attached policies. In this case, these clients should also use LPA.

You should use LPA whenever you want to override the globally attached policy. The user name and specifying an alternate key are common examples of overriding a globally attached policy.

In summary, use LPA when the Web service is a public service, when the service requires elevated privileges to connect using a particular user name and password, or when the service requires additional security hardening.

The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For background about globally policy sets, see the “Understanding Oracle WSM Policy Framework” chapter of the Administering Web Services, in the Oracle Fusion Middleware Online Documentation Library.

### 53.3 Attach Policies Globally

All Oracle Fusion application Web services and Web service clients should use global policy attachment wherever possible. The developer and system administrator work together to enable GPA, as the following process describes.

To enable global policy attachment:
1. Application developer removes LPA from all clients and Web services (except for the situations that need to use LPA).

A system administrator can do this using either Oracle Enterprise Manager Fusion Middleware Control or using WebLogic Scripting Tool (WLST).

2. Application developer makes sure that the no_authentication_service_policy policy has been attached to those services that do not require authentication.

Note that unless you attach a no behavior policy (oracle/no_authentication_service_policy or oracle/no_authentication_client_policy), public Web services will inherit GPA and will no longer be accessible, thus it is necessary to perform this step before enabling GPA.

Developers can do this in Oracle JDeveloper directly in the ADF Business Components Web service implementation class file, as described in Attaching Policies Locally. Also, a system administrator can do this either using Oracle Enterprise Manager Fusion Middleware Control or using WebLogic Scripting Tool (WLST).

3. System administrator decides which policy to attach globally.

Profile choices are Authentication (AuthN), SSL and Message protection. Oracle Fusion Applications are configured to use the AuthN profile by default. For background about profiles choices, see Table 53-1.

4. System administrator creates the global policy sets.

A system administrator does this using either Oracle Enterprise Manager Fusion Middleware Control or using WLST. They will need to define a separate GPA policy set for each kind of service–SOA service, SOA reference, ADF Business Components Web service, and so on.

5. Application developer in cooperation with the system administrator verifies that the client and Web services are using GPA.

A system administrator does this using either Oracle Enterprise Manager Fusion Middleware Control or using WLST.

Related Links
The following documents provide additional information about Oracle Fusion Middleware topics discussed in this section:

- For details about how a system administrator creates global policy sets, see the "Managing Web Service Policies" chapter of the Administering Web Services, in the Oracle Fusion Middleware Online Documentation Library.

- For details about how a system administrator attaches local policies on Oracle WebLogic Server, see the "Attaching Policies to Web Services" chapter of the Administering Web Services, in the Oracle Fusion Middleware Online Documentation Library.

- For a summary of the predefined policies, see the "Predefined Policies" appendix of the Administering Web Services, in the Oracle Fusion Middleware Online Documentation Library.
• For details about how a system administrator creates global policy sets, see the "Creating and Managing Policy Sets" chapter of the *Administering Web Services*, in the Oracle Fusion Middleware Online Documentation Library.

## 53.4 Attaching Policies Locally

Because certain scenarios exist in which GPA cannot be used, Oracle Fusion application developers may need to use local policy attachment (LPA) for Web services and Web service clients. In some cases, LPA must be used on the service side and client side, while other cases exist where only the client side requires LPA.

You should use local policy attachment:

• When a Web service should be public (those that do not require user authentication)

• When a Web service client requires elevated privileges to connect using a particular user name and password (GPA only handles identity propagation, thus LPA is required when identity switching is required)

• When a Web service requires additional security hardening

• When Fusion Web service clients (for example, a JRF client or a SOA client) need to connect to external non Fusion Web services

The following table shows the recommended Oracle WSM policies and the components to which they apply.

### Table 53-1  Recommended Oracle Web Services Manager Policies for Oracle Fusion Applications

</tbody>
</table>

### 53.4.1 How to Make a Web Service Publicly Accessible

One side effect of enabling GPA is that even public Web services (those that do not need any authentication) will now suddenly prompt for security credentials. To prevent this, all such Web services should use LPA to locally attach the `oracle/no_authentication_client_policy` on the client side and `oracle/no_authentication_service_policy` on the service side. After this is done,
these clients and Web services will ignore any global policy, and will work without authentication as before.

For example, suppose there is a non-Oracle external client calling a Fusion Web service. If this Web service did not have any security policy, and you turned on GPA, then this service will inherit the GPA setting, but because the client is an external client, it will not. Consequently, the service will be expecting secure messages that the client will not be sending, and the service will reject those messages.

In the case of an ADF Business Components Web service, you can enter service annotations in the Web service implementation class to specify the no behavior policy, as shown in the following example.

**Related Links**
The following documents provide additional information about Oracle Fusion Middleware topics discussed in this section:

- For more information about directly attaching the no behavior policy to a Web service endpoint, see the "Creating and Managing Policy Sets" chapter of the *Administering Web Services*, in the Oracle Fusion Middleware Online Documentation Library.

- For more information about ADF Business Components Web services, see the "Integrating Service-Enabled Application Modules" chapter of the *Developing Fusion Web Applications with Oracle Application Development Framework*, in the Oracle Fusion Middleware Online Documentation Library.

- For details about locally attaching the no behavior policy on Oracle WebLogic Server using Fusion Middleware Control and the WebLogic Scripting Tool (WLST), see the "Attaching Policies to Web Services" chapter of the *Administering Web Services*, in the Oracle Fusion Middleware Online Documentation Library.

**Example 53-1  Enabling No Behavior Policy for an ADF Business Components Web Service**

```java
@SecurityPolicy( { "oracle/no_authentication_service_policy"})
@CallbackSecurityPolicy("oracle/no_authentication_service_policy")
```

### 53.4.2 How to Support Elevated Privileges for Web Service Clients

By default, GPA supports identity propagation on the client side. However, because GPA is attached globally it is not possible to do any local configuration overrides. For example, if you have a Web service client that needs to connect using a particular user name and password (this is known as elevated privileges or identity escalation), then you cannot use GPA. With GPA you cannot specify this user name/password on a per client basis.

**Note:**

Even though you need to use LPA on the client side to perform configuration overrides, you can still use GPA on the service side. This is because on the service side you do not need a configuration override to set up a particular user name, instead you just attach the saml_or_username policy which will accept either user names (for identity escalation) or saml (for identity propagation).
Oracle Fusion Applications can use either RMI or SOAP to invoke the service. An RMI invocation of the service does not require security configuration. A SOAP invocation of the service can support identity propagation or identity switch.

To support identity propagation by the client, use the SAML token policy. To support identity switch, use the user name policy.

In the case of an ADF Business Components Web service, you can enter service annotations in the Web service implementation class to specify the locally attached policy, as shown in the following example.

Note that Fusion Web services should have asynchronous method calls enabled.

**Example 53-2 Attaching a Local Policy for an ADF Business Components Web Service**

```java
@SecurityPolicy("oracle/wss11_saml_or_username_token_with_message_protection_service_policy")
@CallbackSecurityPolicy("oracle/wss11_saml_token_with_message_protection_client_policy")
```

### 53.4.3 How to Provide Additional Security Hardening for Web Service Clients

Typically, Fusion Web services use a common domain wide key, which is necessary both for encryption and signing. Since this key is global it works very well with GPA. However, if certain Web services requires additional security hardening, because, for example, they want to use a key that is different from the domain key, then those services would need to use LPA and specify this key using a configuration override.

Another use case that would require LPA to provide additional security hardening exists when a non-Oracle Fusion application invokes an Oracle Fusion application Web service. In this case, because Fusion Web services do not use message protection by default, additional protection will be required to comply with the invoking application security policies.

**Related Links**

The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For details about locally attaching Web service client policy and configuring override properties on Oracle WebLogic Server, see the "Attaching Policies to Web Services" chapter in the *Administering Web Services*, in the Oracle Fusion Middleware Online Documentation Library.

### 53.4.4 How to Connect to Third Party Web Services

Fusion Web service clients that need to connect to external non-Fusion Web services will most likely need to use policies that are different from the globally set policy. Because the Oracle Fusion default for GPA is no message protection, this might not be sufficient for external services. In this case, clients should also use LPA.

**Related Links**

The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For details about locally attaching Web service client policy on Oracle WebLogic Server, see the "Attaching Policies to Web Services" chapter in the *Administering Web Services*, in the Oracle Fusion Middleware Online Documentation Library.
53.5 Authorize the Web Service with Entitlement Grants

When you want to secure an ADF Business Components Web service to require user authorization, you use JDeveloper to define entitlement-based function security policies directly in the file-based security repository for your Oracle Fusion application.

Before you begin:

You will need to complete the following tasks.

1. Consult a security administrator to export all predefined function security policies of the application that you are customizing into a `jazn-data.xml` file.

2. Copy the exported `jazn-data.xml` file into your application workspace.
   This is the file that JDeveloper will update when you create function security policies. In order for JDeveloper to use the file, copy the file to your application workspace in the `<JDevAppHome>/src/META-INF` folder.

To secure an ADF Business Components Web service:

1. In the exported `jazn-data.xml` file, grant access to the Web service using the JDeveloper security policy editor. For details, see How to Grant Access for the Service.

2. Enforce ADF Security authorization for the Web service in the Web service implementation class. For details, see How to Enforce Authorization for the Service.

Related Links

The following document provides additional information about Oracle Fusion Applications topics discussed in this section:

- For details about how the security administrator exports the application policy store, see the "Extracting Data from an OID Store to a File" section in the Administrator’s Guide.

53.5.1 How to Grant Access for the Service

Oracle ADF Security is responsible for authorizing Web services, that is, Oracle ADF Security decides whether a Web service is available to a given user by checking against the Oracle Platform Security Services (OPSS) policy store.

To grant access:

1. Create an entitlement to group one or more custom resources and their corresponding actions that together entitle end users to access the resource when needed to complete a specific duty.

   In the Oracle Fusion Applications environment, the basic security artifact for entitlement-based security policies is the entitlement (an entitlement is defined by an OPSS permission set).

2. Grant access to the Web service by defining an entitlement grant with a custom duty role that was added to the Oracle Fusion application policy store as the grantee.
The entitlement grant to the role specifies that the end user must be a member of the role to access the resources specified by the entitlement. As a security guideline, do not modify a predefined data security policy by granting additional permissions to a predefined duty role; you should use custom duty roles and you should not grant entitlements to predefined duty roles.

Example 53-3 Entitlement-Based Policy Definition in the jazn-data.xml File

```xml
<?xml version="1.0" ?>
<jazn-data>
   <policy-store>
      <applications>
         <application>
            <name>MyApp</name>
            <app-roles>
               <app-role>
                  <name>AppRole</name>
                  <display-name>AppRole display name</display-name>
                  <description>AppRole description</description>
                  <guid>F5494E409CFB11DEBFEBC112962B4F58</guid>
                  <class>oracle.security.jps.service.policystore.ApplicationRole</class>
               </app-role>
            </app-roles>
            <role-categories>
               <role-category>
                  <name>MyAppRoleCategory</name>
                  <display-name>MyAppRoleCategory display name</display-name>
                  <description>MyAppRoleCategory description</description>
               </role-category>
            </role-categories>
            <!-- resource-specific OPSS permission class definition -->
            <resource-types>
               <resource-type>
                  <name>WebserviceResourceType</name>
                  <display-name>WebserviceResourceType</display-name>
                  <description>Webservice Resource</description>
                  <matcher-class>oracle.wsm.security.WSFunctionPermission</matcher-class>
                  <actions-delimiter>,</actions-delimiter>
                  <actions>invoke</actions>
               </resource-type>
            </resource-types>
            <resources>
               <resource>
               </resource>
               <resource>
                  <name>http://xmlns.oracle.com/apps/contracts/termsAuthoring/deliverables/service/DeliverableService#findDeliverableByDeliverableId</name>
               </resource>
            </resources>
         </application>
      </applications>
   </policy-store>
</jazn-data>
```
<permission-sets>
  <permission-set>
    <name>MyWebServiceEntitlement</name>
    <display-name>MyEntitlement display name</display-name>
    <description>MyEntitlement description</description>
    <member-resources>
      <member-resource>
        <type-name-ref>WebserviceResourceType</type-name-ref>
        <resource-name>xmlns.oracle.com/apps/financials/subledgerAccounting
          /accountingMethodSetup/accountRulesService/AccountRulesService#*
        </resource-name>
        <actions>invoke</actions>
      </member-resource>
      <member-resource>
        <type-name-ref>WebserviceResourceType</type-name-ref>
        <resource-name>http://xmlns.oracle.com/apps/contracts/
termsAuthoring/deliverables/service/
  DeliverableService#findDeliverableByDeliverableId
</resource-name>
        <actions>invoke</actions>
      </member-resource>
    </member-resources>
  </permission-set>
</permission-sets>

<!-- Oracle function security policies -->
<jazn-policy>
  <!-- function security policy is a grantee and permission set -->
  <grant>
    <!-- application role is the recipient of the privileges -->
    <grantee>
      <principals>
        <principal>
          <class>
            oracle.security.jps.service.policystore.ApplicationRole
          </class>
          <name>AppRole</name>
          <guid>F5494E409CFB11DEBFEBC11296284F58</guid>
        </principal>
      </principals>
    </grantee>

    <!-- entitlement granted to an application role -->
    <permission-set-refs>
      <permission-set-ref>
        <name>MyWebServiceEntitlement</name>
      </permission-set-ref>
    </permission-set-refs>
  </grant>
</jazn-policy>
</application>
</applications>
</jazn-data>

For details about creating entitlement-based security policies using JDeveloper tools, see How to Create Entitlement Grants for Custom Application Roles.

The following example shows a complete set of required grants enabling Web service authorization. The entitlement definition MyWebServiceEntitlement defines an
invoke action permission for two Web service member resources, where the resource identified as `AccountRulesService#*` uses the asterisk wildcard character to identify a set of resources (where the asterisk specifies any number of arbitrary characters). The `jazn-policy` definition grants the invoke permission conferred by `MyWebServiceEntitlement` to the members of the `AppRole`.

The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For details about the ADF Security, see the "Enabling ADF Security in a Fusion Web Application" chapter in the *Developing Fusion Web Applications with Oracle Application Development Framework*, in the Oracle Fusion Middleware Online Documentation Library.

### 53.5.2 How to Enforce Authorization for the Service

In the case of ADF Business Components Web services, there is no need to run the ADF Security wizard to enforce authorization checking on the defined Web service security policies. Additionally, Oracle Fusion applications do not use Oracle WSM policies for authorization. Instead, the Oracle Fusion application uses the policy interceptor defined by the ADF Business Components to enforce authorization checking. The service factory is used to invoke an ADF Business Components service synchronously within a domain. Security information is passed from the calling program to the service automatically. And, whether the service is invoked by the service factory directly or through a BPEL process, authorization is enforced by the EJB implementation of the ADF Business Components Web service.

The following table shows the recommended policy interceptor used to enforce entitlement-based policies for Oracle Fusion applications and the components to which they apply.

<table>
<thead>
<tr>
<th>On this component...</th>
<th>Use this interceptor...</th>
</tr>
</thead>
<tbody>
<tr>
<td>ADF Business Components Web services (at the service or operation level)</td>
<td>Use <code>ServicePermissionCheckInterceptor</code> to implement authorization.</td>
</tr>
</tbody>
</table>

The ADF Business Components policy interceptor works for both RMI and SOAP cases and supports the EJB implementation of ADF Business Components Web services. Therefore, if `ServicePermissionCheckInterceptor` is specified in the ADF Business Components Web service implementation class, an Oracle WSM authorization policy is not required for Fusion Web services.

In the case of an ADF Business Components Web service, you enter the `@Interceptors` annotation and import statements in the Web service implementation class to specify the policy interceptor, as shown in the following example.

In order for this interceptor to work, you need to configure the policy interceptor in your `ejb-jar.xml` file. In the Application Navigator, expand the `META-INF` node of the Web service project and double-click the `ejb-jar.xml` node. In the source editor, add the `JpsInterceptor` definition required by the EJB for authorization checking, as shown in the following example.

```
53.6 What Happens At Runtime: How Policies Are Enforced

When a service is invoked there is security for the client side (caller) and for the server side (callee).

The client side can invoke the service through a SOAP service invocation, where the client can be a JAX-WS proxy or a SOA composite (service factory via SOAP is still JAX-WS proxy). Invoking the service, requires the client to pass the security context to the server side; the client side will either propagate the current user credential or switch identity, based on the client side authentication policy.

Alternatively, the client side can invoke the service through an RMI invocation. This type of invocation applies only to the ADF Business Component Web service. In this case, there is no client side authentication policy, since the client side always just propagates the identity to the server side.

Security for the server side is based on the Oracle WSM authentication policy. The server side first authenticates the user. A SOA composite service will not perform authorization, but ADF Business Components Web services will check whether the user is authorized to invoke the service. This type of service performs the authorization check using the EJB `ServicePermissionCheckInterceptor` interceptor before executing any service method.

The following figure illustrates how Oracle WSM policies are enforced within the Oracle Fusion Applications use case described in Introduction to Securing Web Services Use Cases.

**Figure 53-2 Using Oracle Web Services Manager Security Policies**

---

Security Policy Legend

- **Client**: Client side
- **A1**: Authentication
- **A2**: Authorization
This example use case illustrates the following:

- Each SOAP client includes an attached client policy.
- Authorization is enforced in the ADF Business Components Web services only.
- SOA components have no authorization policies.
- Oracle Web Services Manager policies do not apply to events.

The following document provides additional information about Oracle Fusion Middleware topics discussed in this section:

- For more information about Oracle Web Services Manager policies, see the "Understanding Oracle WSM Policy Framework" chapter of the Administering Web Services, in the Oracle Fusion Middleware Online Documentation Library.

## 53.7 Maintain Application Session Context Across Web Service Requests

When the user invokes a function defined by a Web service, the current application session context must be propagated across Web service requests. The application session context contains important information that is stored for the duration of the user's HTTP session. This includes information that defines a context for the application, such as its language preferences, date, and number formatting.

In order for application session context propagation to occur, you need to register the 
App1SessionContext class with the context interceptor infrastructure. Then when a SOAP request is generated by the invoked Web service, the request calls out to the infrastructure and adds the application session context onto the SOAP payload.

To register the ApplSessionContext class, you must add the oracle.applcore.config library to the weblogic-application.xml file for projects on both ends of the Web service request. In order for propagation to work, both the client sending the request and the server receiving the request must have this library.

Before you begin:

It may be helpful to have an understanding of application user sessions. For more information, see Implementing Application User Sessions.

You will need to complete this task:

- Configure your project to use application user sessions. For more information, see Configuring Your Project to Use Application User Sessions.

To add the Oracle Applications Core (Config) JDev library to the classpath:

1. In the Application Resources panel of the Application Navigator, double-click the weblogic-application.xml file of the project that defines the incoming side of the Web service request.

2. In the source editor for the file, add the following lines alongside the other <library-ref> tags:

```xml
<library-ref>
  <library-name>
    oracle.applcore.config
  </library-name>
</library-ref>
```
The order of the `<library-ref>` tags is not important; however, all `<library-ref>` tags must be grouped together.

3. Repeat this change in the project that defines the outgoing side of the Web service request.

In order for propagation to work, both the client sending the request and the server receiving the request must have the `oracle.applcore.config` library.
Secure End-to-End Portlet Applications

This chapter describes how to authenticate and authorize portlet services, as well as configure key and credential stores. The process of securing portlet services is similar to that of securing web services.

- Introduction to Securing End-to-End Portlet Applications
- Securing the Portlet Service
- Securing the Portlet Client
- Registering the Key Store and Writing to the Credential Store

54.1 Introduction to Securing End-to-End Portlet Applications

In Oracle Fusion Applications, portlets are WSRP portlets, therefore, web services. Oracle Web Services Manager (WSM) policies secure portlets, in the same way that they secure ordinary web services.

Oracle Web Services Manager implements web service security, and allows for run time enforcement and declarative policy attachment within Oracle Fusion Middleware.

Oracle Fusion applications make use of an Oracle WSM feature called global policy attachment (GPA). In GPA, policies are not attached locally, but specified at a global level. At runtime, components inherit the global policy and Oracle WSM enforces it.

For each portlet, these four ports require Oracle WSM policies:

- WSRP_v2_Markup_Service
- WSRP_v2_PortletManagement_Service
- WSRP_v2_Registration_Service
- WSRP_v2_ServiceDescription_Service

Only the WSRP_v2_Markup_Service markup port requires an authentication policy. By default, no policy should be locally attached to the markup port; this port will inherit the policy from GPA.

However, if the WSRP_v2_Markup_Service port has unique requirements not fulfilled by GPA, then a locally attached policy will be necessary. Additionally, if the locally attached policy specifies message protection or SSL, the necessary key store setup must be in place.

The three non-markup ports are anonymous and therefore you will need to locally attach a "no behavior" policy (defined by oracle/no_authentication_service_policy) to override GPA.
The requirements for the client counterparts for each of these ports is the same. Clients of the WSRP_v2_Markup_Service port inherit GPA, and clients of the three non-markup ports propagate an anonymous token defined by the oracle/no_authentication_client_policy policy.

The following table summarizes the policies attached to the portlet service and the client.

<table>
<thead>
<tr>
<th>Port</th>
<th>Service Side Policy</th>
<th>Client Side Policy</th>
</tr>
</thead>
<tbody>
<tr>
<td>WSRP_v2_Markup_Service</td>
<td>No local policy. Inherits from GPA, which by default is oracle/wss_saml_or_username_token_service_policy.</td>
<td>No local policy. Inherits from GPA, which by default is oracle/wss_saml_or_username_token_client_policy.</td>
</tr>
<tr>
<td>WSRP_v2_PortletManagement_Service</td>
<td>Local anonymous policy: oracle/no_authentication_service_policy</td>
<td>Local anonymous policy: oracle/no_authentication_client_policy</td>
</tr>
<tr>
<td>WSRP_v2_Registration_Service</td>
<td>Local anonymous policy: oracle/no_authentication_service_policy</td>
<td>Local anonymous policy: oracle/no_authentication_client_policy</td>
</tr>
<tr>
<td>WSRP_v2_ServiceDescription_Service</td>
<td>Local anonymous policy: oracle/no_authentication_service_policy</td>
<td>Local anonymous policy: oracle/no_authentication_client_policy</td>
</tr>
</tbody>
</table>

To override GPA and secure end-to-end portlet applications with a locally attached policy:

- Secure the portlet service.
- Secure the portlet client.
- Register the key store.
- Write to the credential store.

### 54.2 Secure the Portlet Service

Securing the portlet service with a locally attached policy that overrides GPA involves the following main steps:

- Authenticating the service
- Configuring the key store and credential store
- Authorizing the service

### 54.2.1 How to Authenticate the Service

Authenticating the service is necessary only in two cases:
When applying the "no behavior" policy to the anonymous ports.

When GPA is being overridden for the WSRP_v2_Markup_Service port.

When a policy is attached locally, Oracle ADF must authenticate the portlet service against an Oracle Web Services Manager policy, such as wss10_saml_token_with_message_protection_service_policy. In addition, it is necessary to configure security for the Oracle Fusion web application EAR file.

Authenticating the services involves the following main steps:

- Attach the policy (for example, wss10_saml_token_with_message_protection_service_policy) to the provider. You can do this in one of the following ways:
  - Use Oracle Enterprise Manager.
  - Alternatively, manually update oracle-webservices.xml. This is a packaging artifact, meaning it is not available in Oracle JDeveloper during design time. To edit the file, deploy your application to an EAR file. Extract the oracle-webservices.xml file, update it and repackage it into the EAR file.

To edit the oracle-webservices.xml file when overriding GPA:

Open the oracle-webservices.xml file, find port-component name="WSRP_v2_Markup_Service" and add the code shown in the following example.

Example 54-1 Edit the oracle-webservices.xml File

```xml
<port-component name="WSRP_v2_Markup_Service" style="document"
    binding QName="(urn:oasis:names:tc:wsrp:v2:bind)WSRP_v2_Markup_Binding_SOAP" enabled="true"
    schemaValidateInput="false">
  <policy-references>
    <policy-reference enabled="true" uri="oracle/wss10_saml_token_with_message_protection_service_policy" category="security"/>
  </policy-references>
<brick operations>
  <operation name="performBlockingInteraction" inputName="performBlockingInteraction"
    outputName="performBlockingInteractionResponse"
    input="(urn:oasis:names:tc:wsrp:v2:types)performBlockingInteraction" use="literal"/>
  <operation name="releaseSessions" inputName="releaseSessions"
    outputName="releaseSessionsResponse"
    input="(urn:oasis:names:tc:wsrp:v2:types)releaseSessions" use="literal"/>
  <operation name="getMarkup" inputName="getMarkup" outputName="getMarkupResponse"
    input="(urn:oasis:names:tc:wsrp:v2:types)getMarkup" use="literal"/>
  <operation name="handleEvents" inputName="handleEvents" outputName="handleEventsResponse"
    input="(urn:oasis:names:tc:wsrp:v2:types)handleEvents" use="literal"/>
  <operation name="initCookie" inputName="initCookie" outputName="initCookieResponse"
    input="(urn:oasis:names:tc:wsrp:v2:types)initCookie" use="literal"/>
  <operation name="getResource" inputName="getResource" outputName="getResourceResponse"
    input="(urn:oasis:names:tc:wsrp:v2:types)getResource" use="literal"/>
</brick operations>
</port-component>
<!-- start:deployment time generated info -->
<deployment>
  <tie-class-name>oasis.names.tc.wsrp.v2.bind.runtime.WSRP_v2_Markup_Binding_SOAP_Tie</tie-class-name>
  <service QName namespaceURI="urn:oasis:names:tc:wsrp:v2:wadl" localpart="WSRP_v2_Service"/>
  <soap-version>soap1.1</soap-version>
</deployment>
<!-- end:deployment time generated info -->

Secure End-to-End Portlet Applications 54-3
54.2.2 How to Configure the Key Store and Credential Store

By default, a globally attached policy profile specifies (authentication [AuthN]) and there is no need to use Oracle Enterprise Manager to configure a key store or a credential store. You only need to perform this task when a policy has a message protection or a SSL profile.

The key store contains the signing and encryption keys used to encrypt and decrypt messages. The key store itself and all the keys are password protected. The keys are also referred to using aliases, which are stored, along with their corresponding passwords, in the credential store. When accessing the key store, query the credential store first for the necessary aliases and passwords.

You can verify the creation of the key store and credential store as follows.

To verify the creation of the key store and credential store:

1. Open $DOMAIN_HOME/config/fmwconfig/jps-config.xml.
2. Verify the existence of the entry shown in the following example. This code should be configured out of the box.
3. Make sure the default context references the key store and credential store service instances as shown in the following example.

Note:

There is no need to restart your domain if this configuration is already in place.

Example 54-2 Verify the credstore and keystore serviceInstance Elements

Example 54-3 Default Context References to the Credential Store and Key Store
54.2.3 How to Authorize the Service

Oracle ADF Security is responsible for authorizing portlets, that is, Oracle ADF Security decides whether a portlet is available to a given user by checking it against the Oracle Platform Security Services (OPSS) policy store. Portlets are just one way of exposing local task flows to remote applications. A component called a portlet bridge is responsible for bridging between portlets and task flows. A portlet bridge enables exposing a task flow as a portlet.

After you create an entitlement grant for the desired task flow in jazn-data.xml, you must create a resource grant for the portlet bridge component to the authenticated role, as shown in the following example.

The following examples shows an entitlement grant enabling access to the task flow.

Note when the Oracle Fusion application needs to provide anonymous access to a portlet, the bridge wrapper task flow needs a grant to the anonymous-role, and the markup port needs a no_authentication policy, or it can use GPA, but needs to specify a Default User in the producer registration, using a valid guest user account, as described in Securing the Portlet Client.

Example 54-4  Resource Grant to the Authenticated Role

<jazn-policy>
  <grant>
  <grantee>
    <principals>
      <principal>
        <class>oracle.security.jps.internal.core.principals.JpsAuthenticatedRoleImpl</class>
        <name>authenticated-role</name>
      </principal>
    </principals>
  </grantee>
  <permissions>
    <permission>
      <class>oracle.adf.controller.security.TaskFlowPermission</class>
      <name>/WEB-INF/adfp-portlet-bridge-container.xml#adfp-portlet-bridge-container</name>
      <actions>view</actions>
    </permission>
  </permissions>
  </grant>
  ...
</jazn-policy>

Example 54-5  Entitlement-Based Policy Definition in the jazn-data.xml File

<?xml version="1.0" ?>
<jazn-data>
  <policy-store>
    <applications>
      <application>
        <name>MyApp</name>
        <app-roles>
          <app-role>
            <name>AppRole</name>
            <display-name>AppRole display name</display-name>
            <description>AppRole description</description>
            <guid>F5494E409CFCB11DEBF6FC11296284F58</guid>
          </app-role>
        </app-roles>
      </application>
    </applications>
  </policy-store>
</jazn-data>
<class>oracle.security.jps.service.policystore.ApplicationRole</class>
</app-role>
</app-roles>

        </member-resource>
      </member-resources>
    </permission-set-ref>
  </permission-set-ref>
</jazn-policy>
54.3 Secure the Portlet Client

Securing the portlet client is necessary only when applying the "no behavior" policy to the anonymous ports.

Securing a portlet consumer, or client, means enabling identity propagation. You can enable identity propagation while registering the portlet producer in Oracle JDeveloper. When registering the portlet producer, make sure you select following values in the WSRP Portlet Producer Registration wizard.

In the Configure Security Attributes window, select the following:

- **Token Profile**: Select a policy that overrides GPA. For example, you might select No Authentication Client Policy when locally attaching a policy for any of the three non-markup ports.

- **Configuration**: Select Default.

- **Default User**: Leave empty or enter a valid guest user account ID to propagate to the portlet.

  Note that **Default User** is only used when the consumer identity is in fact anonymous. In this case, the **Default User** field lets you specify some valid identity that is necessary to propagate to the portlet, when the consumer is anonymous, and the producer needs to receive a valid identity.

Within the portlet consumer domain, make sure the key store and credential store are the same ones used by the portlet producer or service. The key store and credential store are located at $DOMAIN_HOME/config/fmwconfig. For more information, see the section about verifying the creation of the key store and credential store under How to Configure the Key Store and Credential Store.

54.4 Register the Key Store and Writing to the Credential Store

By default, globally attached policy profile specifies (authentication [AuthN]) and there is no need to use Oracle Enterprise Manager to register a key store or create a credential store. You only need to perform this task when a policy profile offers message protection or SSL.

However, if you need to configure another key store for your domain, use Oracle Enterprise Manager to register the key store and write to the credential store.

54.4.1 How to Register the Key Store and Write to the Credential Store

To register the key store and write to the credential store:

1. In Oracle Enterprise Manager, expand your domain. Select **WebLogic Domain > WebLogic Domain Name**.
2. In the right-hand pane, click the WebLogic Domain menu at the top of the page and select Security > Credentials.

3. If there is no map called oracle.wsm.security, create one. If the map exists, skip this step. The following figure displays the Create Map window.

\[\text{Figure 54-1  Create a Map If None Exists}\]

- Click the Create Map button.
- For the Map Name, enter oracle.wsm.security.
  
  Do not create any keys. Keys are created when configuring the domain's service provider.

4. In the right-hand pane, click the WebLogic Domain menu at the top of the page and select Security > Security Provider Configuration.

5. In the Service Provider Configuration page, under the Key Store section, click the Configure button. The Service Provider Configuration page is shown in the following figure.

\[\text{Figure 54-8  Register the Key Store and Writing to the Credential Store}\]
6. If the Keystore Path displays .default-keystore.jks, follow the instructions here. Otherwise, skip this step.

Uncheck the **Configure KeyStore Management** box and click **OK**. This displays the window shown in the previous figure.

Under the Keystore section, click **Configure** again and enter the following information. The file producer.jks is assumed to be located under the directory path $DOMAIN_HOME/config/fmwconfig which contains a certificate alias called producer. The following figure displays the Keystore Configuration page.
Figure 54-3  Configure the Keystore

- **Keystore Path**: Enter the path of the keystore, in this case ./producer.jks.
- **Password/Confirm Password**: Enter the required password, then confirm the password.

**Signature Key**
- **Key Alias**: Enter the name of the signature key.
- **Signature Password/Confirm Password**: Enter the required password, then confirm the password.

**Encryption Key**
- **Crypt Alias**: Enter the name of the encryption key.
- **Crypt Password/Confirm Password**: Enter the required password, then confirm the password.

7. Restart your domain.

### 54.4.2 What Happens When You Register the Key Store and Write to the Credential Store

Entering this information enables the creation of keystore-csf-key, sign-csf-key and enc-csf-key in the credential store of the domain. You can verify that the keys have been created by viewing the credential store page of the domain in Oracle Enterprise Manager.

### 54.5 Maintain Application Session Context Across Web Service Requests

When the user invokes a function defined by a web service, the current application session context must be propagated across web service requests. The application session context contains important information that is stored for the duration of the user’s HTTP session. This includes information that defines a context for the application, such as its language preferences, date, and number formatting.

In order for application session context propagation to occur, you need to register the ApplSessionContext class with the context interceptor infrastructure. Then when a
SOAP request is generated by the invoked web service, the request calls out to the infrastructure and adds the application session context onto the SOAP payload.

To register the ApplSessionContext class, you must add the oracle.applcore.config library to the weblogic-application.xml file for projects on both ends of the web service request. In order for propagation to work, both the portlet consumer and the portlet producer must have this library.

**Before you begin:**

It may be helpful to have an understanding of application user sessions. For more information, see Implementing Application User Sessions.

You will need to complete this task:

Configure your project to use application user sessions. For more information, see Configuring Your Project to Use Application User Sessions.

**To add the Oracle Applications Core (Config) JDev library to the classpath:**

1. In the Application Resources panel of the Application Navigator, double-click the weblogic-application.xml file of the project that defines the portlet producer.

2. In the source editor for the file, add the following lines alongside the other <library-ref> tags:

   ```xml
   <library-ref>
     <library-name>
       oracle.applcore.config
     </library-name>
   </library-ref>
   
   The order of the <library-ref> tags is not important; however, all <library-ref> tags must be grouped together.

3. Repeat this change in the project that defines the portlet consumer.

   In order for propagation to work, both the portlet consumer and the portlet producer must have the oracle.applcore.config library.
This chapter provides a basic overview of the Oracle WebLogic Server environment and information about how to run your applications on Integrated WebLogic Server. It also provides information about how to deploy your applications to the Administration Server instance of WebLogic Server to perform end-to-end testing of new applications. If you are deploying customizations or extensions, see the Oracle Fusion Applications Extensibility Guide for Developers.

This chapter includes the following sections:

- Introduction to Deploying Applications to Oracle WebLogic Server
- Running Applications on Integrated WebLogic Server
- Preparing to Deploy Oracle ADF Applications to an Instance of Standalone WebLogic Server
- Deploying Your Oracle ADF Applications to an Administration Server Instance of WebLogic Server
- Deploying Your SOA Projects to an Administration Server Instance of WebLogic Server

The scope of this chapter is limited to what is unique in the Oracle Fusion Applications environment. For general details about Oracle WebLogic Server, references are made to the generic Oracle Fusion Middleware guides.

55.1 Introduction to Deploying Applications to Oracle WebLogic Server

Deployment is the process of packaging application files as an archive file and installing it to a target application server. You can use JDeveloper to deploy your Oracle Applications Development Framework (Oracle ADF) applications or SOA applications directly to Oracle WebLogic Server or indirectly to an archive file as the deployment target, and then install this archive file to the target server. You also can run Oracle ADF applications (but not SOA applications) in JDeveloper using Integrated WebLogic Server.

JDeveloper contains Integrated WebLogic Server that allows the developer to run the application using the Run command. You do not need to manually create deployment descriptors or WebLogic Server domains, as you would if you were deploying the application to an instance of Standalone WebLogic Server. However, Standalone WebLogic Server allows more configuration options, such as support for SOA. For more information on using Integrated WebLogic Server, see Running Applications on Integrated WebLogic Server.

If you are deploying the application to a standalone WebLogic Server instance, you may need to perform security-related configuration to prepare the application for
deployment. You may need to create or edit deployment descriptors and deployment profiles to prepare the application.

Whether you are using standalone or Integrated WebLogic servers to host the application, you will need to configure the WebLogic domains for Oracle Fusion Applications. You must run the Configure Fusion Domain Wizard from JDeveloper to configure the Integrated WebLogic Server or create a property file that is used to configure standalone WebLogic Server instances. For more information about the wizard, see Setting Up Your Development Environment.

Table 55-1 describes some common deployment techniques that you can use during the application development and deployment cycle.

<table>
<thead>
<tr>
<th>Deployment Technique</th>
<th>Environment</th>
<th>When to Use</th>
</tr>
</thead>
<tbody>
<tr>
<td>Run directly from JDeveloper</td>
<td>Test or Development</td>
<td>When you are developing your application. You want deployment to be quick because you will be repeating the editing and deploying process many times. JDeveloper contains Integrated WebLogic Server, on which you can run and test your application.</td>
</tr>
<tr>
<td>Use JDeveloper to directly deploy to the target application server</td>
<td>Test or Development</td>
<td>When you are ready to deploy and test your application on an application server in a test environment. This also can be done on Integrated WebLogic Server, and it may be required in cases where there may be nothing to Run, such as deploying an ADFbc service. For example, you can also use the test environment to develop your deployment scripts.</td>
</tr>
<tr>
<td>Use JDeveloper to deploy to an EAR file, then use the Oracle WebLogic Server Administration console, WLST commands, or Enterprise Manager for deployment.</td>
<td>Test or Development</td>
<td>When you are ready to deploy and test your application on an application server in a test environment. As an alternative to deploying directly from JDeveloper, you can deploy to an EAR file and then use other tools to deploy to the WebLogic Server instance. This also can be done on Integrated WebLogic Server. You can also use the test environment to develop your deployment scripts.</td>
</tr>
</tbody>
</table>

After you have performed the tasks required for standalone deployment, you can use JDeveloper to deploy directly to a WebLogic Server instance or to create an Enterprise Archive (EAR) file and deploy the EAR file using WebLogic Server Administration Console, Enterprise Manager, or WebLogic Scripting Tool (WLST) commands.

For more information on how to deploy an application directly using JDeveloper, see Deploying Your Oracle ADF Applications to an Administration Server Instance of WebLogic Server.

For more information about deploying the application using WebLogic Server Administration Console, or WLST, see the Oracle Fusion Middleware Administering Oracle Fusion Middleware guide and the Oracle Fusion Middleware Administering Oracle ADF Applications guide.
Note:
This chapter discusses deploying applications. If you are deploying customizations or extensions, see the “Deploying Oracle ADF Customizations and Extensions” and the “Deploying SOA Composite Applications Customizations and Extensions” sections of the Extensibility Guide for Developers.

55.1.1 Prerequisites for Deployment

Before you deploy an application, you should perform the following tasks:

1. You must run the Configure Fusion Domain Wizard to set up the Integrated WebLogic Server domain or create a property file to be used to set up the standalone WebLogic Server domain. For instructions, see Setting Up Your Development Environment.

2. If you want more debugging output, set the environment variable using one of the shell commands as shown in Example 55-1, before starting the Administration Server instance of WebLogic Server or before starting JDeveloper if you are going to run Integrated WebLogic Server.

   Note: If using Integrated WebLogic Server, you might want to set this on run-time properties so that this can be controlled directly from JDeveloper.

3. You must disable the Auto Generate and Synchronize weblogic-jdbc.xml Descriptors During Deployment option to use the Global Java Database Connectivity (JDBC) datasource. To do this, open Application Properties and choose the Deployment category as shown in Figure 55-1. Unselect the Auto Generate and Synchronize weblogic-jdbc.xml Descriptors During Deployment option and click OK.

   For additional details, see Setting Up JDBC Data Sources on Oracle WebLogic Server.
Example 55-1 Setting Environment Variable

# For csh shell
setenv JAVA_OPTIONS "$JAVA_OPTIONS -Djbo.debugoutput=console"

# For bash shell
export JAVA_OPTIONS="$JAVA_OPTIONS -Djbo.debugoutput=console"

For Windows
set JAVA_OPTIONS=%JAVA_OPTIONS% -Djbo.debugoutput=console

55.1.1.1 Setting Up JDBC Data Sources on Oracle WebLogic Server

To avoid passwords being present in plain text in deployed files, JDeveloper uses password indirection, which means that passwords for the data sources must be set on the server before the application will run correctly.

You do this using global data sources, which are set up in the Oracle WebLogic Server Administration Console using the Data Sources link under JDBC.

JDeveloper ensures that your web application web.xml, or EJB application ejb-jar.xml, contains the necessary <resource-ref> entry to identify an application resource name. The name is jdbc/connection-nameDS, where connection-name is the name of the application resources connection.

The application looks up this data source using the application-specific resource JNDI namespace of java:comp/env/jdbc/connection-nameDS, and it finds this resource because web.xml contains the <resource-ref> entry for jdbc/connection-nameDS.

An important control for the files that are generated is the Auto Generate and Synchronize weblogic-jdbc.xml Descriptors During Deployment field on the WebLogic page of the Application Properties dialog.

When the Auto Generate field is selected, JDeveloper does the following:
• Generates an application-name-jdbc.xml file for each connection in the application resources, and sets the indirect password attribute.

```xml
<jdbc-driver-params>
  <use-password-indirection>true</use-password-indirection>
</jdbc-driver-params>
```

Upon deployment, JDeveloper determines the JDBC connection password from the username in application-name-jdbc.xml, and populates the JDBC connection password using an Mbean.

• `weblogic-application.xml` is updated to add each application-name-jdbc.xml as a module.

• `web.xml` (if it exists) has a resource reference to each JDBC JNDI name.

### 55.1.1.1 How to Create a Global Data Source on Oracle WebLogic Server

You create a global data source on Oracle WebLogic Server Administration Console. To set up a global data source:

1. Login to the Oracle WebLogic Server Administration Console.
2. Click the **Data Sources** link under **JDBC**.
3. On the Summary of JDBC Data Sources page, click **New**.
4. In the Create a New JDBC Data Source page, enter details of the data source.
   - The name can be anything.
   - The JNDI name must be of the form `jdbc/connection-nameDS`. For example, if the application has a connection name `connection1`, the JNDI name is `jdbc/ connection1DS`.
5. Ensure that the database type is Oracle and that the driver is Oracle's Driver (Thin) for Service Connections; Version 9.0.1, 9.2.0, 10, 11.
6. Click **Next** twice to navigate to the Create a New JDBC Data Source page, where you enter the connection details.
   - The database name is the Oracle SID.
   - The host name is the name of the machine the database is on.
   - The default port is 1521.
7. Enter the user name and password, for example `hr/hr`.
8. Click **Next** and click **Test Configuration**.
9. Click **Next** to navigate to the Select Targets page, where you select a target for this data source. If you fail to select a target, the data source is created but not deployed.
10. Click **Finish**.

### 55.1.1.2 Deploy to an EAR File to Run on Oracle WebLogic Server

To deploy an application to an EAR file to run on Oracle WebLogic Server, you can:
• Select the **Auto Generate and Synchronize weblogic-jdbc.xml Descriptors During Deployment** field, and set up passwords using application level credential mapping.

• Alternatively, you can deselect the **Auto Generate and Synchronize weblogic-jdbc.xml Descriptors During Deployment** field and set up passwords by creating a global data source on Oracle WebLogic Server.

If you are deploying using ojdeploy:

• You can use the **-nodatasources** switch, in which case you can set up passwords on Oracle WebLogic Server by either:
  
  – Creating a global data source.
  
  – Manually creating application level data sources.

• If you do not use the **-nodatasources** switch, you can only set up passwords using application level credential mapping.

### 55.1.2 Introduction to the Standalone Administration Server WebLogic Server Instance

A Weblogic Server instance is a configured instance to host applications, such as Web applications, Enterprise applications, and Web services, and resources, such as Java Message Service (JMS), and JDBC, Diagnostics.

There are two types of WebLogic Server instances: Administration Server and Managed Server.

The Administration Server instance is the central configuration controller for the entire domain. Its purpose is to:

• Host the Administration Console.

• Enable you to start and stop the servers from a central location.

• Enable you to migrate servers and services within the domain.

• Enable you to deploy applications within the domain.
There is only one Administration Server instance of WebLogic Server in a domain, and an Administration Server instance of WebLogic Server controls only one domain.

A Managed Server WebLogic Server instance is a running instance that hosts the applications and the resources that are needed by those applications. Each Managed Server WebLogic Server instance is independent of all other Managed Server WebLogic Server instances in the domain, unless they are in a cluster. You can have as many Managed Server WebLogic Server instances as you need in a domain.

The Administration Server instance of WebLogic Server stores the master copy of the domain configuration, including the configuration for all Managed Server WebLogic Server instances in the domain. Each Managed Server WebLogic Server instance stores a local copy of its configuration. When a Managed Server WebLogic Server instance starts, it connects to the Administration Server instance of WebLogic Server to synchronize the configuration.

In most cases, a single server environment is used for development purposes. This is where a single server acts as the Administration Server instance of WebLogic Server and as the host for applications, as illustrated in Figure 55-3.

However, there are some teams that use a Managed Server for either Oracle Enterprise Scheduler (ESS) runtime or Service-Oriented Architecture (SOA). When you are setting up your standalone WebLogic server, you can choose one of the following options:

- Administration Server - Oracle ADF (includes ESS libraries)
- Administration Server - Oracle ADF + ESS Runtime
- Administration Server - Oracle ADF and Managed Server - ESS Runtime
- Administration Server - Oracle ADF and Managed Server - SOA
- Administration Server and Managed Server - SOA
You deploy applications to the Administration Server instance of WebLogic Server. There are two configurations for Administration Servers:

- Non-SOA
- SOA

Not all components are available in both. For example, WebCenter libraries are not available in SOA and SOA libraries are not available in non-SOA. Oracle ADF applications containing UI must be deployed to the non-SOA WebLogic server, and SOA composites must be deployed to the SOA-configured WebLogic Server.
Some services have a Service Data Object (SDO) co-location requirement and need to be deployed to the SOA container. To deploy the service to the SOA-configured WebLogic Server, create a new EAR profile containing only that service or services from your application workspace.

For more information about SDO and SOA, see the *Developing SOA Applications with Oracle SOA Suite* guide.

For information about how to configure the SOA WebLogic Server, see *How to Set Up the Personal Environment for Standalone WebLogic Server*.

### 55.2 Running Applications on Integrated WebLogic Server

Integrated WebLogic Server is a single server that is included within JDeveloper. This server automates deploying your applications. Integrated WebLogic Server is sufficient to run your application to make sure it displays correctly in browsers, or for testing and debugging portions of the application.

**Note:**

You cannot use Integrated WebLogic Server to run SOA applications. You must deploy SOA applications to a standalone WebLogic Server instance. For more information, see *Deploying Your SOA Projects to an Administration Server Instance of WebLogic Server*.

Integrated WebLogic Server has already been configured with the Oracle Fusion Middleware Extensions for Applications domain extension templates. When the scripts are used to create the Integrated WebLogic Server and Standalone Weblogic Server domains, the Applications Core templates are configured. These templates are required for deploying and running applications using Applications Core functionality. So all of the Oracle Fusion applications will run on instances of both servers.

JDeveloper has a default connection to Integrated WebLogic Server and does not require you to manually create any deployment profiles or descriptors. Integrated WebLogic Server automates creating the same EAR that is used by Standalone WebLogic Server. You can see this when running the application. The run log shows the steps done by JDeveloper, including creating an EAR and deploying it.

When you run your application in JDeveloper using the `run` or `debug` commands, Integrated WebLogic Server automatically starts the server, packages the application to an EAR file, deploys the EAR, opens the browser, and accesses the URL for the deployed application.

When you use JDeveloper to run an application for the first time, it automatically creates the Integrated WebLogic Server instance. Make sure you have configured the domain, following the steps in *How to Use the Oracle Fusion Domain Wizard*.

You can also start the server directly from within JDeveloper. To do this, go to the main menu and select **Run > Start Server Instance**.
Tip:
The first time Integrated WebLogic Server starts, it tries to use the first available port in the 7101 - 7105 range. The following message appears as the first line in the Default server log in JDeveloper. You should use the alternate port for all access:

HTTP port conflict detected. The HTTP port will be reassigned to port 7102.

The server and the application are considered separate entities, so even if you stop the application, it does not stop the server. To terminate the application, select the application name from the terminate button dropdown menu in the Server Instance Log page, as shown in Figure 55-5.

**Figure 55-5   Terminating the Application**

To terminate the server, select the server name, as shown in Figure 55-6.

**Figure 55-6   Terminating the Integrated WebLogic Server Instance**

### 55.2.1 How to Deploy an Application with Metadata to Integrated WebLogic Server

When an application is running in Integrated WebLogic Server, the Metadata Archive (MAR) profile itself will not be deployed to a repository. Instead, a simulated Oracle Metadata Services (MDS) repository will be configured for the application that reflects the metadata information contained in the MAR. This metadata information is simulated and the application runs based on their location in source control.

Any customizations or documents created by the application are written to this simulated MDS repository directory. You can keep the default location for this directory or you can set it to a different directory. You also have the option to preserve customizations across different application runs or to delete the customizations before each application run.

Before you begin, you must first create your MAR deployment profile. For information about how to create a MAR deployment profile, see How to Create Deployment Profiles for Standalone WebLogic Server Deployment.

To deploy a MAR deployment profile to Integrated WebLogic Server:

1. Go to the Application Navigator, right-click the application and select Application Properties.

2. In the Application Properties dialog, expand Run and choose MDS. See Figure 55-7.
3. In the Run MDS page:
   a. Select the MAR profile from the MAR Profile dropdown list.
   b. Enter a directory path in Override Location if you want to customize the location of the simulated repository.
   c. Select the Directory Content option. You can choose to preserve the customizations across application runs or delete customizations before each run.

55.3 Prepare to Deploy Oracle ADF Applications to an Instance of Standalone WebLogic Server

You must prepare the application and the WebLogic Server instance before you deploy applications to an instance of Standalone WebLogic Server.

Before you begin:

Before you deploy the application to a Standalone WebLogic Server instance, you need to:

1. Create and configure the WebLogic Server domains using the Configure Fusion Domain wizard as described in Setting Up Your Development Environment.

2. If the application is using ADF Security, you may need to:
b. Migrate application-level security information to the WebLogic Server instance. For more information, see the "Configuring Security for WebLogic Server" section in the Developing Fusion Web Applications with Oracle Application Development Framework.

c. Set up JDBC URL for WebLogic Server. For more information, see the "Applications with JDBC URL for WebLogic" section in the Developing Fusion Web Applications with Oracle Application Development Framework.

d. Set up JDBC datasource for WebLogic Server. For more information, see the "Applications with JDBC Data Source for WebLogic" section in the Developing Fusion Web Applications with Oracle Application Development Framework.

e. Understand LDAP-based stores. For more information, see What You May Need to Know About Testing.

55.3.1 How to Reference the Shared Libraries

Shared libraries are available in the integrated and standalone WebLogic Server container and your projects must be updated so that they can use a shared library.

When you create your WebLogic Server domain, all the required shared libraries should be automatically created for you. When you choose a new technology or library in JDeveloper, the weblogic.xml and weblogic-application.xml files are automatically updated to reference these shared libraries. If, for some reason, the required references are not created automatically, you must update the weblogic.xml and weblogic-application.xml files manually.

The process below shows how to reference a sample oracle.shared.library shared library in a project.

To reference a shared library into a project:

1. Go to Application Navigator, expand Application Resources > Descriptors > META-INF.

2. Add reference shared library to weblogic-application.xml:
   a. Click the weblogic-application.xml file.
   b. Create a copy of the library-ref element.
      You can either accomplish this manually in the editor, or you can right-click the existing library-ref element to use the copy and paste options.
   c. Change the library-name element to oracle.shared.library. Leave the specification and implementation version values blank.

   Caution:
   Make sure that there are no blank spaces between the tag <library-ref> and the actual entry as they will cause problems.

   d. Repeat steps 2b and 2c to reference additional libraries.

3. Add reference shared library to weblogic.xml using the same steps.
55.3.2 How to Create Deployment Profiles for Standalone WebLogic Server Deployment

The deployment profiles determine how the application is bundled and deployed to Standalone WebLogic Server. When running an application within JDeveloper using Integrated WebLogic Server, these deployment profiles are not used.

Tip:
When you run your application in JDeveloper Integrated WebLogic Server, these deployment profiles are not used. Instead, JDeveloper scans the entire workspace or the current working set, (if the Run Working Set option is enabled), to construct the class loader classpaths. If the data model project is eligible to be an EJB then the Libraries and Classpath entries from that project contribute to the application root class loader. The user interface project contributes to the web application class loader.

To deploy the application, you must create deployment profiles applicable to the project or projects. The deployment profiles you need depend on your application requirements. For example, an application may include Business Components Service Interface, Web Application Archive (WAR), and MAR profiles. When you have defined these, create an EAR deployment profile for the application.

You can only deploy the application as an EAR file at the application level. Creating EAR files from the project level are incomplete and this option is disabled. The project level deployment profiles should be included in the EAR deployment profile.

Depending on the type of projects in your application, you may need to create the following deployment profiles:

- Business Components Service deployment profile. For instructions, see the "How to Deploy Web Services to Oracle WebLogic Server” section of the Developing Fusion Web Applications with Oracle Application Development Framework.

- WAR deployment profile. For instructions, see the "Creating a WAR Deployment Profile" section of the Developing Fusion Web Applications with Oracle Application Development Framework

- MAR deployment profile. For instructions, see the "Creating a MAR Deployment Profile" section of the Developing Fusion Web Applications with Oracle Application Development Framework

- EAR deployment profile. For instructions, see the "Creating an Application-Level EAR Deployment Profile" section of the Developing Fusion Web Applications with Oracle Application Development Framework

55.4 Deploying Your Oracle ADF Applications to an Administration Server Instance of WebLogic Server

You can deploy your Oracle ADF applications to a standalone WebLogic Server instance using JDeveloper.

Any necessary MDS repositories must be registered with the WebLogic Server instance. If the MDS repository is a database, the repository maps to a WebLogic Server system data source with MDS-specific requirements. Before you deploy the application, make sure to target this data source to the Administration Server instance.
of WebLogic Server. For more information about registering MDS, see the Oracle Fusion Middleware Administering Oracle Fusion Middleware guide.

---

**Note:**

If you are using the WebLogic Server Administrative Console or WLST scripts to deploy an application packaged as an EAR file that requires MDS repository configuration in `adf-config.xml`, you must run the `getMDSArchiveConfig` WLST command that returns a handle to the `MDSArchiveConfig` object for the specified archive. The returned `MDSArchiveConfig` object's `setAppMetadataRepository` and `setAppSharedMetadataRepository` methods can be used to change application and shared repository configuration in an archive. MDS configuration is required if the EAR file contains a MAR file or if the application is enabled for Design Time at Runtime. For more information about WLST commands, see the Oracle Fusion Middleware WLST Command Reference for WebLogic Server guide.

---

### 55.4.1 How to Create an Application Server Connection Using JDeveloper

To deploy your application using JDeveloper, you create a connection to the application server and then deploy the application.

**To create an application server connection:**

2. Open your application in JDeveloper.
3. Launch the Application Server Connection wizard.

   You can:

   - In the Application Server Navigator, right-click **Application Servers** and choose **New Application Server Connection**.
   - In the New Gallery, expand **General**, select **Connections** and then **Application Server Connection**, and click **OK**.
   - In the Resource Palette, choose **New > New Connections > Application Server**.

4. Complete the wizard:

   a. Enter the following information as you progress through the wizard:
   
   b. **Connection Name**: Enter a name for the connection.
   
   c. **Username** and **Password**: Enter a user name and password for the administrative user authorized to access the application server.
   
   d. **Weblogic Hostname Administration Server**: Enter the name of the WebLogic Server instance containing the TCP/IP DNS where your application (`.jar`, `.war`, `.ear`) will be deployed.
   
   e. **Port**: Enter a port number for the Oracle WebLogic Server instance on which your application (`.jar`, `.war`, `.ear`) will be deployed.
f. In the **SSL Port** field, enter an SSL port number for the Oracle WebLogic Server instance on which your application (.jar, .war, .ear) will be deployed.

g. Select **Always Use SSL** to connect to the Oracle WebLogic Server instance using the SSL port.

h. **WebLogic Domain**: Optionally enter a domain only if Oracle WebLogic Server is configured to distinguish nonadministrative server nodes by name.

i. Test the connection.

j. Click **Finish** to close the wizard and create your application server connection.

### 55.4.2 How to Deploy the Application Using JDeveloper

After you have created an application server connection and an EAR deployment profile, you can deploy the application to a standalone application server.

**To deploy an application:**

1. Deploy your project to the application server:
   
a. In the Application Navigator, right-click your application and choose **Deploy > deployment profile**.
   
b. In the Deploy wizard Deployment Action page, select **Deploy to Application Server** and click **Next**.
   
c. In the Select Server page, select the application server connection, and click **Next**.
   
d. The WebLogic Options page appears. Select a deploy option and click **Next**.

   If the adf-config.xml file in the EAR file requires MDS repository configuration, the Deployment Configuration dialog appears for you to choose the target metadata repository or shared metadata repositories, as shown in **Figure 55-8**.
The **Repository Name** dropdown list allows you to choose a target metadata repository from a list of metadata repositories registered with the Administration Server instance of WebLogic Server. The **Partition Name** dropdown list allows you to choose the metadata repository partition to which the application's metadata will be imported during deployment. For more information about managing the MDS repository, see the *Oracle Fusion Middleware Administering Oracle Fusion Middleware* guide.

**Note:**

If you are deploying an Oracle ADF application, do not use the **Deploy to all instances in the domain** option.

de. Click **Finish**.

2. Verify the run-time application as:

   http://httpHost:httpPORT/<CONTEXT>/faces/<landing jspex>

   For example, http://server06.us.company.com:7001/UIPatternsDemo/faces/ServiceRequest

55.4.3 How to Create an EAR File for Deployment

You can also use the deployment profile to create an archive file (EAR file). You can then deploy the archive file using Enterprise Manager, WLST, or the Oracle WebLogic Server Administration Console.

Although an application is encapsulated in an EAR file (which usually includes WAR, MAR, and JAR components), it may have parts that are not deployed with the EAR. For instance, ADF Business Services can be deployed as a JAR.

To create an EAR archive file:

- In the Application Navigator, right-click the application containing the deployment profile, and choose Deploy > deployment profile > to EAR file.

See How to Create Deployment Profiles for Standalone WebLogic Server Deployment.

55.5 Deploy Your SOA Projects to an Administration Server Instance of WebLogic Server

You can deploy your SOA projects using either JDeveloper or the other administration tools described in Table 55-1.

55.5.1 How to Deploy Your SOA Projects Using JDeveloper

This section discusses how to deploy your SOA projects into the Administration Server instance of WebLogic Server using JDeveloper.

The basic steps to deploying your SOA project from within JDeveloper are:

1. Define a connection. For instructions to create an application server connection, see "Creating an Application Server Connection" in the Developing SOA Applications with Oracle SOA Suite.

2. Deploy the Project. For instructions to deploy a SOA project, see "Deploying the Profile" in the Developing SOA Applications with Oracle SOA Suite.

3. Check the deployed SOA Project.

For details about deploying a SOA project, see "Deploying SOA Composite Applications" in the Developing SOA Applications with Oracle SOA Suite.

55.5.1.1 Check the Deployed SOA Project

You can check and run your deployed SOA project from two locations:

From Enterprise Manager on port 7001 by opening the Weblogic Hostname (Administration Server) URL for which you created the Connection, such as:

http://xyzzy-on.example.com:7001/em

After you log in, a screen similar to Figure 55-9 displays (the SOA tree in the left pane has been expanded and the first deployment has been selected):
Figure 55-9  Checking SOA Deployment from the EM
This chapter provides information about Oracle WebCenter Content Server (Content Server), Oracle Data Integrator (ODI), and Oracle Business Activity Monitoring (Oracle BAM) Server repositories, which are used in Oracle Fusion applications, and describes how to connect to each of these repositories using Oracle JDeveloper.

This chapter includes these sections:

- Creating a Content Repository Connection
- Creating an Repository Connection
- Creating Server Repository Connection

### 56.1 Creating a Content Repository Connection

Oracle WebCenter Content Server (Content Server), which serves as the base for the WebCenter Content system, provides a web-based repository that manages all phases of the content lifecycle from creation and approval to publishing, searching, expiration, and archiving or disposition. The Attachment component enables you to add attachments to the user interface (UI) pages that you create for Fusion web applications. Before you can implement attachments at design time in Oracle JDeveloper, you must set up a content server-based content repository connection.

For more information about Attachment components, see Implementing Attachments.

For more information about content integration, see the "Introduction to Integrating and Publishing Content" chapter of the Developing WebCenter Portal Assets and Custom Components with Oracle JDeveloper.

### 56.1.1 How to Create a Content Repository Connection

How you create a content repository connection depends upon whether your connection is for Oracle Fusion Applications development or for ad hoc development.

#### 56.1.1.1 Create a Connection for Oracle Fusion Applications Development

To set up a content server-based repository connection from an Oracle Fusion application, you run Oracle WebLogic Scripting Tool (WLST) commands to synchronize the Oracle WebLogic Server (WebLogic Server) credential store with the Content Server credential store, and then you use the Create Content Repository Connection wizard to set up a content server-based content repository connection.

**Before you begin:**

- Verify that Content Server has been deployed and you have a working server that works with the Oracle Fusion applications.
• Ensure that the code grant entry for the Attachments-Model.jar file exists in the application's jazn-data.xml file, as described in About Creating Attachments. When the application is deployed, the policies in jazn-data.xml are merged into the system-jazn-data.xml file in weblogic_server_domain_home/config/fmwconfig.

• Log in to the content server and verify that your user name is a member of the AttachmentsUser role. Note that employees and contingent workers have this role automatically.

To create a connection for Oracle Fusion Applications development:

1. Make a backup of the WebLogic Server domain's default keystore located at weblogic_server_domain_home/config/fmwconfig/default-keystore.jks.

2. Replace the weblogic_server_domain_home/config/fmwconfig/default-keystore.jks file with a copy of the domain default keystore for Content Server, which is located at content_server_domain_home/config/fmwconfig/default-keystore.jks.

3. At the command line, type the following line to start the WLST tool, if it is not currently running.

   sh jdev_install/oracle_common/common/bin/wlst.sh

   On Windows, use wlst.cmd.

4. If you have not yet connected to the server, type the following WLST command to connect to WebLogic Server, replacing the user name and password arguments with your WebLogic Server user name and password.

   connect('wls_username', 'wls_password', 'wls_uri')

   The values must be wrapped in single-quotes. The wls_uri value is typically T3://localhost:7101.

5. From WLST, execute the following commands to store the credentials. The user names and passwords must be the same as for the Content Server domain.

   When executing the commands, replace user name and password for user with the user names and passwords that are used in the WebCenter Content credentials.

   updateCred(map="oracle.wsm.security", key="keystore-csf-key", user="user name", password="password for user", desc="Keystore key")
   updateCred(map="oracle.wsm.security", key="enc-csf-key", user="user name", password="password for user", desc="Encryption key")
   updateCred(map="oracle.wsm.security", key="sign-csf-key", user="user name", password="password for user", desc="Signing key")
   exit()
Note:

If the keys do not exist, use the following commands instead:

```java
createCred(map="oracle.wsm.security", key="keystore-csf-key", user="user name", password="password for user", desc="Keystore key")
createCred(map="oracle.wsm.security", key="enc-csf-key", user="user name", password="password for user", desc="Encryption key")
createCred(map="oracle.wsm.security", key="sign-csf-key", user="user name", password="password for user", desc="Signing key")
exit()
```

6. From the Application Resources panel in JDeveloper, right-click Connections and choose New Connection > Content Repository from the menu.

7. In the Create Content Repository Connection wizard shown in Figure 56-1, complete the following information:

Create Connection In: Select Application Resources.

Connection Name: Enter FusionAppsContentRepository. Do not enter any other value. This name is copied to adf-config.xml as the primary connection for this application. If you use a different value, the name might be overwritten when installed on customer sites and cause connection problems.

Repository Type: Select Oracle Content Server.

Set as Primary Connection for Document Library: Select this checkbox.

Configuration Parameters: Enter values for the parameters listed in Table 56-1. If a parameter is not listed in the table, leave the value blank.

Contact your system administrator to obtain the correct information.

### Table 56-1  Example Configuration Parameters

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>RIDC Socket Type</td>
<td>jaxws</td>
</tr>
<tr>
<td>Admin Username</td>
<td>The name of a user who has been granted Content Server administration privileges.</td>
</tr>
<tr>
<td>URL of the Web Server Plugin</td>
<td>The idcnativews web service that is defined on the server. This is typically <a href="http://host:port/idcnativews">http://host:port/idcnativews</a>. Check with your system administrator.</td>
</tr>
</tbody>
</table>

Authentication Method: Select Identity propagation.
8. Click **Test Connection** and verify that the status returned is **Success**!

   **Note:**
   
   If the test is unsuccessful, verify that the values that you entered are correct and try again.

9. Click **OK**.

10. From the Application Resources panel, expand **Connections** to see the new content repository connection, as shown in **Figure 56-2**.

11. Complete the following steps to verify that the application contains all required libraries and jazn-data.xml entries.

   a. Create a new JavaServer Faces page named **DocumentLibrary.jspx**.
   
   b. From the Applications Resources panel, select the content repository, drag it onto the JavaServer Faces page, and choose **Document Manager**.
   
   c. Delete **DocumentLibrary.jspx**.
56.1.1.2 Create a Connection for Ad Hoc Development

Sometimes you might need a quick connection for prototyping or assessment purposes and you do not want to use the central WebCenter Content environment. In this situation, use the Create Content Repository Connection wizard to create a connection in your own environment.

Before you begin:

- Ensure that the code grant entry for the Attachments-Model.jar file exists in the application's jazn-data.xml file, as described in About Creating Attachments. When the application is deployed, the policies in jazn-data.xml are merged into the system-jazn-data.xml file in weblogic_server_domain_home/config/fmwconfig.

- Ensure that the sockets on the WebCenter Content Managed Server are enabled.

- You need the following information to create a content repository connection:
  - Host name of the machine that is running the WebCenter Content Managed Server.
  - WebCenter Content Managed Server listener port.
  - URL for the login page to the content server instance.
  - WebCenter Content shared credentials user name and password

  Contact your system administrator to obtain this information.

To set up a content repository connection for ad hoc development:

1. From the Application Resources panel in JDeveloper, right-click Connections and choose New Connection > Content Repository from the menu.

The Create Content Repository Connection wizard is displayed, as shown in Figure 56-3.
2. Complete the following information:

**Create Connection In:** Select *Application Resources*.

**Connection Name:** Enter `FusionAppsContentRepository`. Do not enter any other value. This name is copied to `adf-config.xml` as the primary connection for this application. If you use a different value, the name might be overwritten when installed on customer sites and cause connection problems.

**Repository Type:** Select *Oracle Content Server*.

**Set as Primary Connection for Document Library:** Select this checkbox.

**Configuration Parameters:** Enter values for the parameters shown in Table 56-2. Except for the RIDC Socket Type parameter, all values shown are examples only. If a parameter is not listed in the table, leave the value blank.

Contact your system administrator to obtain the correct information.

### Table 56-2 Example Configuration Parameters

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>RIDC Socket Type</td>
<td>socket</td>
</tr>
<tr>
<td>Server Hostname</td>
<td>abc.example.com</td>
</tr>
<tr>
<td>Content Server Listener Port</td>
<td>4444</td>
</tr>
</tbody>
</table>

**Authentication:** Select *External Application*. Click the *Add* icon and complete the following information to create a new External Application:
a. Enter a unique name for the **External Application**. Click **Next** to continue to Step 2.

b. Enter the following information, as shown in **Figure 56-4**.
   - **Login URL**: Paste the URL for the login page. (Contact your system administrator for this information). For example:
     - `http://abc.example.com:2244/abc/abcplg?
       AbcService=LOGIN&Action=GetTemplatePage&Page=HOME_PAGE&Auth=Internet`
   - **User Name/ID Field Name**: Enter the field name for the user name or ID, such as `username`.
   - **Password Field Name**: Enter the field name for the password, such as `password`.
   - **Tip**: The User Name and Password field names are derived from the HTML input field names.

![Figure 56-4 Register External Application Wizard — General (Step 2)](image)

c. Click **Next** to continue to Step 3 and click **Next** to continue to Step 4.

d. Complete the following information:
   - **Specify Shared Credentials**: Select this checkbox.
   - **User Name** and **Password**: Enter the Shared Credentials user name and password. (Contact your system administrator for this information).
   - Click **Next** to continue to Step 5.

e. Complete the following information:
   - **Specify Public Credentials**: Select this checkbox.
   - **User Name** and **Password**: Enter the Shared Credentials user name and password. (Contact your system administrator for this information).
Click Finish to save your entries, create the External Application, close the wizard, and return to the Create Content Repository Connection page.

**Authentication:** Choose the newly created External Application from the dropdown list.

3. Click **Test Connection** and verify that the status returned is **Success**.

**Note:**
If the test is unsuccessful, verify that the values that you entered are correct and try again.

4. Click **OK**.

5. From the Application Resources panel, expand **Connections** to see the new content repository connection, as shown in Figure 56-5.

![Figure 56-5](image)

**Figure 56-5**  **JDeveloper — Application Navigator**

6. Complete the following steps to verify that the application contains all required libraries and jazn-data.xml entries.

   b. From the Applications Resources panel, select the content repository, drag it onto the JavaServer Faces page, and choose **Document Manager**.

   c. Delete `DocumentLibrary.jspx`.

**56.1.2 Troubleshooting Content Server Connections**

Exceptions can occur when the connection is improperly configured. The four most common exceptions are the following errors:

- Insufficient user privileges error
- WS-Security header processing error
- Access denied due to incorrect access grants for the application
- Access denied error due to incorrect access grants for attachments

For more information, see the "Diagnosing Problems" chapter in the *Administering Web Services*.

**56.1.2.1 User Does Not have Sufficient Privileges**

If you are sure that the user is a member of the AttachmentsUser role, then you must consult logs for the cause of the insufficient privileges error message. The most common cause is a blank or invalid signature, but this exception can be the consequence of several different misconfiguration issues.
To diagnose the problem, enable applications logging for the
oracle.apps.fnd.applcore.attachments.model.% module with a logging
level of FINEST. Search the application log files for the string "Unable to generate
digital signature." The stack trace might indicate the cause. For example, if it reports
that the "keystore has been tampered with, or the password is wrong," verify that the
password in credentials store for the application's server domain matches the
password in the credentials for the content server's domain. If the stack trace reports
"Access Denied," verify that the code grants described in About Creating Attachments
have been added to the jazn-data.xml file. For information about applications
logging, see the "Troubleshooting Oracle Fusion Applications Using Incidents, Logs,
QuickTrace, and Diagnostic Tests" chapter in the Administrator's Guide.

If your search through the application logs does not find an "Unable to generate digital
signature" string, the cause might be that the content server cannot verify the digital
signature. To diagnose the problem, set up tracing for fusionappsattachments. Be
sure to enable full verbose tracking and enable save. Access the system audit
information server output and search for XFND_SIGNATURE. A blank signature
indicates that the signature was not generated by the Oracle Fusion application. If the
signature is not blank and the "$DefaultCheckinSigningScheme: Signature Verification
Failed" message exists, the cause might be that the credentials for the application's
server domain do not match the credentials for the content server's domain and you
need to repeat the connection steps described in this section for the appropriate
application type.

Related Links
The following documents provide additional information related to the topics
discussed in this section:

- For more information about setting up tracing for fusionappsattachments,
  see the "System Audit Tracing Sections Information" section in the Oracle

- For more information about system audit, see the "System Audit Information"
  section in the Administering Oracle WebCenter Content.

56.1.2.2 Invalid Security: Error in Processing the WS-Security Header
The common cause for the WS-Security header processing exception is that global
policy attachment (GPA) has not been set up.

56.1.2.3 Access Denied: Policy Enforcement Exception
If you receive the following message, then your application does not have the correct
access grants.

oracle.fabric.common.PolicyEnforcementException: access denied
(oracle.wsm.security.WSIdentityPermission resource=AppName assert)

If you are using the file-based policy store for grants, then ensure that you have a
<grant> element similar to Example 56-1 in the <jazn-policy> element in the
jazn-data.xml file. Replace application-short-name with the name for your
application. Note that the application short name appears as the resource value in
the error message.

Example 56-1 Application Permissions Entry

<grant>
  <grantee>
    <codesource>
56.1.2.4 Access Denied: Credential AccessPermission

The following exception typically indicates that the code grants described in About Creating Attachments have not been added to the jazn-data.xml file or have not been merged into the system-jazn-data.xml file in weblogic_server_domain_home/config/fmwconfig.

access denied (oracle.security.jspservice.credstore.CredentialAccessPermission context=SYSTEM, mapName=oracle.wsm.security, keyName=enc-csf-key read)

56.2 Creating an Oracle Data Integrator Repository Connection

Oracle Data Integrator (ODI) combines all the elements of data integration—data movement, data synchronization, data quality, data management, and data services—to ensure that information is timely, accurate, and consistent across complex systems.

ODI is built on several components all working together around a centralized metadata repository. The ODI architecture is organized around a modular repository, which is accessed in client-server mode by components.

The Oracle Fusion Applications ODI repository consists of a master repository and a work repository. The master repository contains the security information, the topology information (definitions of technologies and servers), and the versions of the objects. A work repository stores information for:

- **Models** — Includes datastores, columns, data integrity constraints, cross-references, and data lineage.

- **Projects** — Includes declarative rules, packages, procedures, folders, knowledge modules, and variables.

- **Runtime information** — Includes scenarios, scheduling information, and logs.

You use Oracle Data Integrator Studio to access the repositories; administer the infrastructure; reverse-engineer the metadata; develop projects; and perform scheduling, operating, and monitoring executions.

For information about the role of ODI in securing Oracle Fusion applications, see c__2798.

**Related Links**

The following document provides more information about the topics discussed in this section:

- For more information about connecting to the ODI master and work repositories, see the "Administering Repositories" chapter in the Oracle Fusion Middleware Developing Integration Projects with Oracle Data Integrator.
56.3 Creating Oracle Business Activity Monitoring Server Repository Connection

Oracle Business Activity Monitoring (Oracle BAM) provides an active data architecture that dynamically moves real-time data to end users through every step of the process. This solution actively collects data, applies rules designed to monitor changes, and delivers the information in reports to users.

You must create a connection to Oracle BAM Server to browse the available data objects and construct transformations while you are designing your applications. When the application is running, the Oracle BAM Server connection is used to publish data to Oracle BAM data objects. Only one Oracle BAM Server connection per Business Process Execution Language (BPEL) project is currently supported. For more information about BPEL integration, see the Developing SOA Applications with Oracle SOA Suite guide.

When building an application in JDeveloper, the methods of connecting to Oracle BAM Server are:

- Oracle BAM Adapter in a service-oriented architecture (SOA) composite application
- Oracle BAM sensor actions in a BPEL process

56.3.1 How to Create an Oracle BAM Connection

Use the BAM Connection wizard to create a connection to Oracle BAM Server.

**Note:**

Do not create an Oracle BAM Server connection through the Resource Palette that displays when you select View > Resource Palette. Create Oracle BAM Server connections from the Application Resources panel, either directly or by copying an existing connection from the Resource Catalog.

**To create an Oracle BAM Server connection:**

1. In JDeveloper, select New from the File menu to open the New Gallery dialog.

2. Select the General > Connections category, then select BAM Connection. Click OK to open the Oracle BAM Connection wizard, as shown in Figure 56-6.
3. Enter a unique name to identify this connection.

4. Select Application Resources and click Next.

5. Enter the following connection information:

   **BAM Web Host**: Enter the name of the host on which Oracle BAM Report Server and the web server are installed. In most cases, the web host and the server host are the same.

   **BAM Server Host**: Enter the name of the host on which the Oracle BAM Server is installed.

   **User Name** and **Password**: Enter the Oracle BAM Server user name and password. The user name is typically `bamadmin`.

   **HTTP Port**: Enter the port number or accept the default value of 9001. This is the HTTP port for the Oracle BAM Web Host.

   **JNDI Port**: Enter the port number or accept the default value of 9001. The Java Naming and Directory Interface (JNDI) port is for Oracle BAM Report Cache, which is part of Oracle BAM Server.

   **Use HTTPS**: Select this option if you want to use HTTP with Secure Sockets Layer (HTTPS) to connect to the Oracle BAM Server during design time.

6. Click Next.

7. Click Test Connection to ensure that the connection is properly configured.

8. Click Finish.

### 56.3.2 How to Use Oracle BAM Adapter in a SOA Composite Application

Oracle BAM Adapter is a Java EE Connector Architecture (JCA) compliant adapter, which can be used from a Java EE client to send data and events to Oracle BAM Server. Oracle BAM Adapter supports the following operations on Oracle BAM data...
objects: inserts, updates, upserts, and deletes. Oracle BAM Adapter can perform these operations over Enterprise JavaBeans (EJB) calls or over Simple Object Access Protocol (SOAP), all configurable in JDeveloper.

The Oracle BAM Adapter supports batching of operations, but behavior with batching is different from behavior without batching. In general, the Oracle BAM sensor action is not part of the BPEL transaction. When batching is enabled, BPEL does not wait for an Oracle BAM operation to complete. It is an asynchronous call.

When batching is disabled, BPEL waits for the Oracle BAM operation to complete before proceeding with the BPEL process, but it will not roll back or stop when there is an exception from Oracle BAM. The Oracle BAM sensor action logs messages to the same sensor action logger as BPEL.

Oracle BAM Adapter provides three mechanisms by which you can send data to Oracle BAM Server in your SOA composite application as you develop it in JDeveloper.

- Oracle BAM Adapter can be used as a reference binding component in a SOA composite application. For example, Oracle Mediator can send data to Oracle BAM using Oracle BAM Adapter.
- Oracle BAM Adapter can also be used as a partner link in a BPEL process to send data to Oracle BAM as a step in the process.
- Oracle BAM sensor actions can be included within a BPEL process to publish event-based data to Oracle BAM data objects.

For more information about using Oracle BAM Adapter in a SOA composite application, see the "Integrating Oracle BAM with SOA Composite Applications" chapter in the Developing SOA Applications with Oracle SOA Suite.

### 56.3.3 How to Integrate Sensors With Oracle BAM

You can create sensor actions in Oracle BPEL Process Manager to publish sensor data as data objects on Oracle BAM Server. When you create the sensor action, you can select an Oracle BPEL Process Manager variable sensor or activity sensor that you want to get the data from, and also the data object in Oracle BAM Server in which you want to publish the sensor data.

For more information about integrating sensors with Oracle BAM, see the "Integrating Oracle BAM with SOA Composite Applications" chapter in the Developing SOA Applications with Oracle SOA Suite.
This chapter describes how to define a profile, which is a set of changeable options that affect the way your application looks and behaves. Profiles control how Oracle Fusion Applications operate for users by the values that are set. Profiles can be set at different levels depending on how the profiles are defined.

This chapter includes the following sections:

- Introduction to Profiles
- About Integrating Profiles Task Flows into
- About Setting and Accessing Profile Values
- About Managing Profile Definitions
- About Managing Profile Categories

### 57.1 Introduction to Profiles

Profiles are permanent user preferences and system configuration options. They allow for the centralized management of configuration data but with sophisticated, customized user, security, and session-context access to the values. The Profile Service application programming interface (API) provides the access to profile values.

Hierarchies enable system administrators to group and set profiles according to their business needs. The hierarchy is fixed in the profile definition, you cannot just randomly mix and match the levels. For more information about profile levels, see About Managing Profile Definitions.

Users may be able to set their own profile options, depending on settings in the profile definition. However, not all profiles are visible to end-users, and some profiles, while visible, may not be updated by end-users.

Categories can be used to group profiles based on their functional area. Administrators can categorize profiles and then easily search on profiles by category.

**When to define a profile:**

- Evaluate if there is a genuine need for an option before creating a profile. Do not force the customer to make a decision about an issue that is of no concern to them.
- Look for duplicate or similar profiles, even in other products, before creating a new one. For example, you do not need multiple profiles to choose a preferred currency.
- Do not use profiles to cache temporary session attributes. Profiles are permanent user preferences and system configuration options.
Every Oracle application registers task flows with a product called Oracle Fusion Functional Setup Manager. Functional Setup Manager provides a single, unified user interface that allows customers and implementers to configure all Oracle applications by defining custom configuration templates or tasks based on their business needs.

The Functional Setup Manager user interface (UI) enables customers and implementers to select the business processes or products that they want to implement.

Function Security controls your privileges to a specific task flow, and users who do not have the required privilege cannot view the task flow. For more information about how to implement function security privileges and roles, see Implementing Function Security.

For information about implementing your specific product family, do the following:

1. Access the Oracle Fusion Applications library.

2. See the Implementing Common Features guides for your product family.

Table 57-1 lists the task flows related to profiles and their parameters.

Table 57-1 Profiles Task Flows and Parameters

### 57.3 About Setting and Accessing Profile Values

You can set profile values using the Setup UI, and access them programmatically or by using expression language.

### 57.3.1 How to View and Set Profile Values Using the Setup UI

You can use the Profile Option Values page to view the profile values. The page is shown in Figure 57-1.
Note:

- Any change you make to a profile option has an immediate effect on the way your applications run for that session. And, when you log on again, changes you made to your User-level options in a previous session are still in force.
- When a profile value is changed, the user setting the value will always see the update immediately. Other users may not see the changed value until logging out and back in.

To view or edit profile values, do the following:

1. Go to the Manage Profile Option Values page to search for the required profile option.

   **Figure 57-1  Manage Profile Option Values Page**

2. Enter your search criteria, then click **Search**.

   **Note:**
   You can also select **Reset** to clear your entries and start again, or **Save** to save the entries for a future search.

3. In the **Search Results: Profile Options** section, highlight the required profile option.

4. In the **Profile Values** section, add a new value or delete an existing one.
Create a new row for every value set for this profile for every level/level value pair. The Profile Value is the value that has been defined in the profile definition’s SQL Validation.

57.3.2 About Accessing Profile Values Programmatically

The ProfileServiceAM API can be found in the following package:

oracle.apps.fnd.applcore.profiles.profileService.applicationModule

Before you can use this profile, you must add the Applications Core library to your Model project. For more information, see Adding Necessary Libraries to Your Data Model Project.

Import the Profile class and call the Profile.get() method to get the values for the profile name provided.

For example:

```java
import oracle.apps.fnd.applcore.Profile;
...
fnfDiagnostics = Profile.get("AFLOG_ENABLED");
```

57.3.3 About Accessing Profile Values Using Expression Language

Accessing a profile value using expression language (EL) simply requires defining the oracle.apps.fnd.applcore.Profile managed bean with the name Profile in the adfc-config.xml file at requestScope. See Figure 57-2.

![Edit adfc-config.xml File](image)

After the bean is defined, you can refer to any profile value as:

```java
# {Profile.values.PROFILE_OPTION_NAME}
```

57.4 About Managing Profile Definitions

You can update profile definitions using either Functional Setup, or a standalone "super-web" type UI Shell page that embeds calls to the task flow directly in the menu.

When defining profile definitions you also define profile levels, which are part of a hierarchy. When working with profile levels, carefully consider the levels you enable for your profiles. Only enable them at the levels that make sense. You do not want end-users changing settings for profiles that they do not understand. Currently, only the following hierarchy is available:

- Site (lowest level)
- Product
• User (highest level)

As most profiles are user preferences and can potentially be set at these three levels, this is the default hierarchy. Profiles can be set at one or more levels.

---

**Note:**

A higher-level profile value overrides a lower-level value.

---

**Table 57-2** describes how profile settings are used:

<table>
<thead>
<tr>
<th>Hierarchy</th>
<th>Level</th>
<th>Profile Setting</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 (Lowest)</td>
<td>Site</td>
<td>All users at an installation site.</td>
</tr>
<tr>
<td>2</td>
<td>Product</td>
<td>This level is intended to be the product owning the current code module. The product level is only available if it has been set on the session. Typically this is in a servlet filter, but it may be in other places in other technologies.</td>
</tr>
<tr>
<td>3 (Highest)</td>
<td>User</td>
<td>An individual user, identified by their UserID (UserGUID) for the current session.</td>
</tr>
</tbody>
</table>

When a profile is set at more than one level, Site has the lowest priority, superseded by Product, with User having the highest priority. A value entered at the Site level may be overridden by values entered at any other level. A value entered at the User level has the highest priority and overrides values at any other level.

For example, assume the Printer profile is set only at the Site and Product levels. When a user logs on, the Printer profile assumes the value set at the Product level, since it is the highest-level setting for the profile.

---

**Tips:**

- System administrators should set site-level profile values before specifying values at any other level.

- The profile values specified at the site-level work as defaults until profile values are specified at the other levels. Profiles are enterprise-striped. In a multi-tenant environment, VPD policies restrict the profile values to only those defined in the relevant enterprise. Consequently, in a multi-tenant environment, a site-level profile value behaves like an enterprise-level profile value.

---

### 57.4.1 How to Edit Profile Definitions

You can use the Profile editor to update profile definitions. **Figure 57-3** shows the Manage Profiles Options page.

To edit profile definitions, do the following:

1. Go to the Manage Profiles Options page to search for the profile that you want to update.
2. In the **Search Results: Profile Options** section, highlight a profile option and do any of the following:
   - Use the **Actions** or **View** options
   - **Create** a new profile option
   - **Edit** an existing profile option. The Edit window is shown in **Figure 57-4**.

![Manage Profiles Options Page](image)

![Edit Profile Option](image)

3. In the **Search Results: Profile Option Levels** section, do any of the following:
   - **Delete** an existing profile option
   - **Detach** a profile option to open it in a new window
• Create a new profile level

• Enable or disable user access to this profile:
  
  – **Enabled**: Select this option to allow user access.
  
  – **Updateable**: Select this option to give the user update privileges. Leave unselected if you want the user to have read-only access. This option is disabled unless the **Enabled** option is selected.

  Enabling the profile for end-user access allows the user to set their own values.

  **Note:**
  
The **Enabled** and **Updateable** check boxes determine whether you can read or write (respectively) values at that level.

• Delete an existing profile level

  **Note:**
  
Deleting a Profile Option level (or never creating one) is effectively the same as disabling it.

• Detach the profile levels child table to open it in a new window

### 57.4.2 About Registering a New Profile Option

When registering a new profile option for a profile definition, one of the key properties is the SQL validation property. If the values for a profile option are limited to a discrete list from which to choose, the SQL validation property must be set.

• It must be a valid SQL statement that selects two columns.

• The first column should be the display value that the administrator will see in the Manage Profile Option Values task flow. This column can be a translated value if appropriate for the particular profile option.

• The second column should be the code or ID that the product business logic will understand how to process. For example:

```
SELECT MEANING, LOOKUP_CODE
FROM FND_LOOKUPS
WHERE LOOKUP_TYPE = 'YES_NO'
```

### 57.5 About Managing Profile Categories

Grouping profiles into categories makes them easier to find because **Category** is the main driver when searching for profiles. Group profiles into categories that make sense, such as categories based on their functional areas. Categories can be used to search for related profiles in the Administration UIs and also for defining data security rules. You can use the Manage Profile Categories editor to add new categories or add profiles to an existing category.
The grouping is many to many, which means that profiles can be in more than one category and categories can have more than one profile. The basic guideline for grouping profiles is that profiles affecting the same feature, or profiles an Administrator would likely want to see at the same time, should all be in the same category. Oracle seeds a number of categories out of the box; customers are free to create their own or edit those that are shipped.

57.5.1 How to Manage Profile Categories

Like profile definitions, you can manage profile categories using either Functional Setup, or a standalone "super-web" type UI Shell page that embeds calls to the task flow directly in the menu.

To manage profile categories, do the following:

1. Go to the Manage Profile Categories page and search for the required profile category, as shown in Figure 57-5.

**Figure 57-5 Manage Profile Categories Page**

2. In the **Search Results: Profile Categories** section, highlight the required profile category and do any of the following:
   - Use the **Actions** or **View** options
   - **Create** a new profile category
   - **Edit** an existing profile category. The Edit window is shown in Figure 57-6.
Figure 57-6  Edit Profile Category

- Delete an existing profile category
- Detach a profile category to open it in a new window

3. In the Search Results: Profile Options section, do any of the following:
   - Use the Actions or View options
   - Create a new profile option
   - Delete an existing profile category
   - Detach a profile category to open it in a new window
This chapter discusses the Seed Data Loader and using it from within Oracle JDeveloper.

This chapter includes the following sections:

- Introduction to the Seed Data Loader
- Using the Seed Data Loader in JDeveloper
- Translating Seed Data

58.1 Introduction to the Seed Data Loader

Application Seed Data is the essential data to enable Oracle Fusion applications. Some examples include static lists of values, functional or error messages and lookup values. Seed data is generally static in nature, although it is possible for customers to customize some seed data values after delivery. Any non-transactional data values loaded into a database at customer delivery time can be considered seed data.

Seed data is extracted from Oracle development databases at design time into external files. These files are delivered to the customer and uploaded to the customer’s database. Seed data can be delivered and installed at any point in the application lifecycle, such as for a new installation, a major or minor release upgrade, or a patch/change delivery.

Applications that manage seed data need to have a certain amount of knowledge about the seed data. This is so that data to be recreated on the target database is loaded to the correct tables, while preserving referential integrity. This seed data knowledge, or seed meta-data, also must be delivered in some form along with the extracted seed data files. This meta-data drives how the data is extracted and uploaded.

The Seed Data Utility, which runs only under JDeveloper, will provide data extraction from the development instances of Oracle Fusion applications. It will also load the extracted data to the customer database instances of Oracle Fusion applications, by integrating with Oracle Fusion Applications Patch Manager.

Note:

Each entity type, such as Profile and Messages, will have its own dedicated utility. See Table 58-1.
58.2 Using the Seed Data Loader in JDeveloper

The Seed Data Extract and Upload processes are run directly from the Seed Data-configured Oracle Application Development Framework (Oracle ADF) Business Components application modules. The Seed Data Configuration, Extract, and Upload processes are all run from within JDeveloper, the same development environment in which the Business Object components are defined.

58.2.1 Introduction to the Seed Data Framework

The Seed Data Framework is delivered as a plug-in extension to the JDeveloper environment. The Seed Data Framework is installed by default; there are no other installation or setup steps to perform to begin using the Seed Data Framework tasks. There are support libraries that need to be present in the Business Component project class path before running the Seed Data tasks. See How to Set Up the Seed Data Environment.

Available Seed Data Loaders

The loaders and view objects listed in Table 58-1 are supported.

Legend

- **Loader**: Location of a seed loader-enabled application module. Assume a prefix of oracle.apps.fnd.applcore.
- **VO**: Driving view object.
- **Is the Module Striped?**: Does this view object require a module argument?

<table>
<thead>
<tr>
<th>Loader</th>
<th>View Object</th>
<th>Is the Module Striped?</th>
</tr>
</thead>
<tbody>
<tr>
<td>attachments.attachmentLoader.applicationModule.attachmentsLoaderAM</td>
<td>FndDocumentEntitiesVL</td>
<td>N</td>
</tr>
<tr>
<td>attachments.attachmentLoader.applicationModule.attachmentsLoaderAM</td>
<td>FndDocumentCategoriesVL</td>
<td>Y</td>
</tr>
<tr>
<td>attachments.attachmentLoader.applicationModule.attachmentsLoaderAM</td>
<td>FndDocCategoriesToEntitiesVO</td>
<td>N</td>
</tr>
</tbody>
</table>

**Note**: Before running this loader, you need to run the first two loaders listed in this table that have the FndDocumentEntitiesVL and the FndDocumentCategoriesVL view objects.

<table>
<thead>
<tr>

58.2.2 How to Set Up the Seed Data Environment

To set up the Seed Data environment, follow these steps in JDeveloper before starting the Seed Data Framework tasks:

1. Start JDeveloper using the Oracle Fusion Applications Developer profile.
   Seed Data user interface tasks are run from within a JDeveloper Business Components project.

2. Create the ADF Business Components artifacts to represent the logical data model, including entity objects and view objects in the project. Create the relationships between the entity objects and view objects in accordance with the Applications Standards. Add the objects to an application module that will serve as the entry point for the Business Service Object. The application module also serves as the container for the Seed Data Framework Configuration meta-data.

3. Run the Seed Data Configuration wizard.
   The wizard is the graphical user interface tool used to configure Application Modules for Seed Data.
   To launch the Seed Data Configuration Wizard, right-click the application module name in the Application Navigator tree view, and select Seed Data > Configuration > Edit as shown in Figure 58-1.
Figure 58-1 Starting Seed Data Configuration

Note:

If the seed application module in use is derived from a subclass of OAApplicationModuleImpl, that subclass and its dependencies, if any, should be made available in compiled form using the Libraries/Classpath feature of JDeveloper. If this step is not done, extract and upload will fail.

The Seed Data Configuration wizard launches and displays the Driver Definition Panel.

This panel, shown in Figure 58-2, initially shows the available view objects in the root level of the application module data model that can serve as Driver view objects.

Figure 58-2 Seed Data Configuration Driver Panel

a. Select the Driver check box for those view objects to serve as the Driver for Seed Data Extract. More than one Driver can exist within an application module; however, only one Driver can be specified at Extract time.
b. Select the **Configure** radio button for the Driver view object to configure it during this session. Only one driver view object can be configured during a single editing session.

4. Click **Container Panel**.

The Container Panel, as shown in **Figure 58-3**, shows the contained and reference relationships of the Driver view object. Also shown are the underlying table names that will be extracted from and updated to during the Extract and Upload processes.

**Figure 58-3 Seed Data Configuration Container Panel**

![Seed Data Configuration Container Panel](image)

**View object relationships**: The tree displays the model of the Seed Data Configuration. Relationships between the view objects are displayed. The relationship is either contained or just a reference. View links between the view objects that are based on Associations marked explicitly as Composition Association are shown as contained. Seed Data operations will be performed for all the view objects that are identified as contained.

Foreign key relationships are called reference relationships. They are identified by the existence of a view link between view objects backed by non-composite entity associations, or no entity associations at all, or a join between two entity objects (the referred entity object is marked as **Reference** in the View Definition) and a List of Values on the **name** field.

**Tables Information**: The list shows the tables that are updated during Seed Data upload. A non-editable list of tables is generated based on the declared data model indicated by a Source column value of **Model**. The Type column indicates whether the table is just Referenced or Updated. These tables and the explicitly added tables with Type **Updated** will be frozen for (near) Zero-Downtime patching.

**Table Freeze** involves making the table in the Production edition read-only and creating a replacement table in the **Patch** edition. The list of seed tables that will be inserted, updated or referenced during seed data upload is provided as metadata to the patching utility. This is auto-generated by the Configuration...
wizard by inspecting the underlying entity objects and base tables for a given
driver view object.

If the entity objects of the configuration are not ADF Business Components-based,
or custom insert or updates exist (such as through PL/SQL code), the seed data
framework will not be able to accurately determine the set of tables participating
in the seed data upload. In such cases, the seed data framework will not be able to
accurately determine the set of tables to be frozen. The owner of the seed
application module must declare the additional tables in the container panel.
Failure to review and declare tables (such as by specifying a list that is incorrect or
incomplete) that are participating in seed data upload is likely to cause data
invalidation or corruption, as some tables will not be frozen and the Production
Instance will directly be aware of seed data upload changes that should be limited
to Patch Instance. Patch rollback also could leave orphan records in these cases.

Use the Add and Remove buttons to add or remove additional tables that are
affected from the list. The list of updated tables is for information only. This
information is used during patch application.

**Table Name**: This column shows the name of the table that is affected during seed
data upload.

**View Name**: This column shows the name of the ADF Business Components view
object where this table is declared. This column can also contain the name of the
Java class or PL/SQL procedure which would be used for seed data upload.

**Source**: Shows the source of this definition. The value of M is reserved to indicate
that the Table Name is derived from the ADF Business Components Model. You
can create your own definitions for additional table entries.

**Type**: This column shows the update type of the definition. A value of Updated
indicates that the definition table will be Updated at Seed Data Upload time. A
value of Referenced indicates that this is a Referenced table only, and will not be
updated by Seed Data Upload.

Click the **Surrogate Panel**.

Use the Surrogate Panel, shown in **Figure 58-4**, to declare surrogate attributes of
the view objects of the Seed Data Configuration.
The tree displays the model of the Seed Data Configuration. View objects can be selected in the tree to declare a surrogate attribute of the selected view object.

**Note:**

If you have an entity object with a Surrogate ID that is involved in a parent-child relationship, but you are not able to view or select that Surrogate ID on the Surrogate panel, check the data model and confirm that you have checked the composition check box for that association. See the "Creating and Configuring Associations" section of the *Developing Fusion Web Applications with Oracle Application Development Framework*.

**Surrogate Attribute – Available:** The left panel lists the attributes of the selected view object that can possibly be a surrogate attribute. The list will include primary key (PK) attributes that are of data type numeric.

**Surrogate Attribute:** The list on the right contains the attribute of the view object that has been identified as a Surrogate Attribute.

**Alternate Key:** Select the Alternate Key that will be used as the unique row identifier for the selected view object. The Alternate Key choice is based on the Alternate Keys available on the entity object of the selected view object. If the Primary Key has many attributes and one of them is being marked as a surrogate, all the other attributes in the Primary Key, except the one being marked as surrogate, must be included in the alternate key for that alternate key to be displayed in the list.

For Date Effective models, the above rule has been relaxed so that Effective Start Date, Effective End Date, Date Effective Sequence and Date Effective Flag are not required to be in the alternate key, even if they happen to be in the Primary Key to appear in the list.

To declare an attribute as a Surrogate Attribute:
a. Select the view object that contains the surrogate attribute. The left bottom panel will show the list of attributes that are potential surrogate attributes.

b. Select the Surrogate Attribute and click the shuttle button.

Click **Reference Panel**.

Use the Reference Panel, shown in Figure 58-5, to declare the Data Upload Mode for the Seed Data Configuration. Provide reference information on reference view objects.

**Figure 58-5  Seed Data Configuration Reference Panel**

The tree displays the model of the Seed Data Configuration. Reference view objects can be selected in the tree to declare information about the Seed Data Configuration of the referred view object. *All the external references must be specified for the patch to succeed.*

a. In the tree view, select the reference view object. The bottom left panel will contain a list of available application modules.

b. Select the application module that contains the Seed Data Configuration information for the reference view object.

c. Add a reference in the current application module to this application module by clicking the shuttle button.

**Note:**

If there are any Service Foreign Key LOVs defined in your model, review the different scenarios in Table 58-2 and verify that the steps listed for the scenario corresponding to your FK LOV are followed. Failure to follow the instructions in the document can cause problems during Seed Data Extract and Upload processes.
Table 58-2 Service Foreign Key LOV Scenarios

<table>
<thead>
<tr>
<th>Scenario</th>
<th>What must be done</th>
</tr>
</thead>
<tbody>
<tr>
<td>#1: Single attribute Foreign Key and single attribute Alternate Key (Example: PersonVO has Deptno and Dname. Deptno is the foreign key ID, and Dname is the foreign alternate key.)</td>
<td>An LOV should be defined on the alternate key attribute, with the foreign key ID as a derived attribute.</td>
</tr>
</tbody>
</table>

1. Create PersonVO based on EmpEO and a reference DeptEO. The foreign alternate key (Dname) from the reference entity object is included in the EmpVO.
2. Define the LOV view object (DeptVVO).
3. Define a view accessor on EmpEO/PersonVO pointing to DeptVVO.
4. Define an LOV on the foreign alternate key (Dname) using the above view accessor, and configure the LOV to populate the foreign key id (Deptno) as the derived attribute.
5. Manually edit the VO.xml and add LBThrowOnMisMatch="true", such as:

```xml
<VObject xmlns="http://xmlns.oracle.com/bc4j" Name="SdLovrefReferringVO" Version="11.1.1.53.68" SelectList="SdLovrefReferringEO.ID, SdLovrefReferringEO.REFERRING_DATA, SdLovrefReferedEO.REFERRED_ALTATTR_2, SdLovrefReferedEO.REFERRED_ALTATTR_1, SdLovrefReferedEO.REFERRED_ID, SdLovrefReferringEO.REFERENCE_ID" FromList="SD_LOVREF_REFERRING SdLovrefReferringEO, SD_LOVREF_REFERRED SdLovrefReferedEO" BindingStyle="OracleName" CustomQuery="false" RowClass="oracle.apps.fnd.applcore.oaext.model.OAViewRowImp" ComponentClass="oracle.apps.fnd.applcore.oaext.model.OAViewObjectImp" PageIterMode="Full" LBThrowOnMisMatch="true" UseGlueCode="false" Where="SdLovrefReferringEO.REFERENCE_ID = SdLovrefReferedEO.REFERRED_ID(+)>

Using the Seed Data Loader in JDeveloper
### Table 58-2  (Cont.) Service Foreign Key LOV Scenarios

<table>
<thead>
<tr>
<th>Scenario</th>
<th>What must be done</th>
</tr>
</thead>
<tbody>
<tr>
<td>#3: Single attribute Foreign Key and multiple attribute Alternate Key and one of the alternate key attributes is another foreign key. (Example: PersonVO has BirthOfCountry as foreign key ID, and BirthOfCity as another foreign key ID. BirthOfCity has BirthOfCountry+CityName as a composite alternate key.)</td>
<td>The first foreign key (BirthOfCountry) must be resolved first, either based on Scenario #1 or #2. Then the second alternate key should filter by the first alternate key.</td>
</tr>
<tr>
<td></td>
<td>1. Define an LOV view object based on CountryEO.</td>
</tr>
<tr>
<td></td>
<td>2. Define an LOV view object based on CityEO. Define a view criteria to filter by CountryId.</td>
</tr>
<tr>
<td></td>
<td>3. Define a view accessor on EmpEO/PersonVO pointing to CountryVVO.</td>
</tr>
<tr>
<td></td>
<td>4. Define a view accessor on EmpEO/PersonVO pointing to CityVVO, and bind CountryId to BirthOfCountry.</td>
</tr>
<tr>
<td></td>
<td>5. Define an LOV on CountryName using CountryVVO view accessor, with BirthOfCountry as a derived attribute from CountryId from CountryVVO.</td>
</tr>
<tr>
<td></td>
<td>6. Define an LOV on CityName using CityVVO view accessor, with BirthOfCity as a derived attribute from CityId from CityVVO.</td>
</tr>
<tr>
<td></td>
<td>7. Manually edit the VO.xml and add LBThrowOnMisMatch=&quot;true&quot;</td>
</tr>
<tr>
<td>#4: Composite foreign key</td>
<td>Each foreign key ID will be dealt with individually. For example, the foreign key id is OrgId+SourceId, then orgId and SourceId should be resolved based on solution in #1 or #2 or #3 separately. Then a validator must be defined to make sure combination of OrgId and SourceId is valid. This has the assumption that each individual attribute are a primary key itself.</td>
</tr>
</tbody>
</table>
Note:

A UI-only LOV can be defined without a derived attribute. The Seed Data Framework normally would ignore such an LOV and no external reference metadata would be generated for it.

In some cases, it might be desirable to let the Seed Data Framework treat such an LOV as a regular LOV with derived attributes. To do this, you need a "fake" derived attribute defined on the LOV.

For example:

\[ \text{LinesStatusEO(LineStatusId, StatusCode)} \]
\[ \text{StatusEO(StatusCode)} \]

1. Create a join between LineStatusEO and StatusEO in LineStatusVO.
2. Mark StatusEO as Reference.
3. Include the StatusCode attribute from StatusEO into LineStatusVO.
   
   Note: The attribute would be named StatusCode1, since StatusCode from LineStatusEO is already a part of LineStatusVO.
4. Define the LOV on StatusCode with the derived attribute as StatusCode1.

58.2.3 How to Use the Seed Data Extract Manager

Use the Seed Data Extract Manager tool to extract seed data from the pre-configured application modules. The generated extract files are partitioned by the module owner. Data can be filtered during extract time to limit the number of data files generated.

Note:

If you change the name of a seed data file after Extract, you also must manually update any references to that file name. Otherwise, proper ordering for Upload during patching run time for the files will not work as expected. So long as the physical file names and the names in task references match, the patching utilities will sequence the seed data tasks correctly.

The Seed Data Extract is driven off the Driver view object, as defined in the application module Configuration. This Driver view object serves as the root of the extract, and any contained child objects are extracted as containing data. Only one Driver view object is active during the Extract process.

There are two methods of starting a Seed Data Extract process:

- From JDeveloper using the Seed Data Framework Console
- By using an external Command Line Interface, as shown in Using the Extract Seed Data Command Line Interface

**To launch the Seed Data Framework Console from JDeveloper:**

The Seed Data Console is the graphical user interface (GUI) tool used to run both Extract and Upload Seed Data tasks. The Console also can be used to view the underlying table data for the view objects of the application module data model.
Right-click the application module name in the Application Navigator tree view and select **Seed Data > Extract** to launch the Seed Data Framework Console, as shown in **Figure 58-6**.

**Figure 58-6 Launching the Seed Data Console**

If there are multiple database connections in the workspace, the Seed Data Console – Select Database dialog, shown in **Figure 58-7**, displays.

Although this is not the normal case, if you need to debug data on two different databases, this lets you choose which one to use.

**Figure 58-7 Select Seed Data Database**

Select from the list of database connections available to the project. The default selected database is the default connection set on the Project Properties, under Business Components.

Click **OK** to launch the Seed Data Console with the selected connection information.

The Seed Data Console main page, as shown in **Figure 58-8**, displays.
The tree view shows the selected application module name as the root node, and each of the configured Driver view objects as child nodes under the root. Only Driver view objects as configured by the Seed Data Configuration wizard will show in this view.

The right side of Console is the output area, where processing messages of Seed Data tasks are displayed.

Note:

The Seed Data Console does not specify the last applied version of the seed data file. Consequently, users always will see a warning message indicating incremental uploads have been turned off. This is harmless and can be ignored.

In the log, the warning will appear similar to:

```plaintext
[WARNING] 14:38:58 : -cfver parameter not passed, incremental uploads turned off
```

### 58.2.4 How to Use Seed Data Extract Processing

To start a Seed Data Extract operation, right-click the Driver view object from which you want to extract and select **Extract Seed Data** from the context menu, as shown in Figure 58-9.

The Select Extract Path dialog, shown in Figure 58-10, displays.
58.2.4.1 Understand Extract Taxonomy Partition Selection Dialogs

Seed Data Extract uses selection dialogs for Taxonomy partitions. The information here covers the functional design and the various dialogs and partitions you will encounter.

**Functional Design**

When starting the Extract process, if a Taxonomy Partition Attribute is found in the Driver view object, Extract will show the Taxonomy Partition selection dialogs. See "Determining the Taxonomy Partitioning Attribute" for steps taken by Extract to find the Taxonomy partition attribute, if any.

**Taxonomy Products Dialog**

The Select Application Taxonomy Product Modules, as shown in Figure 58-11, will display a fixed list of all the Taxonomy products enabled for use with the Seed Data Framework. If the list of products for which seed data extract needs to happen is known beforehand, users can pick them from the list of available products. Optionally, click Filter to filter the list of products to show only those products and Logical Business Area (LBA) modules for which records exist in the selected view object. Occasionally, when there are a large number of records involved, the it might take a while to filter the list of products.
If any Products or LBAs are selected that are not actually available in the view object, no attempt is made to extract for that partition. This is done by applying implicit Partition criteria, binding for each selected partition, and verifying at least one row exists for the Partition row set before attempting to extract.

For internal development test cases and debugging for Extract, you will need to know which partitions are available. To do so, you have to select the ModuleIds from the driver and discover which Product that ModuleId equates to from the Taxonomy table. If the driver view object moduleId is an LBA, you also will need to know under which Product that LBA falls; this involves selecting from the Taxonomy hierarchy table.

An alternate method is to just select all the Products and all the LBAs when prompted by the dialog. Then extract files are created for only those modules that actually exist. This will be a little slower, since building the complete LBA list from all Products can take a few seconds or longer. Then each selected partition is bound to determine the availability. This will not be the typical Applications use case, as developers will know which Products to select. It is necessary in a development case in which the Products are not known.

**LBA Taxonomy Partitions**

After selecting the Products, the second dialog, Select Application Taxonomy LBA Modules, may or may not be shown. If the selected Products were parents of explicitly available seed-enabled LBA modules, all the available LBAs for the selected Products are shown. Again, only LBA module types found in the driver view object rows, and set as Seed Enabled in the Taxonomy Service, are shown in the list.

If the selected Products were not parents, or there are no LBAs available, no LBA selection dialog is shown, and Extract is started for all the selected Products.

For the LBA selection dialog, the full LBA taxonomy path is shown, showing any parents of subLBAs, and the parent Product short name. Again, the user selects the desired LBA values by shuttling values to Selected.

**Figure 58-12** shows the Select LBA Taxonomy Partitions dialog showing all the available LBAs found for the previously selected Receivables (AR), Payments (IBY), and Human Resources (PER) Products.
Extract Processing

After selecting LBAs, Extract proceeds to extract selected LBAs and selected base (non-parent) Product types, if any. Each Product and LBA type name value corresponds to a unique Extract file. Each Extract file will contain all rows containing the Taxonomy Partition Attribute (ModuleId or ApplicationId) value corresponding to each selected type.

Extract files are placed in folders according to the taxonomy path, starting at the Product short name, and including any LBAs and subLBAs as subdirectories. All the Extract file names follow the same pattern: <driver view object name>SD.xml.

Figure 58-13 shows a sample output selecting the three Receivable (AR) LBAs, creditCardErrors, customerProfileClasses, and miscellaneousReceipts, and General Ledger (AR) and Opportunity Management (MOO) Applications. The applications, AR and MOO, were explicitly defined in the entity, and contained no child LBAs.

Determining the Taxonomy Partitioning Attribute

The Taxonomy Partition Attribute on the Seed Driver view object is determined in the following manner, in order of precedence:

1. Attribute serving as ViewLink to ApplTaxonomySeedDataPVO ModuleId or AlternativeId attributes, or ApplicationPVO ApplicationId attribute.

2. Attribute serving as LOV to ApplTaxonomySeedDataPVO UserModuleName or AlternativeName attributes.
3. Hard-coded ModuleId attribute

4. Hard-coded ApplicationId attribute

Single File Implicit Partitioning

If no driver view object attributes pass above, single file implicit partitioning will be used and all rows will be extracted to a single extract file. In this case, no taxonomy partitioning dialogs will be shown.

The taxonomy owner for the corresponding file path is determined from the ApplicationModule package name.

For example, extracting from `oracle.apps.fnd.lookups.service.FndLookupsAM` will create the extract file in the FND folder under the user-specified extract root path.

Extract Manager Support for Seed Data File Dependencies

The Extract function adds metadata of the file on which the current file is dependent.

For example, the metadata shown in Example 58-1 would be added using adxml comments for the case where the current file is dependent on it.

Example 58-1 Sample Metadata Using ADXML Comments

```xml
<!-- <run_after_tasks> -->
<!-- adxml: <task_reference te="CZ" subdir="CZ"
file_basename="ReferredSD.xml" identifier="UPLOAD"/> -->
<!-- adxml: </run_after_tasks> -->
```

adxml are the comments added to the extract file at the beginning of the file. They are the same as normal xml comments except they have `adxml:` prepended to the commented text.

Extract gathers this information by using the Reference view object from Reference application module. Reference application module is configured by the user in the Reference panel of Seed Data Configuration. See Figure 58-5.

This information is used by the Patching Utility to create the order in which the files need to be uploaded so that the Reference data is available before the Referring data is loaded.

Static File Dependencies

For the cases where dynamically finding the file dependencies is not possible, or dynamic dependencies are not complete, you can set static file dependencies using an application module custom property for a view object instance, as shown in Table 58-3.

All files extracted from that view object would have the dependencies stamped in adxml comments.
Table 58-3  Application Module Custom Property for a View Object Instance

</table>

Turning Off Dynamic File Dependency Generation

You can turn off the dynamic file dependency generation by defining the custom property shown in Table 58-4 on the application module.

Table 58-4  Property to Turn Off Dynamic File Dependency

<table>
<thead>
<tr>
<th>Application Module Custom Property Name</th>
<th>Value</th>
<th>Example</th>
</tr>
</thead>
</table>
| SD_NO_DYNAMIC_EXT_REFS_<view object instance name> | true  | Property: SD_NO_DYNAMIC_EXT_REFS_FndObjects
|                                          |       | Value: true |

Output Log Level

The Log Level for the Seed Data tasks is used to increase or decrease the amount and type of log messages generated during processing. The default Log Level is set to INFO. This will display generated severe errors, warnings, and informational processing messages. To limit the number of log messages generated, set the log level higher, to Severe or Warning. To see more processing messages generated for debugging purposes, set the Log Level to a lower level. Set the Log Level to FINEST to see the most processing messages generated. These messages will generally only be useful to developers.

58.2.4.2 Using the Extract Seed Data Command Line Interface

The Seed Data Extract process also can be initiated externally from JDeveloper using the Command Line Interface (CLI). Seed Data Extract command line parameters can be passed using one of two methods:

- Directly on the Java command line
- By using a command property file that is singularly passed on the command line
Extract Seed Data Java Command Line Syntax

If you are using a Linux operating system, use these commands:

```java
java -cp $jdev_install/jdeveloper/jdev/oaext/lib/oracle.apps.fnd.applseed-rt.jar:
$jdev_install/oracle_common/modules/oracle.odi_11.1.1/ojdl.jar
oracle.apps.fnd.applseed.rt.extract.Extract
   -dburl <database connect url string without username and password>
   -dbuser <database user>
   -AM <fully qualified path to seed configured AM>
   -VO <seed Driver view object instance name>
   -dburl <database connect URL string without username and password>
   -dbuser <database user>
   -AM <fully qualified path to seed configured AM>
   -VO <seed Driver view object instance name>

[-ExtractRootPath <output path location>]
[-PartitionKeyIds <Taxonomy ModuleId values> | -PartitionKeyNames <Taxonomy short name values>]
[-PartitionKeyIds <partition key id values>]
[-PartitionKeyNames <partition key names>]
[-log <Used to give the log Level (SEVERE to FINEST)>]
[-loglevel <Used to give the location of the log file>]
[-entid <enterprise id>]
```

If you are using a Windows operating system, use these commands:

```java
java -cp %jdev_install%\jdeveloper\jdev\oaext\lib\oracle.apps.fnd.applseed-rt.jar;
%jdev_install%\oracle_common\modules\oracle.odi_11.1.1\ojdl.jar
oracle.apps.fnd.applseed.rt.extract.Extract
   -dburl <database connect url string without username and password>
   -dbuser <database user>
   -AM <fully qualified path to seed configured AM>
   -VO <seed Driver view object instance name>
   -dburl <database connect URL string without username and password>
   -dbuser <database user>
   -AM <fully qualified path to seed configured AM>
   -VO <seed Driver view object instance name>

[-ExtractRootPath <output path location>]
[-PartitionKeyIds <Taxonomy ModuleId values> | -PartitionKeyNames <Taxonomy short name values>]
[-PartitionKeyIds <partition key id values>]
[-PartitionKeyNames <partition key names>]
[-log <Used to give the log Level (SEVERE to FINEST)>]
[-loglevel <Used to give the location of the log file>]
[-entid <enterprise id>]
```

Command Property File

The command property file is an external file that contains the command line properties in standard Java Properties format for each of the required and optional Extract command line properties. The format can be name=value, or name:value.

If you are using a Linux operating system, use this command:

```java
java -cp $jdev_install/jdeveloper/jdev/oaext/lib/oracle.apps.fnd.applseed-rt.jar:
$jdev_install/oracle_common/modules/oracle.odi_11.1.1/ojdl.jar
oracle.apps.fnd.applseed.rt.extract.Extract [command property file]
```

If you are using a Windows operating system, use this command:
java -cp "$jdev_install%/\jdeveloper\jdeveloper\oaext\lib\oracle.apps.fnd.appseed-rt.jar; $jdev_install%/oracle_common\modules\oracle.odi_11.1.1.1\ojdl.jar oracle.apps.fnd.appseed.rt.extract.Extract [command property file]

**Seed Data Extract Command Line Parameters**

The available Seed Data Extract parameters are listed in Table 58-5.

**Table 58-5  Available Seed Data Parameters**

<table>
<thead>
<tr>
<th>Property</th>
<th>Value</th>
<th>Required?</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>dburl</td>
<td>database connection URL in JDBC format without username and password</td>
<td>Yes</td>
<td>jdbc:oracle:thin:@fully_qualified_server_name:1991:database_name</td>
</tr>
<tr>
<td>dbuser</td>
<td>database user to be used for extract</td>
<td>Yes</td>
<td>fusion</td>
</tr>
<tr>
<td>AM</td>
<td>Application module name, fully package qualified</td>
<td>Yes</td>
<td>oracle.apps.fnd.applcore.flex.dff.descriptiveFlexfieldService.</td>
</tr>
<tr>
<td>V0</td>
<td>Driver ViewObject instance name</td>
<td>Yes</td>
<td>DescriptiveFlexfield</td>
</tr>
<tr>
<td>ExtractRootPath</td>
<td>Path to extract seed data files</td>
<td>No</td>
<td>/home/seed/data</td>
</tr>
<tr>
<td>PartitionKeyId</td>
<td>Comma delimited Taxonomy Id values to extract, either ModuleId or ApplicationId, depending on partition strategy.</td>
<td>No</td>
<td>Taxonomy Module Ids: 4F1F0DFC58F87DB4E04044981FC6 2F46, 47110F64AC8F08E2E040449823C60 DB6 Application Ids: 250, 667, 10047</td>
</tr>
<tr>
<td>PartitionKeyName</td>
<td>Comma delimited Taxonomy name values to extract, either Product codes, or LBA names, or combination thereof</td>
<td>No</td>
<td>FND, HCM, invoices, receivables, cashManagement</td>
</tr>
<tr>
<td>loglevel</td>
<td>The Log Level (SEVERE to FINEST).</td>
<td>No</td>
<td>-loglevel FINE</td>
</tr>
<tr>
<td>log</td>
<td>The location of the log file.</td>
<td>No</td>
<td>-log /home/seed/ex.log</td>
</tr>
<tr>
<td>Entid</td>
<td>Enterprise Id numeric value.</td>
<td>No</td>
<td>-entid 1</td>
</tr>
</tbody>
</table>

**Note:**

The database password would be prompted. To avoid prompting, pipe it on the command line. The password must be piped in when output is redirected. For example, to pipe a password from the $FUSION_PASS environment variable to the Extract command line:

```
java Extract cmdline... <<! $FUSION_PASS
```
**PartitionKey<Ids|Names> Properties**

The PartitionKey properties drive how the seed data extract derives the data file partitions, which is the number of files generated. Each partition key will equate to a single extracted seed file, with all the rows that are owned by that particular module being extracted to its seed file.

You can use either the PartitionKeyId or the PartitionKeyName property, or a combination of both, to supply to the extract each of the unique file partitions that will be created. If no PartitionKey properties are specified, the default behavior is to extract all file partitions found from the driver view object, and all rows extracted to each corresponding seed data file.

You should use one of the PartitionKey parameters to limit the amount of files generated. Otherwise, the expected partitions will need to be determined from executing the driver view object query and perform a complete table scan of all rows. For very large tables with many thousands of rows, this could be a potentially large performance hit, and, depending on the complexity of the view object query and its joins, could take several minutes to hours to determine.

**Property File Comments**

In the command property file, any lines beginning with a pound sign (#) will be considered comments, and not processed in any way by the Extract tool.

You also can comment out specific entries in the multi-value comma delimited properties. For example:

```
PartitionKeyName = FND, HCM, #FCM, GL, AM
```

This will ignore the FCM value entry, but keep others intact. A sample PartitionKeyName command line option is shown in Example 58-2.

**Example 58-3** shows the contents of the sample Seed Extract Command Property File, located at `/home/extract.properties`:

**Sample command line showing command line parameter to `/home/extract.properties` command property file.**

```
java -cp $jdev_install/jdeveloper/jdev/oaext/lib/oracle.apps.fnd.applseed-rt.jar:
$jdev_install/oracle_common/modules/oracle.odl_11.1.1/ojdl.jar
oracle.apps.fnd.applseed.rt.extract.Extract /home/extract.properties
```

If you are using a Windows operating system, follow this example:

```
#Sample extract property file, comment line
AM
=oracle.apps.fnd.applcore.flex.dff.descriptiveFlexfieldService.applicationModule.Desc
riptiveFlexfieldServiceAM
dburl = jdbc:oracle:thin:fusion/fusion@fully_qualified_server_name:1991:database_name
dbuser = fusion
VO = DescriptiveFlexfield
ExtractRootPath = C:\seed\data
PartitionKeyName = FND,HCM
```

**Sample command line showing command line parameter to C:\extract.properties command property file.**

```
java -cp %jdev_install%\jdeveloper\jdev\oaext\lib\oracle.apps.fnd.applseed-rt.jar;
%jdev_install%\oracle_common\modules\oracle.odl_11.1.1\ojdl.jar
oracle.apps.fnd.applseed.rt.extract.Extract C:\extract.properties
```
**Example 58-2 Sample Command Line**

If you are using a Linux operating system, follow this example:

```java
java -cp ${jdev_install}/jdeveloper/jdev/oaext/lib/oracle.apps.fnd.applseed-rt.jar:
  ${jdev_install}/oracle_common/modules/oracle.odl_11.1.1/ojdl.jar
oracle.apps.fnd.applseed.rt.extract.Extract
  -dburl jdbc:oracle:thin:@fully_qualified_server_name:1991:database_name
  -dbuser fusion
  -AM oracle.apps.fnd.applcore.flex.dff.descriptiveFlexfieldService.applicationModule.Descr
  -VO DescriptiveFlexfield
  -ExtractRootPath /home/seed/data
  -PartitionKeyNames HCM, invoices, cashManagement
  -loglevel FINER
```

If you are using a Windows operating system, follow this example:

```java
java -cp %jdev_install%\jdeveloper\jdev\oaext\lib\oracle.apps.fnd.applseed-rt.jar;
%jdev_install%\oracle_common\modules\oracle.odl_11.1.1\ojdl.jar
oracle.apps.fnd.applseed.rt.extract.Extract
  -dburl jdbc:oracle:thin:@fully_qualified_server_name:1991:database_name
  -dbuser fusion
  -AM oracle.apps.fnd.applcore.flex.dff.descriptiveFlexfieldService.applicationModule.Descr
  -VO DescriptiveFlexfield
  -ExtractRootPath C:\seed\data
  -PartitionKeyNames HCM, invoices, cashManagement
  -loglevel FINER
```

**Example 58-3 Sample Command Property File**

If you are using a Linux operating system, follow this example:

```properties
#Sample extract property file, comment line
AM = oracle.apps.fnd.applcore.flex.dff.descriptiveFlexfieldService.applicationModule.Descr
/dburl = jdbc:oracle:thin:fusion/fusion@fully_qualified_server_name:1991:database_name
/dbuser = fusion
/VO = DescriptiveFlexfield
/ExtractRootPath = /home/seed/data
/PartitionKeyNames = FND,HCM
```

**58.2.5 How to Use the Seed Data Upload Manager**

To launch the Seed Data Framework Console, refer to "To launch the Seed Data Framework Console from JDeveloper:" but select **Seed Data > Upload**.

When you right-click a Driver view object in the tree list, the menu shown in **Figure 58-14** displays so you can select the **Load Seed Data** option.
In addition to the Load Seed Data option, discussed in Uploading Seed Data, three other options are available:

**Set Log Level**

Set how much information you want written to the log file. The least amount of information will be if this is set to Severe, and the largest amount of information will be if this is set to Finest. The default setting is Info, which will log Information, Warning and Severe messages.

**Clean Mode**

The default setting is Disabled. If Clean Mode is Enabled, it basically deletes all the existing records before proceeding to upload the given file. This option is exposed both through the command line interface for upload (-clean) and here.

---

**Caution:**

*This option should be used extremely carefully as it might lead to irreversible data loss.*

---

**Customization Mode**

The default setting is Do Not Preserve.

Seed Data Loader always sets the last_updated_by and created_by to zero when it inserts new records, and it always sets the last_updated_by to zero when it updates existing records.

Customers who have customized some of the Seed Data records are expected to set last_updated_by to a non-zero value.

*By default when using the Seed Data Console, customizations are not preserved. They are overwritten.*

However, on the command line, which is primarily intended for use at the customer site and for automated uploads, customizations are preserved by default. To override this, use the -nocust option.

### 58.2.5.1 Upload Seed Data

To upload Seed Data, right-click the desired Driver view object from the Console view object tree list. Select Load Seed Data.
**Note:**

When you upload files, if the row already exists in the database and if it has been customized (last_updated_by <> 0), a "Skipped" message will be placed in the log and the row will not be updated. To correct this, change last_updated_by to 0 in both the database and the file before uploading.

The Select a file to load dialog, shown in Figure 58-15, displays.

**Figure 58-15 Selecting a File to Load**

![Select a file to load dialog](image)

Select either an XML file or its corresponding translation xmliff file to initiate a National Language Support (NLS) upload.

Click **OK** to begin the Upload process on the selected file.

**Upload Output**

When the Seed Data upload finishes, the processing messages are shown in the output tabbed view window, in the tab corresponding to the view object against which the upload was run. See Figure 58-16.
You may see warning messages about columns being not updateable. Review these messages to determine if you can ignore them for your specific case.

58.2.5.1.1 How to Upload Seed Data Using the Command Line Interface

The Seed Data Upload process can be initiated externally from JDeveloper using the Command Line Interface (CLI).

To run the command line version of the Seed Data Loader from within an ADE view, ensure the JDEV_HOME environment variable, shown in Table 58-6, is set to a valid JDeveloper installation directory. Include the jdeveloper sub folder if you are using JDeveloper integrated with WebLogic Server.

### Table 58-6 Environment Variables for the Seed Data Upload CLI

<table>
<thead>
<tr>
<th>Variable name</th>
<th>Required?</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>JDEV_HOME</td>
<td>No</td>
<td>Should point to the full path to the JDeveloper installation.</td>
</tr>
<tr>
<td>APPLSEED_CLASS_PATH</td>
<td>No</td>
<td>Used to add additional classpath entries to the loader (in addition to the regular CLASSPATH setting which might not be modifiable in certain circumstances). This parameter is expected to include folders where Apps EAR archives are available in an exploded format (typically the product family level deploy folders). If the same ADF library is available from multiple locations, only one will be added to the classpath.</td>
</tr>
</tbody>
</table>
Table 58-6 (Cont.) Environment Variables for the Seed Data Upload CLI

<table>
<thead>
<tr>
<th>Variable name</th>
<th>Required?</th>
<th>Purpose</th>
</tr>
</thead>
</table>
| APPLSEED_TS_CLASSPATH | No        | Used to add additional classpath entries to the loader (in addition to the regular CLASSPATH setting which might not be modifiable in certain circumstances). This parameter is expected to include folders where techstack libraries are made available. On a provisioned system, it should include at least these directories:  
  fmw1/atgpf/atgpf/modules/  
  oracle.applcore.model_11.1.1  
  fmw1/oracle_common/modules  
  fmw1/atgpf/modules  
  Note: The primary difference between APPLSEED_CLASSPATH and APPLSEED_TS_CLASSPATH is that the JAR files coming from APPLSEED_CLASSPATH are put through a unique filter that filters unique JAR files by file name. This is possible because ADF libraries follow a naming convention. However, there is no common naming convention across techstack libraries (there could be a util.jar from JDBC and another from the XML parser). Therefore, the JAR files coming from APPLSEED_TS_CLASSPATH are not filtered by filename. |
| APPLSEED_CLASSPATH_FILE | No        | Used to specify a file path, each line of which will be treated as a classpath entry similar to the entries in APPLSEED_CLASSPATH. |
| APPLSEED_TS_CLASSPATH_FILE | No        | Used to specify a file path, each line of which will be treated as a classpath entry similar to the entries in APPLSEED_TS_CLASSPATH. |

Command Line Syntax

Example 58-4 shows a sample Seed Data upload command entered on the CLI, and Example 58-5 shows a sample command line command for a Key Flexfield application module.

Example 58-4 Sample Seed Data Upload Command on the CLI

```java
java -cp $jdev_install/jdev/oaext/lib/key_ff_app_module_name.jar  
key_ff_app_module_name.loader.Loader  
-am <fully qualified application module name>  
-dburl <database url in jdbc format without username and password>  
-dbuser <database user>  
-file <complete path to the data file>  
[-config <bc4j config name>] // Example:  
  KeyFlexfieldServiceAMLocal, KeyFlexfieldServiceAMShared, KeyFlexfieldServiceAMTest  
[-atomic] // If used, the loader will load all the records or none of them (basically will stop after the first failure)  
[-nls] // Used to indicate to the loader that it should treat the given file as an xliff
```

Using the Seed Data Loader in JDeveloper

58-30 Oracle Fusion Applications Developer's Guide
[-clean]  // Cleans up any existing records before starting to upload from the file (use with caution)
[-loglevel]  // Used to give the log Level (SEVERE to FINEST)
[-log]  // Used to give the location of the log file
[-commitsize]  // This parameter is optional. The default value of commitsize is 1; the maximum allowed value is 9999. The commitsize parameter is used to decide the frequency for committing the seed loader transaction. For the default case with commitsize at 1, the transaction is committed after every 1 records, or after all the records are processed, whichever comes first. Note that the commits are only at the top level entity (and not in middle of child records), so commit may not occur exactly every N records, but at the top level entity after N records (top level and child records together) have been processed.

// Note: The previous name for the commitsize parameter was batchsize. However, this was getting confused with the JDBC batch value, and hence, it was decided to rename it to commitsize.
[-entid <enterprise id>]  // load data only for the given enterprise

Note:
The database password would be prompted. To avoid prompting, pipe it on the command line. The password must be piped in when output is redirected. For example, to pipe a password from the $FUSION_PASS environment variable to the Loader command line:

```
java Loader cmdline... <<! $FUSION_PASS
```

### Example 58-5  Sample Command Line Invocation for a KFF Application Module

If you are using a Linux operating system; follow this example:

```
java -cp $jdev_install/jdeveloper/jdev/oaext/lib/key_ff_app_module_name.jar:
$jdev_install/oracle_common/modules/oracle.odl_11.1.1/ojdl.jar
key_ff_app_module_name.loader.Loader
```

If you are using a Windows operating system; follow this example:

```
java -cp %jdev_install%\jdeveloper\jdev\oaext\lib\key_ff_app_module_name.jar;
%jdev_install%\oracle_common\modules\oracle.odl_11.1.1\ojdl.jarkey_ff_app_module_name.loader.Loader
```

#### 58.2.5.1.2 How to Invoke Seed Loader Modes

Three modes can be invoked when running a Seed Data Upload from the command line.

- **-clean**: This flag’s primary purpose is to make the set of records in the database reflect exactly what is delivered in the seed data file. If the set of records in the database becomes out of sync with what is delivered in the file, the -clean flag can be used to load the seed data file and make sure the database only has those records delivered from the file. This is turned off by default.

- **-atomic**: This flag’s primary purpose is to let the seed framework ensure that all the records in a given file are loaded. If all records are not loaded, none will be loaded. If even one record fails, the loading is stopped and all the previously loaded records are rolled back. That is, a single commit is issued towards the end of the file. This is turned off by default and a commit is done after every top level record.
- **nocust**: This flag's primary purpose is to let the seed framework know that it should not preserve any customizations done by the customer in the database version of the records. Data from the file is expected to overwrite anything that is in the database. This is turned off by default.

**Important Points**

- The -clean and -nocust flags are targeted for internal Oracle development. Given their potential to cause irrecoverable data loss, they are not recommended for production environments.

- The database password would be prompted. The password can be piped in to avoid prompting. The password must be piped in if output is redirected.

- A failure during the cleanup stage does not prevent the subsequent loading of the records from the file.

- The -clean, -nocust and -atomic flags can be used independently of each other.

- What is deleted when -clean is used?
  - The clean mode deletes all the records that satisfy a particular condition. In normal use cases, this is the partitioning criteria (ModuleId or ApplicationId) used when the data was extracted. The Seed data file has metadata about the partitioning attribute (ModuleId, ApplicationId or any other partitioning scheme) and the exact values for those attributes used during extract.

**Example**

Using the Messages model from the Oracle Fusion Middleware Extensions for Applications, when PER/SomePerLba developers extract their messages, they will receive a set of Messages owned by that LBA. The seed data file captures this metadata that is used during -clean to determine the set of records to remove. In this case, all the messages owned by PER/SomePerLba will be removed.

- The set of records deleted does not depend on the set of records in the file. It is only driven by the partitioning metadata stored inside the file. The loader would not have even read the records in the file by the time the cleanup is made.

**Example**

If PER/SomePerLba owns 10 messages in the database and an incoming MessageSD.xml brings in only six messages, which might be the same as or different from those in the database, the 10 messages in the database are all removed and the ones from the file are all loaded. If the loading succeeds, the database should have only six records owned by PER/SomePerLba - exactly what the seed data file brought in.

- Customizations and -clean

  The -clean mode currently does not preserve customizations. The seed framework identifies customized records by a non-zero last_updated_by. Such records are not updated by the seed framework and a warning is issued that the record has been customized in the database. The clean mode, however, does not currently honor this principle and deletes even the customized records.

- When are deletes committed?
The cleanup and the subsequent loading run in a single transaction. Therefore, a failure during the loading will roll back the deletes. Because the seed framework - by default - commits after every top level record, the cleanup - by default - is committed or rolled back along with the very first top level record. If subsequent top level records fail, they all will be left out of the database. Therefore, only a subset of the records that came in the file will remain. This behavior changes when using the -atomic flag. This flag essentially says “make sure all the records, or none of the records, in the file are loaded.” In this case, the cleanup and the loading are committed only once towards the end of the file. Even if one record fails, the deletes and any intervening loads are rolled back.

58.2.6 How to Share Application Modules

In some cases, Application Modules developed and owned by one team might have to be shared by some other team. In such cases, the team that developed the application module owns the module and the data-model associated with it, but the team that is consuming it owns the seed data and the relevant extract files.

In Figure 58-17, the team that is developing the application module packages the module into an ADF Business Components library.

The consuming team includes these libraries in the project using the Libraries/Classpath feature of JDeveloper. Once imported, developers can use these libraries to extract and upload seed data, but cannot edit the Seed Data configuration.

**Figure 58-17 Including Shared Libraries**

The imported Business Components can be seen using the Business Components Import feature of JDeveloper. Once imported, developers can use these libraries to extract and upload seed data, but cannot edit the Seed Data configuration.
Since Application Modules shared using an ADF Business Components library are not shown by JDeveloper in the Application Navigator, users must right-click the Business Components project into which they imported the shared libraries. The Seed Data menus would also be available on any Business Components project node in the Applications Navigator tree of JDeveloper.
Clicking any of the Seed Data Framework menu items will display a tree structure showing all the Seed Data Framework-enabled Application Modules (those that have at least one Seed Data driver view object configured within them) available to that project.

**Figure 58-20  Selecting an Application Module**

Users can choose an available application module and click **OK** to display the familiar Seed Data console to perform and extract or upload activities.

### 58.2.7 How to Update Seed Data

The Seed Data Loader supports incremental updates and Java Database Connectivity-based National Language Support updates. These are summarized in Table 58-7.

<table>
<thead>
<tr>
<th>Feature</th>
<th>Applicable to</th>
<th>Default Setting</th>
<th>Design time Control</th>
<th>Runtime Control</th>
</tr>
</thead>
<tbody>
<tr>
<td>Incremental Updates</td>
<td>Only US language seed data files</td>
<td>On</td>
<td>Disabled by setting SD_INCR_MIDTIER_&lt;ViewDefinitionName&gt; to false.</td>
<td>Disabled by using optional command line parameter -noincr</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>- Disabled by setting APPLSEED_NO_INCREMENTAL to true</td>
<td>- Disabled by setting APPLSEED_NLS_USE_ADF to true</td>
</tr>
<tr>
<td>JDBC Mode</td>
<td>Only translation seed data files</td>
<td>On for newly extracted files</td>
<td>Disabled by setting SD_NLS_USE_ADF_&lt;ViewDefinitionName&gt; to true</td>
<td>Disabled by setting APPLSEED_NLS_USE_ADF to true</td>
</tr>
</tbody>
</table>
58.2.7.1 Using Incremental Updates

The Seed Data Loader always updates all the records from the seed data file, even if those records are already present in the target database. The Seed Data Loader only updates the records from the seed data file that have changed in the target database. For certain kinds of requirements where it is desirable to have the seed data loaded as a set, and therefore incremental updates are not desirable, the Seed Data Framework provides an optional feature that allows product teams to disable this feature.

During extract, the Seed Data Framework computes MD5 checksums on the source record by taking all the fields that make up the record (excluding key attributes, history columns and non persistent fields). This checksum is embedded in the seed data file as additional record level metadata. At load time, if the record is found existing in the target database, the same algorithm is used to compute the checksum on the target record. By comparing the two checksum values, the seed data loader identifies if the record has undergone a change and needs an update. Updates are triggered only for those records for which the checksums do not match.

This incremental update feature is applicable to only US language Seed Data SD XML files and is enabled by default. For translated seed data, there is no provision to do incremental updates.

To disable this feature for a particular seed data driver view object and all its child view objects, the SD_INCR_MIDTIER_<ViewDefinitionName> property should be added to the application module.

Set the value of this property to false to turn off incremental updates.

SD_INCR_MIDTIER_ValueSetVO false

Note that the incremental updates feature requires new metadata, in the form of checksums, to be embedded into the seed data file. Consequently, only newer seed data files can take advantage of this feature. Note that the incremental updates feature requires new metadata in the form of checksums to be embedded into the seed data file. Consequently, only newer seed data files can take advantage of this feature. With older seed data files, the seed data loader shall continue to update all the records, even if the application module has the feature enabled using the SD_INCR_MIDTIER property.

As a debugging aid, the seed data loader also allows for incremental updates to be conditionally turned off at run time. Use the -noincr optional command line parameter to the loader or set the APPLSEED_NO_INCREMENTAL environment variable to true.

58.2.7.2 Implementing Java Database Connectivity-based National Language Support Updates

The Seed Data Loader loads seed data using the ADF components developed by product teams. Consequently, all the business rules, validation logic, and custom code built into Oracle Fusion Applications ADF components also are invoked. Translation seed data delivery usually involves only simple updates to existing records. Using plain JDBC calls, instead of ADF, to update existing records allows for much faster loads of translated seed data.

Newer translation seed data files have additional metadata that signal the loader to use the JDBC mode wherever possible. This additional metadata includes SQL fragments that the loader uses at load time to trigger JDBC updates, instead of the well-known ADF-based loads. This JDBC mode is designed to achieve functional
parity with the existing ADF mode, and is the preferred way to deliver translation seed data.

It is enabled by default for newly-created translation seed data files, except date effective translation seed data, which rely on additional logic built into the ADF. It should be noted that US language (XML) seed data files continue to be loaded through ADF. The JDBC mode is tailored only for translation (XML) seed data files. If certain kinds of translated seed data need to be always loaded using ADF, it is possible to do so using one of these ways:

- **Design time** - Define a custom property `SD_NLS_USE_ADF_<ViewDefinitionName>` and set its value to `true`.
- **Runtime** - Define an environment variable `APPLSEED_NLS_USE_ADF` and set its value to `true`.

### 58.3 Translating Seed Data

The Seed Data Framework will handle localized data stored in translation tables in a consistent manner. Translatable attribute data will be extracted separately for only the US base language into Ora-XLIFF compliant format files.

Translation teams will translate the base US language XLIFF into the various language translation files, one file for each supported language. The files are to be stored in a separate language folder, named for its language code.

At upload time, Seed Data Loader will recognize an incoming translation language XLIFF file automatically, and perform the necessary updates to the language tables.

#### 58.3.1 How to Extract Translation Data

Ora-XLIFF format files are automatically generated for those data models which have translatable data. Only the US language data is extracted. The XLIFF file is created in a language sub-folder, named US, and the file name is named the same as the base Seed Data SD XML file, with an extension of .xlf.

**58.3.1.1 Treating Seed Data Base XML and Language XLIFF as a Single Entity**

The seed data base and XLIFF files must be treated as a single entity. Any changes to either base or translated attributes that would require a re-extract, would necessitate that both the re-extracted base XML and US XLIFF files be delivered as units. There is metadata in the files to ensure that the base and XLIFF files match and were extracted together.

#### 58.3.2 How to Process Seed Data Translations

Translation teams will create the translation XLIFF files starting from the initial US file. Each supported language will have its own XLIFF file. The files will be stored in a separate language sub-folder, named for the language code. The files will be named the same as the base XML name, with the .xlf extension.

#### 58.3.3 How to Load Translation Seed Data

At upload time, the Seed Data Loader will recognize an incoming translation language XLIFF file automatically, and perform the necessary updates to the language tables, based on the target language value from the XLIFF file.

Each translated language XLIFF file is loaded individually as a separate entity.
**Base XML Must Be Loaded First**

The base Seed Data SD XML file must be successfully loaded before loading any language translation XLIFF files. No new inserts of language rows are performed, only updates to existing rows.

When loading the base seed XML file, the language rows are initially created using the US translation values. Then when loading the language translation files, the rows are updated using the incoming language values. This way, it is not necessary to have translations for every single row. If no translations exist, the fall back is then to use the US language row.

It is not necessary to upload the US language XLIFF file, as US translation data is already saved in the base Seed Data SD XML file.

### 58.3.4 Oracle Fusion Middleware Extensions for Applications Translation Support

For the Seed Data Framework to work with translated data and perform the necessary read and updates to the language translation tables, the application data model must conform to the Oracle Applications Multi-language support guidelines.

See [Understanding Multi-Language Support Features](#) for more information on creating translatable data models.
Use the Database Schema Deployment Framework

This chapter discusses database modeling and database schema deployment in Oracle Fusion Middleware.

When designing an application to interact with the database, you will need to understand the database schema and be able to modify the schema as needed. This chapter contains information regarding database modeling and database schema deployment in Oracle Fusion Middleware. Developers should not use SQL DDL scripts for deployment and source control of database objects, because they tend to be error-prone and do not serve as a single accurate source. Instead, developers should use the JDeveloper offline database schema object files in SXML persistence mode.

Note:
Before SXML migration, these were referred to as XDF (extension) files.

This chapter includes the following sections:

- Introduction to Using the Database Schema Deployment Framework
- Implementing Applications Data Modeling and Deployment JDeveloper Extensions (Data Modeling Extensions)
- Using Schema Separation to Provide Grants

59.1 Introduction to Using the Database Schema Deployment Framework

The Oracle Fusion Schema Deployment framework includes JDeveloper plugins that handle applications-specific metadata, data modeling standards for applications database modeling, and deployment of database schema objects to a target application database. The database schema deployment component can be invoked standalone outside of JDeveloper, such as from the command line, build scripts, or a patching tool.

59.2 Implementing Applications Data Modeling and Deployment JDeveloper Extensions (Data Modeling Extensions)

Oracle uses source-controlled schema metadata files produced from JDeveloper. The Offline Database is a way to persist database object definitions in a JDeveloper project using SXML files, rather than accessing the database directly. It provides an abstract layer that can be used to access a store of database object definitions. Therefore, it is possible to create, edit, delete and manipulate aspects of a database schema offline and access database objects in a database through JDeveloper’s connections.
All schema modeling can be done through JDeveloper. The XDF extension provides developers with a set of tools to do the data physical modeling, such as create, edit, deploy, and import the schema objects used in applications. The extension also provides Application Data Modeling Standard validation, modification, and template object plugins in JDeveloper to help users to follow the Data Model standards. Developers will use XDF extensions for their database modeling development.

Information covered here includes:

- The purpose of the offline database and how to create the database objects in the offline database using JDeveloper.
- The functions provided by the XDF extension how to use the XDF deployment and import tools in JDeveloper.
- The definitions of all User Defined Properties (UDP) that are provided by the XDF extension user property library.
- The UDPS developers should and can define for their schema objects in JDeveloper.

59.2.1 How to Use the Offline Database

JDeveloper provides the tools you need to create and edit database objects, such as tables and constraints, outside the context of a database, using the offline Database model. You can create new tables and views, and generate the information to a database, or you can import database objects from a database schema, make the changes you want, and generate the changes back to the same database schema, to a new database schema, or to a file that you can run against a database at a later date.

59.2.2 How to Create an Offline Database

Follow these directions to create an offline database.

1. In the Application navigator within JDeveloper, locate the project you want to work in.

2. Select File > New to display the New Gallery.

3. From the New Gallery, select Database Tier > Offline Database Objects > Offline Database, as shown in Figure 59-1.
Figure 59-1  Creating a New Offline Database

4. In the Create Offline Database dialog, enter a name for the offline database, as shown in Figure 59-2. For more information at any time, press F1 or click Help from within the Create Offline Database dialog.

Figure 59-2  Naming the New Offline Database

The following types of objects are modeled using offline database objects.

- Table
- Trigger
- View
- Materialized View
JDeveloper offline database objects do not support these objects. However, SXML persistence files for these object types can be imported using the applxdf extension.

59.2.3 How to Deploy an Offline Database in XML Persistence Format

See Deploying in SXML Persistence Format.

59.2.4 How to Validate Application Data Model Standards

A Framework plug-in on the JDeveloper database object editor provides warnings and errors to enforce Data Modeling standards and XDF deployment requirements.

Additional Validations for Schema Object Deployment

To better service the Schema Deployment on Application Data Model, these validations have been added on some User Defined Property (UDP) and other object properties in the plugin.

- Table Owner (UDP)
  
  For a table object, if the User Property Table Owner is not defined, an error will be displayed.

- Short Name (UDP)
  
  All schema objects:
  
  - If the length of the object name is greater than the length standard and if the short name is null or empty, display a warning.
    
    If the short name is not null or empty, check if the length of the short name is greater than the length standard. If it is, display a warning message.

  - If the length of the object name is not greater than the length standard and if the short name is null or empty, automatically set the short name to be the same as the object name.
    
    If the short name is not null or empty, check if the length of the short name is greater than the length standard. If it is, display a warning message.

    The name length standard for a Table is 24; for all others, it is 27.

- Adxml (UDP)
  
  The UDP adxml is set automatically for these schema object types:
The content of the UDP adxml will be determined by the current value of the UDP adxml and the UDP useExistingAdxml.

- AdxmlFK (UDP)
  For table type only, automatically set the UDP adxmlFk according to the values of the UDP adxmlFk and useExistingAdxml.

- AdxmlDeferredIndexes (UDP)
  For table and MaterializedView.type only, automatically set the UDP adxmlDeferredIndexes according to the current value of this UDP and the value of UDP useExistingAdxml.

- Active Constraint or Index’s Columns Checking
  Check the status of a column to which an active constraint or index refers. If its value is obsolete, an error message be displayed and block the work flow.

- Index for Unique Constraint
  Check if an index of unique constraint exists. If not, add one automatically.

- Constraint Deployment Violation Checking
  If a constraint is defined as disabled, but its UDP isLogical is set to N, a warning message will be displayed, because this case will cause a deployment error.

- Dependencies/Risk
  This feature uses JDeveloper’s Offline database APIs and therefore has a dependency on all the offline database JAR files. The risk for this feature is some enforcement of standards may fire wrongly due to potential bugs preventing developers from modeling their objects as needed.

### 59.2.5 Application User Defined Properties

JDeveloper provides a large number of User Defined Properties (UDP). Their mapping with the tables in the dictionary are detailed in:

- User Defined Properties for Tables
- User Defined Properties for Columns
- User Defined Properties for Indexes
- User Defined Properties for Constraints
- User Defined Properties for Views
- User Defined Properties for Sequence
- User Defined Properties for Materialized View
- User Defined Properties for Materialized View Log
- User Defined Properties for Trigger
### 59.2.5.1 User-defined Properties for Tables

Table 59-1 shows the User Defined Properties that are defined for the tables.

<table>
<thead>
<tr>
<th>UDP</th>
<th>Display Name</th>
<th>Values in JDeveloper</th>
<th>Definition in FND_TABLES</th>
</tr>
</thead>
<tbody>
<tr>
<td>enableAudit</td>
<td>Enable Audit</td>
<td>Y - Enable Audit. Indicates that audit is enabled on the table. A corresponding shadow table is created. The shadow table is used for maintaining audit on the table. N (default): Audit on the table is not enabled.</td>
<td>ENABLE_AUDIT Not Null</td>
</tr>
<tr>
<td>isFlashbackAllowed</td>
<td>Is Flashback Allowed</td>
<td>Y: Flashback of the table is allowed. That is, you can use Flashback Query to examine the state of a table at a previous time, or use the FLASHBACK TABLE statement to restore an earlier state of a table in the event of human or application error. N (default): Flashback of the table is not allowed.</td>
<td>FLASHBACK_Allowed Not Null</td>
</tr>
<tr>
<td>isLogical</td>
<td>Editioning View</td>
<td>Y (default): The deployment program will create an editioning view for this table. N: The deployment program will not create an editioning view for this table.</td>
<td>LOGICAL VARCHAR2(1)</td>
</tr>
<tr>
<td>runTwice</td>
<td>Run Deployment Twice</td>
<td>Y: Specifies that the table must be deployed twice and the appropriate patching metadata will be stamped in the file. This is typically used when a product team adds or modifies a column as a not-null column to an existing table, and does not want to use a RBMS default value. The column will be populated with an upgrade script having a more complex logic. The column needs to exist in the target database before the upgrade script is run. Also, the upgrade script cannot enforce the not-null constraint since it is against the standards to have DDL in scripts. Setting this UDP to Y will accommodate this.N (default).</td>
<td>N/A</td>
</tr>
<tr>
<td>shortName</td>
<td>Table Short Name</td>
<td>N/A</td>
<td>SHORT_NAME VARCHAR2(30)</td>
</tr>
</tbody>
</table>

#### Notes
- The short name of the table is used by the Zero Downtime programs to uniquely identify the table. The maximum length of this UDP is 24 characters.
- The value of this UDP is defaulted to the table name when the length of the table name is less than 24 characters. When the length of the table name is greater than 24 characters, this UDP is required.
Table 59-1  (Cont.) User Defined Properties for Tables

<table>
<thead>
<tr>
<th>UDP</th>
<th>Display Name</th>
<th>Values in JDeveloper</th>
<th>Definition in FND_TABLES</th>
</tr>
</thead>
<tbody>
<tr>
<td>objectOwner</td>
<td>Table Owner</td>
<td>N/A</td>
<td>APPLICATION_SHHORT_NAME VARCHAR2(10)</td>
</tr>
<tr>
<td>tsClassification</td>
<td>Tablespace Classification</td>
<td>TRANSACTION TABLES (default) REFERENCE INTERFACE SUMMARY ARCHIVE TOOLS MEDIA</td>
<td>N/A</td>
</tr>
<tr>
<td>mlsSupportModel</td>
<td>MLS Support Model</td>
<td>Not MLS (default): The table is not an MLS table. Fully Synched: For Standard MLS (pair of _B and _TL tables) or Single MLS (single _TL) tables. A record will exist in the _TL table for each licensed language in the instance. The _TL table must have LANGUAGE and SOURCE_LANG columns. Partially Synched: For Partially Synchronized MLS tables. These tables have a LANGUAGE column but do not have a SOURCE_LANG column. A record may or may not exist in the table for the licensed languages in the instance. Single Language: For Single Language tables. These tables do not have either a LANGUAGE or a SOURCE_LANG column. The language of the data in the translatable columns in the table is considered to be the language classified as the default or base language of the instance.</td>
<td>MLS_SUPPORT_MODEL VARCHAR2(30)</td>
</tr>
<tr>
<td>status</td>
<td>Status</td>
<td>Active (default): The table is active. Obsolete: The table is obsolete and can be deleted from the database.</td>
<td>STATUS VARCHAR2(30)</td>
</tr>
<tr>

59.2.6 How to Create an Offline Database Object

To create new offline database objects from within JDeveloper, in the Application Navigator:

1. Right-click the offline Database or schema.
2. Select New Database Object.
3. Select any Offline database object definition that you wish to create.
You also can create an offline database object definition by importing an existing definition from an online database schema.

### 59.2.7 How to Edit an Offline Database Object

To edit an offline database object:

1. In the Application Navigator, expand the workspace, project, and schema.

2. Right-click the offline database object that you wish to edit and choose **Properties**. Or double-click the offline database object.

   The Edit offline database object dialog opens. For more information at any time, press **F1** or click Help from within the Edit dialog.

3. In the Edit dialog, select an information category on the left and change the values in the panel on the right. Any items that are grayed out cannot be selected or changed.

### 59.2.8 How to Import an Offline Database Object

Database objects from a database schema can be imported to an offline database project in JDeveloper. JDeveloper extensions will also handle the additional Oracle Fusion metadata, if available in the target database. The additional metadata will be copied to an offline database object as user-defined properties. For objects not supported by JDeveloper, such as Policy and Advanced queue tables, import of object definitions from the database will be provided. Implementation of unsupported object import process APIs depends on functionality provided by the Metadata team (dbms_metadata).

**Using the Import Offline Database Object Wizard**

Object definitions can be generated to the Offline Database by right-clicking an Offline Database Source and selecting the **Reverse Engineer Fusion Applications Objects** option, extended to invoke the relevant import API, as shown in Figure 59-3.

*Figure 59-3    Starting the Import Database Object Wizard*
1. The target database connection name can be selected from the list of all defined database connections, or a new connection can be created in the Specify Source dialog, shown in Figure 59-4.

Figure 59-4   Specifying the Source

2. Select the Project and Offline database to which the objects from the target database need to be imported, as shown in Figure 59-5.

Figure 59-5   Specifying the Target

Filters can be applied to select the objects that are displayed as available for import. When there are a large number of objects in the schema, you should apply filters. In the Object Picker, shown in Figure 59-6, you can:
• Enter characters in the Name Filter to filter the list of available objects by name. The Name Filter is case sensitive.

• When there are a large number of objects, you can turn off Auto-Query and click **Query** when you have entered the filter you want to use.

• Select the object types you want to view.

**Figure 59-6  Picking an Object**

3. Click **Next** to display the summary information.

4. Click **Finish** to import the selected objects to the specified offline database.

### 59.2.9 How to Deploy the Offline Database Objects

When an offline database object is created, it can be deployed to a target database using the deployment extension provided in JDeveloper.

#### 59.2.9.1 Deploying in SXML Persistence Format

As part of the Oracle Middleware Extensions for Applications (Applications Core) labels, the `applxdf` extensions for the JDeveloper offline database include a deployment program that operates on JDeveloper offline database objects in SXML format. It checks for and compares the object definitions in SXML format with the object definitions in the target database, and then executes the necessary create/alter DDL to deploy the objects. This deployment program is available in two forms:

• Deployment wizard extension that can be invoked from within JDeveloper.

• Standalone deployment program that can be invoked from the command line.

##### 59.2.9.1.1 How to Use the Database Object Deployment Wizard in JDeveloper

To start the deployment wizard in JDeveloper, you need to choose **APPS: Deploy DB Object** from the context menu on the offline object definition in the Application Navigator.
This can be used to deploy an offline database to a target online database. These options are available for deployment:

- Deploying a single database object file. Only one item is selected, as shown in Figure 59-7.

**Figure 59-7  Deploying a Single Database Object File**

- Deploying multiple database object files (Bulk Deployment). Several items are selected, as shown in Figure 59-8.
• Deploying offline schema object (and thereby deploying the entire designed data model), as shown in Figure 59-9.
The Generate Fusion Applications Objects wizard will prompt for the following information:

- **Database Connection**: The target database connection name can be selected from the list of all defined database connections, or a new connection can be created, as shown in Figure 59-10.
• Deployment Parameters. Figure 59-11 shows how the dialog appears for single database deployment parameters.

**Figure 59-11 Single Database Object Deployment Parameters**

Figure 59-12 shows how the Deployment Parameters dialog appears for multiple database deployment parameters.
Owner User: Oracle schema name in which the object exists or should be created.

Log File Path: Specify a logfile name if it has to be written to a log file. By default, the log will be displayed in the JDeveloper log window.

For Single Database Object deployment, this is optional. For bulk Database Object and schema deployment, it is mandatory to provide a directory for saving log files.

Log File Format: The format of the log file. Permitted values are text (the default) or xml.

Debug Level: The Debug level controls the level of detail to be captured in the log. Debug Level=3 will show the most information. Permitted values are 0 (the default), 1, 2 or 3.

Db Object Mode: A single database object can be deployed independently in table and in tablefk mode.

In case of bulk and schema deployment, the database objects first will be deployed in table mode and then tablefk mode, by default.

This is standard for bulk and schema deployment; therefore, the Db Object Mode is not displayed on the wizard.

Stand Alone: If this option is selected, the XDF comparison utility will execute in a standalone mode. This mode does not have any applications dependencies and it creates database objects without applications standards for physical attributes such as TABLESPACE/STORAGE; the database defaults are used.
- **Change Database**: This option indicates whether the deployment should just report or execute the necessary Alter DDLs, based on comparison of the offline Database object definition against target database. If unchecked, the deployment will report on the differences but will not actually apply the changes to the database.

- **Force Mode**: If this option is selected, any additional column, index or constraints that are present in a target database, but not in the current object file, will be dropped.

### 59.2.9.1.2 How to Use the Database Object Deployment Command Line Interface

Use this command and parameters shown in Example 59-1 to deploy a database object from the command line.

**Mandatory Arguments**

- **owner_un**: Oracle schema name in which the object exists or should be created.
- **apps_un**: Oracle schema name of the current APPS schema.

Note that in the consolidated fusion schema model, owner_un will be the same as apps_un. These parameters are maintained for cases where they could be different.

- **jdbc_protocol**: The JDBC protocol (thin or oci8).
- **jdbc_db_addr**: JDBC tns information, either formatted as a Net8 connect string enclosed in double quotes, or as hostname:port:oracle_sid.
- **xdf_mode**: The object type information - table, qtable, mview, mviewlog, sequence, type, trigger, view, policy, bootstrap.
- **xdf_file_name**: The XDF file name, which contains the object definition. It is not mandatory if the xdf_mode is bootstrap.

**Password Arguments**

The command line deployment tool will prompt to get the database password from the user in an interactive mode. The password cannot be a parameter, because it is against Security guidelines. If you have a script in which you are invoking schema deployment, you can pipe the password in the script, such as:

```
$JDEV_JAVA_HOME/bin/java oracle.apps.fnd.applxdf.comp.XdfSchemaDeploy owner_un=
$FUSION_SCH apps_un=$FUSION_SCH jdbc_protocol=thin jdbc_db_addr=$JDBC_ADDR
changedb=y logfileformat=text xdf_file_name=$xdfFile xdf_mode=$xdf_mode logfile=
$logfile <<! $FUSION_PASS
```

**Optional Parameters**

- **xdf_xsl_dir**: The XSL directory, which contains all the XSL files required for XSLT transformation. This parameter is optional and is automatically determined in most cases if the JAR file format of deploying Java class files is being used. This parameter is maintained for flexibility, in case the format for deploying Java files becomes similar to what existed in previous versions.

- **standalone**: This option is used to execute the XDF comparison utility in a standalone mode. Permitted values are y, Y, n or N. The default value is n. Standalone=y does not have any applications dependency. This mode creates database objects without applications standards for physical attributes such as
TABLESPACE/STORAGE and uses the database defaults. It also does not update applications metadata.

- `changeDb`: The default is "y." If changedb is specified as "n," the SQL statements generated by the XDF comparison utility are not executed but are displayed on the standard output or a log file.

- `logfileformat`: The format of the log file. Permitted values are text or xml. If logfileformat is not set, the default is text.

- `logfile`: The output of the comparison utility is written to standard out. Specify a logfile name if it has to be written to a log file. If logfile is not set, the outputs will be displayed on the screen.

- `debuglevel`: Debug levels determine how much information is to be shown in the log. Debuglevel=3 will show the most information. Permitted values are 0, 1, 2 or 3. The default value is 0.

- `from_jdev`: This parameter is set to "y" when the XDF comparison utility is called from JDeveloper. The default value is "n."

- `force_mode`: The force deployment mode introduces an additional input parameter that when specified will drop any additional column, index or constraints that are present in a target database. The applications metadata stored for the object is also updated to be in sync with the new definition.

- `index_category`: Values are small, large, and both. If the table is partitioned, the index is always created. If the table is not partitioned, there is no index creation if one of these conditions is true:
  - index_category=small and unused dbms block size greater than parallel_index_threshold
  - index_category=large and unused dbms block size less than parallel_index_threshold

- `parallel_index_threshold`: Parallel index threshold, default is 0.

- `no_error`: This option is used when you add a not-null column to an existing table with data, or change a null column to a not-null column. XdfSchemaDeploy results in FAILURE without this option. XdfSchemaDeploy results in WARNING if you have no_error=y. Default value is "n."

- `idxnolog`: Pass idxnolog=y to add a NOLOGGING clause in the Index creation to improve the performance of creation. The default value is "n."

**Example 59-1 Sample Database Object Deployment Using the CLI**

```java
java oracle.apps.fnd.applxdf.comp.XdfSchemaDeploy <owner_un={schemaId}>
<apps_un={appId}> <jdbc_protocol={jdbc driver type}> <jdbc_db_addr={jdbc tns info}>
<xdf_file_name={xdf file name}> <xdf_mode={xdf mode}> [xdf_xsl_dir={xsl file directory}] [standalone={y|n}] [changedb={y|n}] [logfileformat={text|xml}]
[logfile={log file path and name}] [debuglevel={0|1|2|3}] [from_jdev={y|n}]*
```

### 59.2.9.2 Setting the CLASSPATH Variable

The XdfSchemaDeploy tool requires JDK 1.6, the standard Oracle JDBC driver, the XML parser, and the applxdf JAR file.

Set the CLASSPATH environment variable to contain these JAR files:
Example 59-2 shows the set of commands to set the CLASSPATH.

The JDeveloper installation directory could potentially change with newer versions of JDeveloper being available. Check the JDeveloper installation directory to make sure that it exists. You could also use the XML parser and JDBC driver that comes with the database. Note that so far XDF has been tested with the same JAR files with which it has been compiled. It should not be a problem setting the CLASSPATH with a higher version of these JAR files and testing them. If you encounter any issues, try using 11g JDBC and xmlparsers.

**Example 59-2  Example of Setting CLASSPATH**

```
setenv CLASSPATH $ADE_VIEW_ROOT/fmwtools/BUILD_HOME/oracle_common/modules/oracle.nlsrtl_11.1.0/orai18n.jar:
$ADE_VIEW_ROOT/fmwtools/BUILD_HOME/oracle_common/modules/oracle.xdk_11.1.0/xmlparserv2.jar:
$ADE_VIEW_ROOT/fmwtools/BUILD_HOME/wls/server_10.3/server/ext/jdbc/oracle/11g/ojdbc6.jar:
$ADE_VIEW_ROOT/fmwtools/BUILD_HOME/oracle_common/modules/oracle.odl_11.1.1/ojdl.jar:
$ADE_VIEW_ROOT/fmwtools/BUILD_HOME/oracle_common/modules/oracle.odl_11.1.1/ojdl2.jar:
$MW_HOME/jdeveloper/jdev/extensions/oracle.apps.fnd.applxdf.jar
```

### 59.2.9.3 Using Bootstrap Mode

Bootstrap mode for XDF Schema deployment is available using the parameter xdf_mode=bootstrap. XDF currently depends on several database components, such as pl/sql and tables, for it to work completely in all modes. The bootstrap mode can be used to make sure that the XDF database dependencies are set up correctly and to avoid any manual steps to get XDF working on a particular database.

In bootstrap mode, the mandatory parameter xdf_file_name becomes optional and only the remaining mandatory parameters are applicable.

To run XDF in bootstrap mode, use the command shown in **Example 59-3**.

**Example 59-3  Sample of Running XDF in Bootstrap Mode**

```
$JDEV_JAVA_HOME/bin/java oracle.apps.fnd.applxdf.comp.XdfSchemaDeploy
owner_un=fusion apps_un=fusion jdbc_protocol=thin jdbc_db_addr={jdbc tns info}
xdf_file_name="dummy" xdf_mode=bootstrap runtime_schema=<runtime schema name>
```

### 59.2.9.4 Deployment FAQ

Examining these frequently-asked questions about deployment will help you prevent and fix problems.

**To add a not-null column to an existing table with data, or change a null column to a not-null column:**

There are two options to add a not-null column to an existing table with data, or change a null column to a not-null column.
• Option 1
  – Adding a not null column to an existing table with data
    Product teams can specify an RDBMS default value for the column which will be used by the databases to successfully alter the table to add the not-null column.
  – Modifying a null column to not-null in a table with data
    Product teams can specify an RDBMS default value for the column. This default value will be used by schema deployment utility to update the existing null rows with that value before changing the column to not null.

• Option 2
  If a product team does not want to use a RDBMS default value, it can add or modify a column as a not-null column to an existing table by using a script having a more complex logic. The column needs to exist in the target database before the script is run. The script cannot enforce the not-null constraint because it is against the standards to have DDL in scripts.

  To use a script to populate the column, the UDP named runTwice must be set to Yes. This UDP will be used by XDF to ensure that the required patch metadata is present in XDF to run it twice in a patch. In the first run, the script will not error out if it is not able to enforce the not-null constraint, but it will error out in the second run if it still is not able to enforce the not-null constraint.

  If the user does not set this UDP, the default behavior of the deployment utility is to error out if it is not able to enforce the not-null constraint while adding or modifying the column.

To remove a table, column or view:
See How to Use fnd_cleanup_pkg and fnd_drop_obsolete_objects.

To rename a table, column or view:
Deployment does not support renaming a table, column or view. The workaround that can be used is to make the object obsolete and introduce a new renamed object. The development team must separately handle data migration and update information in the Automatic Diagnostic Repository (ADR), if required.

To implement a non-additive change to the data type of a column, such as varchar2 to number:
Developers can create a script that runs before deployment of the object to rename or drop the column, based on whether data must be preserved or migrated. When the deployment successfully adds the column with the correct data type, another script may be needed to make sure that data is migrated and that the renamed column is dropped. This is applicable only if the initial script renames the column.

To add or change the unique constraints or indexes on a populated table:
If the populated table does not meet the criteria for creating unique constraint or unique index, to remove the invalid data create a script to clean the table before deploying a unique index or constraint.

59.2.9.5 Cleaning Database Objects
To maintain efficiency, database objects should be cleaned of no-longer-used data. As part of that process, it is important to keep the FND data dictionary synchronized with
existing objects (it can be table, sequence or view) in the database. The XDF team provides packages to make this process easier.

**59.2.9.5.1 Making a Database Object Obsolete**

Use this information to correctly make a database object obsolete. It is applicable after the release of the initial version of the product to customers.

Modeling database schema for new releases or upgrades to new releases may involve making certain database objects or certain attributes of the database object, such as Columns, obsolete. Doing this may make a significant effect to existing customizations or extensions currently implemented on the system. Making obsolete database objects that contain data, such as Tables, requires particularly close analysis for potential effects. Development teams should take the necessary steps to review and understand the implications of such updates in these areas.

Making obsolete certain database objects or certain attributes of a database object may require those objects to be dropped as part of clean up. Considering any existing customization or extensions to such objects, the act of making obsolete and dropping the object should be kept separate. Dropping the obsolete database objects or columns should be an optional step that is invoked at the demand of customers. The Patching (AD) utilities will provide such an option as a post-patching step.

Follow these steps to make obsolete a database object or attribute.

1. Set Status User Defined Property for the specific database objects or attributes to Obsolete. This can be done using User Defined Properties for Applications specific metadata that is part of the offline database model.

2. Status User Defined Property will be captured in the Applications/XDF data dictionary as part of deploying XDF to the database.

These steps ensure that:

- If the table does not already exist in the database, the Applications schema deployment utilities (XDF) will create the table without columns marked as obsolete.

- If the column does not already exist in the table, the Applications schema deployment utilities (XDF) will not add the column to the table.

- If the column already exists in the table, the Applications schema deployment utilities (XDF) will remove any NOT NULL, PK/FK constraints on the column.

- Any indexes that comprise only the obsolete columns could be dropped. In other cases, the development team owning the obsolete objects will be expected to update the definition of any affected indexes.

**59.2.9.5.2 How to Use the Force Mode Option in Schema Deployment**

During the initial development of the product before release, product teams may not want to mark the object as obsolete and may prefer directly dropping the object; that is, removing the definition from the offline database file. To support this, the force_mode=y parameter can be passed to the schema deployment tool. The additional input parameter which, when specified, will drop any additional column, index or constraints that are present in a target database and not present in the offline object file definition. The XDF dictionary metadata stored for the object is also updated to be synchronized with the new definition. Note that this option, in certain cases, will not change the definition of the table to exactly match the definition in the file. For example, if the database does not allow some changes, such as changing of certain
column datatype, or changing an unpartitioned table to a partitioned table, force mode will not override the database.

Force mode only handles the removal of column, index and constraints, and synchronizing the corresponding definition in the XDF dictionary. If the primary object, such as a table, sequence or view, is dropped, the fnd_cleanup_pkg must be used to synchronize the XDF dictionary.

59.2.9.5.3 How to Use fnd_cleanup_pkg and fnd_dropObsolete_objects

Use fnd_cleanup_pkg and fnd_dropObsolete_objects to clean a database.

Using fnd_cleanup_pkg

Procedure fndcleanup(name): Remove table, sequence, or view with name that is in fnd_tables, fnd_views or fnd_sequences tables, but not in the database. All the required XDF dictionary tables will be updated when fnd_tables, fnd_views, or fnd_sequences is updated.

name: Optional, but using fnd_cleanup_pkg.fndcleanup without the name parameter may cause some issues. You should use fndcleanup(object name) for a clean and safe removal. This can be a table name, a view name or a sequence name. If a name is provided, the procedure will clean only the named object and related components. If it is not defined, the fndcleanup procedure removes all table, view, or sequences that are in fnd_tables, fnd_views, or fnd_sequence tables, but that do not exist in the database.

It also removes the entries that refer to that name object in all related database schema deployment (xdf) dictionary tables, including fnd_columns, fnd_indexes, fnd_primary_keys, fnd_primary_key_columns, fnd_foreign_keys, fnd_foreign_key_columns, and fnd_histogram_cols.

Procedure clean_fndcons(tname): Remove the tname table’s Primary Key (PK), Unique Keys (UKs), and Foreign Keys (FKs) that are not in the database from the fnd constraint dictionary tables. Although the tname parameter is optional, you should use it. If tname is not specified, then all tables’ PK, UKs, and FKs that are not in the database will be removed from the fnd constraint tables.

Procedure TableFndCleanUp(tname, deleteType, delname): Remove the specified deleteType with the specified delname on the specified tname table from related fnd tables. Although the delname parameter is optional, you should include it. If it is not specified, all table properties on that deleteType will be removed from the specified table. The deleteType includes column, index, pkuk, and fk.

Examples

• Remove table1 from the fnd_tables table if table1 is not in the database. All required XDF dictionary tables will be updated when fnd_tables is updated.
  
  execute fnd_cleanup_pkg.fndcleanup('table1')

• Remove view1 from the fnd_views table if view1 is not in the database.
  
  execute fnd_cleanup_pkg.fndcleanup('view1')

• Remove all table names LIKE HZ% in fnd_tables or fnd_views tables that do not exist in the database.
  
  execute fnd_cleanup_pkg.fndcleanup('HZ%')

• Remove table XF1’s PK, UKs, and FKs that are not in the database, from the fnd constraint dictionary tables.
exec fnd_cleanup_pkg.clean_fndcons('XF1');

- Remove a Foreign Key named XF2_T1_FK on table XF2 from the fnd constraint dictionary tables. XF2_T1_FK may or may not be in the database.
  
  exec fnd_cleanup_pkg.tablefndcleanup('XF2', 'fk', 'XF2_T1_FK');

**fnd_drop_obsolete_objects**

**Procedure drop_object(objectname):** Drop obsolete objectname from the database. This procedure is used to delete obsolete views, tables and columns that are marked as Obsolete in the table.

**Examples**

- Drop Table table1 from the database if it is marked as obsolete. If table1 is not obsolete, drop any columns in table1 that are obsolete.
  execute fnd_drop_obsolete_objects.drop_object(table1)

- Drop View view1 from the database if it is marked as obsolete.
  execute fnd_drop_obsolete_objects.drop_object(view1)

- Verify all tables and views with name like 'HZ_\%' for dropping tables and views, or drop columns if the tables are not obsolete.
  execute fnd_drop_obsolete_objects.drop_object('HZ_\%')

**59.2.9.5.4 Frequently Asked Questions**

Use this information when dropping an object in the database.

- How do I make an object obsolete?
  1. Select the object in JDeveloper.
  2. Right-click and select **Properties > User Properties**.
  3. Change the Status to **Obsolete**.

- What happens when you deploy an obsolete object or an object that has obsolete columns or indexes?
  Only the FND dictionary is updated. Objects in the database are not dropped.

- How do I remove an object from the database and keep the FND data dictionary synchronized?
  There are three ways this can be done. SQL scripts can be used to achieve the same outcome.
    - If the object is not a primary object and is a column, index or constraint that is being dropped:
      - Use JDeveloper to remove the definition of these secondary objects from the offline database file definition.
      - Use the **force_mode** optional parameter to deploy the object to the target database.
    - If the object is a primary object, such as a table, sequence or view:
* Drop the object obj from sqlplus.
* Execute this command from sqlplus:
  
  ```sql
  execute fnd_cleanup_pkg.fndcleanup(' obj')
  ```

- Change the object obj status UDP to Obsolete from JDeveloper. Deploy the object to the database either by command line (XdfSchemaDeploy) or use Generate Fusion Applications Objects from JDeveloper.

* Execute this command from sqlplus:
  
  ```sql
  execute fnd_dropObsolete_objects.drop_object(' obj')
  ```

* Execute this command from sqlplus:
  
  ```sql
  execute fnd_cleanup_pkg.fndcleanup(' obj')
  ```

- How do I clean up the FND data dictionary if many objects are no longer in the database?
  
  Execute this command from sqlplus or use a SQL script.
  
  ```sql
  execute fnd_cleanup_pkg.fndcleanup
  ```

- How do I clean up the FND data dictionary if I had deleted columns and indexes from table, but did not cleanup from the FND data dictionary.
  
  Execute this command from sqlplus or use a SQL script.
  
  ```sql
  execute fnd_cleanup_pkg.fndcleanup
  ```

- How do I remove obsolete columns/indexes in objects from FND data?
  
  Execute this command from sqlplus.
  
  ```sql
  execute fnd_cleanup_pkg.fndcleanup
  ```

- How do I remove all table/view/sequence name LIKE HZ% in fnd_tables/fnd_views/fnd_sequences tables that do not exist in the database.
  
  Execute this command from sqlplus.
  
  ```sql
  execute fnd_cleanup_pkg.fndcleanup('HZ%')
  ```

- How do I drop table/view/sequence name xyz in fnd_tables/fnd_views/fnd_sequences tables from the database if it is marked as obsolete?
  
  Execute this command from sqlplus.
  
  ```sql
  execute fnd_dropObsolete_objects.drop_object('xyz')
  ```

- How do I drop table/view/sequence name LIKE HZ% in fnd_tables/fnd_views/fnd_sequences tables from the database if it is marked as obsolete?
  
  Execute this command from sqlplus.
  
  ```sql
  execute fnd_dropObsolete_objects.drop_object('HZ%')
  ```

### 59.3 Using Schema Separation to Provide Grants

The application runtime schema could be different from the database object owning schema for security reasons. To support this model as part of schema deployment, there is a mechanism to granularly provide grants on various database objects. These are granted to a set of fixed roles which are eventually available to runtime schema.
Privilege will be granted on the database object to the role based on privilege User defined properties defined for the object. Table 59-10, Table 59-11, Table 59-12, and Table 59-13 present the user defined properties that will be defined for each object type.

**Table 59-10  ** Table Object Type Properties

<table>
<thead>
<tr>
<th>UDP Name</th>
<th>Description</th>
<th>Values</th>
</tr>
</thead>
<tbody>
<tr>
<td>Insert Allowed</td>
<td>Grant Insert Privilege on the table to the required role</td>
<td>Y/N Default Y</td>
</tr>
<tr>
<td>Update Allowed</td>
<td>Grant Update Privilege on the table to the required role</td>
<td>Y/N Default Y</td>
</tr>
<tr>
<td>Delete Allowed</td>
<td>Grant Delete Privilege on the table to the required role</td>
<td>Y/N Default Y</td>
</tr>
<tr>
<td>Select Allowed</td>
<td>Grant Select Privilege on the table to the required role</td>
<td>Y/N Default Y</td>
</tr>
<tr>
<td>Truncate Allowed</td>
<td>The value of this UDP indicates whether a TRUNCATE statement is allowed on the table</td>
<td>Y/N Default Y</td>
</tr>
<tr>
<td>Maintain Partition</td>
<td>The value of this UDP indicates whether partitions can be maintained on the table. The ADM_DDL program when handling requests for dynamic DDL operations uses this information.</td>
<td>Y/N Default Y</td>
</tr>
<tr>
<td>Exchange Partitions</td>
<td>The value of this UDP indicates whether it is possible to exchange partitions on the table. The ADM_DDL program when handling requests for dynamic DDL operations uses this information.</td>
<td>Y/N Default Y</td>
</tr>
<tr>
<td>Maintain Index</td>
<td>The value of this UDP indicates whether it is possible to maintain indexes on the table. The ADM_DDL program when handling requests for dynamic DDL operations uses this information.</td>
<td>Y/N Default Y</td>

This chapter provides guidelines for you to write high-performing, highly scalable, and reliable applications on Oracle Fusion Middleware.

This chapter includes the following sections:

- Introduction to Improving the Performance of Applications
- ADF Business Components Guidelines
- ADF ViewController Layer Guidelines
- SOA Guidelines for Human Workflow and Approval Management Extensions
- Oracle Fusion Middleware Extensions for Applications Guidelines
- General Java Guidelines
- Caching Data
- Profiling and Tracing Oracle Fusion Applications
- Setting up a Debug Breakpoint

60.1 Introduction to Improving the Performance of Applications

The outcome of performance assessments of several prototypical Oracle Fusion Applications as well as various tests conducted by the Oracle Fusion Middleware performance team are captured in this chapter. It includes best practices for coding and tuning the Oracle Application Development Framework (Oracle ADF) Business Components-based applications with performance, scalability, and reliability (PSR) in mind. Other topics discussed include performance improvement guidelines for ADF ViewController layers and Oracle Fusion Middleware Extensions for applications.

This chapter assumes you are familiar with the concepts described in the Oracle Fusion Middleware Tuning Performance guide.

60.2 ADF Business Components Guidelines

To maximize performance while working with ADF Business Components, such as entity objects, view objects, application modules, and services, consider the best practices described in this section. For more information about tuning Oracle ADF, see the “Oracle Application Development Framework Performance Tuning” chapter in the Tuning Performance.

60.2.1 Work with Entity Objects

When working with entity objects, consider the suggestions for improving performance in this section. For more information see the "What You May Need to
Know About Optimizing View Object Runtime Performance” in the Developing Fusion Web Applications with Oracle Application Development Framework.

60.2.1.1 Enable Batch Updates for your Entity Objects

You can enable batch updates of your entity objects by selecting the **Use Update Batching** property on the **Entity Object Editor - Tuning** section as shown in the following figure. You can also set the **Threshold** property to 1, which is important for _TL multi language entities.

**Figure 60-1    Entity Object Editor — Tuning**

When enabled, ADF Business Components combines multiple Data Manipulation Language (DML) operations and executes them in a single round trip. Modified rows are grouped into batches.

Enable batch updates, except in the following three cases:

- You override the DML (PL/SQL entity objects are in this category).
- You have one or more streaming attributes, such as character large object (CLOB) or binary large object (BLOB).
- One or more attributes are marked as retrieve-on-insert or retrieve on-update.

For more information about batch processing, see the "Batch Processing" section in the Tuning Performance.

60.2.1.2 Avoid Children Entity Objects in Composite Entity Associations Setting the Foreign Key Attribute Values of the Parent

Children entity objects can expect that their parent primary key attribute values are passed through the **attributeList** parameter in `create(attributeList)` and ADF Business Components calls `super.create(attributeList)` to populate these foreign key attribute values. Repopulating the foreign key attribute values in the children entity object unnecessarily decreases performance.

60.2.1.3 Avoid Using List Validator Against Large Lists

When you use list validator, it scans the values in a linear fashion. Therefore, limit the list to not more than 20 to 30 values for frequently used list validators. Instead of using the list validator, you can use either an expression validator or a method validator. If this is a foreign key, then you can use a key exist validator.

60.2.1.4 Avoid Repeated Calls to the same Association Accessor

There is some cost to getting the parent or children via the association accessor. For example, if you are calling the same association accessor on the same entity object in a loop, then move the call to outside the loop.
60.2.1.5 Close Unused RowSets

There are various places in ADF Business Components that loop through all rowsets of a view object. Call RowSet.closeRowSet on any rowsets that you no longer need. The typical case where you would have opened a rowset is when you get the "many" end of an association, for example, when retrieving Emp from Dept.

By default, the rowset is cleared when a garbage collection occurs. However, if you can close the rowset as soon as you finish using it, it improves performance and reduces the amount of work done during garbage collection. To close a rowset, call RowSet.closeRowSet. You should close it only if you know you no longer need it, and would not make calls such as previous(). If you are getting a row iterator from an association accessor, you can cast it to a RowSet and call closeRowSet on it.

Caution:

If you use the Retain Association Accessor RowSet option, then you should not call closeRowSet.

The same principle applies for view accessor rowsets. If your view accessor returns more than one row, then every time you start fetching rows from the view accessor with a different bind value, a new row set is created, along with a new underlying database cursor to execute the query. If you do not need all the rows, then you can configure the MaxFetchSize setting on the view accessor to include only the number of rows you need. Then Oracle ADF closes the database cursor immediately upon fetching all the rows up to MaxFetchSize. Alternatively, for cases where you expect to execute the view accessor several times with different bind values, in a single request, consider calling closeRowSet on the view accessor rowset explicitly.

60.2.1.6 Use "Retain Association Accessor RowSet" when Appropriate

By default, the entity object creates a new RowSet object each time you retrieve an entity association accessor rowset, to allow you to work with the rows. However, creating a new RowSet object does not imply re-executing the query to produce the results each time, since only a new instance of a RowSet object is created, with its default iterator reset to the "slot" before the first row. There is some overhead to creating all these new rowsets even though the ones not in use are cleared on Java Virtual Machine (JVM) garbage collections. You may also see additional query executions due to the rowsets, and resulting underlying query collections, not being retained.

For high-traffic entity objects, such as those used for bulk loading, where the same association accessor is called many times, consider using the Retain Association Accessor RowSet option to improve performance. Typically, an association accessor would be used multiple times if:

- Your entity object is Multi-Language Support (MLS)-enabled and has more than one translated attribute.
- You have defaulting logic or multiple validators that need to access the same association attribute.

Using the Retain Association Accessor RowSet option may adversely affect memory usage since it postpones when the retained rowset becomes garbage collectible. Before you enable this option, as shown in the following figure, profile your flow to make sure you would indeed get a noticeable benefit.
When sorting by exclusive CPU, if you see the top CPU consumers are related to code that loops through the rowsets, then you would likely get a benefit by using this option. An example where you may want to consider using the **Retain Association Accessor RowSet** option is if you profile your code and see that `oracle.jbo.server.ViewObjectImpl.addRowSet` is using a lot of CPU, and most of the CPU is in a call stack that includes `AssociationDefImpl.get`. The following figure illustrates an example profiler output showing `addRowSet` being expensive.

Before you decide to retain association accessor, try the guideline in **Close Unused RowSets**.

If you decide to use the **Retain Association Accessor RowSet** option, ensure you are aware of the potential behavior changes.

For information related to the potential behavior changes as the result of using the **Retain Association Accessor RowSet** option, see the **Advanced Entity Association Techniques** section in the "Advanced Entity Object Techniques" chapter of the Developing Fusion Web Applications with Oracle Application Development Framework.

### 60.2.1.7 Mark the Change Indicator Column

If your table has an `OBJECT_VERSION_NUMBER` column, make sure you check the **Change Indicator** attribute property. Columns marked as **Change Indicator** are automatically in any view object that includes that particular entity object.

### 60.2.2 Work with View Objects

When working with view objects, consider the suggestions in this section for improving performance.

#### 60.2.2.1 Tune the View Object SQL Statement

Tune both the list of attributes included in the view object as well as the underlying SQL statement. Avoid using the "one-size fits all" view objects, which include many other attributes that are not needed for your usage. These additional attributes consume unnecessary memory.

Capture the SQLs the view object is generating, with relevant view criteria applied, by enabling Java Business Objects (JBO) debug logging. (For expert-mode view objects, you should capture the SQL that you are providing). You can also generate explain
plans against a volume database to ensure performance is optimal and the correct indexes are in place.

If you must use hints to get a desirable execution plan for your query, set the **Query Optimizer Hint** field in the **View Object Editor - Tuning** section as shown in the following figure.

**Figure 60-4  View Object Editor — Tuning**

For user interface (UI) driven queries, the **FIRST_ROWS(10)** hint is necessary to instruct the optimizer to pick a plan that is optimized to return the first set of rows. Set this hint for view objects that are used for UI components, which typically just display the initial set of rows (such as table). If you are fetching all rows, then do not use the **FIRST_ROWS** hint.

### 60.2.2.2 Select the Correct Usage for View Objects

To maximize view object performance, the view object should match the intended usage. For more information about correct usage for view objects, see the "Creating View Objects" section in the **Tuning Performance**.

### 60.2.2.3 Set Appropriate Fetch Size and Max Fetch Size

How the view object is configured to fetch data plays a large role in the view object performance.

Due to the memory requirements for large batch size, we do not recommend using a fetch size of over 100. For view objects used on UIs, fetch size should not exceed 30.

---

**Caution:**

Java Database Connectivity (JDBC) pre-allocates memory to hold return data based on fetch size, so avoid the practice of applying a fixed fetch size, such as 30, to all view objects.

---

If you have a view object that is used in both query and insert, then call `setMaxFetchSize(0)` programmatically when you know it is being used in insert mode. In this case, you need to unset it when using it in query mode. You cannot set the **No Rows** option because the same view object is used in both insert and query mode in the same application module.

For view objects used for the List of Values (LOV) combo box, the number of rows fetched by Oracle ADF is controlled by the **ListRangeSize** setting in the LOV definition. The default value is 10 and a fetch size of 11 is appropriate. You should modify the value to 11.
For LOV text output, Oracle ADF fetches about 31 rows in the LOV search results window. To simplify retrieval, a fetch size of 11 is acceptable, to make it the same fetch size as the view object used in the LOV combo box. In this case, the data comes back in three round-trips, which is also acceptable.

**Note:**

ADF Business Components only recognizes fetch size if the SQL flavor is Oracle, which is what you should be using.

Fetch size can be set based on the usage of the view object. This is the appropriate place to set the fetch size for view objects that are used in different scenarios and the fetch size cannot be predetermined when the view object is created. You can edit the setting per view object usage by selecting the view object in the **Data Model** panel of the **Application Module editor**, clicking **Edit**, and then selecting the **Tuning** panel.

Fetch size can also be set at the view accessor level. This is typically used by teams consuming public view objects from other teams, such as for LOVs. The producer team would likely not set a fetch size since they cannot anticipate how their public view object would be used.

The following documents provide additional information related to subjects discussed in this section:

- For more information about tuning the *fetch* options for the application, see the "Configuring View Object Data Fetching" section in the *Tuning Performance*.

- For more information about list of values performance, see the "Working with List of Values (LOV) in View Object Attributes" section in the *Developing Fusion Web Applications with Oracle Application Development Framework*.

### 60.2.2.4 Use Bind Variables

Always use bind variables when setting the *WHERE* clause or when defining view criteria, as this allows the SQLs to be shared. However, there are some limited cases where you cannot use bind variables, such as when you need to use histograms. For more information, see "Additional View Object Configurations" in the *Tuning Performance* and "Working with Bind Variables" in the *Developing Fusion Web Applications with Oracle Application Development Framework*.

### 60.2.2.5 Include at Least One Required or Selectively Required View Criteria Item

When creating view criteria, include at least one view criteria item that is required, or selectively required, to use a database index and avoid a full table scan. Otherwise, the SQL generated will be of the form:

```sql
((MyTableColumn_name = :bvOrgId) OR (:bvOrgId IS NULL))
```

In this example, the query cannot be derived from an index on `MyTable.Column_name` due to the presence of the `:bvOrgId IS NULL` condition.

**Note:**

The `:bind IS NULL` condition is generated only if the View Criteria Item (VCI) is against a bind variable and the **Ignore Null Values** option is selected.
60.2.2.6 Use Forward-Only Mode when Possible

If a dataset is only traversed going forward, then forward-only mode can help performance when iterating through the dataset. The setForwardOnly API is defined on the RowSet interface, which ViewObjectImpl implements, so you can use it on secondary rowsets that you create via ViewObjectImpl.createRowSet(String name) as well. For more information about forward-only mode, see the "Configuring View Object Data Fetching" section in the Tuning Performance.

60.2.2.7 Avoid Calling getRowCount

Calling getRowCount on a view object results in all rows being fetched into memory. Unless you intend to actually fetch all the rows, avoid this call. Use a combination of vo.hasNext, hasPrevious, getCurrent, or vo.getFetchedRowCount, if the row set has been executed and you are attempting to see if there is at least one row fetched.

If you really need to find out how many rows are in the result set, and you know the result set is likely going to contain more than 50 rows, you should use getEstimatedRowCount. This triggers a count query but does not fetch all of the matching rows into memory.

There is also a method on the view object, getCappedRowCount(n), which executes a query and a count up to n number of rows. If the row count is less than n, it returns a positive number, and it returns a negative number if row count is more than n.

60.2.2.8 Avoid Entity Object Fault-in by Selecting Necessary Attributes Up-Front

If your view object is based on entity objects, and you request an attribute that is not fetched in the initial view object query, ADF Business Components must execute a "fault-in" SQL to fetch the entire entity object. This is expensive and can be avoided by initially selecting the list of attributes you are fetching in a view object. For example, if you know your validation logic accesses an attribute that is not displayed in the UI, fetch it in the initial view object query.

By default, only the key attributes are selected when executing a Declarative view object programmatically. A "fault-in" query is executed to get the rest of the attributes if they are referenced. To avoid this, use the following ViewObjectImpl methods to specify the columns that need to be selected when executing a Declarative view object programmatically: resetSelectedAttributeDefs, selectAttributeDefs, and unselectAttributeDefs.

If your view object is a declarative-mode view object that is accessed using view accessor, you may still be able to specify which attributes are accessed. If the code looks like the following example, the first line calls the accessor getter. The query is not executed until hasNext() is called on the last line. Therefore, you can use selectAttributeDefs to control which attributes are select after calling the getter and before calling hasNext.

RowSet rowSet = this.getPartySitePartySiteUseVVO();
RowSetIterator iterator = rowSet.createRowSetIterator("sellToUseIterator");
iterator.reset();
Row row = null;
if (iterator.hasNext()) {

60.2.2.9 Reduce the Number of View Object Key Attributes to a Minimum

If your view object is based on multiple entity objects, restrict the number of Key Attributes to a minimal set that uniquely identifies the row.
Note:
By default, the primary key of the view object is the concatenation of the primary key of all the underlying entity objects, which typically will be a lot more columns than what is actually needed to uniquely identify a row.

For those attributes that do not need to be part of the key, deselect the Key Attribute option in the View Object Attribute Editor. However, ensure that you include sufficient attributes. If your view object is updateable, comply with File.AdfModel.112.

### 60.2.2.10 Use Range Paging when Jumping to Different Row Ranges

View objects provide a mechanism to page through large datasets, giving users the ability to jump to a specific page in the results. To implement this feature, select Range Paging Incremental from the Access Mode dropdown list in the View Object Editor - Tuning section, as shown in the following figure.

**Figure 60-5  View Object Editor — Tuning: Access Mode**

For more information, see the "Optimize large data sets" row in the "Additional View Object Configurations" table in the Tuning Performance.

### 60.2.2.11 Use setListenToEntityEvents(false) for Non-UI Scenarios

The setListenToEntityEvents(false) method instructs the view object not to listen to entity events and therefore, the view object and all its row sets do not receive events generated from changes to entity row data. This is useful for batch processing because suppressing events improves performance.

Note:
These events are not related to the business events that you may have defined in the entity object.

When you call an association accessor, an internal view object is created. If you insert or update via the association accessor, you can call setListenToEntityEvents(false) for the internal view object by casting it to a RowSet as shown in the following example.

```java
RowSet myRowSet = (RowSet) myEntityImpl.getAttribute("<Accessor Name>");
((ViewObjectImpl) MyRowSet.getViewObject()).setListenToEntityEvents(false);
```

### 60.2.2.12 Use Appropriate Getter or Setter on View Row

If you have a ViewRowImpl class generated for your view object, call the named getter or setter if possible. For example, getEmployeeName or setEmployeeName, rather than the generic getAttribute or setAttribute.
Note:

Performance alone is not a sufficient reason for creating a custom `ViewRowImpl` class.

If you must use the generic `getAttribute` or `setAttribute`, consider using the index instead of the name for a small performance gain. It may be more troublesome to maintain the numeric attribute indexes, but for cases where you are looping through a large number of attributes, consider using `getAttribute(int index)` and `setAttribute(int index)`.

60.2.2.13 Use Appropriate Indexes with Case-Insensitive View Criteria Items

A view criteria item on a `varchar2` column is, by default, marked as case-insensitive. The generated predicate is in the form of `UPPER (column_name) operator UPPER (:bindVariable)`. Since the left-hand side is `UPPER (column_name)`, the existing non-function-based indexes created based on `column_name` is of no use for this kind of clause, and consequently, expensive table scans can result if this view criteria item is supposed to be the driving filter. Ensure there are appropriate function indexes to support case-insensitive searches.

60.2.2.14 Avoid View Object Leaks

In general, avoid creating a view object at runtime. Instead, add the view object instance to the application module and let the framework create it for you. If you have a use case where you must call `createViewObject` to create the view object, explicitly give it a name and first check if a view object with that name already exists in the application module. If it is already there, reuse it rather than create another one. If you no longer intend to use a dynamically created view object, remove it from the application module to avoid memory leaks.

60.2.2.15 Provide a "Smart" Filter when Using LOV Combobox

When you define a Combo Box with List of Values, provide an additional view criteria using the `Filter Combo Box Using` option so that the user only sees a list of frequently used choices. It typically does not meet business needs to return something like the first 10 customers in the system.

60.2.2.16 Use Small ListRangeSize for LOVs

When you define a LOV for a view object attribute, there is a `ListRangeSize` property (visible only in source), which defaults to 10. This controls the number of values to fetch when the combo box is selected on the UI. Do not change the `ListRangeSize` to a large value. In particular, -1 should never be used as it brings back all the rows.

60.2.2.17 Avoid Reference Entity Objects when not Needed

If your view object includes reference entity objects, they are loaded via separate queries whenever the key column values are changed. Therefore, if you have a scenario where attributes from the reference entity objects are not needed, use a view object that does not include reference entity objects. An example of this is when you are programmatically inserting rows and the reference entity object attributes do not need to be shown.
60.2.2.18 Do Not Use the "All at Once" Fetch Mode in View Objects

If you select the "All at Once" view object fetch mode, the view object query returns all rows, even though you are looking at only the first row. Depending on the query, this could cause OutOfMemory errors as the result of too many rows being fetched. Use the default "As Needed" fetch mode instead.

60.2.2.19 Do Not Use the "Query List Automatically" List of Value Setting

If you use the "Query List Automatically" option in the UI hints panel in the edit LOV screen, a query is executed by default, which could be expensive. This setting impacts only whether a search is executed by default when the LOV search list displays. For LOV combo boxes, regardless of this setting, the smart filter executes when the LOV combo is clicked and the dropdown list displays.

60.2.2.20 Avoid the "CONTAINS" or "ENDSWITH" Operator for Required or Selectively Required View Criteria Items

Required or Selectively Required view criteria items should use indexes so that their queries are efficient. If you use the "CONTAINS" or the "ENDSWITH" operator on a view criteria, the indexes cannot be used efficiently, resulting in poor query performance. Use an "Equals" or "Starts With" operator instead.

60.2.3 Work with Application Modules

When working with application modules, consider the suggestions in this section for improving performance.

60.2.3.1 Enable Lazy Delivery

When the Lazy Delivery option is enabled, ADF Business Components defers the creation of view object instances and nested application modules until they are requested. For more information, see the "Data Delivery - Lazy versus Immediate" section in the Tuning Performance.

60.2.3.2 Make Application Code Passivation-Safe

An application module is an ADF Business Components container that encapsulates business service methods and an active data model for a logical unit of work related to an end-user task. It is a wrapper for view objects and entity objects in a business model, handles all database transactions, and performs custom tasks by invoking application module specific service methods. For an ADF Business Components based web application, an HTTP request related to data operation cannot be processed without involvement of an application module instance. The following figure illustrates the application module position in the Oracle ADF applications architecture.

Figure 60-6    Oracle ADF Applications Architecture — Application Module Functions
Application module state management and application module pooling are important features provided out of the box by Oracle ADF. The combination of application module state management and pooling makes ADF Business Components based web applications more scalable by multiplexing application module instances in pool to serve large volume concurrent HTTP user sessions, and more reliable (failover) by serializing pending user session state into persistent storage (Database or File system).

Passivation is the process of serializing current states of an active application module instance to persist it to make it **passive**. Activation is its reverse process to activate a **passive** application module instance.

After coding and debugging all functional issues of an ADF Business Components based application, disable application module pooling to test and verify that the application code is **passivation-safe**. Disabling application module pooling enforces the application module instance to be released at the end of each request and be immediately removed (destructed), and passivation is triggered before its removal. On subsequent requests made by the same user session, a new application module instance must be created to handle this user request. A pending state must be restored from the passivation storage to activate this application module instance.

To disable application pooling for all application module pools, add `-Djbo.ampool.doampooling=false` to the JVM options when you run your page. You can also disable application pooling for select application modules.

**To disable application pooling for select application modules:**

1. Launch Oracle JDeveloper.
2. Right-click **Application Module** and select **Configurations**.
3. Click **Edit**, and select the **Pooling and Scalability** tab, as depicted in the following figure.
4. Deselect **Enable Application Module Pooling**.

![Figure 60-7 Application Module: Configurations — Pooling and Scalability](image)

The following documents provide additional information related to subjects discussed in this section:
• For more information about application module state management, see the "Application State Management" chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.

• For more information about application module pooling, see the "Tuning Application Module Pools and Connection Pools" chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.

60.2.3.3 Avoid Passivating Read-Only View Objects

There is performance overhead associated with passivation and activation. It is important to know of cases of where not to use this feature without impacting scalability and reliability. For example, there usually is no need to passivate view objects used in validators or helper functions. Similarly, if you have View objects where none of the attribute values are used across requests, such as view objects used only in service calls, then disable passivation.

To disable passivation for a view object, uncheck the Passivate State option in the View Object Editor, as shown in the following figure.

Figure 60-8  View Object Editor — Tuning

60.2.3.4 Avoid Passivating Certain Transient Attributes of a View Object

In addition to read-only view objects, some transient values of a view object, including transient view object attribute and calculated view object attribute, are read-only or their values are derived from other attributes via getter or groovy logic. There is no need passivate them.

• A transient view object attribute is an attribute which is not mapped to a table column or SQL calculation value, but its value is provided by Accessor function code.

• A calculated view object attribute is an attribute which is not mapped to a table column but is a SQL calculation expression.

To disable passivation for a subset of view objects' transient values, deselect Include All Transient Values in the View Object Editor - Tuning section, as shown in Figure 60-8. Then check the Passivate check box only for the attributes that require passivation in the view object attribute editor.

For more information, see "Managing the State of View Objects" in the Developing Fusion Web Applications with Oracle Application Development Framework.
60.2.3.5 Maintain Application Session User Tables

By default, Oracle ADF takes care of passivating all necessary states of an application module instance, but some custom information must be addressed by application code. Some examples of custom information are:

- Private member fields in view objects, entity objects, or application modules.
- User session state cached in Application Session UserData hash table. Go through:

  ApplicationModule.getDBTransaction().getSession().getUserData()

Caution:

This is not the user session. This is the Application Module session that ties to an application module and is maintained by ADF Business Components.

It is easy to confuse an Application Module session object with an HttpSession object, which also provides a hash table to cache some session user information. The difference is the HttpSession exists at the ADF Controller layer and the state cached in it can be across HTTP requests independent of the application module instance. However, an Application Session exists at the ADF Model layer and is per application module instance, so state cached in it can not be across HTTP requests after the application module instance switching happens.

Avoid saving a lot of custom session states in HttpSession because it increases memory usage and impacts scalability. This is the exact problem that application module state management and application module pooling is expected to solve.

To handle custom session states, you need to override passivateState() and activateState() functions in your ApplicationModuleImpl class or relevant VOImpl class.

The following is sample code that shows one way from the Pathfinder Application to passivate and activate the UserLoginPrincipal object.

Note:

XML documents can only handle String. Therefore, an object must be serialized before saving.

```java
public void passivateState(Document doc, Element parent)
{
    super.passivateState(doc,parent);

    UserLoginPrincipal principal = (UserLoginPrincipal)
    ApplicationModule.getDBTransaction().getSession().getUserData().get(Constants.LOGIN_PRINCIPAL);

    ByteArrayOutputStream baos=new ByteArrayOutputStream();
    try{
        ObjectOutputStream oos = new ObjectOutputStream(baos);
        oos.writeObject(principal);
        oos.flush();
    } catch(IOException e) {}  
}
```
String strPrincipal = baos.toString();

Node node = doc.createElement(Constants.LOGIN_PRINCIPAL); // Login should easily be converted into String
Node cNode = doc.createCDATASection(Constants.LOGIN_PRINCIPAL);
cNode.setNodeValue(strPrincipal);
node.appendChild(cNode);
parent.appendChild(node);

public void activateState(Element elem) {
    super.activateState(elem);
    if (elem != null) {
        NodeList nl = elem.getElementsByTagName(Constants.LOGIN_PRINCIPAL); // no idea what tags can be used
        if (nl != null) {
            for (int i=0, length = nl.getLength(); i < length; i++) {
                Node child = nl.item(i).getFirstChild();
                if (child != null) {
                    String strPrincipal = (String)child.getNodeValue();
                    ByteArrayInputStream bais = new ByteArrayInputStream(strPrincipal.getBytes());
                    ObjectInputStream ois = null;
                    try {
                        ois = new ObjectInputStream(bais);
                        principal = (UserLoginPrincipal)ois.readObject();
                    } catch (IOException e) {
                    } catch (ClassNotFoundException e) {
                    }
                    getSession().getUserData().put(Constants.LOGIN_PRINCIPAL,principal);
                    break;
                }
            }
        }
    }
}

For more information about how to manage custom user information, see the "Application State Management" chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.

60.2.3.6 Tune the Application Module Release Level

The default release level is Managed, which implies that the application module's state is relevant and has to be preserved for this data control to span over several HTTP requests. In some cases you can programmatically set the release level to Unmanaged ("Stateless") at run time for particular pages to achieve better performance (no passivation). A classic example is the Logout page. Usually you can programmatically
release the application module with the unmanaged level when you want to signal that the user has ended a logical unit of work.

**Caution:**

When using `DCDataControl::resetState()` to set an *Unmanaged* release level, it only affects the current application module instance in the current request. For the next request, the application module instance automatically uses the default *Managed* release level again.

Setting the release level to *Reserved* makes Data Control "sticky" to an application module instance and all requests from the same `HttpServletRequest` associated with this Data Control are served by the same application module instance. This is contrary to the initiative of introducing application module state management and application module pooling, so using this release level is strongly discouraged.

**Caution:**

When the release level is changed to *Reserved* by calling `DCJboDataControl::setReleaseLevel()` with input argument `ApplicationModule.RELEASE_LEVEL_RESERVED`, it stays at this level until explicitly changed.

The following table illustrates application module release mode comparisons.
<table>
<thead>
<tr>
<th>Release Mode</th>
<th>Unmanaged (Stateless)</th>
<th>Managed (Stateful)</th>
<th>Reserved</th>
</tr>
</thead>
<tbody>
<tr>
<td>Application Module Behavior</td>
<td>Does not preserve the state of the application module instance between page-processing requests. The instance is immediately released when a JavaServer Page (JSP) page terminates. <strong>Note:</strong> Select this option when you expect many users to access your JSP application simultaneously. The stateless option allows more users to access a JSP application simultaneously at the cost of requiring the user to reconnect to a new application module instance every time a JSP page is invoked (or re-invoked).</td>
<td>Preserves the application module instance’s state in the database between page-processing requests. This permits the application to maintain a user’s data without involving a single application module instance for long periods of time. <strong>Note:</strong> Stateful mode provides failover support for the HTTP session and is the preferred choice when the application module uses a standard JDBC connection.</td>
<td>Allocates the application module instance for the duration of the browser session. The instance is released only at the end of the session. This mode is provided primarily for compatibility with certain application module definitions. Failover is not supported in this mode. <strong>Note:</strong> Reserved mode is primarily useful when the application module requires a non-standard JDBC connection definition. Failover is not supported in this mode.</td>
</tr>
<tr>
<td>Release Mode &amp; User Action</td>
<td>Unmanaged (Stateless)</td>
<td>Managed (Stateful)</td>
<td>Reserved</td>
</tr>
<tr>
<td>---------------------------</td>
<td>-----------------------</td>
<td>--------------------</td>
<td>----------</td>
</tr>
<tr>
<td><strong>DBTransaction</strong></td>
<td>Oracle ADF automatically posts and commits any changes because the application module state is not maintained between requests in stateless mode. The user is not expected to initiate the commit in stateless mode: the <strong>Commit</strong> and <strong>Rollback</strong> buttons are disabled in the JSP page.</td>
<td>Oracle ADF merely saves the application module state, including the data changes, to the database at the end of a page request. In this mode, the user is expected to initiate the commit by clicking the <strong>Commit</strong> button in the process JSP page. When the user clicks the <strong>Commit</strong> button, Oracle ADF immediately initiates a post and commit (together, as one step) on the database. Optionally, the user can click the <strong>Rollback</strong> button to prevent their changes from entering the database without ever initiating a post. Because the application module state is preserved, the user can initiate the Commit or Rollback at any point during the HTTP session.</td>
<td>Oracle ADF automatically posts any changes to the database (and initiates DML-specified database triggers on the effected tables). In this mode, the user is expected to click either the <strong>Commit</strong> button or <strong>Rollback</strong> button in the process JSP page. Because the application module itself is not released for the duration of the HTTP session, the user can initiate the Commit or Rollback at any point.</td>
</tr>
<tr>
<td><strong>Application Module Locking Behavior</strong></td>
<td>In stateless mode, the Business Components property <code>jbo.locking.mode</code> should be set to <code>optimistic</code>. Pessimistic locking is not compatible with stateless mode because the database transaction is always rolled back to allow the connection to be reused by another user. This results in the lock being released and makes pessimistic locking unusable.</td>
<td>In stateful mode, the Business Components property <code>jbo.locking.mode</code> should be set to <code>optimistic</code>. Pessimistic locking is not compatible with stateful mode because after the application module is preserved, the database transaction is rolled back to allow the connection to be reused by another user. This results in the lock being released and makes pessimistic locking unusable.</td>
<td>In release mode, you can reliably use pessimistic locking and may set the property <code>jbo.locking.mode</code> to <code>pessimistic</code>.</td>
</tr>
</tbody>
</table>
For more information about application module release level and state management, see the "Application State Management" chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.

60.2.3.7 Do Not Leave Uncommitted Database Updates Across Requests

If you make database updates during a request, using either a DBTransactionImpl.pst changes call or PLSQL, and ensure the changes are committed within the same request, or rolled back if there are errors. All exceptions must be caught and rolled back to prevent partial updates from lingering in the database.

60.2.3.8 Release Dynamically Created Root Application Modules

If you create an application module using createRootApplicationModule calls, call the releaseRootApplicationModule to avoid a memory leak. Oracle ADF internally maintains references to these application modules, so they are not freed until you release them. You must also call releaseRootApplicationModule if you call one of the *AMIImpl.getInstance calls for the various Applcore application modules.

60.2.3.9 Do Not Destroy the Application Module when Calling Configuration.releaseRootApplicationModule.

Call Configuration.releaseRootApplicationModule(am, false) instead of Configuration.releaseRootApplicationModule(am, true). If true is passed, the application module is destroyed and the next request for this application module will be expensive because it must be created. If false is passed, the application module is released back to the application module pool and the next request can simply check out the application module from the pool, thereby avoiding the creation cost.

60.2.4 Work with Services

When working with services, consider the following suggestions for improving performance.

60.2.4.1 Set the Find Criteria to Fetch Only Attributes that are Needed

By default, when you call the find service, the child service data objects are also fetched. If you do not need those children, set the find criteria to fetch only the attributes you need.

The following example is sample code showing how to create a find criteria.

```java
FindCriteria fc = (FindCriteria)DataFactory.INSTANCE.create(FindCriteria.class);
//create the view criteria item
List value = new ArrayList();
value.add(new Integer(10));
ViewCriteriaItem vci = (ViewCriteriaItem)DataFactory.INSTANCE.create(ViewCriteriaItem.class);
vci.setAttribute("Deptno");
List<ViewCriteriaItem> items = new ArrayList(1);
items.add(vci);
//create view criteria row
ViewCriteriaRow vcr = (ViewCriteriaRow)DataFactory.INSTANCE.create(ViewCriteriaRow.class);
vcr.setItem(items);
//create the view criteria
List group = new ArrayList();
```
group.add(vcr);
ViewCriteria vc = (ViewCriteria)DataFactory.INSTANCE.create(ViewCriteria.class);
vc.setGroup(group);
// set filter
fc.setFilter(vc);

List cfcl = new ArrayList();
ChildFindCriteria cfc = (ChildFindCriteria)DataFactory.INSTANCE.create(ChildFindCriteria.class);
cfc.setChildAttrName("Emp");
cfc.setFetchStart(1);
cfc.setFetchSize(1);
cfcl.add(cfc);
fcl.setChildFindCriteria(cfcl);
DeptResult dres = svc.fndDept(fc, null);
pw.println("### Dept 10 and 2nd Emp ###");

60.2.4.2 Expose Service for Frequently Used Logical Entities
If you are doing frequent fetches of a business entity that is not the top level of a business object, it is better to expose a find service for that business entity rather than expose a find service for the highest level. Otherwise, the service call must be made against the topmost level entity, incurring unnecessary cost.

60.2.4.3 Use Correct ChangeOperation when Calling a Service
When you are using the processXXX() method to insert new rows, call the processXXX() method using ChangeOperation.CREATE. Do not call the processXXX() method with ChangeOperation.MERGE because it issues extra queries to the database to check if the rows already exist.

60.2.4.4 Set Only Changed Columns on Service Data Objects for Update
When creating a list of service data objects to pass for update using the processXXX() method, set only the columns that you really need to change, if possible. Service data objects with fewer attributes that have been set are updated faster than service data objects with all the attributes set.

60.3 ADF ViewController Layer Guidelines
Follow the best practices described in this section while working with various ADF ViewController layer components, such as geometry management, page templates, and partial page refresh.

60.3.1 Work with Various ADF ViewController Components
When working with ADF ViewController components, consider the suggestions in this section for improving performance.

60.3.1.1 Minimize the Number of Application Module Data Controls
For a specific page or page fragment, try to use only one application module data control. Use nested application modules rather than a separate application module data control to minimize the number of database connections your page uses. When using a nested application module, be sure to drag the nested application module from under the root application module in the data control panel.
**Note:**
If you use nested application modules, you can not pull data from different databases.

### 60.3.1.2 Use the Visible and Rendered Attributes

All ADF Faces Rich Client display components have two properties that relate to whether the component is displayed on the page. For more information about how to use these properties, see "ADF Faces Component Attributes" in the Tuning Performance.

### 60.3.1.3 Remove Unused Items from Page Bindings

If you decide to remove an unused item, such as a column from a table, remove the corresponding item from the tree binding. If you forget to do so for an expensive computed attribute, the logic to compute the attribute still executes even after removing the computed attribute from the table. In addition, remove any unused iterator bindings from the page definition file.

### 60.3.1.4 Disable Column Stretching

Columns in the `table` and `treeTable` components can be stretched so that there is no unused space between the end of the last column and the edge of the `table` or `treeTable` component. This feature is turned off by default due to high performance impact. Turning this feature on has a performance impact on the client rendering time so it should not be used for complex tables.

### 60.3.1.5 Use Appropriate Values for Refresh and RefreshCondition

The default values of the `Refresh` and `RefreshCondition` properties of iterator binding and action binding are *deferred* and *NULL*, which means that the related action binding will be invoked only if needed. The default value is appropriate for most cases. If you select the *ifNeeded* value for the `Refresh` property, the iterator or action may get refreshed twice and impact performance. The following figure shows how the JavaServer Faces (JSF) and Oracle ADF phases integrate in the lifecycle of a page request.
In particular, the value *always* should not be used as the Refresh property for `invokeAction` bindings. Using *ifNeeded* is the best option for most cases. Note that if `invokeAction` binds to the `methodAction`, which does not accept any parameters, or to any action, then it fires twice per request. To avoid this situation, use the `RefreshCondition` attribute on `invokeAction` to control when the action needs to fire.

For more information about the Refresh property, see the *What You May Need to Know About Using the Refresh Property Correctly* section in the "Understanding the Fusion Page Lifecycle" chapter of the *Developing Fusion Web Applications with Oracle Application Development Framework*.

**60.3.1.6 Disable Estimated Row Count if Necessary**

In addition to the query used to fetch the data for display, Oracle ADF issues a count query to calculate the estimated result set size for view objects that are bound to a table on the UI. This is used to size the scroll bar and is capped at a certain threshold to avoid scanning the entire result set. If your query is expensive and this additional query results in your page not meeting your performance target, consider setting the `RowCountThreshold` setting to a negative value, to turn off the row count query.

You can consider disabling row count completely by setting `RowCountThreshold` to `-1` after extensive tuning. Then you could apply the global `RowCountThreshold` if your count query still has performance issues.

---

**Caution:**

When you disable the estimated row count, the scrolling behavior of your table is different. The user can scroll forward only one range at a time.

---

**60.3.1.7 Use HTTPSession Hash Table in Moderation**

`HTTPSession` provides a hash table to cache user information. However, all the information is saved in memory, so inappropriate use of `HTTPSession` cache causes some scalability issues, including:
- High memory usage on the server
- User information loss if the server is down
- Increased network traffic to replicate session state in a clustered environment

Putting critical, large volume information in `HttpServletRequest` cache is not recommended. Instead, you should leverage application module state management and application module pooling. See Make Application Code Passivation-Safe.

The following example shows how to use `HttpServletRequest` cache in a backing bean.

```java
((HttpServletRequest)
  (FacesContext.getCurrentInstance().getExternalContext().getRequest()))
getSession().setAttribute("UserLoginPrincipal", sessionLoginPrincipal);
```

### 60.3.1.8 Use Short Component IDs

Sometimes you must provide an ID for a UI component. For example, an ID is required for a component that is a source of a partial page refresh (PPR) event. Also, Oracle ADF generates default component IDs for certain components, such as when a task flow is added to a page as a region. (The default region ID is the first 5 characters of the task flow name plus a digit). If you have pages with a region ID that is greater than 7 characters, you should shorten the IDs of the task flow regions to 7 characters or fewer (including the digit), with 3 characters being ideal.

If IDs are specified for other naming containers (such as tables), a length of 3 or fewer is best. Using short naming for container IDs helps to reduce the size of each response, as well as network traffic, because the IDs of the parent naming containers are appended to a child's generated ID.

### 60.3.1.9 Follow UI Standards when Using Search

When using Search, follow these UI standards:

- Blind queries are not allowed.
- Use Match All instead of Match Any when there are multiple criteria.

### 60.3.1.10 Do not set Client Component Property to True

ADF Rich Client has a sparse component tree on the client. This means only required components are created on the client. The component instance is instantiated on the client if:

- Client component property is true by default. For example, as required by Oracle ADF
- Client-side event listener is registered, which you should not be using
- Due to needed client-side interaction with component, the client component property is set to true

To achieve the best performance, do not set the client component property to true.

### 60.3.1.11 Set Immediate Property to True when Appropriate

ADF Rich Client components have an immediate attribute. There are some cases where setting immediate to true can lead to better performance. For more information, see the "ADF Faces Component Attributes" section in the Tuning Performance.
60.3.1.12 Use Appropriate Content Delivery Mode for a Table or a Tree Table

By default, the data for Table, Tree and other stamped components uses the lazy data delivery mechanism. This means that page content is delivered with the first response from the server and the next request fetches the data. This option should be used when the page has enough content to be displayed and a table query may be slow. Underneath, the data fetch request uses the table streaming feature, which delivers table data to the client as soon as it is available. Also, it provides the ability to execute data fetch requests on the server in parallel, making them faster. To enable fetching data in parallel, set the RenderHint property of the iterator to background. This option could increase the number of database connections.

The other option to deliver data is immediate mode, which is set on the table. In this mode, the data is delivered with the initial page. This is better in terms of CPU and memory consumption on the server, and should be used if the table is the main context of the page.

For more information, see "Data Delivery - Lazy versus Immediate" in the Tuning Performance.

60.3.1.13 Set the Appropriate Fetch Size for a Table

Tables have a fetch size which defines the number of rows to be sent to the client in one round-trip. To get the best performance, keep this number low while still allowing enough rows to fulfill the initial table view port. This ensures the best performance while eliminating extra server requests.

In addition, consider keeping the table fetch size and iterator range size in sync. By default, the table fetch size is set to the EL expression #{$bindings.<name>.rangeSize} and should be equal to the iterator size. The iterator range size should be set to number of displayed rows + 1. In particular, for auto-height tables, set the iterator range size to the value of autoHeightRows + 1.

60.3.1.14 Avoid Frozen Columns and Header Columns if Possible

Frozen columns and header columns in the table are very expensive on the client side and should be avoided if possible. Overhead can be 20% to over 100% for a simple page with limited content when there are frozen columns. If frozen columns must be used, ensure the row height of the columns to the left and the right of the frozen column are of the same height.

60.3.1.15 Avoid Unnecessary Regions

Regions are very powerful and provide extreme flexibility. However, there is an associated cost with every region. To have the best performance, use the region only when it is needed. Generally, the Oracle ADF guideline is to not have more than 15 regions on the page.

60.3.1.16 Set the Data Control Scope to "Shared"

Set the Data Control Scope to "Shared" for a task flow to allow sharing of the data control. (This is the default). This reduces the number of database connections. There may be some cases where using Isolated is functionally necessary. For more information, see the "Sharing Data Controls Between Task Flows" section in the Developing Fusion Web Applications with Oracle Application Development Framework.

If you use the same task flow multiple times on a page, and you are using shared data control scope, by default it may not work because the data controls will show the same data. To address this, instead of switching to isolated data control scope, follow the
60.3.1.17 Select the No Save Point Option on a Task Flow when Appropriate

Select the **No Save Point** option if you do not need the functionality to roll back changes at the end of the task flow. If you do not use this option, the model state is passivate at the beginning of the task flow, which is expensive.

60.3.1.18 Use Click-To-Edit Tables when Appropriate

For tables where most rows are usually view-only and rarely edited, set the **Edit** mode property to *Click-To-Edit*. This reduces the response size significantly and improves performance.

60.3.1.19 Avoid Unnecessary Task Flow Activation for Regions Under Popups

By default, task flows that use a region under popups are activated when the page loads, not when the popup displays. This causes unnecessary memory and CPU usage if the user does not use the popup. There are two approaches for activating the task flow region only when the popup displays:

1. Set the following properties to "deferred":
   - The **childCreation** property on the popup.
   - The activation property on the task flow binding. (This is under the **Executables** section in the page definition file.)

2. Set the activation property on the task flow binding to "conditional" and specify a condition in the "active" to an EL expression that returns true when the popup displays. Usually this requires creating a view scope variable that is set using a **setPropertyListener** executed on **popupFetch**. The EL expression must return true if the popup is displayed. (A request scope variable will not work in most cases unless you cannot submit any server requests from the popup.)

Approach (1) is simpler but you must use approach (2) for the following cases:

- Any of the following tags are present inside the popup attribute:
  - `f:attribute`
  - `af:setPropertyListener`
  - `af:clientListener`
  - `af:serverListener`

- You need to refer to any child components of the popup before the popup is displayed. Setting **childCreation="deferred"** postpones the creation of any child components of the popup and you cannot refer to them until after the popup displays.

60.3.1.20 Delay Creation of Popup Child Components

This recommendation is similar to **Avoid Unnecessary Task Flow Activation for Regions Under Popups**, but is applicable to popups that do not contain regions. By default, the child components under a popup are created even when the popup is not accessed. This causes unnecessary memory and CPU usage if the user does not use the...
popup. To avoid this overhead, set the childCreation property on the popup to "deferred".

This approach cannot be used for the following cases:

- Any of the following tags are present inside the popup attribute:
  - f:attribute
  - af:setPropertyListener
  - af:clientListener
  - af:serverListener
- You need to refer to any child components of the popup before the popup is displayed. Setting childCreation="deferred" postpones the creation of any child components of the popup and you cannot refer to them until after the popup displays.

60.3.1.21 Avoid Unnecessary Task Flow Activation for Regions Under Switchers

By default, task flows that use an \texttt{af:region} under switchers are activated regardless of whether the facet displays. This causes unnecessary memory and CPU usage for the facets that do not display. To activate the task flow region only when it displays, set the 'activation' property on the task flow binding to 'conditional', under the Executables section in the page definition file. Also specify a condition in the "active" to an EL expression that returns true when the facet displays.

Typically, you may already have an EL expression to control the return value for the facetName property in the switcher. For example, if your switcher looks like this:

```xml
<af:switcher id="s1" defaultFacet="1" facetName="#{pageFlowScope.facet}">
  <f:facet name="1">af:region value="#{bindings.TF1.regionModel}" id="r1"/>
  <f:facet name="2">af:region value="#{bindings.TF2.regionModel}" id="r2"/>
</af:switcher>
```

The associated binding should have activation set to "conditional", and active set to an EL, as follows:

```xml
<taskFlow id="tTF1" taskFlowId="<some task flow>" active="#{pageFlowScope.facet=='1'}" activation="conditional" xmlns="http://xmlns.oracle.com/adf/controller/binding"/>
<taskFlow id="tTF2" taskFlowId="<some other task flow>" active="#{pageFlowScope.facet=='2'}" activation="conditional" xmlns="http://xmlns.oracle.com/adf/controller/binding"/>
```

60.3.1.22 Avoid Unnecessary Root Application Module Creation from UI-layer Code

Creating additional root application modules is expensive when you can reuse the root application module that is associated with the data bindings on your page. For example, do not access an application module instance by calling the \texttt{Configuration.createRootApplicationModule()} API from a backing bean. This results in creating additional application module instances, which are distinct from the application module instance that is automatically checked out and in by the Oracle ADF data binding layer, used by UI pages and task flow method call activities. This can lead to performance and memory issues if your backing bean calls \texttt{Configuration.createRootApplicationModule()} API without calling \texttt{releaseRootApplicationModule()}. 
Use an ADFM action binding to invoke a client interface method declaratively on an application module instead. This approach requires no code and often prevents the need for a backing bean. It also ensures that any exceptions are handled in a consistent way as if Oracle ADF had invoked the method declaratively. Also ensure that your backing bean is invoked in a context where a pageDef has been defined.

The following code excerpt is an example that follows our recommendation:

```java
private ComponentReference<RichTable> allocationTableRef;
public void setAllocationTable(RichTable allocationTable) {
    if (this.allocationTableRef == null)
        this.allocationTableRef =
            ComponentReference.newUIComponentReference(allocationTable);
}
publi RichTable getAllocationTable() {
    return allocationTableRef==null ? null : allocationTableRef.getComponent();
}
```

The following example is not recommended:

```java
private RichTable allocationTable;
publi void setAllocationTable(RichTable allocationTable) {
    this.allocationTable = allocationTable; }
publi RichTable getAllocationTable() {
    return allocationTable; }
```

60.3.1.23 Avoid Unnecessary Savepoints on Task Flow Entry

When the transaction setting of a task flow is "Always Use Existing Transaction" or "Reuse Existing Transaction if Possible", and the "No savepoint on taskflow entry" box is not checked, Oracle ADF automatically creates a savepoint when entering the taskflow. Check the box to avoid the savepoint cost if you do not have functionality to rollback to this particular savepoint.

60.3.1.24 Cache Return Values in Backing Bean Getters

The common usage of backing beans is to reference values from EL expressions. Bean getters may also be called from other places in the code, as well as being called multiple times in a request. If you have expensive computations inside the bean getter logic, consider caching the results inside the bean. This is fairly safe to do for request-scope beans unless you expect the result to change within the request. For view-scope or page flow-scope beans, be careful about when to invalidate the cached results.

60.3.1.25 Do Not Maintain References to UI Components in Managed Beans

If you maintain direct references to UI Component instances from view scope or page flow scope beans, this could cause both functional errors and impact performance. If you must maintain a reference, use the ComponentReference pattern instead.

60.3.1.26 Set childCreation Property to Delay Child Component Creation

By default, child components for showDetailItem (under panelAccordion or panelTabbed), showDetailHeader, showDetail, panelBox, and showDetailFrame are created even if the parent is not disclosed. Set the childCreation property to "lazy" or "lazyUncached" to improve performance by postponing child component creation, including activating underlying task flow regions. Note that if the child component is a taskflow region, the activation property of the taskflow executable in the page definition must be set to "deferred" for this to work.
60.3.1.27 Delay Activation of Taskflow Regions That are not Always Rendered

If the parent component of a taskflow region has an EL expression on the rendered property, set the activation property of the taskflow executable in the page definition to "conditional". Set the active property to the same EL expression as the one that controls the rendered property. This setup avoids activating the taskflow unless the region is actually rendered.

60.3.2 Enable ADF Rich Client Geometry Management

ADF Rich Client supports geometry management of the browser layout where parent components are in the UI explicitly. The children components are sized to stretch and fill up available space in the browser. While this feature makes the UI look better, it has a cost. The impact is on the client side where the browser must spend time resizing the components. The components that have geometry management by default are:

- PanelAccordion
- PanelStretchLayout
- PanelTabbed
- BreadCrums
- NavigationPane
- PanelSplitter
- Toolbar
- Toolbox
- Table
- Train

Note the following recommendations for using geometry management:

- Consider using `panelGridLayout` to flatten HTML hierarchy and improve performance when designing page layouts for non-stamped component. `panelGridLayout` uses JavaScript to accomplish page layout like PSL, but it does not have the overhead of nesting JS layout components. To avoid performance degradation, do not use PanelGridLayout in stamped components.

- Try to minimize the number of child components that are under a parent geometry managed component.

- The cost of geometry management is directly related to the complexity of child components.

- The performance cost of geometry management can be smaller, as perceived by the user, for the pages with table or other data stamped components when table data streaming is used. The client-side geometry management can be executed while the browser is waiting for the data response from the server.

60.3.3 Use Page Templates

Page templates allow you to build reusable, data-bound templates that can be used as a shell for any page. You can build one or more templates that provide structure and
consistency for other developers building web pages. The templates have both static areas on them, that cannot be changed when they are used, and dynamic areas on them, where the developer can place content specific to the page they are building. Note the following important considerations when using templates:

- Since templates are present in every application page, they must be optimized so that common performance impacts are avoided. Adding round corners to the template, for example, can impact the performance for every page.

- When building complex templates, sometimes it is easier to build them in multiple pieces and include them in the top-level template using `<f:subview>` tag. However, from a performance perspective, this is not typically recommended since it can impact memory usage on the server side. `<f:subview>` introduces another level into the ID scoping hierarchy, which results in longer IDs. Long IDs have a negative impact on performance. Avoid using `<f:subview>` unless it is required. It is not necessary to use `<f:subview>` around `<jsp:include>` if you can ensure that all IDs are unique. For example, if you are using `<jsp:include>`, break a large page into multiple pieces for easier editing. Whenever possible, avoid using `<f:subview>`. If you are including content developed by someone else, use `<f:subview>` if you do not know which IDs the developer used. In addition, you do not have to put `<f:subview>` at the top of a region definition.

### 60.3.4 Use ADF Rich Client Partial Page Rendering (PPR)

ADF Rich Client is based on Asynchronous JavaScript and XML (Ajax) development technique. Ajax is a web development technique for creating interactive web applications, where web pages feel more responsive by exchanging small amounts of data with the server behind the scenes, without the whole web page being reloaded. The effect is to improve a web page's interactivity, speed, and usability.

With ADF Faces, the feature that delivers the Ajax partial page refresh behavior is called partial page rendering (PPR). PPR enables small areas of a page to be refreshed without having to redraw the entire page. For example, an output component can display what a user has chosen or entered in an input component or a command link or button can cause another component on the page to be refreshed.

Two main Ajax patterns are implemented with partial page rendering (PPR): native component refresh and cross-component refresh. While the framework builds in native component refresh, cross-component refresh has to be done by developers in certain cases.

Cross-component refresh is implemented declaratively or programmatically by the application developer defining which components are to trigger a partial update and which other components are to act as partial listeners, and so be updated. Using cross-component refresh and implementing it correctly is one of the best ways to improve client-side response time. While designing the UI page always think about what should happen when the user clicks a command button.

Consider a typical situation in which a page includes an `af:inputText` component, an `af:commandButton` component, and an `af:outputText` component. When the user enters a value for the `af:inputText`, then clicks the `af:commandButton`, the input value is reflected in the `af:outputText`. Without PPR, clicking the `af:commandButton` triggers a full-page refresh. Using PPR, you can limit the scale of the refresh to only those components you want to refresh, in this case, the `af:outputText` component. Perform the following steps to achieve this:
• Set up the af:commandButton for partial submit by setting the partialSubmit attribute to true. Doing this causes the command component to start firing partial page requests each time it is clicked.

• Define which components are to be refreshed when the partial submit takes place. In this example, the af:outputText component, by setting the partialTriggers attribute for each of them to the id of the component, triggers the refresh. This means setting the partialTriggers attribute of the af:outputText component to give the id of the af:commandButton component.

The main reason that partial page rendering can significantly boost performance is because the full page refresh does not happen and the framework artifacts (such as ADF Rich Client JS library, and style sheets) are not reloaded and only a small part of the page is refreshed. In several cases, this means no extra data is fetched or no geometry management occurs.

The ADF Rich Client has shown that partial page rendering results in the best client-side performance. Besides the impact on the client side, server-side processing can be faster and can have better server-side throughput and scalability.

60.4 SOA Guidelines for Human Workflow and Approval Management Extensions

For best practices while working with Human Workflow and Approval Management extensions (AMX), see the Oracle Human Workflow Performance Tuning chapter in the Tuning Performance.

60.5 Oracle Fusion Middleware Extensions for Applications Guidelines

When working with application modules, consider the best practices in this section, related to using a nested service and releasing application modules returned from getInstance calls.

60.5.1 Use Profile.get to Get Profile Option Values

To get a profile option value, use

```java
oracle.apps.fnd.appcore.Profile.get(<Profile Option Name>)
```

This is optimized to first find the profile value in an internal cache, so it checks out an application module only if needed. Avoid calling ProfileServiceAM.getInstance as it checks out a ProfileService application module instance, which is expensive.

60.5.2 Release any Application Modules Returned from getInstance Calls

If you have no other option and must use getInstance to get an application module back, such as ProfileServiceAM.getInstance, you must release it to avoid a memory leak via a Configuration.releaseRootApplicationModule call, as shown in the following example.

```java
ProfileServiceAM profileService = null;

try {
    profileService = ProfileServiceAMImpl.getInstance();
    String value = profileService.getProfileValue("<ProfileOptionName>");
}```
60.5.3 Avoid Unnecessary Activation of Attachments Task Flow

When the attachments feature is used, it creates a new task flow in the page bindings, as shown in the following example:

```xml
<taskFlow id="attachmentRepositoryBrowseTaskFlow1"
  taskFlowId="#{backingBeanScope.AttachmentBean.taskFlowId}"

or:

<taskFlow id="attachmentRepositoryBrowseTaskFlow1"
  taskFlowId="/WEB-INF/oracle/apps/fnd/applcore/attachments/ui/attachments-docpicker-
  taskflow.xml"

This task flow is unnecessarily activated. To avoid this situation, navigate to the bindings tab of the page where the Attachments component was added. Select attachments task flow, attachmentRepositoryBrowseTaskFlow1, from the list of Executables. Set the following attributes in the property inspector under Common:

- activation="conditional"
- active="#{pageFlowScope.FND_ATTACHMENTS_LOAD_TF==true}"

60.5.4 Use Static APIs on Message Get Message Text

Use static APIs from oracle.apps.fnd.applcore.messages.Message to get message text. Avoid using MessageServiceAMImpl.getInstance, or calling createRootApplicationModule to get MessageServiceAM, as this results in checking out and initializing an instance of MessageServiceAM from the AM pool, which has a cost.

60.5.5 Set the Data Control Scope to Isolated for Page Level Item Nodes

If the data control scope is shared for task flows pointed to by certain item nodes, then the life span of these task flow data controls is tied to the parent, which is either Main TF or Regional TF in the UI shell. This scenario applies to those item nodes with taskType equal to "defaultMain", "dynamicMain", or "defaultRegional". This means that DC frame is not removed for the duration of the session, regardless of any navigation or closing tab. This is because the Main TF and Regional TF in the UI shell have the DC scope set to shared, due to the requirement to share CE between the regional and main areas.

If there is no requirement to share transactional data between the regional and main areas, then set dataControlScope="isolated" on the page level item node in the menu file. This recommendation assumes that the underlying task flows used in the regional area or the task menu already have data control scope set to isolated. Note that you should not change the data control scope on the task flow itself.

60.6 General Java Guidelines

When working with Java, consider these best practices in this section, related to Strings and StringBuilder, Collections, Synchronization, as well as other Java features.
60.6.1 Work with Strings and StringBuilder

When working with Strings and StringBuilder, consider the suggestions in this section for improving performance.

60.6.1.1 Use StringBuilder Rather than the String Concatenation Operator (+)

When doing String concatenations inside a loop, see if the operation can be moved outside of the loop. Frequently, the concatenation code is put inside the loop even though the value can never change there.

The String concatenation operator + involves the following:

- A new StringBuilder is created.
- The two arguments are added to it with append().
- The final result is converted back with toString().

This increases cost in both space and time, especially if you are appending more than one String. Consider using a StringBuilder directly instead.

StringBuilder was introduced in Java Development Kit (JDK) 1.5 and is more efficient than StringBuffer since the methods are not synchronized. When using StringBuilder (or StringBuffer), optimally size the StringBuilder instance based on the expected length of the elements you are appending to it. The default size of a StringBuilder is 16. When its capacity is exceeded, the JVM has to resize the StringBuilder, which is expensive. For example, instead of doing this:

```java
String key = granteeType + "::" + granteeKey;
```

Follow this example instead:

```java
String key = new StringBuilder(granteeType.length() + 1 +
    granteeKey.length()).append(granteeType).append("::").append(granteeKey)
    .toString();
```

The StringBuilder object is initialized with the correct capacity so it can hold all the appended strings it needs to resize its internal storage structure.

For the sake of simplicity, it is acceptable to do String concatenation using "+" for debug log messages, if you follow the logging standard and check the log level before constructing the log message.

Avoid unnecessary use of String.substring calls since it creates new String objects. For example, instead of doing this:

```java
if (formattedNumericValue.substring(0,1).equals("-")) negValue = true;
```

Follow this example instead:

```java
if (formattedNumericValue.charAt(0) == '-') negValue = true;
```

The hashCode method is another common place where you do String concatenation. The following example uses the hashCode implementation and requires String concatenation on every call.

```java
public int hashCode()
{
    // ...
}
```
h = new StringBuffer(len).append(resp).append(rapl).toString().hashCode();
return h;
}

The following example does not use String concatenation.

public int hashCode()
{
    ... ...
    h = 37*h + (int)(m_respID ^ (m_respID >>> 32));
    h = 37*h + (int)(m_respApplID ^ (m_respApplID >>> 32));
    return h;
}

---

**Note:**
This example was taken from the book *Effective Java*.

---

Plan carefully before deciding to concatenate Strings. There are often alternative ways to implement the intended logic without concatenation.

60.6.1.2 Check the Log Level Before Making a Logging Call

Always check the log level before make a logging call, otherwise, many objects may be constructed unnecessarily. For example, if logging is disabled, but your code still calls the logging API that passes in the log message, this concatenates several String objects together and the String concatenation is a waste of resources. The log message is constructed and passed into the logging API, and then discarded since logging is disabled. If you first check if the target log level is enabled, then the log message does not need to be created unless it is actually needed.

The amount of information that applications log depends on how the environment is configured and how the application code is instrumented. To maximize performance, do not set the logging level higher than the default INFO level logging. If the logging setting does not match the default level, reset the logging level to the default for best performance. Once the application and server logging levels are set appropriately, ensure that the debugging properties or other application level debugging flags are also set to appropriate levels or disabled. To avoid performance impacts, do not set log levels to levels that produce more diagnostic messages, including the FINE or TRACE levels.

60.6.1.3 Use Proper Logging APIs for Debug Logging

Use proper logging APIs, such as AppsLogger, instead of using System.out.println and System.err.println for debug logging. This way, log messages are properly formatted with the correct context information.

60.6.1.4 Lazy Instantiation

Avoid instantiating objects until they are needed by using lazy loading for application modules. In the Application Module tuning section, customize runtime instantiation behavior to use lazy loading. Lazy loading can also be set JVM-wide by adding the following JVM argument: -Djbo.load.components.lazily=true. For example, if you are coding a method to do String replacement, do not allocate a StringBuilder object to do the replacement until you have found a fragment that must be replaced.
60.6.2 Configure Collections

When working with collections, consider the following:

- Legacy collections (like Vector and Hashtable) are synchronized, whereas new collections (like ArrayList and HashMap) are unsynchronized, and must be wrapped via Collections.SynchronizedList or Collections.synchronizedMap if synchronization is desired. Do not use synchronized classes collections, including collections from java.util.concurrent package, that are not shared among threads.

- Do not use object collections for primitive data types. Use custom collection classes instead.

- Size a collection based on the number of elements it is intended to hold to avoid frequent reallocations and rehashing in case of hashtables or hashmaps.

For more information about collections, see "Configuring Garbage Collection" in the Tuning Performance.

60.6.3 Manage Synchronization

When working with synchronization methods, consider the following:

- Avoid synchronized methods if possible, because even with the latest versions of the JVM, there is still significant overhead.

- Bad candidates for synchronization are:
  - Read-only objects
  - Thread local objects

- Minimize the size of the synchronized block of code. For example, instead of synchronizing the entire method, it may be possible to synchronize only part of the method.

- In JDK 1.5, there is a new package, java.util.concurrent, that contains many classes designed to reduce contention. For example, java.util.concurrent.ConcurrentHashMap provides efficient read access while still maintaining synchronized write access. These new classes should be evaluated instead of simply using a Hashtable whenever synchronization is required.

60.6.4 Work with Other Java Features

When working with Java features, consider the following:

60.6.4.1 Avoid Autoboxing

Autoboxing is a feature introduced in JDK 1.5, which allows direct assignment of primitive types to the corresponding object type, such as int => Integer. Avoid using autoboxing in code that is called repeatedly, as shown in this example:

```
Integer myInteger = 1000;
```

The following example shows how the compiled code basically creates a new Integer object based on the integer value:
8: bipush 100
10: invokestatic #2;
   //Method
   java/lang/Integer.valueOf:(I)Ljava/lang/Integer;
13: astore_2

If this piece of code is called repeatedly, then each call creates one Integer object and could have adverse performance impact.

60.6.4.2 Do not use Exceptions for Code Path Execution

Exception object and snapshot of stack have to be created. This is expensive, especially for typical Oracle ADF applications, which have very deep execution stacks. For example, if your code needs to detect whether a certain object can be casted to a certain type, use instanceof instead of doing the cast and catching the exception. In other words, use instanceof instead of relying on ClassCastException.

60.6.4.3 Reuse Pattern Object for Regular Expression Matches

If using regular expression classes to match against a known pattern, create the Pattern object only once and reuse it for subsequent matches. Only the Matcher object must be created each time.

60.6.4.4 Avoid Repeated Calls to the same APIs that have Non-Trivial Costs

Avoided repeated calls to the same APIs that have non-trivial costs. Use a local variable to hold the result instead. For example, instead of:

```java
if (methodA() >= 0)
   return methodA() + methodB();
```

Use:

```java
int res = methodA();
If (res >= 0)
   return res + methodB();
```

60.6.4.5 Close Unused JDBC Statements to Avoid Memory Leaks

To avoid memory leaks, closed unused JDBC statements. The following example depicts a statement leak in java code.

```java
String s1 = "BEGIN FND_GRANTS_PKG.UPDATE_GRANT("+
   " :1, "+
   " :2, "+
   " :3, "+
   " :4, "+
   " :5);"+
   " END;";

setGrant = txn.createCallableStatement(s1,1);
setGrant.setInt(1,v);
setGrant.setString(2,guid);
setGrant.setDate(3,sd);
setGrant.setDate(4,edt);
setGrant.registerOutParameter(5,Types.VARCHAR);
setGrant.execute();

There should be a setGrant.close() call to close the statement.
```
For every call to `createStatement()`, `prepareStatement()`, `prepareCall()`, `createCallableStatement()`, or `createPreparedStatement()` there should be a `close()` to prevent memory leaks.

In the case of query execution, it is possible that the result set may be closed, but the underlying statement has not been closed, as shown in the following example.

```java
public static AppsCtxtFileInfo readAppsCtxtFile(Connection pCon,
        AppsCtxtFileInfo fileInfo, boolean update)
    {
        AppsCtxtFileInfo ret = null;
        try
        {
            String query = getReadAppsCtxtFileString(false, update);
            PreparedStatement stmt = pCon.prepareStatement(query);
            stmt.setString(1, fileInfo.getNodeName());
            stmt.setString(2, fileInfo.getPath());
            ResultSet rs = stmt.executeQuery();

            if (rs.next())
            {
                ret = getAppsCtxtFileInfoFromResultSet(rs);
            }
            rs.close();
        }
        catch(SQLException e)
        {
            Logger.println(e, Logger.DEV_LEVEL);
            if (update)
            {
                if (e.getErrorCode()== ROW_LOCKED_ERROR_CODE )
                    throw new RowLockedException();
            }
            else
                throw e;
        }
        return ret;
    }
```

In this case, the result set is being closed via `rs.close()`. However, the statement (stmt) has not been closed. For every statement opened, close it in the final block of a `try-catch`, as shown in the following example.

```java
try
{
    ...
    <open the statement>
    <process the statement>
    ...
} catch
{
    ...
    <process any exceptions>
    ...
}
finally {
...
try {
  <close the statement>
}
catch {
  <process any exceptions>
}
...
}

Make sure to catch exceptions around something like `stmt.execute()`.  

60.6.4.6 Use registerOutParameter to Specify Bind Types and Precisions  

In Java files, whenever a callable statement is fired, such as in a begin-end block, the out bind types and precision have to be specified. This is done after creating the callable statement but before the query is executed. The method call to specify the type is called `registerOutParameter()`. This call should exist for every out bind in the callable statement regardless of its return type. There are two overloaded versions of this method call that can be used:

```
registerOutParameter(int paramIndex, int sqlType, int scale, int maxLength)
registerOutParameter(int paramIndex, int sqlType)
```

60.6.4.7 Avoid JDBC Connection Leaks  

If you are getting a connection directly from Data Source or through `ApplSessionUtil.getConnection`, ensure you release the connection in a final block.

60.7 Cache Data  

Caching is one of the most common approaches for improving the performance of accessing commonly used data. Shared application modules and view objects provide a mechanism for storing database results and other objects, such as in-memory ADF Business Components objects for repeated usage. This minimizes expensive object initializations and database round-trips, which ultimately results in improved application performance.

60.7.1 Identifying Data to Cache  

It is important to correctly identify the best data to cache. Generally, this is the data that is common to different users, frequently used and infrequently changed, expensive to retrieve from the database or data source, and expensive to create. Data suitable for caching should have some or all of the following characteristics:

- **Shared Objects**: Data that is common across users is more appropriate than user specific data.
- **Long-Lived**: Data that is long-lived is more appropriate than short-lived data that is valid only for a user request.
• **Expensive to Retrieve**: Objects that take a long time to retrieve, such as objects that are obtained from expensive SQL queries, are good candidates.

• **Expensive to Create**: Objects that are frequently created or take a long time to create are appropriate. Frequent creation can be avoided by caching the instances.

• **Frequent Use**: Objects that have a high probability of being frequently used are appropriate. Caching objects that are not actively used needlessly occupy JVM memory.

• **Infrequently Changed**: The cached data is invalidated and removed from cache whenever it is changed, which makes caching frequently changed data more costly.

Lookup codes are an example of data that meets most of the above criteria.

### 60.7.2 How to Add Data to Cache

Cached objects are stored in view objects, which are added to an application module. This application module is configured as shared at the application level so that the cached objects are available to all users. To stripe cached data, view criteria with bind parameters are used. For example, a view accessor on top of a shared `DeptVO` with a view criteria such as `location=:bindLocation` results in one cache for each distinct value of `:bindLocation`.

Perform the following steps to add data to cache:

1. Create a view object or identify an existing view object to store the cached data.

2. (Optional) Create commonly used view criteria for the shared view object.

3. (Optional) Configure the shared view object's property, such as time to live, and so on.

4. Create one application module for each product that contains all the view objects to store the cached data.

5. Cache a short list of data by pre-loading all the data into memory. This prevents subsequent queries requiring additional database trips. To do this, generate the `VOImpl` class for the shared view object and override the `create()` function of `VOImpl` to fully populate the view object cache, as shown in the following example.

```java
protected void create()
{
    super.create();
    setRangeSize(-1);
    executeQuery();
    getAllRowsInRange();
}
```

**Note:**

This step is optional as there may be caches, such as profile cache, that you would want to populate lazily.
For information about how to create a shared application module, see the "Sharing Application Module View Instances" chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.

60.7.3 How to Cache Multi-Language Support Data

In addition to the instructions provided in How to Add Data to Cache, you must also perform the following steps to cache multi-language support (MLS) data. These steps are required because the shared application module and view object cache only stripes data by bind parameters. Therefore, you must build your MLS view objects for caching differently than other normal MLS view objects. For example, you must add bind parameters to the MLS cache view objects.

60.7.3.1 Create ADF Business Components Objects for Shared MLS Data

The procedure for creating ADF Business Components objects for shared MLS data varies depending on where the shared data requirement exists. The steps you follow are different for sharing data from the base table, from the translatable, or _TL, table or from both the base and the _TL table.

60.7.3.1.1 How to create objects if only the data from the base table must be shared

1. Create an entity object on top of the base table if you need the change notification feature. This means that your data in cache is refreshed when there is a change in the underlying table. This is required because the database change notification feature doesn't work against database views.

2. Create a view object on top of the _VL entity object if you do not require change notification. Otherwise, create a view object on top of the entity object created from the previous step.

3. Exclude all language dependent attributes from the _VL entity object.

60.7.3.1.2 How to create objects if only the data from the _TL table must be shared

1. Create the entity object on top of the _TL table. This is required by MLS Framework. For more information, see Understanding Multi-Language Support Features.

2. Create a view object on top of the _TL entity object.

3. Create commonly used view criteria, with language being part of the criteria using a bind variable.

Caution:
The language must always be part of any view criteria. This is very important.

60.7.3.1.3 How to create objects if both the data from the base table and the _TL table must be shared

1. Create the entity object on top of the _TL table.

This is required by MLS Framework. For more information, see Understanding Multi-Language Support Features.
2. Create an entity object on top of the base table if you need the change notification feature. This means that your data in cache is refreshed when there is a change in the underlying table. This is required because the database change notification feature does not work against database views.

If you do not need the change notification feature, then you can use the existing _VL entity object, which should have been created already because it is required by MLS Framework.

3. Create a view object to join the entity object created in the previous step (either a _VL entity object or an entity object based on the base table) and the _TL entity object. The view object should have all the language dependent attributes from the _VL entity object excluded, which allows the language dependent attribute to always come from the _TL entity object.

   **Tip:**
   This is important as it allows different users to see data for their language.

4. Create commonly used view criteria, with language being part of the criteria using a bind variable.

   **Caution:**
   The language must always be part of any view criteria. This is very important.

### 60.7.3.2 Create ADF Business Components Objects that Join to MLS tables

The procedure for creating ADF Business Components objects that join to MLS tables varies depending on where the data requirement exists. The steps you follow are different if the data is from the base table, from the translatable, or _TL, table, or from both the base and the _TL table.

#### 60.7.3.2.1 How to create objects if only the data from the base table is required

1. Create an entity object on top of the base table if you need the change notification feature. This means that your data in cache is refreshed when there is a change in the underlying table. This is required because the database change notification feature does not work against database views.

2. Create a view object that joins to the _VL entity object if you do not need the change notification feature, or create one that joins to the entity object created in previous step if change notification feature is required.

3. Exclude all the language dependent attributes from the _VL entity object.

#### 60.7.3.2.2 How to create objects if only data from the _TL table is required

1. Create a view object that joins to the _TL entity object.

2. Create view criteria with language being part of the criteria using a bind variable.

   **Caution:**
   The language must always be part of any view criteria. This is very important.
60.7.3.2.3 How to create objects if data from both the base table and the _TL table is required

1. Create an entity object on top of the base table if you need the change notification feature. This means that your data in cache is refreshed when there is a change in the underlying table. This is required because the database change notification feature does not work against database views.

2. Create a view object that joins to the _VL entity object or the entity object created in the previous step, and the _TL entity object.

3. Exclude all the language dependent attributes from the _VL entity object so that the language dependent attributes always come from the _TL entity object.

   **Tip:**
   This is important as it allows different users to see data for their language.

4. Create commonly used view criteria, with language being part of the criteria using a bind variable.

**Caution:**
The language must always be part of any view criteria. This is very important.

60.7.4 How to Consume Cached Data

The most common approach for accessing the shared data is to create a view accessor. You can also instantiate a shared application module programmatically, if required.

60.7.4.1 Consume Shared Data Using a View Accessor

Follow these steps to consume shared data using a view accessor:

1. Identify the shared application module that contains the shared data.

2. (Optional) Create view accessors on top of a shared view object.

   If the shared view object contains language specific attributes, make sure to include a view criteria that filters by language and bind the language to the current session language when defining your view accessor.

3. (Optional) Build validators on top of the view accessors that you created in Step 2.

   This allows defaulting and derivation, and other business logic to use these view accessors.

4. (Optional) Use the shared view object instead of using entity object as the validation target type for the key exist validator that validates shared data.

   **Tip:**
   If you use entity object target type, it does not use application-level cache.

For information about how to create view accessors, see the Accessing View Instances of the Shared Service section of the "Sharing Application Module View Instances" chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.
60.7.4.2 Create a shared application module programmatically

If you have an existing local application module, use the findOrCreateSharedApplicationModule method to create a shared application module. If you do not have a handle to an existing local application module, then use createRootApplicationModuleHandle from the oracle.jbo.client.Configuration class. Ensure that you release the application module after you are done, for example:

```java
ApplicationModuleHandle handle = Configuration.createRootApplicationModuleHandle("mypkg.AppModule", "AppModuleShared");
ApplicationModule sharedAM = handle.useApplicationModule();
...
Configuration.releaseRootApplicationModuleHandle(handle, false);
```

If you rely upon the database change notification feature to refresh your shared AM cache, then you also need to manually invoke the processChangeNotification method on the shared AM to get the latest data.

For more information, see the "Sharing Application Module View Instances" chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.

60.7.5 What Happens at Runtime: When Another Service Accesses the Shared Application Module Cache

During runtime, only one instance of a shared application module is created in the application module pool. If there is an existing application module in the pool, then the existing application module instance is returned when you request a shared application module. For more information, see the "What Happens at Runtime: When Another Service Accesses the Shared Application Module Cache" section in the Developing Fusion Web Applications with Oracle Application Development Framework.

60.8 Profile and Trace Oracle Fusion Applications

To monitor performance in Oracle Fusion Applications you can use the JDeveloper Profiler and capture SQL Trace for Oracle Fusion Applications. For detailed information about monitoring and debugging techniques, see the "Monitoring Oracle Fusion Middleware" chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.

60.8.1 How to Profile Oracle Fusion Applications with JDeveloper Profiler

The JDeveloper Profiler is used to provide information about the CPU, elapsed time, and memory metrics, as well as call counts. It can be very helpful when you are dealing with a performance issue or just trying to understand the performance characteristics of your code.

For more information about JDeveloper Profiler, consult the JDeveloper Help documentation.

Useful profiling modes are:

- **Sample CPU time with Collect Elapsed Time**: Using this mode, you can find the methods using the most CPU. The Collect Elapsed Time option also shows the method taking the most time, including time spent in the database. This mode has low overhead and does not significantly slow down the application.
If you find a method with a high elapsed time but low CPU time and that method includes a database call, this could indicate either a slow query or too many database roundtrips between the database and the middle-tier over a slow network. Look for methods with the highest exclusive CPU (sort on the CPUx field), and use the stack trace to determine where they are called from and if they can be optimized.

- **Memory Profiling**: Using this mode, you can find out how much memory is allocated during the test.
- **Call Count Profiling**: This is part of the CPU profiler and can be used to find out how many times each method is called.

**Caution:**

Call count profiling has very high overhead and therefore, you should increase Oracle JDeveloper starting memory before using it.

To reduce resource consumption, set appropriate filters to include only the classes you are interested in.

### 60.9 Set up a Debug Breakpoint

If you are interested in where a certain method is called, you can set a breakpoint on that method and capture the stack trace. You can do this either interactively or preferably, you can set up a debug breakpoint at the target line and print the stack automatically.

**To set up a debug breakpoint at the target line:**

1. Highlight your breakpoint in the Breakpoints page.
2. Click **Edit** and select the **Actions** tab.
3. Deselect the **Halt Execution** option and select the **Log Breakpoint Occurrence** and the **Stack** option. Selecting the **Stack** option gives you the stack trace, as shown in the following figure.
Each time the breakpoint is hit, the stack is written to the console. To capture this, you must log the console output to a file.

**To log the console output to a file:**

1. Go to **Tools, Preferences** and select the **Environment: Log** category.

2. Select the **Save Logs to File** option and specify the Log directory, as shown in the following figure.

**Figure 60-12 Preferences — Environment: Log**

After running your project, you can find the console logged to a file in the specified directory.
This chapter describes the process of debugging your Oracle Application Development Framework (Oracle ADF) and Oracle SOA Suite applications. It describes how to diagnose and correct errors and how to use the debugging tools.

This chapter includes the following sections:

- Introduction to Debugging and Collecting Diagnostics
- Diagnosing Problems
- Debugging in JDeveloper
- Troubleshooting
- Testing and Troubleshooting

### 61.1 Introduction to Debugging Oracle ADF and Oracle SOA Suite

Debugging Oracle Application Development Framework (Oracle ADF) is a process of collecting and isolating factors that contribute to problems that occur when the web page components interact with the ADF Model layer.

You can use diagnostics tools for collecting contextual information for isolating the problem. One of the most useful diagnostic tools is the ADF Logger. You use this logging mechanism in JDeveloper to capture runtime traces messages. With Oracle ADF logging enabled, JDeveloper displays the application trace in the Message Log window. The trace includes runtime messages that may help you to quickly identify the origin of an application error. Another useful diagnostic tool is SQL trace, which enables tracing of the current database session and logs all SQL statements to a server-side trace file.

Once you have gathered the diagnostic information, you can use the JDeveloper debugging tools to investigate where your application failure occurs. These include the JDeveloper Debugger, which is a comprehensive debugger to assess and repair your code, and the ADF Declarative Debugger for declaratively setting breakpoints on ADF task flow activities, page definition executables, method, action, and value bindings, and Oracle ADF lifecycle phases.

Oracle SOA Suite provides a complete set of service infrastructure components for designing, deploying, and managing composite applications. Test cases enable you to simulate the interaction between a SOA composite application and its web service partners before deployment in a production environment. This helps to ensure that a process interacts with web service partners as expected by the time it is ready for deployment to a production environment.
61.2 Collecting Diagnostics

Collecting diagnostics information helps you to obtain more contextual information for isolating the problem.

61.2.1 How to Collect Diagnostics in the Integrated WebLogic Server Environment

In the Integrated WebLogic Server environment, you can maximize the availability of diagnostics information by:

- Enabling diagnostic logging in the development environment
- Enabling database tracing

61.2.1.1 Enabling Diagnostic Logging in the Development Environment

You can also enable logging in the development environment by setting the Java system property named `jbo.debugoutput` to the value `console`.

**Related Links**

The following document provides more information about the topic discussed in this section:

- For more information, see the "How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers" section in *Developing Fusion Web Applications with Oracle Application Development Framework*.

61.2.1.2 Enabling Database Tracing in Integrated WebLogic Server Instances

Database tracing can be a very useful way of verifying whether the queries executed by ADF Business Components are actually returning any data. The ADF Business Components tracing output (`-Djbo.debugoutput=console`) lists the query and the bind variable, but it is not always clear how many rows are fetched or how the fetching takes place, that is, in batches or one row at a time. If you are investigating a suspected bug or performance issue in ADF Business Components, it is always good to have the database trace to help understand the problem.

Database tracing is usually used for performance tuning. You should know how to generate a SQL trace, find the query you are interested in, check the bind variables, and tell how many rows were returned. It is usually the quickest way of telling whether missing data in your application is a middle tier application bug, or missing data in the database. It is also useful when you are investigating ORA errors being returned from the database.

You should consider the following with database tracing:

- When you test using Integrated WebLogic Server with Oracle WebLogic Server data sources, the database connection is obtained from `fusion_apps_wls.properties` and not from `connections.xml`. However, when you use the application module tester to run an application module, the connection details from `connections.xml` are used, even when you set your application module configuration to use an Oracle WebLogic Server data source. Since the application module tester does not use Oracle WebLogic Server, it builds a database connection from the information in `connections.xml`.

- If you change the database details in `fusion_apps_wls.properties`, the updates are not picked up until the Oracle WebLogic Server domain is re-created.
Shutting down the Integrated WebLogic Server instance is not enough. The domain for the Integrated WebLogic Server is automatically created when you launch the Integrated WebLogic Server instance for the first time in a new Oracle Fusion Applications ADE view, or re-created the next time you run the Integrated WebLogic Server instance after deleting the domain directory. If in doubt, you can view the ApplicationDBDS JDBC data source in the Oracle WebLogic Server Administration Console to see what database it is pointing to. You can change the database in the Oracle WebLogic Server Administration Console to point to the new database, but the next time the domain is re-created it will be set to the connection defined in fusion_apps_wls.properties.

- When you try to examine data from a SQL*Plus session for views based on translated data, check that `select userenv('lang') from dual; returns US`. If it does not, change the language with:
  ```sql
  alter session set nls_language='American';
  ```
  If you do not do this, some of the translated view will not return any data. For example, if you are based in the United Kingdom, `select userenv('lang')` may return `GB` by default, which does not match any of the data in the TL tables. This is particularly important in the development environment where only the US messages are available.

- There may be other security restrictions that prevent you from viewing certain data from a SQL*Plus session, such as data that is protected by virtual private database (VPD) or data that requires you to initialize your `userenv`.

- You may receive ORA-600 errors, which typically manifest themselves as ORA-3114 or ORA-3113 on the client and indicate that the database session has terminated abnormally. In this case, a trace file is always created automatically, and the database alert log is updated with a record of the failure and the name of the trace file. You do not need to enable SQL trace in this case because the trace file is always created and should include a full dump, which will help database Support and Development diagnose the cause. Both the alert log and the trace file will be in the database User Directory.

You can also enable Oracle ADF tracing. For information, see the "Use SQL Tracing to Identify Ill-Performing Queries" section in Developing Fusion Web Applications with Oracle Application Development Framework.

### 61.2.2 How to Collect Diagnostics in the Standalone WebLogic Server Environment

In the standalone WebLogic Server environment, you can maximize the availability of diagnostics information by:

- Enabling diagnostic logging
- Adding debug messages to your code
- Enabling database tracing

#### 61.2.2.1 Enable Diagnostic Logging in the Provisioned Environment

Use logging profile options to enable diagnostic logging in the provisioned environment so you can view your log statements in the directory configured against your apps-handler.

```
${domain.home}/servers/${weblogic.Name}/logs/apps/${weblogic.Name}-diagnostic-log
```
To enable diagnostic logging in the provisioned environment:

1. Get the user GUID for which you want to enable JBO logging. You can obtain the user GUID from the `WLS_Users_and_Groups.ldift` file by searching for "uid=". The string for `orclguid` is the user GUID.

2. Add the following logging profile options for the required user:
   - AFLOG_ENABLED USER Y to enable logging for the user.
   - AFLOG_LEVEL USER 300 to set the level to the lowest severity (FINEST) for the user.
   - AFLOG_MODULE USER % to enable logging for all modules for the user.

   For information on setting the profile options for logging, see Defining Profiles.

3. Make sure your `logging.xml` has the `oracle.apps` logger configured against a handler. In your standalone server, `logging.xml` is located in the standalone domain at `<.....> / domains/fusion_domain/config/fmwconfig/servers/AdminServer/logging.xml`.

   The following logger should exist in `logging.xml`:
   ```xml
   <logger name='oracle.apps' level='ALL'
       useParentHandlers='false'>
       <handler name='apps-handler'/>
   </logger>
   ```

   The handler `apps-handler` should also exist in the handlers section.

### 61.2.2.2 Adding Debug Messages to Your Code

To help you investigate problems in the standalone WebLogic Server instance, you can add debug messages to your code so that messages, such as `System.out.println()`, which are normally displayed on the Java console, are written to the server log file (`AdminServer.log`) in the default domain.

Since the log file may get rather large, particularly if more than one user is using the environment, you may want to prefix your messages with an identifier that you can easily find through a search.

Log in to the Environment Management System (EMS) WebLogic Server host using the Applmgr username and password. The default password is the username in uppercase letters, but your family environment owner may have changed it, so check with them if necessary. The server log should be in the Applmgr home directory. To locate other log files, use the `find . -name "*.log"` command.

### 61.2.2.3 Enabling Database Tracing in Standalone WebLogic Server Instances

Enabling database tracing allows the standalone WebLogic Server instance to write all your actions to an associated trace file. When an internal error is detected by a process, it dumps information about the error to its corresponding trace file.

#### 61.2.2.3.1 Enable Database Tracing

Enable database tracing before you start your test flow.
To enable database tracing:

1. Sign in to the Oracle Fusion application with a user account that is provisioned with the necessary role, such as the predefined Application Implementation Consultant role. Contact your security administrator for details.

2. From the Help menu in the work area of the Oracle Fusion application, choose Troubleshooting and select Troubleshooting Options.

3. In the Options dialog, select the Database trace checkbox.

   This option enables SQL trace for all database connections used by the current user session.

   You can also select options to enable the SQL trace option to capture bind variables and wait events.

61.2.2.3.2 Locate Your Trace File

The trace file can be found in the USER_DUMP_DEST directory specified by the user_dump_dest init.ora parameter, which is usually ORACLE_HOME/log/diag/rdbms/sid/sidtrace. The trace filename includes the FND session ID appended to the end, for example, mysid ora 4473 881497BF7770BEEE040E40A0D807BB1.trc. You must identify the session ID to locate your trace file.

Note:

From SQL*Plus, you can execute SQL> show parameter user to show user_dump_dest. An operation system login is required to access this directory.

To identify the session ID in Mozilla Firefox:

1. From the Tools menu in Firefox, choose Options, then select the Privacy panel.

2. From the Firefox will list, select Use custom settings for history, then click Show Cookies.

3. In the Search field, enter Oracle, then look for a cookie that contains FND_SESSION in the name.

4. Inspect the value of the cookie, for example, DEFAULT_PILLAR: BsdhOZScx9NeAA...:12490558567373.

   Note the middle portion (using : as separator), for example, BsdhOZScx9NeAA...

5. Open a SQL*Plus session (log in as fusion user) and locate your Applications Core session ID by executing:

   select session_id from fnd_sessions where session_cookie = value from Step 4

   For example,

   select session_id from fnd_sessions where session_cookie = 'BsdhOZScx9NeAA...'

   The value returned if your session ID, which you can use to locate your trace file.
61.3 Diagnosing Problems

In addition to reviewing the diagnostics information, you can perform various tasks to diagnose problems in your server environment.

61.3.1 How to Diagnose Problems in the Integrated WebLogic Server Environment

Perform the following tasks to diagnose problems in the Integrated WebLogic Server environment:

61.3.1.1 Test the JDBC Data Source Connections

While you are diagnosing problems in the Integrated WebLogic Server environment, you may want to verify that the JDBC data source connections are pointing to the correct database connection string.

To test the connections:

1. From the JDeveloper menu, select Run, then Start Server Instance.
2. Select Application Server Navigator from the View menu.
3. Expand the Application Servers folder, then right-click IntegratedWebLogicServer, and select Launch WebLogic Console.
4. Log in to the Integrated WebLogic Server console using the username and password weblogic and weblogic1.
5. In the Domain Structure tree of the Oracle WebLogic Server Administration Console, navigate to Services, then JDBC, then Data Sources.
6. From the list of configured data sources, select each data source and click the Test button to make sure that the specified database can be reached with the connection information.

61.3.1.2 Viewing the Application Module Pooling Statistics

When running on Integrated WebLogic Server, you can view the application module pooling statistics to verify that the domain is properly configured for Oracle ADF.

To view the application module pooling statistics:

2. Log in as an administrator.
3. Click the ampool metric.
4. Scroll your browser to the right to view all the statistics.

61.3.1.3 Sanity Checking Your EAR File in the Integrated WebLogic Server Environment

Sanity checking your EAR file helps to diagnose problems in the Integrated WebLogic Server environment. Download the EAR file and open it using a decompression utility. You can then drill down into the WAR file and individual Oracle ADF libraries.

While sanity checking your EAR file, verify the following:
• The UI libraries are in the `WEB-INF/lib` directory of the WAR file.
• The Model libraries are in the `APP-INF/lib` directory of the EAR file.
• The service middle tier JAR and the service WAR files are directly under the EAR file.
• The service common JAR file is directly under the EAR file or under the `APP-INF/lib` directory, depending on how it was set up.
• The individual Oracle ADF libraries only contain components from the project that was deployed to create the Oracle ADF library, and do not contain any components from referenced projects. (This could happen if you have "build output" dependencies.) If components from other projects were included, it should be obvious from the package, since every project has a unique default package.
• All standalone components (that is, those not in an Oracle ADF library) in the WAR file belong to the UI project that was deployed (such as SuperWeb for Oracle Fusion Applications). There should therefore be no standalone model components in the WAR file.
• None of the Model and Service Oracle ADF libraries have a `public_html` directory.
• No technology JAR files are included in the EAR and WAR files. Tech stack JAR files added to the WAR or EAR file take precedence over the ones in the shared libraries, but the shared libraries contain the correct versions. The technology JAR files in your EAR or WAR file may not be the correct versions.

61.3.2 How to Diagnose Problems in the Standalone WebLogic Server Environment

Perform the following tasks to diagnose problems in the standalone WebLogic Server environment:

• Sanity check your enterprise archive (EAR) file
• Examine the Oracle WebLogic Server classloaders

61.3.2.1 Sanity Checking Your EAR File in the Standalone WebLogic Server Environment

The procedure for sanity checking your EAR file in the standalone WebLogic Server environment is the same as the procedure for Integrated WebLogic Server. For information, see Sanity Checking Your EAR File in the Integrated WebLogic Server Environment.

61.3.2.2 Examining the Oracle WebLogic Server Classloaders

Using a tool called CATX (Classloader Analysis Tool), you can diagnose problems in the standalone WebLogic Server environment by examining the JAR files and loaded classes when your application is running from Oracle WebLogic Server.

CATX is a web application that is deployed by default to every Oracle Fusion Applications Oracle WebLogic Server domain. To launch CATX, run `http://host:port/catx/`. 
With CATX, you can identify a duplicate class by determining from which JAR file a class file was loaded. You can also identify any other locations where the class is duplicated in the J2EE application classpath or web application classpath.

As an alternative to CATX, you can add the following code to your custom classes to display in the console the JAR file from which the class was loaded:

```
File moduleFile = new File
(YOURCLASSHERE.class.getProtectionDomain().getCodeSource().getLocation().
toURI());
System.out.println("Jar file name = " + moduleFile.fullPath());
```

This method may be useful if you are actively debugging code from JDeveloper or using the AM Tester.

### 61.4 Debug in JDeveloper

The following debugging tools are available for debugging in JDeveloper:

- JDeveloper Debugger.
  
  For information, see the JDeveloper online help.

- ADF Declarative Debugger.

**Related Links**

The following document provides more information about the topic discussed in this section:

- For information, see the "Using the ADF Declarative Debugger" section in *Developing Fusion Web Applications with Oracle Application Development Framework*.

### 61.4.1 How to Debug an Application Remotely

Use JDeveloper to perform remote debugging for your application.

Oracle WebLogic Server logs and Fusion Middleware ODL (Oracle Diagnostic Logging) logs are located in the following directory:

```
 JDEV_USER_HOME/system11.1.1.32.52.37/DefaultDomain/servers/DefaultServer/logs/
```

**To perform remote debugging of your application:**

1. `setenv debugFlag true`
2. Start Oracle WebLogic Server.
3. Using JDeveloper, go to Application Navigator and select your ViewController project.
4. Select Run, Choose Active Run Configuration, Manage Run Configurations.
5. Select New and enter a name for the new profile. For example, Remote Debug.
6. Click OK.
7. Edit the new Remote Debug profile by entering the following information:
   - a. Add a default Run Target. For example:
b. Select the remote Debugging and Profiling option.

c. Go to Debugger, Remote. Enter the following information:
   Protocol: Attach to (Java Platform Debugger Architecture (JPDA))
   Host: Enter the host where Oracle WebLogic Server is running.
   Port: Enter the Java Debugger Wire Protocol (JDWP) port number.

   The Java Virtual Machine (JVM) is listening for JDPA requests. The default port is 8453. Use the `setenv DEBUG_PORT new port number` command to change the port number.

**Note:**
Alternatively, you can create a profile by selecting your ViewController project, right-click and select Project Properties, Run/Debug/Profile.

8. On the toolbar, click the Bug icon. Select the new Remote Debug profile. A dialog appears to confirm attaching to the Administration Server.

   The debugging log file will contain an entry similar to the following:

   Debugger attempting to connect to remote process at ab6052cdef.us.example.com
   8453. Debugger connected to remote process at ab6052cdef.us.example.com
   8453. Processing 10008 classes that have already been prepared...Finished processing prepared classes. Debugger process virtual machine is Java HotSpot(TM) Server VM.

   Set your break points and initiate your program. When you have finished, click the red Stop button, and a dialog will appear asking if you want to Detach, Terminate, or Cancel. Detach detaches from the remote Oracle WebLogic Server, and Terminate terminates the remote Oracle WebLogic Server.

   **Tip:**
   Only one developer can debug at a given time on a specific port.

### 61.5 Troubleshooting Oracle ADF

This section describes common problems that you might encounter when using Oracle ADF with Oracle Fusion Applications and explains how to solve them.

#### 61.5.1 Problems and Solutions

The following are common problems you may encounter and solutions that solve them:

- "Too many files" Error Occurs on Local Linux Servers
- Compilation Error Occurs
- "No def found" or "No class def found" Exception Occurs
- Breakpoints Are Not Functioning Correctly
- Empty List in the Data Controls Panel
• Runtime Error Related to DataBindings.cpx File
• "Application module not found" Errors Related to DataBindings.cpx File
• Hot Reloading Does Not Work
• Missing ADF Component at Runtime in
• Odd ADF Component Errors
• is Not Responding
• Missing Base Class
• Unavailable FND Components
• JavaServer Pages Compilation Errors
• ApplicationDB Errors While Running the Integrated WebLogic Server
• Metadata Services Runtime Exception
• Application Cannot Fetch Data from Database
• "The task cannot be processed further" Message Appears
• TimedOut Exception Occurs

61.5.1.1 "Too many files" Error Occurs on Local Linux Servers
You receive an error that indicates that too many files are open.

Problem
The open file limit on local Linux servers has been exceeded.

Solution
Increase the open file limit.
For information, see Increasing Open File Limit on Linux Machines.

61.5.1.2 Compilation Error Occurs
You encounter a compilation error.

Problem
A reference to an Oracle ADF business component or Java class in an Oracle ADF library cannot be resolved, such that it does not exist or is incompatible with the existing reference.

Solution
All references to components contained in Oracle ADF libraries are resolved when the workspace is loaded in JDeveloper. Refresh the library in one of the following ways:

• Close the workspace and re-open it to refresh the references to the Oracle ADF libraries. (Closing and restarting JDeveloper with a workspace open does not refresh the references to the Oracle ADF libraries.)

• If you have a specific project selected in the JDeveloper navigator pane, select View, then Refresh ADF Library Dependencies for ....jpr to refresh the references to the Oracle ADF libraries.
When you make any changes to the components in a project, where the components are being referenced as an Oracle ADF library by your user interface (UI) project, you must redeploy the Oracle ADF library and refresh the Oracle ADF library dependencies for your UI project. The same applies to one model project referencing from another model project. If you are developing or debugging code in a model project while running the referencing UI project to test it, it may be easier to add the model project as a build output dependency, so you do not need to go through the cycle of redeploying the Oracle ADF library or refreshing the Oracle ADF library references each time you make a change.

61.5.1.3 "No def found" or "No class def found" Exception Occurs

Either a *No Def Found* or *No Class Def Found* runtime exception occurs.

**Problem**

Lower level dependency changes were made outside of the design time session.

**Solution**

Refresh the library in one of the following ways:

- Close the workspace and re-open it to refresh the references to the Oracle ADF libraries. (Closing and restarting JDeveloper with a workspace open does not refresh the references to the Oracle ADF libraries.)
- If you have a specific project selected in the JDeveloper navigator pane, select *View*, then *Refresh ADF Library Dependencies for ....jpr* to refresh the references to the Oracle ADF libraries.

**Note:**

When you make any changes to the components in a project, where the components are being referenced as an Oracle ADF library by your user interface (UI) project, you must redeploy the Oracle ADF library and refresh the Oracle ADF library dependencies for your UI project. The same applies to one model project referencing from another model project. If you are developing or debugging code in a model project while running the referencing UI project to test it, it may be easier to add the model project as a build output dependency, so you do not need to go through the cycle of redeploying the Oracle ADF library or refreshing the Oracle ADF library references each time you make a change.

61.5.1.4 Breakpoints Are Not Functioning Correctly

Execution stops before or after the line with the breakpoint, depending on whether you have added or removed lines of code from the source.

**Problem**

If you consume the components from another project in the same workspace and run in debug mode, you can open the source Java classes from the referenced project in the JDeveloper edit window and set breakpoints. However, if you consume the components at runtime through an Oracle ADF library, the compiled objects from the
Oracle ADF library may not be synchronized with the source if you made changes since you last deployed the Oracle ADF library. If you are using a build output dependency, then you are not affected by this issue.

**Solution**

Redeploy the Oracle ADF library to synchronize the source code.

61.5.1.5 Empty List in the Data Controls Panel

The Applications Core wizards display an empty list of data controls after you make changes to an application model and add additional view object instances or additional view criteria to the view objects.

**Problem**

The Data Controls panel in JDeveloper was not opened in a new view or refreshed following changes made to the data bound Applications Core component.

**Solution**

If using the Applications Core wizards to create an applications panel, applications table, or other data bound Applications Core component, you must open the Data Controls panel in JDeveloper at least once in a new view, or at least once after deleting the system directory, before launching the Applications Core wizards. If necessary you should refresh from the Data Controls panel before launching the Applications Core component wizards.

61.5.1.6 Runtime Error Related to DataBindings.cpx File

A runtime error occurs while the runtime model is being located using the information in the DataBindings.cpx file.

**Problem**

You have more than one UI project (for example, task flows referenced from an Oracle ADF library) when the DataBindings.cpx files are merged at runtime.

**Solution**

Make sure that each instance of DataBindings.cpx resides in its own package.

61.5.1.7 "Application module not found" Errors Related to DataBindings.cpx File

An Application module not found error occurs.

**Problem**

The DataBindings.cpx file was moved because the default package was set incorrectly.

**Solution**

Make sure that the package defined in the Application tag of DataBindings.cpx matches the current package location.

61.5.1.8 Oracle WebLogic Server Hot Reloading Does Not Work

You get unexpected behavior, blank components, or unexpected exceptions when you hot reload in either of the following ways:

- In the Message Log window, select the Running Integrated WebLogic Server tab and click the URL that launched your page in Integrated WebLogic Server.
• Remove the Oracle ADF state related information from the URL displayed in the browser (for example, ?_adf.ctrl-state=ku8gus1cz_4) and reload the page.

**Problem**

Changes were made to the page binding definition file (PageDef), the resource (XLF) files, or the Oracle ADF libraries.

**Solution**

Generally if the change you make is contained within a page or page fragment of the current project, you do not need to redeploy your application. However, if changes are made to the page binding definition file (PageDef), the resource (XLF) files, or the Oracle ADF libraries then you must redeploy your application.

**61.5.1.9 Missing ADF Component at Runtime in Oracle WebLogic Server**

You discover a missing ADF component at runtime in Oracle WebLogic Server.

**Problem**

There is a second version of the ADF component erroneously included when the Oracle ADF libraries and WAR or EAR files were built.

**Solution**

Check the EAR file to make sure that the missing component is actually present in the expected location.

**61.5.1.10 Odd ADF Component Errors**

You receive odd errors related to an ADF component that suggests a recent change was not picked up.

**Problem**

A second copy of that component is incorrectly referenced in another Oracle ADF library via a build output reference.

**Solution**

Perform one of the following tasks to resolve the problem:

• Refresh the library in one of the following ways:
  
  – Close the workspace and re-open it to refresh the references to the Oracle ADF libraries. (Closing and restarting JDeveloper with a workspace open does not refresh the references to the Oracle ADF libraries.)
  
  – If you have a specific project selected in the JDeveloper navigator pane, select View, then Refresh ADF Library Dependencies for ....jpr to refresh the references to the Oracle ADF libraries.
Note:
When you make any changes to the components in a project, where the components are being referenced as an Oracle ADF library by your user interface (UI) project, you must redeploy the Oracle ADF library and refresh the Oracle ADF library dependencies for your UI project. The same applies to one model project referencing from another model project. If you are developing or debugging code in a model project while running the referencing UI project to test it, it may be easier to add the model project as a build output dependency, so you do not need to go through the cycle of redeploying the Oracle ADF library or refreshing the Oracle ADF library references each time you make a change.

- Force recompilation by right-clicking the JSP and selecting Build, then Clean All, then rebuild and redeploy.

61.5.1.11 Oracle WebLogic Server is Not Responding
The Oracle WebLogic Server instance may seem unresponsive.

Problem
The Oracle WebLogic Server Java process may be CPU intensive.

Solution
Use `kill -3 pid` to write a Java thread dump to the administration console for Integrated WebLogic Server or to the server log file for standalone WebLogic Server.

`kill -3 pid` is the same as `kill -QUIT pid`, which sends SIGQUIT to the process.

The Java process implements a signal.

If you are using Jrockit Java, use this command to print threads:

```
jrcmd <pid> print_threads [nativestack=true]
```

61.5.1.12 Missing Base Class
The base class is missing when you test the Model project in the Oracle Business Component Browser.

Problem
The Model project is missing the Applications Core library.

Solution
Add the Applications Core library to the Model project.

61.5.1.13 Unavailable FND Components
The FND components are not available when you add components to your page or page fragment.

Problem
The Applications Core (ViewController) tag library is missing.

Solution
Add the Applications Core (ViewController) library to your project to automatically add the Applications Core (ViewController) tag library. You may need to close the
Project Properties dialog, save the changes, and reopen the Project Properties dialog before you see all the dependent changes made when adding the Applications Core library.

61.5.1.14 JavaServer Pages Compilation Errors

You get JavaServer Pages (JSP) compilation errors or other JSP errors.

Problem

The page or page fragment is invalid. In the source editor, you can see that there are errors in the page, often because of malformed XML (for example, missing or mismatched XML tags) or some other error reported by the design time audits. This can occur if you cut and paste directly into the XML source. JDeveloper allows you to run the page even though it is invalid.

Solution

In the Preferences option of the Tools menu, you can set an audit to run during compilation. If there are failures, it will prevent the run. However, the audit only executes during compilation. The first time you try to run, it may need to compile and the audit kicks in and it fails, which causes the run to stop. The second time you try to run, everything that needs to compile may have already successfully compiled. In this case, there is no compilation, so there is no audit.

61.5.1.15 ApplicationDB Errors While Running the Integrated WebLogic Server

You get errors related to ApplicationDB when you are running the Integrated WebLogic Server.

Problem

The settings for ApplicationDB are not configured correctly.

Solution

Check the settings for the ApplicationDB in the Oracle WebLogic Server Administration Console.

61.5.1.16 Metadata Services Runtime Exception

You get the following Metadata Services (MDS) runtime exception:

```
oracle.mds.exception.MDSRuntimeException: MDS-02401: The operation ModifyAttribute on the showDetailItem node is not allowed.
MDS-02404: The subelement RAshowdetail2 in the MDX document does not allow customization of /oracle/apps/fnd/applcore/patterns/uishell/RegionalArea.jsff#RAshowdetail2.
```

Problem

The CHANGE_PERSISTENCE parameter value is incorrect.

Solution

Locate the following context parameter in `web.xml`:

```xml
<context-param>
  <description>
    This parameter turns on the session change persistence.
  </description>
  <param-name>org.apache.myfaces.trinidad.CHANGE_PERSISTENCE</param-name>
```
Change the value of CHANGE_PERSISTENCE to oracle.adf.view.page.editor.change.ComposerChangeManager.

### 61.5.1.17 Application Cannot Fetch Data from Oracle Fusion Applications Database

Your application is unable to fetch data from the Oracle Fusion Applications database.

**Problem**

The fusion_apps_wls.properties file does not contain the correct connection strings for the application’s data source.

**Solution**

Run the Configure Fusion Domain Wizard to create or update the fusion_apps_wls.properties file with the correct connection information. For instructions on using the wizard, see Chapter 2, "Setting Up Your Development Environment."

### 61.5.1.18 "The task cannot be processed further" Message Appears

You get the following message:

Deployer: 149140 The task cannot be processed further until the current edit session is activated.

**Problem**

You modified the configuration of the server and did not activate the changes.

**Solution**

Go to the Administration Console (http://localhost:7101/console). Check the upper left hand corner regarding messages about changes not being activated.

### 61.5.1.19 TimedOut Exception Occurs

You get the following exception:

weblogic.transaction.internal.TimedOutException

Service logic is taking longer than the default 300 seconds defined for Java Transaction API (JTA). Services may have heavy validation which will take more time to create row.

**Solution**

Set the JTA timeout condition to more than 300.

2. Log in using your username and password.
3. Go to Domain Structure, choose Service.
4. Go to Services and select JTA.
5. Increase the value of the Timeout Seconds property based on the expected completion time of the longest transaction. The default value is 300.
61.6 Testing and Troubleshooting Oracle SOA Suite

For more information about testing and troubleshooting SOA composite applications, see the "Testing and Troubleshooting" section in Developing SOA Applications with Oracle SOA Suite.

You can also automate the SOA composite applications testing. For information, see the "Automating Testing of SOA Composite Applications" section in Developing SOA Applications with Oracle SOA Suite.
This chapter provides guidelines and best practices for designing and securing Oracle Application Development Framework (Oracle ADF) view objects and other supporting business component objects for use by Oracle Business Intelligence Applications.

This chapter includes the following sections:

- Introduction to View Objects for Oracle Business Intelligence Applications
- Understanding General Design Guidelines
- Understanding Design Patterns
- About Designing and Securing Fact View Objects
- About Designing and Securing Dimension View Objects
- About Designing Date Dimensions
- About Designing Lookups as Dimensions
- About Designing and Securing Tree Data
- About Supporting Flexfields for Oracle Business Intelligence Applications
- About Supporting SetID
- About Supporting Multi-Currency

### 62.1 Introduction to View Objects for Oracle Business Intelligence Applications

The view objects that are designed and created for Oracle Business Intelligence Applications (Oracle BI Applications) are shared between Oracle Transactional Business Intelligence and Oracle BI Applications.

The Oracle BI Applications warehouse is populated from Oracle Fusion Applications databases using an ETL (extract, transform, and load) process. The ETL process uses the tool to source data from the source system (Oracle Fusion Applications) to the target Oracle BI Application stable. The extract from the source system is done using the Oracle Application Development Framework (Oracle ADF) view objects.

*Figure 62-1* illustrates the Oracle Business Intelligence architecture.
Oracle BI Enterprise Edition (Oracle BI EE) needs to efficiently access data from two or more master/detail-linked view objects to aggregate, present, or report on that combined data set. An essential requirement is to efficiently retrieve the multiple-levels of related information as a single, flattened query result, to perform subsequent aggregation or transformation on it. Oracle ADF Composite View Object API allows the caller to create a new view object at runtime that composes the hierarchical results from two or more existing view-linked view objects into a single, flattened query retrieving the same effective set of data.

From a performance perspective, such queries would need to be performed on low-level data in Oracle BI EE, since the Oracle ADF layer does not directly support aggregation. This would generally slow query performance down. Also, going through additional servers (that is, JavaHost and Oracle ADF) in the network would also be slower than directly querying the database. Therefore, the SQL Bypass feature has been introduced to directly query the database and push aggregations and other transformations down to the database server, where possible, thereby reducing the amount of data streamed and worked on by Oracle BI EE.

The SQL Bypass functionality in Oracle BI EE utilizes the Composite View Object API feature to construct and return a flattened SQL Bypass query that incorporates all of the required columns, filters, and joins required by the Oracle Business Intelligence query. Oracle BI EE then executes this query directly against the database.

### 62.2 Understanding General Design Guidelines

When designing view objects for Oracle Business Intelligence Applications, you should use the following guidelines with regards to entity objects, associations, view objects, view links, and view criteria.
62.2.1 About Entity Object Guidelines

An entity object represents a row in a database table and simplifies modifying its data by handling all data manipulation language (DML) operations for you. It can encapsulate business logic for the row to ensure that your business rules are consistently enforced. Entity objects are required for all Oracle Business Intelligence view objects to support SQL pruning of declarative view objects and to leverage many Fusion specific features. For more information see "Creating a Business Domain Layer Using Entity Objects" in Developing Fusion Web Applications with Oracle Application Development Framework.

All attributes from the physical table (except special, highly sensitive attributes) should be exposed on the entity objects.

62.2.2 About Association Guidelines

An association reflects relationships between entity objects and can be by either reference or composition. All view objects composed of multiple entity objects are flattened using entity object associations.

For more information about associations, see "Creating Entity Objects and Associations" in Developing Fusion Web Applications with Oracle Application Development Framework. For more information about flattening, see Understanding Flattened View Objects.

62.2.3 About View Object Guidelines

A view object represents a SQL query. You use the full power of the familiar SQL language to join, filter, sort, and aggregate data into exactly the shape required by the end-user task. For more information, see "Defining SQL Queries Using View Objects" in Developing Fusion Web Applications with Oracle Application Development Framework.

This section includes some technical requirements, how to use declarative SQL mode, and guidelines regarding view object attributes and outer joins.

62.2.3.1 Understanding the Technical Requirements

The following are the technical requirements driven by use of the Composite View Object API, SQL Bypass, and SQL Pruning.

**Composite View Object API**

- Use view links to establish relationships between view objects.
- View links must not contain custom SQL functions such as `TRUNC` and `BETWEEN`.
- Use the `BI_JOINTYPE` custom view link property to define outer joins on view links.
- There is no support for Java or Groovy calculated attributes.
- Programmatic view objects, transient view objects, and transient attributes are not supported.

**SQL Bypass**

- Full SQL can be obtained at runtime using `vo.getQuery()`.
- There is no support for transient attributes.
• View objects must not contain bind parameters.
• There is no support for Java logic or Java calculated attributes.
• Do not apply data security view criteria programmatically.
• If you are using Multi-Organization Access Control (MOAC) you must not enable MOAC for the view objects for Oracle Business Intelligence Applications. You should use the underlying Fusion Data Security instead.

For more information, see "About Specifying a SQL Bypass Database" in Metadata Repository Builder’s Guide for Oracle Business Intelligence Enterprise Edition.

SQL Pruning

• You should create your view objects in Declarative SQL Mode.
  For more information about Declarative SQL Mode, see "Working with View Objects in Declarative SQL Mode" in Developing Fusion Web Applications with Oracle Application Development Framework.
• You should set primary entity usage to identify the fact and dimension grain because primary entity usage cannot be pruned.
• You must set the Selected in Query property for non-primary key and unsecured attributes to false.
• You should limit view criteria on non-primary entity derived attributes because attributes used in applied view criteria cannot be pruned.
• You should limit order by clauses on non-primary entity derived attributes because attributes used in applied order by clauses cannot be pruned.

62.2.3.2 About View Object Attributes Guidelines

• As a general rule, you should include all attributes from the underlying primary and reference entity objects in your view objects.
  Flex attributes are an exception from this rule. These attributes are not required because they are exposed using the Flex Extender utility.
• You should only include name and description attributes from the reference entity objects that are included to only resolve ID and Code columns.
• You should include Standard Who Columns from all participating entity objects on your view objects for Oracle Business Intelligence Applications. This is to support Oracle BI Applications’s Change Data Capture requirements.
  Exceptions include entity objects that are only included to resolve ID and Codes into meaningful descriptions. For example, entity objects included to only resolve Business Transactional Intelligence-only attributes into a view object using entity object associations.
  Table 62-1 shows the Standard Who Columns.

Table 62-1 Standard Who Columns

<table>
<thead>
<tr>
<th>Standard Who Columns</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>CREATED_BY</td>
<td>The user who created the row.</td>
</tr>
</tbody>
</table>
### Table 62-1  (Cont.) Standard Who Columns

<table>
<thead>
<tr>
<th>Standard Who Columns</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>CREATION_DATE</td>
<td>The date and time the row was created.</td>
</tr>
<tr>
<td>LAST_UPDATED_BY</td>
<td>The user who last updated the row.</td>
</tr>
<tr>
<td>LAST_UPDATE_DATE</td>
<td>The date and time the row was last updated.</td>
</tr>
<tr>
<td>LAST_UPDATE_LOGIN</td>
<td>The session login associated to the user who last updated the row.</td>
</tr>
</tbody>
</table>

- You should set the **Selected in Query** property to be `false` on all non-primary key view object attributes.
- You should resolve duplicate attribute names on view objects, which are made up of multiple entities, by using an attribute prefix. Use an alias property as both the table alias and column alias in the SQL as well as the view object attribute prefix. For example:
  - The `POLinesVO` includes both the `HeaderEO` and the `LinesEO`.
  - The `LinesEO` is specified as the primary entity on `POLinesVO`. The `HeaderEO` is specified as a reference entity.
  - This view object includes `HeaderId` attributes from both `HeaderEO` and `LinesEO`.
  - To avoid duplication of attributes across `Header` and `Lines` entities, an entity object alias is specified. For example, `Header` and `Lines` for `HeaderEO` and `LinesEO` respectively.
  - The `POLinesVO` is then created using `Header` as the prefix for all `Header` attributes, and `Lines` as the prefix for all `Lines` attributes. For example, `HeaderHeaderId` and `LinesHeaderId`; `HeaderBusinessUnitId` and `LinesBusinessUnitId`.

- Use the following guidelines to resolve view object foreign keys:
  - If the foreign key is a dimension, Oracle Business Intelligence requests a dimension view object and a view link to the dimension view object.
  - If the foreign key is a warehouse domain, Oracle BI Applications requests a view object for ETL. No view link is requested. Oracle BI EE lookup functionality is used to resolve foreign keys.
  - If the foreign key is neither a dimension nor a warehouse domain, you should resolve the foreign key using entity object associations. For MLS-enabled entities, `ID` and `Code` attributes should be resolved using `_VL` views.

#### 62.2.3.3 About Outer Joins

An outer join is generally required when creating a view object based on multiple entity objects, so as to handle situations when not all of the reference entities’ values are present. The specific outer join type (left, right, or full) used should be determined based on the expected data relationships between the primary and reference entities. Note, however, that in some cases, security considerations will require an inner join,
instead. (For an example, see About Designing Fact View Objects.) If a join is required to resolve an ID or Code attribute, use a _VL view instead.

62.2.4 Understanding View Links Guidelines

View links are required to flatten view objects using the Composite View Object API. To define outer joins on view links, you must add the BI_JOINTYPE custom property on the view link definition. Valid values for this custom property include:

- LEFTOUTER
- RIGHTOUTER
- FULLOUTER
- INNER (default)

For more information, see "Working with Multiple Tables in a Master-Detail Hierarchy" in Developing Fusion Web Applications with Oracle Application Development Framework.

62.2.5 Understanding View Criteria Guidelines

A view criteria identifies filter information for the rows of a view object collection. Required filters for view objects for Oracle BI Applications should be created using named view criteria. This includes:

- Security filters
  For more information about security filters, see Understanding Business Intelligence Filters.

- Functional filters for Transactional Business Intelligence or Oracle BI Applications.
  Only filters required by both Transactional Business Intelligence and Oracle BI Applications should be created for view objects that are shared by both products.

- Filters to distinguish different logical entities based on the same entity object. (For single entity object view objects).

For more information, see "Working with Named View Criteria" in Developing Fusion Web Applications with Oracle Application Development Framework.

62.3 Understanding Oracle Business Intelligence Design Patterns

This section discusses Oracle Business Intelligence design patterns including flattened view objects, fact-dimension relationships, self referencing entities, filters, and translations.

62.3.1 Understanding Flattened View Objects

The grain of a fact table represents the most atomic level by which the facts may be defined. The fact or dimension grain required for Oracle Business Intelligence modeling should determine the flattening required for view objects. You should only create flattened view objects for fact or dimension levels required for either Transactional Business Intelligence or Oracle BI Applications. For example, if neither Transactional Business Intelligence nor Oracle BI Applications requires (purchase order) PO Shipments, then do not create a flattened POShipmentsVO.
When flattening entity objects in a view object, include only entity objects that do not change the grain of the fact or dimension. For example:

If attributes from a backing requisition line are needed on the POLinesVO, then the Requisition Line entity object should only be included in the flattened POLinesVO if the join does not change the grain of the POLinesVO to Requisition Line.

A 1:n relationship requires two view objects only if you want to aggregate attributes from the child and store the result at the grain of the parent.

Flattened view objects should be modeled in the Oracle Business Intelligence layer as a single logical table with multiple logical table sources.

62.3.2 Understanding Fact-Dimension Relationships

You should follow these rules when designing and creating fact and dimension view objects:

- Create separate view objects for fact entities and dimension entities.
- Do not flatten relationships between facts and dimensions into a single view object.
- Create a view link between the FactVO and the DimensionVO.
- Specify the FactVO as the source of the view link.
- Specify the DimensionVO as the target of the view link.

62.3.3 Understanding Self Referencing Entities (Self-Joins)

In the case of a fact view object where the self-joins represent two different but functionally important objects, you should create separate view object instances that represent the two objects. You should then define a view link between them.

If the self-join does not need to be represented as separate objects, you should resolve the Foreign Key ID column to a more meaningful column. For example:

The InvoiceheaderVO contains the following attributes:

- InvoiceId
- InvoiceNum
- TaxRelatedInvoiceId
- CreditedInvoiceId

If you decide that these should be modeled as three separate facts, then you create two additional view instances, TaxRelatedInvoicesVO and CreditedInvoicesVO, with view links to the InvoiceHeaderVO.

If you decide that they do not need to be modeled as separate objects, then you should create the two additional joins inside the InvoiceHeaderVO to bring in TaxRelatedInvoiceNum and CreditedInvoiceNum.

Row and Column flattening is required for view objects with self-joins that are modeled as dimensions in Oracle Business Intelligence Applications. You should determine the level of flattening required on a case-by-case basis.
62.3.4 Understanding Business Intelligence Filters

Only filters that are common to both Transactional Business Intelligence and Oracle BI Applications should be defined on shared view objects. If Transactional Business Intelligence requires additional filtering for a Transactional Business Intelligence specific application then it should be defined on the Oracle BI EE layer. If Oracle BI Applications needs to filter data from a shared view object for extraction, these filters need to be defined in the ETL layer.

Also note that view criteria cannot be pruned from the SQL at runtime.

62.3.5 Understanding Translations

All Fusion translatable entities with a corresponding _TL table require entity objects based on both _B and _TL entity objects. You should create a flattened view object to join _B and _TL entity objects.

Oracle BI Applications performs ETL (extract, transform, and load) processes from the flattened view object with no additional filters. However, Transactional Business Intelligence requires an additional session language filter in Oracle Business Intelligence layer.

Note:
The entity object associations required for ID and Code resolutions to Multi-Language Support-enabled entities should use a _VL view.

62.3.6 Understanding Date Effectivity

All date effective entities for a logical fact or dimension should be flattened and adhere to the following:

- Date effective entity objects and view objects should be marked as such according to Oracle ADF.
- Flattening requirement excludes scenarios where other design considerations require not flattening the entity objects in the view object. For example, 1:n relationships.
- Both entity objects are date effective.
- The PersonsVO should be flattened to include both PersonEO and PersonDetailEO and should also be marked as Date Effective.

In other words, there should be a single current person details record for each person record.

For more information, see "How to Store Data Pertaining to a Specific Point in Time" in Developing Fusion Web Applications with Oracle Application Development Framework.

62.3.6.1 About Date Effectivity Exceptions for Oracle BI Applications

Oracle BI Applications identifies any date effective entity objects from which historical information is needed; single view object flattening does not meet their requirements. To compensate, you need to:
• Create a separate view object for these entity objects. The entity object is removed from the flattened view object.

• Create view links to join these view objects.

• You must only include one historical entity object for any given view object in Oracle BI Applications.

You should still mark view objects as date effective so that Transactional Business Intelligence can share and date effective predicate can be applied in the Oracle Business Intelligence layer.

62.4 About Designing and Securing Fact View Objects

Separate view objects should be created for fact entities and dimension entities. Relationships between facts and dimensions should not be flattened into a single view object. Instead, you should create a separate FactVO and DimensionVO and then create a view link between them. Specify the FactVO as the source of the view link, and the DimensionVO as the target of the view link.

62.4.1 About Designing Fact View Objects

A flattened view object should be created for each logical fact grain in Transactional Business Intelligence and Oracle BI Applications. For example:

A purchase order contains four fact levels: Header, Lines, Shipments, Distributions. Flattened view objects should be created to represent each of the four fact grains, as shown in Table 62-2.

<table>
<thead>
<tr>
<th>Flattened View Objects</th>
<th>Fact Grains</th>
</tr>
</thead>
<tbody>
<tr>
<td>POHeaderVO</td>
<td>Header</td>
</tr>
<tr>
<td>POLinesVO</td>
<td>Header +Lines</td>
</tr>
<tr>
<td>POShipmentsVO</td>
<td>Header +Lines +Shipments</td>
</tr>
<tr>
<td>PODistributionsVO</td>
<td>header +Lines +Shipments +Distributions</td>
</tr>
</tbody>
</table>

Entity objects can be included in flattened view objects as required if the view object grain does not change.

---

**Note:**

View links are not required between these view objects.

---

**Join Type for Multi-Level Facts**

Join types on entity associations between multi-level facts should be inner joins. This is because there are some security impacts if entity associations are modeled as outer joins. For example:

To support the query “Show me all PO headers with no associated distributed rows”. If an outer join is used, you would need to implement security on both the header and the distribution entities in the DistributionVO. This would prevent pruning of the
header entity from the DistributionVO; it is also a change from current guidelines to only secure the primary entity.

### 62.4.2 About Securing Fact View Objects

The following are general guidelines for securing fact view objects. The sub-sections describe different design patterns that may arise for Oracle Business Intelligence use cases. Also included are solutions for each design pattern.

Fusion Data Security view criteria should be applied to the fact view object.

For more information about Fusion Data Security view criteria, see How to Secure Rows for Read_ Update and Delete Access.

The data security view criteria should contain:

- **Privilege** – Relevant object privilege.
- **Object** – Object being secured.
  
  For Multi-Organization Access Control (MOAC) style grants, the object being secured is Business Unit, based on the way MOAC grants are authored. For other grants, it can be the transactional object.
- **Alias** – Alias for object.
  
  Alias is mandatory for view objects for Oracle Business Intelligence Applications privileges.

For example, For Payment Invoices fact view object using Business Unit security (MOAC style), the privilege is:

"FNDDS__AP_MANAGE_PAYABLES_INVOICE_DATA__FUN_ALL_BUSINESS_UNITS_V__BU"

The fact view object requires an entity object for securing the table. (BU in this example). The join between the fact and the securing table should be properly resolved. The alias used in the view criteria should be that of the entity object corresponding to the **Object** in privilege (BU in this example).

If a non-MOAC grant is made for a transaction object, such as, for example, the Payment fact of the Fusion Incentive Compensation Management (ICM) Application, the object and alias refer to the ICM Payment entity. For example:

"FNDDS__VIEW_INCENTIVE_COMPENSATION_PAYSHEET_DATA__IC_INCENTIVE_COMPENSATION_PAYSHEET__ICPAY"

### 62.4.2.1 Secure the Same Transaction by Multiple Entities for Different Roles

In Oracle Fusion Applications, transaction data can be secured by more than one entity, based on the role used to access the transaction data. For example, consider the case of the Fusion Incentive Compensation Management (ICM) Application, in which:

- **Role Incentive Compensation Paysheet Management Duty** can see Incentive Compensation paysheets for the participants for whom they are responsible.
- **Role Incentive Compensation Process Management Duty** can see Incentive Compensation paysheets for the business units for which they are authorized.

In the above case, because the view object for the transaction object implements single data security privilege, the privilege should be able to provide access based on business unit as well as participants. Building this privilege provides a logical filter similar to:
You can achieve this by creating a new privilege and having two policies created using the same privilege. One policy should be created using instance set to provide "for business units for which they are authorized", and the second policy should be created using instance set to provide "for the participants for who they are responsible". The policies should be granted to existing roles.

**To secure transaction by more than one entity:**
The following steps are based on the Fusion ICM Paysheet use case.

1. Create a new data privilege titled View Incentive Compensation Paysheet Data.

2. Author the following data security policies, using existing duties and the new data privilege defined in Step 1:
   a. `<Incentive Compensation Paysheet Management Duty>` can `<view>` `<Incentive Compensation Paysheets>` `<for the participants for who they are responsible>`
   b. `<Incentive Compensation Process Management Duty>` can `<view>` `<Incentive Compensation Paysheets>` `<for business units for which they are authorized>`

3. Define the following grants:
   a. For the data security policy described in Step 2a:
      For this data security policy, you should attach the View Incentive Compensation Paysheet Data data privilege to the same FND_MENU that contains the grant for the Manage data privilege. This grants VIEW privileges to the same roles that have Manage privilege, reducing the number of grants to be managed.
   b. For the data security policy described in Step 2b:
      For this data security policy, you would create a non-MOAC grant against the Incentive Compensation Paysheet object against the business unit (BU) data role. This grant is parameterized instance set based, with the instance set returning Paysheet data by BU, using BU on the data role as the parameter value. This grant carries only the VIEW data privilege.

   **Note:**
   This is a data role grant and the role and grant is generated during the implementation phase using the data role template.

4. Use privilege View Incentive Compensation Paysheet Data in data security view criteria in Incentive Compensation Paysheet. The view criteria should be like Example 62-1 assuming IC_INCENTIVE_COMPENSATION_PAYSHEET is the object registered in FND_OBJECT and ICPAY is the alias used for the entity object.

**Example 62-1  Data Security View Criteria Example**

"FNDDS__VIEW_INCENTIVE_COMPENSATION_PAYSHEET_DATA__IC_INCENTIVE_COMPENSATION_PAYSHEET__ICPAY"
Caution:

With regards to the above proposal, if a user happens to have both Incentive Compensation Paysheet Management Duty and Incentive Compensation Process Management Duty roles granted; the Business Intelligence report will show the UNION of data, such as data for authorized business units AND data for responsible participants.

Whether such reporting behavior is acceptable should be decided on a case by case basis.

For Oracle BI Applications, the UNION effect for the above example, based on Oracle Fusion Incentive Compensation Management reporting (Access by Participants and access by business units), must be achieved in Oracle BI EE based on the OR join for individual dimensions. This can potentially be achieved by using two separate groups (one for business unit and another for participants) and having a user access to both groups (since predicates are ORed across Oracle BI EE groups).

There are other use cases that fall into same design pattern of a transaction being secured by multiple entities and Oracle Business Intelligence implementation needing UNION access. For example, in Oracle Fusion Projects, the transaction table Expenditure Item is secured by Business Unit as well as by Project. For Oracle Business Intelligence reporting, the query on Expenditure Item should return rows for authorized business units for a user as well as authorized project for user.

In general, while the Oracle Business Intelligence use cases for transaction being secured by multiple entities will be similar; application teams can make their own decisions about how they implement an Oracle Business Intelligence solution. For example, in the case of the Oracle Fusion Incentive Compensation Management and Oracle Fusion Projects applications, you can implement different solutions for achieving the same results by having different styles of grants and roles. Therefore, application teams should choose their own implementation based on their existing roles and privileges, and the approach they want to take for Oracle Business Intelligence solution.

62.4.2.2 Secure Transactions Different from Securing Dimensions

When transactions are analyzed in context of dimensions, sometimes the dimensions have their own security, which is not applicable for usage with the transaction.

For example, Grade data is secured using Fusion data security. When analyzing Assignment data, relevant information from the Grade dimension is required; however, the data security for the Grade dimension is not applicable when being used for analyzing assignments. Instead, the Grade dimension behaves as an unsecured source of data when used with assignment fact.

A solution for this use case is to create two view objects for the dimensions for which security is not required when analyzing fact. The two view objects should form two logical table sources (LTS) for the dimensions:

- The first dimension view object implements data security. This is used in dimension browsing and can include all columns required for dimension browsing. To ensure BI EE uses the secured version for dimension browsing, make sure it is higher up in the list of Logical Table Sources (LTS) than the unsecured one.
The second dimension view object should be unsecured. To ensure that the unsecured view object is used to combine with the fact, physical joins should be defined between the physical fact table and the physical table for the unsecured version of the dimension view object.

Caution:
Dimensions, for which unsecured view objects are created, may contain sensitive attributes. If this is the case, then you must make sure that the unsecured view object does not contain these sensitive attributes.

Dual (secured and unsecured) view objects are only required for entities that fall in this design pattern. Entities not requiring both secured and unsecured access do not require dual view objects.

62.4.2.3 Join Facts to Facts
Analysis of a fact may need reference information from another fact. In Transactional Business Intelligence, this is handled by creating a degenerate dimension for a fact whose attribute information is used in other facts. The degenerate dimension is just a logical layer entity in the RPD and it uses the same view object as the underlying fact. Consequently, the data security for degenerate fact is the same as that of underlying fact table.

This may create a problem when the degenerate dimension is used in another fact that has different security than the degenerate dimension (or more accurately, the fact underlying the degenerate dimension). For example:

- There is a degenerate dimension, Dimension A on top of Fact A.
- Dimension A is used in Fact B as a reference.
- Fact B is secured using a different dimension (or different privilege) than Fact A, which was used to source for Dimension A.

In such cases, the security of both Fact B and Fact A should be applied; whereas the desired result was just to apply security of Fact B.

62.4.2.4 Secure MOAC-Based transactional Applications
Multi-Org Access Control (MOAC) ADF infrastructure enables Fusion transaction applications to implement business unit based data security. Because the Oracle Business Intelligence technical stack works on the view definitions, the ADF Business Components MOAC infrastructure does not work for view objects for Oracle Business Intelligence Applications. These view objects should instead use underlying Fusion Data Security to support business unit based security.

62.5 About Designing and Securing Dimension View Objects
This section discusses how to design and secure dimensions.

62.5.1 Overview of Designing Dimension View Objects
A flattened view object should be created for each logical dimension grain in Transactional Business Intelligence and Oracle BI Applications. For example, for the Geography dimension, the following view objects are required to represent each dimension grain:
• Zip Grain — Zip Code
• City Grain — City + Zip Code
• State Grain — State + City + Zip Code

These should be modeled as a single Geography logical dimension table with multiple logical table sources, one for each of the dimension grains.

**62.5.2 About Designing Business Unit Dimensions**

Create a view link between the Transactional Business Intelligence fact view objects that have Business Unit dimensionality to the common business unit dimension view object based on Business Unit ID.

**62.5.3 About Securing Dimension View Objects**

If the dimension must be secured, then the FND view criteria should be applied on the dimension view object.

**62.5.3.1 About Securing Dimensions Composed of Multiple Entities**

The following use case, is an example of how you should secure dimensions that are composed of multiple entities.

The Dimension Inventory Organization is composed of the following three entities:

• InventoryOrgParameters
• HrOrganizationUnits
• HrLocations

Human Resources (HR) entities may have their own security. However, for the InventoryOrgParameters entity, only the security defined by inventory product Manage Inventory Org Parameters is necessary. In other words, data security on HR entities should be ignored when consumed in InvOrg.

This use case is similar to Securing Transactions Different from Securing Dimensions, where unsecured view objects are used for dimensions.

**62.5.3.2 About Securing Transactions Using Dimension with Dimension Browsing Unsecured**

The Dimension Business Unit is used to secure transaction data. When used in conjunction with transaction data, a secured version of the Business Unit, which can return business units allowed for a user for a function, is required. For example, a secured version of Business Unit is required to populate init block security variables for Oracle BI Applications.

However, if a user needs to browse only the business unit data, the user is allowed to see all dimensions. Therefore, it is deemed an unsecured dimension when dimension browsing in Oracle BI Applications. To use an unsecured view object for dimension browsing, make sure it is higher up in the list of LTSs than the unsecured one.

**62.5.4 About Using Multi-Valued Dimension Attributes**

Separate view objects should be created for primary dimension entity and multi-valued dimension attribute entities. For example:

Using the Person model, the following view objects should be created:
• PersonVO — Person Only
• PersonAddressesVO — Addresses Only
• PersonPhonesVO — Phones Only.

The following view links establish relationships between view objects:
• PersonToAddressesVL — PersonVO -> PersonAddressesVO
• PersonToPhonesVL — PersonVO -> PersonPhonesVO

Note:
The above example uses the Person model with a person having address and phone. Keep in mind that Transactional Business Intelligence models only the primary address and phone number while Oracle BI Applications can model more than one address and phone number per person.

62.5.5 About Using Junk Dimensions and Mini Dimensions

Junk dimensions should not be directly sourced from view objects. Oracle BI Applications should build them from Fact Stage tables. Transactional Business Intelligence should build them from the degenerate attributes in Fact tables.

Mini dimensions should not be sourced from view objects. Oracle BI Applications should build them from Dimension tables.

62.5.6 About Using Secured and Unsecured Dimension View Objects

There are several situations in which a secured dimension view object must be deployed with an accompanying unsecured dimension view object. In this case, the term unsecured does not simply mean that security is disabled, but also that a subset of the column set of the secured dimension view object may also be excluded from the unsecured version.

Generally, the strategy for developing and deploying a pair of corresponding dimension view objects, where one is secured and the other unsecured, consists of the following:

• A base dimension view object satisfying the basic, functional requirements for data retrieval is initially developed.

• The base dimension view object is used to create a secured dimension view object by using the methods and strategies described earlier in this section.

• An unsecured dimension view object is developed by manually creating an exact copy of the original base dimension view object.

  The unsecured dimension view object is named <VO Name> ListPVO, where <VO Name> is the name of the base dimension view object.

• The unsecured dimension view object is modified so as to exclude sensitive columns from its column sets.

  The unsecured dimension view object is deployed in the same application module as its associated secured dimension view object.
Consuming applications must build View Links to both the secured and unsecured dimension view object definitions. Once the secured and unsecured dimension view objects have been deployed, you can begin developing models based upon them in Oracle Business Intelligence.

62.6 About Designing Date Dimensions

This section discusses the gregorian calendar as well as the special handling that is required for fiscal calendar, projects calendar, Timestamp columns, and role-playing data dimensions.

62.6.1 About Using the Gregorian Calendar

Date dimension view objects for the gregorian calendar are delivered through the ATG libraries.

You should create a view link between the gregorian calendar day level view object and all the facts that join with the date dimension. Create the view link with the Fact view object as the source and the day level view object as the target.

For all other calendars needed for the fact in a particular functional area, a view link should be created to the time dimension at the day level of the fact. For example, if the fact is at day level in Financials and the reporting calendar is fiscal (in addition to gregorian), view links should be created to the day level of the fiscal calendar.

62.6.2 About Using the Fiscal Calendar

If the fact is at the day level, you should create view links to the day level of the fiscal calendar only.

For all facts at the day level, the view link between the Fact view object to the Day Level flattened view object should include the ADJUSTMENT_PERIOD_FLAG =N condition to avoid double counting if the same day belongs to a normal period as well as an adjusting period.

62.6.3 About Using the Projects Calendar

Projects facts that need to be analyzed by the fiscal calendar requires a view link between the fact and the day level of the fiscal calendar on the date. Also required is a view link between the fact and the General Ledger on the Ledger ID column using the Fun_all_business_units_V table that is present in the fact side.

Projects facts that need to be analyzed by the projects calendar requires a view link between the fact and the day level of the projects calendar on the date. Also required is a view link between the fact and the pjf_bu_impl_all_v table on the Business Unit Id.

62.6.4 About Using Timestamp Columns

If the date column of a fact view object involves timestamp then teams will need to create a new SQL derived attribute to populate the date without the timestamp. A view link will also need to be created using the new date column of the fact view object and day level time dimension view object.

If the fact view object date column does not have the timestamp then it can be used for creating the view link.
62.6.5 About Using Role-Playing Date Dimensions

If role-playing date dimensions are required, Transactional Business Intelligence is required to create aliases of the date view object in the Oracle BI EE physical layer. Duplicate view object instances should not be included in the model.

62.7 About Designing Lookups as Dimensions

If a lookup type is used as a dimension in Transactional Business Intelligence, you must deliver the dimension view object as follows:

- Create a `<Product short name>LookupsVO`.
- This new view object should be based on the product specific lookup view on `FND_LOOKUPS`.
  
  If a view to `FND_LOOKUPS` is not available or not required for online transaction processing, the view object should be based on `FND_LOOKUPS` directly with an additional filter on all included Application IDs for the product.

- View criteria should be created for each Lookup Type.
- Create a view instance using the above view criteria for each dimension.

Foreign keys to low cardinality lookups, such as `FND_LOOKUPS`, should not be resolved in fact or dimension view objects. These should be resolved in the logical layer through the lookup function.

Business Transactional Intelligence-only low cardinality lookups should be resolved using entity object associations based on a `_VL` view.

62.7.1 About Securing Data on Lookups

Lookup data can be striped by set ID. However, no use cases have been brought forward to date where the lookup data has been secured by explicit data security policies.

62.8 About Designing and Securing Tree Data

Application trees managed by Fusion tree management infrastructure may be exposed to Oracle Business Intelligence systems, such as Oracle BI EE, for analysis. This is done by providing a view object that contains a column-flattened version of tree data joined with tree data sources. Such a view object is called a `column-flattened view object for Business Intelligence (BICVO)`.

Designing and securing tree data for Oracle Business Intelligence involves the following activities:

- Designing a column-flattened view object
- Customizing the FND table structure and indexes
- Using declarative SQL mode to design view objects
- Securing Oracle ADF view objects for trees
62.8.1 About Designing a Column-Flattened View Object for Oracle Business Intelligence

Column-flattening is generally available for level-based trees. For those trees that may be exposed to Oracle Business Intelligence systems, such as Oracle BI EE, column-flattening for value-based trees also is available.

Figure 62-2 illustrates a generic example of a value-based tree.

Figure 62-2  Value-Based Tree Example

![Value-Based Tree Example](image)

Each node has a unique identity, in this case denoted by dot-separated numbers that correspond to the node’s relative ordering in the overall parent-child structure. Such value hierarchies may be arbitrarily recursive (in terms of recurring node types), and are usually ragged, or unbalanced. There is only a general concept of “level” in these hierarchies, which refers to the path distance (or depth) from the root node to some specified node.

Two nodes the same distance from the root are thought of as being at the same level. However, unlike true level-based trees, there is no requirement for nodes at the same level to possess a common set of properties. In fact, a node in a value-based tree may have any arbitrary collection of properties. When these trees are used to represent dimensional hierarchies, facts, metrics, or transactions, values may be joined to any node. There is no constraint that facts or transactions only be joined to lowest-level nodes, as is usually the case with level-based trees.

The example value-based tree shown in Figure 62-2, also has multiple top-level or root-level nodes. Since it has five levels (or equivalently, a maximum depth of four), a column-flattened representation of this tree requires a minimum of five columns. This is illustrated in Table 62-3.

Note:
In practice, you would never have single node trees. However, root nodes 2.0 and 3.0 are in Figure 62-2 to simply illustrate multiple top-nodes.
The following conventions apply to the logical column-flattened representation shown in Table 62-3.

- The first column (C0) contains a complete enumeration of each node in the tree. In this example, each node is represented by the value of its unique identity.

  Having the unique identity of each node of the hierarchy represented exactly once in the C0 column means that it is always possible to directly address each node, such as for purposes of joining with a transaction or measure, or for performing a calculation on that node.

- The last column (C4 in the example) always represents the root node of some rooted ancestral path of the tree.

- The intermediate ancestral path nodes between a given node in the C0 column and its ancestral root node in the C4 column, is represented by columns C1 through C3. Each column stores a reference to some node of the ancestral path, descending from C3 toward C0, filling each column (from right to left) with a reference to the next child node of the path. When a reference to the C0-th column node occurs, this reference is then repeated, if necessary, so as to pad the remaining columns until the C0 column is reached.

  Having the complete ancestral path, with unused columns padded toward the C0 node value, facilitates more efficient drill down operations.

- There is no implied ordering of the rows in the column-flattened representation. The complete hierarchy is represented by the table content, and a normalized representation can always be inferred or reconstructed from the flattened data set.

As far as Fusion tree management is concerned, the column-flattened representation always consists of several columns greater than, or equal to, the depth of the tree. If this were not the case, you would need a strategy for pruning or condensing the tree (for example, removal of intermediate nodes from the ancestral paths). However,
having the number of columns exceed the depth of the tree is never problematic, because of the repeated padding of C0 node values.

ATG services allows you to specify some fixed maximum depth of up to 32 levels when defining a tree. For example, if you specify a 20-level tree, your column-flattened representation will contain 20 columns, C0 through C19, with padding of values toward the leaf, as shown in Table 62-4.

Table 62-4  Column-Flattened Value-Based Tree Fixed at 20 Levels

Think of the tree in Figure 62-2 as a true level-based tree, with fixed levels, single top-nodes, and all leaf nodes residing at the same lowest level of the tree (such as level zero, represented by column C0). In this case, you would actually have three separate trees, and the tree rooted at node 1.0 would have the logical column-flattened representation shown in Table 62-5, assuming the same “pad toward leaf values” scheme as with the value-based tree.

</tbody>
</table>

The notion of distance from the root is still relevant, even though all of the leaf nodes are assumed to reside at the same level (level zero, or C0).

62.8.1.1 How to Generate a BICVO Automatically Using Tree Management

Attributes from the column-flattened version of the tree data use standard ADF Business Components attribute naming conventions. Attributes from the tree data
sources also use the same naming convention, but are prefixed with DepN, where N is
the zero-based height of the node within the tree; for example, Dep7EmployeeName
or Dep13ProjectName. The Dep0 prefix is used for leaf nodes.

The following procedure is a summary of the overall process of defining and
generating declarative BICVOs for trees. For more detailed information about the
strategy for creating these BICVOs, see Guidelines for ATG-Registration and BICVO
Generation and About Securing ADF Business Components View Objects for Trees.

To generate BICVO automatically, do the following:

1. Ensure that the namespace path /oracle/apps/fnd/appcore/trees/
analytics is configured in Oracle Metadata Service (MDS). Example 62-2 shows a
sample MDS configuration.

2. Ensure that each view object attribute of the tree data source view objects is marked
as relevant to Oracle Business Intelligence (or not) via the BI Relevant property
that is exposed in the Property Inspector for the view object attribute.

   **Note:**
   By default, only primary key attributes are "BI Relevant". For performance
   reasons, it is recommended that only those attributes that are really relevant to
   Oracle Business Intelligence be marked as such to avoid generating very large
   BICVOs.

3. Ensure that column flattening is enabled by specifying the column-flattened table
and, optionally, the entity object for the table while setting up the tree structure.
For more information, see How to Create a Tree Structure.

   The tree management infrastructure then generates the BICVO for the tree
structure into MDS.

4. Secure the generated BICVO using the data security infrastructure. For more
information, see About Securing ADF Business Components View Objects for
Trees.

   The generated BICVO includes a special view criteria named FNDDS__BICVO. To
secure access to data through the BICVO, this view criteria must be enabled for
instances of the BICVO in any application module. At runtime, data security rules
affecting access to the tree data source view objects are automatically carried over
to the BICVO.

   **Note:**
   In Oracle Fusion Applications V1, only filter-based data security rules are
supported. In addition, only the "is descendant of" operator is supported.

**Example 62-2   MDS Configuration**

```xml
<adf-mds-config xmlns="http://xmlns.oracle.com/adf/mds/config"
    version="11.1.1.000">
  <mds-config version="11.1.1.000" xmlns="http://xmlns.oracle.com/mds/config">
    <persistence-config>
      <metadata-namespaces>
        <namespace path="/sessiondef" metadata-store-usage="mdsRepos"/>
        <namespace path="/persdef" metadata-store-usage="mdsRepos"/>
      </metadata-namespaces>
    </persistence-config>
  </mds-config>
</adf-mds-config>
```
62.8.2 About Customizing the FND Table Structure and Indexes

When using Oracle Fusion tree management to create and manage your trees, you should create and register its own, custom versions of the FND_TREE_NODE and FND_TREE_NODE_CF tables. This prevents applications from competing for use of the FND tables. Your custom tables must comply to the following rules:

- They must have custom, (preferably application-specific) names; for example, PJF_PROJ_ELEMENTS_CF is currently being used by the Projects team to implement a column-flattened table for the Task Hierarchy.

- The column names and column data types of each custom table must be the same as those of the corresponding FND table.

- Custom versions of FND_TREE_NODE_CF can define an index on each of the level-based foreign key references to support efficient drill-downs. However, it is understood that certain application query patterns do not necessitate this degree of indexing. Indexing is also not necessary if the column-flattened table is guaranteed to be relatively small.

- Custom versions of the FND_TREE_NODE_CF should not include the ENTERPRISE_ID column as part of the primary key index defined on the custom table. This is because this column is not currently used by Oracle Fusion tree management.

62.8.3 About Using Declarative SQL Mode to Design View Objects for Oracle Business Intelligence Applications

All view objects for Oracle Business Intelligence Applications should be constructed in declarative SQL mode. This ensures that correct SQL pruning can be applied to any composite view object incorporating the Oracle Business Intelligence view object. This requirement also applies to the BICVO generated by Oracle Fusion tree management. However, of all the possible configurations of ADF Business Components objects defining a tree data source, only two configurations in particular actually lend themselves to the generation of declarative-mode BICVOs by Oracle Fusion tree management.

These configurations have been formalized as two distinct design patterns:

- Design Pattern #1: Single data source view object, single data source entity object
• Design Pattern #2: Multiple data source view objects, unique data source view object per depth of tree, single data source entity object per data source view object

Although either pattern can be used in the realization of either tree type, the first pattern is generally better suited to value-based trees, while the second pattern is more natural for level-based trees. However, the patterns are aimed primarily at supporting the automated generation of declarative-mode BICVOs, rather than supporting either particular type of tree.

62.8.3.1 About Using Single Data Source View Object Design Pattern

This pattern ensures that Oracle Fusion tree management can generate a declarative-mode BICVO from an Oracle Applications Technology (ATG)-registered data source. Figure 62-3 illustrates the ADF Business Components object configuration defining declarative BICVO pattern #1.

Figure 62-3 Declarative BICVO Based on Single Data Source View Object, Single Data Source Entity Object

In this pattern, there is a single data source entity object and a single data source view object based on that entity object. The data source view object is a declarative-mode view object built by developers and registered with Oracle Fusion tree management. The data source entity object in turn is based on a _VL database view that joins the data source base table (_B) with a table of translated values (_TL).

A second entity object is defined for the column-flattened table. Currently, the column-flattened table entity object must be created manually and made known to the generated BICVO via a manual workaround. Additionally, a collection of entity object associations, each joining the column-flattened entity object with the data source entity object for a unique level or depth of the tree, must also be created manually. If the application design requires that the base data source table expose multiple entity objects for any reason, then a _VL database view must be defined to join the multiple entity objects (possibly along with any translated attribute values), and that _VL database view must support the single data source entity object.

Once the data source view object is registered with Oracle Fusion tree management as part of the tree structure definition process, and the required manually-created objects
are all in place, a declarative BICVO may then be generated by Oracle Fusion tree management.

This declarative-mode BICVO pattern is well-suited for value-based trees, since value-based trees are most often represented at the data source level by a single table with a recursive self-join. However, there is nothing about the pattern that strictly requires its use in value-based hierarchies, nor prohibits its use from other types of hierarchies (such as level-based or hybrid). The primary objective of this pattern is to facilitate the automatic generation of a declarative-mode BICVO from an ATG-registered tree.

62.8.3.2 About Using Multiple Data Source View Objects Design Pattern

This pattern ensures that Oracle Fusion tree management can generate a declarative-mode BICVO from an ATG-registered tree. Figure 62-4 illustrates the ADF Business Components object configuration defining declarative BICVO Pattern #2.

Figure 62-4  Declarative BICVO Based on Multiple Data Source View Objects, Unique Data Source View Object per Level, Single Data Source Entity Object per Data Source View Object

In this pattern, there are multiple data source view objects, with a unique data source view object representing each level or depth of the tree. Each data source view object is based on a single, unique data source entity object. Each data source view object is a declarative-mode view object built by developers and registered with Oracle Fusion tree management. All of the data source view objects must be declarative-mode view objects; otherwise, a declarative-mode BICVO can not be generated. As with the previous pattern, each data source entity object in turn is based on a _VL database view that joins some data source base table (_B) with a table of translated values (_TL). While multiple _VL database views are represented in the diagram, there is no hard-and-fast requirement that each data source entity object actually be built on top of a unique _VL database view. The diagram simply admits the possibility of multiple such views, presumably one per level or depth of the tree.

The same as with design pattern #1, an entity object is also defined for the column-flattened table, and must also be created manually, and is made known to the generated BICVO via a manual workaround. This column-flattened table entity object is also joined to the data source entity objects via a collection of entity object associations. However, each entity object association relates the column-flattened table entity object to a unique data source entity object representing a particular level or depth of the tree.

If the application design requires that the base data source table expose multiple entity objects per tree level or depth, then a _VL database view must be defined to join the
multiple entity objects (possibly along with any translated attribute values) at that tree level or depth, and that _VL database view must support the single data source entity object for that tree level or depth.

Once the data source view objects have been registered with Oracle Fusion tree management as part of the tree structure definition process, and the required manually-created objects have all been put in place, a declarative BICVO may be generated by Oracle Fusion tree management.

This declarative-mode BICVO pattern is well-suited for level-based trees, since level-based trees are often built on top of multiple data sources, with a unique data source per level. However, there is nothing about the pattern that strictly requires its use in level-based hierarchies, nor prohibits its use from other types of hierarchies (such as value-based or hybrid). The primary objective of this pattern is to facilitate the automatic generation of a declarative-mode BICVO from an ATG-registered tree.

62.8.3.3 About Setting the Declarative-Mode BICVO Properties

To ensure correct SQL pruning, you must set the property values of the generated declarative-mode BICVO as follows:

- Designate the column-flattened table entity object as the primary entity of the BICVO.
- Designate the data-source entity objects as secondary or reference entities of the BICVO.
- Do not mark primary key attributes of the data source entity objects as primary-key attributes in the resulting column-set. (These are exposed by the generated BICVO).
- Set the `selectedInQuery` property of any non-primary key attribute of the generated BICVO to `false`.

62.8.4 Guidelines for ATG-Registration and BICVO Generation

The Oracle Fusion Applicationsteam that owns the tree is responsible for creating a custom tree node (parent-child relationship) table that is structurally equivalent to `FND_TREE_NODE`. Once the tree node table has been created, it is registered with ATG via the Oracle Fusion tree management tree creation UI.

The Oracle Fusion Applicationsteam is also responsible for creating a custom column-flattened table that is structurally equivalent to `FND_TREE_NODE_CF`. This custom table is depicted in Figure 62-3. Once created, it is also registered with Oracle Fusion tree management as the column-flattened table associated with the tree in the Oracle Fusion tree management creation UI.

The Oracle Fusion Applicationsteam must then create both data source view objects and associated data source entity objects, according to either of the structural patterns illustrated in Figure 62-3 and Figure 62-4. As with the tree node and column-flattened tables, the data source view object is also registered with Oracle Fusion tree management, via the Oracle Fusion tree creation UI. During the registration process, the developer may specify a custom property on any of the data source columns, indicating to Oracle Fusion tree management that these columns are relevant to Oracle Business Intelligence and need to be exposed at each level within the BICVO. This collection of Oracle Business Intelligence attributes is represented by the set of view attributes attached to the data source view object. Consequently, the generated BICVO will join these columns in from the data source entity object at each level of the tree, immediately following the level-specific data source foreign key references; that is, the
sequence of DEP*_PK* columns are followed by a set of columns representing each of
the BI-relevant attributes.

In addition to view attributes representing the Oracle Business Intelligence-relevant
columns of the data source, the data source view object may also be configured with
one or more view criteria filters. In particular, a view criteria must be defined to
enforce data security if there’s a requirement for data security at the source level. Any
other relevant filters required by reporting may also be specified and attached to the
data source view object. Each of these view criteria must specify a logical AND
condition as its connective to other defined view criteria.

Next, using the Oracle Fusion trees creation UI, the developer automatically generates
the BICVO; that is, the column-flattened BICVO based on the column-flattened table.
In Figure 62-3 and Figure 62-4, dashed lines represent joins on the underlying entities
that are automatically added by Oracle Fusion tree management to the BICVO
definition at runtime. These joins are inferred by ATG internal generation logic via
inspection of the data source view object and its attendant view attributes and view
criteria, as well as inspection of the registered column-flattened table.

The BICVO, as generated by Oracle Fusion tree management, also includes a
placeholder view criteria that is otherwise empty and specifies a logical OR condition as
its connective to any other view criteria that might be defined as part of the BICVO.
This placeholder view criteria is defined for data security purposes, and at the current
time, simply directs ATG logic to invoke the data security view criteria defined on the
data source view object.

---

**Note:**

There may also be a requirement to supply Oracle Data Integrator (ODI) with
translations via a view object that is separate from the base data source table
or _VL database view. In this case, you must develop a view object and entity
object pair that directly goes against the translations table (_TL).

---

You must take this entire collection of ADF Business Components objects, both hand-
crafted and generated alike, and package them for deployment as part of an
appropriate application module. Note that any ATG-generated artifacts, such as the
BICVO, is generated to reside within the Oracle Fusion Middleware Extensions for
Applications package namespace, which is:

`oracle.apps.fnd.bi.applicore.trees.bi.model.view`

Most of the Oracle Business Intelligence view objects and other artifacts are packaged
under the Oracle Business Intelligence analytics namespace, which is:

`oracle.apps.<LBATop>.<LBACore>.publicview.analytics`

However, the Oracle Fusion Middleware Extensions for Applications package
namespace is acceptable for ATG-generated objects seeing as they are artifacts of the
ATG-Oracle Fusion Middleware Extensions for Applications services infrastructure. If
the interfaces of these objects are publicly visible, this should not present any
problems to clients of these objects.

### 62.8.5 Guidelines for Hierarchy Depth and Conformance

It is possible for an inconsistency to arise between the three realizations of a particular
application hierarchy across the application, and the Transactional Business
Intelligence and Oracle BI Applications technologies.
Hierarchies on the Oracle BI EE server are necessarily limited to a maximum of 15 levels. However, Oracle BI Applications uses data warehouse tables to represent these hierarchies, and although the tables are not inherently bounded in size, restrictions on the number of levels of a given hierarchy being imported into the data warehouse are enforced by the ETL process. The majority of Oracle BI Applications hierarchies are fixed at eight levels plus a top-level for a total of nine fixed levels. A very small number of Oracle BI Applications hierarchies have greater than eight levels, plus a top-level and a base-level, with the largest of these hierarchies consisting of 21 fixed levels.

Trees, especially value-based trees, are generally unbounded in size. However, trees that have been implemented using Oracle Fusion tree management services are limited to 32 levels by the ATG infrastructure.

Problems can potentially arise when an application tree exceeds 15 levels. When this occurs, the corresponding Oracle BI EE representation of the tree, such as a Oracle Business Intelligence hierarchy stored within the repository (RPD), must be compressed to 15 levels. This is accomplished by retaining the leaf-level of the source tree (base-level), as well as the root-level (top-level), and pruning the tree starting with the base-1 level and working up the tree until enough levels have been removed.

Table 62-6 illustrates the general mapping of levels on the Oracle Business Intelligence hierarchy to levels or depths of application trees. The logical representation of the application tree is expressed in terms of the columns of the column-flattened Oracle Business Intelligence view object for that tree, which has a maximum of 32 levels. In this case the 15-level (maximum) Oracle Business Intelligence RPD representation of the hierarchy is mapped to the 32-level (maximum) application BICVO representation of the tree by pruning the levels of the source tree designated by columns C1 through c17 of the BICVO.

<table>
<thead>
<tr>
<th>BI (RPD)</th>
<th>Application (BICVO)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Top</td>
<td>C31</td>
</tr>
<tr>
<td>Level Top +1</td>
<td>C30</td>
</tr>
<tr>
<td>.....</td>
<td>.....</td>
</tr>
<tr>
<td>Level Base - 1</td>
<td>C18</td>
</tr>
<tr>
<td>Base</td>
<td>C0</td>
</tr>
</tbody>
</table>

When mapping application trees to Oracle Business Intelligence hierarchies, there are two types of problems that may arise:

- The application tree exceeds 15 levels and the Transactional Business Intelligence realization of the hierarchy (provided by the Oracle BI EE server) has been pruned to 15 levels. However, the Oracle BI Applications realization of the hierarchy (provided by the ETL process) is allowed to exceed 15 levels. In this case, the Transactional Business Intelligence and Oracle BI Applications realizations of the hierarchy have different resolutions at their lowest levels.

- The application tree exceeds 15 levels and the Transactional Business Intelligence and Oracle BI Applications realizations of the hierarchy are both pruned to 15 levels. In this case, Transactional Business Intelligence and Oracle BI Applications
are the same in terms of resolution, but the Oracle Business Intelligenceside and the application side are not the same. For example, the application tree has greater resolution than its Oracle Business Intelligence counterpart.

The following are two possible consequences that may result from the problems outlined:

- Loss of information (loss of resolution) resulting from the pruning away of several lower levels of the hierarchy, as well as potential differences in information (resolution) between Transactional Business Intelligence and Oracle BI Applications.

- An effect on fact-based security at the pruned levels. For example, you have established certain privileges on facts joined to nodes at tree levels that are ultimately pruned away. The security privileges of facts that had been joined to the pruned nodes may have been more restrictive than those at ancestral levels.

62.8.5.1 Resolve Problems

There are basically two choices for either completely resolving, or at least mitigating, the potential problems.

**Note:**

Neither of the following resolutions require any actual implementation work. However, they do require a combination of policy and documentation.

- **Complete Resolution:**
  
  Any application tree that has a realization on the Oracle Business Intelligenceside (Transactional Business Intelligence or Oracle BI Applications) must be restricted to no more than 15 levels.

- **Mitigation:**
  
  Ensure that, if any application tree exceeds 15 levels, and that tree has realizations on both Transactional Business Intelligence and Oracle BI Applications, that both technologies maintain pruned realizations of this tree and have the same number of levels (such as 15 or less).

  For this resolution, it will be necessary that these situations be investigated and documented on a case-by-case basis. You must decide how you want to adjust the security privileges of metrics that had previously been joined to the pruned levels, and then revise your Oracle Business Intelligence models accordingly.

62.8.6 About Securing ADF Business Components View Objects for Trees

Data security privileges are effectively applied to the column-flattened representation of the tree (as described in Table 62-3) in the form of a filter based on an OR condition on the columns. For example, a reporting client has viewing privileges on nodes 1.1 and 1.2.2. This means that any row that contains either node in any of its columns (at any level in the tree) is viewable to the client, but the other rows are not. The viewable rows are shown in Table 62-7 in bold.
### Table 62-7  Column-Flattened Result Set with Data Security

</tr>
</tbody>
</table>
Note:

The generalized OR filter can be restricted. For example, to apply only to the C0 column. This ensures that only nodes and optionally their descendants, for which a client has sufficient privileges, are viewable from the column-flattened result set.

62.8.6.1 About Security Implementation

The base table view object and column-flattened view objects (BICVO) are separate view objects. However, the data security definition must be consistently applied to both the base table view object and BICVO. For example, BICVOs must not have different data security behavior than the base entity on which security has been defined by Oracle Fusion Applications. This is achieved by Fusion tree management using the following process:

• When Oracle Fusion tree management generates the BICVO, it automatically adds an Oracle Fusion data security view criteria to the BICVO (FNDDS__BICVO). You must not change this view criteria’s name but must ensure that it is enabled for the application module for the Transactional Business Intelligence.

• The view criteria predicate for BICVO is generated from the base table view object at runtime by Oracle Fusion tree management. This ensures that BICVO data security is in sync with the base object.

• The following restrictions are placed on the base object view criteria so that the base view criteria is mapped to the BICVO view criteria, (which may have different column names), at runtime:

  – The base object view criteria must only use "Filter", which stores predicates using metadata. It cannot use SQL.

  – The base object view criteria must only use the DescendantOf hierarchy operator. It must not use any other hierarchy operators.

There may be situations in which a tree must support both secured and unsecured access. In this case, the BICVO that exposes the tree structure is deployed as both secured and unsecured versions.

The generated BICVO already has a security mechanism associated with it that is based on its data source view object. An unsecured version of the BICVO can be created by manually making a copy of the generated BICVO and editing it to exclude sensitive columns. Then, secured access to this edited BICVO is turned-off by de-activating the dummy FNDDS__BICVO view criteria associated with the BICVO. This causes the data source security view criteria to not be enforced. Again, both the secured and unsecured versions of the BICVO for the tree are to be deployed together in the same application module.

62.9 About Supporting Flexfields for Oracle Business Intelligence

You must do the following to allow the Flexfields ADF Modeler to generate a flattened view object containing only those attributes marked as BI Enabled:

• Set the BIEnabledFlag for your key flexfield

• Set the BIEnabledFlag for your descriptive flexfield
• Create Flexfield business components
• Define custom properties on the Oracle Business Intelligence application module
For information on how to perform these tasks, see the following sections in this book:
• Preparing Descriptive Flexfield Business Components for
• How to Prepare Key Flexfield Business Components for

62.10 About Supporting SetID

To properly resolve meanings for set-enabled attributes, the setID attribute must be exposed to the Oracle Business Intelligence layer. The setID attribute should be exposed using the appropriate method for the following reference types:

• Set-enabled lookups
• Set-enabled reference tables

62.10.1 How to Expose the SetID Attribute for Set-Enabled Lookups

The setID is required to retrieve appropriate meaning if the lookup is set-enabled. The Set Assignments Query is required to retrieve the setID.

To expose the setID attribute, do the following:

Set-enabled lookups (shared and Transactional Business Intelligence) are registered as warehouse domains and the SetAssignment entity object is already provided by ATG.

1. Build an entity object association between the Fact entity object and the SetAssignment entity object for each set-enabled lookup on the fact.

2. Expose setID as an attribute on the FactVO for each set-enabled lookup type on the FactVO.

The Lookup function is used to retrieve the translated meaning from the warehouse using setID parameter.

62.10.2 How to Expose the SetID Attribute for Set-Enabled Reference Tables

The setID is stored on set-enabled reference tables. A Unique ID is used as the primary key of the reference table; ID and language form the unique key of the translated reference table. The determinant value is not stored on the reference table; the foreign key used to reference the table is stored on transaction tables.

To expose the setID attribute, do the following:

Because the foreign key to the reference table already exists on the transaction, meanings for set-enabled attributes should be resolved depending on usage.

• Transactional Business Intelligence only:
  Resolve meaning on the base view object using entity object association, bringing in the setID attribute.

• Warehouse domain:
  A separate view object is required. Build a view link from the base view object to the reference view object. The setID attribute exists on the reference table view object.
62.11 About Supporting Multi-Currency

Oracle Fusion Middleware Extensions for Applications provides special MLS Currency view objects for Oracle Business Intelligence.

To support multi-currency, create view links from the primary entity currency code fields on transaction view objects to the new currency view object.
Implement ADF Desktop Integration

This chapter describes how to combine third party desktop applications with Oracle Fusion web applications.

The chapter includes these sections:

- Oracle Application Development Framework Desktop Integration Standards and Guidelines
- Skinning Excel ADF Desktop Integration Workbooks
- Configuring the WebLogic Server Frontend

63.1 Oracle Application Development Framework Desktop Integration Standards and Guidelines

ADF Desktop Integration makes it possible to combine third party desktop productivity applications with Oracle Fusion web applications, so you can use a program like Microsoft Excel as an interface to access Oracle Fusion web application data. Currently, ADF Desktop Integration supports using an Excel workbook to access descriptive and key flexfield data in your application.

ADF Desktop Integration is intended to provide integrated access across a variety of Oracle Fusion products from a variety of third-party interfaces. Consequently, it is important that you apply consistent standards for deployment and for look and feel to your implementation of ADF Desktop Integration.

For more general information about integrating Oracle Fusion web applications with desktop applications, see the Oracle Fusion Middleware Developing Applications with Oracle ADF Desktop Integration guide.

For information about using ADF Desktop Integration technology with flexfields, see Accessing Descriptive Flexfields from an ADF Desktop Integration Excel Workbook and How to Access Key Flexfields from an ADF Desktop Integration Excel Workbook.

Caution:

The Desktop Integration Developer’s Guide does not make explicit reference to technologies documented in this book, and this book does not repeat the content in the Desktop Integration Developer’s Guide, so you must read the Desktop Integration Developer’s Guide for a full understanding of how to use ADF Desktop Integration technology in general.
Standards for Naming and Organization

ADF Desktop Integration projects have many of the same code artifacts as standard ADF application UI projects. As such, the directory and naming standards for ADF Desktop Integration projects already have a good example to follow.

ADF Desktop Integration artifacts shall follow the same set of directory and naming standards as core ADF UI artifacts. However, you are also encouraged to distinguish your business component names as appropriate. For example, for the General Ledger Journal Entry functionality, the core ADF page has an application module called "JournalEntryAM." For the ADF Desktop Integration Journal Entry, the application module should be given a name similar to "DesktopJournalEntryAM" to prevent duplicate names.

63.1.1 How to Structure the ADF Desktop Integration Directories

The way that you code backing beans, page definitions and JSPX pages for ADF Desktop Integration will be different from the way you code core ADF UIs. For example, JSPX dialogs for ADF Desktop Integration require JavaScript. It is desirable to be able to distinguish between core UI artifacts and UI artifacts used by ADF Desktop Integration workbooks. Therefore, instead of checking in ADF Desktop Integration web picker artifacts into a "ui" package, it is recommended that you instead use a "di" (Desktop Integration) folder. Note that "di" and "ui" are the same length, so path string lengths will not change.

Following is an example of such a directory structure:

```
|-- adfmsrc
   |-- META-INF
       |-- <various generated files>
       |-- oracle
           |-- apps
               |-- <LBA Top>
                   |-- <LBA Core>
                       |-- di

|-- public_html
   |-- oracle
       |-- apps
           |-- <LBA Top>
               |-- <LBA Core>
                   |-- di
```

A major benefit to putting ADF Desktop Integration web picker dialog artifacts into a di folder is that automated standards checks can easily distinguish Desktop Integration-related objects and adjust their logic as needed. The directory structure under di will be organized the same way as the directory structure under the ui folder. For example, the bean, controller, page and util folders under di will be found in the same relative locations as the equivalent folders under ui.

The Excel Microsoft Office Open XML Format (XLSX) workbooks (and XLSM files, if required) should be checked into an excel folder within the public_html directory structure:

```
|-- public_html
   |-- oracle
       |-- apps
           |-- <LBA Top>
```

Oracle Application Development Framework Desktop Integration Standards and Guidelines
Example 63-1 shows some full directory paths for the ADF Desktop Integration artifacts on a Windows system, for a project in a leaf LBA called desktopJournalEntry. The folders contain page definitions, Excel and JSPX files, and beans, respectively:

Example 63-2 shows some directory paths for the ADF Desktop Integration artifacts in source control, for a project in a leaf LBA called desktopJournalEntry. The folders contain page definitions, [excel] and JSPX files, and beans, respectively:

Example 63-1  Directory Structure in Windows

D:\FinDashboardPrototype\gl\components\journals\desktopJournalEntry\di\adfmsrc\oracle\apps\financials\generalLedger\journals\desktopJournalEntry\di\pageDefs

D:\FinDashboardPrototype\gl\components\journals\desktopJournalEntry\di\public_html\oracle\apps\financials\generalLedger\journals\desktopJournalEntry\di\[excel|page]

D:\FinDashboardPrototype\gl\components\journals\desktopJournalEntry\di\src\oracle\apps\financials\generalLedger\journals\desktopJournalEntry\di\bean

Example 63-2  Directory Structure in Source Control

scs/gl/components/journals/desktopJournalEntry/di/adfmsrc/oracle/apps/financials/generalLedger/journals/desktopJournalEntry/di\pageDefs

scs/gl/components/journals/desktopJournalEntry/di/public_html/oracle/apps/financials/generalLedger/journals/desktopJournalEntry/di\bean

scs/gl/components/journals/desktopJournalEntry/di/src/oracle/apps/financials/generalLedger/journals/desktopJournalEntry/di\bean

63.1.2 How to Name Your ADF Desktop Integration Files

Because users can download workbooks to their desktops, providing each workbook with a unique name across applications is advisable. Make an effort to incorporate either the name of your product or the name of the primary Logical Business Object (LBO) involved, to create a meaningful name for your workbook. For example, the expenses workbook could be called ExpensesEntry.xlsx; the General Ledger journal entry workbook could be called JournalEntry.xlsx. However, because there is no current runtime or release requirement for unique names, the ADF Desktop Integration team will not coordinate this.

There is an open question regarding which workbook to source control and release: the design time version or the published version. For now, assume that both versions are source controlled. To that end, the published version should have the final name and the design time version should include the suffix "DT" in its filename. So in the expenses example, two workbooks will be source controlled: ExpensesEntry.xlsx and ExpensesEntryDT.xlsx, where the former is the published version and the latter is the design time version.
63.1.3 How to Implement the Dialog Attributes Declarative Component

The main function of the Dialog Attributes declarative component is to render the ADFDi reserved elements (ADFdi_CloseWindow, ADFdi_AbortUploadOnFailure and ADFdi_DownLoadAfterUpload) in the ADF pages that are used as dialogs in the spreadsheet.

This component replaces the ADFdi_CloseWindow, ADFdi_AbortUploadOnFailure and ADFdi_DownLoadAfterUpload span tags/outputText/JavaScript elements used in JSPX pages to render them as DI dialogs.

Since the component needs to render the value of the span tags (such as ADFdi_CloseWindow) based on the user's use case, it takes as an input the values to be rendered for these tags. To implement this, three properties are exposed on the component, one for each tag (ADFdi_CloseWindow, ADFdi_AbortUploadOnFailure and ADFdi_DownLoadAfterUpload). These properties need to be set based on how the page is used as a dialog in the spreadsheet. An overview of the properties is described in Table 63-1.

Table 63-1  Tag Properties Exposed on the Declarative Component

<table>
<thead>
<tr>
<th>Component Property</th>
<th>Data Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>closeWindowBinding</td>
<td>String</td>
<td>This property maps to the DI Dom element: ADFdi_CloseWindow. The value supplied for this property will be set as the value of the ADFdi_CloseWindow tag. You can bind the property to a backing bean. Example: closeWindowBinding=&quot;#{SubmissionOptionsBean.dialogResult}&quot; where dialogResult is a string that is defined in a backing bean and the value is set when the OK or Cancel button is clicked.</td>
</tr>
<tr>
<td>downloadAfterUpload</td>
<td>Boolean</td>
<td>This property maps to the DI Dom element: ADFdi_DownLoadAfterUpload. This value usually is a constant, such as true or false. It appears in the component property inspector as a list from which you can choose a true/false value. This property must be specified only if you are using the dialog as a custom upload dialog. Example: downloadAfterUpload=&quot;false&quot;</td>
</tr>
<tr>
<td>abortUploadOnFailure</td>
<td>Boolean</td>
<td>This property maps to: ADFdi_AbortUploadOnFailure. This value usually is a constant, such as true or false. It appears in the component property inspector as a list from which you can choose a true/false value. This property must be specified only if you are using the dialog as a custom upload dialog. Example: abortUploadOnFailure=&quot;false&quot;</td>
</tr>
</tbody>
</table>
63.1.3.1 Add the Component to Your Page

Before you can add the component to a web page, you need to add its containing JAR file as a library reference.

To add the JAR file as a library reference:

1. Create a file system connection.
   - Enter the connection name, such as DI Components, and the directory path as /ade/<view name>/fusionapps/jlib.
   - Test the connection to make sure it is valid. If it is, click OK.

2. Select your user interface project in the application navigator pane.

3. Expand the connection you just created (FileSystem > <connection name>).

4. Right-click the library AdfFinFunPublicDeclarativeComponentsDi.jar and select Add to Project.

5. To make sure the library was added, open Project Properties > Libraries and Classpath > ADF Library. You should see an entry for AdfFinFunPublicDeclarativeComponentsDi.jar.

When you add the library as a library reference to your project, the component palette will contain the Di Components option that lists all the DI components available for use.

To add the component to the web page:

1. In the component palette (View > Component Palette), select the DialogAttributes component and drag it onto the desired web page.

   The DI component namespace is added to the jsp:root tag at the top of your page:

   The component is rendered as:

   `<di:dialogAttributes id="da1" />

2. Set the component attributes.
You can view the available properties on this component by looking at the property inspector. Set the properties as required. The component tag will look like:

```xml
<di:dialogAttributes id="da1"
abortUploadOnFailure="false"
downloadAfterUpload="false"
closeWindowBinding="#{SubmissionOptionsBean.dialogResult}"/>
```

You are now ready to run your project.

### 63.2 Skinning Excel ADF Desktop Integration Workbooks

Oracle Fusion ADF Desktop Integration workbooks share a common set of style definitions. This enables them to easily apply required changes to the look and feel. The various style definitions that are needed by applications developers are defined in a common Excel styles template file, which is the accurate source for ADF Desktop Integration styles in Oracle Fusion. Figure 63-1 shows an example of the ADF Desktop Integration styles in use; keep in mind that the look and feel is subject to change at any time.

*Figure 63-1 Example of ADF Desktop Integration Look and Feel in Excel*

### 63.3 Configure the WebLogic Server Frontend

When ADF Desktop Integration sends a spreadsheet to the client, it embeds the server public callback address. Then, when the spreadsheet is opened, it is able to authenticate and perform operations on the address.

To set the Frontend URL for the Administration Console:

1. Log in to Oracle WebLogic Server Administration Console.
2. Click *Lock & Edit*.
3. Expand the Environment node in the Domain Structure window.
4. Click *Servers*. The Summary of Servers page displays.
5. Select *Admin Server* in the Names column of the table. The settings page for AdminServer(admin) is displayed.
6. Click the Protocols tab.
7. Click the HTTP tab.
8. Set the Front End Host field to admin.mycompany.com (your LBR address).

9. Save and activate the changes.

To eliminate redirections, you should disable the Administration Console’s "Follow changes" feature. To do this, log on to the Administration Console and click Preferences and then Shared Preferences. Clear the Follow Configuration Changes check box and click Save.

To configure HTTP settings for a cluster:

1. If you have not already done so, in the Change Center of the Administration Console, click Lock & Edit.

2. In the left pane of the Console, expand Environment and select Clusters.

3. Select the name of the cluster for which you want to configure HTTP.

4. Select HTTP and enter the following HTTP frontend information. These HTTP settings should be set when host information coming from the URL may be incorrect due to a firewall or proxy.
   - Frontend Host
   - Frontend HTTPPort
   - Frontend HTTPSPort

5. Click Save.

6. To activate these changes, in the Change Center of the Administration Console, click Activate Changes. Not all changes take effect immediately; some require a restart.
Create Customizable Applications

Oracle Metadata Services (MDS) framework allows you to create customizable Oracle Fusion applications. This chapter describes how to configure your application at design time so that it can be customized by end users.

This chapter includes the following sections:

- Introduction to Creating Customizable Applications
- Preparing an Application for Customizations
- Enabling Runtime Customization of Pages and Components

64.1 Introduction to Creating Customizable Applications

With the customization features provided by Oracle Metadata Services (MDS), both developers and customers can customize Oracle Fusion applications. Customizing an application involves taking a generalized application and making modifications to suit the needs of a particular group, such as a specific industry or site.

When an application is customizable, an end user can customize a user interface page at runtime in several ways. For example, the user can use the following methods to customize a page:

- Implicitly: Implicit customizations occur when a customer changes certain component attributes, such as the size of a panel or whether detail content is displayed.

- Using Page Composer: Page Composer enables end users who have the correct permissions, such as administrators, to change a user interface page to suit their company's needs, such as change the page layout, add task flows, documents, and other objects to a page, or wire pages to each other.

- Using the Personalization menu: The Personalization menu in the global area of Oracle Fusion Applications gives an end user access to Page Composer to customize a page to suit their needs. Only the end user sees the changes. End users can also use the Personalization menu to reset a page to display the default content and layout.

- Using the Customization Manager: Customization Manager enables end users who have the correct permissions, such as administrators, to download, upload, reset, and delete application customizations on objects such as pages and task flows.

Some customizations, such as changes to the model or to task flow roles, must be done from Oracle JDeveloper, as described in the "Using Oracle JDeveloper for Customizations" chapter in the Extensibility Guide for Developers. Customizations made from JDeveloper are referred to as design-time customizations. Design-time
customizations that are created and shipped with Oracle Fusion Applications are known as seeded customizations.

**Note:**
End users with the correct permissions can also customize some menus, such as the navigator menu.

For more information about customization, see the "Customizing and Extending Oracle Fusion Applications" chapter in the *Extensibility Guide for Developers*.

A customized application contains a base application and one or more layers of customized metadata content. The customized metadata objects are stored in an MDS repository and, when a customized application is launched, the customized content is retrieved and applied over the base content.

**Note:**
When you run your page in JDeveloper, all customizations created at runtime are, by default, written to a simulated MDS repository directory, which is stored at a temporary location in your system directory. The simulated MDS repository that is configured for the application reflects the metadata information that is contained in the Metadata Archive (MAR).

For more information, see Section 55.2.1, "How to Deploy an Application with Metadata to Integrated WebLogic Server."

To enable runtime customizations of an application, you first prepare the application for customizations, then you enable the runtime customization of pages and components.

### 64.2 Prepare an Application for Customizations

To enable an application for customization, you must complete the following steps in your JDeveloper application workspace in the order shown.

1. Set project properties to enable user and seeded customizations.
2. Configure the persistence change manager parameter to use the composer change manager.
3. Enable end-user translations of customized strings.
4. Add Oracle WebCenter Portal — Composer technology scope to your project. This technology scope contains the components that are used for Page Composer customization.
5. (Optional) Enable user customization of the user interface (UI) shell template.
6. (Optional) Create an IDE connection to your database (in addition to the application connection) to enable access to layer values that are populated from a database call.
After you complete these steps, you can enable runtime customization for the application’s web pages and task flows as described in Enabling Runtime Customization of Pages and Components.

64.2.1 How to Set Project Properties to Enable User and Seeded Customizations

To enable user customizations, you must configure the view project to persist the customized metadata objects to an Oracle Metadata Services (MDS) repository so that the objects are available across sessions. You must also enable seeded customizations so that the page fragments and JSPX pages that you create will be configured to allow customizations.

**Note:**

ADF components (such as controller, model, and business components objects) must have a unique identifier so that they can be customized. ADF components that are generated by JDeveloper are created with identifiers by default, except for fragments and pages in your user interface projects. To cause JDeveloper to generate identifiers for components on pages that you create in your user interface projects, you must explicitly specify this at the project level by enabling seeded customizations.

To set project properties for your view project:

1. In the Application Navigator in JDeveloper, right-click your view project and choose *Project Properties*.

2. In the Project Properties dialog, select *ADF View* to display the ADF View settings.

3. Select *Enable User Customizations* and select *Across Sessions Using MDS*, as shown in Figure 64-1.

4. Select *Enable Seeded Customizations*. 
5. Click OK.

64.2.2 How to Configure the Persistence Change Manager

You must configure the persistence change manager to cause the following runtime behavior to occur:

- The Persist and Don’t Persist attributes that you set for components at design time will govern which implicit changes that the end users make at runtime will be persisted during the session as well as across sessions.

- The changes that end users make in the design view of Page Composer will be stored in the MDS repository.

When you enabled user customizations across sessions by completing the procedure in How to Set Project Properties to Enable User and Seeded Customizations, the IDE added the `CHANGE_PERSISTENCE` context parameter to the view project’s `web.xml` file, and set the parameter to use the filtered persistence change manager. You must modify this parameter to use the composer change manager, and you must add the composer filter and its mapping.

Before you begin:

Modify your view project’s properties to enable user customizations across sessions as described in How to Set Project Properties to Enable User and Seeded Customizations.

To configure the persistence change manager:

1. In the Application Navigator, expand the WEB-INF node for your view project and double-click `web.xml`.

2. In the source editor, change the `org.apache.myfaces.trinidad.CHANGE_PERSISTENCE` context parameter
value to
oracle.adf.view.page.editor.change.ComposerChangeManager, as shown in the following code.

<context-param>
<param-name>org.apache.myfaces.trinidad.CHANGE_PERSISTENCE</param-name>
<param-value>
  oracle.adf.view.page.editor.change.ComposerChangeManager
</param-value>
</context-param>

3. Add the filter and filter-mapping elements for the WebCenterComposerFilter class as shown in bold in Example 64-1.

---

Note:
Filters must be configured in the following order.

a. JpsFilter
b. ApplSessionFilter
c. WebCenterComposerFilter
d. ADFBindingFilter

---

4. Enable sessions for the JSPX pages and task flows that you create in your view project as described in How to Configure Your Project to Use Application User Sessions.

This step, among other modifications, adds the Applications Core and Web Service Data Control libraries to your project, which you need to complete the tasks to prepare your application for customization.

Example 64-1 composerFilter and Mappings in web.xml

....
<!-- composerFilter goes here -->
<filter>
  <filter-name>composerFilter</filter-name>
  <filter-class>
    oracle.adf.view.page.editor.webapp.WebCenterComposerFilter
  </filter-class>
</filter>
<filter>
  <filter-name>adfBindings</filter-name>
  <filter-class>oracle.adf.model.servlet.ADFBindingFilter</filter-class>
</filter>
....

<!-- composerFilter mapping goes here -->
<filter-mapping>
  <filter-name>composerFilter</filter-name>
  <servlet-name>Faces Servlet</servlet-name>
  <dispatcher>FORWARD</dispatcher>
  <dispatcher>REQUEST</dispatcher>
</filter-mapping>
<filter-mapping>
  <filter-name>adfBindings</filter-name>
  <servlet-name>Faces Servlet</servlet-name>
</filter-mapping>
64.2.3 How to Enable Translations of Customized Strings

You must configure your application to enable end users to provide translated values for customized strings at runtime, as described in the "Translating Custom Text" chapter in the Extensibility Guide for Developers.

The resource string editor enables the runtime editing of strings. The changes made using the resource string editor are saved into an application override bundle, which can be translated and imported back into the application.

For more information about configuring the runtime resource string editor, see the "Configuring Runtime Resource String Editing" section in the Developing WebCenter Portal Assets and Custom Components with Oracle JDeveloper.

**Note:**
This procedure only enables resource string editing if the changes are customizations and not user personalizations, as user personalizations do not need to be translated.

To set up runtime resource string editing for customizations:

1. In the Application Navigator in JDeveloper, right-click the application and select Application Properties.
2. In the Application Properties dialog, select Resource Bundles.
3. Click Add.
4. Type the following string in the File Name field in the Select Resource Bundle dialog.

   oracle.adf.view.page.editor.resource.ComposerOverrideBundle.xlf

5. Click Open.
6. Select the Overridden check box.
7. Click OK to save your changes.
8. Open the adf-config.xml file, which is located in the Application Resources > Descriptors > ADF META-INF folder.
9. Add the resource-string-editor element shown in Example 64-2 to the page-editor-config section to enable resource string editing.

**Example 64-2  Configuration to Turn On Resource Editor**

```
<pe:page-editor-config>
  ...
  <resource-string-editor>
    <enabled>
      #{GlobalAreaBackingBean.tipLayerNonUser}
    </enabled>
```
64.2.4 How to Add Composer Technology Scope to Your Project

You must add the Oracle WebCenter Portal — Composer technology scope to access the technologies for consuming Page Composer components and enabling runtime customization.

To add Composer technology scope:

1. Right-click your view project and select Project Properties.
2. Select Technology Scope.
3. Add the Oracle WebCenter Portal — Composer technology scope to your project and click OK.

64.2.5 How to Enable the User Customization of the UI Shell Template

You can configure the UI Shell template so that it can be customizable out-of-the-box. This functionality enables customers to use Page Composer to customize UI Shell pages.

To enable users to customize the UI shell template, you add a link or button to the page fragment from which you want end users to launch the UI Shell template for editing. You then configure the link (or button) to enable end users to modify the template.

To enable the user customization of the UI Shell Template:

1. From JDeveloper, open the JSF page fragment (.jsff) from where the UI Shell can be edited.
2. In the Application Navigator, expand the Data Controls hierarchy to locate and expand the FndUIShellController.
3. Drag and drop the customizeUIShellTemplate operation onto the page, and choose Create > Method > ADF Button or choose Create > Method > ADF Link.
4. In the Edit Action Binding dialog, provide a comma delimited list of fully packaged qualified customization classes for the custClass parameter, as shown in Example 64-3.

Each of the customization classes supplied in the list must be valid and configured in the adf-config.xml file, as shown in Figure 64-2.
If any of the classes cannot be instantiated, or if they are not pre-configured in the \texttt{adf-config.xml} file, an exception is thrown at runtime.

The last customization class specified is the \textit{tip} customization layer and the modifications to the UI Shell is written to this layer. In \texttt{Example 64-3}, the customization of the UI Shell takes place in SiteCC. The purpose of the earlier customization in the list is to view the UI Shell with any other customizations applied.

For information about customization layers, see the "Understanding Customization Layers" section in the \textit{Extensibility Guide for Developers}.

5. Click OK.
6. Open the page definition file for the page fragment.
7. In the editor window, click the \texttt{Source} tab.
8. Add the \texttt{<methodAction>} element shown in \texttt{Example 64-4} to the \texttt{<bindings>} element. The \texttt{id} attribute must be set to custNavigate, which is the key to the \texttt{customizeUIShellTemplate} operation that you dropped on the page in Step 3.
9. Add the view permission for oracle.apps.fnd.appcore.template.customization.TemplateCustomizationUIShellPageDef (the customization page) for each role for which you want to enable the view action as described in \textit{How to Authorize the Runtime Customization of Pages and Task Flows}. To access oracle.apps.fnd.appcore.template.customization.TemplateCustomizationUIShellPageDef in the \texttt{Resource Grants} navigation tab, select \texttt{Web Page} from the \texttt{Resource Type} dropdown list and select \texttt{Show web pages} imported from ADF libraries.

\textit{Example 64-3} \hspace{1em} \textbf{Sample custClass List}

oracle.apps.fnd.appcore.customization.GlobalCC, oracle.apps.fnd.appcore.customization.SiteCC

\textit{Example 64-4} \hspace{1em} \textbf{custNavigate methodAction Binding}

\begin{verbatim}
<bindings>
  <methodAction id="custNavigate" RequiresUpdateModel="true"
              Action="invokeMethod" methodName="navigate"
              IsViewObjectMethod="false" dataControl="FndUIShellController"
              instanceName="FndUIShellController.dataProvider"
              returnName="FndUIShellController.methodResults.navigate_FndUIShellController_dataProvider_naviga"

```
64.2.6 How to Create a Database Connection at the IDE Level

In addition to the application level connection to your application database, you might also need to create an Integrated Development Environment (IDE) connection. The IDE connection is required when implementing design-time customizations from JDeveloper, as described in the "Using Oracle JDeveloper for Customizations" chapter in the Extensibility Guide for Developers.

To create a database connection at the IDE level

1. From the Database Navigator, right-click the ApplicationDB node under your application's node and choose Properties.
2. Make a note of the settings and click Cancel.
3. Right-click IDE Connections and choose New Connection.
4. Enter the settings that you noted in Step 2.
5. Click Test Connection to ensure the settings are correct.
6. Click OK.

The database connection appears under the IDE Connections node.

64.3 Enable Runtime Customization of Pages and Components

After you have completed the non-optional procedures described in Preparing an Application for Customizations, you can enable pages, task flows, and components for runtime customization.

To enable an application's pages, task flows, and components for runtime customization:

1. Enable runtime customization of web pages.
2. Enable end-user personalization for the desired pages.
3. (Optional) Restrict customizations of specific page fragments and components. (By default, customization is allowed for pages, page fragments, and the components on a page.)
4. (Optional) Control the editing of components in Page Composer and control the views that are available in Design view.
5. Authorize runtime customization of pages and task flows.

6. (Optional) Enable and disable persistence of attributes for implicit runtime customizations.

As shown in Figure 64-3, the settings that you make by following the procedures in this section affect whether an end user can customize an object under the following scenarios.

---

**Note:**

For simplicity, the Page Composer scenarios assume that the settings for the page are set to enable the editing of components. For more information, see How to Control the Editing of Components in .

---

- User performs an implicit customizations: If the component can be persisted and customization is allowed, the implicit customization is persisted for the session as well as across sessions.

- User accesses Customization Manager: If the end user has an administrative role or privilege, the user can access the Customization Manager. If the task flow has edit permissions for a user’s role or privilege, the user can import, export, or delete customizations of objects for which customization is allowed.

- User accesses Page Composer to customize a page: If the end user has an administrative role or privilege and customization is allowed for the page (JSPX root), the user can access Page Composer. If the task flow has edit permissions for the user’s role or privilege, the user can customize any object for which customization is allowed.

- User accesses Page Composer to personalize a page: If the page enabled for end-user personalizations and customization is allowed for the page (JSPX root), the user can access the page in Page Composer. If the task flow has edit permissions for the user’s role or privilege, the user can customize any object for which customization is allowed.

- User accesses Page Composer to reset content and layout: If customization is allowed for the page and the task flow has edit permissions for the user’s role or privilege, the user can reset the content and layout for which customization is allowed.

To determine whether customization is allowed, the application looks at the component’s Customization Allowed property to see if it has an explicit value. If there is no explicit value, the application looks at the parent object and continues up the tree, ending at the JSF page fragment (.jspx root), until it finds an explicit value. For example, if Customization Allowed is not set for a component, but is set to true for the page fragment, then customization is allowed for the component. However, if Customization Allowed is false for the component, the application disallows customization of that object, even if the page fragment’s Customization Allowed property is set to true. Conversely, if the page fragment’s Customization Allowed property is set to false, but a component’s property is set to true, the end user can customize the component.

By default the Customization Allowed property for the page (.jspx) root is true. Therefore, you must explicitly set Customization Allowed to false at some level, such as for a component, region, or page (.jspx), to disallow customization for that
object and its child objects. A fragment (.jsff) is loaded by MDS as a separate document and does not inherit the **Customization Allowed** property from the containing page (.jspx).

---

**Note:**

You can optionally use the **Customization Allowed By** property to permit customizations only for certain roles.
64.3.1 How to Enable Pages for Runtime Customization

Perform the following steps to enable runtime customization of a web page using Page Composer:

1. Ensure that the customizable pages have page definition files.
2. Make pages runtime editable by adding Page Composer components to the pages.

3. If you are enabling the runtime addition of content, set up a resource catalog.

4. (Optional) Set up a default catalog definition file to facilitate testing.

64.3.1.1 Ensure Customizable Pages Have Page Definitions

Page definition files define the binding objects that populate data the data in UI components at runtime. A page definition is required for runtime customizations that add additional components such as task flows and portlets. Page definition files can be found under Projects > View Controller > Application Sources > oracle.apps.view. If a required page definition file does not exist, complete the following steps to create one.

To create a page definition file for a JSPX page:

1. In the Application Navigator, right-click the JSPX page and choose Go to Page Definition.

2. If the page does not have a page definition, a Confirm Create New Page Definition dialog appears. Click Yes to create the page.

64.3.1.2 Making a JSPX Document Editable at Runtime

To make a JSPX document editable at runtime, you add Composer components to the page at design time. You use the Panel Customizable component to define an area of the page onto which users can add components at runtime. You use the Layout Customizable component to enable users to lay out its child components in several predefined ways, such as two-column or three-column.

The Layout Customizable and Panel Customizable components are from the Oracle WebCenter Portal — Composer technology scope, which you added when you completed the steps in How to Add Technology Scope to Your Project, and which are available from the Composer page in the Component Palette.

For more information about the Panel Customizable and Layout Customizable components, see the Composer Components section in the Developing WebCenter Portal Assets and Custom Components with Oracle JDeveloper.

64.3.1.3 Setting Up a Resource Catalog

If you have a Panel Customizable component on your page to enable the runtime addition of content, you must set up a resource catalog to list the available content.

To learn how to create a custom resource catalog, see the Creating and Managing Resource Catalogs chapter in the Developing WebCenter Portal Assets and Custom Components with Oracle JDeveloper.

64.3.1.4 Using the Default Catalog Definition File for Testing

A considerable amount of work is involved in setting up a resource catalog. If you want to test runtime customizations before you finish setting up your catalog, you can use the default catalog definition file.

To use the default catalog for testing:
1. Create the application_root/ViewController/src/oracle/adf/rc/metadata directory structure.

2. Copy the Oracle WebCenter Portal default catalog definition file default-catalog.xml to the newly created application_root/ViewController/src/oracle/adf/rc/metadata directory.

Caution:
The Oracle WebCenter Portal default catalog should only be used for testing purposes. You must create your own catalog for production purposes.

64.3.2 How to Enable End-User Personalizations for a Page

Control whether an end user can personalize a page by setting the page's isPersonalizableInComposer property.

Note:
You must enable personalizations for all your dashboards. However, workareas should have personalizations enabled only if absolutely required.

To enable end-user personalizations:

1. In the Application Navigator, select the .jspx page.
2. In the Structure window, select the af:pageTemplate component.
3. In the Property Inspector, select true from the isPersonalizableInComposer dropdown list.

64.3.3 How to Restrict Customization of a Page, Page Fragment, or Component

Customization is enabled for pages, page fragments, and components by default. However, there might be situations where you want to prevent customization for some objects.

You can specify at the page, page fragment, or component level whether customizations for a component are permitted at runtime and who is permitted to customize that component.

Before you begin:
Review the introduction to Enabling Runtime Customization of Pages and Components to understand how the application uses the value of the Customization Allowed property to determine whether an object can be customized.

To restrict customization of a page, page fragment, or component:

1. In the Application Navigator, select the page or fragment for which you want to edit customization properties.
2. If you are restricting the customization of a component, select the component in the Structure window.
3. If the Property Inspector is not open, choose **Property Inspector** from the **View** menu.

4. In the Property Inspector, expand **Customization**.

5. Set the appropriate customization attribute.
   - To disable runtime customization, set **Customization Allowed** to **false**.
   - To restrict customization to specific sets of users and layers, set **Customization Allowed By** to a space-separated list of the security roles for which you wish to permit customization.

For more information about these attributes, see the *Extended Metadata Properties* section in the *Developing Fusion Web Applications with Oracle Application Development Framework*.

For information about customization layers, see the *Understanding Customization Layers* section in the *Extensibility Guide for Developers*.

### 64.3.4 How to Control the Editing of Components in Page Composer

As described in *How to Restrict Customization of a Page_ Page Fragment_ or Component*, all end users who can personalize or customize a page can use Page Composer to change the layout on a page by default.

For some pages, Page Composer enables end users to configure a page in either Source view or Design view. For other pages, end users can only configure the page in Design view. By default, end users can add and edit components in Source view. In Design view the default is to allow end users to add components to a page but not edit existing components. You can configure the page to allow users to select components for editing in Design view, as shown in *Figure 64-4*, or you can configure the page to disallow both adding and editing components.

*Figure 64-4 Page Configured to Allow Users to Add and Edit Components*

If a page has properties with EL expressions that you do not want changed, you can set all existing property EL expressions to read-only. For example, the page in *Figure 64-4* was configured to disallow the editing of existing EL expressions and, therefore, the user cannot edit the **Action Listener** property. In addition, you can configure a page to disallow entering new EL expressions. That is, you can prevent users from entering EL expressions in property fields that do not currently contain EL expressions.
Table 64-1 lists the properties that you set at the af:pageTemplate level to control the editing of components in Page Composer.

### Table 64-1  af:pageTemplate Properties for Page Composer

<table>
<thead>
<tr>
<th>Property</th>
<th>Type</th>
<th>Supports EL</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>allowELInComposer</td>
<td>Boolean</td>
<td>No</td>
<td>Specifies if EL expressions can be entered for form element properties. The default value is true.</td>
</tr>
<tr>
<td>designViewsInComposer</td>
<td>String</td>
<td>No</td>
<td>Specifies the views available to the user in Page Composer Design view. This property can take a space-separated list of elements. The following options are available:</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>• all: Makes both Add Content and Select views available and displays a toolbar with buttons to switch between views.</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>• add-content (default): Makes the Add Content view the only available view.</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>• select add-content: The same as the all option.</td>
</tr>
<tr>
<td>protectELInComposer</td>
<td>Boolean</td>
<td>No</td>
<td>Specifies if existing EL expressions in the page's form elements are read-only. The default value is false.</td>
</tr>
</tbody>
</table>

Table 64-2 lists all possible combinations of allowELInComposer and protectELInComposer property values and describes how each combination affects the user's ability to add and edit EL expressions.

### Table 64-2  Affects of allowELInComposer and protectELInComposer Property Settings

<table>
<thead>
<tr>
<th>Combination</th>
<th>Affect</th>
</tr>
</thead>
<tbody>
<tr>
<td>protectELInComposer = true, allowELInComposer = true</td>
<td>Users can add an EL expression to a property if it does not currently have an EL expression and if EL expressions are allowed for that property. However, users cannot edit existing EL expressions.</td>
</tr>
<tr>
<td>protectELInComposer = false, allowELInComposer = true</td>
<td>Users can add and edit EL expressions in properties for which EL expressions are allowed</td>
</tr>
</tbody>
</table>
Table 64-2  (Cont.) Affects of allowELInComposer and protectELInComposer
Property Settings

<table>
<thead>
<tr>
<th>Combination</th>
<th>Affect</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>protectELInComposer = false</code></td>
<td>Users cannot add an EL expression to a property if it does not currently contain an EL expression, but they can edit existing EL expressions.</td>
</tr>
<tr>
<td><code>allowELInComposer = false</code></td>
<td></td>
</tr>
<tr>
<td><code>protectELInComposer = true</code></td>
<td>User cannot add or edit EL expressions.</td>
</tr>
<tr>
<td><code>allowELInComposer = false</code></td>
<td></td>
</tr>
</tbody>
</table>

64.3.5 How to Authorize the Runtime Customization of Pages and Task Flows

As illustrated in Figure 64-3 a user can edit customizable components in a user interface page at runtime only if they have permission to edit the page and permission to edit the task flow that contains the component. For example, an end user can only customize components in a task flow using Page Composer if that user has permission to customize the task flow. You use the `jazn-data.xml` file to define which roles can edit the page or task flow.

**Before you begin:**

Enable the desired pages for editing in Page Composer as described in Enabling Runtime Customization of Pages and Components.

**To authorize pages and task flows for runtime customizations:**

1. In the Application Resources panel, expand Descriptors, expand META-INF nodes, and then double-click `jazn-data.xml`.

   **Tip:**

   If the `jazn-data.xml` file does not exist, you can create it by right-clicking the META-INF node, selecting New Oracle Deployment Descriptor, selecting `jazn-data.xml`, and then clicking Finish.

2. In the overview editor, click the Resource Grants navigation tab, as shown in Figure 64-6.
3. Select **Web Page** from the **Resource Type** dropdown list.

   You use the **Web Page** resource type for both web pages and page fragments.

4. Set the **Source Project** to **ViewController**.

5. For each Page Composer enabled web page, select the **Customize** action for each role for which you want to enable page customization.

   You must also authorize customization for the task flows, as described in the following two steps.

6. Select **Task Flow** from the **Resource Type** dropdown list.

7. For each task flow, select the **Customize** action for each role for which you want to enable customization of the components in the task flow.

8. If you want the task lists that are exposed in your pages to be customizable for your application, select the entry for **TaskList** in the **Resources** list, and, for each role for which you want to enable task list customization, select the **customize** and **grant** actions.

   For more information, see the **Implementing Task Flow Security** section in the Developing WebCenter Portal Assets and Custom Components with Oracle JDeveloper.

### 64.3.6 How to Persist Implicit Runtime Customizations

Certain ADF Faces components have attributes that can be saved during a user session. For example, if a user expands a panel box component, the box will be expanded when the user returns to the page. This type of change is referred to as implicit runtime customization. For information about which component properties can be persisted, see the **Allowing User Customizations at Runtime** chapter in the Developing Fusion Web Applications with Oracle Application Development Framework.
In How to Set Project Properties to Enable User and Seeded Customizations, you configured the application to persist implicit runtime customizations across sessions as well as within sessions.

The attributes that can be persisted are set in the tag library, but you can override these settings. For example, you might not want the end users to change column widths, but you want all other default attribute changes for columns to be persisted. You set and unset these values in the Overview Editor for the `adf-config.xml` file, as described in the Configuring User Customizations section in the Developing Fusion Web Applications with Oracle Application Development Framework. You can also override these settings for specific components, as described in the Controlling User Customizations in Individual JSF Pages section in the Developing Fusion Web Applications with Oracle Application Development Framework.
This chapter explains how to use extensions to Oracle Enterprise Scheduler to manage job request submissions in the context of Oracle Fusion Applications. This chapter includes the following sections:

- Introduction to Extensions
- Understanding Standards and Guidelines
- About Creating and Implementing a Scheduled Job in
- About Creating a Job Definition
- About Configuring a Spawned Job Environment
- About Implementing a PL/SQL Scheduled Job
- About Implementing a SQL*Plus Scheduled Job
- About Implementing a SQL*Loader Scheduled Job
- About Implementing a Perl Scheduled Job
- About Implementing a C Scheduled Job
- About Implementing a Host Script Scheduled Job
- About Implementing a Java Scheduled Job
- About Elevating Access Privileges for a Scheduled Job
- About Creating an User Interface for Submitting Job Requests
- About Submitting Job Requests Using the Request Submission API
- About Defining Postprocessing Actions for a Scheduled Job
- About Monitoring Scheduled Job Requests Using an UI
- About Using a Task Flow Template for Submitting Scheduled Requests Through an UI
- About Securing UIs
- About Integrating Scheduled Job Logging with
- About Logging Scheduled Jobs and Writing to Output Files
65.1 Introduction to Oracle Enterprise Scheduler Extensions

Oracle Enterprise Scheduler provides the ability to run different job types, including Java, PL/SQL, and spawned jobs. Jobs can run on demand, or be scheduled to run in the future.

Oracle Enterprise Scheduler provides scheduling services for the following purposes:

- Distributing job request processing across a grid of application servers.
- Running Java, PL/SQL, and process or spawned jobs.
- Processing multiple jobs concurrently.
- Running the same job in different languages.

Using Oracle JDeveloper, application developers can create and implement jobs. While implemented in JDeveloper, Oracle Enterprise Scheduler runs the jobs. APIs provide an interface between jobs executed within applications developed in JDeveloper and Oracle Enterprise Scheduler.

The Oracle JDeveloper extensions to Oracle Enterprise Scheduler enable the following:

- Running scheduled Oracle Business Intelligence Publisher (Oracle BI Publisher), spawned, Java, PL/SQL, Perl, SQL*Plus, SQL*Loader, and C jobs.
- Running the same job in multiple locales, time zones, currencies, and so on.
- Creating log and output files for jobs, as well as acting upon those files, such as enabling notifications.
- Creating Oracle Application Development Framework (Oracle ADF) task flows to schedule jobs and job sets, as well as monitor job requests.

Before you begin:

Install Oracle Enterprise Scheduler to Oracle WebLogic Server. For more information, see Chapter 2, "Setting Up Your Development Environment."

65.2 Understanding Standards and Guidelines

The following standards and guidelines apply to working with extensions to Oracle Enterprise Scheduler:

- Always use the preconfigured job types provided when defining metadata for job definitions.

65.3 About Creating and Implementing a Scheduled Job in Oracle JDeveloper

Submitting job requests from an Oracle Fusion application requires developing the following components:

- A job definition, created in JDeveloper
- The Java, PL/SQL, SQL*Loader, SQL*Plus, Perl, C, or host scripts job implementation
• A user interface enabling end users to submit job requests and/or additional properties for the job

A wizard enables defining a new job within the context of an Oracle Fusion application. The job can be any one of the following types: Java, PL/SQL, SQL*Loader, SQL*Plus, Perl, C, or host scripts.

65.3.1 How to Create and Implement a Scheduled Job in JDeveloper

Creating and implementing a scheduled job in JDeveloper involves creating a package or class from which to call the job, as well as defining a job definition. The job must then be deployed and tested, and a job request submission interface defined.

To create and implement a scheduled job in JDeveloper, do the following:

1. Create a package, class, or job, and include the minimum required methods or functions.
   - Define the job request
   - Define any subrequests, if required.

2. If a job requires parameters to be filled in by end users using an Oracle ADF user interface, define a standard ADF Business Components view object with validation.

   For example, if a job requires information regarding duration, date, and time, create an ADF Business Components view object with the properties duration, date, and time.

3. Create a job definition in JDeveloper using the wizard.

   If using an ADF Business Components view object to collect additional values at runtime from end users, specify the name of the view object as a property of the job definition.

4. Deploy the job.

5. Test the job.

6. Create the end user job request submission interface.

   For more information about creating the end user job request submission interface, see About Creating an User Interface for Submitting Job Requests.

65.3.2 What Happens When You Create and Implement a Scheduled Job in JDeveloper

Once a job has been defined, it is implemented in Java, PL/SQL, SQL*Loader, SQL*Plus, Perl, C or a host script. The Fusion application requests Oracle Enterprise Scheduler to run the implemented jobs using the provided APIs.

65.3.3 What Happens at Runtime: How a Scheduled Job Is Created and Implemented in JDeveloper

An Oracle ADF interface is provided to enable application end users to submit job requests from an Oracle Fusion application. The Oracle ADF interface is integrated into an Oracle Fusion application. As soon as a job request is submitted through the interface, Oracle Enterprise Scheduler runs the job as scheduled.
65.4 About Creating a Job Definition

To submit a job request, you must first create a job definition.

The following documents provide additional information related to subjects discussed in this section:

- For more information about defining an Oracle BI Publisher job, see the Oracle Fusion Middleware Report Designer’s Guide for Oracle Business Intelligence Publisher, Oracle Fusion Middleware Administrator’s Guide for Oracle Business Intelligence Publisher, and the Oracle Fusion Developer’s Guide for Oracle Business Intelligence Publisher.

- For more information about using entity objects, see the section Creating a Business Domain Layer Using Entity Objects in Developing Fusion Web Applications with Oracle Application Development Framework guide.

- For more information about log levels, see the Developing Applications for Oracle Enterprise Scheduler guide.

65.4.1 Understanding Job Definitions and Job Types

A job definition and job type are required to submit a job request.

- **Job Definition**: This is the basic unit of work that defines a job request in Oracle Enterprise Scheduler.

- **Job Type**: This specifies an execution type and defines a common set of properties for a job request.

The extensions to Oracle Enterprise Scheduler provide the following execution types:

- **JavaType**: for job definitions that are implemented in Java and run in the container.

- **SQLType**: for job definitions that run as PL/SQL stored procedures in a database server.

- **CJobType**: for job definitions that are implemented in C and run in the container.

- **PerlJobType**: for job definitions that are implemented in Perl and run in the container.

- **SqlLdrJobType**: for job definitions that are implemented in SQL*Loader and run in the container.

- **SqlPlusJobType**: for job definitions that are implemented in SQL*Plus and run in the container.

- **BIPJobType**: for job definitions that are executed as Oracle BI Publisher reports. Oracle BI Publisher jobs require configuring the parameter `reportID`.

- **HostJobType**: for job definitions that run as host scripts executed from the command line.
65.4.1.1 How to Create a Job Definition in Oracle JDeveloper

If your job definition requires additional properties to be filled in by end users at submission time, you’ll need to create a view object that defines these properties. The view object must be associated with the job definition you create. The view object is later associated with the user interface you create to allow end users to submit job requests along with the properties at submission time.

For more information about defining properties to be filled in at runtime by end users, see About Creating a User Interface for Submitting Job Requests.

To create a new job definition in JDeveloper, do the following:

1. In Oracle JDeveloper, create an Oracle Fusion web application by clicking the Application Menu icon on the Application Navigator, selecting New Project > Projects > Generic Project and clicking OK.

2. Right-click the project and select Properties. In the Resources tab, add the directory $MW_HOME/jdeveloper/integration/ess/extJobTypes.

3. If your job includes any properties to be filled in by end users using an Oracle ADF user interface at runtime, create an ADF Business Components view object with validation and the parameters to be filled in by end users.

   a. Right-click the Model project and select Properties. In the Resource Bundle section, configure one bundle per file and select resource bundle type Xliff Resource Bundle.

   b. Define attributes for the view objects sequentially, ATTRIBUTE1, ATTRIBUTE2, and so on, with an attribute for each required parameter. Use ADF Business Components attribute control hints to specify required prompt, validation, and formatting for each parameter.

   c. Add the property parametersVO to your job definition and specify the fully qualified path of the view object as the value of parametersVO. For example, set parametersVO to oracle.my.package.TestVO. A maximum of 100 attributes can be used for parametersVO. The attributes should be named incrementally, for example ATTRIBUTE1, ATTRIBUTE2, and so on.

   d. Define the following required properties:

      • jobDefinitionName: The short name of the job.
      • jobDefinitionApplication: The short name of the application running the job.
      • jobPackageName: The name of the package running the job.

Additional properties can be defined as shown in Table 65-1.
### Table 65-1  Additional Job Definition Properties

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>completionText</td>
<td>An optional string value that can be used to communicate details of the final state of the job. This property value is displayed in the UI used to monitor job request submissions in the details section of the job request. It can be useful for displaying a short explanation as to why a request ended in an error or warning state.</td>
</tr>
<tr>
<td>CustomDatacontrol</td>
<td>The name of the data control for the application to which the parameter task flow is bound. Following is an example.</td>
</tr>
<tr>
<td></td>
<td>&lt;parameter name=&quot;CustomDatacontrol&quot; data-type=&quot;string&quot;&gt;ExtParameterAM&lt;/parameter&gt;</td>
</tr>
<tr>
<td></td>
<td>Use this property when adding a custom task flow to an Oracle ADF user interface used to submit job requests at runtime. For more information, see How to Add a Custom Task Flow to an User Interface for Submitting Job Requests.</td>
</tr>
<tr>
<td>defaultOutputExtension</td>
<td>The suffix of the output file. Possible values are txt, xml, pdf, html.</td>
</tr>
<tr>
<td>enableTimeStatistics</td>
<td>A Boolean parameter that enables or disables the accumulation of time statistics (Y or N).</td>
</tr>
<tr>
<td>enableTrace</td>
<td>A numerical value that indicates the level of tracing control for the job. Possible values are as follows:</td>
</tr>
<tr>
<td></td>
<td>• 1: Database trace</td>
</tr>
<tr>
<td></td>
<td>• 5: Database trace with bind</td>
</tr>
<tr>
<td></td>
<td>• 9: Database trace with wait</td>
</tr>
<tr>
<td></td>

About Creating a Job Definition

---

65-6  Oracle Fusion Applications Developer's Guide
Table 65-1  (Cont.) Additional Job Definition Properties

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>incrementProc</td>
<td>Enables a PL/SQL procedure evaluated at runtime which calculates the next set of date parameter values for a recurring request. Enter the name of the PL/SQL procedure. The procedure expects one argument—a number signifying the change in milliseconds between the start dates of the first and current requests.</td>
</tr>
</tbody>
</table>

```sql
-- incr_test - Sample PL/SQL incrementProc procedure
-- This procedure gets the list of arguments to be incremented
-- using the incrementProcArgs property and increments each
-- argument by the delta provided. This behavior is identical
-- to the default behavior if no incrementProc is set for the
-- job.

procedure incr_test(   delta IN number ) is
    request_id number;
    incrProcArgs varchar2(200);
    curr_arg_n varchar2(100);
    curr_arg_v varchar2(2000);
    del_pos number := 0;
    prev_pos number := 1;
    old_date date;
    new_date date;
    delta_days number;
    begin
        request_id := FND_JOB.REQUEST_ID;
        delta_days := delta / (1000*60*60*24);

        -- incrProcArgs must be defined for this procedure to be
        -- called.
        incrProcArgs := ESS_RUNTIME.GET_REQPROP_VARCHAR(request_id,
                                                         FND_JOB.INCR_PROC_ARGS_P) || ',

        LOOP
            del_pos := INSTR(incrProcArgs, ',', prev_pos);
            EXIT WHEN del_pos = 0;
            curr_arg_n := FND_JOB.SUBMIT_ARG_PREF_P || SUBSTR(incrProcArgs,
                                                             prev_pos, del_pos-prev_pos);
            curr_arg_v := ESS_RUNTIME.GET_REQPROP_VARCHAR(request_id,
                                                            curr_arg_n);

            old_date := FND_DATE.CANONICAL_TO_DATE(curr_arg_v);
            new_date := old_date + delta_days;
            ESS_RUNTIME.UPDATE_REQPROP_VARCHAR(request_id, curr_arg_n,
                                                 FND_DATE.DATE_TO_CANONICAL(new_date));

            prev_pos := del_pos+1;
        END LOOP;
    end incr_test;
```

About Creating a Job Definition

Work with Extensions to Oracle Enterprise Scheduler  65-7
### Table 65-1 (Cont.) Additional Job Definition Properties

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>incrementProcArgs</td>
<td>A list of comma-separated date arguments to be incremented. The incrementProc property is used to increment these values. Alternatively, a default calculation is used if the property incrementProc is not defined. Enter a list of argument numbers to identify which job arguments are to be incremented (for example, &quot;1, 2, 5&quot;). In the incrementProc example shown above, an incrementProc procedure calculates the next set of date parameter values for a recurring request. The procedure expects one argument: a number signifying the change in milliseconds between the start dates of the first and current requests.</td>
</tr>
<tr>
<td>logLevel</td>
<td>The level at which events are logged (between 0 and 4). Each job type has a logLevel of 1 by default. This optional value is used to override the job type logLevel in the job definition.</td>
</tr>
<tr>
<td>optimizerMode</td>
<td>This flag enables setting the database optimizer mode for the job. Optimizer mode is useful for fine-tuning performance.</td>
</tr>
<tr>
<td>parametersVO</td>
<td>The ADF Business Components view object you define for additional properties to be entered at runtime by end users using an Oracle ADF user interface.</td>
</tr>
<tr>
<td>ParameterTaskflow</td>
<td>Enter the name of the task flow as a parameter. The name of the taskflow.xml file must be the same as the taskflowId. Following is an example.</td>
</tr>
<tr>
<td></td>
<td><code>&lt;parameter name=&quot;ParameterTaskflow&quot;  data-type=&quot;string&quot;&gt;/WEB-INF/oracle/apps/prod/project/ParamTestTaskFlow.xml#ParamTestTaskFlow&lt;/parameter&gt;</code></td>
</tr>
<tr>
<td></td>
<td>Use this property when adding a custom task flow to an Oracle ADF user interface used to submit job requests at runtime. For more information, see How to Add a Custom Task Flow to an User Interface for Submitting Job Requests.</td>
</tr>
<tr>
<td>reportID</td>
<td>The Oracle BI Publisher report value specified in the Oracle BI Publisher repository. Required parameter for Oracle BI Publisher jobs only.</td>
</tr>
<tr>
<td>rollbackSegment</td>
<td>Enables setting a database rollback segment for the job, which will be used until the first commit. When implementing the rollback segment, use FND_JOB.AF_COMMIT and FND_JOB.AF_ROLLBACK to commit and rollback.</td>
</tr>
<tr>
<td>srsFlag</td>
<td>A Boolean parameter (Y or N) that controls whether the job displays in the job request submission user interface (see About Creating an User Interface for Submitting Job Requests).</td>
</tr>
<tr>
<td>SYS_runasApplicationID</td>
<td>Enables elevating access privileges for completing a scheduled job. For more information about elevating access privileges for the completion of a particular job, see About Elevating Access Privileges for a Scheduled Job.</td>
</tr>
</tbody>
</table>

4. Create a new job. From the New Gallery, select **Business Tier > Enterprise Scheduler Metadata** and click **Job Definition**.
5. In the Job Definition Name & Location page in the Job Definition Creation wizard, do the following:

- **Name**: Enter a name for the job.
- **JobType**: Select the job type from the drop-down list.

Click **Finish**. The new job definition displays.

6. Edit the following properties in the job definition as required for the selected job type:

- **JavaJobType**: Uncheck the read-only checkbox next to `className` and set its value to the value of the business logic class.

- **PlsqlJobType**: Uncheck the read-only checkbox next to `procedureName` and set its value to the name of the procedure (such as `myprocedure.proc`). Create a new parameter named `numberOfArgs`. Set `numberOfArgs` to the number of job submission arguments, excluding `errbuf` and `retcode`.

- **CJobType**: Add the parameter `executableName` and set its value to the name of the C job to be executed. The executable file identified by the `executableName` parameter must exist in the directory `$APPLICATIONS_BASE/$APPLBIN`.

- **PerlJobType**: Add the parameter `executableName` and set its value to the name of the Perl script.

- **SqlLdrJobType**: Add the parameter `executableName` and set its value to the name of the control file to be executed (located under `PRODUCT_TOP/$APPLBIN`). Add SQL*Loader options such (such as `direct=yes`) as a `sqlldr.directoption` parameter in the job definition.

- **SqlPlusJobType**: Add the parameter `executableName` and set its value to the name of the SQL*Plus job script to be executed (located under `PRODUCT_TOP/$APPLSQL`).

- **HostJobType**: Add the parameter `executableName` and set its value to the name of the host script job to be executed. The executable file identified by the `executableName` parameter must exist in the directory `PRODUCT_TOP/$APPLBIN`.

**Note:**

Configure the `$APPLBIN` and `$APPLSQL` variables in the `environment.properties` file. The `$APPLBIN` and `$APPLSQL` variables point to the location of executable files under `PRODUCT_TOP`. These variables enable the extensions to Oracle Enterprise Scheduler to locate the jobs to be run. Typically, these variables are set in a preexisting environment properties file in the system.

---

65.4.2 How to Define File Groups for a Job

A file group is a collection of output files such as text files, XML files, and so on. File groups enable categorizing files together for a specific purpose, such as file groups for human resources or financial reports.
File groups are used for postprocessing jobs such as Business Intelligence Publisher jobs. Using postprocessing actions, the results of a job can be saved as an HTML file, for example, or printed. File groups specify the type of postprocessing action to be taken for a given job.

There are two types of file groups: output and layout. Postprocessing layout actions create additional output files using the job request output files. For example, an XML job output file can be processed as an HTML or PDF file.

Postprocessing output actions act upon job request output files by printing, faxing, or emailing the files, for example. Output postprocessing actions can be taken on job request output files, as well as files created by layout postprocessing actions. For example, a job request output XML file can be converted to a PDF file using layout postprocessing actions, and then emailed using output postprocessing actions.

To define file group properties, do the following:

1. In the job definition for which you want to define postprocessing, define a file group.
   a. Name the property Program.FMG.
   b. For the value of the property, enter a list of comma-separated File Management Groups, where each file group is prefixed by an L or O to indicate a layout or output file group, respectively. A sample file group property is shown in Example 65-1.

   Three file groups are listed in this example.

2. In the job definition, create a property containing a regular expression used to filter the files in the output work directory of the job request. Any output files that match the filter will be part of the relevant file group.

   Example regular expressions are shown in Example 65-2, Example 65-3, and Example 65-4.

   An example of file group properties in a job definition is shown in Example 65-5. These properties specify the use of the Business Intelligence Publisher postprocessing action on the MYXML file group, followed by the print postprocessing action on either ALL or PDF file groups.

3. Optionally, rename the file group and store it in the Oracle Metadata Service repository so that it displays in a more user-friendly way in the scheduled job request submission UI.

   Example 65-1  File Group Property Sample Value
   Program.FMG = L.MYXML, O.ALL, O.PDF

   Example 65-2  File Group Regular Expression Filtering for All Files with the Suffix XML
   MYXML = '.*.\xml$'

   Example 65-3  File Group Regular Expression Filtering for All Files
   ALL = '.*$'

   Example 65-4  File Group Regular Expression Filtering for All Files with the Suffix PDF
   PDF = '.*.\pdf$'
Example 65-5  File Group Properties with File Group Regular Expression Filtering

Program.FMG = L.MYXML, O.ALL, O.PDF
MYXML = '.*\.xml$'  ALL = '.*$'  PDF = '.*\.pdf$'

65.4.3 What Happens When You Create a Job Definition

The job definition is written to an XML file called <job name>.xml.

65.4.4 What Happens at Runtime: How Job Definitions Are Created

The Oracle Fusion application passes the job definition file to Oracle Enterprise Scheduler, which runs the job defined in the file.

65.5 About Configuring a Spawned Job Environment

Configuring a spawned job involves creating an environment file and configuring an Oracle wallet.

65.5.1 About Creating an Environment File for Spawned Jobs

Spawned jobs require an environment.properties file to provide the correct environment for execution. The environment.properties file should be located in the config/fmwconfig directory under the domain.

Additional environment variables may be added to the same directory in a similar file called env.custom.properties. Variables defined in this file take precedence over those in the environment.properties file.

Similarly, server-specific environment variables may be set in the server config directory in files called environment.properties and env.custom.properties.

65.5.1.1 How to Create an Environment File for Spawned Jobs

The following variables are used to identify the correct interpreters for various spawned job types:

- **AFSQLPLUS**: The executable for SQL*Plus scripts.
- **AFSQLLDR**: The executable for SQL*Loader uploads.
- **AFPERL**: The Perl interpreter.
- **ATGPF_TOP**: The TOP directory for ATGPF files, needed to locate key files for SQL*Plus and Perl jobs.

The following environment properties are available to all spawned jobs:

- **REQUESTID**: The request ID of the current job request.
- **WORK_DIR_ROOT**: The directory on the local file system where the request can perform file operations.
- **OUTPUT_WORK_DIR**: The directory to which the job writes all output files.
- **LOG_WORK_DIR**: The directory to which the job writes all log files.
- **INPUT_WORK_DIR**: The directory to which input files are saved before the job is spawned.
• OUTFILE_NAME: The default name for the job output file.

• LOGFILE_NAME: The name of the log file for the job.

• USER_NAME: The name of the user submitting the job. The job runs in the context of this user.

• REQUEST_HANDLE: The Oracle Enterprise Scheduler request handle for the current request.

The environment variables must point to the client ORACLE_HOME and environment so that spawned jobs can connect to the database.

**Note:**

Ensure the variables you define in the environment.properties file do not include any trailing spaces. Follow the guidelines required by java.util.properties.

Restart the server after editing the environment.properties file.

To create an environment file, do the following:

1. Use a text editor to create an environment.properties file for the spawned job.

2. Set the following environment variables in the environment.properties file:
   - LD_LIBRARY_PATH
   - ORACLE_HOME
   - PATH: The full path of the spawned job. In Windows environments, the PATH must include all directories that are typically part of LD_LIBRARY_PATH.
     - TNS_ADMIN: The directory which stores files related to the database connection (such as tnsnames.ora, sqlnet.ora).
   - TWO_TASK: The TNS name identifying the database to which spawned jobs should connect. In Windows environments, the environment variable is LOCAL.

3. Configure the following variables, which are required to locate spawned jobs:
   - APPLBIN: C executables and SQL*Loader control files must reside in the $APPLBIN directory under the product TOP.
   - APPL_TOP: Set this property to the top level directory where the bin directory of C executables resides.
   - APPLSQL: SQL*Plus scripts must reside in the $APPLSQL directory under the product TOP. This means that the product TOP should be accessible to the environment.
   - ATGPF_TOP: This variable is required for SQL*Plus jobs. This should point to where the wrapper script is available.

4. Save the environment.properties file and restart the server.
65.5.2 How to Configure an Oracle Wallet for Spawned Jobs

Use the TNS_ADMIN and ORACLE_HOME variables specified in the environment.properties file created in About Creating an Environment File for Spawned Jobs.

A configured Oracle wallet enables spawned jobs to connect to the database at the command line. A provisioned Oracle Fusion Applications environment will have this wallet preconfigured.

To configure an Oracle wallet for the spawned job, do the following:

1. At the prompt, enter the following commands as shown in Example 65-6.

2. When prompted, choose a password for the wallet.

3. At the prompt, enter the following command as shown in Example 65-7.

   where TWO_TASK is the variable in the environment.properties file and <fusion password> is the password for the fusion user name.

   This command creates permissions for accessing the wallet.

4. When prompted, enter the wallet password created earlier.

5. In a text editor, create a file called sqlnet.ora that includes the lines shown in Example 65-8.

6. In a text editor, create a file called tnsnames.ora that includes the lines shown in Example 65-9.

7. [Only for Unix OS] Execute the following commands as shown in Example 65-10.

   The first command enables anyone to read and execute files in the directory, while reserving write access to the directory creator.
   The second command enables only the file owner to read, write and execute the file, while anyone can read the file.

8. Test the wallet by connecting to it. Execute the following command as shown in Example 65-11.

Example 65-6 Creating a Wallet

If you are using a Linux operating system, use these commands:

   cd $TNS_ADMIN
   mkdir wallet
   mkstore -wrl ./wallet -create

If you are using a Windows operating system, use these commands:

   cd %TNS_ADMIN%
   mkdir wallet
   mkstore -wrl wallet -create

Example 65-7 Creating Wallet Credentials

If you are using a Linux operating system, use this command:

   mkstore -wrl ./wallet -createCredential <$TWO_TASK> fusion_runtime <fusion_runtime_password password>

Work with Extensions to Oracle Enterprise Scheduler 65-13
If you are using a Windows operating system, use this command:

```
mkstore -wl wallet -createCredential <%TWO_TASK%> fusion_runtime
<fusion_runtime_password password>
```

**Example 65-8  Create a File Called sqlnet.ora**

If you are using a Linux operating system, use these commands:

```sql
SQLNET.WALLET_OVERRIDE = TRUE
WALLET_LOCATION =
  (SOURCE =
   (METHOD = FILE)
   (METHOD_DATA =
    (DIRECTORY = <$TNS_ADMIN>/wallet)
  )
)
```

If you are using a Windows operating system, use these commands:

```sql
SQLNET.WALLET_OVERRIDE = TRUE
WALLET_LOCATION =
  (SOURCE =
   (METHOD = FILE)
   (METHOD_DATA =
    (DIRECTORY = <%TNS_ADMIN%>/wallet)
  )
)
```

**Example 65-9  Create a File Called tnsnames.ora**

```
dbnname =
  (DESCRIPTION =
   (ADDRESS =
    (PROTOCOL = TCP)
    (HOST = host.example.com)
    (PORT = 1521)
   )
   (CONNECT_DATA = (SID=sidname))
  )
```

**Example 65-10  Set Directory and File Permissions**

```
chmod 755 wallet
chmod 744 wallet/cwallet.sso
```

**Example 65-11  Connect to the Wallet**

If you are using a Linux operating system, use this command:

```
sqlplus /@$TWO_TASK$
```

If you are using a Windows operating system, use this command:

```
sqlplus /@<%TWO_TASK%>
```

### 65.5.3 About Migrating Spawned Job Environment Properties to the Production Environment

Oracle Enterprise Scheduler provides a plug-in to migrate spawned job environment properties from the testing environment to the production environment. The
The migration plug-in moves the data-sources, LDAP, JMS, and other configurations that are part of the domain of the testing environment to the production environment.

The plug-in aims to incorporate properties created for spawned job processing. As such, the test to production plug-in parses the environment.properties file created in the testing environment and migrates it to the production environment. The file resides in the location specified in the testing environment as defined in the system property ess.config.dir.

As the properties to be moved reside in a flat file, it is unnecessary to annotate any MBeans with the property MovableProperty. Changes in the Oracle Enterprise Scheduler connections.xml are handled by the plug-in.

The migration plug-in includes the following components: CopyConfig, MovePlans, PasteConfig.

- **CopyConfig**: This script accomplishes the following tasks.
  - Reads the EssConfigDir location property from the system.
  - Reads and parses the environment.properties file.
  - Creates a MovableComponent with the name ESS-EXT and creates another MovableComponent with the name ENV-PROPS which it then adds to the ESS-EXT movable property.
  - Loops through every property in the environment.properties file and adds it to the ESS-EXT MovableComponent as a ConfigProperty.
  - Moves all the properties available in the properties file of the testing environment to the same file of the production environment.
  - Analyzes properties to determine whether they are changeable in the production environment. If they are, then those properties are defined as READ_WRITE. If they are not changeable, the properties are defined as READ_ONLY.
  - Returns the list of MovableComponent objects.
  - In post-processing, sets the EssConfigDir property to componentProperties so that the PasteConfig script can fetch the correct value.
  - Generates the MovePlan.xml file, whose values can be modified as required for the production environment.

- **MovePlans**: The environment.properties file is located outside the domain home or Oracle Fusion Middleware home. As such, a test to production plug-in must extract these properties and makes them movable through the test to production framework. The Plug-in extracts the key and value of the properties defined in the environment.properties file and makes them available in MovePlan.xml so that the values may be modified accordingly to suit the needs of the production environment.

  An example of the hierarchy of a MovePlans.xml file is shown in Example 65-12.

- **PasteConfig**: This script writes all the required values to the environment.properties file of the production environment.
– Gets the MovableComponent from FMWT2PPasteBean with type ESS-EXT. Gets the internal MovableComponent with name ENV-PROPS from ESS-EXT.

– Creates a new environment.properties file in the UserFileDir location of the production environment.

– Extracts the ConfigProperty values added to this MovableComponent and constructs an output steam.

– Writes all the values to the production environment.properties file.

**Example 65-12  MovePlan.xml File**

```xml
movePlan

  |_movableComponent (componentType:J2EEDomain, componentName:base_domain)
    //Default root movable component
  |_movableComponent (componentType:ESS-EXT, componentName:'Oracle Enterprise Scheduler Extension components')
    |_moveDescriptor
      |_configGroup (type: ENVIRONMENT_PROPERTIES)
        |_configProperty (id="/machine/user/instance/ess/config")
          // Location of the environment.properties
        |_<configProperty>
          <name>APPL_TOP</name>
          <value>/machine/user2/Test/</value>
          <itemMetadata>
            <dataType>STRING</dataType>
            <scope>READ_WRITE</scope>
          </itemMetadata>
        </configProperty>
        |_configProperty-2
        |_configProperty-3
        |_configProperty-4
```

**65.5.3.1 How to Migrate Spawned Job Environment Properties to the Production Environment**

To migrate spawned job environment properties, do the following:

1. Make sure the file cloningclient.jar is located at `<MW_HOME>/oracle_common/jlib`.

2. Make sure the Oracle Enterprise Scheduler plug-in JAR and the registration XML file are located under `<MW_HOME>/Oracle_atgpf/clone/provision`.

3. Pass the location of the original testing environment environment.properties file to the migration plugin by entering the following at the prompt:

   For a Linux operating system, use this command:
   ```bash
   setenv T2P_JAVA_OPTIONS "-Dess.config.dir=\<LocationOfPropsFile>"
   ```

   For a Windows operating system, use these commands:
   ```cmd
   set "T2P_JAVA_OPTIONS=-Dess.config.dir=\<LocationOfPropsFile>"
   cd <MW_HOME>\oracle_common\bin
   ```

4. At the command line, execute the copyConfig script after entering the names of all the servers in the domain or cluster, as shown.

   For a Linux operating system, use this command:
About Configuring a Spawned Job Environment

5. At the command line, execute the `extractPlans` script as shown in the following example.

For a Linux operating system, use this command:

```bash
extractPlans.sh -javaHome /usr/local/packages/jdk16 -archiveLocation /machine/user/11gWLS/DIST/a.jar -planDirLocation /machine/user/11gWLS/EXTRACT -logDirLoc /tmp
```

For a Windows operating system, use this command:

```cmd
extractMovePlan.cmd -javaHome "C:\Program Files\Java\jdk6" -archiveLocation C:\user\11gWLS\DIST\a.jar -planDirLocation C:\user\11gWLS\EXTRACT -logDirLoc C:\tmp
```

This script extracts the `MovePlan.xml` file from the archive to the `planDirLocation`. The extracted XML document contains `environment.properties` entries within the `movableComponent` of type `ESS-EXT`.

6. Change the `MovePlan.xml` file under `planDirLocation` as required by the production environment.

7. At the command line, execute the `pasteConfig` script to recreate the target environment. This step configures the data sources, LDAP, and so on, and starts the servers. Following is an example.

For a Linux operating system, use this command:

```bash
pasteConfig.sh -javaHome /usr/local/packages/jdk16/ -archiveLocation /machine/user/11gWLS/DIST/a.jar -targetDomainLoc /machine/user/11gWLS/user_projects/domains/domain9 -targetMiddlewareHomeLoc /machine/user/11gWLS -movePlanLocation /machine/user/11gWLS/EXTRACT/moveplan.xml -logDirLoc /tmp -silent true
```

For a Windows operating system, use this command:

```cmd
pasteConfig.cmd -javaHome "C:\Program Files\Java\jdk6" -archiveLocation C:\user\11gWLS\DIST\a.jar -targetDomainLoc C:\user\11gWLS\user_projects\domains\domain9 -targetMiddlewareHomeLoc C:\user\11gWLS -movePlanLocation C:\user\11gWLS\EXTRACT\moveplan.xml -logDirLoc C:\\tmp -silent true
```
65.5.4 What Happens When You Configure a Spawned Job Environment

A configured Oracle wallet enables spawned jobs to connect to the database at the command line.

65.6 About Implementing a PL/SQL Scheduled Job

Implementing a PL/SQL scheduled job requires creating a job definition and creating a PL/SQL package.

Related Links

The following documents provide additional information related to subjects discussed in this section:

For more information about implementing a PL/SQL stored procedure scheduled job see the chapter "Creating and Using PL/SQL Jobs" in the Developing Applications for Oracle Enterprise Scheduler.

65.6.1 Standards and Guidelines for Implementing a PL/SQL Scheduled Job

Run subrequests through Oracle Enterprise Scheduler using the Oracle Enterprise Scheduler APIs to access Oracle Enterprise Scheduler.

A PL/SQL stored procedure scheduler job should have a signature with the first two arguments being `errbuf` and `retcode`. The remaining arguments are used as required for defining job parameters. All arguments have a data type of `varchar2`.

65.6.2 About Defining Metadata for a PL/SQL Scheduled Job

Create a job definition as described in About Creating a Job Definition.

PL/SQL jobs require setting an additional property `numberOfArgs` in the job definition. This property identifies the number of job submission arguments (not including the required arguments `errbuf` and `retcode`).

65.6.3 How to Implement a PL/SQL Scheduled Job

Oracle Enterprise Scheduler provides runtime PL/SQL APIs for implementing PL/SQL jobs and running the jobs using Oracle Enterprise Scheduler. A view object is defined and associated with the job definition for the job.

When creating a PL/SQL job, use the `fusion` database user. For information about granting access privileges to database users in the context of Oracle Fusion Applications, see Implementing Oracle Fusion Data Security.

To implement a PL/SQL scheduled job, do the following:

1. Create a PL/SQL package.
2. Deploy the package to a database.
3. Test the package.

65.6.4 What Happens When You Implement a PL/SQL Job

The sample PL/SQL job shown in Example 65-13 provides a signature of a PL/SQL procedure run as a job. The first two arguments to the PL/SQL procedure, `errbuf`
and retcode, are required. The remaining arguments are properties filled in by end
users and passed to Oracle Enterprise Scheduler when the job is submitted.

The example shown in Example 65-13 illustrates a sample PL/SQL job that uses the
PL/SQL API.

The sample shown in Example 65-14 illustrates a PL/SQL job with a subrequest
submission. The no_requests argument identifies the number of subrequests that
must be submitted.

Example 65-13  Running a Job Using the PL/SQL API

```
procedure fusion_plsql_sample(
  -- The first two arguments are required: errbuf and retcode
  -- The errbuf is logged when a job request ends in a warning or error state to
  -- provide a quick indication as to why the job request ended in an error or
  -- warning state.
  -- Job submission arguments, as collected from the view object associated with the
  -- job as configured in the job definition. The view object is used to present a
  -- user interface to end users, allowing them to enter the properties listed in
  -- the following lines of code.
  -- interface. These values are submitted by the end user.
  --
  errbuf    out NOCOPY varchar2,
  retcode   out NOCOPY varchar2,
  run_mode  in  varchar2 default 'BASIC',
  duration  in  varchar2 default '0',
  p_num     in  varchar2 default NULL,
  p_date    in  varchar2 default NULL,
  p_varchar in  varchar2 default NULL) is
begin
  -- Write log file content using FND_FILE API
  FND_FILE.PUT_LINE(FND_FILE.LOG, "About to run the sample program");

  -- Implement the business logic of the job here.
  --
  FND_FILE.PUT_LINE(FND_FILE.OUT, "RUN MODE : " || run_mode);
  FND_FILE.PUT_LINE(FND_FILE.OUT, "DURATION: " || duration);
  FND_FILE.PUT_LINE(FND_FILE.OUT, "P_NUM: " || p_num);
  FND_FILE.PUT_LINE(FND_FILE.OUT, "P_DATE: " || p_date);
  FND_FILE.PUT_LINE(FND_FILE.OUT, "P_VARCHAR: " p_varchar);

  -- Retrieve the job completion status which is returned to Oracle
  -- Enterprise Scheduler.
  errbuf := fnd_message.get("FND", "COMPLETED NORMAL");
  retcode := 0;
end;
```

Example 65-14  Submitting a Subrequest Using the PL/SQL Runtime API

```
procedure fusion_plsql_subreq_sample(
  --
  errbuf    out NOCOPY varchar2,
  retcode   out NOCOPY varchar2,
  no_requests  in  varchar2 default '5',
) is

  req_cnt number := 0;
  sub_reqid number;
  submitted_requests varchar2(100);
  request_prop_table_t jobProp;
```
begin
   -- Write log file content using FND_FILE API
   FND_FILE.PUT_LINE(FND_FILE.LOG, "About to run the sample program with subrequest functionality");

   -- Requesting the PAUSED_STATE property set by job identifies request as having started for the first time or restarting after being paused.
   if ( ess_runtime.get_reqprop_varchar(fnd_job.job_request_id, 'PAUSED_STATE') is null )  -- first time start
      then
         -- Implement the business logic of the job here.
         FND_FILE.PUT_LINE(FND_FILE.OUT, " About to submit subrequests : " ||
         no_requests);

         -- Loop through all the subrequests.
         for req_cnt 1..no_requests loop
            -- Retrieve the request handle and submit the subrequest.
            sub_reqid := ess_runtime.submit_subrequest(request_handle =>
                  fnd_job.request_handle,
                  definition_name => 'sampleJob',
                  definition_package => 'samplePkg',
                  props => jobProp);
            submitted_requests := sub_reqid || ',';
         end loop;

         -- Pause the parent request.
         ess_runtime.update_reqprop_varchar(fnd_job.request_id, 'STATE',
                   ess_job.PAUSED_STATE);

         -- Update the parent request with the state of the subrequest, enabling the job to retrieve the status during restart.
         ess_runtime.update_reqprop_int(fnd_job.request_id, 'PAUSED_STATE',
                   submitted_requests);
      else
         -- Restart the request, retrieve job completion status and return the status to Oracle Enterprise Scheduler.
         errbuf := fnd_message.get("FND", "COMPLETED NORMAL");
         retcode := 0;
      end if;
end;

65.6.5 What Happens at Runtime: How a PL/SQL Job is Implemented

Oracle Enterprise Scheduler calls routines to initialize the context of the PL/SQL job, including PL/SQL global values, local values (such as language and territory), and request-specific values such as request ID and request handle.

The view object associated with the job definition displays a user interface so that end users may fill in values for each property. The Oracle Fusion web application calls Oracle Enterprise Scheduler using the provided APIs and submits the job request. Oracle Enterprise Scheduler runs the job, which calls the context routines and then runs the job logic. The job ends with a retcode value of 0, 1, 2 or 3, representing SUCCESS, WARNING, FAILURE or BUSINESS ERROR, respectively. The Oracle Fusion web application can retrieve the result from Oracle Enterprise Scheduler and display it in the user interface.
65.7 About Implementing a SQL*Plus Scheduled Job

Implementing a SQL*Plus scheduled job involves writing a SQL*Plus script and configuring an environment file for the job.

65.7.1 Standards and Guidelines for Implementing a SQL*Plus Scheduled Job

Run subrequests through Oracle Enterprise Scheduler using the Oracle Enterprise Scheduler APIs to access Oracle Enterprise Scheduler.

65.7.2 How to Implement a SQL*Plus Job

Implementing a SQL*Plus stored procedures job involves writing the SQL*Plus script, storing the script and configuring a spawned job environment.

To implement a SQL*Plus job, do the following:

1. Write the SQL*Plus job as a SQL*Plus script. Include the FND JOB.set_sqlplus_status call so as to report the final job status.

   Include the following in the SQL*Plus scheduled job:

   - FND JOB.set_sqlplus_status: Call to report the final job status. Statuses include:
     - FND JOB.SUCCESS_V: Success.
     - FND JOB.WARNING_V: Warning.
     - FND JOB.FAILURE_V: Failure.
   - FND_FILE routines: Can be used for producing log data and output files.
   - FND_JOB API for request values: API calls are initialized for SQL*Plus jobs.

   Note:
   SQL*Plus jobs must **not** exit.

2. Store the script under PRODUCT_TOP/$APPLSQL.

3. Configure the spawned job environment as described in About Configuring a Spawned Job Environment. Configure the ATGPF_TOP value in the environment.properties file for spawned jobs.

4. Run and test the job.

65.7.3 About Using the SQL*Plus Runtime API

Oracle Enterprise Scheduler provides runtime SQL*Plus APIs for implementing SQL*Plus jobs and running the jobs using Oracle Enterprise Scheduler.

This sample SQL*Plus job provides a signature of a SQL*Plus procedure run as a job. Any necessary arguments are properties filled in by end users and passed to Oracle Enterprise Scheduler when the job is submitted. A view object is defined and
associated with the job definition for the job. The view object is then used to display a user interface so that end users may fill in values for each property. Finally, the sample prints to an output file.

### 65.7.4 What Happens When You Implement a SQL*Plus Job

Example 65-15 shows a sample SQL*Plus scheduled job, which is executed by a wrapper script.

**Example 65-15  Implementing a SQL*Plus Scheduled Job**

```sql
SET VERIFY OFF
SET linesize 132
WHENEVER SQLERROR EXIT FAILURE ROLLBACK;
WHENEVER OSERROR EXIT FAILURE ROLLBACK;
REM dbdrv: none
/* ----------------------------------------------------------------------*/
DECLARE
  errbuf varchar2(240) := NULL;
  retval boolean;
  run_mode varchar2(200) := '&1';
BEGIN
  DBMS_OUTPUT.PUT_LINE(run_mode);
  update dual set dummy = 'Q';
  FND_FILE.PUT_LINE(FND_FILE.LOG, 'Parameter 1 = ' || nvl(run_mode,'NULL'));
  /* print out test message to log file and output file */
  /* by making direct call to FND_FILE.PUT_LINE */
  /* from sql script. */
  FND_FILE.PUT_LINE(FND_FILE.LOG, '-----------------------------------------
  Printing a message to the LOG FILE
  -----------------------------------------
  SUCCESS!
  -----------------------------------------
 ,'
  FND_FILE.PUT_LINE(FND_FILE.OUTPUT,'-----------------------------------------
  Printing a message to the OUTPUT FILE
  -----------------------------------------
  SUCCESS!
  -----------------------------------------
  ',
  retval := FND_JOB.SET_SQLPLUS_STATUS(FND_JOB.SUCCESS_V);
```
65.7.5 What Happens at Runtime: How a SQL*Plus Job Is Implemented

Oracle Enterprise Scheduler calls routines in a wrapper script to initialize the context of the SQL*Plus job, including global values, local values (such as language and territory), and request-specific values such as request ID and request handle. The wrapper script introduces the prologue of commands shown in Example 65-16.

The Oracle Fusion application calls Oracle Enterprise Scheduler using the provided APIs. Oracle Enterprise Scheduler runs the job, and the final job status—SUCCESS, WARNING, BUSINESS ERROR, or FAILURE—is communicated to Oracle Enterprise Scheduler. The Oracle Fusion web application can retrieve the result from Oracle Enterprise Scheduler and display it in the user interface.

Example 65-16  SQL*Plus wrapper script

```
SET TERM OFF
SET PAUSE OFF
SET HEADING OFF
SET FEEDBACK OFF
SET VERIFY OFF
SET ECHO OFF
SET ESCAPE ON
WHENEVER SQLERROR EXIT FAILURE
```

65.8 About Implementing a SQL*Loader Scheduled Job

Implementing a SQL*Loader scheduled job involves creating a SQL*Loader control file and configuring a spawned job environment.

65.8.1 How to Implement a SQL*Loader Scheduled Job

Like all executable jobs (C, SQLPlus, host, and Perl scripts), SQL*Loader jobs require an executable file that is located in the read-only APPLTOP folder. For SQL*Loader jobs, this is the control file. The control file determines which database tables are to be affected by the SQL*Loader command.

It is possible to use a dynamic control file for SQL*Loader subrequest jobs. A SQL*Loader job submitted as a subrequest using a dynamic control file must access the control file from the working directory of the parent job request, rather than the APPLTOP folder.

Keep in mind that the control file and data file must conform to the following SQL*Loader standards:

- Place control files in the $APPLBIN directory under the product TOP. (Subrequests using dynamic control files must instead access the working directory of the parent job request.)
- The control file's name must be the same as the executableName parameter in the job definition.
- Ensure that the full path of the data file's location is the first submit argument to the job.
• Add SQL*Loader options such as `direct=yes`, if needed, as the `sqlldr.directoption` parameter in the job definition.

• Set the job log file as the SQL*Loader LOG parameter so it will automatically contain all SQL*Loader log messages.

• Set the job output file as the SQL*Loader BAD parameter so it will automatically receive any output directed there. Alternatively, you can create two output files for a SQL*Loader job request.

  - `<requestid>_bad.txt`: This is the output of the bad parameter.
  - `<requestid>_discard.txt`: This is the output of the discard parameter, however a discard file is not always generated.

To implement a SQL*Loader scheduled job, do the following:

1. Create a SQL*Loader control file (.ctl).
2. In the parent job request, make sure you have set the system property `workDirectoryRoot` to the working directory of the parent job request.
3. Alternatively, in the case of SQL*Loader subrequests only, configure the job to use a dynamically created control file.
   a. In the job definition for the subrequest, configure the property `execPRWD`. Set this property to `Y` to enable the dynamic control file.
   b. In the parent job request, configure the name of the control file using the `executableName` system property.
4. Enter the full path of the data file as the first submit argument to the job.
5. Store the control file under `PRODUCT_TOP/$APPLBIN`. Skip this step if you are implementing a SQL*Loader subrequest.
6. Configure the spawned job environment as described in About Configuring a Spawned Job Environment.
7. Test the file.

65.8.2 What Happens When You Implement a SQL*Loader Scheduled Job

A sample SQL*Loader scheduled job is shown in Example 65-17.

What Happens When You Implement a SQL*Loader Scheduled Job Subrequest

When the SQL*Loader subrequest completes, the parent request can discover the status of the completed SQL*Loader job request as with any other subrequest. The log and output files are written to the content repository.

What Happens When You Implement a SQL*Loader Scheduled Job Subrequest Using a Dynamic Control File (execPRWD)

When the SQL*Loader subrequest runs, the command line creates the path to the control file by looking for the file named in the system property `executableName` under the directory indicated in the parent job request as the system property `workDirectoryRoot`. 
**Example 65-17  Sample SQL*Loader scheduled job**

This sample control file will upload data from the data file into the `fnd_applcp_test` table, into the columns listed here (`id1`, `id2`, `idn`, `mesg`). See the SQL*Loader documentation for more information about writing control files.

```sql
OPTIONS (silent=(header, feedback, discards))
LOAD DATA
INFILE *
INTO TABLE fnd_applcp_test
APPEND
FIELDS TERMINATED BY ','
(id1,
 id2,
 id3,
 func CHAR(30),
 time SYSDATE,
 action CHAR(30),
 mesg CHAR(240))
```

### 65.9 About Implementing a Perl Scheduled Job

Implementing a Perl scheduled job involves creating a job definition, enabling the Perl job to connect to a database and configuring a spawned job environment.

**Related Links**

The following documents provide additional information related to subjects discussed in this section:

For more information about creating a Perl scheduled job see the chapter "Creating and Using Process Jobs" in *Developing Applications for Oracle Enterprise Scheduler*.

### 65.9.1 How to Implement a Perl Scheduled Job

To implement a Perl scheduled job, do the following:

1. Place the Perl job under the directory `PRODUCT_TOP/$APPLBIN`.

2. Create a job definition for the Perl job, setting the `executableName` parameter to the name of the Perl script. The following functions can be used in the Perl script:
   - `writeln()`: Write a message to the log file.
   - `timestamp()`: Write a timestamped message.

3. To enable the Perl job to connect to a database, use `/@$TWO_TASK` as a connection string without specifying a user name or password.

4. Configure the spawned job environment as described in About Configuring a Spawned Job Environment. The context provides values for the following:
   - `reqid`: The request ID.
   - `outfile`: The full path to the output file.
   - `logfile`: The full path to the log file.
   - `username`: The name of the user submitting the job request.
   - `log`: The log object.
About Implementing a Perl Scheduled Job

5. Implement an exit code for the job, with values of 0, 2 or 3 representing the

following states: success, warning, and business error. All other values represent an
errored state.

6. Test the job.

65.9.2 What Happens When You Implement a Perl Scheduled Job
Example 65-18 shows a sample scheduled Perl job which does the following:
1.

Checks for basic or full mode.

2.

Prints arguments.

3.

Gets the context object of the scheduled job request.

4.

Retrieves contextual information about the scheduled job request, which is stored
in the context object.

5.

Writes the request to the log file.

6.

Prints information as required.

Example 65-18

Perl Scheduled Job

# dbdrv: none
use strict;
(my $VERSION) = q$Revision: 120.1 $ =~ /(\d+(\.\d+)*)/;
print_header("Begin Perl testing script (version $VERSION)");
# check first argument for BASIC or FULL mode
# if not FULL mode, exit successfully without doing anything
if (! $ARGV[0] || uc($ARGV[0]) ne "FULL") {
exit(0);
}
# -- If argument #1 was passed, use it as a sleep time
if ($ARGV[1]) {
if ($ARGV[1] =~ /\D/) {
print "** Argument #1 is not a valid number, unable to sleep!\n\n";
} else {
printf("Sleeping for %d seconds...\n", $ARGV[1]);
sleep($ARGV[1]);
}
}
# -- Arguments
print_header("Arguments");
my $i = 1;
foreach (@ARGV) {
print "Argument #", $i++, ": $_\n";
}
# -- Get the request context object
my $context = get_context();
# -- Use this object to retrieve context information about this request

65-26 Oracle Fusion Applications Developer's Guide


print_header("Context Information");
printf "Request id \t= %d\n", $context->reqid();
printf "User name \t= %d\n", $context->username();
printf "Logfile \t= %s\n", $context->logfile();
printf "Outfile \t= %s\n", $context->outfile();

# -- Writing to the request log file
print_header("Writing to log file");

# -- retrieve a Logfile object from the context
my $log = $context->log();
$log->writeln("This message should appear in the request logfile");
$log->timestamp("This is a timestamped message to the request logfile");

print "Wrote two messages to the request logfile\n";

# -- Print out some useful information

print_header("Environment");
foreach (sort keys %ENV) {
    print "$_=\$ENV{$_}\n";
}

print_header("Perl Information");
print "PROCESS ID = \$\n";
print "REAL USER ID = \$<\n";
print "EFF USER ID = \$>\n";
print "SCRIPT NAME = \$0\n";
print "PERL VERSION = \$\n";
print "OS NAME = \$^O\n";
print "EXE NAME = \$^X\n";
print "WARNINGS ON = \$^W\n";

print "\n\@INC path:\n";
foreach  (@INC) {
    print "\$_\n";
}

print "\nAll loaded perl modules:\n";
foreach (sort keys \%INC) {
    print "\$_ => \$INC{\$_}\n";
}

# -- Exiting the script
# -- The exit status of the script will be used as the request exit status.
# -- A zero exit status is reported as state of success.
# -- An exit status of 2 is reported as a warning state.
# -- An exit status of 3 is reported as a business error state.
# -- Any other exit status is reported as an error state.

print_header("Exiting script with status 0. (Normal completion)" );
exit(0);

sub print_header {
    my $msg = shift;
    print "\n\n", "-" x 40, "\n", $msg, "\n", "-" x 40, "\n";
}
65.10 About Implementing a C Scheduled Job

The main steps required to implement a C scheduled job are as follows:

- Creating a job definition
- Configuring a spawned job environment
- Implementing and testing a C scheduled job

65.10.1 About Defining Metadata for a C Scheduled Job

Create a job definition as described in About Creating a Job Definition.

65.10.2 How to Implement a C Scheduled Job

To implement a C scheduled job, do the following:

1. In a separate function or file rather than in main, implement your required business logic.
   
   Include the following header files:
   
   - afcp.h: This is the header file for Oracle Enterprise Scheduler.
   - afstd.h and afstr.h: These are Oracle Fusion application header files.

2. Call afpend in the business logic function.

3. In the main function, call afprcp, passing to it a pointer to the business logic function.

   The business logic function is called by afprcp, taking the arguments argc, argv, and reqinfo.

4. Save the executable job file to the $APPLICATIONS_BASE/$APPLBIN directory.

5. Configure the spawned job environment, as described in About Configuring a Spawned Job Environment.

   Set both the TOP and APPLBIN variables for your application in the environment.properties file.

65.10.3 About the Scheduled C Job API

Several C functions are available for use in developing Oracle Fusion applications, while several others are not. Table 65-2 and Table 65-3 list the available and unavailable functions.
<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>afprcp</strong></td>
<td>Run C program. The recommended API for writing a C program. The main OC file should call this function to run the program logic. It initializes the context and calls the program.</td>
</tr>
<tr>
<td></td>
<td>int afprcp (uword argc, text **argv, afsqlopt *options, afpfcn *function);</td>

65.10.4 About Testing a C Scheduled Job

When developing a C job, it is possible to test the job by running it from a command line interface.

Running a C job from the command line involves the following main steps:

- Invoking the job
- Obtaining a database connection and setting the runtime context by passing special arguments.
- Passing any program-specific parameters at the command line.
- To run a C job from the command line, use the syntax shown in Example 65-19 to run a C job from the command line for testing purposes.

where

<heavyweight user connection string> is the username/password@TWO_TASK pair used to connect to the database

<lightweight user name> is the name of the lightweight user submitting the job. This value is used to set the user context in the database connection.

<flag> must be set to 'L' for lightweight user.

An example illustrating running a C job from the command line is shown in Example 65-20.

**Example 65-19  Syntax for Running a C Job from the Command Line**

```bash
%program <heavyweight user connection string> <lightweight username> <flag> <job parameters> ...
```

**Example 65-20  Running a C Job from the Command Line for Testing Purposes**

```bash
program username/password@my_db MYUSER L <parameter1> <parameter2> ....
```

65.10.5 What Happens When You Implement a C Scheduled Job

The sample C job shown in Example 65-21 uses afprcp to initialize and obtain a database connection. It uses both Pro*C and afupi.

**Example 65-21  Using the C Runtime API**

```c
#ifndef AFSTD
#include <afstd.h>
#endif

#ifndef AFSTR
#include <afstr.h>
#endif

#ifndef AFCP
#include <afcp.h>
#endif

#ifndef SQLCA
#include <sqlca.h>
#endif
```

65.10.6 What Happens at Runtime: How a C Scheduled Job Is Implemented

When Oracle Enterprise Scheduler runs a C job, afprcp() runs first to initialize the context and obtain the database connection. The function afprcp() then calls the function containing the program logic. Oracle Enterprise Scheduler runs the job, and the result of the job is returned to Oracle Enterprise Scheduler. The Oracle Fusion application can retrieve the result from Oracle Enterprise Scheduler and display it in the user interface.

Note:

Wallet configuration is required for the client ORACLE_HOME to obtain the database connection. The operating system environment in which the job runs (including the location of the client ORACLE_HOME, which is also required) is set in the environment.properties file. The environment.properties file must be configured and placed in the config/fmwconfig directory under the domain.

You can add your own environment variables by creating an env.custom.properties file in the same directory. Variables you define in this file take precedence over those in the environment.properties file.

Similarly, you can set server-specific environment variables with environment.properties and env.custom.properties files in the server config directory.

65.11 About Implementing a Host Script Scheduled Job

Arguments submitted for a host script job request are passed to the script at the command line. Host scripts may access the standard environment variables to get REQUESTID, LOG_WORK_DIRECTORY, OUTPUT_WORK_DIRECTORY, and so on. Script output is redirected to the request log file by default.

Use the following steps when implementing a host script job:

- Complete the steps for configuring a spawned job as described in About Configuring a Spawned Job Environment.
- Create one script file each for Unix and Windows platforms. Name each script file the same as executableName parameter in the job definition. For example, if
your executableName is "myscript", the script files would be called
myscript.sh (on Unix platforms) and myscript.cmd (on Windows).

• Put host scripts in the $APPLBIN directory under the product TOP.
• The script should exit with one of the following exit codes (anything else is
considered a SYSTEM ERROR):
  – 0 for SUCCESS
  – 2 for WARNING
  – 3 for BUSINESS ERROR

65.12 About Implementing a Java Scheduled Job

For more information about implementing Java scheduled jobs, see the chapter "Using
Oracle JDeveloper to Generate an Oracle Enterprise Scheduler Application" in
Developing Applications for Oracle Enterprise Scheduler.

65.12.1 About Defining Metadata for a Scheduled Java Job

Create a job definition as described in About Creating a Job Definition.

65.12.2 About Using the Java Runtime API

For information about the Java runtime API, see the Oracle Fusion Applications Java API
Reference for Oracle Enterprise Scheduler Service.

You can access the Oracle Fusion Middleware Extensions for Applications Message
and Profile objects directly, using those APIs which handle the service accessing
themselves.

65.12.3 About Cancelling a Scheduled Java Job

You can cancel a scheduled Java job by implementing the Cancellable interface.

The Cancellable implementation in Example 65-22 checks as logic progresses to see
if the job has been canceled. If it has, the code cleans up after itself before exiting.

Example 65-22  Handling a Job Cancellation Request

import oracle.as.scheduler.Cancellable;
import oracle.as.scheduler.Executable;
import oracle.as.scheduler.ExecutionCancelledException;
import oracle.as.scheduler.ExecutionErrorException;
import oracle.as.scheduler.ExecutionPausedException;
import oracle.as.scheduler.ExecutionWarningException;
import oracle.as.scheduler.RequestExecutionContext;
import oracle.as.scheduler.RequestParameters;

public class MyExecutable
  implements Executable, Cancellable
{
    private volatile boolean m_cancel = false;

    public void execute( RequestExecutionContext reqCtx,
                         RequestParameters reqParams )
      throws ExecutionErrorException, ExecutionWarningException,
             ExecutionPausedException, ExecutionCancelledException
{  
  // Do some work and check if this request has been canceled.  
  // ... work ...  
  checkCancel(reqCtx);  
  
  // Do more work and check if this request has been canceled.  
  // ... work ...  
  checkCancel(reqCtx);  
  // Finish work.  
  // ... work ...  
}

// Set flag that the app logic should check periodically to  
// determine if this request has been canceled.  
public void cancel()  
{  
  m_cancel = true;  
}

// Check if request has been canceled. If not, do nothing.  
// Otherwise, do any cleanup work that may be needed for  
// this request and end by throwing an ExecutionCancelledException.  
private void checkCancel(RequestExecutionContext reqCtx)  
  throws ExecutionCancelledException  
{  
  if (m_cancel)  
  {  
    // Do work any cleanup work that may be needed  
    // before ending this executable.  
    // ... cleanup work ...  
    String msg = "Request " + reqCtx.getRequestId() +  
    " was cancelled.";
    
    throw new ExecutionCancelledException(msg);  
  }  
  
}  

65.12.4 What Happens at Runtime: How a Java Scheduled Job Is Implemented

Oracle Enterprise Scheduler initializes the context of the job. The Oracle Fusion application calls Oracle Enterprise Scheduler using the provided APIs. Oracle Enterprise Scheduler runs the job, and a result of success or failure is returned to Oracle Enterprise Scheduler. The Oracle Fusion application can retrieve the result from Oracle Enterprise Scheduler and display it in the user interface.

65.13 About Elevating Access Privileges for a Scheduled Job

Oracle Enterprise Scheduler executes jobs in the user context of the job submitter at the scheduled time. Some scheduled jobs require access privileges that are different from those of the submitting user. However, information regarding the submitter of the scheduled job must be retrievable for auditing purposes.

In Oracle Enterprise Scheduler, it is prohibited to run a job in the context of a user other than the submitting user with the runAs property. Doing so would be considered a security breach. Using an application identity enables running a job with different access privileges from those allotted to the submitting user.

Application identity is a SOA and Java Platform Security (JPS) concept that addresses the requirement for escalated privileges in completing an action. The application installer creates an application identity in Oracle Identity Management Repository.
For more information, see the following chapters:

- Implementing Application User Sessions
- Implementing Oracle Fusion Data Security
- Implementing Function Security

### 65.13.1 How to Elevate Access Privileges for a Scheduled Job

The Oracle Enterprise Scheduler job system property `SYS_runasApplicationID` enables elevating access privileges for completing a scheduled job.

To elevate access privileges, do the following:

1. Create a job definition, as described in About Creating a Job Definition.
2. Under the Parameters section, add a parameter called `SYS_runasApplicationID`.
3. In the text field for the `SYS_runasApplicationID` property, enter the application ID under which you want to run the job, as shown in Figure 65-1.

The input string must be a valid `ApplicationID` value that exists when the job executes.

**Figure 65-1  Defining the runAs User for the Job**

![Job Definition](image)

You can retrieve the executing user by running either of the methods shown in Example 65-23 and Example 65-24.

**Example 65-23  Retrieving the Executing User with getRunAsUser()**

```java
requestDetail.getRunAsUser()
```
Example 65-24  Retrieving the Executing User with getRequestParameter()

String sysPropUserName =
    (String) runtime.getRequestParameter(h, reqid, SystemProperty.USER_NAME);

Given a request ID, you can retrieve the submitting and executing users of a job request.

65.13.1.1 About Retrieving the Submitting and Executing Users of a Job Request in Oracle Enterprise Scheduler RuntimeService Enterprise JavaBeans Object

Example 65-25 shows a code sample for retrieving the submitting and executing users of a job request using the Oracle Enterprise Scheduler RuntimeService Enterprise JavaBeans object.

Example 65-25  Retrieving the Submitting and Executing Users of a Job Request Using the RuntimeService Enterprise JavaBeans Object

// Lookup runtimeService
RequestDetail requestDetail = runtimeService.getRequestDetail(h, reqid);
String runAsUser = requestDetail.getRunAsUser();
String submitter = requestDetail.getSubmitter();

65.13.1.2 About Retrieving the Submitting and Executing Users of a Job Request from Within an Oracle Fusion Application

Example 65-26 shows a code sample for retrieving the submitting and executing users of a job request from within an Oracle Fusion application.

Example 65-26  Retrieving the Submitting and Executing Users of a Job Request from an Oracle Fusion application

import oracle.apps.fnd.applcore.common.ApplSessionUtil;
// The elevated privilege user name.
ApplSessionUtil.getUserName()
// The submitting user.
ApplSessionUtil.getHistoryOverrideUserName()

65.13.2 How Access Privileges Are Elevated for a Scheduled Job

When a job request schedule executes, Oracle Enterprise Scheduler:

1. Validates the submitter's execution privileges on the job metadata.

2. Retrieves the application identity information from the job metadata. If the job metadata does not specify an application identity for the job, Oracle Enterprise Scheduler executes the job in the context of the job submitter.

   • Java job: An FND session is established as the user with elevated privileges.

       The executing user is taken from the current subject as viewed from the job logic.
Note:
Oracle Enterprise Scheduler does not directly support invoking a web service or composite. If your job logic invokes a web service or composite, you must write the client code logic in your job, establish a connection and propagate the job submitter information as data for auditing purposes. For an asynchronous web service call, the job must wait for a response.

- **Spawned C job:** An application user session is established as the executing user. The submitter information is an attribute of the application user session. The spawned job executes as the operating system user who starts Oracle WebLogic Server.
- **PL/SQL job:** An FND session is established as the executing user. The submitter information is attribute of the FND session. The job runs in the context of the FND session in the RDBMS job scheduler.

3. Executes the job logic.

### 65.13.3 What Happens When Access Privileges Are Elevated for a Scheduled Job
Oracle Enterprise Scheduler validates the user's execution privileges on the job metadata. If so, the user context is captured and stored in the Oracle Enterprise Scheduler database as the submitting user, and the request is placed in the queue.

### 65.14 About Enabling Multiple Language Support for Jobs
Multiple language jobs enable repeatedly running an end-user's submitted request in different languages such that the data processes accordingly.

Enabling multiple language support for jobs involves the following steps:

1. Identify a set of languages in which the job runs.
2. Develop a multiple-language support function (PL/SQL, Java, or ADF Business Components) and register it with concurrent processing.
3. Associate the multiple language support function with one or more programs.

The following multiple language support functions can be defined:

- **About Defining Java Multiple Language Support Functions**
- **About Defining PL/SQL Multiple Language Support Functions**
- **How to Define ADF Business Components Multiple Language Support Functions**

### 65.14.1 About Defining Java Multiple Language Support Functions
Java multiple language support functions can be defined in the client interface.

#### 65.14.1.1 About Defining Concurrent Processing in the Client Interface Using Java
The client interface for the Java multi-language function should be a fully qualified class name that implements the interface shown in Example 65-27.
The `ExecutionLanguageList` interface is available in the `oracle.apps.fnd.applcp.mls.server` package.

This class implements a default constructor. Parameters to the program are passed through the parameters array. Parameter n0 contains the parameter token and parameter n1 contains the parameter value. The returned string array is a valid list of languages, such that both positional and named parameters are supported for clients. The connection object should be valid and secured to the relevant schema.

A sample class is shown in Example 65-28.

**Example 65-27  The ExecutionLanguageList Interface**

```java
public interface ExecutionLanguageList {
    public String[] getLanguageList(Connection conn, String[][] parameters);
}
```

**Example 65-28  Defining Concurrent Processing in the Client Interface Using Java**

```java
public class MyLanguageList implements ExecutionLanguageList {
    public String[] getLanguageList(Connection conn, String[][] parameters) {
        String[] myStrArray;
        ...
        return myStrArray;
    }
}
```

### 65.14.1.2 About Using the Java Support API for Multiple Language Functions

Currently, no Java support APIs are provided.

### 65.14.2 About Defining PL/SQL Multiple Language Support Functions

PL/SQL multiple language support functions can be defined in the client interface or using the PL/SQL support API.

#### 65.14.2.1 About Defining Concurrent Processing in the Client Interface Using PL/SQL

The client interface for a PL/SQL multi-language support function should be a PL/SQL function name optionally prefixed with a package name and separated by a period. The PL/SQL function does not take any input parameters and returns a `VARCHAR2` value. The returned `VARCHAR2` value includes a list of acceptable comma separated languages (such as those listed in the `FND_LANGUAGES` property). If a returned language is not listed in the `FND_LANGUAGES` property or the language is not installed, the caller of the client interface can raise an exception or cause the request to fail either at submission time or at runtime.

A sample return value for this function is shown in Example 65-30:

In the previous example, the concurrent processing program's multi-language support function property is `PROD_MLS_PKG.GET_LANGUAGES`.

**Example 65-29  A Sample PL/SQL Multiple Language Support Function**

```sql
FUNCTION PROD_MLS_PKG.GET_LANGUAGES RETURN VARCHAR2;
```

**Example 65-30  Sample Return Value**

```
US,F,AR,KO
```
65.14.2.2 About Defining Concurrent Processing Using the PL/SQL Support API

The API package FND_REQUEST_INFO is provided to enable interrogating the current context and act accordingly.

The following functions and procedures are provided:

- **GET_PROGRAM**: Returns the name of the program being executed and the application to which it belongs. This is useful in cases where the same multi-language support function is used for multiple programs.

- **GET_PARAMETER**: Given a parameter number from the ordered list of parameters, returns the parameter name for the current request.

**Example 65-31  GET_PROGRAM Syntax**

```sql
procedure GET_PROGRAM (prog_name out varchar2, prog_app_name out varchar2);
```

**Example 65-32  GET_PARAMETER Syntax**

```sql
function GET_PARAMETER (param_num in number) return varchar2;
```

65.14.3 How to Define ADF Business Components Multiple Language Support Functions

A list of supported languages can also be retrieved from an ADF Business Components view object.

To define ADF Business Components multiple language support functions, do the following:

1. Create a view object that returns a list of supported languages, with the first column in the view object listing the language code.

2. Configure the view object to extend the interface oracle.apps.fnd.applcp.mls.server.MLSViewObject. The view object implements the method initQuery(String[][] parameters), which accepts a string array as its parameter. The string array contains the parameter tokens and values submitted to the request in the same sequence in which they are registered. The initQuery() method should then use one or more of these parameters to create or append the where clause of the view object, and execute the corresponding query.

3. Associate the view object with an application module.

4. Create an ADF Business Components multiple language support function and set the value to the fully qualified package name, followed by the Application Module name and the view object name.

A sample value for the multiple language support function is shown in Example 65-33:

```
The view object name should be specific to the view object instance, such that calling the findViewObject("MyLanguageVO1") method returns the view object instance to the caller.
Example 65-33  Value for the ADF Business Components Multiple Language Support Function

oracle.apps.fnd.cp.MySampleAM.MyLanguageVO1.

65.14.3.1 What Happens When You Define an ADF Business Components Multiple Language Support Function

When a program executes this multi-language support function, the following occurs:

1. The Application Module specified in the function is located.
2. The method findViewObject() is called on the module to get a handle for the view object.
3. The method initQuery(String[][]) is called on the view object.

65.14.3.2 About ADF Business Components Support APIs

Currently, no support APIs are provided.

65.14.4 About Processing Output for Multiple Language Jobs

The output generated from each request may need to be formatted into readable output formats. For example, XML output may need to be formatted to be readable to end users. Output can be formatted using templates during postprocessing. Usually, a particular formatting template is associated with a program for a given language. If a program is not associated with a template, end users can specify a formatting template for one or more languages when submitting a job. If no template is specified for a specific language, a designated default template should be applied for that language.

The generated output can be sent to zero or more printers based on the language being run. In some cases, printers may not have the fonts required to print documents in a particular language. Alternatively, all print output can be sent to the same printer. The printing interfaces to concurrent processing handle sending the output to the correct printer based on the parameters specified by the user.

Users who submit requests can also choose to specify completion notifications to be automatically sent to zero or more recipients. This notification may contain a link to the output, for example. In the case of multiple language requests, users can specify zero or more recipients of notifications for all languages or for an individual language. As in the case of printing, the notification interfaces handle the delivery of notifications according to the sender’s instructions.

The list of languages that can be selected by the user is driven by the languages supported by the installed software. Any function written for multiple language support returns a valid subset of languages from this list.

65.14.5 What Happens When You Enable Multiple Language Support for Jobs

The multiple language support function returns a list of supported languages in a format supported by concurrent processing. The programs associated with the multiple language support function execute multiple times for each request, once for each returned language.

If a program has no associated multiple language support function but is aware of the language context, users can explicitly choose one or more languages in which the program runs when submitting a request.
When a job is submitted for a program with an attached multiple language support function, the submission interface evaluates the function to retrieve the list of languages. This language list is used to drive postprocessing options such as publishing and printing.

65.14.6 What Happens at Runtime: How Multiple Language Support Is Enabled for Jobs

Multiple language support functions are not evaluated at runtime. Convenience messages may be provided to users when attempting to submit a program already scheduled for multiple language support execution if there is an overlap in the set of languages in the two submissions.

65.14.7 Standards and Guidelines Regarding Multiple Language Support Functions

The following standards and guidelines apply to using multi-language support functions:

- Runtime evaluation of multi-language support functions is no longer supported.
- Multiple language support functions can be registered in the program definition user interface.
- Multiple language support functions are evaluated at the time of request submission.

65.15 About Creating an Oracle ADF User Interface for Submitting Job Requests

When implemented as part of an Oracle Fusion application, the Oracle ADF user interface enables end users to submit job requests.

The following documents provide additional information related to subjects discussed in this section:

- For more information about configuring security certificates, see the chapter "Managing Keystores, Wallets, and Certificates" in the Administering Oracle Fusion Middleware.

- For more information about creating task flows and binding them to an Oracle ADF user interface, see the following chapters in Developing Fusion Web Applications with Oracle Application Development Framework:
  - "Getting Started with ADF Task Flows"
  - "Working with Task Flow Activities"
  - "Using Task Flows as Regions"

- For more information about creating an ADF Business Components view object, see the chapters "Defining SQL Queries Using View Objects" and "Advanced View Object Techniques" in Developing Fusion Web Applications with Oracle Application Development Framework.

- For more information about passing parameters to the Oracle ADF task flow, see the chapter "Using Parameters in Task Flows" in Developing Fusion Web Applications with Oracle Application Development Framework.
• For more information about deploying Oracle Enterprise Scheduler applications, see the section "Deploying and Running the EssDemoApp Application" in the Developing Applications for Oracle Enterprise Scheduler.

65.15.1 How to Create an Oracle ADF User Interface for Submitting Job Requests

The Oracle ADF UI enables end users to submit job requests. End users can enter complex data types for the arguments of descriptive and key flexfields. The Parameters tab in the Oracle ADF UI interface allows end users to enter parameters to be used when submitting the job request.

Flexfields display in a separate task flow region. This region is a child task flow of the parent task flow displayed in the Parameters tab.

---

**Note:**

Define customization layers and authorize runtime customizations to the adf-config.xml file as described in Creating Customizable Applications.

---

To create a user interface for submitting job requests, do the following:

1. Create a new Oracle Fusion web application by clicking New Application in the Application Navigator and selecting Fusion Web Application (ADF) from the Application Templates drop-down list.
   Model and ViewController projects are created within the application.

2. Right-click the Model project and select Project Properties > Libraries and Classpath > Add Library.

3. From the list, select the following libraries, as shown in Figure 65-2.
   • Applications Core
   • Applications Concurrent Processing
   • Enterprise Scheduler Extensions
4. Right-click the View Controller project and select Project Properties > Libraries and Classpath > Add Library.

Add the library Applications Core (ViewController), as shown in Figure 65-3.

5. In the Project Properties dialog, in the left-hand pane, click Business Components.
6. The Initialize Business Components Project window displays. Click the Edit icon to create a database connection for the project. Fill in the database connection details as follows:

- **Connection Exists in:** Application Resources
- **Connection Type:** Oracle (JDBC)
- **User name/Password:** Fill in the relevant user name and password for the database.
- **Driver:** thin
- **Host Name:** Enter the host name of the database server.
- **JDBC port:** Enter the port number of the database.
- **SID:** The unique Oracle system ID for the database.

Click OK.

7. In the file `weblogic.xml`, import the `oracle.applcp.view` library.

8. In the file `weblogic-application.xml`, import the following libraries:
   - `oracle.applcore.attachments` (for ESS-UCM)
   - `oracle.applcp.model`
   - `oracle.applcp.runtime`
   - `oracle.ess`
   - `oracle.sdp.client` (for notification)
   - `oracle.ucm.ridc.app-lib` (for ESS-UCM)
   - `oracle.webcenter.framework` (for ESS-UCM)
   - `oracle.xdo.runtime`
   - `oracle.xdo.service.client`
   - `oracle.xdo.webapp`

   The libraries `oracle.applcp.model` and `oracle.applcp.view` are deployed as part of the installation while running the `config.sh` wizard.

9. Create a new Java Server Pages XML (JSPX) page for the ViewController project by right-clicking ViewController and selecting **New > Web Tier > JSF > JSF JSP Page**.

10. Create a new File System connection. In the Resource Palette, right-click File System, select **New File System Connection**, and do the following:

   a. Provide a connection name and directory path for the Oracle ADF Library files (`<jdev_install>/jdev/oaext/adflib`).

   b. Click **Test Connection** and click **OK** after the connection succeeds.
11. Expand the contents of the SRS-View.jar file to display the list of available task flows that can be used in the application, as shown in *Figure 65-4.*

*Figure 65-4  Displaying the List of Available Task Flows*

12. To include the job request submission page in the application, select the ScheduleRequest-taskflow item from the Resource Palette and drop it onto the Java Server Faces (JSF) page in the area where you want to create a call to the task flow. Create the task flow call as a link or button.

For example, to invoke the job request submission page from within a dialog in the application, do the following:

a. From the Component Palette, drag and drop a Link onto the form in the JSPX page.

b. In the Property Inspector, configure the behavior of the link to the value showpopup.

c. From the Component Palette, drag and drop a Popup component with a dialog component onto the form.

d. To enable submitting a job request, drag and drop the ScheduleRequest-taskflow item onto the dialog component as a dynamic region.

To enable submitting a job set request, drag and drop the ScheduleJobset-taskflow item onto the dialog component.

*Figure 65-5* displays the task flows in the Resource Palette.
13. When prompted, add the required library to the ViewController project by clicking Add Library. Save the JSF page.

14. Edit the task flow binding. Define the following parameters for the task flow, as shown in Figure 65-6.

   a. **jobdefinitionname**: Enter the name of the job definition to be submitted. This is not the name that displays. This is the job definition defined in About Creating a Job Definition. Required.

   b. **jobdefinitionpackagename**: Enter the package name under which the job definition metadata is stored. This should be the namespace path appended to the package name, for example /oracle/ess/Scheduler. The namespace path typically begins with a forward slash (“/”), but should have no forward slash at the end. Required.

   c. **centralui**: When setting this parameter to true, then the task flow UI does not display the header section containing the name, description and basic Oracle BI Publisher actions (such as email, print and notify). This parameter must be a Boolean value. Optional.

   d. **pageTitle**: When passed, the task flow will render this passed String value as the page title. The pageTitle value is currently configured to be truncated at 30 characters. Optional.

   e. **requireRootOutcome**: If true is passed as the value, then the task flow will generate a value of root-outcome when the user clicks the Submit or Cancel buttons. By default, the task flow generates a value of parent-outcome. Optional.

   f. **requestparametersmap**: Enter the name of the map object variable that contains the parameters required for the job request submission. If this parameter is filled in, the Parameters tab in the request scheduling submission page will not prompt end users to enter parameters for executing
the request. The map can be passed to the task flow as a parameter. Typically, this parameter takes the data type `java.util.Map` in which keys are parameter names and values are parameter values. For example, if you will be using a `paramsMap` object in the `pageFlowScope` context, you might enter a `requestparametersmap` value of `#{pageFlowScope.paramsMap}`. Optional.

In the page that holds the task flow region in the job request submission page, set the following property for the popup window that opens the job request submission page window: `contentDelivery = immediate`.

In the page definition file of the page that contains the task flow region, set the following property for the task flow: `Pagedef > executables > taskflow > Refresh=IfNeeded`.

15. If you are using a map to pass parameters to the task flow (as shown in Figure 65-6, the map is called `requestparametersmap`), create a new task flow parameter, such as the `paramsMap` object in the `pageFlowScope` element of a page flow.

![Figure 65-6 Defining Parameters for the Task Flow](image)

These values can be accessed in the job executable, for example from the `RequestParameters` object in the case of a Java job. Example 65-34 illustrates passing the values stored in the `RequestParameters` object to a Java job. This code is used in the class that implements the `oracle.as.scheduler.Executable` interface.

**Note:**

When using a `requestparametersmap` object, set the following properties for the popup window within which the task flow is started.

- Set Content Delivery to `Immediate`.
- In the page definition XML file for the page that contains the region, select `PageDef > Executables > taskflow > set Refresh = IfNeeded`.

16. If the job is defined with properties that must be filled in by end users, the user interface allows end users to fill in these properties before submitting the job...
request. For example, if the job requires a start and end time, end users can fill in the desired start and end times in the space provided by the user interface.

The properties that are filled in by end users are associated with a view object, which in turn is associated with the job definition itself. When the job runs, Oracle Enterprise Scheduler accesses the view object to retrieve the values of the properties.

If using a view object to pass parameters to the job definition, do the following:

a. Create a view object called TestVO using a query such as the one shown in Example 65-35.

b. Specify control UI hints, for example set the display label for Attribute1 to Run Mode and for Attribute2 to Duration.

The parameters tab in the job request submission UI renders with the input fields Run Mode and Duration.

c. To render the Parameters tab in the job request submission UI, add the DynamicComponents 1.0 library as follows. Right-click ViewController and select Project Properties > JSP Tag Libraries > Add. In the Choose Tag Libraries window, select the library DynamicComponents 1.0 and click OK. Figure 65-7 displays the Choose Tag Libraries window.

Figure 65-7 Adding the Library DynamicComponents 1.0

17. In the JSF application you created, create another project called Scheduler. Select File > New, and choose General > Empty Project. This project will be used to create Oracle Enterprise Scheduler metadata and job implementations.

18. In the Scheduler project, add the Oracle Enterprise Scheduler Extensions library to the class path. Right-click the Scheduler project and select Project Properties > Libraries and Classpath > Add Library > Oracle Enterprise Scheduler Extensions.
19. Deploy the libraries `oracle.xdo.runtime` and `oracle.xdo.webapp` to the Oracle Enterprise Scheduler UI managed server. These libraries are located in the directory `${MW_HOME}/jdeveloper/xdo`, where `${MW_HOME}` is the Oracle Fusion Middleware home directory.

20. Deploy the application.

---

**Note:**

When testing the UI in a web browser, you may need to add a security exception to your browser so that the UI renders correctly. Follow the directions in the online help for your web browser.

---

**Example 65-34 Passing Values in a Map Object to a Java Job**

```java
public void execute(RequestExecutionContext ctx, RequestParameters props) throws ExecutionErrorException, ExecutionWarningException, ExecutionCancelledException, ExecutionPausedException {
    String pageTitle = (String) props.getValue("pageTitle");
    // Retrieve other parameters.
    // ...
}
```

**Example 65-35 Creating a View Object Using a Query**

```sql
select null as Attribute1, null as Attribute2 from dual
```

65.15.2 How to Add a Custom Task Flow to an Oracle ADF User Interface for Submitting Job Requests

You can add a custom task flow to an Oracle ADF user interface used to submit job requests at runtime.

To add a custom task flow, do the following:

1. Create a task flow and bind it to your Oracle ADF user interface for submitting a job request created in How to Create an User Interface for Submitting Job Requests.

2. Create an ADF Business Components view object for each UI field. Name the view objects that are bound to UI fields `ParameterVO1`, `ParameterVO2`, and so on.

   Name the attributes of the view objects as follows: `ATTRIBUTE1`, `ATTRIBUTE2`, and so on.

3. Include the view objects in the relevant application module. Even if their names are different, the view object instance names ought to be `ParameterVO1`, `ParameterVO2`, `ParameterVO3`, and so on.

4. In the job definition, define the properties `CustomDataControl` and `ParameterTaskflow`. For more information, see Understanding Job Definitions and Job Types.

5. Optionally, include the method `preSubmit()` in the application module. Oracle Enterprise Scheduler invokes this method before retrieving the parameter values for the submission request.

   Your implementation of the `preSubmit()` method (which returns a Boolean value) could include validation code in the custom task flow. If the validation fails,
your code can throw an exception with the proper internationalized error message. If this validation fails while submitting the request, the error message is displayed to the user and the submission doesn’t go through.

65.15.3 About Handling Schedule Request Submission and Jobset UI Submit and Cancel Button Events

The schedule request submission and jobset UI taskflows include Submit and Cancel buttons. Typically, clicking the Submit button submits the job request, closes the transaction, and returns the user to the page that launched the schedule request submission or jobset UI taskflow (the container taskflow). Clicking the Cancel button resets the internal data structures in the schedule request submission or jobset UI and returns the user to the page that launched the schedule request submission or jobset UI taskflow.

Clicking the Submit or Cancel buttons notifies the containing bounded or unbounded parent taskflow of the result of the Submit or Cancel event, and the container taskflow decides what to do next. The containing taskflow may be a popup or an inline page. The container taskflow handles any navigation required after clicking either button.

The schedule request submission and jobset UI taskflows define two root outcomes and two parent outcomes, which the parent taskflow can use to handle navigational requirements.

The following sample shows the schedule request submission UI parent outcomes.

The following sample shows the jobset UI parent outcomes.

As shown in the preceding samples, the containing taskflow defines the root/parent outcomes that occur when the user clicks the Submit or Cancel button, respectively. These outcomes are onSRSSubmitted and onSRSCanceled, in the case of the schedule request submission UI taskflow, and onJobsetRequestSubmitted and onJobsetRequestCanceled in the case of the jobset UI taskflow.

The consuming or parent taskflow uses these root/parent outcomes in their view definition files (*taskflow.xml or adfc-config.xml) and defines control flow rules accordingly.

Note:
The taskflows must be dropped as a region on a page for the parent actions to work. Make sure to drop the schedule request submission or jobset UI taskflow as a region on a page.

Example 65-36 Schedule request submission UI parent outcomes

```xml
<parent-action id="rootSubmitActionId">
  <description id="__1">Parent action when the submit button is clicked for root parent</description>
  <root-outcome id="submitOutcome">onSRSSubmitted</root-outcome>
</parent-action>

<parent-action id="rootCancelActionId">
  <description id="__2">Parent action when the cancel button is clicked for root parent</description>
  <root-outcome id="cancelOutcome">onSRSCanceled</root-outcome>
</parent-action>
```
Example 65-37  Jobset UI parent outcomes

65.15.3.1 About Handling Schedule Request Submission and Jobset UI Submit and Cancel Button Events

In some cases, you may want to place the taskflow in a region component within an explicitly defined popup window. In such cases, the taskflow must be refreshed after the popup window closes.

65.15.3.1.1 How to Display the Popup Window

To display the popup window, do the following:

1. Drop the taskflow onto the popup window as a dynamic region. Dynamic regions have the advantage of not being tied to a single taskflow ID.

2. In your page definition file, map the taskflow’s taskflowId attribute to a method in your managed bean. This bean should typically be in a view scope.

   The managed bean method should return the taskflow ID as a string. By default, the ID should be an empty string, but not null. You can define a string member variable to store the current taskflow ID and return that string variable to the method.
3. Define a `popupFetchListener` in your JSFF file, and map it to a method in the same managed bean. In this `popupFetch` method, you can swap the taskflow ID with the schedule request submission taskflow ID, so that the method returning the taskflow ID now returns the schedule request submission taskflow ID.

When the popup window opens, it displays the schedule request submission UI taskflow.

### 65.15.3.1.2 How to Close the Popup Window

To close the popup window, do the following:

1. In the view definition file of your taskflow, define the control flow rules to handle the parent actions to be returned by the schedule request submission UI taskflow upon clicking the Submit and Cancel buttons.

2. Define a method call activity in the same taskflow definition file, and call that method from the control flow rule. This method call activity can call a method in the same view scope managed bean.

3. The managed bean method should swap the schedule request submission UI taskflow ID with an empty taskflow ID, an empty string. The taskflow ID in the page definition file (and the dynamic region) will now reference an empty taskflow.

The taskflow is now finalized, and garbage collection has occurred. The schedule request submission taskflow has been re-initialized. The next time the schedule request submission UI taskflow is called, it will execute a new instance of the taskflow.

### 65.15.3.2 How to Handle Schedule Request Submission and Jobset UI Submit and Cancel Buttons in an ADF Popup Window

Following is an example of how the parent taskflow can use these parent/root outcomes to define the navigational rules for closing or navigating away from the schedule request submission UI taskflow. The steps are the same for jobset UI taskflows, but the outcomes have different names.

In this example, the schedule request submission UI taskflow is placed in an ADF popup window. When the user clicks the Submit or Cancel button, the popup window closes, returning the user to the page that launched the popup.

**Note:**

This is only an example of how to use the root/parent outcomes. The actual implementation may vary according to the usecase of the user.

You can either use the parent or root outcome at any given time, depending on the use case. By default, the schedule request submission or jobset UI taskflows always pass a parent outcome. If the consuming application needs a root outcome, then you must pass the `requireRootOutcome` parameter with a value of `true` to the schedule request submission or jobset UI taskflow.

To handle **Submit** and **Cancel** buttons, do the following:

1. Define the control flow rule in your view definition file.
<control-flow-rule>
  <from-activity-id>*</from-activity-id>
  <control-flow-case id="__101">
    <from-outcome id="__121">onSRSCanceled</from-outcome>
    <to-activity-id id="__111">cancelSRS</to-activity-id>
  </control-flow-case>
  <control-flow-case id="__102">
    <from-outcome id="__122">onSRSSubmitted</from-outcome>
    <to-activity-id id="__112">cancelSRS</to-activity-id>
  </control-flow-case>
</control-flow-rule>

2. Define the taskflow activity to handle the navigation. This activity is invoked by the control flow rule. A method call activity has been defined in this example.

<method-call id="cancelSRS">
  <method>#{myManagedBean.closeSRSPopup} </method>
  <outcome>
    <fixed-outcome>srsPopupClosed</fixed-outcome>
  </outcome>
</method-call>

3. Define the corresponding method in the managed bean of the parent taskflow.

```java
public void closeSRSPopup() {
    RichPopup srspopup = getPopup();
    if (srspopup != null) {
        srspopup.cancel(); // closes the popup
    }
}
```

4. To use a root outcome, set the `requireRootOutcome` taskflow parameter to true.

5. Deploy the parent taskflow and launch the page to test out the navigation.

65.15.3.3 About Schedule Request Submission and Jobset UI Submit and Cancel Buttons in a UIShell Popup Window

If you are launching the schedule request submission taskflow in a UIShell popup window, then use the `closePopup()` method described in Implementing OK and Cancel Buttons in a Popup.

If you are launching the schedule request submission UI taskflow in the main task area of the UIShell, then you need to follow the navigation options described in How to Implement End User Preferences.

---

**Note:**

The UIShell APIs `closeMainTask()` and `openMainTask()` can only be invoked from within a bounded taskflow. You must wrap the schedule request submission UI taskflow in a dummy container taskflow, and define the control flow rules to consume the parent actions in the view definition file of the container taskflow.
65.15.4 How to Enable Support for Context-Sensitive Parameters in an Oracle ADF User Interface for Submitting Job Requests

After integrating your application with the Oracle ADF UI for submitting job requests, enable context-sensitive parameter support in the UI.

The request submission UI will render the context-sensitive parameters first so that the end user will specify the context-sensitive parameter values. Context is set in the database based on these parameters. After setting the context, it renders the rest of the parameters based on context set at database layer. When the job runs, the actual business logic will run after setting the context based on the context-sensitive parameter values inside the database.

To enable context-sensitive parameter support in the UI, do the following:

1. Follow the instructions described in How to Create an User Interface for Submitting Job Requests.
2. Create a native ADF Business Components view object with attributes CTXATTRIBUTE1, CTXATTRIBUTE2, and so on, with a maximum of 100 attributes.
   For example, create a view object with the query Select null as CTXATTRIBUTE1, CTXATTRIBUTE2, CTXATTRIBUTE3 from dual. Include required UI hints such as display label, tool tip, and so on.
3. Create a PL/SQL procedure or function to set the context.
4. Specify the parameters shown in Example 65-38 and Example 65-39 in the job definition metadata.
   - contextParametersVO: Enter the fully qualified name of the view object that holds the context sensitive parameters.
   - setContextAPI: PL/SQL API to set the context, along with the package name. The _myPkg1.mySetCtx procedure receives arguments based on attributes in the contextParametersVO.

Example 65-38 contextParametersVO
<parameter name="contextParametersVO" data-type="string">_oracle.apps.mypkg.TestCtxVO</parameter>

Example 65-39 setContextAPI
<parameter name="setContextAPI" data-type="string">_myPkg1.mySetCtx</parameter>

65.15.5 How to Save and Schedule a Job Request Using an Oracle ADF UI

Saving and scheduling a job request using an Oracle ADF UI involves using the Oracle Enterprise Scheduler Extensions library with a JSF application that includes a task flow in which a job is scheduled and saved.

To schedule a job request, do the following:

1. Follow the instructions in How to Create an User Interface forSubmitting Job Requests up to step 9.
Note:
If the custom parameters task flow has no transactions of its own, it must set the `data-control-scope` to `isolated`. This ensures that multiple `parametersVO` properties using the same application module get their independent application module instance.

2. Drag and drop the `SaveSchedule-taskflow` object onto the dialog. No input parameters are required.

3. When prompted, add the required library to the ViewController project by clicking Add Library. Save the JSF page.

4. In the JSF application you created, create another project called Scheduler. Select File > New, and choose General > Empty Project. This project will be used to create Oracle Enterprise Scheduler metadata and job implementations.

5. In the Scheduler project, add the Oracle Enterprise Scheduler Extensions library to the class path. Right-click the Scheduler project and select Project Properties > Libraries and Classpath > Add Library > Oracle Enterprise Scheduler Extensions.

6. Deploy the application.

7. Start the application using the following URL:

8. Enter a schedule name, description and package name with the namespace appended, as shown in Figure 65-8.

   **Figure 65-8  Saving a Job Submission Schedule**

   ![Image of schedule creation interface]

9. Save the schedule.

   A message displays indicating the metadata object ID of the saved schedule. This ID can be used for further job or job set request submissions.
65.15.6 How to Submit a Job Using a Saved Schedule in an Oracle ADF UI

Submitting a saved job request schedule using an Oracle ADF UI involves using the Oracle Enterprise Scheduler Extensions library with a JSF application that includes a task flow in which a saved job schedule can be submitted.

To submit a job, do the following:

1. Follow the instructions in How to Create an User Interface for Submitting Job Requests.

2. Deploy the application. Open the page using the following URL:

3. Click the Schedule tab. In the Run option field, select the Use a Schedule radio button.

4. From the Frequency drop-down list, select Use a Saved Schedule.

5. Enter the namespace and package names for the schedule along with the name of the schedule.

6. To view the list of scheduled jobs, click Get Details. Click Submit to submit the saved job request.

65.15.7 About Notifying Users of the Status of Executed Jobs

The Oracle ADF user interface for submitting job requests provides the ability to notify users of the status of submitted jobs (via the Notification tab of the user interface). For example, users can request a notification to be sent to the originator of the job request.

A notification includes two components: the user to whom the notification is to be delivered, and the completion status of the job that triggers the notification. For example, notifications can be sent upon the successful completion of a job, or when a job completes in an error or warning state.

65.15.8 What Happens When You Create an Oracle ADF User Interface for Submitting Job Requests

The Oracle ADF interface is integrated with the Oracle Fusion application, and the application is tested and deployed. End users access the Oracle ADF user interface, fill in optional job properties, and click a button to submit the job request.

65.15.9 What Happens at Runtime: How an Oracle ADF User Interface for Submitting Job Requests Is Created

The application receives the submitted job request and calls Oracle Enterprise Scheduler to run the job. The Oracle Fusion application accesses the values of the properties entered by end users through the view object in which these properties were defined at design time. The job returns a result of success or failure, and the result passes from the Oracle Fusion application to Oracle Enterprise Scheduler.

Custom Task Flow

A job that includes properties to be filled in by end users through an Oracle ADF user interface at runtime includes ADF Business Components view objects with validation.
and the parameters to be filled in by end users. These parameters are submitted at runtime in the order in which they have been defined, meaning the first custom parameter to be defined is submitted first. The custom parameters must be named as follows:

ParameterVO1.ATTRIBUTE1, ParameterVO1.ATTRIBUTE2, ParameterVO2.ATTRIBUTE1, ParameterVO3.ATTRIBUTE1, and so on.

If the job definition includes the properties ContextParametersVO, ParameterTaskflow and parametersVO, these properties render in that order at runtime.

Context-Sensitive Parameters

When starting the job request submission page UI to submit a job or job set request with context-sensitive parameters, the contextParametersVO parameter initially renders in the Parameters tab of the Oracle ADF user interface. The end-user can then enter values for the context-sensitive parameters. Clicking Next invokes an API called setConextAPI by passing the context parameters. The context is set at the database level and the remaining parametersVO job parameters are rendered.

When the context-sensitive parameters are modified, end users must click Next to set the context with the new values.

Notifications

When the final status of the job is determined, Oracle Enterprise Scheduler delivers the notifications to the relevant users using the User Messaging Service. Users receive notifications based on their messages preferences. The notification view object defined at design time populates the input box in the submission request user interface at runtime.

65.16 Specify Optional Parameters

TBD

* Applying Language Templates
* Specifying a Printer for Language Output
* Configuring Automatic Notifications Upon Completion of Language-Specific Requests

65.17 About Submitting Job Requests Using the Request Submission API

You can submit, cancel and otherwise manage job requests using the request submission API.

For information about using the request submission API, see the chapter "Using the Runtime Service" in Developing Applications for Oracle Enterprise Scheduler.

65.17.1 About Using the Java Request Submission API

Use the Oracle Enterprise Scheduler Java API to request job submission in a Java application. For more information about the API, see the Oracle Enterprise Scheduler Service javadoc documentation.

Sample code: TBD
65.17.2 About Using the PL/SQL Request Submission API

The package ESS_RUNTIME_SERVICE enables submitting job requests using PL/SQL. The following samples illustrate the use of the PL/SQL request submission API.

In the first example, a request is submitted to run a job defined in the metadata of a J2EE application called app1. The procedure takes two arguments set to myarg1 and myarg2. The job is scheduled to run every two hours beginning at the time of job submission.

In the second example, a subrequest is submitted. A sub request is a request submitted from a running job, where the running job passes its own execution context in the form of a parameter called request_handle. Passing the execution context ties the request being submitted to the currently running request. This routine is designed to be called from a running PL/SQL request.

The request is submitted to J2EE application called app1, and the procedure takes two arguments whose values are myarg1 and myarg2. The job is scheduled to run every two hours from the time of submission.

**Example 65-40  Submitting a job request using the PL/SQL API**

request_prop_table_t myprops;
ess_runtime.set_submit_args( myprops, 'myarg1', 'myarg2');
ess_runtime.submit_request_adhoc_sched(
    application => 'app1',
    definition_type => 'JOB',
    definition_name => 'jobA',
    interval=>2,
    frequency=>'HOURLY',
    props => myprops);

**Example 65-41  Submitting a Subrequest Using the PL/SQL API**

procedure myjob (request_handle IN varchar2, arg1 IN varchar2, arg2 IN varchar2) as
    number reqid;
    request_prop_table_t myprops;
    ...
    begin
        ...
        reqid := ess_runtime.get_request_id(request_handle);
        ess_runtime.set_submit_args( myprops, 'subarg1', 'subarg2');
        ess_runtime.submit_subrequest(
            request_handle => request_handle,
            definition_name => 'jobA',
            definition_package => 'Test_Package',
            props => myprops)
        ...
    end

65.17.3 About Using the C Request Submission API

C routines are provided to enable request submission. For more information, see TBD. Currently, no samples are available.
65.18 About Defining Oracle Business Intelligence Publisher Postprocessing Actions for a Scheduled Job

Oracle Business Intelligence Publisher enables generating reports from a variety of data sources, such as Oracle Database, web services, RSS feeds, files, and so on. BI Publisher provides several delivery options for generated reports, including print, fax, and email.

To create an Oracle BI Publisher report, an Oracle BI Publisher report definition is required. Oracle BI Publisher report definitions consist of a data model that specifies the type of data source (database, web service, and so on) and a template for output formatting.

With report definitions in place, options for reporting are available to end users in the Output tab of the Oracle ADF user interface. The Output tab provides options through which an end user can define templates for reports. They can specify layout templates, document formats (such as PDF, RTF, and more), report destinations (email addresses, fax numbers, or printer addresses), and so on. When the user submits a request, this information is stored in the Oracle Enterprise Scheduler schema. The preprocessor then invokes the Oracle BI Publisher service and passes the saved data to it.

Extensions to Oracle Enterprise Scheduler provide the ability to run Oracle BI Publisher reports as batch jobs. The Oracle Enterprise Scheduler postprocessing infrastructure enables applying Oracle BI Publisher formatting templates to XML data and delivering the formatted reports by printing, faxing, and so on.

Related Links

The following documents provide additional information related to subjects discussed in this section:

- For more information about defining postprocessing actions for scheduled jobs, see "Creating a Business Domain Layer Using Entity Objects" in the Developing Fusion Web Applications with Oracle Application Development Framework.

- For more information on the web service, see the chapter "Using the Oracle Enterprise Scheduler Web Service" in Developing Applications for Oracle Enterprise Scheduler.

- For more information about configuring security certificates, see the chapter "Managing Keystores, Wallets, and Certificates" in the Administering Oracle Fusion Middleware.

65.18.1 Perform Prerequisite Tasks

Before you start defining Oracle BI Publisher postprocessing for a scheduled job, do the following:

1. Follow the instructions for setting up Oracle BI Publisher reporting as described in the "Creating and Editing Reports" chapter in Report Designer's Guide for Oracle Business Intelligence Publisher.

   Use the following file to set up reporting and seed your database with the relevant Oracle BI Publisher data:

2. Create an Oracle BI Publisher job definition, following the instructions in the Oracle BI Publisher documentation.
3. Define File Management Group (FMG) properties for the Oracle BI Publisher job definition as described in How to Define File Groups for a Job.

Example 65-42 Location of the File for Setting Up Oracle BI Publisher Reporting and Seeding the Database

$BEAHOME/jdeveloper/jdev/oaext/adflib/PPActions.jar

65.18.2 How to Define Oracle BI Publisher Postprocessing for a Scheduled Job

Defining postprocessing for a scheduled job involves the following:

- Define the postprocessing action.
- Create a Java class for the postprocessing action. The Java class uses the parameters collected by the Oracle Enterprise Scheduler UI and calls Oracle BI Publisher APIs as required.
- Create a native ADF Business Components view object to save parameters for postprocessing, such as template name, output format, locale, and so on.

To create an Oracle BI Publisher postprocessing action, do the following:

1. In the table called APPLCP_PP_ACTIONS, define the postprocessing action to be executed for the job.

The columns to be seeded in the APPLCP_PP_ACTIONS table are as follows:

- **Action_SN**: Define a short name for the action, used when postprocessing actions are submitted programatically. For example, OBFUSC8.
- **Action Name**: Enter a name for the action to be displayed in the user interface. This name is stored separately for translation purposes.
- **Class**: Enter the name of the Java class that defines the logic for the postprocessing action. For example, oracle.apps.shh.obfuscate.PPobfuscate.
- **VO_Def_Name**: Enter the name of the view object used to collect the arguments for the postprocessing action. For example, oracle.apps.shh.obfuscate.PPobfuscateVO.
- **Type**: Enter the category of the postprocessing action to be taken. Enter one of the following categories of postprocessing actions:
  - **L**: Indicates a Layout postprocessing action. Layout actions change the output of the job, and produce new output.
  - **O**: Indicates an Output postprocessing action. Output actions act on the output created by the job and its layout actions, performing delivery, publishing, printing, and so on.
  - **F**: Indicates a Final postprocessing action. Final Actions take no input. Final postprocessing actions execute using the final status of the job after all Layout and Output actions have executed.
- **On_Success**: Indicate whether the postprocessing action runs following a successful job. Enter Y or N.
• **On Warning**: Indicate whether the postprocessing action runs following a job that ends in a warning. Enter Y or N.

• **On Failure**: Indicate whether the postprocessing action runs following a failed job. Enter Y or N.

• **SEQ_NUM**: Enter a number to sequentially order the postprocessing actions. Only registered postprocessing actions of the same type can be sequentially ordered. This value determines both the order in which the tabs corresponding to the actions appear in the user interface, and the order in which the actions run.

Each action can also specify request parameters used by the postprocessing action view object. These parameters must be set in the job definition for any job using this action. The parameter names are stored in the APPLCP_PP_ACTION_PARAMS table. The values of these parameters are accessible from the parameter view object at the time of job request submission. Postprocessing actions can access all request parameters at runtime using the request ID.

2. Define a Java class for the postprocessing action, implementing the interface oracle.apps.fnd.applcp.request.postprocess.PostProcess. Use the methods required by the interface as described in Table 65-4.

<table>

An example of a Java class that defines a postprocessing action is shown in Example 65-43:

3. Create a native ADF Business Components view object to collect the parameters to be used in the postprocessing action. Follow the procedure described in About Creating a Job Definition. Define any view object attributes sequentially.

If the view object requires access to action-specific values from the job definition, specify the required job definition parameters in the action definition. The submission UI automatically retrieves the values from the job definition metadata and sets them as Oracle Fusion Middleware Extensions for Applications (Applications Core) Session attributes that may be retrieved using the ApplSession standard API.

Example 65-43 A Java Class that Defines a Postprocessing Action

```java
package oracle.apps.shh.Obfuscate;

import oracle.apps.fnd.applcp.request.postprocess.PostProcess;
import oracle.apps.fnd.applcp.util.ESSContext;
import oracle.apps.fnd.applcp.util.PostProcessState;
import oracle.as.scheduler.*;

public class PPobfuscate implements PostProcess {
    ArrayList myOutputFiles;

    ArrayList getOutputFileList() {
        return myOutputFiles;
    }

    PostProcessState invokePostProcess(long requestID, String ppArguments[],
                                        ArrayList files)
    {
        RuntimeService rService = null;
        RuntimeServiceHandle rHandle = null;
        try {
            // Accessing Runtime Details for a given requestID
            RequestDetail rDetail = null;
            RequestParameters rParam = null;
            String obfuscationSeed = ppArguments[0];
            String codedFileName = ppArguments[1];
```
String myNewFile;
String outDir = null;

rService = ESSContext.getRuntimeService();
if (rService != null) rHandle = rService.open();
if (rHandle != null) rDetail = getRequestDetails(rHandle, requestID);
if (rDetail != null) rParam = rDetail.getParameters();
if (rParam != null) outDir = rParam.getValue("outputWorkDirectory");
if (outDir == null) 
    // Details not received, usually an exception would have been thrown
    // by now. We handle this case to be robust.
    // Log the ERROR to Oracle Diagnostic Logging
    return PostProcessState.ERROR;
}
// Check files
if (files[0] == null) 
    // no files - PostProcessing should never call us in this state
    // in case it does - log Error to Oracle Diagnostic Logging
    return PostProcessState.ERROR;

// This example expects a single file
myNewFile = outputDir + System.getProperty("file.separator") +
codedFileName;
Obfuscate.performObfuscation( files[0], obfuscationSeed, myNewFile );
myOutputFiles[0] = myNewFile;

// In case multiple files are used.
for (i = 1; files[i] != null; i++) 
    // Appending a counter to the filename to be unique.
    myNewFile = outputDir + System.getProperty("file.separator") +
codedFileName + i;
    Obfuscate.performObfuscation( files[i], obfuscationSeed, myNewFile );
    myOutputFiles[i] = myNewFile;
}
return PostProcessState.SUCCESS;
}

} // end class

65.18.3 About Defining Oracle BI Publisher Postprocessing Actions for a Scheduled PL/SQL Job

Example 65-44 shows a PL/SQL job that includes Oracle BI Publisher postprocessing actions. The PL/SQL job calls the method ess_runtime.add_pp_action so as to
generate a layout for the data from the postprocessing action. This example formats
the XML generated by the job as a PDF file.

**Example 65-44  Defining a Scheduled PL/SQL Job with Oracle BI Publisher
Postprocessing Actions**

declare
l_reqid   number;
l_props   ess_runtime.request_prop_table_t;
begin
.
   ess_runtime.add_pp_action ( 
      props              => l_props,               -- IN OUT
      request_prop_table_t,
      action_order       => 1,                     -- order in which this post
processing action will execute.
      action_name        => 'BIPDocGen',           -- Action for Document
      Generation (layout)
      on_success         => 'Y',                   -- Should this be called on
success,
      on_warning         => 'N',                   -- Should this be called on
warning,
      on_error           => 'N',                   -- Should this be called on
error,
      file_mgmt_group    => 'XML',                 -- File types this action
will process. It has to be defined in Job Defintion,
      step_path          => NULL,                  -- IN varchar2 default NULL,
      argument1          => 'XLABIPTEST_RTF',      -- Template name needed for
Documnet Generation action,
      argument2          => 'pdf'                  -- What type of layout file
will be generated by Document Generation action,
    );
    l_reqid :=
      ess_runtime.submit_request_adhoc_sched 
      (application => 'SSEssWls',               -- Application
      Application
      definition_type => 'JOB',
      definition_name => 'BIPTestJob',
      definition_package => '/mypackage',
      props => l_props);
commit;
dbms_output.put_line('request_id = :'||l_reqid);
end;

**65.18.4 About Invoking Postprocessing Actions Programmatically**

You can invoke postprocessing actions programmatically from a client using a Java or
web service API. Both APIs require the same set of parameter values described in table
Table 65-7.

For Java clients, call the `addPPAction` method of
`oracle.as.scheduler.cp.SubmissionUtil`. The method takes the values
needed to invoke the action and throws an exception called
`IllegalArgumentException` if the number of arguments exceeds 10. **Example 65-45** shows the declaration of the method.

For web service clients, you invoke the method using a proxy, as in **Example 65-46**.
### Table 65-7  Parameters for Adding a Postprocessing Action

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>params</td>
<td>A RequestParameters object into which this method adds parameters.</td>
</tr>
<tr>
<td>actionOrder</td>
<td>The ordinal location of this action in the sequence of actions to be performed within the action domain. Oracle BI Publisher process requests starting with action order index 1.</td>
</tr>
<tr>
<td>actionName</td>
<td>The name of the action to perform. The following lists acceptable values for this parameter, along with the acceptable values you can use in the arguments parameter of this method.</td>
</tr>
<tr>
<td></td>
<td>• BIPDocGen: for applying Oracle BI Publisher templates. Acceptable argument parameter values are:</td>
</tr>
<tr>
<td></td>
<td>– argument1: maps to report parameter TEMPLATE, the template name.</td>
</tr>
<tr>
<td></td>
<td>– argument2: maps to report parameter OUTPUT_FORMAT, the output format for Oracle BI Publisher document generation, for example, &quot;pdf&quot; or &quot;html&quot;.</td>
</tr>
<tr>
<td></td>
<td>– argument3: maps to report parameter LOCALE, the locale to be used while generating output.</td>
</tr>
<tr>
<td></td>
<td>• BIPPrintService: for specifying the print action. Acceptable argument parameter values are:</td>
</tr>
<tr>
<td></td>
<td>– argument1: maps to printerName</td>
</tr>
<tr>
<td></td>
<td>– argument2: maps to numberOfCopies</td>
</tr>
<tr>
<td></td>
<td>– argument3: maps to side</td>
</tr>
<tr>
<td></td>
<td>– argument4: maps to tray</td>
</tr>
<tr>
<td></td>
<td>– argument5: maps to pagesRange</td>
</tr>
<tr>
<td></td>
<td>– argument6: maps to orientation</td>
</tr>
<tr>
<td></td>
<td>• BIPDeliveryEmail: for specifying the email action. Acceptable argument parameter values are:</td>
</tr>
<tr>
<td></td>
<td>– argument1: maps to emailServerName</td>
</tr>
<tr>
<td></td>
<td>– argument2: maps to from</td>
</tr>
<tr>
<td></td>
<td>– argument3: maps to to</td>
</tr>
<tr>
<td></td>
<td>– argument4: maps to cc</td>
</tr>
<tr>
<td></td>
<td>– argument5: maps to bcc</td>
</tr>
<tr>
<td></td>
<td>– argument6: maps to replyTo</td>
</tr>
<tr>
<td></td>
<td>– argument7: maps to subject</td>
</tr>
<tr>
<td></td>
<td>– argument8: maps to messageBody</td>
</tr>
<tr>
<td></td>
<td>• BIPDeliveryFax: for specifying the fax action. Acceptable argument parameter values are:</td>
</tr>
<tr>
<td></td>
<td>– argument1: maps to faxServerName</td>
</tr>
<tr>
<td></td>
<td>– argument2: maps to faxNumber</td>
</tr>
<tr>
<td>description</td>
<td>Description of this post processor action.</td>
</tr>
<tr>
<td>onSuccess</td>
<td>Determines whether this action should be performed on successful completion of the job.</td>
</tr>
<tr>
<td>onWarning</td>
<td>Determines whether this action should be performed when the job or step has completed with a warning.</td>
</tr>
<tr>
<td>onError</td>
<td>Determines whether this action should be performed when the job or step has completed with an error.</td>
</tr>
</tbody>
</table>
### Table 65-7 (Cont.) Parameters for Adding a Postprocessing Action

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>fileMgmtGroup</td>
<td>The name of the File Management Group. When using a Oracle BI Publisher template, the value of this parameter is XML, as defined in the job definition Program.FMG property with the value L.XML.</td>
</tr>
<tr>
<td>arguments</td>
<td>A list of arguments for the post processor action. See the actionName parameter for values you can use for the arguments parameter.</td>
</tr>
</tbody>
</table>

#### Example 65-45 Sample declaration of the addPPAction method

```java
public static void addPPAction (RequestParameters params, 
    int actionOrder, 
    String actionName, 
    String description, 
    boolean onSuccess, 
    boolean onWarning, 
    boolean onError, 
    String fileMgmtGroup, 
    String[] arguments) 
    throws IllegalArgumentException
```

#### Example 65-46 Adding Postprocessing Actions for a Request

```java
ESSWebService proxy = createProxy("addPPActions");

PostProcessAction ppAction = new PostProcessAction();
ppAction.setActionOrder(1);
ppAction.setActionName("BIPDocGen");
ppAction.setOnSuccess(true);
ppAction.setOnWarning(false);
ppAction.setOnError(false);
ppAction.getArguments().add("argument1");
ppAction.getArguments().add("argument2");

List<PostProcessAction> ppActionList = new ArrayList<PostProcessAction>();
ppActionList.add(ppAction);

RequestParameters reqParams = new RequestParameters();
reqParams = proxy.addPPActions(reqParams, ppActionList);
```

### 65.18.5 What Happens When You Define Oracle BI Publisher Postprocessing Actions for a Scheduled Job

Depending on the FMG property set for the job definition, the relevant postprocessing action is selected for the job.

The ppArguments array stores the values collected from the view object attributes. The array is passed to the `invokePostProcess` method which executes in the Java class that defines the postprocessing action.
65.18.6 What Happens at Runtime: How Oracle BI Publisher Postprocessing Actions are Defined for a Scheduled Job

At runtime, the user interface uses the view object to collect the arguments for executing the postprocessing action as defined in the table `APPLCP_PP_ACTIONS`. These arguments also instruct the user interface as to how to invoke the action logic.

The postprocessing action accesses the XML output file from the job request, and passes the XML output to Oracle BI Publisher. The postprocessing action creates a report request containing the XML data.

The postprocessing action displays in the submission Oracle ADF UI. The UI enables adding a postprocessing action for the scheduled job, selecting arguments for the action using the view object and selecting output options for the action. The user interface also displays the name of the File Management Group with which the output files are associated.

Note:

When testing the UI in a web browser, you may need to add a security exception to your browser so that the UI renders correctly. Follow the directions in the online help for your web browser.

65.19 About Monitoring Scheduled Job Requests Using an Oracle ADF UI

It is possible to view previously submitted jobs by integrating the Monitoring Processes task flow into an application.

For information about enabling tracing for jobs, see Debugging and .

Related Links

The following document provides additional information related to subjects discussed in this section:

For more information about tracing Oracle Enterprise Scheduler jobs, see the section "Tracing Oracle Enterprise Scheduler Jobs" in the chapter "Managing Oracle Enterprise Scheduler Service and Jobs" in the Administrator’s Guide.

65.19.1 How to Monitor Scheduled Job Requests

The main steps involved in monitoring scheduled job requests using an Oracle ADF UI are as follows:

- Configure Oracle Enterprise Scheduler in JDeveloper
- Create and initialize an Oracle Fusion web application
- Create a UI Shell page and drop the Monitor Processes task flow onto it

Note:

Fields such as submission date, ready time, scheduled date, process start, name, type, definition, and so on, are not set unless the job request or subrequest is successfully validated.
To monitor scheduled job requests, do the following:

1. Follow the instructions in How to Create an User Interface for Submitting Job Requests up to and including step 5.

2. Under the ViewController project, right-click Web Content and create a new JSF page called Consumer.jspx. Select the following options:
   - UIShell (template)
   - Create as XML Document

3. Create a new JSF page fragment. This page initializes the project.

5. Right-click adfc-config.xml and select Create ADF Menu.
   The Create ADF Menu Model window displays.

6. Rename the default file root_menu.xml to something else.

7. Open the XML file created in the previous step. Look for an itemNode element as follows:

   `<itemNode id="itemNode_JSF/JSPX page name">`

   For example, the Consumer.jspx page has the following itemNode value:

   `<itemNode id="itemNode_Consumer">`

8. In the Structure window, right-click the root itemNode and select Insert inside itemNode-itemNode_JSF/JSPX page name > itemNode.

9. In Common Properties, enter the following values:
   - `id`: MonitorNode
   - `focusViewId`: /Consumer

10. In Advanced Properties, enter Monitor Processes in the label field.

11. Right-click the itemNode you just added and select Go to Properties.

12. In the Property Inspector, select Advanced and do the following:
   - Select the dynamicMain task type.
   - In the taskFlowId field, enter the following:
     
     ```
     /WEB-INF/oracle/apps/fnd/appclp/monitor/ui/flow/MonitorProcessesMainAreaFlow.xml#MonitorProcessesMainAreaFlow
     ```
   - Enter a string for the pageTitle parameter, which will become the title for the monitoring page. If this parameter is not specified, then the page title will be shown as "Manage Scheduled Processes".

13. Repeat steps 8-12 to create a second itemNode element with the following properties:
   - `id`: __Launcher_itemNode__FndTaskList
• **focusViewId**: /Launcher
• **label**: #{applcoreBundle.TASKS}
• **Task Type**: defaultRegional
• **taskFlowId**: /WEB-INF/oracle/apps/fnd/applcore/patterns/uishell/ui/publicFlow/TasksList.xml#TasksList

14. Right-click adfc-config.xml and select Link ADF Menu to Navigator.

16. Deploy and test the application.

### 65.19.2 How to Embed a Table of Search Results as a Region on a Page

You can embed a table of job request search results as a region on a page. Task flow parameters can be used to further specify the job requests returned by the search.

To embed a search-results table, do the following:

1. Add the **Applications Concurrent Processing (View Controller)** library to the ViewController project.
   
   For more information about adding this library to the project, see *How to Create and Implement a Scheduled Job in JDeveloper*.

2. In the Resource Palette, select **File System > Applications Core > MonitorProcesses-View.jar > ADF Task Flows**.

3. Drag and drop onto the page as a region the **SearchResultsFlow** task flow.

The task flow accepts the following parameters:

• **processId**: The request ID number uniquely identifying the process.

• **processName**: The name of the process, which corresponds to the name of the job definition.

• **processNameList**: Fetches the job requests of multiple process names using a list which contains the relevant job names.

   When specifying the task flow parameter **processName**, this parameter takes precedence over the task flow parameter **processNameList**. The requests returned are for the single process name specified by the **processName** parameter only.

• **scheduledDays**: Queries requests for the last \( n \) days. If this parameter is not specified in a work area task flow, job requests from the last three days are displayed. If the value of this parameter is greater than three days, then the parameter value will be taken as three and only the last three days of job requests display.

• **status**: The status of the request. This filter narrows down the result set to display only the requests with the selected status in the filter.

   If the **status** input parameter is not specified, then the results table shows all requests with all statuses (by default, the **All** value is selected in the status filter list).
If the status input parameter is specified, then the results table show only the requests of the given status. The selected status is chosen as the default in the status filter list.

• isEmbedResults: A Boolean value that indicates whether search results are embedded in the task flow. True or false.
  
  Set to true to embed table results.

• Time Range Filter: This filter is used to narrow down the result set to show only the requests for last \( n \) hours. This filter lists the following values in a dropdown list: (1) Last 1 Hour, (2) Last 12 Hours, (3) Last 24 Hours, (4) Last 48 Hours and (5) Last 72 Hours.
  
The default selected item displays based on the value assigned or given to the task flow parameter scheduledDays.
  
  A scheduledDays value of 1 means the time range filter list displays only the first three items.
  
  A scheduledDays value of 2 means the time range filter list displays only the first four items.
  
  If the value of scheduledDays is 1, then by default, the time range dropdown list displays Last 24 Hours.
  
  If the value of scheduledDays is 3 or more, then by default, the time range dropdown list displays Last 72 Hours.

• pageTitle: When passed, the task flow will render this passed String value as the page title. Optional.

• requireRootOutcome: If the value true is passed, then the task flow will generate a value of root-outcome when the user clicks on the Submit or Cancel buttons. By default the task flow generates a value of parent-outcome.

Specifying more than one of these parameters causes the search to run using the AND conjunction.

65.19.3 How to Log Scheduled Job Requests in an Oracle ADF UI

You can enable Oracle Diagnostic Logging in an Oracle ADF UI used to monitor scheduled job requests. When enabling logging, the UI displays a View Log button.

The View Log functionality in the monitoring UI applies only to scheduled requests with a persistenceMode property set to a value of file. Hence, the View Log button in the scheduled request submission monitoring UI displays only when viewing requests with persistenceMode property set to a value of file.

The only other valid value for the persistenceMode property is the value content. The View Log button is hidden for all requests with a persistenceMode property value of content. If the persistenceMode property is not specified for a given request, then the monitoring UI defaults to a persistenceMode value of file, and displays the View Log button when viewing relevant requests.

To log scheduled job requests, do the following:

1. Open the server's logging.xml file.

2. In the logging.xml file, enter the required logging level for oracle.apps.fnd.applcp.srs, for example: INFO, FINE, FINER or FINEST.
Example 65-47 shows a sample of a logging.xml file with Oracle Diagnostic Logging configured.

3. Save the logging.xml file and restart the server.

Example 65-47 Enabling Logging in the logging.xml File

```xml
<logger name='oracle.apps.fnd.applcp.srs' level='FINEST'
        useParentHandlers='false'>
    <handler name='odl-handler'/>
</logger>
```

65.19.4 Tips for Troubleshooting an Oracle ADF UI Used to Monitor Scheduled Job Requests

Some useful tips for troubleshooting the Oracle ADF UI used to monitor scheduled job requests.

- **Displaying a readable name.** When defining metadata, use the display-name attribute to configure the name to be displayed in the Oracle ADF UI. The monitoring UI will display the value defined for the display-name attribute. If this attribute is not defined, the UI displays the value of the metadata-name attribute assigned to the metadata.

- **Displaying multiple links in the task flow UI that each display a popup window with a different job definition.** The recommended approach is to create a single page fragment that contains the scheduled request submission task flow within an Oracle ADF region. This page is reused by each link to display a different job definition in the scheduled request submission UI. For each link, pass the relevant parameters such as the job definition name, package name, and so on. This approach ensures that the UI session creates and uses a single instance of the task flow.

- **Displaying the correct name given the metadata name and display name attributes.** By default, the display name takes precedence and displays in the UI. If the display name is not defined, then the UI displays the job or job set name.

- **Resolving name conflicts between a job metadata parameter name and a request parameter with the same name.** Oracle Enterprise Scheduler uses the following rules to resolve parameter name conflicts.
  - **The last definition takes precedence.** When the same parameter is defined repeatedly with the read-only flag set to false in all cases, the last parameter definition takes precedence. For example, a property specified at the job request level takes precedence over the same property specified at the job definition level.
  - **The first read-only definition takes precedence.** When the same parameter is defined repeatedly and at least one definition is read-only (that is, the ParameterInfo read-only flag is set to true), the first read-only definition takes precedence. For example a read-only parameter specified at the job type definition level takes precedence over a property with the same name specified at the job definition level, regardless of whether it is read-only.

- **Resolving name conflicts between the job or job set metadata name and display name attributes.** By default, the display name takes precedence over the metadata
name. If the display name is not defined, then the UI defaults to displaying the job or job set name.

- **Understanding the state of a job request.** There are 20 possible states for a job request, each with a corresponding number value. These are shown in Table 65-8.

Table 65-8  Job Request States

<table>
<thead>
<tr>
<th>Job State Number</th>
<th>Job Request State</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>-1</td>
<td>UNKNOWN</td>
<td>The state of the job request is unknown.</td>
</tr>
<tr>
<td>1</td>
<td>WAIT</td>
<td>The job request is awaiting dispatch.</td>
</tr>
<tr>
<td>2</td>
<td>READY</td>
<td>The job request has been dispatched and is awaiting processing.</td>
</tr>
<tr>
<td>3</td>
<td>RUNNING</td>
<td>The job request is being processed.</td>
</tr>
<tr>
<td>4</td>
<td>COMPLETED</td>
<td>The job request has completed and postprocessing has commenced.</td>
</tr>
<tr>
<td>5</td>
<td>BLOCKED</td>
<td>The job request is blocked by one or more incompatible job requests.</td>
</tr>
<tr>
<td>6</td>
<td>HOLD</td>
<td>The job request has been explicitly held.</td>
</tr>
<tr>
<td>7</td>
<td>CANCELLING</td>
<td>The job request has been canceled and is awaiting acknowledgement.</td>
</tr>
<tr>
<td>8</td>
<td>EXPIRED</td>
<td>The job request expired before it could be processed.</td>
</tr>
<tr>
<td>9</td>
<td>CANCELLED</td>
<td>The job request was canceled.</td>
</tr>
<tr>
<td>10</td>
<td>ERROR</td>
<td>The job request has run and resulted in an error.</td>
</tr>
<tr>
<td>11</td>
<td>WARNING</td>
<td>The job request has run and resulted in a warning.</td>
</tr>
<tr>
<td>12</td>
<td>SUCCEEDED</td>
<td>The job request has run and completed successfully.</td>
</tr>
<tr>
<td>13</td>
<td>PAUSED</td>
<td>The job request paused for subrequest completion.</td>
</tr>
<tr>
<td>14</td>
<td>PENDING_VALIDATION</td>
<td>The job request has been submitted but has not been validated.</td>
</tr>
<tr>
<td>15</td>
<td>VALIDATION_FAILED</td>
<td>The job request has been submitted, but validation has failed.</td>
</tr>
<tr>
<td>16</td>
<td>SCHEDULE_ENDED</td>
<td>The schedule for the job request has ended, or the job request expiration time specified at submission has been reached.</td>
</tr>
<tr>
<td>17</td>
<td>FINISHED</td>
<td>The job request, and all child job requests, have finished.</td>
</tr>
<tr>
<td>18</td>
<td>ERROR_AUTO_RECOVERY</td>
<td>The job request has run, resulted in an error, and is eligible for automatic retry.</td>
</tr>
<tr>
<td>19</td>
<td>ERROR_MANUAL_RECOVERY</td>
<td>The job request requires manual intervention to be retried or transition to a terminal state.</td>
</tr>
</tbody>
</table>

- **Fixing an Oracle BI Publisher report that does not generate, even though the Oracle Enterprise Scheduler schema REQUEST_PROPERTY table contains all the relevant postprocessing parameters.** Verify that the postprocessing parameters
begin with index value of 1. If a set of parameters begins with an index value of 0 (such as the parameter pp.0.action), then the Oracle BI Publisher report will not generate. Oracle BI Publisher expects parameters to begin with an index value of 1. In the case of a job set with multiple Oracle BI Publisher jobs, verify that all the individual step postprocessing actions begin with an index value of 1.

- Fixing a scheduled request submission UI that does not display, and throws a partial page rendering error in the browser indicating that the drTaskflowId property is invalid. This error may occur due to any of the following.
  - The object oracle.as.scheduler.JobDefinition may be unavailable to the scheduled request submission UI, which attempts to query the object using the MetadataService API.
  - The job definition name or the job definition package name is incorrect when passed as task flow parameters. Ensure that the package name does not end with a trailing forward slash.
  - The metadata permissions are not properly configured for the user who is currently logged in. The JobDefinition object, being stored in Oracle Metadata Services Repository, requires adequate metadata permissions to read and modify the JobDefinition metadata. Ensure that the Oracle Metadata Services Repository to which you are referring contains the job definition name in the proper package hierarchy.

65.20 About Integrating Data Security Task Flows into Applications Setup Manager

Every Oracle application registers task flows with a product called Oracle Fusion Applications Setup Manager. Applications Setup Manager provides a single, unified user interface that allows customers and implementers to configure all Oracle applications by defining custom configuration templates or tasks based on their business needs.

The Applications Setup Manager UI enables customers and implementers to select the business processes or products that they want to implement.

Oracle Function Security controls your privileges to a specific task flow, and users who do not have the required privilege cannot view the task flow. For more information about how to implement function security privileges and roles, see Implementing Function Security.

Table 65-9 lists the task flows and their parameters.

<table>
<thead>
<tr>
<th>Task Flow Name</th>
<th>Task Flow XML</th>
<th>Parameters Passed</th>
<th>Behavior</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Schedule Requests</td>
<td>/WEB-INF/ScheduleRequest-taskflow.xml</td>
<td>None.</td>
<td>Schedules a job request submission.</td>
<td>None.</td>
</tr>
</tbody>
</table>
65.21 About Using a Task Flow Template for Submitting Scheduled Requests Through an Oracle ADF UI

The Oracle ADF UI used to submit scheduled requests supports basic and advanced modes. Switching between modes requires page navigation between two view activities.

In some cases, you may want to use a custom parameter task flow for the UI in the context of an Oracle Fusion web application. One such use case is when you require a method call activity as the default activity of a custom bounded task flow so as to initialize the parameters view object and Flexfield filters defined in that task flow.

When using page navigation between two view activities and custom bounded task flows with a default method call activity, switching between basic and advanced modes might reinitialize the related view objects and entity objects. If this happens, any data entered in basic mode is lost when changing to advanced mode.

The task flow template enables switching between basic and advanced modes in the scheduled request submission Oracle ADF UI without losing data.

Related Links

The following document provides additional information related to subjects discussed in this section:

For more information about creating task flows, see the part "Creating Oracle ADF Task Flows" in Developing Fusion Web Applications with Oracle Application Development Framework.” Alternatively, add the lines of code shown in Example 65-49 to the task flow XML file.

65.21.1 About Using a Task Flow Template for Submitting Scheduled Requests through an Oracle ADF UI

A bundled task flow template is provided, containing the components required to enable switching between basic and advanced modes in the Oracle ADF UI. The task flow template adds a router activity and an input parameter to the custom bounded task flow. Configure the router activity as the default activity.

You need only extend the task flow template as needed and implement the activity IDs defined in the task flow template.

Example 65-48 shows a sample implementation of the task flow template.

The task flow template defines the following:

- A default-activity,
- An input parameter of Boolean type,
- A router activity,
- A control-flow-rule containing two cases.

Example 65-48  Task Flow Template

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <task-flow-template id="srs-custom-task-flow-template">
    <default-activity id="defActivity">defaultRouter</default-activity>
    <input-parameter-definition id="param1">
      <!-- Input parameter details here -->
    </input-parameter-definition>
    <router activity="defaultRouter">
      <!-- Router activity details here -->
    </router>
    <control-flow-rule rule="true">
      <case condition="param1=true">
        <!-- Case 1 details here -->
      </case>
      <case condition="param1=false">
        <!-- Case 2 details here -->
      </case>
    </control-flow-rule>
  </task-flow-template>
</adfc-config>
```
65.21.2 How to Extend the Task Flow Template for Submitting Scheduled Requests through an Oracle ADF UI

If you need to create your own custom bounded task flow UI for the parameters section of the scheduled request submission UI, you will need to extend this template. To extend the taskflow template, do the following:

1. When creating a new task flow, extend the task flow by selecting **Use a template**.

   **Note:**
   Ensure your bounded task flow does not define any default activity.

2. Implement the activity IDs defined in the template, which are invoked by the router activity in the template.
   - **initActivity**: The ID of the method call activity.
   - **defaultView**: The ID of the default view activity.

   To do this, to the task flow drag and drop the `createInsert` method from the view object used in the default view. This creates a pagedef file and adds the binding details in `DateBinding.cpx`.

3. Define a control flow rule to navigate from the `initActivity` object to the `defaultView` object. This navigation depends on the outcome of the `initActivity` object, as well as individual use cases.
Example 65-50 shows a sample implementation of a control flow rule.

**Example 65-49  Extending a Task Flow**

```xml
<template-reference>
  <document id="doc1">/WEB-INF/srs-custom-task-flow-template.xml</document>
  <id id="temid">srs-custom-task-flow-template</id>
</template-reference>

**Example 65-50  Implementing a Control Flow Rule**

```xml
<control-flow-rule>
  <from-activity-id>initActivity</from-activity-id>
  <control-flow-case>
    <from-outcome>outcome_of_init_activity</from-outcome>
    <to-activity-id>defaultView</to-activity-id>
  </control-flow-case>
</control-flow-rule>
```

65.21.3 What Happens When you Use a Task Flow Template for Submitting Scheduled Requests through an Oracle ADF UI

Based on the value of the input parameter, the router invokes the method call activity or skips it, and invokes the view activity directly. The Oracle ADF UI must pass the correct parameter values to the task flow while switching modes.

65.21.4 What Happens at Runtime: How a Task Flow Template Is Used to Submit Scheduled Requests through an Oracle ADF UI

When loading the initial page in basic mode, the method call activity is invoked. While loading the page in the advanced mode, the custom bounded task flow directly invokes the view activity. This ensures that the user entered data persists in the view objects across modes.

If the custom task flow UI does not render correctly, check whether transactional properties have been set in the custom task flow, such as the `requires-transaction` property, and so on.

Remove transactional properties from the task flow definition and set the data control scope to shared.

As the parent scheduled request submission UI task flow already has a transaction, Oracle ADF will commit all called task flow transactions if the data controls are shared.

---

**Note:**

When using the UI to schedule a job to run for a year, for example, a maximum of 300 occurrences display when clicking **Customize Times**.

---

65.22 About Securing Oracle ADF UIs

When creating Oracle ADF UIs for scheduled jobs, you can secure the individual task flows involved using a security policy.

The task flows you can secure are the following:
65.23 About Integrating Scheduled Job Logging with Oracle Fusion Applications

Oracle Enterprise Scheduler is fully integrated with Oracle Fusion Applications logging. The logger captures Oracle Enterprise Scheduler-specific attributes when invoking logging from within the context of a running job request. You can set the values to these Oracle Enterprise Scheduler attributes within the context of defining a job.

Jobs can generate a log file on the file system that can be viewed with the Monitoring UI.

In a typically configured Oracle Enterprise Scheduler hosting application, log and output files are stored in an Oracle WebCenter Content repository rather than on the file system. These files are available to end users through a page you provide for monitoring scheduled job requests. For more information about request monitoring, see About Monitoring Scheduled Job Requests Using an UI.

65.24 About Logging Scheduled Jobs and Writing to Output Files

Log messages written using the request log file APIs are written to the request log file and Oracle Fusion Applications logging at a severity level of FINE (only if logging is enabled at a level of FINE or lower).

For more information about managing log files, see the chapter "Managing Log Files and Diagnostic Data" in Administering Oracle Fusion Middleware.
65.24.1 About Using the Request Log

Note:

Do not use the request log for debugging and internal error reporting. For Oracle Enterprise Scheduler jobs, the request log is equivalent to the end-user UI for online applications. When writing Oracle Enterprise Scheduler job code, you should ideally log only translatable end user-oriented messages to the request log. You should not use the request log for debug messages or internal error messages that are oriented to system administrators and/or Oracle Support. The audience for debug messages and detailed internal error messages is typically system administrators and Oracle Support, not end users.

Therefore, debug and detailed internal error messages should be logged to the log called FND_LOG only.

For Oracle Enterprise Scheduler jobs, the request log is equivalent to the end user interface for web applications. When developing an Oracle Enterprise Scheduler job, log to the request log only translatable end-user oriented messages.

For example, if an end user enters a bad parameter to the Oracle Enterprise Scheduler job, a translated error message logged to the request log is displayed to the end user. The end user can then take the relevant corrective action.

Example 65-51 shows how to set log messages using the request log.

If the Oracle Enterprise Scheduler job fails due to an internal software error, log the detailed failure message to the log called FND_LOG for the system administrator or support. You can also log a high-level generic message to the request log so as to inform end users of the error. An example of a generic error message intended for end users: "Your request could not be completed due to an internal error."

Example 65-51 Setting Log Messages Using the Request Log

```
-- Seeded message to be displayed to the end user.
FND_MESSAGE.SET_NAME('FND', 'INVALID_PARAMETER');
-- Runtime parameter information
FND_MESSAGE.SET_TOKEN('PARAM_NAME', pName);
FND_MESSAGE.SET_TOKEN('PARAM_VALUE', pValue);
-- The following is useful for auto-logging errors.
FND_MESSAGE.SET_MODULE('fnd.plsql.mypackage.myfunctionA');
fnd_file.put_line( FND_FILE.LOG, FND_MESSAGE.GET );
```

65.24.2 About Using the Output File

Note:

Do not use the output file for debugging and internal error reporting.

The output file is a formally formatted file generated by an Oracle Enterprise Scheduler job. An output file can be sent to a printer or viewed in a UI window. Example 65-52 shows an invoice sent to an output file.
65.24.3 About Debugging and Error Logging

Debug and error logging should be done using the Oracle Diagnostic Logging APIs only. The Oracle Enterprise Scheduler request log should not be used for system administrator or Oracle support-oriented debug and error logging purposes. The request log is for the end users and it should only contain messages that are clear and concise. When an error occurs in an Oracle Enterprise Scheduler job, use an appropriate high-level (and, ideally, translated) message to report the error to the end user through the request log. The details of the error and any debug messages should be logged with Oracle Diagnostic Logging APIs.

Common PL/SQL, Java, or C code that could be invoked by both Oracle Enterprise Scheduler jobs and interactive application code should only use Oracle Diagnostic Logging APIs. If needed, the wrapper Oracle Enterprise Scheduler job should perform appropriate batching and logging to the request log for progress reporting purposes.

Using Logging in a Java Application

In Java jobs, use the log called AppsLog for debugging and error logging. You can retrieve an AppsLog instance from the CpContext object, by calling the method getLog().

Example 65-53 shows the use of logging in a Java application.

---

Note:

Example 65-53 uses an active WebAppsContext object. Do not attempt to log messages using an inactive or freed WebAppsContext object, as this can cause connection leaks.

---

Using Logging in a PL/SQL Application

PL/SQL APIs are part of the FND_LOG package. These APIs require invoking relevant application user session initialization APIs—such as the method FND_GLOBAL.INITIALIZE()—to set up user session properties in the database session.

These application user session properties, including UserId, RespId, AppId, SessionId, are needed for the log APIs. Typically, Applications Core invokes these session initialization APIs.

Log plain text messages with the method FND_LOG.STRING(). Log translatable message dictionary messages with the method FND_LOG.MESSAGE().

FND_LOG.MESSAGE() logs messages in encoded, but not translated, format, and allows the Log Viewer UI to handle translating messages based on the language preferences of the system administrator viewing the messages.

For details regarding the FND_LOG API, run the script $fnd/patch/115/sql/AFUTLOGB.pls at the prompt. Example 65-54 shows the PL/SQL logging syntax.

Example 65-55 shows how to log a message in PL/SQL after the AOL session has been initialized.

The global variable FND_LOG.G_CURRENT_RUNTIME_LEVEL allows callers to avoid a function call for messages at a lower level than the current configured level. If logging
is disabled, the current runtime level is set to a large number such as 9999 so that it is sufficient to simply log messages with levels greater than or equal to this number. This global variable is automatically populated by the FND_LOG_REPOSITORY package during session and context initialization.

**Example 65-56** shows sample code that illustrates the use of the global variable FND_LOG.G_CURRENT_RUNTIME_LEVEL.

---

**Note:**
For PL/SQL in a forms client, use the same APIs. Use the method FND_LOG.TEST() to check whether logging is enabled.

---

**Example 65-57** shows logging message dictionary messages.

**Using Logging in C**

**Example 65-58** illustrates the use of logging in a C application.

**Example 65-53  Logging in Java Using AppsLog**

define boolean authenticate(AppsContext ctx, String user, String passwd) throws SQLException, NoSuchUserException {
    AppsLog alog = (AppsLog) ctx.getLog();
    if(alog.isEnabled(Log.PROCEDURE))     /* To avoid String Concat if not enabled */
        alog.write("fnd.security.LoginManager.authenticate.begin",
                    "User=" + user, Log.PROCEDURE);
    /* Never log plain-text security sensitive parameters like passwd! */
    try {
        validUser = checkinDB(user, passwd);
    } catch(NoSuchUserException nsue) {
        if(alog.isEnabled(Log.EXCEPTION))
            alog.write("fnd.security.LoginManager.authenticate",nsue, Log.EXCEPTION);
    throw nsue; // Allow the caller to Handle it appropriately
    } catch(SQLException sqle) {
        if(alog.isEnabled(Log.UNEXPECTED)) {
            alog.write("fnd.security/LoginManager.authenticate", sqle, Log.UNEXPECTED);
            Message Msg = new Message("FND", "LOGIN_ERROR"); /* System Alert */
            Msg.setToken("ERRNO", sqle.getErrorCode(), false);
            Msg.setToken("REASON", sqle.getMessage(), false);
            /* Message Dictionary messages should be logged using write(..Message..),
             * and never using write(..String..) */
            alog.write("fnd.security/LoginManager.authenticate", Msg, Log.UNEXPECTED);
        }
    throw sqle; // Allow the caller to handle it appropriately
    } // End of catch(SQLException sqle)
    if(alog.isEnabled(Log.PROCEDURE))     /* To avoid String Concat if not enabled */
        alog.write("fnd.security/LoginManager.authenticate.end",
                    "validUser=" + validUser, Log.PROCEDURE);
    return success;
}

**Example 65-54  PL/SQL Logging Syntax**

```
PACKAGE FND_LOG IS
    LEVEL_UNEXPECTED CONSTANT NUMBER := 6;
    LEVEL_ERROR CONSTANT NUMBER := 5;
    LEVEL_EXCEPTION CONSTANT NUMBER := 4;
    LEVEL_EVENT CONSTANT NUMBER := 3;
```
LEVEL_PROCEDURE CONSTANT NUMBER := 2;
LEVEL_STATEMENT CONSTANT NUMBER := 1;

/*
** Writes the message to the log file for the specified
** level and module
** if logging is enabled for this level and module
*/
PROCEDURE STRING(LOG_LEVEL IN NUMBER,
                  MODULE    IN VARCHAR2,
                  MESSAGE   IN VARCHAR2);

/*
** Writes a message to the log file if this level and module
** are enabled.
** The message gets set previously with FND_MESSAGE.SET_NAME,
** SET_TOKEN, etc.
** The message is displayed from the message dictionary stack,
** if POP_MESSAGE is TRUE.
** Pass FALSE for POP_MESSAGE if the message will also be
** displayed to the user later.
** Example usage:
** FND_MESSAGE.SET_NAME(...); -- Set message
** FND_MESSAGE.SET_TOKEN(...); -- Set token in message
** FND_LOG.MESSAGE(..., FALSE); -- Log message
** FND_MESSAGE_RAISE_ERROR; -- Display message
*/
PROCEDURE MESSAGE(LOG_LEVEL   IN NUMBER,
                  MODULE      IN VARCHAR2,
                  POP_MESSAGE IN BOOLEAN DEFAULT NULL);

/*
** Tests whether logging is enabled for this level and module,
** to avoid the performance penalty of building long debug
** message strings unnecessarily.
*/
FUNCTION TEST(LOG_LEVEL IN NUMBER, MODULE IN VARCHAR2)
RETURN BOOLEAN;

Example 65-55  Logging a Message in PL/SQL After the AOL Session Has Been
Initialized

begin
/* Call a routine that logs messages. */
/* For performance purposes, check whether logging is enabled. */
if( FND_LOG.LEVEL_PROCEDURE >= FND_LOG.G_CURRENT_RUNTIME_LEVEL ) then
  FND_LOG.STRING(FND_LOG.LEVEL_PROCEDURE,
                 'fnd.plsql.MYSTUFF.FUNCTIONA.begin', 'Hello, world!');
end if;
/

Example 65-56  Logging a Message in PL/SQL Using
FND_LOG.G_CURRENT_RUNTIME_LEVEL

if( FND_LOG.LEVEL_STATEMENT >= FND_LOG.G_CURRENT_RUNTIME_LEVEL ) then
  dbg_msg := create_lengthy_debug_message(...);
  FND_LOG.STRING(FND_LOG.LEVEL_STATEMENT
                 'fnd.form.ABCDEFGH.PACKAGEA.FUNCTIONB.firstlabel', dbg_msg);
end if;
Example 65-57  Logging Message Dictionary Messages

```sql
if( FND_LOG.LEVEL_UNEXPECTED >=
    FND_LOG.G_CURRENT_RUNTIME_LEVEL) then
    FND_MESSAGE.SET_NAME('FND', 'LOGIN_ERROR'); -- Seeded Message
    -- Runtime Information
    FND_MESSAGE.SET_TOKEN('ERRNO', sqlcode);
    FND_MESSAGE.SET_TOKEN('REASON', sqlerrm);
    FND_LOG.MESSAGE(FND_LOG.LEVEL_UNEXPECTED,
        'fnd.plsql>Login.validate', TRUE);
end if;
```

Example 65-58  Logging in C

```c
#define  AFLOG_UNEXPECTED  6
#define  AFLOG_ERROR       5
#define  AFLOG_EXCEPTION   4
#define  AFLOG_EVENT       3
#define  AFLOG_PROCEDURE   2
#define  AFLOG_STATEMENT   1

/*
 ** Writes a message to the log file if this level and module is
 ** enabled
 */
void aflogstr(/*_ sb4 level, text *module, text* message _*/);

/*
 ** Writes a message to the log file if this level and module is
 ** enabled.
 ** If pop_message=TRUE, the message is popped off the message
 ** Dictionary stack where it was set with afdstring() afdtoken(),
 ** etc. The stack is not cleared (so messages below will still be
 ** there in any case).
 */
void aflogmsg(/*_ sb4 level, text *module, boolean pop_message _*/);

/*
 ** Tests whether logging is enabled for this level and module, to
 ** avoid the performance penalty of building long debug message
 ** strings
 */
boolean aflogtest(/*_ sb4 level, text *module _*/);

/*
 ** Internal
 ** This routine initializes the logging system from the profiles.
 ** It will also set up the current session and user name in its state */
void afloginit();
```
This chapter explains how Oracle Enterprise Scheduler security features provide access control for Oracle Enterprise Scheduler resources and application identity propagation for job execution.

- Introduction to Security
- Configuring Metadata Security for
- Configuring PL/SQL Job Security for
- Elevating Privileges for Jobs
- Configuring a Single Policy Stripe in
- Configuring Oracle Fusion Data Security for Job Requests

66.1 Introduction to Oracle Enterprise Scheduler Security

Oracle Enterprise Scheduler security includes the following:

- Protected operations on MetadataService; protected by MetadataPermission, which enforces access control on metadata objects. Only privileged users may create, delete, and update jobs and schedule metadata. For more information, see Oracle Enterprise Scheduler Metadata Access Control.

- Access control for job requests, enforced by Oracle Fusion Data Security policies. For more information about using Oracle Fusion Data Security policies, see Configuring Oracle Fusion Data Security for Job Requests.

- Support for the use of an application identity. Using an application identity enables elevated privileges to complete a job that requires higher privileges than those allotted to the user who submitted the job. For more information, see Job Execution Security.

66.1.1 Oracle Enterprise Scheduler Metadata Access Control

At design time, the metadata creator must decide which job functions can access which metadata objects. This is expressed by associating each metadata object with one or more roles and specifying one or more actions for each role. Figure 66-1 shows the metadata security summary.
The summary of design metadata security for Oracle Enterprise Scheduler is as follows:

1. Define Oracle Enterprise Scheduler metadata objects.
2. Create grants to control access to all metadata.
3. Define principals to be used for security.
4. Create grants to assign permissions for the metadata objects.
5. Assign relevant roles to the metadata, and specify actions for each role.
6. Assemble the EAR file for the application, including any security-related files.
7. Deploy the EAR file to Oracle WebLogic Server, which verifies grants in the Oracle Metadata Store and permissions assigned to roles with the LDAP server.

### 66.1.2 Oracle Enterprise Scheduler Job Execution Security

When submitting a job request, the submitting user is the user under whose permissions the job request is submitted. At job request execution time, all code, including pre-processing, post-processing, Java jobs, and substitution, runs as the submitting user, retaining all roles and credentials.

If the job metadata specifies `SYS_RUNAS_APPLICATIONID`, however, the job runs under the elevated privileges of an application ID. For more information, see [Elevating Privileges for Jobs](#).

### 66.2 Configuring Metadata Security for Oracle Enterprise Scheduler

When a user accesses Oracle Enterprise Scheduler services using the `RuntimeService` or `MetadataService`, the identity of the user is acquired and
Oracle Enterprise Scheduler checks whether the user has the required permissions to access resources such as metadata objects. For example, if a user named teller1 must call `getJobDefinition` to access a metadata object named `calculateFees`, Oracle Enterprise Scheduler ensures that teller1 has READ permission for the metadata object `calculateFees` before returning the object.

At design time, you must determine the job functions for which you want to enable access to particular metadata objects by associating each metadata object with one or more roles and specifying one or more actions for each role.

There are two options for metadata role assignments:

- Using Oracle JDeveloper Tools Oracle ADF Security Wizard
- Using Oracle JDeveloper Oracle Enterprise Scheduler add-in metadata pages

Oracle JDeveloper ADF Security wizard creates the roles you use; the roles must be created before you can register roles with a metadata object.

### 66.2.1 How to Enable Application Security with Oracle ADF Security Wizard

These steps describe a minimal, validated security setup for an application using Oracle Enterprise Scheduler.

Follow these steps to create a working `jps-config.xml` and a partially-populated `jazn-data.xml`. Use these steps to configure servlets to work with JPS.

1. In Oracle JDeveloper, with an application open, from the Application menu select Secure.
2. From the dropdown list, select Configure ADF Security. The Configure ADF Security wizard displays.
3. In the Enable ADF Security page, select either ADF Authentication and Authorization or ADF Authentication and click Next.
4. In the Select authentication type page, select either HTTP Basic Authentication or Form-Based Authentication and click Next.
5. In the Enable automatic policy grants page, select the appropriate options from the Enable Automatic Grant area, and click Next.
6. In the Specify authenticated welcome page, select options as needed and click Next.
7. In the Summary page verify the options and click Finish.
8. In the Security Infrastructure Created dialog, click OK.

Next, to enable security and ensure that the `jazn-data.xml` is included in the application deployment, perform the following steps after assembling the EAR file for the application.

**Ensure the security-related files are included with the EAR file:**

1. In Oracle JDeveloper, select Application > Application Properties.
2. In the Application Properties page, in the Navigator select Deployment.
3. In the Deployment Profiles area, select the EAR file Deployment descriptor.
4. Click Edit.
   The Edit EAR Deployment Profile Properties page displays.

5. In the Edit EAR Deployment Profile Properties page, expand File Groups > Application Descriptors > Filters.

6. In the Filters area, select the Files tab.

7. Ensure that the files jazn-data.xml, jps-config.xml, and weblogic-application.xml are selected under the META-INF folder.

8. Click OK to save the descriptor.

### 66.2.2 How to Define Principals for Security

You need to define roles before the roles are used in Oracle Enterprise Scheduler security. You can define two types of roles:

- Enterprise roles: These are defined directly in Oracle WebLogic Server either using the Oracle WebLogic Server console, using the WLST scripts, or using the Oracle ADF Security Wizard in Oracle JDeveloper.
- Application roles: These can be defined in the jazn-data.xml file or using the Oracle ADF Security Wizard.

**To define principals security:**

1. In Oracle JDeveloper, open the application and expand Application Resources in the Application Navigator.

2. In the Application Resources area, expand Descriptors and META-INF.

3. In META-INF, double-click to open jazn-data.xml.

4. In the page showing jazn-data.xml, select the Overview tab. If the Overview tab is not shown, try closing jazn-data.xml and then opening it again.

5. Click Application Roles...(Manage Users and Roles).

7. In the navigator, select Roles and click Add....
   The Add Role window displays.

8. In the Add Role window, enter a name in the Name field.

9. Click OK.

10. On the Edit JPS Identity and Policy Store page, in the navigator select Application Policy Store. If there is a sub-element with the same name as the application, go to the next step, Otherwise, do the following:
   a. Select Application Policy Store.
   b. Click New.
      The Create Application Policy window displays.
c. In the Create Application Dialog the **Display Name** field should contain the application name.

d. Click **OK** to accept the default Display Name.

11. On the Edit JPS Identity and Policy Store page, in the navigator expand **Application Policy Store** and expand the **application name**.

12. In the navigator, select **Application Roles**.

   The Application Roles page displays.

13. In the Application Roles page, click **Add**... to add roles. For correct functionality, at least one enterprise role must be mapped to the application role by adding enterprise roles in the **Member Roles** tab.

14. Click **OK**.

### 66.2.3 How to Create Grants with Oracle Enterprise Scheduler Metadata Pages

Access to all metadata is controlled by grants. To ensure access by the right identities, you need to give the correct grants.

First, create any required Oracle Enterprise Scheduler metadata in an application using **File > New > Business Tier > Enterprise Scheduler Metadata**. For more information about defining metadata, see About Creating a Job Definition.

Using Oracle JDeveloper, you can add security grants to Oracle Enterprise Scheduler metadata objects.

**To secure Oracle Enterprise Scheduler metadata objects:**

1. Open the Editor page for any Oracle Enterprise Scheduler metadata object.

2. In the Access Control area, click **Add** to add a new access control item.

3. In the Add Access Control dialog, select a Role from the dropdown list. This selects a role to grant access privileges.

4. Select one or more actions from the list, **Read**, **Execute**, **Update**, or **Delete**.

5. Click **OK**. This displays the updated role, as shown in **Figure 66-2**.

6. Repeat for as many roles as needed.
There may be occasions when you want to create grants explicitly, for example when using wild cards. These steps show how to set up grants using the Oracle ADF Security wizard.

Note that these steps assume you have already created application roles.

To specify grants with the Oracle ADF Security wizard:

1. In the Application Navigator, expand the Application Resources panel.
2. Expand Descriptors and META-INF, as shown in Figure 66-3.
3. Double-click `jazn-data.xml` to open the file. In the editor panel for `jazn-data.xml`, select the Overview tab, and click Application Roles... (Manage Users and Roles). This displays the JPS Identity & Policy Store dialog. Note, if the Overview tab is not shown, try closing `jazn-data.xml` and then opening it again.

4. In the JPS Identity & Policy Store dialog, in the navigator expand Application Policy Store.

5. Expand `application-name`, and select Application Roles.

6. Click New.

7. Enter the display name you wish for this grant, and click OK.

8. Select the Principals tab, and click Add.

9. Enter the name of the application role which will receive the grant; this should be one of the role names created. Leave the Class field as is.

10. Click OK.

11. With the new role selected in the Principals tab, make sure the Type is role.

12. Select the Permissions tab, and click Add....

13. For the Name field, enter a full permission string or a partial string with wildcards; see Table 66-1 for examples. In the Class field, enter `oracle.as.scheduler.security.MetadataPermission`. Click OK.

14. With the new permission selected in the Permissions tab, enter the desired actions in the Actions Field.

15. Click OK to save the grant.
**Note:**
If necessary, use the following workaround:

1. Right-click the jazn-data.xml file and select **Open**.
2. Click the Source tab.
3. Under `<jazn-policy><grant><grantee>`, remove the elements `<display-name>` and `<type>`.

### Table 66-1 Sample Permission Grants for Security Using Oracle ADF

<table>
<thead>
<tr>
<th>Name</th>
<th>Actions</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>packag-&lt;br/&gt;part.JobDefinition.MyJavaSucJobDef</td>
<td>EXECUTE</td>
<td>Grants the ability to submit requests for a single metadata item.</td>
</tr>
<tr>
<td>mypackage.subpackage.*</td>
<td>CREATE, EXECUTE</td>
<td>Grants the ability to create and execute any new metadata items in /mypackage/subpackage.</td>
</tr>
<tr>
<td>JobDefinition.SYS_AdHo&lt;br/&gt;cRequest</td>
<td>CREATE, EXECUTE</td>
<td>Grants ad hoc submission permission</td>
</tr>
<tr>
<td>mypackage.*</td>
<td>CREATE, EXECUTE, DELETE</td>
<td>Grants wide-open permissions</td>
</tr>
</tbody>
</table>

### 66.2.5 MetadataPermission APIs

Grants for metadata are part of the class `oracle.as.scheduler.security.MetadataPermission`. The name, or target of the permission is based on the package, metadata object type and name of the metadata object being protected. This identifier can be retrieved from `MetadataObjectId#toPermissionString()`.

**Table 66-2** lists the actions for the grants. The notation `<Type>` is a placeholder for all of the metadata object types. For example, `get<Type>()` refers to the methods `getJobDefinition()`, `getJobType()`, `getJobSet()`.

<table>
<thead>
<tr>
<th>Action</th>
<th>Implies</th>
<th>Metadata Functions</th>
</tr>
</thead>
<tbody>
<tr>
<td>READ</td>
<td>None</td>
<td><code>get&lt;Type&gt;()</code>, <code>query&lt;Type&gt;()</code></td>
</tr>
<tr>
<td>EXECUTE</td>
<td>READ</td>
<td><code>submitRequest()</code></td>
</tr>
<tr>
<td>CREATE</td>
<td>READ</td>
<td><code>add&lt;Type&gt;()</code></td>
</tr>
<tr>
<td>UPDATE</td>
<td>READ</td>
<td><code>update&lt;Type&gt;()</code></td>
</tr>
<tr>
<td>DELETE</td>
<td>READ</td>
<td><code>delete&lt;Type&gt;()</code></td>
</tr>
</tbody>
</table>

If you are submitting ad-hoc requests, you can have full wildcard ("*") permission with both `EXECUTE` and `CREATE` actions. When submitting ad-hoc requests, that is, using
submitRequest() without certain MetadataObjectIds, you can grant permissions with the full wildcard ("*") name using the EXECUTE and CREATE actions.

66.2.6 What Happens When You Configure Metadata Security

Each time a user application calls a MetadataService or RuntimeService method, Oracle Enterprise Scheduler checks the current subject for privileges on the metadata accessed by the methods. For example, submitting a request requires EXECUTE permissions on the job definition or job set metadata object associated with the submission. Methods that change metadata, for example calling updateJobDefinition(), require UPDATE permissions.

For all MetadataService methods except queries, an exception is thrown when the user tries to access a metadata object for which the user does not have permission.

The MetadataService query methods have different behavior. When a user performs a query Oracle Enterprise Scheduler only returns metadata objects that have READ permission. Thus a user who has no permissions on metadata objects receives an empty list for all queries, but this user would not see an exception thrown due to lack of permissions.

The value of SystemProperty.USER_NAME is overwritten at submission time; the user cannot spoof an identity at submission time using SystemProperty.USER_NAME.

66.2.7 Related Links

The following document provides additional information related to subjects discussed in this section:

For more information, see "Assembling Oracle Enterprise Scheduler Oracle Fusion Applications" in the Extensibility Guide for Developers.

66.3 Configure Web Service Security for Oracle Enterprise Scheduler

For information about securing the Oracle Enterprise Scheduler web service, see the chapter "Securing the Oracle Enterprise Scheduler Web Service" in Developing Applications for Oracle Enterprise Scheduler.

66.4 Configure PL/SQL Job Security for Oracle Enterprise Scheduler

For standalone cases, implement the application user session using Java or the PL/SQL API as described in Implementing Application User Sessions.

66.5 Elevating Privileges for Oracle Enterprise Scheduler Jobs

When a user accesses Oracle Enterprise Scheduler services using the RuntimeService or MetadataService interfaces, the identity of the user calling the methods is acquired. This identity is used to check whether the user has the required permissions to access certain resources such as metadata objects. For example, if user teller1 calls the method getJobDefinition for metadata object caculateFees, Oracle Enterprise Scheduler ensures that teller1 has read permissions for metadata object caculateFees before returning the object.

The caller identity is also used to run jobs requested by the user. For example, if user teller1 calls the method submitRequest() for a Java job, the requested jobs run under teller1 and retain all roles and credentials assigned to that user.
Oracle Enterprise Scheduler supports the use of an application identity. Using an application identity enables elevated privileges for completion of a job that requires higher privileges than those allotted to the submitting user.

For more information about enabling elevating privileges, see About Elevating Access Privileges for a Scheduled Job.

66.6 Configuring a Single Policy Stripe in Oracle Enterprise Scheduler

Oracle Platform Security policy store serves as the repository for authorization policies. Authorization policies load at run time into the Java Virtual Machine, and are used to make decisions regarding authorization. Authorization policies comprise a hierarchy of application roles, the mapping of enterprise roles to application roles and permissions grants to application roles. Application roles can also be hierarchical.

Aside from authorization policies, Oracle Platform Security policy store also stores administrative constructs that help in maintaining these authorization policies, including resource catalogs (with associated resource types), permission sets and role categories. The authorization polices and administrative components are scoped to an application. This is known as an application stripe.

An application stripe is a collection of JAAS policies applicable to the application with which it is associated. Out of the box, an application stripe maps to an Oracle Java EE application. Oracle Platform Security also supports mapping multiple Java EE applications to one application stripe. The application ID string identifies the name of the application or applications.

66.6.1 How to Configure a Single Policy Stripe in Oracle Enterprise Scheduler

Oracle Enterprise Scheduler allows specifying an applicationStripe name and mapping it to a JPS policy context ID. You can assign multiple Oracle Enterprise Scheduler hosting applications to a single policy context.

To configure an Oracle Enterprise Scheduler hosting application to a specific applicationStripe:

1. Open the ejb-jar.xml file.
2. Under the message-driven element, add an activation-config-properties element with the value applicationStripe.
3. Under the jpsinterceptor-class element, configure the JpsInterceptor.
   Make sure to match the value of applicationStripe under the <message-driven> element with the application.name value under the <interceptor> element.
   Example 66-1 shows an applicationStripe configuration for the policy context ESS_FUNCTIONAL_TEST_APP_STRIPE.
4. If your application has a web module, configure the web module JpsFilter to use the same applicationStripe in the file web.xml. Example 66-2 shows a code sample.

Example 66-1 Configuring the applicationStripe and the JpsInterceptor

```
<ejb-jar>
  ....
```
<enterprise-beans>
<message-driven>
  <ejb-name>ESSAppEndpoint</ejb-name>
  <ejb-class>oracle.as.scheduler.ejb.EssAppEndpointBean</ejb-class>
  <activation-config>
    ....
    <activation-config-property>
      <activation-config-property-name>applicationStripe</activation-config-property-name>
      <activation-config-property-value>ESS_FUNCTIONAL_TESTS_APP_STRIPE</activation-config-property-value>
    </activation-config-property>
  </activation-config>
</message-driven>
....
</enterprise-beans>

<interceptors>
  <interceptor>
    <interceptor-class>oracle.security.jps.ee.ejb.JpsInterceptor</interceptor-class>
    <env-entry>
      <env-entry-name>application.name</env-entry-name>
      <env-entry-type>java.lang.String</env-entry-type>
      <env-entry-value>ESS_FUNCTIONAL_TESTS_APP_STRIPE</env-entry-value>
    </env-entry>
  </interceptor>
</interceptors>
</ejb-jar>

Example 66-2 Configuring the Web Module in web.xml

<web-app>
  <filter>
    <filter-name>JpsFilter</filter-name>
    ...
    <init-param>
      <param-name>application.name</param-name>
      <param-value>ESS_FUNCTIONAL_TESTS_APP_STRIPE</param-value>
    </init-param>
  </filter>
</web-app>

66.6.2 What Happens When You Configure a Single Policy Stripe

At design time, an application stripe manifests as:

- An `<application>` element under the `<policystore>` element in the jazndata.xml file.
- A node under the node `cn=<Weblogic.domain.name>,cn=JPSContext,cn=<root.node>, such as cn=ATGDemo, cn=base_domain, cn=JPSContext, cn=MY_Node.`
66.6.3 What Happens at Runtime

At run time, an application stripe manifests as an instance of the class `oracle.security.jps.service.policystore.ApplicationPolicy`.

66.7 Configure Oracle Fusion Data Security for Job Requests

Oracle Fusion Data Security for Oracle Fusion application enforces security authorizations for access and modification of specific data records. Oracle Fusion Data Security integrates with Oracle Platform Security Services (OPSS) by granting actions to OPSS principals. The grant defines who (the principals) can do what (the actions) on a given resource. A grant in Oracle Fusion Data Security can use any enterprise user or enterprise group as principals. For more information about implementing Oracle Fusion Data Security, see Implementing Oracle Fusion Data Security.

In the context of Oracle Enterprise Scheduler, a job request access control data security policy comprises a grant, a grantee and a set of `ESS_REQUEST` privileges for a set of job requests as follows:

- A grantee, represented by grantee ID such as a user or application role, the ID should match the user GUID or application role GUID retrieved from Oracle Fusion Middleware.

- A set of `ESS_REQUEST` privileges represented by a menu ID mapped to a set of form functions.

- A set of data represented by an `INSTANCE_SET` ID. An `INSTANCE_SET` is typically represented by a predicate which can be appended to a query to the job request data exposed to Oracle Fusion Applications (see Oracle Fusion Data Security Artifacts).

The job request access control data security policy can be managed using Oracle Authorization Policy Manager as are other Oracle Fusion Data Security policies. If Oracle Authorization Policy Manager is not available, you can use SQL scripts to manipulate the Oracle Fusion Data Security artifacts.

66.7.1 Oracle Fusion Data Security Artifacts

To use Oracle Enterprise Scheduler job request access control feature in the context of Oracle Fusion Applications, the Oracle Fusion Applications schema and Oracle Enterprise Scheduler schema must be located in a single database.

Oracle Enterprise Scheduler implements job request data security on top of the `request_history` and `request_property` tables. It exposes Oracle Enterprise Scheduler job request related data to the Oracle Fusion Applications schema through the following views: `request_history_view` and `request_property_view`. Two synonyms are created in the Oracle Fusion Applications schema which are linked to the Oracle Enterprise Scheduler schema.

The `request_history_view` contains all columns that correspond to `RuntimeService.QueryField`, which is used when constructing the filter for `queryRequest()` operations, as well as two other columns: `submitter` and `submitterguid`. Be sure to define your `INSTANCE_SET` based on these columns only.
Table 66-3 lists the Oracle Fusion Applications schema tables and their Oracle Enterprise Scheduler synonyms, as well as the columns used to define data security policies.

### Table 66-3  Mapping Oracle Fusion Applications Schema Synonyms to Oracle Enterprise Scheduler Schema Views and Relevant Columns

<table>
<thead>
<tr>
<th>Oracle Fusion Applications Schema Synonym</th>
<th>Link to Oracle Enterprise Scheduler Schema View</th>

<td>The runAs user is permitted to view the output of the job requests they executed.</td>
</tr>
</tbody>
</table>

For more information about the runAs user, or elevating access privileges, see About Elevating Access Privileges for a Scheduled Job.
66.7.2 How to Apply Oracle Fusion Data Security Policies

The Oracle Fusion Data Security components described in Oracle Fusion Data Security Artifacts can be applied as follows.

To apply Oracle Fusion Data Security policies:

1. Examine the policies described in Table 66-8 and determine whether you can use any of them in your application.
   - If you can use one of these policies, skip to the last step.
   - If the policies do not apply, continue to the next step.

2. Determine whether any of the FND_MENUS listed in Table 66-5 suit the out-of-the-box Oracle Fusion Data security policy you selected for your application. If you cannot apply any of the FND_MENUS listed in Table 66-5, create your own FND_MENUS and FND_MENUS_ENTRIES as described in Implementing Oracle Fusion Data Security.

3. Determine whether you can use the INSTANCE_SET conditions in Table 66-7 and the Oracle Fusion Data Security policies in your application. If you cannot use the conditions, create your own FND_INSTANCE_SET. For more information about creating an FND_INSTANCE_SET, see Implementing Oracle Fusion Data Security.

4. Create an Oracle Fusion Data Security policy, as described in How to Create Functional and Data Security Policies for Components.

Note:
If developing an Oracle Fusion application, do not grant an Oracle Enterprise Scheduler access policy to the grantee of an authenticated-role or anonymous-role, as doing so may affect the behavior of Oracle Enterprise Scheduler or other products.

5. Test your application.

66.7.3 How to Create Functional and Data Security Policies for Oracle Enterprise Scheduler Components

You can use Oracle Authorization Policy Manager to create functional and data security policies for Oracle Enterprise Scheduler.

To create functional and data security policies for Oracle Enterprise Scheduler:

1. Create a resource.
   a. From the list of policies, expand the fcsm policy stripe and select fcsm > Resource Catalog > Resources.
   b. From the Actions menu, click New.
   c. Define a resource with the resource type ESSMetadataResourceType, as well as the name and display name of the Oracle Enterprise Scheduler component using the following syntax:
d. Save the resource.

2. Define a resource policy.
   a. Select the resource you just created and click Create Policy.
   b. Add principals (grantees) by clicking the Add button.
   c. In the Add Principal window, search for the relevant application role or roles. Select the roles and click Add.
   d. In the Actions field, select the relevant actions and click Apply.

3. Create an authorization condition.
   a. In the Authorization Management tab, select Global and search for the database resource you want to use. Table 66-8 lists the database resources related to Oracle Enterprise Scheduler.
   b. Select the resource and click Edit.
   c. Click the Conditions tab and select Actions > New.
   d. Enter a name, display name and SQL predicate for the condition.

4. Define a data policy.
   a. From the Actions menu, select New Policy.
   b. In the New Policy window, use the Role and Database Resource fields to add the relevant roles and resources.
   c. Select the role you defined. In Database Resource Details region, select the condition name you just created and choose the actions you require.

66.7.4 Related Links

The following document provides additional information related to subjects discussed in this section:

For more information about creating policies in Oracle Authorization Policy Manager, see the section "Managing Authorization Policies" in the "Securing Oracle Fusion Applications" chapter of the Administrator’s Guide.
This chapter documents how developers can implement Oracle Social Network in an application by creating the Model project in JDeveloper and by displaying it in the Global Area of the UIShell.

The chapter includes these sections:

- Prerequisites for Oracle Social Network Integration
- Implementing the Oracle Social Network Model Project
- Implementing the Oracle Social Network Setup UI
- Adding Oracle Social Network to Your Application UI
- What Happens When Functional Administrators Manage Oracle Social Network Objects
- What Happens When End Users Interact with Oracle Social Network Object Instances
- Testing End-To-End Flow

67.1 Prerequisites for Oracle Social Network Integration

For Oracle Social Network integration to work, there first must be a connection defined between Oracle Fusion applications and Oracle Social Network. This connection normally is set up by the provisioner (see Table 67-1) and must be able to be configured because Oracle Fusion applications and Oracle Social Network will not reside on the same server. These configuration items must be in place:

- Oracle Social Network URL must be defined in Topology Manager with a Module Short Name of 'OSN'.
  
  On a production instance, there will be an internal and external Topology Manager URL for Oracle Social Network. The internal URL will be used for all data sent to Oracle Social Network. The external URL will be used when navigating from within Fusion Applications.

- The Oracle Social Network credential must exist in the WebLogic Server credential store.

- In the weblogic-application.xml file that is present at the workspace level, add a reference to the Oracle Social Network model shared library:

  <library-ref>
  <library-name>oracle.social.client</library-name>
  </library-ref>
In the `weblogic.xml` file for the UI project (that is mapped to the WAR deployment), add a reference to the Oracle Social Network view shared library. This entry is needed in any UI project that needs to test or run the Oracle Social Network integration using the UIShell as described in Adding Oracle Social Network to Your Application UI.

```xml
<library-ref>
<library-name>oracle.social.client.view</library-name>
</library-ref>
```

### 67.2 Implementing the Oracle Social Network Model Project

Each of the roles listed in Table 67-1 involves a different part of the entire Oracle Fusion Applications-Oracle Social Network integration work flow.

**Table 67-1  Oracle Social Network Integration Roles**

<table>
<thead>
<tr>
<th>Role</th>
<th>Description</th>
<th>Primary responsibilities for integration</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fusion Applications</td>
<td>A developer in a product team that has view object data that is to be sent to Oracle Social Network.</td>
<td>• Defining which view objects are to be available for Oracle Social Network integration.</td>
</tr>
<tr>
<td>Developer</td>
<td></td>
<td>• Configuring the view object and its Attributes for Oracle Social Network integration.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• Updating the product User Interface to include the Oracle Social Network <strong>Share</strong> button to allow for Manual Oracle Social Network integration.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• Configuring their Oracle Fusion Functional Setup Manager to have a task flow entry for &quot;Manage Social Network Objects&quot;.</td>
</tr>
<tr>
<td>Provisioner</td>
<td>The person who provides and configures the Oracle WebLogic Server environment in which the Oracle Fusion application is to be run.</td>
<td>• Creating the Oracle Social Network credential in the credential store (if not pre-provisioned).</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• Configuring Topology Manager to have a deployed application entry for &quot;Oracle Social Network.&quot;</td>
</tr>
<tr>
<td>Functional Administrator</td>
<td>The person on the site who will configure which view objects will be used at product runtime from the list of available view objects for Oracle Social Network integration.</td>
<td>• Choosing the type of integration each of the available view objects will have.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• Selecting which attributes will be sent to Oracle Social Network for the list of view objects that have integration enabled.</td>
</tr>
<tr>
<td>End User</td>
<td>The user who generates transactions using Oracle Fusion applications with Oracle Social Network and who is saving the view object row in the product UI.</td>
<td>• Triggering the send of the view object row as a Social Object to Oracle Social Network.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• Launching and using Oracle Social Network to view the Social Object.</td>
</tr>
</tbody>
</table>

At different times during the development process, a person must be able to perform several of these roles. For example, an Oracle Fusion Applications developer who is performing development through to testing will need to wear the hats for most or all of these roles to ensure that their integration pieces work correctly to send the data to Oracle Social Network.
67.2.1 How the Oracle Fusion Applications Developer Role Works

For developers, there are several phases of the development process in which they need to perform setup and configuration of the Oracle Social Network integration with their products.

- **Design Time** - Making a Business Object available for Oracle Social Network integration.
  
  The prerequisite is that the JDeveloper environment has at minimum the "Applications Core" extension loaded.

- **Configuring the Business Object for Oracle Social Network Integration**
  
  When implementing the Oracle Fusion Applications-Oracle Social Network integration provided by Oracle Fusion Middleware Extensions for Applications, the product team must already have a view object that meets the following criteria:
  
  - The view object is underpinned by one or more entity objects that are derived from the OAViewObjectImpl and OAEntityObjectImpl respectively.
  - Any rows from the view object must be derived from OAVewRowImpl.
  - The view object must not be "Expert" (SQL) based.
  
  Any view object that matches these criteria can be considered for Oracle Social Network integration availability. When a view object has been made available for Oracle Social Network integration, it can be enabled on the site using the "Manage Social Network Objects" page.

To set up a view object for Oracle Social Network integration, there is a common set of steps to provide basic integration. This basic integration can be customized based upon how the integration is to work for that view object. Customizations that can be applied are:

- Adding translated labels.
- Changing Oracle Social Network field data types, object title, object key, view details URL and registration name.

67.2.1.1 Configure the Business Object for Oracle Social Network Integration

The business object is underpinned by one or more entity objects that are derived from the OAVewObjectImpl and OAEntityObjectImpl respectively.

A wizard helps make view objects available for Oracle Social Network integration. The wizard will guide you through selecting the view objects and the set of attributes within the view object that are available for a site to send through to Oracle Social Network. All view objects that are to be available for Oracle Social Network integration must follow the steps listed here. Then they can have additional configuration made to tailor the integration further. The required steps to have a basic integration with Oracle Social Network are:

1. In JDeveloper’s Navigator pane, find the application module that contains the view object to be made available for Oracle Social Network integration.

2. Right-click the application module and select the Add OSN View Instances menu item. This will start the OSN Enabled View Instances wizard, shown in Figure 67-1.
At the top of the wizard is a dropdown list called Module. Choose the module that best represents the line of business for the current project.

Just beneath the Modules, there is a list of available view objects and a data model list. Find the view objects that are to be made available for Oracle Social Network integration from the list of available view objects and shuttle them into the data model. This signifies that the view object will be available for Oracle Social Network integration.

Click the view object in the data model pane to show the list of attributes for that view object in the Attributes tab.

Select the Enable check box next to any attribute that is to be available within that view object for Oracle Social Network integration. Only attributes that are enabled will be allowed to be sent to Oracle Social Network.

Click OK to finish the wizard.

If the deployment profile for the project is an ADF Library JAR file, then the META-INF folder and the fnd-osn-integration.xml file automatically will be bundled into the JAR file at the correct location. However, if the deployment profile is a regular JAR file, then the META-INF folder will need to be added as Project Output Contributor and ensure that the fnd-osn-integration.xml file is selected for inclusion in the JAR file. There should be no additional steps required for product integrators or special build steps so long as the META-INF/fnd-osn-integration.xml file is included in the root of the JAR file.

When the Model project is deployed and loaded at the client site, the view objects that were moved to the Data Model pane will be available in "Manage Social Network Objects," allowing them to be Oracle Social Network-enabled.
What happens when using the "OSN Enabled View Instances" wizard

After clicking OK to close the wizard, several tasks are performed with new artifacts generated. The first thing that happens is that a new file is created (if it did not already exist) called fnd-osn-integration.xml under the META-INF folder (that also will be created if it did not exist) of the JDeveloper project’s Application Source. There will only be one of these files per JDeveloper project and it will be re-loaded if the developer re-opens the wizard. This XML file contains the module information and the names of the view objects that have been made available for Oracle Social Network integration. A sample fnd-osn-integration.xml file looks like:

```xml
<?xml version="1.0" encoding="utf-8"?>
<fnd-osn-metadata xmlns="http://xmlns.oracle.com/apps/fnd/applcore/osn"
moduleId="84944D4BE32F441AE0401490D3C52A40">
  < AppModule Name="ProjectTaskAM"
    ApplicationModuleName="oracle.apps.fnd.applcore.demo.applicationModule.ProjectTaskAM" >
    <ViewUsage Name="Projects"
      ViewObjectName="oracle.apps.fnd.applcore.crmdemo.model.ProjectsVO"/>
    <ViewUsage Name="Tasks"
      ViewObjectName="oracle.apps.fnd.applcore.crmdemo.model.TasksVO">
      <ViewLinkUsage Name="ProjectsToTasksVL"
        ViewLinkObjectName="oracle.apps.fnd.applcore.crmdemo.model.ProjectsToTasksVL"
        SrcViewUsageName="oracle.apps.fnd.applcore.crmdemo.model.applicationModule.ProjectsTasksAM.Projects"
        DstViewUsageName="oracle.apps.fnd.applcore.crmdemo.model.applicationModule.ProjectsTasksAM.Tasks"
        Reversed="false"/>
      </ViewUsage>
    </ AppModule>
  </fnd-osn-metadata>
```

When deployed in an ADF Library JAR file, this file will be located at META-INF/fnd-osn-integration.xml allowing it be looked up directly on the class path from the "Manage Social Network Objects" page.

The other change that the wizard makes is to modify the view object definition XML file for the attributes that are available for Oracle Social Network integration. It adds or updates a new custom property called fnd:OSN_ENABLED_ATTR within the attribute XML node with a value of true to make that attribute available.

```xml
<ViewAttribute Name="DeptName">
  <Properties>
    <SchemaBasedProperties>
      <fnd:OSN_ENABLED_ATTR Value="true"/>
    </SchemaBasedProperties>
  </Properties>
</ViewAttribute>
```

67.2.1.2 Translating Oracle Social Network Labels

The view object and its attributes are displayed to the functional administrator and end users in the "Manage Social Network Objects" page and also within Oracle Social Network, so these strings must be translated. A functional administrator can use the "Manage Social Network Objects" taskflow to enable Oracle Social Network integration by selecting view objects and attributes. When Oracle Social Network displays a view object Social Object, the data is displayed as name-value pairs. The
Oracle Social Network integration re-uses the standard view object process for defining prompts for the translations that are sent to Oracle Social Network. This is done using the UI Hints properties that are already defined upon the business objects.

These UI Hint properties are used from the view object for translations:

- **Display Name** - used to show when a label is required for the view object.
- **Display Name (Plural)** - used to show when a plural label is required for the view object.
- **Description** - used for showing the description in the "Manage Social Network Objects" page.

These UI Hint properties are used from the view object’s attributes as Oracle Social Network field label translations:

- **Label** - used to show when a label is required for the attribute.
- **Display Name (Plural)** - used to show when a plural label is required for the attribute.

What happens when translated Oracle Social Network labels are provided

The view object definition XML file will be modified with these custom properties set:

- **View Object Property node names:**
  - LABEL - Display Name
  - LABEL_PLURAL - Display Name (Plural)
  - TOOLTIP - Description

- **Attribute Property node names:**
  - LABEL - Label
  - LABEL_PLURAL - Display Name (Plural)

The values provided in the Edit property window will be seeded into the translation bundle and the key will be stored as the ResId attribute of the relevant property node in the view object definition file. These are sample changes to the view object definition file:

```xml
<ViewObject Name="SndDemoDeptVO">
  <Properties>
    <SchemaBasedProperties>
      <LABEL ResId="DEMO_DEPARTMENT"/>
      <LABEL_PLURAL ResId="DEMO_DEPARTMENTS"/>
      <TOOLTIP ResId="DEMONSTRATION_DEPARTMENT_FOR_S"/>
    </SchemaBasedProperties>
  </Properties>
  <ViewAttribute Name="DeptName">
    <Properties>
      <SchemaBasedProperties>
        <LABEL ResId="DEPARTMENT_NAME"/>
        <LABEL_PLURAL ResId="DEPARTMENT_NAMES"/>
      </SchemaBasedProperties>
    </Properties>
  </ViewAttribute>
</ViewObject>
```
67.2.1.3 Configuring Oracle Social Network Field Data Types

Oracle Social Network integration is restricted to sending data using a limited number of data types. The view object attributes can be configured to provide some contextual information about how the attribute value will be shown as a field value in Oracle Social Network. For example, a string representing a URL will be kept in the attribute as a String but can be configured to show in Oracle Social Network to display as a clickable link rather than as a static String.

The supported data types, explanations, and their usage are listed in Table 67-2.

Note: A Gadget Type is a type definition for data sent to Oracle Social Network that allows the Oracle Social Network server to provide additional functionality when rendering the value in the UI. For example, a Percent gadget type can be displayed with a % symbol after it and must be a value between 0.0 and 100.0.

Table 67-2    Supported Data Types

<table>
<thead>
<tr>
<th>Gadget Type</th>
<th>Description</th>
<th>When to Use</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Boolean</td>
<td>Allows the value sent to Oracle Social Network to be treated like a boolean. If the gadget that the conversation/wall is using has been modified in the gadget editor to show the editable representation of the field, then this will be displayed as a check box.</td>
<td>If the attribute being sent to Oracle Social Network is to be viewed as a boolean value.</td>
<td>If the Java Type of the attribute is anything other than java.lang.Boolean, then refer to the Boolean entry in Special Cases - Boolean.</td>
</tr>
</tbody>
</table>
### Table 67-2 (Cont.) Supported Data Types

<table>
<thead>
<tr>
<th>Gadget Type</th>
<th>Description</th>
<th>When to Use</th>
<th>Notes</th>
</tr>
</thead>
</table>
| Currency    | When sending a numeric attribute value representing a value in a currency to Oracle Social Network, this gadget type can send the additional currency code information relating to that attribute. To send the currency code with the numeric value perform the following steps:  
  - Set the Gadget Type on the numeric value attribute to "currency".  
  - Set the Currency Code Attribute property to be the name of another attribute in the view object whose value at runtime will be the Currency Code for the numeric value attribute. For example if the following attributes exist:  
    Attribute #1: "Credit"  
    Gadget Type="CURRENCY"  
    OSN_ENABLED="true"  
    OSN_CURRENCY_CODE_ATTR="CreditCurrencyCode"  
    Value="23"  
    Attribute #2:  
    "CreditCurrencyCode"  
    Gadget Type="STRING"  
    OSN_ENABLED="false"  
    Value="USD"  
    When sent to Oracle Social Network, the credit field will show as Credit: 23 USD | If the numeric value being sent to Oracle Social Network specifies a currency value and the currency code is also required to be sent to Oracle Social Network. | - The attribute for currency code should be a String value.  
- The attribute for currency code does not need to be flagged as OSN_ENABLED="true" as the currency code value will be sent as part of the numeric value payload being sent to Oracle Social Network.  
- If the attribute for currency code is marked as OSN_ENABLED="true" then it will be shown in a separate Oracle Social Network field from the currency code and if it also is flagged as the "Currency Code Attribute" property value on the numeric value attribute then it will be shown twice: in its own field and also as the numeric attribute’s currency code. |
| Date        | Display the attribute value as a formatted date. | If the attribute value is defined as a Date and can be shown as such in Oracle Social Network. | |
| Double      | Display a number as a floating point with a decimal fraction representation of the number. | When the attribute value will have a decimal fraction to be displayed. | |
### Table 67-2  (Cont.) Supported Data Types

<table>
<thead>
<tr>
<th>Gadget Type</th>
<th>Description</th>
<th>When to Use</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>Integer</td>
<td>Display a number as a whole number.</td>
<td>When the attribute value will not have a decimal fraction to be displayed.</td>
<td></td>
</tr>
<tr>
<td>Percent</td>
<td>Display a number as a percentage.</td>
<td>When the attribute value is to be displayed as a percentage.</td>
<td>The values can only be numbers between 0.0 and 100.0.</td>
</tr>
<tr>
<td>Person</td>
<td>Display the attribute as a clickable user who exists in Oracle Social Network. By sending the username or identifiable value for a user (most likely an email address in an LDAP-based Oracle Social Network) as a Person Gadget Type, Oracle Social Network will look up the display name for the user in its user security store (local/LDAP) and display a link using the user's display name. When the link is clicked, it will redirect to the Wall for the user represented by the person attribute.</td>
<td>When the attribute value represents the username/identifiable value for a user in Oracle Social Network. Only email addresses are supported.</td>
<td>• Attribute value must be a String, • Attribute value must be the identifiable value for a user in the security store being used by Oracle Social Network (local/LDAP).</td>
</tr>
<tr>
<td>String</td>
<td>Display a value.</td>
<td>If the Java Type of the object being retrieved from the view object does not conform to any of the other Gadget Types.</td>
<td></td>
</tr>
<tr>
<td>URL</td>
<td>Display a string value as a clickable URL link in Oracle Social Network.</td>
<td>If the attribute value is a fully qualified URL that an Oracle Social Network user will be allowed to click.</td>
<td>• The URL rendered in Oracle Social Network will not have a label appear next to it. • The URL value should be a fully qualified URL to the destination.</td>
</tr>
</tbody>
</table>

If the `OSN_GADGET_TYPE` is not provided (default state for the property), then the Oracle Social Network integration code will use the Java Type to Gadget Type mapping shown in Table 67-3 for sending the data to Oracle Social Network.
### Table 67-3  Java Type to Gadget Type Mapping

<td>Display a number as a percentage.</td>
</tr>
<tr>
<td>java.lang.String</td>
<td>Person</td>
<td>Display the attribute in Oracle Social Network as a clickable user who exists in Oracle Social Network. By sending the username or identifiable value for a user, most likely email address in an LDAP based Oracle Social Network, as a Person Gadget Type Oracle Social Network will look up the display name for the user in its user security store (local/LDAP) and display a link with using the users display name. When the link is clicked it will redirect to the Wall for the user represented by the person attribute.</td>
</tr>
</tbody>
</table>
Table 67-3  (Cont.) Java Type to Gadget Type Mapping

<table>
<thead>
<tr>
<th>ADFBC /Java Type</th>
<th>Gadget Type</th>
<th>Gadget Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>java.lang.String</td>
<td>URL</td>
<td>Display a string value as a clickable URL link in Oracle Social Network.</td>
</tr>
</tbody>
</table>

To configure the attributes for the Oracle Social Network field gadget types (non-Currency):

- Open the view object.
- Open the Attributes tab and click an Attribute.
- In the Property Inspector, open the Applications - Oracle Social Network section.
- Change the value in the Oracle Social Network Gadget Type to the required type.
- Click Save to keep the changes.

For setting an attribute to the Currency gadget type, an additional step must be followed to add the currency code for the currency value. By setting the Currency Code attribute property for the attribute, when the Social Object is sent to Oracle Social Network, the currency code value also will be sent with the currency value so that Oracle Social Network can display both values when it displays the currency value. Note that the currency code attribute does not need to be available to Oracle Social Network integration for its value to be used when sending the currency so long as the attribute for the Currency is available to Oracle Social Network integration. These are the steps to set up an attribute for currency:

- Open the view object.
- Open the Attributes tab and click an attribute that is to have the gadget type of Currency.
- In the Property Inspector, open the Applications - Oracle Social Network section.
- Change the Oracle Social Network Gadget Type to Currency.
- In the Currency Code attribute property, enter the name of the attribute whose value will contain the currency code value.
- Click Save to keep the changes.

What happens when setting the Gadget Type

The View Attribute node in the view object definition XML file will be modified with these modified custom properties:

- fnl:OSN_GADGET_TYPE - the Oracle Social Network Gadget Type.
- fnl:OSN_CURRENCY_CODE_ATTR - the name of the attribute on the view object whose value will contain the currency code when fnl:OSN_GADGET_TYPE=currency.

For non-currency attributes:

```
<ViewAttribute Name="ColBoolean">
<Properties>
```
<SchemaBasedProperties>
  <fnd:OSN_ENABLED_ATTR Value="true"/>
  <fnd:OSN_GADGET_TYPE Value="boolean"/>
</SchemaBasedProperties>
</Properties>
</ViewAttribute>

For currency attributes:

<ViewAttribute Name="ColCurrency">
  <Properties>
    <SchemaBasedProperties>
      <fnd:OSN_ENABLED_ATTR Value="true"/>
      <fnd:OSN_GADGET_TYPE Value="currency"/>
      <fnd:OSN_CURRENCY_CODE_ATTR Value="ColCurrencyCode"/>
    </SchemaBasedProperties>
  </Properties>
</ViewAttribute>
<ViewAttribute Name="ColCurrencyCode"/>

### Special Cases - Boolean

If an attribute represents a boolean value, a conversion will be required to send the value to Oracle Social Network. The recommended way to perform a Boolean conversion is to use the Attribute Conversion Framework, described in [Implementing the Integration Attribute Conversion Framework](#). If the conversion framework cannot be used, then below are the alternative instructions on how to use a transient to achieve the conversion.

The Oracle Social Network integration requires that any attribute marked as Gadget Type Boolean must provide the string value "T" to represent true or "F" to represent false. As part of the Oracle Social Network integration, if a Java Type of `java.lang.Boolean` is provided, it implicitly is sent to Oracle Social Network as "T" or "F."

An additional exception was made that if an attribute was of type String with Gadget Type of Boolean and the value provided being "T" or "F," then that value will be sent to Oracle Social Network. Any other values or types will not be sent to Oracle Social Network with a message being written to the Diagnostic log.

In Oracle Fusion Applications, it is common practice to define a Boolean value as a String and use values such as "Y" and "N" or "1" and "0." However, it is not just restricted to those values. In this case, just setting the Gadget Type to Boolean will not send any value to Oracle Social Network.

Follow these alternative instructions on how to use a transient to achieve the conversion if the conversion framework cannot be used:

- Add a new transient attribute to the view object.
- Set the Type of the attribute to be Boolean.
- Implement the conversion between the string boolean attribute and the Java Boolean attribute as a Groovy expression or as a Java override of the getter attribute of the transient attribute in the RowImpl class for the view object. For example, this Groovy expression can be used in the "Y"/"N" case:

  ```groovy
  "Y".equalsIgnoreCase(<your attribute name>)
  ```

- In the **Dependencies** page of the attribute wizard, make the Boolean transient attribute dependent upon the String boolean attribute.
• Set the Gadget Type for the Boolean transient attribute as boolean.

• Either re-open the OSN Enabled View Instances wizard, find the view object and click the Enabled check box for the transient attribute and click OK.

  or

  Open the Attributes tab in the view object, select the transient attribute, go to the Property Inspector and change the OSN Enabled property to be "true."

• Click Save to keep the changes.

Special Cases - Lookups and Conversion Values

Attributes that are a lookup code must provide a meaning or translated value to Oracle Social Network. The preferred method of conversion for lookups is to use the lookup converters in the conversion framework, as described in Implementing the Integration Attribute Conversion Framework.

The primary use case is lists of values where the lookup code is stored in the view object attribute and a lookup list of values provides a mapping between the lookup code and the descriptive meaning. Supporting the lookups in Oracle Social Network integration requires creating a new attribute that contains the lookup display value. There are two ways the attribute can be defined to provide the meaning value.

• Foreign key lookup

  Most view objects with a lookup code will already have a join to get the lookup display value. Essentially, a foreign key is defined through the lookup entity object in the view object definition. In this case, the meaning attribute can be Oracle Social Network enabled by using one of these methods:

  – Open the Add OSN View Instances wizard, find the view object, select the Enabled check box for the meaning attribute, and click OK.

  – Open the Attributes tab in the view object, select the meaning attribute, go the Property Inspector and change the OSN Enabled property to be "true".

• Transient attribute lookup

  A string transient attribute will be defined and the view object Row Impl’s getter for the transient will perform the lookup based upon the lookup code and return the meaning value. This is similar to how boolean values are handled where the transient attribute will be Oracle Social Network enabled.

Special Cases - Timezone Affected Values

The function of Oracle Social Network requires that a date value be passed to Oracle Social Network as the number of milliseconds since Epoch. The Oracle Social Network integration takes the date value provided from the attribute count in milliseconds and sends it to Oracle Social Network. Oracle Social Network then will display that value with the settings configured with Oracle Social Network. If there must be a deviation to how this works to account for timezoned dates, then a transient attribute approach where the time is modified and passed to Oracle Social Network integration as a new date will need to be performed.

• Add a new transient attribute to the view object.

• Set the Type of the attribute to be Date/TimeStamp.
• Implement the timezone conversion between the original Date/Time Stamp attribute and the Date/Time Stamp transient attribute so that the value will be correct when being retrieved as milliseconds since Epoch as a Groovy expression or as a Java override of the getter attribute of the transient attribute in the RowImpl class for the view object.

• In the Dependencies page of the attribute wizard, make the Date/Time Stamp transient attribute dependent upon the Original Date/Time Stamp attribute.

• Set the Gadget Type for the transient attribute as Date.

• Either re-open the Add OSN View Instances wizard, find the view object and select the Enabled check box for the transient attribute and click OK.

  or

  Open the Attributes tab in the view object, select the transient attribute, go to the Property Inspector and change the OSN Enabled property to be "true".

• Click Save to keep the changes.

Special Cases - Other types of attributes that do not fit the defined list of Oracle Social Network Gadget Types

If there are other value types in a view object attribute that need to be sent to Oracle Social Network or provided in a different format, the preferred method to convert other types is a custom conversion as described in How Custom Attribute Conversions Are Implemented. If the conversion framework cannot be used, then follow these alternative instructions on how to use a transient to achieve the conversion.

• Add a new transient attribute to the view object.

• Set the Type of the attribute to be String.

• Implement the conversion between the custom value type and the String transient attribute as a Groovy expression or as a Java override of the getter attribute of the transient attribute in the RowImpl class for the view object.

• In the Dependencies page of the attribute wizard, make the String transient attribute dependent upon the custom value type attribute.

• Set the Gadget Type for the transient attribute as String.

• Either re-open the Add OSN View Instances wizard, find the view object, select the Enabled check box for the transient attribute, and click OK.

  or

  Open the Attributes tab in the view object, select the transient attribute, go to the Property Inspector and change the OSN Enabled property to be "true".

• Click Save to keep the changes.

67.2.1.4 Implement the Integration Attribute Conversion Framework

An Oracle Fusion Applications developer can choose attributes from a view object that can be sent to Oracle Social Network. However, in some circumstances, the value that is retrieved may not be the value that is required to be sent. In these cases, a converter is required to take the attribute value from the view object row and change it into the value required. The converter is defined against the view object's attribute definition.
and executed automatically by the Oracle Social Network integration code. The converters:

- Allow being able to send to Oracle Social Network a modified version of the value stored in Oracle Fusion Applications.
- Provide the ability for lookup values (such as LOV values) to be looked up without having to add additional transient attributes to the original view object.
- Ensure the modification tracking of updates will work correctly as the modification is made to the "code" value in a lookup, not the "display" value. Previous to this enhancement, the "display" value would be required to be Oracle Social Network-enabled rather than the "code".

For example, Oracle Fusion Applications developers configure the view objects and attributes for the Oracle Social Network integration. However, restrictions on the Oracle Social Network server, and product team requirements mean that the value stored in the database table for a record cannot be sent to Oracle Social Network as-is. In these cases, a converter is required to be assigned to the attribute definition to take the stored value and convert it into the required format or value required by Oracle Social Network without any additional effect on the send to Oracle Social Network process.

There are four out-of-the-box converters ready to be used. A single converter can be added to the Attribute by using the values in the OSN Converter property in the property inspector. The OSN Converter property has a dropdown list containing these out-of-the-box converters. If the converter requires additional values to be supplied before the conversion can occur, then these can be set in the OSN Converter Parameters property that resides immediately below the OSN Converter property. The list of additional converter parameters to fill in can be seen by choosing the Edit... option from the property menu. The four out-of-the-box converters are:

- **Boolean Converter**
  
  Provides the ability to convert the object passed in into a boolean type based upon a customizable list of accepted (whitelist/true) or rejected (blacklist/false) values. If the object passed into `convertBoolean()` is of type `java.lang.Boolean`, then this will be returned immediately. Otherwise, `toString()` will be called on the object and the resultant String will be compared using a case-insensitive comparison to the `trueValues` or `falseValues` using the following algorithm:

  - `trueValues` and `falseValues` provided, then use `trueValues` and ignore `falseValues`.
  
  - `trueValues=null` and `falseValues=null`, default `trueValues` to be "y,t,1,yes,true".
  
  - `trueValues` supplied, then split the `trueValues` CSV and see if the passed-in value matches one of the values. If so, return true, otherwise false.
  
  - `falseValues` supplied and `trueValues=null`, then split the `falseValues` CSV and see if the passed-in value matches one of those values. If so, return false, otherwise true.

  The CSV parameters will conform to a standard CSV encoding to ensure the parameters do not become corrupt during persistence. Double quotes will be escaped by a second double quote (for example, " becomes """) and each entry in the CSV can be quoted.
Note: This converter is strictly meant for converting "code values" into boolean values. Looked-up translated values are not supported with the OsnBooleanConverter. If a translated value is required to be sent to Oracle Social Network, either the translation can be sent as a string (using the LovConverter or LookupConverter) or a custom converter will need to be written. When mentioning the default trueValues whitelist, the values of yes/true are constant code values, not translatable versions of yes/true.

OSN Converter: BooleanConv

Parameters:
- trueValues - (optional) - the CSV string list of values that when matched will return true from the converter.
- falseValues - (optional) - the CSV string list of values that when matched will return false from the converter.

Validates For: If attribute value to convert is null.

Upon Validation Failure Return: null

Can Convert Null: No

Example:

ColBoolean field in Oracle Social Network will be true if the attribute value is either "y" or "yes" (case-insensitive). All other values will return false.

```
<ViewAttribute
  Name="ColBoolean"
  PrecisionRule="true"
  EntityAttrName="ColBoolean"
  EntityUsage="FndDemoOsnFieldsEO"
  AliasName="COL_BOOLEAN">
  <Properties>
    <SchemaBasedProperties>
      <fnd:OSN_ENABLED_ATTR
        Value="true"/>
      <fnd:OSN_GADGET_TYPE
        Value="boolean"/>
      <fnd:OSN_CONVERTER
        Value="BooleanConv"/>
      <fnd:OSN_CONVERTER_PARAM
        Value="trueValues=y,yes"/>
    </SchemaBasedProperties>
  </Properties>
</ViewAttribute>
```

- Percentage Converter - 0.0-1.0 range converted to 0.0-100.0 range

Converts the value between 0.0 and 1.0 that is provided and returns the matching percentage value between 0.0 and 100.0 required by Oracle Social Network for the percent Gadget Type. The convertPercentage method takes the value supplied, ensures that it meets the exception statement, converts it to a double value, and multiplies it by 100.0.

OSN Converter: ZeroToOnePercentConv

Parameters: None

Validates For: A null, a non-numeric value, or a value not between 0.0 and 1.0 is passed in.
Upon Validation Failure Return: null
Can Convert Null: No

Example:

```xml
<ViewAttribute
    Name="ColPercent"
    PrecisionRule="true"
    EntityAttrName="ColPercent"
    EntityUsage="FndDemoOsnFieldsEO"
    AliasName="COL_PERCENT">
    <Properties>
      <SchemaBasedProperties>
        <fnd:OSN_ENABLED_ATTR
          Value="true"/>
        <fnd:OSN_GADGET_TYPE
          Value="percent"/>
        <fnd:OSN_CONVERTER
          Value="ZeroToOnePercentConv"/>
      </SchemaBasedProperties>
    </Properties>
</ViewAttribute>
```

• **Attribute Lookup Converter**

  The converter will look up another attribute value from the same view object row and substitute it for the actual attribute value.

  **OSN Converter: OsnFieldValueConverter**

  **Parameters:**
  
  displayAttributeName - mandatory - the name of another attribute in the view object to return the value of.

  **Validates For:** A null or a non-existent display attribute name supplied.

  Upon Validation Failure Return: null
Can Convert Null: No

**Example:**

The value assigned to the **ColString** attribute will be sent to Oracle Social Network as the value for the **ColLookupString** Oracle Social Network field.

```xml
<ViewAttribute
    Name="ColLookupString"
    PrecisionRule="true"
    EntityAttrName="ColLookupString"
    EntityUsage="FndDemoOsnFieldsEO"
    AliasName="COL_LOOKUP_STRING">
    <Properties>
      <SchemaBasedProperties>
        <fnd:OSN_ENABLED_ATTR
          Value="true"/>
        <fnd:OSN_CONVERTER
          Value="LookupConv"/>
        <fnd:OSN_CONVERTER_PARAM
          Value="displayAttributeName=ColString"/>
        <LABEL
          ResId="LOOKUP_CONVERTED"/>
      </SchemaBasedProperties>
    </Properties>
</ViewAttribute>
```
• **LOV Converter**

If an attribute has an LOV associated with it, then the LOV converter will use the definition of the attribute and look up the LOV associated with the attribute. It can then look up the display value from the LOV that is associated with the attribute value and send the LOV display value to Oracle Social Network.

**OSN Converter: OsnAttributeLookupLovConverter**

**Parameters:** None

**Validates For:** An LOV List Binding must be defined for the attribute.

**Upon Validation Failure Return:** null

**Can Convert Null:** No

**Example:**

In this example the display value from the LOV_ColStatus LOV will be sent that matches the value of this attribute.

```xml
<ViewAttribute
Name="ColStatus"
PrecisionRule="true"
EntityAttrName="ColStatus"
EntityUsage="FndDemoOsnFieldsEO"
AliasName="COL_STATUS">
<Properties>
<SchemaBasedProperties>
<fnd:OSN_CONVERTER Value="LovConv"/>
</Properties>
</ViewAttribute>
```
67.2.1.4.1 How Custom Attribute Conversions Are Implemented

If the conversions supplied do not meet the requirement for a conversion of an attribute value being sent to Oracle Social Network, then a custom converter can be written. The conversion framework converters are based around a central Java class called OsnFieldValueConverter (oracle.apps.fnd.appcore.oaext.osn.publicutil.converter). It is the abstract base class that all converters will inherit. There must be a zero parameter default constructor that will be used to create the instance of the converter. It contains a solitary public method, run, that will be passed the value to convert and a context object comprised of the attribute name, the intended Oracle Social Network gadget type, and the ViewRowImpl containing the value to convert.

The run method is responsible for executing the conversion by calling the abstract convert method and not allowing any exceptions that happen during conversion to be bubbled outside of the converter. If an exception occurs during the conversion, the implementing converter can choose to return the passed-in value, or null (the default behavior) back from the conversion.

It also has logging around the convert call to describe the performance and the converted result of the conversion attempt. A short circuit is built in for null handling using the canConvertNull override method. If a converter returns false for this method (which is the default implementation), then the convert method will not be called and null immediately will be returned from the run method. If a converter can convert null into another value, then the converter can override this method and return true so that the convert method will always be called.

Any converter that is built as a sub-class of OsnFieldValueConverter must implement the convert method that has the same signature as the run method, except that it can throw a checked OsnConversionException. This exception can provide details from the converter implementation about why a conversion attempt failed.

To provide more type checking abilities during conversion, three abstract "base" converters, which implement the OsnFieldValueConverter, are available that implement the convert method but call another abstract method that any sub-classes must implement that will ensure that the return value from a conversion is of the type required:

- **OsnBaseBooleanValueConverter** - Has an abstract convertBoolean method that takes the same parameters as convert but requires that a Java boolean native type be returned. Since the Oracle Social Network server requires that a boolean be provided as either "T" or "F", the boolean result from convertBoolean will be returned from the convert method as "T"/"F".

- **OsnBasePercentageValueConverter** - Has an abstract convertPercentage method that takes the same parameters as convert but requires that a Java double native type be returned. It also will do post processing to ensure that the value conforms with the expected range of 0.0 to 100.0 from Oracle Social Network and throw an OsnConversionException if the converted value from convertPercent is out of range.

- **OsnBaseDateValueConverter** - Has an abstract convertDate method that takes the same parameters as convert but requires that a Java long native type be returned. The long value signifies the Oracle Social Network requirement that all Date gadget type values be represented as the number of milliseconds since Epoch.
For an Oracle Fusion Applications product team to consume a converter for its attributes, the fully-qualified class name for the converter can be manually typed into the OSN Converter property (fnd:OSN_CONVERTER). If there are custom parameter values required for the converter, they will be read from the view object Attributes Converter Parameters parameter. The fnd:OSN_CONVERTER_PARAM is in the format "parameter1=value1;parameter2=value2". Each parameter will need to have its own getter and setter on the converter class. In this example, the setParameter1 method would be called with value1 and the setParameter2 method would be called with value2 before the run method was called. The getter for these parameters will need to be annotated with @OsnConverterParam to identify it as a converter parameter and show in the OSN Converter Parameters property menu UI. Any parameter values that are supplied in fnd:OSN_CONVERTER_PARAM that do not have a matching getter and setter will be ignored in the property menu. Expression Language expressions are not supported as the fnd:OSN_CONVERTER_PARAM, or as the values within the parameter list.

What happens at runtime when sending to OSN:

When the view object row attribute value is loaded and is about to be put into the payload to send to Oracle Social Network, the converter will be enacted using the following process:

- Read the Converter parameter (fnd:OSN_CONVERTER).
- Create the instance of the converter class using the fully-qualified class name.
- Read and set any parameters from fnd:OSN_CONVERTER_PARAM on the converter instance.
- Determine the run method called to execute the conversion.
- Put the value returned from the converter into the Oracle Social Network payload for that attribute.

### 67.2.1.5 Configuring Oracle Social Network Object Title

When a view object row is sent to Oracle Social Network as a Social Object, it will be displayed in the Oracle Social Network UI as a record with a title and a collection of name-value pairs. The value that is shown as the title of the Social Object can be configured on the view object. The following steps describe how to set the title for the Social Object:

- Open the view object in JDeveloper and click the **Attributes** tab.
- Determine that the attribute is to be used as the Social Object title value. If this is a pre-existing attribute value, skip the next three optional steps.
- [Optional-generated title] Define a new transient attribute that has a type of String.
- [Optional-generated title] Implement the title generation in the transient attribute as a Groovy expression or as a Java override of the getter attribute of the transient attribute in the RowImpl class for the view object.
- [Optional-generated title] In the **Dependencies** page of the attribute wizard, make the String transient attribute dependent upon the custom value type attribute.
- Select the attribute (transient or actual).
• Access the **Property Inspector** in the **Applications - Oracle Social Network** section and set the **Oracle Social Network User Key** to be "true".

• Click **Save** to keep the changes.

**What happens when you define the Oracle Social Network Social Object Title**

The Attribute definition within the view object definition XML file will be modified with the following custom property:

```xml
fnd:OSN_USER_KEY - The Oracle Social Network User Key custom attribute.
```

The following is an example of the modification in the view object attribute definition XML file:

```xml
<ViewAttribute Name="DeptName">
  <Properties>
    <SchemaBasedProperties>
      <fnd:OSN_ENABLED_ATTR Value="true"/>
      <fnd:OSN_USER_KEY Value="true"/>
    </SchemaBasedProperties>
  </Properties>
</ViewAttribute>
```

**Note:**

• There should be **only one** attribute with the Oracle Social Network User Key custom property value set to "true". If there are multiple attributes with the custom property set, then the first one that is found during processing will be used and all others will be **ignored**.

• If no attributes are provided with this custom property set, then the concatenated values of the attributes that comprise the view object primary key will be used.

**67.2.1.6 Configuring Oracle Social Network Object Key**

When a view object row is sent to Oracle Social Network, the Social Object will be assigned an internal unique identifier that will represent the Social Object during any interactions with Oracle Social Network. To perform subsequent updates to the Social Object from the view object, the Social Object also retains an external key based upon a single attribute value that must be sent to Oracle Social Network with every call. Without any additional configuration, the Oracle Social Network integration will build a concatenated value based upon the values of the attributes marked as the primary key that should suffice in most scenarios. If this concatenated value is longer than 256 characters, or the developer has a better key to use to uniquely identify the row, the Oracle Social Network integration provides the ability to override the automatically-generated value with a value of a custom property called OSN Object Key. For example, if a child object in a parent-child relationship is being sent to Oracle Social Network, then its primary key may be comprised of the parent object's primary key plus a unique value for the child. If the child value is unique within the child table, then the parent primary key is not required for the Social Object to uniquely identify with the view object row. So by marking the child unique value as the Oracle Social Network Object Key, there will be a slight performance gain as the external key for the Social Object does not need to be calculated.

To set up the Oracle Social Network Object Key:
Open the view object in JDeveloper and click the Attributes tab.

Determine that attribute is to be used as the Social Object external key value. If this is a pre-existing attribute value then skip the next three optional steps.

[Optional-generated key] Define a new transient attribute that has a type of String.

[Optional-generated key] Implement the key generation in the transient attribute as a Groovy expression or as a Java override of the getter attribute of the transient attribute in the RowImpl class for the view object.

[Optional-generated key] In the Dependencies page of the attribute wizard, make the String transient attribute dependent upon the custom value type attribute.

Select the attribute (transient or actual).

Access the Property Inspector in the Applications - Oracle Social Network section and set the Object Key to be "true."

Click Save to keep the changes.

**What happens when you define the Oracle Social Network Social Object Key**

The Attribute definition within the view object definition XML file will be modified with the following custom property:

```
fnd:OSN_OBJECT_KEY - The Object Key attribute.
```

The following is an example of the modification in the view object Attribute definition XML.

```
<ViewAttribute Name="DeptNum">  
 <Properties>  
   <SchemaBasedProperties>  
     <fnd:OSN_ENABLED_ATTR Value="true"/>  
     <fnd:OSN_OBJECT_KEY Value="true"/>  
   </SchemaBasedProperties>  
 </Properties>  
</ViewAttribute>
```

**Note:**

- Single attribute primary key view objects do not need to set this value because no concatenations need to occur to get the primary key value to use.

- There should only one attribute with the Oracle Social Network Object Key custom property value set to "true". If there are multiple attributes with the custom property set, then the first one that is found during processing will be used and all others will be ignored.

- If no attributes are provided with this custom property set, then the concatenated values of the attributes that comprise the view object primary key will be used.
67.2.1.7 Configuring the View Details URL

Use the information in this section to navigate from the Oracle Social Network Social Object into the Oracle Fusion Applications user interface.

After a view object row is sent to Oracle Social Network as a Social Object there may be a need for the user to modify the original values for that row. The mechanism that allows navigating from the Social Object back into the record in Oracle Fusion Applications uses a "View Details" URL that is shown when viewing the Social Object details. To be able to generate a URL that can navigate into Oracle Fusion Applications, there must be a taskflow to be called that can accept parameters to load the row in the product application page as well as configuration on the view object that provides the information allowing the Oracle Social Network integration to build the URL. The configuration on the view object is performed by setting the following properties:

- **Nav Web Application** (fnd:OSN_FA_WEBAPP) - This is a *mandatory* field. It is the identifier for a registered web application that is to be called back into. The value provided here must be seeded into Topology Manager as a deployed application. It is used in the Oracle Social Network integration to determine the web applications that will be called back into when the View Details link is clicked. This web application will be used to look up the base URL for the callback URL. An example is shown here:

```xml
<Properties>
  <SchemaBasedProperties>
    <fnd:OSN_FA_WEBAPP>
      Value="ApplcoreCRMDemo"/>
  </SchemaBasedProperties>
</Properties>
```

- **Nav View Id** (fnd:OSN_FA_VIEW_ID) - This is a *mandatory* field. This is the identifier for the view that will be displayed upon callback. It is used in the Oracle Social Network integration to determine what view is to be loaded when the callback is made from the View Details link. An example is shown here:

```xml
<Properties>
  <SchemaBasedProperties>
    <fnd:OSN_FA_VIEW_ID>
      Value="MyPage"/>
  </SchemaBasedProperties>
</Properties>
```

- **Nav Page Params List** (fnd:OSN_FA_PAGE_PARAMS_LIST) - This is a semicolon separated list of name-value pairs to be passed to the Oracle Fusion application's page as page level parameters when the callback is made from the View Details link. An example is shown here:

```xml
<Properties>
  <SchemaBasedProperties>
    <fnd:OSN_FA_PAGE_PARAMS_LIST>
      Value="key1=value1;key2=value2"/>
  </SchemaBasedProperties>
</Properties>
```

- **Nav Taskflow Id** (fnd:OSN_FA_NAV_TASKFLOW_ID) - This is a *mandatory* field. This is an Id to a bound task flow available in the page. This task flow will be
called and passed parameters from `OSN_FA_NAV_TASK_PARAMS_LIST` when the callback is made from the View Details link. An example is shown here:

```xml
<Properties>
  <SchemaBasedProperties>
    <fnd:OSN_FA_NAV_TASKFLOW_ID Value="/WEB-INF/StartupDefaultMainTaskFlow.xml#StartupDefaultMainTaskFlow"/>
  </SchemaBasedProperties>
</Properties>
```

- **Nav Task Key List** (`fnd:OSN_FA_NAV_TASK_KEY_LIST`) - This is a semicolon separated list of name-value pairs to be passed to the page containing the task flow. These parameters are used to distinguish one instance of the task flow from any others that are also running. An example is shown here:

```xml
<Properties>
  <SchemaBasedProperties>
    <fnd:OSN_FA_NAV_TASK_KEY_LIST Value="key1=value1;key2=value2"/>
  </SchemaBasedProperties>
</Properties>
```

- **Nav Task Params List** (`fnd:OSN_FA_NAV_TASK_PARAMS_LIST`) - This is a semicolon separated list of name-value pairs to be passed to the called bound task flow in the Oracle Fusion application's page. These will be specific to the task flow and need to be defined as input parameters on the task flow. An example is shown here:

```xml
<Properties>
  <SchemaBasedProperties>
    <fnd:OSN_FA_NAV_TASK_PARAMS_LIST Value="key1=value1;key2=value2"/>
  </SchemaBasedProperties>
</Properties>
```

- **Task Label** (`fnd:OSN_FA_NAV_TASK_LABEL`) - This is the label to be shown on the tab displayed that contains the bound task flow. This label will be a key into the appropriate translated bundle. An example is shown here:

```xml
<SchemaBasedProperties>
  <fnd:OSN_FA_NAV_TASK_LABEL Value="SearchFlatTableVO1_OSN_FA_NAV_TASK_LABEL"/>
</SchemaBasedProperties>
```

```xml
<trans-unit id="SearchFlatTableVO1_OSN_FA_NAV_TASK_LABEL">
  <source>Flat Table</source>
  <target/>
</trans-unit>
```

- **Task Label Attribute** (`fnd:OSN_FA_NAV_TASK_LABEL_ATTR`) - This is the name of an attribute in the view object that contains the label to be shown on the tab displayed that contains the bound task flow. An example is shown here:

```xml
<Properties>
  <SchemaBasedProperties>
    <fnd:OSN_FA_NAV_TASK_LABEL_ATTR Value="TaskLabelAttribute"/>
  </SchemaBasedProperties>
</Properties>
```
Note:

- This should not be used if the Task Label property is set. If both are set, then this one will take precedence and the Task Label will be ignored.
- The attribute to which this property refers can be a transient or actual attribute.

The values supplied for Nav Page Params List, Nav Task Key List, Nav Task Params List and Task Label can contain attribute name tokens that will be resolved when the View Details URL is being generated before it is sent to Oracle Social Network. The token is made up of an attribute name contained within curly brackets {}.

For example, if the Nav Task Params List is defined as "deptNumParam={DeptNum}" then the value of the view object row Attribute called "DeptNum" will replace the {DeptNum} token.

To set up the view object for the View Details URL:

- Open the view object in JDeveloper and click the General tab.
- In the Property Inspector, go to the Applications - Oracle Social Network section.
- Fill in the following custom properties:
  - Nav Web Application
  - Nav View Id
  - Nav Page Params List
  - Nav Taskflow Id
  - Nav Task Key List
  - Nav Task Params List
  - Task Label
  - Task Label Attribute
- Click Save to keep the changes.

What happens when you configure the View Details URL Properties

The view object definition XML file will be modified with the following custom properties:

```xml
<ViewObject Name="SndDemoDeptVO">
  <Properties>
    <SchemaBasedProperties>
      <fnd:OSN_FA_WEBAPP Value="SocialNetworkDemo"/>
      <fnd:OSN_FA_VIEW_ID Value="SocialNetworkDemo"/>
      <fnd:OSN_FA_NAV_TASKFLOW_ID Value="/WEB-INF/DemoDepartmentTF.xml#DemoDepartmentTF"/>
      <fnd:OSN_FA_NAV_TASK_PARAMS_LIST Value="deptNumParam={DeptNum}"/>
      <fnd:OSN_FA_NAV_TASK_KEY_LIST Value="deptNumKeyParam={DeptNum}"/>
      <fnd:OSN_FA_PAGE_PARAMS_LIST Value="deptNumPageParam={DeptNum}"/>
      <fnd:OSN_FA_NAV_TASK_LABEL ResId="NAVIGATE_DEPT_DEPTNUM"/>
    </SchemaBasedProperties>
  </Properties>
</ViewObject>
```
When the end user submits the view object row this will trigger the Social Object to be generated for sending to Oracle Social Network. As part of this generation the View Details URL will be constructed and added to the Social Object payload. The URL is generated using an algorithm that will perform lookups, such as determining the base URL from the Web App Id, and other parameter manipulations that will convert these parameters into a string that UIShell will accept as secure and valid. The UIShell, when called with this URL, will be able to determine what the parameters were and how to load the page and taskflow. For example, the following parameters will generate into the URL.

- **View Object Custom Properties**
  
  &nbsp;&nbsp;&nbsp;&nbsp;fnd:OSN_FA_WEBAPP="SocialNetworkDemoApp"
  &nbsp;&nbsp;&nbsp;&nbsp;fnd:OSN_FA_VIEW_ID="SocialNetworkDemo"
  &nbsp;&nbsp;&nbsp;&nbsp;fnd:OSN_FA_NAV_TASKFLOW_ID="/WEB-INF/DemoDepartmentTF.xml#DemoDepartmentTF"
  &nbsp;&nbsp;&nbsp;&nbsp;fnd:OSN_FA_NAV_TASK_PARAMS_LIST="deptNumParam={DeptNum}"
  &nbsp;&nbsp;&nbsp;&nbsp;fnd:OSN_FA_NAV_TASK_LABEL="Navigated {DeptNum}Department"

- **Topology Manager Setup**
  

- **View Object Row**
  
  DeptNum attribute value=350

- **Generated View Details URL**
  
  http://localhost:7001/snd-context-root/faces/SocialNetworkDemo?fnd=%252FWEB-INF%252FDemoDepartmentTF.xml%2523DemoDepartmentTF%3BdeptNumParam%253D350%3B%3BNavigated%2B350%2BDpartment%3Bfalse%3B256

### 67.2.1.8 Changing the Oracle Social Network Registration Name

When a view object is registered with Oracle Social Network as a Social Object definition, the definition must have a unique name assigned to it that will be used to identify the definition. Without any additional configuration, the registration name will be the concatenation of the application module Id and the fully qualified view object Name. For example, if the application module Id was FND and the view object was oracle.apps.fnd.applcore.demo.FndDemoDeptVO, then the registration definition would be FND.oracle.apps.fnd.applcore.demo.FndDemoDeptVO. In addition to the registration name for the view object, the Social Object Field Names are based upon the names of the attributes in the view object.

The Oracle Social Network integration provides a way to override the view object Social Object registration name and the Social Object Field Names. This can be done for the continued support of the existing Oracle Social Network registrations (such as for CRM/HCM) or to ensure that the length of the names does not exceed the 256 character limit.

To set the overrides of the Social Object definition registration names:

- Open the view object in JDeveloper and click the General tab.
- In the Property Inspector go to the **Applications - Oracle Social Network** section.
- Set the following custom property to override the view object's Social Object registration definition name:
  
  fnd:OSN_DEFINITION_NAME - This must be in the format &lt;module id&gt;.&lt;name&gt;. For example: FND.FndDempDept.
• Click the Attributes tab and select the attribute that is to have its Social Object Field Name overridden.

• Set the following custom property:
  \[fnd:OSN_DEFINITION_NAME\] - The Social Object Field name the attribute will be referred to as.

• Click Save to keep the changes.

What happens when you change the Social Object Registration Name

The following custom properties are modified within the view object XML definition.

• \[fnd:OSN_DEFINITION_NAME\] - Definition Name
• \[fnd:OSN_ATTR_DEFINITION_NAME\] - Oracle Social Network Attribute Name Override

The view object definition XML file will be modified with these custom properties:

```xml
<ViewObject Name="FndDemoOsnFieldsVO">
  <Properties>
    <SchemaBasedProperties>
      <fnd:OSN_DEFINITION_NAME Value="fnd.FndDemoOsnFieldsVO"/>
    </SchemaBasedProperties>
  </Properties>
  <ViewAttribute Name="OsnTestRecordId">
    <Properties>
      <SchemaBasedProperties>
        <fnd:OSN_ENABLED_ATTR Value="true"/>
        <fnd:OSN_ATTR_DEFINITION_NAME Value="TestId"/>
      </SchemaBasedProperties>
    </Properties>
  </ViewAttribute>
</ViewObject>
```

67.2.1.9 Configuring View Objects that Have Multiple Updatable Entities

The Oracle Social Network integration can support view objects that are comprised of multiple updatable entity objects.

A multi-updatable entity object view object is:

• A view object that has multiple entity objects selected to be within it.

• The Join Type must be an inner join.

• The entity objects that are participating in the update must have an association defined between them that creates an accessor in the Primary entity object that returns an instance of an \[OAEntityImpl\] (or one of its sub-classes) objects that is the instance of the Secondary entity object.

There are several cases in Oracle Fusion Applications where an Oracle Social Network integration available view object is tied to multiple updatable entity objects. For example, several Oracle Fusion applications use TCA (HZ_PARTIES) to manage key attributes about a person or company. Many teams, such as Procurement and CRM, extend the TCA schema with their own tables and columns to meet the information gathering requirements for their product. Procurement owns an entity called Supplier that extends the TCA Party schema to maintain information about a company from which you would like to purchase goods and services. The Supplier view object would therefore have updateable attributes from both the Supplier entity object and the TCA Party entity object. ATG business event registration for Oracle Social Network...
integration typically only references the primary entity object. In the TCA case, a customer can go to the Maintain Supplier UI and update a single attribute, such as Supplier Name. The Supplier Name is maintained in the TCA Party entity object that, in this case, is not the primary entity object. We must publish these cases to Oracle Social Network as update events but we do not want to place the Oracle Social Network integration events on multiple entity objects to avoid mass duplication of events.

The solution for this use case is to register the Primary entity object (Supplier entity object) as a post transaction listener for the Secondary entity object (Party entity object). Whenever an update occurs in the Secondary entity object, the primary entity object will also be notified and its post transaction processing will send the view object data from both entity objects to Oracle Social Network.

These implementation steps are required to enable Oracle Social Network for multi-entity entity objects. This assumes the pre-condition of the accessor being as described at the beginning of this section.

- In Jdeveloper, open the definition of the Primary entity object class.
- Access the Java tab and click the Edit icon.
- Click Generate Entity Collection Class.
- Click OK to generate the EOCollImpl class for the entity object.
- Open the EOCollImpl class for the entity object in the source editor.
- Add the following code:

```java
@Override
protected EntityImpl add(EntityImpl srow)
{
    OAEntityImpl eo = (OAEntityImpl) super.add(srow);
    byte state = srow.getPostState();
    if (EntityImpl.STATUS_UNMODIFIED == state ||
        EntityImpl.STATUS_MODIFIED == state)
    {
        eo.registerOsnExternalListener("SecondaryEOAccessor");
    }
    return eo;
}
```

- Change the SecondaryEOAccessor to be the name of the accessor attribute in the Primary entity object that returns the OAEntityImpl (or sub-class) for the Secondary entity object.

**What happens when the secondary Entity Object Accessor Registration occurs**
The "add" method override accomplishes these actions:

- Ensures that Oracle Social Network integration on the primary entity object exists before performing any registration.
- Ensures that the accessor provided refers to an instance of an OAEntityImpl object.
- Checks to see that attributes in the Secondary entity object are to be sent to Oracle Social Network as marked in the view object. If there are no fields from the Secondary entity object to be sent, then no listener will be registered. If there are fields to be sent to Oracle Social Network, then an internal reference is set up in
the instance of the Secondary entity object marking that column it is to track for Oracle Social Network.

At runtime, each entity object will track which fields are to be sent to Oracle Social Network (if any). When a post action occurs, the Secondary Entity Object will notify the Primary Entity Object that it has been modified. The Primary Entity Object retrieves the associated view object to collate all fields that have been traced for sending to Oracle Social Network from all participating entity objects. The view object then will perform the send to Oracle Social Network. The Primary Entity Object will ensure that if multiple Secondary Entity Objects are modified, then only one send to Oracle Social Network will occur.

What happens if "add" in the Primary EOCollImpl is not performed and attributes from the Secondary entity object have been marked as Oracle Social Network enabled in the view object?

There are three types of events that will occur:

- Primary entity object fields only updated - The post event occurs on the Primary entity object and those fields in the Primary entity object will be sent to Oracle Social Network.

- Primary entity object and Secondary entity object fields updated - When the post event occurs, it will fire on the Primary entity object. Because the send is done from the view object, all fields that can be sent to Oracle Social Network from both the Primary and Secondary entity objects will be sent to Oracle Social Network.

- Secondary entity object fields only updated - Only a post transaction event will occur on the Secondary entity object and therefore no data will be sent to Oracle Social Network.

What if Multiple Updateable Entity Objects are included in View Object as non-reference

Having multiple entity objects included in the view object is generally not recommended by the BC4J framework but it is possible to implement. The complication for Oracle Social Network integration is that it uses the non-reference entity object to identify the Primary Entity Object. If there are multiple non-reference entity objects within the view object, then it is most likely that the Oracle Social Network integration will choose the incorrect entity object to be the Primary Entity Object. The solution to this is to add the fnd:OSN_PRIMARY_EO property to the view object’s properties and provide the EntityUsage name of the entity object to use as the Primary Entity Object. This property can only be added in the view object source because there intentionally is no Property Inspector fnd:OSN_PRIMARY_EO property.

This example demonstrates the use of the fnd:OSN_PRIMARY_EO property:

```xml
<ViewObject
 xmlns="http://xmlns.oracle.com/bc4j"
 Name="MeoDeptAttachNonReferenceVO"
 xmlns:fnd="http://xmlns.oracle.com/apps/entityview">
 <Properties>
  <SchemaBasedProperties>
   <fnd:OSN_PRIMARY_EO Value="MeoFndDemoDeptEO"/>
  </SchemaBasedProperties>
 </Properties>
 <EntityUsage
 Name="MeoFndDemoDeptEO"
 Entity="oracle.apps.fnd.applcore.socialnetwork.model.test.setup.multieo.attach.MeoFnd"
/>
</ViewObject>
```
By identifying which entity object is the Primary Entity Object for the view object, the Manage Oracle Social Network Objects UI will correctly configure the Oracle Social Network integration to ensure all send requests are sent using the declared Primary Entity Object.

**Note:**

`fnd:OSN_PRIMARY_EO` only needs to be implemented where there are multiple entity objects in the view objects that are flagged as non-reference. If there is only one entity object in the view object as non-reference, do not set this flag.

---

**When not to use multiple updateable entity objects Oracle Social Network Integration for a view object**

Consider this scenario:

- There are two view objects: the first view object (FirstVO) has two entity objects contained within it (OneEO + TwoEO) and the second view object (SecondVO) has only one entity object in it (TwoEO).
- The secondary entity object of the first view object (TwoEO) is the primary, and only, entity object of the second view object.

In this scenario, it does not make sense to use Oracle Social Network integration as there will be a synchronization issue. Since there are two view objects that contain data from TwoEO, there will be two Social Objects in Oracle Social Network that contain this data. When TwoEO data is updated from the SecondVO, only the Social Object that relates to the SecondVO will be updated. There is no way to determine that the FirstVO has been affected and its data should be re-synchronized to Oracle Social Network. The following is the recommended outcome to ensure that the data remains synchronized on Oracle Social Network:

- Do not perform the Secondary entity object registration steps as outlined in the Additional Advanced Configuration - View Objects That Have Multiple Updatable Entities section.
- Leave the second view object to send all updateable information relating to the secondary entity object (TwoEO).
- In the first view object, only include attributes from the secondary entity object that will not change after the Social Object has been created. For example: Social Object title or primary key value.
- In the first view object you should include attribute values that will help an end user find the associated Social Object for the second view object. For example: Social Object title or primary key value.

There is a future feature that has been mentioned (but has no schedule for implementation) where two social objects can be associated with each other. This feature, when implemented and uptaken by ATG-OSN integration, will allow the end user to quickly navigate between the two associated social network objects that will make the above recommendation more user friendly.
67.2.1.10 Configuring Multiple View Objects to Share the Same Social Object

A common scenario in Fusion Applications is to have two different UI pages for a single Business Object:

- A summary page that outlines the information in a logical read-only way and may include other information that is logical to show with that object.
- An edit page where the information about that object can be modified.

To achieve this in Fusion Applications, two different view objects are required (one per page) that refer to the same business object (such as Opportunity). Therefore, a logical business requirement would be to have both view objects update and view the exact same Social Object on the Oracle Social Network server. This would require Oracle Social Network to enable both view objects individually, because they need to be able to access the Oracle Social Network server independently of each other. The following instructions demonstrate how to share the same Social Object when there are two different view objects that can provide the attribute definitions, translations, and so on.

Before you begin

Pick one of your view objects which will be the Reference View Object. The Reference View Object:

- Is a view object that has already been Oracle Social Network-enabled using these instructions.
- Will be used as an "Oracle Social Network integration template" for all other view objects that will share the same Social Object.

In the Reference View Object, make a note of the following:

- Property values for these properties:
  - Nav Web Application
  - Nav View Id
  - Nav Page Params List
  - Nav Taskflow Id
  - Nav Task Key List
  - Nav Task Params List
  - Task Label
  - Task Label Attribute
- Names of all attributes that are Oracle Social Network-enabled.
- For each attribute, note the attribute property values for these properties:
  - Oracle Social Network Attribute Name Override
  - Oracle Social Network Gadget Type
  - Oracle Social Network User Key
67.2.1.10.1 Configuring the Reference View Object to Be Enabled by Oracle Social Network

To configure the Reference View Object to be enabled by Oracle Social Network:

- Open the Reference View Object and in the property inspector set the Applications > Oracle Social Network > Definition Name property. This will ensure that the view object's Oracle Social Network definition name will be consistent among all the view objects that are sharing the Social Object. This definition name must have the application short name at the beginning, and should be unique from all other existing view objects that are not to share the Social Object.

- [Optional] If there are any translated values that are different between the two view objects, set the Registration VO property on the view objects to true. This will set the fn:OSN_REGISTRATION_VO property on the view objects and ensure that any translations are read from this view object.

67.2.1.10.2 Configuring the Other View Objects to Be Enabled by Oracle Social Network

For each view object (not the Reference View Object):

1. Open the view object.

2. Set the Applications > Oracle Social Network > Definition Name to be the exact same value as the Reference View Object set in the previous section.

3. Set the property values to the values noted in the "Before you begin" steps.

4. Open the Add OSN View Instances wizard by right-clicking the Application Module containing the view objects and selecting the wizard.

5. For each attribute in the view object that matches an Oracle Social Network-enabled attribute in the Reference View Object:

- Set the Oracle Social Network enabled flag to True.

- Set the Oracle Social Network Gadget Type, Oracle Social Network User Key, Object Key and Currency Code Attribute property value to those noted in the Before you begin steps.

- Has the Oracle Social Network Attribute Name Override been set in the attribute of the Reference View Object?

  - If Yes, set the Oracle Social Network Attribute Name Override to be the same value between the two attributes.

  - If No, set the Oracle Social Network Attribute Name Override to be the name of the attribute in the Reference View Object unless the two attribute names are the same.

6. Open the Add OSN View Instances wizard by right-clicking the Application Module containing the view objects and selecting the wizard.

7. Shuttle the view objects from the Available View Objects to the Data Model.
This will ensure that all view objects are set up to use the same Oracle Social Network Social Object.

**Social Link Configuration**

Because each view object now is set up to match the Social Object definition in Oracle Social Network, the row from the view object that is on the page that is being displayed can be used as the osnRow in the applications panel.

### 67.2.1.11 Configuring Transient Entity Objects and View Objects

Under certain circumstances, there is a requirement to send data to Oracle Social Network without having an entity object that is based upon a database table. For example, a team could be using an Oracle Enterprise Scheduler job to update data that does use an entity object but still want that data sent to Oracle Social Network. The way to do this would be to use a Transient entity object and Transient view object.

Sending to Oracle Social Network from a Transient view object or entity object is possible with Oracle Social Network integration, however, the solution does have some restrictions. Performing a send to Oracle Social Network that creates a record is relatively straightforward. The entity object and view object were created using the wizard in JDeveloper and all attributes manually entered. The view object was then added to an application module that will control the transaction in which this will occur. A transaction is required for this functionality because the send to Oracle Social Network happens upon the commit of the transaction. The configuration of the Oracle Social Network properties and setup UI is identical to a regular view object, except there must be a minor fix to the VOImpl to change its default of looking at database tables, to directly looking at the entity cache so that the Oracle Social Network integration can find the row upon commit. This is done using the following code:

```java
@override
protected void create()
{
    super.create();
    setQueryMode(QUERY_MODE_SCAN_ENTITY_ROWS | QUERY_MODE_SCAN_UNPOSTED_ENTITY_ROWS | QUERY_MODE_SCAN_VIEW_ROWS);
}
```

**What happens when a transient entity object/view object is used for Oracle Social Network integration**

When a row is created or inserted in the transient view object, populated with attribute data, and the commit happens, the row’s data is sent to Oracle Social Network as a create request. This works well for transient entity objects and view objects.

It is during an Update that the situation becomes less clear. Due to the nature of transient view objects and entity objects, such as when they have no persistent state, it is impossible to change their entity state away from STATUS_NEW/INITIALIZED until a commit occurs on that instance of the transient entity object or view object. The Oracle Social Network integration uses the entity state to determine whether to perform a create/update/delete request to Oracle Social Network. However, the Oracle Social Network client library handles the update issue. When a second create request is sent to Oracle Social Network that contains all of the Social Object fields (view object attributes) that were sent to Oracle Social Network originally, it will detect that the Social Object was already created and only will perform an update of the fields whose values have changed between the two Oracle Social Network sends. The only issue with this is in the detail: *all* fields need to be sent the second time, even if the field value has not changed. If a field value is not supplied, it will be treated as if
null was sent and the field value will be removed from Oracle Social Network, but if the field value is supplied and its value has not changed, then the field will be treated as not-updated.

Therefore, the update solution becomes a non-issue as the transient view object can be populated in the exact same mechanism and committed in the same way as the original insert. When the payload of the second create request gets to Oracle Social Network, it will determine the correct course of action for the insert/update of the Social Object data.

**67.2.1.12 Working with Special Cases**

This section discusses situations that are not covered elsewhere.

- **Date Effective Entity Objects**
  A date effective entity object is one in which an update on an existing entity object row puts an end date on it and creates or inserts a new row with the updated details. In Oracle Social Network, this should only submit the details of the update and not the insert of the new row. Only the last chronological date effective row data will be sent to Oracle Social Network. This is the date effective row where the Effective End Date is 31-Dec-4712. Data from any other date effective row that does not contain that end date will not be sent to Oracle Social Network.

  It is possible for the last chronological date effective row to be effective from a future date. To communicate this to the viewer, a new attribute "As Of" automatically will be included for a date effective object when it is enabled for Oracle Social Network. The value of this attribute will come from the attribute that contains the start date of the date effective range.

- **Parent-Child View Objects**
  You can send view object rows for both the parent and child rows individually, but you cannot send both Social Objects together as a Master - Detail since Oracle Social Network does not support this relationship. There are ways to view the parent from the details rows using the parent id and tie them together through URLs in the Oracle Social Network UI.

- **Descriptive Flexfields**
  The Oracle Social Network integration supports descriptive flexfields which have been deployed for an Oracle Social Network-enabled view object. An Oracle Fusion applications developer does not need to configure any properties at design time to enable the descriptive flexfield integration. When the Functional Administrator uses the "Manage Social Network Objects" UI to add attributes to send to Oracle Social Network, the descriptive flexfields attributes will also be shown in the list in a tree structure organized by value set.

**67.3 Implementing the Oracle Social Network Setup UI**

There are several features of the Oracle Fusion Applications-Oracle Social Network integration that can be used when designing Oracle Fusion applications user interfaces and their application.

**67.3.1 Configuring the Setup Application**

The task flow shown here will be available for users who will configure the Oracle Social Network integration on a client site.
The "Manage Oracle Social Network Objects" task flow definition and its available parameters are:

- **Component**: Oracle Social Network
- **Task flow**: Manage Oracle Social Network Objects
- **Function Security Privilege**: FND_MANAGE_SOCIAL_NETWORK_TRACKING_PRIV
  
  **Display Name**: Manage Oracle Social Network Tracking

- **Task Flow Invocation Artifact**:

  /WEB-INF/oracle/apps/fnd/applcore/socialnetwork/ui/flow/SocialNetworkTF.xml#SocialNetwork

- **Parameters**
  
  - `[moduleType] Note: If moduleType is passed, moduleKey also must be passed. Together they form a unique key for a module.
  
  - `[moduleKey] Note: If moduleKey is passed, moduleType also must be passed. Together they form a unique key for a module.
  
  - `[pageTitle]`

- **Description**: Manage the Social Network Tracking setup.

The parameter values that can be provided are shown in Table 67-4.

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>moduleType</td>
<td>The type of module to filter the list of application modules shown. This parameter is used with the moduleKey to perform the filtering. The application modules contain the view objects that are available to be sent to Oracle Social Network. Examples: APPLICATION, FAMILY</td>
<td>When no value is supplied, all modules will be shown.</td>
</tr>
<tr>
<td>moduleKey</td>
<td>The module key to filter the view objects in the task flow. The mapping between the module key and the application modules comes from the fnd-osn-integration.xml setup in the &quot;Add OSN View Instances&quot; wizard.</td>
<td>When no value is supplied, all modules will be shown.</td>
</tr>
<tr>
<td>pageTitle</td>
<td>The title to show at the top of the &quot;Manage Oracle Social Network Objects&quot; page.</td>
<td>&quot;Manage Oracle Social Network Objects&quot;</td>
</tr>
</tbody>
</table>

In Functional Setup Manager, Applications Core will add the "Manage Oracle Social Network Objects" task to provide access to the setup task flow with no moduleType or moduleKey specified. This task will give access to the task flow for managing any Oracle Social Network object in Oracle Fusion Applications.

You can create your own product module-specific Oracle Social Network setup tasks in your own task lists that provide access to the setup task flow but that are filtered by the relevant modules. For example, Financials can create a Manage Financials Oracle Social Network Objects by passing in the correct moduleType and moduleKey.
If a valid `moduleType` and `moduleKey` pair is specified, the UI provides access to all objects whose modules roll up to the specified module. That is, if a family is specified, the UI displays all objects whose modules roll up to the family.

**Note:**
Oracle Social Network Object settings are moved using the customization sets on the Customization Migration page instead of using the export and import function in the Setup and Maintenance work area of Functional Setup Manager. Customization Migration is not module-specific.

### 67.3.2 Accessing the Credential Store

As part of the Provisioning role, credentials must be created that allow the Oracle Social Network client libraries (the interface between Applications Core and Oracle Social Network) to create an authenticated connection to the Oracle Social Network server. To access the credential store, the Oracle Social Network library will need to be granted permission by the security of the containing application. The following code snippet must be added to the `jazn-data.xml` file so the Oracle Social Network client library can access the credential store:

```xml
<grant>
  <grantee>
    <codesource>
      <url>file:${domain.home}/servers/${weblogic.Name}/tmp/_WL_user/oracle.social.client/-</url>
    </codesource>
    <permission>
      <class>oracle.security.jps.service.credstore.CredentialAccessPermission</class>
      <name>context=SYSTEM,mapName=oracle.social.security,keyName=FUSION_APPS_OSN_INTEG_APP_ID-KEY</name>
      <actions>read</actions>
    </permission>
  </grantee>
  <permissions>
    <permission>
      <grantee>
        <codesource>
        </codesource>
        <grantee>
        </grantee>
        <permissions>
        </permissions>
      </permission>
  </permissions>
</grant>
```

Before adding this block to the `jazn-data.xml` file, verify if there is already a grant block for the URL `${domain.home}/servers/${weblogic.Name}/tmp/_WL_user/oracle.social.client/-`. If this already exists, then just add the `<permission>` node to the existing grant.

### 67.3.3 Avoiding Overwriting Registrations and Data

When there are multiple developers working on Oracle Social Network integration with the same view object, there is a high risk of the developers overwriting other developers' Social Object registrations and data on the Oracle Social Network server. To avoid this scenario, use the `oracle.applicore.socialnetwork.registrationprefix` system property. This property can be set on the Java Options command line to a different value for each developer and will be prefixed to the Oracle Social Network registration definition name. This will allow the same view object to be registered multiple times on the Oracle Social Network server, thus allowing each developer to have his or her own Social Object registration.
67.4 Adding Oracle Social Network to Your Application UI

Oracle Social Network provides an ADF declarative component to launch the Oracle Social Network UI within an Oracle Fusion application. This declarative component is rendered as a Social link and is available in two areas—Global Area and application panel.

Note that once the Social link is implemented, the application’s end users can see the Social link only if they are internal to the organization. That is, if MegaCorp is the organization running the Oracle Fusion application’s instance, MegaCorp’s internal employees can access the Social link, but the company’s external suppliers and partners cannot. Access to the Social link in the two aforementioned locations is controlled by the Launch Oracle Social Network privilege that is granted to internal users by the Worker duty role.

When the Social link is clicked, it launches the Oracle Social Network UI that is displayed in a layover panel on the right side of the Oracle Fusion application page.

The ADF declarative component is available in four versions for use in various areas of the Oracle Fusion applications pages:

- image +link
- link only
- image +button
- button only

The component itself has been integrated out of the box as a link in two places using Applications Core and is available for use by developers.

The Social link has been added as a text-only link to the Global Area/Menu as shown in Figure 67-2. Therefore, the link will be available on all Oracle Fusion application pages.

Figure 67-2 Social Link in the Global Area

Note:

Language and time zone preference settings in Oracle Fusion Applications and Oracle Social Network are not integrated. Preferences set in Oracle Fusion Applications do not propagate to the Oracle Social Network server.

When the Social link is clicked, the Oracle Social Network UI is launched on the right side as shown in Figure 67-3. This view displays all the Conversations, Social Objects,
Users and Groups to which a user has access (displayed within the All tab in the Oracle Social Network UI).

**Figure 67-3  Example of the Oracle Social Network Popup**

The Social link also is added to the left of the toolbar (buttons) in the application panel. The link will appear automatically in Oracle Fusion application pages if the application panel has been used for object detail pages.

Clicking the **Social** link in the application panel also launches the Oracle Social Network UI on the right side as a layover panel. In this view, Oracle Social Network UI is displayed in the context of the current Oracle Fusion application page or object.

The Social link in the Application Panel typically appears as shown in **Figure 67-4**.

**Figure 67-4  Example Showing the Social Link in an Applications Panel**

The link currently is supported only within the application panel. The Social link should not be directly consumed outside an application panel. Also, you should not use the Oracle Social Network ADF declarative component (link/button) directly.

When the Social link is clicked from within the application panel, the Oracle Social Network UI should appear as shown in **Figure 67-5**. Within the Oracle Social Network UI there are two tabs:

- In the context of the Oracle Fusion application Object (depending on the context passed as explained below), the Oracle Social Network UI displays the associated Social Object and any Related Conversations.
• The All tab displays all the Conversations, Social Objects, Users and Groups to which a user has access.

**Figure 67-5  Example Showing Popup from Applications Panel**

67.4.1 How to Render the Behavior of the Social Link in an Application Panel

There are some checks made internally within the application panel and in the Oracle Social Network ADF declarative component that control the display of the Social link in the Oracle Fusion application pages.

The Social link in the application panel will render only when some context is passed to the application panel. The rules that control the rendering are:

• If the Oracle Social Network URL is not configured, the link will not show (it also will not show in the Global Menu).

• If there is no context passed to the application panel, the link will not render. The end-user will need to use the link from the Global Menu to see all Oracle Social Network Conversations and Social Objects.

• If the view object is not enabled (out of the box using Design Time) for Oracle Social Network, then the link will not render. See Configuring the Business Object for Oracle Social Network Integration.

• If the view object is enabled (out of the box using Design Time) for Oracle Social Network, but the Oracle Social Network task flow has not been enabled using Oracle Fusion Functional Setup Manager, then the link will not render.

**Note:**

Developers can control the rendering of the Social link by setting an Expression Language expression on the `osnRendered` attribute (see Table 67-5). For example, when the same UI is used for both create and edit cases, the developer may want to hide the Social link in the Create case because the business object may not be ready at that point.

67.4.2 How to Pass Context and Parameters to an Application Panel

This step must be performed for the objects (context) that are enabled for Oracle Social Network.

The application panel exposes a subset of parameters that can be used to control the behavior of the Oracle Social Network Social link. Some additional parameters
exposed by the Oracle Social Network Social ADF component are used internally by
the application panel and are not exposed. Table 67-5 lists the parameters available to
control the behavior of the Social link and pass the context to it:

Table 67-5  Parameters that Control the Behavior of the Social Link

<table>
<thead>
<tr>
<th>Attribute Name</th>
<th>Type</th>
<th>Description</th>
<th>Valid Values</th>
</tr>
</thead>
<tbody>
<tr>
<td>osnDisable</td>
<td>Boolean</td>
<td>Explicitly controls whether the Social link (if rendered) is disabled or not. This is optional.</td>
<td>true or false. The default is false.</td>
</tr>
<tr>
<td>osnRendered</td>
<td>Boolean</td>
<td>Explicitly controls (apart from internal checks made) whether or not to render the Social link. This is optional.</td>
<td>true or false. The default is true.</td>
</tr>
<tr>
<td>osnRow</td>
<td>oracle.jbo.Row</td>
<td>An Expression Language expression that returns a view object Row that must contain the Social Object ID (that is, the primary external ID).</td>
<td></td>
</tr>
<tr>
<td>osnType</td>
<td>String</td>
<td>The fully-qualified view object type/ID as registered with Oracle Social Network through Functional Setup Manager&quot;Manage OSN task flow.&quot;</td>
<td>Do not use.</td>
</tr>
<tr>
<td>osnTypeGroup</td>
<td>String</td>
<td>The application module ID that was used to group together a set of view objects for Oracle Social Network.</td>
<td>Do not use.</td>
</tr>
<tr>
<td>osnDisableShare</td>
<td>Boolean</td>
<td>Controls whether the Oracle Social Network UI should show the Share button when the current row is not yet shared or sent to Oracle Social Network. This parameter is only useful when osnRow is passed.</td>
<td>true or false. The default is false.</td>
</tr>
<tr>
<td>osnDisableJoin</td>
<td>Boolean</td>
<td>Controls whether the Oracle Social Network UI should allow the current user to Join (become a member of) the Social Object (if shared). This parameter is only useful when osnRow is passed.</td>
<td>true or false. The default is false.</td>
</tr>
</tbody>
</table>

Examples of Parameters

- For a specific object/row (only osnRow is specified)

  <fnd:applicationsPanel Id="ap1"
    osnRow="#{bindings.Dept1.currentRow}"
  .../>

- For a specific object/row ID but disabling Share

  <fnd:applicationsPanel Id="ap1"
    osnRow="#{bindings.Dept1.currentRow}"
    osnDisableShare="true"/>

67.4.3 How Share and Join Behave

The Share and Join buttons are displayed within the Oracle Social Network UI that is
launched from the Social link in the application panel. These actions are applicable
only in the contextual view displayed for an Oracle Fusion application object.

The core state transitions for the Share and Join buttons are:
• The **Share** button is displayed when the view object is enabled with Manual mode and the object has not yet been shared in Oracle Social Network. In this case, the **Share** button will be displayed and the user can choose to create the Oracle Social Network Social Object manually. In Automatic mode, you should not see the **Share** button unless the business object was created before it was Enabled for OSN. This is because the Oracle Social Network Social Object will be created automatically when the Oracle Fusion application business object is created.

• Once a user clicks the **Share** button, the button will not be displayed again, unless there is an error in sharing with Oracle Social Network. The Oracle Social Network UI then displays the Social Object.

• The **Join** button is displayed for both Manual and Automatic modes for the current user who is not yet a member of the Social Object in Oracle Social Network. The **Join** button will be displayed only after the object is shared, either automatically or manually by another user, in Oracle Social Network.

• Once a user clicks the **Join** button, the user is made a member of the Social Object in Oracle Social Network. The Oracle Social Network UI then displays the Social Object and any related conversations.

• The **Join** and **Share** buttons can be hidden by setting the `osnDisableShare` and `osnDisableJoin` parameters to the application panel. See Table 67-5.

### 67.5 What Happens When Functional Administrators Manage Oracle Social Network Objects

The Functional Administrator will use the Functional Setup Managers supplied by the product team to take the set of view objects available for Oracle Social Network integration and choose which are to be enabled for sending data to the site's Oracle Social Network instance.

**Prerequisites**

- The deployed JAR files containing the view object definitions and the `META-INF/fnd-osn-integration.xml` file must be in the classpath of the product team's Functional Setup Manager.
- The Functional Setup Manager has had the "Manage Social Network Objects" task flow added to it.
- The person fulfilling the provisioner role has set up the Oracle Social Network location and the Oracle Social Network credential.

#### 67.5.1 Enabling a View Object for Oracle Social Network Integration

When the functional administrator loads the Functional Setup Manager, a list of tasks is displayed. One will be "Manage Social Network Objects." After this task is selected, the setup UI for enabling the view objects for Oracle Social Network integration will be shown. When the "Manage Social Network Objects" page has finished loading, the list of view objects that the developer made available for Oracle Social Network can be seen.
67.5.2 Change the Oracle Social Network Enabled Status

To enable or disable the view object for Oracle Social Network integration at the site when the "Manage Social Network Objects" page is loaded, the configurer can use the following steps:

1. Select the view object in the Business Objects tree that is to be Oracle Social Network enabled.

2. Click Enable OSN Tracking.

3. When the popup window is displayed, choose either:
   - Manual - The end user consuming the Oracle Fusion application will need to click the Share button to send the view object row to Oracle Social Network.
   - Automatic - When the end user commits the view object row with which they are working, the send to Oracle Social Network will occur automatically.
   - None - Disable Oracle Social Network integration.

4. Click OK.

The view object shown in the tree now will have the updated Enabled status to match the selection. There is a shortcut to disabling Oracle Social Network integration for a view object by selecting it in the Business Objects tree and clicking Disable OSN Tracking.

67.5.2.1 How to Add and Remove Attributes to Send to Oracle Social Network

Changing the OSN Enabled state of the view object is only the first half of the configuration that is required to send a Social Object to Oracle Social Network. The attribute values that will become the Social Object fields also need to be selected. Use these steps to select the attributes that will be Oracle Social Network enabled:

1. Select the view object in the Business Objects tree that is to have attributes Oracle Social Network enabled. This should show the list of Oracle Social Network enabled attributes in the table at the bottom of the page.

2. Click New. This will display a dialog showing all of the attributes that the developer marked as Oracle Social Network integration available.

3. Check or uncheck the check boxes next to each attribute to add and remove attributes. Attributes that are selected are Oracle Social Network enabled.

4. Click OK.

The attributes that were checked in the dialog will now be shown in the table at the bottom of the page. This is the list of attributes for the view object that have been marked as Oracle Social Network enabled. There is a shortcut for marking the attributes as not Oracle Social Network enabled. Select the attribute and click Delete to remove it from the list.

67.5.3 Committing the Oracle Social Network Enabled View Objects

Until this point, there has been no change to the stored configuration of the Oracle Social Network Enabled view objects. This means that if the functional administrator leaves this page or cancels, then the way in which the Oracle Fusion application
integrates with Oracle Social Network at runtime will not have changed. By clicking Save at the top of the page, the information about all displayed view objects' Oracle Social Network enabled status and their attributes are committed locally for use at runtime and the definition of the Social Object based upon the selections made by the developer for the view object will be built and sent to Oracle Social Network.

What happens when Save is clicked

Two key functions happen when Save is clicked:

- **Oracle Social Network Enabled Configuration Is Saved Locally**
  
  When the developer saved the Oracle Social Network configuration for the view object, all of that information was stored as properties in the view object XML definition file. A very similar process happens for enabling the view object for XML. When Save is clicked, the custom properties for these view objects are changed:

  - `fnd:OSN_VO_ENABLED_BY_CUSTOMER` - Stores whether the user selected Automatic/Manual/None for the Enabled status.
  
  - `fnd:OSN_ENABLED_ATTR_BY_CUSTOMER` - Will be set to "true" on all attributes that the user selected to be Oracle Social Network enabled.

  In addition to the view object property being modified, the primary entity object for the view object will have these custom properties set upon it:

  - `fnd:OSN_EO_ENABLED_BY_CUSTOMER` - A mirror of the view object's `fnd:OSN_ENABLED_ATTR_BY_CUSTOMER` property.
  
  - `fnd:OSN_VIEW_OBJECT_NAME` - The fully-qualified name of the view object that will need to be used to send data to Oracle Social Network when a Data Manipulation Language (DML) event occurs on this entity object.

  Since the view object and entity object definition XML cannot be changed at runtime, these modifications will be stored in Oracle Metadata Services (MDS) at the persdef layer. For each view object that was displayed in the "Manage Social Network Objects" there will be four persdef files and entries stored. An example of these files are for the SndDemoDeptVO:

  ```
  persdef/oracle/apps/model/entity/mdssys/cust/site/site/SndDemoDeptEO.xml.xml
  persdef/oracle/apps/model/entity/SndDemoDeptEO.xml
  persdef/oracle/apps/model/view/SndDemoDeptVO.xml
  persdef/oracle/apps/model/view/mdssys/cust/site/site/SndDemoDeptVO.xml.xml
  ```

  These entries can be imported and exported if the enabled Oracle Social Network integration configuration must be ported between server instances.

- **Social Object Definition Is Sent to Oracle Social Network**

  After the view object Oracle Social Network enabled configuration has been stored into MDS view objects, the Oracle Social Network structure must be sent to Oracle Social Network as a Social Object definition. All view objects that have an Enabled status of Manual or Automatic will have the definition sent to Oracle Social Network. The Social Object definition provides details such as the attributes (name, data type) as Social Object field definitions and the translations for all of the attributes to be used as the field labels when a Social Object is shown to the user in Oracle Social Network.

  To see the registered definition on Oracle Social Network and confirm that it was correctly sent, the Oracle Social Network social definition can be directly retrieved
using the REST API. To return the Social Object definition, create a request in the following structure from within a web browser: `<Oracle Social Network URL>/social/api/v1/socialDefinition/<definition name>

The definition name is either the value of the fnd:OSN_DEFINITION_NAME property set on the view object by the developer or the family module name concatenated with the view object name (if the definition name was not set).

Using the SndDemoDeptVO example again, if it is in the FND family with an Oracle Social Network server of http://server_name.company.com:9003/osn, it would resolve to the Social Object definition URL of: http://server_name.company.com:9003/osn/social/api/v1/socialDefinition/FND.oracle.apps.model.view.SndDemoDeptVO.

When Save is clicked, a progress popup will be shown that displays the current status of the save and send to the OSN server.

67.5.4 Updating Translations

"Manage Social Network Objects" also provides updated translations. When the Social Object definition has been sent to Oracle Social Network by clicking Save, the initial set of translations is sent to the Oracle Social Network server for the view objects. However, users on a site can choose to enable more languages within Oracle Fusion Applications by loading language bundles. The Update Translations button provides a quick way to send all the Oracle Social Network enabled view object translations for all enabled languages to Oracle Social Network. For example, a site has been running in English and has registered the view objects as Social Object definitions on Oracle Social Network. The site then loads the French language. The site then can use Update Translations to send both the English and French translations for the Oracle Social Network enabled view object to Oracle Social Network, thereby allowing the user to see all of the field labels in French.

An individual view object can have its translations updated in isolation by selecting a view object in the Business Objects table and clicking Update Translations at the top of the Business Objects table.

What happens when clicking Update Translations

Each view object that is displayed that has an Enabled state of Automatic or Manual will have its translated strings for the view object and its attributes loaded and sent as a social definition update to Oracle Social Network. The only values that can change in this upload are the translated strings. To confirm if the new translations are correctly seeded in Oracle Social Network, the social definition URL for the view object can be used to see the translated strings for the Social Object definition.

When the page-level Update Translations button is clicked, a progress popup will be shown that displays the current status of the save and send to the Oracle Social Network server. The progress indicator is not shown for the Update Translation button in the Business Objects table.

67.5.5 Synchronizing

If there is an issue with a previous send to the Oracle Social Network server within the "Manage Oracle Social Network Objects" UI, or if a migration of Oracle Social Network integration configuration has occurred between servers, then the state of the definition on the Oracle Social Network server will be different from what is stored in persdef. To correct this, the Synchronize button was added. This will take the definitions of all view objects and resend them to Oracle Social Network. An individual view object can
be synchronized in isolation by selecting a view object in the Business Objects table and clicking Synchronize at the top of the Business Objects table.

**What Happens When Clicking Synchronize**

Each view object that is displayed and that has an Enabled state of Automatic/ Manual, will have its Oracle Social Network definition re-created and sent to the Oracle Social Network server. To confirm if the synchronized view objects are correctly seeded in Oracle Social Network, the social definition URL for the view object can be used to verify the Social Object definition. When the page-level Synchronize button is clicked, a progress popup will be shown that displays the current status of the send to the Oracle Social Network server. The progress indicator is not shown for the Synchronize button in the Business Objects table.

### 67.6 What Happens When End Users Interact with Oracle Social Network Object Instances

The only decision an end user needs to make is to share instances when Manual integration mode is enabled.

**Automatic Integration**

When Oracle Social Network is enabled as Automatic for a view object, end users will not see any visual signs that a send to Oracle Social Network has occurred with the data they just committed. The first that they will know about this is when they check in Oracle Social Network and the record has been created in Oracle Social Network. Any future updates or deletes (Oracle Social Network Conversation Close) also will be reflected in Oracle Social Network upon any further commits of the row.

**Manual Integration**

When Oracle Social Network is enabled as Manual for a view object, end users will be able to see the Oracle Social Network Share button on the page. If the users create or update the record, they will not see any information about that view object row in Oracle Social Network. After they have committed the row, they can click Share, which will do the initial send of the row data to Oracle Social Network. By clicking Share, after the initial record has been sent to Oracle Social Network, a new window will appear with the Conversation displayed within it (if the socialShare component was set to launch=true when it was configured in the page). Any future updates or deletes (Oracle Social Network Conversation Close) also will be reflected in Oracle Social Network upon any further commits of the row.

### 67.7 Test End-To-End Flow

The end-to-end test flow provides a basis for testing the Oracle Social Network integration implementation points to prove the success of the integration.

Testing requires that the roles for Oracle Fusion Developer and Provisioner have been completed successfully.

Follow these steps to test the flow:

1. After configuring the Oracle Fusion Developer role, deploy the model library that contains the META-INF/fnd-osn-integration.xml file and the view object definitions into an ADF Library JAR file.
2. Include this JAR file as a library in the Functional Setup Manager project.
3. Deploy and run the Functional Setup Manager in an Integrated WebLogic Server environment.

4. Log into the Functional Setup Manager and choose the Manage Social Network Objects task.

5. Find the view object that has been configured as available for Oracle Social Network integration, change it to have an Enabled state of **Automatic** and add all the attributes to the list of Oracle Social Network enabled attributes.

6. Click **Save** to keep the Automatic enabled state and attribute configuration, and send the Social Object registration to Oracle Social Network.

7. Deploy and run the application that uses the deployed library from the first step.

8. Log in to the application and find the product page that uses the view object.

9. Create a new row for the view object, fill in the required data and commit the row.

10. Log in to Oracle Social Network using the same user as logged in to the application and see the Social Object representing the newly-created or committed view object row.

---

**Note:**

The same MDS partition **must** be used for both Functional Setup Manager and for Oracle Fusion Applications. If this is not done, the Oracle Social Network integration will not occur between the two applications.
Work with the Application Taxonomy

This appendix describes the theory of the Oracle Fusion application taxonomy, how to view the taxonomy, and how to extract taxonomy data from a table and how to insert taxonomy data into a table.

This appendix describes:

• The theory of the application taxonomy
• How to view the taxonomy
• How to extract taxonomy data from a table and how to insert taxonomy data into a table

This appendix includes the following sections:

• Introduction to the Oracle Fusion Application Taxonomy
• Working with Objects and Methods in the Application Taxonomy
• Understanding Taxonomy MBeans

It is important to note that there is no tool for working with the taxonomy; developers use public business objects and do all work within JDeveloper. In general, only developers who are referring to modules, such as Application, will need to work with the taxonomy.

68.1 Introduction to the Oracle Fusion Application Taxonomy

The Oracle Fusion application taxonomy organizes the artifacts and functions of Oracle Fusion Applications into a hierarchical structure. Every Oracle Fusion development artifact or file is tagged. The structure starts with the Application Line and extends through the Logical Business Area.

Application Line
  Application Family
    Application
      Logical Business Area
      Logical Business Area

In the taxonomy user interface, the hierarchy would appear similar to the example shown in Figure 68-1:
68.1.1 Characteristics of the Level Categories

The taxonomy hierarchy provides a map of the dependencies that exist within an application and across applications.

Seed Data

The Oracle Fusion Applications Design Repository (ADR) team has provided Taxonomy seed data for the following levels in the hierarchy: Application Line, Family, Application, and Logical Business Area (LBA).

You can create as fine-grained an application taxonomy as you wish. You can break up an application into sub-applications or pseudo applications. For example, there are many setup use cases where an overall process is made up of many smaller subordinate processes.

68.1.2 How to Manage the Lifecycle

The applications taxonomy is especially useful in managing various phases of the application lifecycle. These phases include:

- Installation and Deployment
- Patch Creation
- System Administration
- Diagnostics and Maintenance

68.1.2.1 Creating Patches and Patch Sets

Patches and patch sets can be constructed based on the data defined in the taxonomy. You can choose any node of the taxonomy as the source for a patch file manifest. That starting node can scale all the way up to the top of the application taxonomy tree for a new release for the entire suite.

68.1.2.2 System Administration

System administrators monitoring performance, processes, system use, and so on, can use the application taxonomy to organize information and navigate to the level of detail they require. Administrator dashboards will start at higher levels of the taxonomy to provide broad overview of system status. When trouble is detected, the taxonomy can be used to drill down to where attention is required.
Patches will be tagged with the versions they contain. When a patch is applied, dependency information in the taxonomy can be used to determine which parts of the system will be affected. This can be used to assess system testing requirements after the patch is applied, or to schedule partial downtimes while patching is in progress.

68.1.2.3 Diagnostics and Maintenance

Diagnostic tests, logging, error messages, online help, support bulletins, and other artifacts are tagged with the module and version in the taxonomy to which they pertain. When trouble is detected, information from the customer’s system can be matched with these tags to direct them to appropriate assistance.

If the problem cannot be resolved through diagnostics and help, the taxonomy can be used to search for patches available for a particular module and version. Patches could be available at any level of the hierarchy, from one-offs, through larger roll-ups. The taxonomy can be used to follow the troublesome module up through the hierarchy to search for larger roll-ups that might be relevant.

If support is required, the taxonomy can be used to automatically construct Support Information Bundles, containing version information, with the results of diagnostics registered for these components.

68.1.3 Benefits of a Logical Hierarchy

The organization of the application taxonomy does not need to match the physical file directory structure, which is unlikely to consistently correspond to the functionality provided by those files. File directory structures often serve to group files according to a high level file type (such as all seed data files in one directory, all Java files in another directory, and so on), rather than by their functionality.

The applications’ Java EE package structure is a simple physical hierarchy based on the directory structure into which you organize your runtime files on disk. It is identical to the package structure that you use when defining Java class file packages. The concept has been expanded to also support metadata files, such as JSPX files. However, the information maintained by the application taxonomy supports many functional capabilities that cannot be supported by the standard Java EE package hierarchy.

Many of the artifacts that comprise a given application are shared among various applications and modules. The relationships among applications and artifacts constitute a network rather than a simple hierarchy, and are essential when interrogating and modeling dependencies. There is no support for such an integrated map of relationships in Java EE package structures.

There are other critical business requirements that cannot be satisfied by using a physical directory structure to organize an application hierarchy. Customers will often extend or subclass various runtime components to customize the application behavior to meet their specific business needs. Over time, application teams will wish to refine or refactor their application hierarchies as they add more features and functionality. Teams will want to refine or reorganize modules that leverage various artifacts. The application taxonomy’s logical definition of applications and their related runtime components saves customers from having to modify their references to these packages if the logical hierarchy is changed.

68.1.4 Delivery Hierarchy

In the application taxonomy, the delivery hierarchy is the master source for all the directories and files that comprise an application.
The delivery hierarchy represents the relationships between files and the application team that is responsible for the development, maintenance, and delivery of those files. Nodes within the delivery hierarchy have unique parents, so there is one path through the delivery hierarchy to any given file.

### 68.1.5 How to Integrate Taxonomy Task Flows into Oracle Fusion Functional Setup Manager

Every application registers task flows with the Functional Setup Manager that provides a single, unified user interface that allows customers and implementers to configure all Oracle applications by defining custom configuration templates or tasks based on their business needs.

The Functional Setup Manager UI enables customers and implementers to select the business processes or applications that they want to implement. For example, a Human Resources application can register setup activities like "Create Employees" and "Manage Employee Tree Structure" with the Functional Setup Manager. Trees task flows then provide the mechanism for an application team to register an activity such as "Manage Employee Tree Structure," which in this case, is a tree structure task flow with the tree structure code parameter set to some HR tree structure. Table 68-1 lists the task flow and its parameters.

<table>
<thead>
<tr>
<th>Task Flow Name</th>
<th>Task Flow XML</th>
<th>Patterns Passed</th>
<th>Behavior</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Manage Taxonomy Hierarchy</td>
<td>/WEB-INF/oracle/apps/fnd/applcore/taxonomy/ui/taskflow/ViewDeliveryHierarchy.xm#ViewDeliveryHierarchy</td>
<td>[pageTitle]</td>
<td>The Manage Taxonomy Hierarchy accepts the optional parameter [pageTitle] and navigates to the Taxonomy Delivery Hierarchy page.</td>
<td>This page serves as the starting point from which a user can select a particular node and perform the available actions, such as create, update, and view components for a selected node. From this page, a user can navigate to other task flows, such as Search Hierarchy, View Components and Search Components.</td>
</tr>
</tbody>
</table>

### 68.2 Working with Objects and Methods in the Application Taxonomy

You can use the application taxonomy at a lower level by using the public entity objects and view objects.

For example, you can create an association between the application team entity object, which has a foreign key reference to alternative_id in ApplTaxonomyPEO, and provided service methods to either join to the taxonomy table or to traverse through the taxonomy hierarchy using an API (for instance, to which Family does a given
Application belong?) or for other lookup information about the nodes (for instance, what is the short name for a given application?).

### 68.2.1 Particular Table Columns and Data

These items are applicable to some Oracle Fusion Middleware Extensions for Applications (Applications Core) tables.

**Who Columns**

All tables containing seeded or transaction data must include the Who columns shown in Table 68-2:

<table>
<thead>
<tr>
<th>Column Name</th>
<th>Type</th>
<th>Null?</th>
</tr>
</thead>
<tbody>
<tr>
<td>CREATED_BY</td>
<td>VARCHAR2 (64)</td>
<td>Not Null</td>
</tr>
<tr>
<td>CREATION_DATE</td>
<td>TIMESTAMP</td>
<td>Not Null</td>
</tr>
<tr>
<td>LAST_UPDATED_BY</td>
<td>VARCHAR2 (64)</td>
<td>Not Null</td>
</tr>
<tr>
<td>LAST_UPDATE_DATE</td>
<td>TIMESTAMP</td>
<td>Not Null</td>
</tr>
<tr>
<td>LAST_UPDATE_LOGIN</td>
<td>VARCHAR2 (32)</td>
<td></td>
</tr>
</tbody>
</table>

If the table has "extended Who" columns used to track updates by Oracle Enterprise Scheduler Service programs, the columns must be changed to those shown in Table 68-3. You do not need to add extended Who columns if the table does not already have them.

<table>
<thead>
<tr>
<th>Column Name</th>
<th>Type</th>
<th>Null?</th>
</tr>
</thead>
<tbody>
<tr>
<td>REQUEST_ID</td>
<td>NUMBER (20)</td>
<td>NULL</td>
</tr>
<tr>
<td>JOB_DEFINITION_NAME</td>
<td>VARCHAR2 (100)</td>
<td>NULL</td>
</tr>
<tr>
<td>JOB_DEFINITION_PACKAGE</td>
<td>VARCHAR2 (900)</td>
<td>NULL</td>
</tr>
</tbody>
</table>

**Replace RAW Columns with VARCHAR2**

Raw columns may only be used in internal tables that are never directly exposed in Oracle Application Development Framework (Oracle ADF).

- Columns containing user GUIDs should be changed to varchar(64).
- Columns containing all other GUIDs should be varchar2(32), and use rawtohex() to convert the raw GUID to a hex value.
- Raw columns containing anything else should be replaced with Binary Large Object (BLOB).
68.2.2 Denormalized Taxonomy Table

The ApplicationLine column of the Taxonomy table has been denormalized to allow data for multiple application lines to prevent hierarchical queries against the taxonomy table.

By default, the ApplicationLineCriteria will be applied on the view objects exposed on the view object by taxonomy (public and private) with the value of 1 for the Oracle Fusion application line. If you need to get data for another application line, you can set the appropriate value for the bind variable bProductLine.

The service methods use the default Oracle Fusion application line value of 1. The application module APIs that do not accept an application line id assume that the data is being queried for the Oracle Fusion application line.

If you query directly against the taxonomy tables, you must take into account the application line denormalization. You will have to add the filter product_line = <appropriate application line id> to prevent returning multiple rows for a given module key or id.

68.2.3 Available Public Business Objects

The following public entity objects are located in the oracle.apps.fnd.applcore.model.publicEntity package and are exposed by Applications Core:

- ApplTaxonomyPEO
- ApplTaxonomyTranslationPEO
- ApplTaxonomyHierarchyPEO

The following public view objects are located in the oracle.apps.fnd.applcore.model.publicView package and are exposed by Applications Core:

- ApplTaxonomyPVO: The view object on top of ApplTaxonomyPEO. It has these view criteria exposed:
  - ProductLineCriteria: Restricts the output to a given Application Line as specified by the bind variable bProductLine. By default, the ProductLineCriteria will be applied on the view objects exposed on the view object by Taxonomy (public and private) with the value of 1 for the Oracle Fusion application line. If you need to get data for another application line, you can set the appropriate value for the bind variable bProductLine.
  - IsSeedDataAllowedCriteria: where
    ApplTaxonomyEO.IS_SEED_DATA_ALLOWED=:bIsSeedDataAllowed, where :bIsSeedDataAllowed is a named bind variable with a default value of N.
  - ApplicationCriteria: Restricts the output to Applications Module Type.
  - FamilyCriteria: Restricts the output to Family Module Type.
  - ModuleIdCriteria: Restricts the output to a given module ID as specified by the bind variable bModuleId.
- **ModuleTypeCriteria**: Restricts the output to a given moduleType as specified by the bind variable `bModuleType`.

- **ApplTaxonomyTranslationPVO**: The view object on top of `ApplTaxonomyTranslationPEO`. It has these view criteria exposed:
  - **ProductLineCriteria**: where `ApplTaxonomyEO.PRODUCT_LINE=:bProductLine` where `:bProductLine` is a named bind variable with a default value of 1 - the Oracle Fusion Productline.
  - **IsSeedDataAllowedCriteria**: where `ApplTaxonomyEO.IS_SEED_DATA_ALLOWED=:bIsSeedDataAllowed`, where `:bIsSeedDataAllowed` is a named bind variable with a default value of `N`.

- **ApplTaxonomyHierarchyPVO**: The view object on top of `ApplTaxonomyHierarchyPEO`. It has these view criteria exposed:
  - **ProductLineCriteria**: where `ApplTaxonomyEO.PRODUCT_LINE=:bProductLine` where `:bProductLine` is a named bind variable with a default value of 1 - the Oracle Fusion Productline.
  - **IsSeedDataAllowedCriteria**: where `ApplTaxonomyEO.IS_SEED_DATA_ALLOWED=:bIsSeedDataAllowed`, where `:bIsSeedDataAllowed` is a named bind variable with a default value of `N`.

- **ApplTaxonomyHierarchyFullPVO**: Has a join between the hierarchy table's `source_module_id` and the taxonomy table's `module_id`, and between the hierarchy table's `target_module_id` and the taxonomy table's `module_id`. This view object is rarely needed. It has these view criteria exposed:
  - **ProductLineCriteria**: where `ApplTaxonomyEO.PRODUCT_LINE=:bProductLine` where `:bProductLine` is a named bind variable with a default value of 1 - the Oracle Fusion Productline.
  - **IsSeedDataAllowedCriteria**: where `ApplTaxonomyEO.IS_SEED_DATA_ALLOWED=:bIsSeedDataAllowed`, where `:bIsSeedDataAllowed` is a named bind variable with a default value of `N`.

- **ApplicationPVO**: This view object is shaped to match the Application view object that was on top of the FND_APPLICATIONS view. Note that `FND_APPLICATIONS`, which was a table in R12, has now been changed to a view on top of Taxonomy tables. It has these view criteria exposed:
  - **ProductLineCriteria**: where `ApplTaxonomyEO.PRODUCT_LINE=:bProductLine` where `:bProductLine` is a named bind variable with a default value of 1 - the Oracle Fusion Productline.
  - **IsSeedDataAllowedCriteria**: where `ApplTaxonomyEO.IS_SEED_DATA_ALLOWED=:bIsSeedDataAllowed`, where `:bIsSeedDataAllowed` is a named bind variable with a default value of `N`.
• **ApplTaxonomyFullDeliveryPVO** — This view object is a join between the Hierarchy table’s `source_module_id` and the Taxonomy table’s `module_id`. When a self-referential view link is created on this view object between the `source_module_id` and `target_module_id` (1..*), it can be used to traverse the taxonomy delivery hierarchy. For more details, see the non-public view object `ApplTaxonomyFullDeliveryVO` and its view link. It has these view criteria exposed:

  - **ProductLineCriteria**: where
    
    ```sql
    ApplTaxonomyEO.PRODUCT_LINE=:bProductLine
    where :bProductLine is a named bind variable with a default value of 1 – the Oracle Fusion Productline.
    ```

  - **IsSeedDataAllowedCriteria**: where
    
    ```sql
    ApplTaxonomyEO.IS_SEED_DATA_ALLOWED=:bIsSeedDataAllowed,
    where :bIsSeedDataAllowed is a named bind variable with a default value of N.
    ```

• **ApplTaxonomySeedDataPVO** — Used for extracting taxonomy seed data. It has these view criteria exposed:

  - **ProductLineCriteria**: where
    
    ```sql
    ApplTaxonomyEO.PRODUCT_LINE=:bProductLine
    where :bProductLine is a named bind variable with a default value of 1 – the Oracle Fusion Productline.
    ```

  - **IsSeedDataAllowedCriteria**: where
    
    ```sql
    ApplTaxonomyEO.IS_SEED_DATA_ALLOWED=:bIsSeedDataAllowed,
    where :bIsSeedDataAllowed is a named bind variable with a default value of N.
    ```

• **ApplTaxonomyApplicationPVO**

  - **ProductLineCriteria**: where
    
    ```sql
    ApplTaxonomyEO.PRODUCT_LINE=:bProductLine
    where :bProductLine is a named bind variable with a default value of 1 – the Oracle Fusion Productline.
    ```

  - **IsSeedDataAllowedCriteria**: where
    
    ```sql
    ApplTaxonomyEO.IS_SEED_DATA_ALLOWED=:bIsSeedDataAllowed,
    where :bIsSeedDataAllowed is a named bind variable with a default value of Y.
    ```

### 68.2.3.1 Access the Entity and View Objects

To access the Entity and View objects, and other taxonomy components, create a new **File System Connection** to `adflib`:

1. In the **Resource Palette**, open the folder icon and select **New Connection > File System** as shown in **Figure 68-2**:
2. Configure the new connection so it resembles the example in Figure 68-3:

**Figure 68-3 Configuring a New File System Connection**

3. The new connection will display in the Connections tree, shown in Figure 68-4:
4. The Entity and View objects are located in Taxonomy-Model.jar > Business Components, shown in Figure 68-5:

![Diagram](image1.png)

**Figure 68-5  Locating the Entity and View Objects in the Connections Tree**

### 68.2.4 How to Use Exposed Service Methods

**Note:**

- The service methods use the default Oracle Fusion Application Line value of 1. The application module APIs that do not accept an application line id assume that the data is being queried for the Oracle Fusion application line unless the API accepts the Taxonomy table primary key moduleId.

- The package for the private view objects and the application module conforms to Applications Packaging standards.

  The application module is
  `oracle.apps.fnd.applcore.taxonomy.taxonomyService.applicationModule`.

  The view objects module is
  `oracle.apps.fnd.applcore.taxonomy.taxonomyService.view`.

Two methods are exposed in the ApplTaxonomyAMImpl class:

- Given a module Id, this returns the taxonomy node:
  ```java
  public ApplTaxonomyFullDeliveryVORowImpl getTaxonomyModule(Raw moduleId);
  ```

- Given a moduleType, this returns an array of taxonomy nodes:
public ApplTaxonomyFullDeliveryVORowImpl[] getTaxonomyModules(String moduleType);

To access a taxonomy application module:

Note:
The ApplTaxonomyAMImpl package is oracle.apps.fnd.applcore.taxonomy.taxonomyService.applicationModule.

ApplTaxonomyAMImpl am = (ApplTaxonomyAMImpl)OAApplicationModuleImpl.getFNDNestedService(OAConstants.TAXONOMY_SERVICE, myAM.getDBTransaction());

Where myAM is the application module that you are working with. You can also create an instance of the ApplTaxonomyAMImpl class directly as needed.

To access a taxonomy node for a given application module, you can call the getTaxonomyModule() API on the module ID:

```
ApplTaxonomyFullDeliveryVORowImpl row = am.getTaxonomyModule(new oracle.jbo.domain.Raw("025000"));
```

To access the module name for that node, you can make a call to getModuleName():

```
String moduleName = row.getModuleName();
```

To access a set of taxonomy nodes for a given module type, you can call the getTaxonomyModules() API:

```
ApplTaxonomyFullDeliveryVORowImpl[] rows = am.getTaxonomyModules("FAMILY");
```

The following methods also are exposed:

- Given an application short name, return the application ID:
  getApplicationId(String shortName);

- Given an application ID, return the application short name:
  getApplicationShortName(int appid);

These APIs work if the existing data in FND_APPLICATIONS has been migrated to the Oracle Application Taxonomy tables.

68.2.5 How to Traverse the Taxonomy Hierarchy

The taxonomy delivery hierarchy can be navigated using the accessors for the children and parents.

To obtain the children of the current node, call getFirstChildApplTaxonomyFullDeliveryVO(), as shown in Example 68-1:

To obtain the parent of the current node, call getParentChildApplTaxonomyFullDeliveryVO(), as shown in Example 68-2.

Example 68-1 Obtaining the Children of the Current Node

```
RowIterator children = row getChildApplTaxonomyFullDeliveryVO();
while (children.hasNext())
{
    ApplTaxonomyFullDeliveryVORowImpl childRow =
```
68.3 Understanding Taxonomy MBeans

Taxonomy MBeans are useful for obtaining information about Oracle Fusion taxonomy, such as domain, application family, application, modules (UI, SOA, Webservices), and admin log configuration. These MBeans are available as Domain Runtime MBeans in WebLogic Server and expose several APIs, each of which provides specific information about the taxonomy of a deployed Oracle Fusion environment. These MBeans are consumed by application teams as utility APIs to verify information about their applications, and are also integrated with other applications. For instance Enterprise Manager for Oracle Fusion uses these APIs for building the discovery user interfaces. Taxonomy MBeans are registered into the application-defined MBeans after the administration server startup.

**Types of Taxonomy MBeans**

Two types of Taxonomy MBeans are available:

- **Topology MBean**: Provides information about the topology of the Oracle Fusion environment. Topology MBean data is dependent on the domain against which it is tested. In a particular domain, such as Setup, you can have more than one Product Family.

- **Log Configuration MBean**: Provides utilities for configuring logs at both User- and Site-level in an application.

MBeans as viewed from Enterprise Manager are shown in Figure 68-6.

**Figure 68-6  MBeans Viewed from Enterprise Manager**

![Topology MBean](image)

**Topology MBean Details:**

- Configuration MBeans
- Runtime MBeans
- Application-Defined MBeans
  - Environment
  - OracleApps
  - oracle.apps.fnd.appcore.diagnostics.config.mbean
  - oracle.apps.fnd.appcore.diagnostics.runtime.mbean
  - Oracle Node List
  - OracleAppsInfo
  - Domain: DefaultDomain
    - ConfigurationRuntimeMBean
    - TopologyRuntimeMBean

- More...
Attributes exposed by Topology MBeans are shown in Table 68-4.

**Table 68-4  Attributes Exposed by Topology MBeans**

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
<th>Access</th>
</tr>
</thead>
<tbody>
<tr>
<td>AllProductFamilyAndDomains</td>
<td>Gets all domains and product families of an Oracle Fusion instance.</td>
<td>R</td>
</tr>
<tr>
<td>ConfigMBean</td>
<td>If true, it indicates that this is a Config MBean.</td>
<td>R</td>
</tr>
<tr>
<td>CurrentDomain</td>
<td>Gets the current domain.</td>
<td>R</td>
</tr>
<tr>
<td>CurrentPillarInfo</td>
<td>Get the current pillar.</td>
<td>R</td>
</tr>
<tr>
<td>CurrentPillarInstanceInfo</td>
<td>Returns all information about current PillarInstanceName.</td>
<td>R</td>
</tr>
<tr>
<td>CurrentProductFamily</td>
<td>Gets the current product family module key list.</td>

Sample Code to Invoke MBean APIs

Sample code is shown in Example 68-3.

Example 68-3  Sample Code to Invoke MBean APIs

```java
String appShortName  = "<ESS/Service Name>";
MBeanServerConnection serverCon =
    ServiceLocator.getInstance().getServerConnection(jmxURL, jmxKey);
ObjectName serviceMBean = new ObjectName("oracle.topology:Location=DefaultServer,name=Topology,
    type=TopologyRuntimeMBean,Application=Topology");
TabularData domainInfo = (TabularData) serverCon.invoke(serviceMBean,
    "getEndPointInfo",
    new Object[]{appShortName},
    new String[]{String.class.getName() } );
Collection domainProps = domainInfo.values();
Iterator iterator = domainProps.iterator();
while (iterator.hasNext())
```
{CompositeData data = (CompositeData) iterator.next();
String AppShortName = (String) data.get("AppShortName");
String CloudName = (String) data.get("CloudName");
String DeployedDomainName = (String) data.get("DeployedDomainName");
String LogicalDomainName= (String) data.get("LogicalDomainName");
String InternalEndPoint = (String) data.get("InternalEndPoint");
String ExternalEndPoint = (String) data.get("ExternalEndPoint");
String AdminEndPoint = (String) data.get("AdminEndPoint");
}
This appendix provides a reference for the commands available for the Oracle Enterprise Crawl and Search (ECSF) Command Line Administration Utility. You can use the ECSF Command Line Administration Utility to quickly test and manage the searchable objects without having to use Oracle Enterprise Manager Fusion Applications Control for ECSF.

### 69.1 ECSF Command Line Administration Utility Commands

Table 69-1 shows the commands you can use to administer search. The commands appear in alphabetical order.

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>activate object ID</td>
<td>Activates a searchable object so that a query of it returns results. Specify the ID number corresponding to the searchable object you want to activate.&lt;br&gt;Only a searchable object that has been deployed can be activated.&lt;br&gt;Customized searchable objects cannot be activated using the ECSF Command Line Administration Utility. You must activate customized searchable objects by using the Fusion Applications Control for ECSF.</td>
</tr>
<tr>
<td>add object ID to category ID</td>
<td>Associates the searchable object you specify with the search category you specify. Specify the ID number corresponding to the searchable object you want to add to the search category, and specify the ID number corresponding to the search category to which you want to add the searchable object.&lt;br&gt;Searchable objects must be deployed before you can associate them with search categories. Search categories must be undeployed before you can associate searchable objects with them. You can associate the same searchable object with multiple search categories. You must issue the command while managing the search engine instance with which the search category is associated.</td>
</tr>
</tbody>
</table>
### ECSF Command Line Administration Utility Commands

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>add object to category ID</strong></td>
<td>Associates a searchable object with the search category you specify. Specify the ID number corresponding to the search category to which you want to add the searchable object. The ECSF Command Line Administration Utility displays a list of available searchable objects and prompts you to enter the ID corresponding to the searchable object you want to associate with the search category. Searchable objects must be deployed before you can associate them with search categories. Search categories must be undeployed before you can associate searchable objects with them. You can associate the same searchable object with multiple search categories. You must issue the command while managing the search engine instance with which the search category is associated.</td>
</tr>
<tr>
<td><strong>add object ID to schedule ID</strong></td>
<td>Associates the searchable object you specify with the index schedule you specify. Specify the ID number corresponding to the searchable object you want to add to the index schedule, and specify the ID number corresponding to the index schedule to which you want to add the searchable object. Searchable objects must be deployed before you can associate them with index schedules. You can only associate each searchable object with one index schedule. Only a searchable object that is not already associated with an index schedule can be added to an index schedule. Index schedules must be undeployed before you can associate searchable objects with them. You must issue the command while managing the search engine instance with which the index schedule is associated.</td>
</tr>
<tr>
<td><strong>add object to schedule ID</strong></td>
<td>Associates the searchable object you specify with the index schedule you specify. Specify the ID number corresponding to the index schedule to which you want to add the searchable object. The ECSF Command Line Administration Utility displays a list of available searchable objects and prompts you to enter the ID corresponding to the searchable object you want to associate with the index schedule. Searchable objects must be deployed before you can associate them with index schedules. You can only associate each searchable object with one index schedule. Only a searchable object that is not already associated with an index schedule can be added to an index schedule. Index schedules must be undeployed before you can associate searchable objects with them. You must issue the command while managing the search engine instance with which the index schedule is associated.</td>
</tr>
<tr>
<td><strong>add unassigned object to instance</strong></td>
<td>Associates a searchable object with the specified search engine instance. The ECSF Command Line Administration Utility displays a list of available searchable objects and prompts you to enter the ID corresponding to the searchable object you want to add to the search engine instance. You must issue the command while managing the search engine instance to which you want to add the searchable object. A searchable object can only be associated with one search engine instance at a time.</td>
</tr>
<tr>
<td><strong>add unassigned object ID to instance</strong></td>
<td>Associates a searchable object with the specified search engine instance. Specify the ID corresponding to the searchable object you want to add to the search engine instance. You must issue the command while managing the search engine instance to which you want to add the searchable object. A searchable object can only be associated with one search engine instance at a time.</td>
</tr>
<tr>
<td>Command</td>
<td>Description</td>
</tr>
<tr>
<td>---------------------------------</td>
<td>-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>connect to database</td>
<td>Creates the connection to a database using a system identifier (SID). Follow the prompts to enter a username and password, as well as field values.</td>
</tr>
<tr>
<td>connect to database hostname port SID</td>
<td>Creates the connection to a database using a system identifier (SID). Specify the host name, port number, and SID. Follow the prompts to enter a username and password.</td>
</tr>
<tr>
<td>connect to database descriptor</td>
<td>Creates the connection to a database using a database descriptor. Follow the prompts to enter a username and password, as well as field values.</td>
</tr>
<tr>
<td>connect to database descriptor 'descriptor'</td>
<td>Creates the connection to a database using a database descriptor. Specify the descriptor, enclosing it in quotes, with either the system identifier (SID) or service name, for example: Using SID: ' (DESCRIPTION= (ADDRESS= (PROTOCOL= tcp) (HOST= fusionhost123) (PORT=5521)) (CONNECT_DATA= (SID= dbmsdb2)))' Using service name: ' (DESCRIPTION= (ADDRESS= (PROTOCOL= tcp) (HOST= fusionhost123) (PORT=5521)) (CONNECT_DATA= (SERVICE_NAME= myservice)))' Follow the prompts to enter a username and password.</td>
</tr>
<tr>
<td>connect to database service</td>
<td>Creates the connection to a database using a service name. Follow the prompts to enter a username and password, as well as field values.</td>
</tr>
<tr>
<td>connect to database service host name port servicename</td>
<td>Creates the connection to a database using a service name. Specify the host name, port number, and service name. Follow the prompts to enter a username and password.</td>
</tr>
<tr>
<td>connect to mbeanserver</td>
<td>Creates the connection to an MBean server. Follow the prompts to enter a username and password, as well as field values.</td>
</tr>
<tr>
<td>connect to mbeanserver hostname port</td>
<td>Creates the connection to an MBean server. Specify the host name and port number. Follow the prompts to enter a username and password.</td>
</tr>
<tr>
<td>create category</td>
<td>Adds a new search category to the ECSF_SEARCH_INDEX_GROUP table in the Oracle Fusion Applications database. Follow the prompts to enter field values. If you issue the command while managing a search engine instance, the search category is automatically associated with the search engine instance you are managing. If you issue the command outside a search engine instance context, the ECSF Command Line Administration Utility displays a list of the available search engine instances and prompts you to choose a search engine instance for the search category you want to create.</td>
</tr>
</tbody>
</table>
Table 69-1 (Cont.) ECSF Command Line Administration Utility Commands

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>create category set</td>
<td>Adds a new search category to the ECSF_SEARCH_INDEX_GROUP table in the Oracle Fusion Applications database. Directly pass in field name-value pairs with the command. The field names and values must be enclosed in quotes. If the field name or value contains a quote, escape it with a backslash, for example, &quot;field name with &quot;escaped&quot; quotes&quot;. If you issue the command while managing a search engine instance, the search category is automatically associated with the search engine instance you are managing. If you issue the command outside of a search engine instance context, the ECSF Command Line Administration Utility displays a list of the available search engine instances and prompts you to choose a search engine instance for the search category you want to create.</td>
</tr>
<tr>
<td>create instance</td>
<td>Adds a new search engine instance to the specified search engine type. Follow the prompts to enter field values. You must issue the command while not managing a search engine instance.</td>
</tr>
<tr>
<td>create instance set</td>
<td>Adds a new search engine instance to the specified search engine type. Directly pass in field name-value pairs with the command. The field names and values must be enclosed in quotes. If the field name or value contains a quote, escape it with a backslash, for example, &quot;field name with &quot;escaped&quot; quotes&quot;. You must issue the command while not managing a search engine instance.</td>
</tr>
<tr>
<td>create object</td>
<td>Adds a new searchable object to the specified search engine type. Follow the prompts to enter field values. If you issue the command while managing a search engine instance, the searchable object is automatically associated with the search engine instance you are managing. If you issue the command outside a search engine instance context, the ECSF Command Line Administration Utility displays a list of the available search engine instances and prompts you to choose a search engine instance for the searchable object you want to create.</td>
</tr>
<tr>
<td>create schedule</td>
<td>Adds a new index schedule to the ECSF_INDEX_SCHEDULE table in the Oracle Fusion Applications database. Follow the prompts to enter field values. If you issue the command while managing a search engine instance, the index schedule is automatically associated with the search engine instance you are managing. If you issue the command outside a search engine instance context, the ECSF Command Line Administration Utility displays a list of the available search engine instances and prompts you to choose a search engine instance for the index schedule you want to create.</td>
</tr>
<tr>
<td>create schedule set</td>
<td>Adds a new index schedule to the ECSF_INDEX_SCHEDULE table in the Oracle Fusion Applications database. Directly pass in field name-value pairs with the command. The field names and values must be enclosed in quotes. If the field name or value contains a quote, escape it with a backslash, for example, &quot;field name with &quot;escaped&quot; quotes&quot;. If you issue the command while managing a search engine instance, the index schedule is automatically associated with the search engine instance you are managing. If you issue the command outside a search engine instance context, the ECSF Command Line Administration Utility displays a list of the available search engine instances and prompts you to choose a search engine instance for the index schedule you want to create.</td>
</tr>
<tr>
<td>Command</td>
<td>Description</td>
</tr>
<tr>
<td>-------------------------</td>
<td>-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>create unassigned object</td>
<td>Adds a new searchable object to the specified search engine type. Follow the prompts to enter field values. The searchable object is not associated with a search engine instance.</td>
</tr>
<tr>
<td>deactivate object ID</td>
<td>Deactivates a searchable object so that a query of it does not return results. Specify the ID number corresponding to the searchable object you want to deactivate. Only an activated searchable object can be deactivated. Deactivated searchable objects are still available for the search engine instance to crawl.</td>
</tr>
<tr>
<td>delete category ID</td>
<td>Disassociates the specified search category from the search engine instance and removes it from the ECSF_SEARCH_INDEX_GROUP table in the Oracle Fusion Applications database. Specify the ID number corresponding to the search category you want to delete. You must issue the command while managing the search engine instance with which the search category is associated.</td>
</tr>
<tr>
<td>delete external category ID</td>
<td>Removes the specified external search category from the ECSF_SEARCH_INDEX_GROUP table in the Oracle Fusion Applications database and makes it unavailable for querying. Specify the ID number of the external searchable category you want to delete.</td>
</tr>
<tr>
<td>delete instance ID</td>
<td>Removes the specified search engine instance. You cannot delete search engine instances while you are managing an engine instance. You cannot delete a search engine instance if there are any deployed objects, categories, or schedules associated with it.</td>
</tr>
<tr>
<td>delete object ID</td>
<td>Removes the specified assigned searchable object (associated with a search engine instance) from the ECSF schema in the Oracle Fusion Applications database. You must issue the command while managing the search engine instance with which the searchable object is associated. If the searchable object has been deployed, you must undeploy it before you can delete its record from the database.</td>
</tr>
<tr>
<td>delete schedule ID</td>
<td>Disassociates the specified index schedule from the search engine instance and removes it from the ECSF_INDEX_SCHEDULE table in the Oracle Fusion Applications database. Specify the ID corresponding to the index schedule you want to delete. You must issue the command while managing the search engine instance with which the index schedule is associated.</td>
</tr>
<tr>
<td>delete unassigned object ID</td>
<td>Removes the specified unassigned searchable object (not associated with a search engine instance) from the ECSF schema in the Oracle Fusion Applications database.</td>
</tr>
<tr>
<td>deploy category ID</td>
<td>Deploys the specified search category to the search engine instance. Specify the ID number corresponding to the search category you want to deploy. Searchable objects must be associated with the search category before you can deploy it. You must issue the command while managing the search engine instance with which the search category is associated.</td>
</tr>
<tr>
<td>Command</td>
<td>Description</td>
</tr>
<tr>
<td>--------------------------</td>
<td>---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>deploy object ID</td>
<td>Deploy the searchable object you specify to the search engine instance to make the objects available for the search engine instance to crawl. Specify the ID number corresponding to the searchable object you want to deploy. The searchable objects deployed to the search engine instance must have a unique and fully qualified name, for example, oracle.apps.crm.Opportunity or oracle.apps.hcm.Opportunity. Only a searchable object that is associated with a search engine instance can be deployed.</td>
</tr>
<tr>
<td>deploy params for objects</td>
<td>Collectively updates all deployed searchable objects with the latest search engine instance parameters.</td>
</tr>
<tr>
<td>deploy params for object ID</td>
<td>Updates the specified searchable object with the latest search engine instance parameters.</td>
</tr>
<tr>
<td>deploy schedule ID</td>
<td>Deploys the specified index schedule to the search engine instance. Specify the ID number corresponding to the index schedule you want to deploy. Searchable objects must be associated with the index schedule before you can deploy it. You must issue the command while managing the search engine instance with which the index schedule is associated.</td>
</tr>
<tr>
<td>disconnect</td>
<td>Disconnects you from the current database or MBean server connection.</td>
</tr>
<tr>
<td>exit</td>
<td>Closes the ECSF Command Line Administration Utility.</td>
</tr>
<tr>
<td>help</td>
<td>Lists all the available help commands.</td>
</tr>
<tr>
<td>help activate</td>
<td>Lists the valid syntax for the activate command.</td>
</tr>
<tr>
<td>help add</td>
<td>Lists the valid syntax for the add commands.</td>
</tr>
<tr>
<td>help category</td>
<td>Lists the commands that can be used for search categories.</td>
</tr>
<tr>
<td>help connect</td>
<td>Lists the valid syntax for the connect commands</td>
</tr>
<tr>
<td>help create category</td>
<td>Lists the fields available for the create category commands.</td>
</tr>
<tr>
<td>help create instance</td>
<td>Lists the fields available for the create instance commands.</td>
</tr>
<tr>
<td>help create object</td>
<td>Lists the fields available for the create object command.</td>
</tr>
<tr>
<td>help create schedule</td>
<td>Lists the fields available for the create schedule command.</td>
</tr>
<tr>
<td>help create unassigned object</td>
<td>Lists the fields available for the create unassigned object command.</td>
</tr>
<tr>
<td>help create schedule</td>
<td>Lists the fields available for the create schedule commands.</td>
</tr>
<tr>
<td>help deactivate</td>
<td>Lists the valid syntax for the deactivate object command.</td>
</tr>
<tr>
<td>help delete</td>
<td>Lists the valid syntax for the delete commands.</td>
</tr>
<tr>
<td>help deploy</td>
<td>Lists the valid syntax for the deploy commands.</td>
</tr>
<tr>
<td>help disconnect</td>
<td>Lists the valid syntax for the disconnect command.</td>
</tr>
<tr>
<td>Command</td>
<td>Description</td>
</tr>
<tr>
<td>---------------------</td>
<td>-----------------------------------------------------------------------------</td>
</tr>
<tr>
<td>help instance</td>
<td>Lists the commands that can be used for search engine instances.</td>
</tr>
<tr>
<td>help list</td>
<td>Lists the valid syntax for the list commands.</td>
</tr>
<tr>
<td>help manage</td>
<td>Lists the valid syntax for the manage commands.</td>
</tr>
<tr>
<td>help object</td>
<td>Lists the commands that can be used for searchable objects.</td>
</tr>
<tr>
<td>help param</td>
<td>Lists the commands that can be used for search engine instance parameters.</td>
</tr>
<tr>
<td>help remove</td>
<td>Lists the valid syntax for the remove commands.</td>
</tr>
<tr>
<td>help schedule</td>
<td>Lists the commands that can be used for index schedules.</td>
</tr>
<tr>
<td>help set</td>
<td>Lists the valid syntax for the set commands.</td>
</tr>
<tr>
<td>help showdetails</td>
<td>Lists the valid syntax for the showdetails commands.</td>
</tr>
<tr>
<td>help start</td>
<td>Lists the valid syntax for the start command.</td>
</tr>
<tr>
<td>help stop</td>
<td>Lists the valid syntax for the stop command.</td>
</tr>
<tr>
<td>help unassigned object</td>
<td>Lists the commands that can be used for unassigned searchable objects.</td>
</tr>
<tr>
<td>help undeploy</td>
<td>Lists the valid syntax for the undeploy commands.</td>
</tr>
<tr>
<td>help unmanage</td>
<td>Lists the valid syntax for the unmanage commands.</td>
</tr>
<tr>
<td>help update category</td>
<td>Lists the fields available for the update category commands.</td>
</tr>
<tr>
<td>help update instance</td>
<td>Lists the fields available for the update instance commands.</td>
</tr>
<tr>
<td>help update schedule</td>
<td>Lists the fields available for the update schedule commands.</td>
</tr>
<tr>
<td>help register object</td>
<td>Lists the fields available for the register object commands.</td>
</tr>
<tr>
<td>import external categories</td>
<td>Lists one by one all the external categories of the search engine instance you are managing and prompts you to confirm whether you want to import each external category. Enter Y to import the external category, which adds it to the ECSF_SEARCH_INDEX_GROUP table in the Oracle Fusion Applications database. Enter N to cancel the importing of the external category. The default value is N. All external search categories that have been previously imported will be replaced by the latest import from Oracle Secure Enterprise Search (Oracle SES). If you had previously deleted any of the records corresponding to the external search categories, you must delete them again to make them unavailable for querying.</td>
</tr>
<tr>
<td>Command</td>
<td>Description</td>
</tr>
<tr>
<td>---------</td>
<td>-------------</td>
</tr>
<tr>
<td>import external categories for instance ID</td>
<td>Lists one by one all the external categories of the search engine instance you specify and prompts you to confirm whether you want to import each external category. Enter Y to import the external category, which adds it to the ECSF_SEARCH_INDEX_GROUP table in the Oracle Fusion Applications database. Enter N to cancel the importing of the external category. The default value is N. All external search categories that have been previously imported will be replaced by the latest import from Oracle Secure Enterprise Search (Oracle SES). If you had previously deleted any of the records corresponding to the external search categories, you must delete them again to make them unavailable for querying.</td>
</tr>
<tr>
<td>list categories</td>
<td>Lists the search categories and their corresponding ID numbers for the search engine instance you are managing.</td>
</tr>
<tr>
<td>list categories for instance ID</td>
<td>Lists the search categories and their corresponding ID numbers for the search engine instance you specify. Specify the ID number corresponding to the desired search engine instance.</td>
</tr>
<tr>
<td>list external search categories</td>
<td>Lists the external search categories and their corresponding ID numbers for the search engine instance you are managing.</td>
</tr>
<tr>
<td>list external search categories for instance ID</td>
<td>Lists the external search categories and their corresponding ID numbers for the search engine instance you specify. Specify the ID number corresponding to the desired search engine instance.</td>
</tr>
<tr>
<td>list instances</td>
<td>Lists the search engine instances and their corresponding ID numbers</td>
</tr>
<tr>
<td>list objects</td>
<td>Lists a summary of the searchable objects associated with the search engine instance you are managing.</td>
</tr>
<tr>
<td>list objects for category ID</td>
<td>Lists a summary of the searchable objects associated with the search category you specify. Specify the ID number corresponding to the desired search category.</td>
</tr>
<tr>
<td>list objects for instance ID</td>
<td>Lists a summary of the searchable objects associated with the search engine instance you specify. Specify the ID number corresponding to the desired search engine instance.</td>
</tr>
<tr>
<td>list objects for schedule ID</td>
<td>Lists a summary of the searchable objects associated with the index schedule you specify. Specify the ID number corresponding to the desired index schedule.</td>
</tr>
<tr>
<td>list params for instance</td>
<td>Lists the parameters that are available for the set param command for the engine instance you are managing.</td>
</tr>
<tr>
<td>list params for instance ID</td>
<td>Lists the parameters that are available for the set param command for the search engine instance you specify. Specify the ID number corresponding to the desired search engine instance.</td>
</tr>
<tr>
<td>list schedules</td>
<td>Lists the index schedules associated with the search engine instance you are managing.</td>
</tr>
<tr>
<td>list schedules for instance ID</td>
<td>Lists the index schedules associated with the search engine instance you specify. Specify the ID number corresponding to the desired search engine instance.</td>
</tr>
<tr>
<td>Command</td>
<td>Description</td>
</tr>
<tr>
<td>---------</td>
<td>-------------</td>
</tr>
<tr>
<td>list unassigned objects</td>
<td>Lists the unassigned searchable objects (not associated with a search engine instance) and their corresponding ID numbers.</td>
</tr>
<tr>
<td>manage instance</td>
<td>Sets the context to the specified search engine instance. The ECSF Command Line Administration Utility lists all the search engine instances and their corresponding ID numbers and prompt you for the ID number of the search engine instance you want to manage.</td>
</tr>
<tr>
<td>manage instance ID</td>
<td>Sets the context to the search engine instance you specify. Specify the ID number corresponding to the search engine instance you want to manage.</td>
</tr>
<tr>
<td>register idplugin</td>
<td>Registers an identity plug-in for the instance you are managing. The deployment of the Federated Trust Entity occurs when the identity plug-in is registered.</td>
</tr>
<tr>
<td>register idplugin for instance ID</td>
<td>Registers an identity plug-in for the search engine instance you specify. Specify the ID number corresponding to the desired search engine instance. The deployment of the Federated Trust Entity occurs when the identity plug-in is registered.</td>
</tr>
<tr>
<td>register object</td>
<td>Associates the specified searchable object with the search engine instance you are managing and creates a new record for the searchable object in the ECSF schema of the Oracle Fusion Applications database. Follow the prompts to enter field values. For BO Name, you must enter a fully qualified view object name defined in your application.</td>
</tr>
<tr>
<td>register object set &quot;fieldname&quot;=&quot;value&quot;,&quot;fieldname&quot;=&quot;value&quot;...</td>
<td>Associates the specified searchable object with the search engine instance you are managing and creates a new record for the searchable object in the Oracle Fusion Applications database. Directly pass in field name-value pairs with the command.</td>
</tr>
<tr>
<td>The field names and values must be enclosed in quotes. If the field name or value contains a quote, escape it with a backslash, for example, &quot;field name with escaped&quot; quotes.</td>
<td></td>
</tr>
<tr>
<td>register unassigned object</td>
<td>Creates a new record of an unassigned searchable object (not associated with a search engine instance) in the Oracle Fusion Applications database. Follow the prompts to enter field values. For BO Name, you must enter a fully qualified view object name defined in your application.</td>
</tr>
<tr>
<td>register unassigned object set &quot;fieldname&quot;=&quot;value&quot;,&quot;fieldname&quot;=&quot;value&quot;...</td>
<td>Creates a new record of an unassigned searchable object (not associated with a search engine instance) in the Oracle Fusion Applications database. Directly pass in field name-value pairs with the command.</td>
</tr>
<tr>
<td>The field names and values must be enclosed in quotes. If the field name or value contains a quote, escape it with a backslash, for example, &quot;field name with escaped&quot; quotes.</td>
<td></td>
</tr>
<tr>
<td>remove object from category ID</td>
<td>Disassociates a searchable object from the search category you specify. Specify the ID number corresponding to the search category from which you want to disassociate the searchable object. The ECSF Command Line Administration Utility displays a list of searchable objects and prompts you to enter the ID corresponding to the searchable object you want to remove from the search category.</td>
</tr>
<tr>
<td>You must issue the command while managing the search engine instance with which the search category is associated. The searchable object is still available for association to other search categories.</td>
<td></td>
</tr>
<tr>
<td>Command</td>
<td>Description</td>
</tr>
<tr>
<td>---------</td>
<td>-------------</td>
</tr>
<tr>

Configure Attachments Component Properties

This appendix provides information about the properties that you can use to change the default behavior of the Attachments, Attachments Carousel, and Attachment Views components user interfaces.

This appendix includes the following sections:

• About Configuring the Attachments Component UI
• About Configuring the Attachments Carousel UI
• About Configuring the Attachment Views Components UI
• About Configuring the Attachment Link Component UI

70.1 About Configuring the Attachments Component UI

The default behavior of the Attachments component can be changed by setting the properties on the component using the Property Inspector.

Following is a list of some of the properties that are supported by the Attachment component. The following table contains basic descriptions of why and how each property is used.

The most important properties to take note of are:

• mode - This property drives the UI that is rendered. It is automatically set when you add attachments to your page and should not be changed. Mode values include link, table, and columnLink.

• repositoryMode - This property indicates whether a user is aware of the content repository. Additional options appear for these users (repositoryMode=true), allowing them to perform advanced functions such as selecting repository files and folders to attach to the business object, and checking in and checking out attached files.

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mode</td>
<td>String. Acceptable values are link, columnLink, and table.</td>
<td>The mode property is set automatically at the time the component is created.</td>
</tr>
</tbody>
</table>

<td>Boolean: <code>true</code> / <code>false</code>. Enables/disables the update icons in the attachments table toolbar. These include the &quot;Check In&quot;, &quot;Check Out&quot; and &quot;Cancel Check Out&quot; icons. This property also enables/disables the users' ability to update the Category, Title and Description of the Attachments. True: enables the icons and makes the Category, Title and Description columns editable for existing attachments. False: disables the update icons and makes the Category, Title and Description columns read-only for existing attachments.</td>
<td>True</td>
</tr>
<tr>
<td>UpdateEnabled</td>
<td>Boolean: <code>true</code> / <code>false</code>. Controls show/hide of the update icons in the attachments table toolbar. These include the &quot;Check In&quot;, &quot;Check Out&quot; and &quot;Cancel Check Out&quot; icons. True: shows the update icons in the toolbar. False: hides the update icons in the toolbar.</td>
<td>True</td>
</tr>
<tr>
<td>InsertMultiple</td>
<td>Boolean: <code>true</code> / <code>false</code>. Determines whether more than one attachment can be assigned. False: User can only add a one attachment.</td>
<td>True</td>
</tr>
<tr>
<td>DeleteAllowed</td>
<td>Boolean: <code>true</code> / <code>false</code>. Enables/disables the &quot;Delete&quot; icon in the attachments toolbar and inline for link and columnLink modes. True: Deleting attachments is allowed. True: enables the icon. False: disables the icon.</td>
<td>True</td>
</tr>
<tr>
<td>DeleteEnabled</td>
<td>Boolean: <code>true</code> / <code>false</code>. Controls show/hide of the &quot;Delete&quot; icon in the attachments table toolbar. True: shows the icon in the toolbar. False: hides the icon in the toolbar preventing users from deleting attachments.</td>
<td>True</td>
</tr>
<tr>
<td>ViewAllowed</td>
<td>Boolean: <code>true</code> / <code>false</code>. True: Viewing attachments is allowed. False: Links for viewing documents in Attachments tables are disabled.</td>
<td>True</td>
</tr>
<tr>
<td>DefaultCategory</td>
<td>String. Value selected as the default in the Category poplist when adding new attachments.</td>
<td></td>
</tr>
<tr>
<td>Rendered</td>
<td>Boolean: <code>true</code> / <code>false</code>. True: Component is rendered in the page. False: the component is not rendered.</td>
<td>True</td>
</tr>
<tr>
<td>Id</td>
<td>String. The identifier of the component.</td>
<td>Auto-generated</td>
</tr>
</tbody>
</table>
### Table 70-1 (Cont.) Attachments Component Properties

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Visible</td>
<td>Boolean: <code>true</code> / <code>false</code>. True: the component is displayed in the page. False: the component is hidden.</td>
<td>True</td>
</tr>
<tr>
<td>Description</td>
<td>String. Displays string as a tip when the user hovers the cursor over the Attachment component.</td>
<td></td>
</tr>
<tr>
<td>Label</td>
<td>String. Specifies the title for the Attachment popup.</td>
<td>Attachment</td>
</tr>
<tr>
<td>AutoHeightRows</td>
<td>Number. Sets the maximum number of rows that the table height will automatically adjust to depending on the amount of data in the table.</td>
<td>10</td>
</tr>
<tr>
<td>ContentDelivery</td>
<td>String. This property is only used with the AutoHeightRows property. If AutoHeightRows is not set, this property should be not be set either.</td>
<td>Immediate</td>
</tr>
<tr>
<td>RowBandingInterval</td>
<td>Number. The interval between which the row banding occurs. This value controls the display of the row banding in the table. For example, <code>rowBandingInterval=1</code> would display alternately banded rows in the grid.</td>
<td></td>
</tr>
<tr>
<td>ColumnBandingInterval</td>
<td>Number. The interval between which the column banding occurs. This value controls the display of the column banding in the table. For example, <code>columnBandingInterval=1</code> would display alternately banded columns in the grid.</td>
<td></td>
</tr>
<tr>
<td>ShowCategory</td>
<td>Boolean: <code>true</code> / <code>false</code>. Controls show/hide of the Category column in the Attachments table.</td>
<td>True</td>
</tr>
<tr>
<td>UpdateCategoryList</td>
<td>String. Stores a comma-separated list of Category Names that will be used at run time to populate Category LOV when a user adds new attachments or attempts to update the Category of an existing attachment. This list must be a subset of the Categories that are assigned to your Entity.</td>
<td></td>
</tr>
<tr>
<td>SecondaryToolbarRendered</td>
<td>Boolean: <code>true</code> / <code>false</code>. True: shows the secondary toolbar. False: hides the icon in the toolbar.</td>
<td>False</td>
</tr>
<tr>
<td>ReadOnly</td>
<td>Boolean: <code>true</code> / <code>false</code>. True disables all creation/update/delete functions in the Attachment component at runtime.</td>
<td>False</td>
</tr>
<tr>
<td>attachmentsTrigger</td>
<td>String. For use when an Attachment component and Attachment Carousel component are on the same page. The Carousel component can be refreshed only when a change is made to the visible details in the Attachment component. Rather than being refreshed on every user event. Enter a space separated list of Attachment Carousel component IDs.</td>
<td></td>
</tr>
</tbody>
</table>
### Table 70-1  (Cont.) Attachments Component Properties

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>enableOrdering</td>
<td>String. Provides the end user with the option to control the order the attachment rows are displayed in the table. Set to <code>true</code> to enable.</td>
<td></td>
</tr>
<tr>
<td>enablePrimaryCategory</td>
<td>String. Users can designate one attachment to be the primary from all of the attachments assigned to a category. Set to <code>true</code> to enable.</td>
<td></td>
</tr>
<tr>
<td>UseResetActionListener</td>
<td>Boolean: <code>true</code> / <code>false</code>. True Activates the declarative af:resetActionListener which is associated with the OK and Cancel buttons for each popup in the Attachments component. The resetActionListener resets all of the values submitted to avoid the data in the form from being stale. For more information, see &quot;How to Use a Command Component to Reset Input Fields&quot; in Developing Web User Interfaces with Oracle ADF Faces.</td>
<td><code>false</code></td>
</tr>
<tr>
<td>fieldRenderOff</td>
<td>String. A space-separated list of fields that will not be rendered into the page. The fields are Attached By (attachedBy), Attached Date (attachedDate), Description, Shared, and Checked Out By (checkedOutBy).</td>
<td></td>
</tr>
<tr>
<td>fuse</td>
<td>Boolean: <code>true</code> / <code>false</code>. True renders the attachment component for a FUSE UI page. Only link mode is supported for FUSE.</td>
<td><code>false</code></td>
</tr>
<tr>
<td>confirmDelete</td>
<td>Boolean: <code>true</code> / <code>false</code>. True displays the Delete Attachment Confirmation page when the delete icon is used.</td>
<td><code>true</code></td>
</tr>
</tbody>
</table>

**Note:**

Activating the `enableOrdering` or `enablePrimaryCategory` properties on an existing page will require an update to the page bindings. Do the following:

1. Select the **Page Bindings** tab. In the Bindings list, select the Attachment Model.
2. Click on the link at the top of the page for the Page Definition File. The file will open with the Attachments collection selected.
3. At the bottom of the selection, add two new attributes so that the end of the entry looks like this:

```xml
<Item Value="SeqNum"/>
<Item Value="PrimaryCategoryFlag"/>
</AttrNames>
</nodeDefinition>
```
70.2 About Configuring the Attachments Carousel UI

The default behavior of the Attachments Carousel component can be changed by setting the properties on the component using the Property Inspector.

Note:
Most of the attributes map directly to either the Attachment, Carousel or CarouselItem attributes. Wherever there is overlap of attribute names, either Carousel or CarouselItem has been prefixed to assist in identifying which attribute is being set.

Following is a list of some of the properties that are supported by the Attachments Carousel component. Refer to Table 70-2 for basic descriptions of why and how each property is used.

The most important property to take note of is:

repositoryMode - This property indicates whether a user is aware of the content repository. Additional options appear for these users (repositoryMode=true), allowing them to perform advanced functions such as selecting repository files and folders to attach to the business object, and checking in and checking out attached files.

Table 70-2  Attachments Carousel Component Properties

</tr>
<tr>
<td>label</td>
<td>String. Specifies the title for the Attachment popup.</td>
<td>Attachment</td>
</tr>
<tr>
<td>rows</td>
<td>Number. Maximum number of rows to display in a single range of rows in attachment table. Some ranges may have fewer than the number specified here, i.e. the last range when there is an insufficient number of rows. To display all rows at once, set this attribute value to 0.</td>
<td>10</td>
</tr>
<tr>
<td>showCategory</td>
<td>Boolean: true / false. Controls show/hide of the Category column in the Attachments table.</td>
<td>True</td>
</tr>
<tr>
<td>auxiliaryOffset</td>
<td>Number. The offset shift factor that a carousel item will have relative to its nearest item towards the current carousel item in circular displayItems mode. This is the distance an auxiliary item will be moved from its nearest item towards the current item (the distance is the size of the next nearest item multiplied by this offset factor).</td>
<td></td>
</tr>
<tr>
<td>auxiliaryPopOut</td>
<td>String. Valid Values: off, hover; whether mouse movements within the auxiliary item area of the carousel in circular displayItems mode causes the auxiliary items to be scaled to match the current carousel item.</td>
<td>off</td>
</tr>
<tr>
<td>Property</td>
<td>Description</td>
<td>Default Value</td>
</tr>
<tr>
<td>------------------</td>
<td>-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
<td>---------------</td>
</tr>
<tr>
<td>auxiliaryScale</td>
<td>Number. The size scaling factor that a carousel item will have relative to its nearest item towards the current carousel item in circular displayItems mode. A value of 1 means the auxiliary items will all be the same size. A value less than 1 means the auxiliary items will become smaller the further they are from the current item. A value greater than 1 means the auxiliary items will become larger the further they are from the current item. Note that regardless of item size, the current carousel item is the only item that is interactive; clicking on an auxiliary item will only spin the carousel.</td>
<td></td>
</tr>
<tr>
<td>controlArea</td>
<td>String. Valid Values: full, small, compact, none; specifies how the area where the user spins the carousel is presented. The “full” option lets a user spin through carousel items one at a time, jump to a specific item, or drag the slider thumb to continuously spin the carousel until the mouse is let go. The “small” option lets a user click the next and previous buttons to spin through carousel items one at a time. The “compact” option is similar to “small” but omits details such as the “x of y” progress information. The “none” option provides no control area at all.</td>
<td>full</td>
</tr>
<tr>
<td>displayItems</td>
<td>String. Valid Values: circular, oneByOne; the current carousel item will always be shown but you can use this attribute to specify how the auxiliary carousel items are displayed. Use “circular” if you want the auxiliary items displayed near the current item in a scaled down pattern with as many items shown as will fit. Use “oneByOne” if you only want the current item shown.</td>
<td>circular</td>
</tr>
<tr>
<td>emptyText</td>
<td>String. The text of an empty carousel. If the text is enclosed in an open and closing html tag, it will be formatted. The formatting behavior is similar to outputFormatted component. If it is not enclosed in an open and closing html tag, it will not be formatted.</td>
<td></td>
</tr>
<tr>
<td>ReadOnly</td>
<td>Boolean: true / false. True: disables all creation/update/delete functions in the Attachment component at runtime.</td>
<td>False</td>
</tr>
<tr>
<td>addAllowed</td>
<td>Boolean: true / false. Enables/disables the “Add” icon in the attachments table toolbar. True: enables the icon in the toolbar. False: disables the icon in the toolbar.</td>
<td>True</td>
</tr>
<tr>
<td>addEnabled</td>
<td>Boolean: true / false. Enables/disables the “Add” icon in the attachments table toolbar. True: shows the icon in the toolbar. False: hides the icon in the toolbar.</td>
<td>True</td>
</tr>
</tbody>
</table>
### Table 70-2 (Cont.) Attachments Carousel Component Properties

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>updateAllowed</td>
<td>Boolean: <em>true / false</em>. Enables/disables the update icons in the attachments table toolbar. These include the &quot;Check In&quot;, &quot;Check Out&quot; and &quot;Cancel Check Out&quot; icons. This property also enables/disables the users' ability to update the Category, Title and Description of the Attachments. True: enables the icons and makes the Category, Title and Description columns editable for existing attachments. False: disables the update icons and makes the Category, Title and Description columns read-only for existing attachments.</td>
<td>True</td>
</tr>
<tr>
<td>updateEnabled</td>
<td>Boolean: <em>true / false</em>. Controls show/hide of the update icons in the attachments table toolbar. These include the &quot;Check In&quot;, &quot;Check Out&quot; and &quot;Cancel Check Out&quot; icons. True: shows the update icons in the toolbar. False: hides the update icons in the toolbar.</td>
<td>True</td>
</tr>
<tr>
<td>deleteAllowed</td>
<td>Boolean: <em>true / false</em>. Enables/disables the &quot;Delete&quot; icon in the attachments toolbar and inline for link and columnLink modes. True: Deleting attachments is allowed. True: enables the icon. False: disables the icon.</td>
<td>True</td>
</tr>
<tr>
<td>deleteEnabled</td>
<td>Boolean: <em>true / false</em>. Controls show/hide of the &quot;Delete&quot; icon in the attachments table toolbar. True: shows the icon in the toolbar. False: hides the icon in the toolbar preventing users from deleting attachments.</td>
<td>True</td>
</tr>
<tr>
<td>viewAllowed</td>
<td>Boolean: <em>true / false</em>. True: Viewing attachments is allowed. False: Links for viewing documents in Attachments tables are disabled.</td>
<td>True</td>
</tr>
<tr>
<td>viewEnabled</td>
<td>Boolean: <em>true / false</em>. True: shows the update icons in the toolbar. False: hides the update icons in the toolbar.</td>
<td>True</td>
</tr>
<tr>
<td>confirmDelete</td>
<td>Boolean: <em>true / false</em>. True: displays the Delete Attachment Confirmation page when the delete icon is used.</td>
<td>True</td>
</tr>
<tr>
<td>EnableOrdering</td>
<td>String. Allows the end-user to modify the display order of the attachments. This can be performed via keyboard commands or a reorder Attachments dialog launched from the Attachments Action menu.</td>
<td>False</td>
</tr>
<tr>
<td>Property</td>
<td>Description</td>
<td>Default Value</td>
</tr>
<tr>
<td>------------------------</td>
<td>-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
<td>---------------</td>
</tr>
<tr>
<td>carouselContentDelivery</td>
<td>Valid Values: immediate, lazy; whether data should be fetched when the component is rendered initially. When contentDelivery is &quot;immediate&quot;, data is fetched and inlined into the component chrome. If contentDelivery is &quot;lazy&quot;, data will be fetched and delivered to the client during a subsequent request.</td>
<td>lazy</td>
</tr>
<tr>
<td>fetchSize</td>
<td>Number. The number of rows in the data fetch block. Not supported on the following renderkits: org.apache.myfaces.trinidad.core</td>
<td>25</td>
</tr>
<tr>
<td>first</td>
<td>Number. The index of the first row in the currently range of rows. This index is zero-based. This attribute is used to control which range of rows to display to the user.</td>
<td>0</td>
</tr>
<tr>
<td>carouselImmediate</td>
<td>Boolean: true / false. Whether or not data validation - client-side or server-side - should take place when events are generated by this component. When immediate is true, the default ActionListener provided by the JavaServer Faces implementation should be executed during Apply Request Values phase of the request processing lifecycle, rather than waiting until the Invoke Application phase.</td>
<td>False</td>
</tr>
<tr>
<td>carouselRows</td>
<td>Number. The maximum number of rows to display in a single range of rows. Some ranges might have fewer than the number of rows specified by this attribute (eg: the last range might have an insufficient number of rows). To display all rows at once, set this attribute to 0. The default is 25.</td>
<td>25</td>
</tr>
<tr>
<td>RowBandingInterval</td>
<td>Number. The interval between which the row banding occurs. This value controls the display of the row banding in the table. For example, rowBandingInterval=1 would display alternately banded rows in the grid.</td>
<td></td>
</tr>
<tr>
<td>attachmentModel</td>
<td>CollectionModel</td>
<td></td>
</tr>
<tr>
<td>deleteMessage</td>
<td>String. Message to be displayed on Delete Attachment confirmation page.</td>
<td>Are you sure you want to delete the selected attachment(s)?</td>
</tr>
<tr>
<td>Description</td>
<td>String. Displays string as a tip when the user hovers the cursor over the Attachment component.</td>
<td></td>
</tr>
<tr>
<td>useResetActionListener</td>
<td>Boolean: true / false.</td>
<td>False</td>
</tr>
<tr>
<td>inlineStyle</td>
<td>String</td>
<td>width:950px</td>
</tr>
</tbody>
</table>
### Table 70-2  (Cont.) Attachments Carousel Component Properties

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>carouselStyleClass</td>
<td>String. A Cascading Style Sheet (CSS) style class to use for this component. The style class can be defined in your string and skinning CSS file, for example, or you can use one of our public style classes, like &quot;AFInstructionText&quot;.</td>
<td>width:500.0px; height:300.0px;</td>
</tr>
<tr>
<td>carouselInlineStyle</td>
<td>String. The CSS styles to use for this component. This is intended for basic style changes. The inlineStyle is a set of CSS styles that are applied to the root DOM element of the component. If the inlineStyle's CSS properties do not affect the DOM element you want affected, then you will have to create a skin and use the skinning keys which are meant to target particular DOM elements, like ::label or ::icon-style.</td>
<td>width:500.0px; height:300.0px;</td>
</tr>
<tr>
<td>carouselItemInlineStyle</td>
<td>String. the CSS styles to use for this component. This is intended for basic style changes. The inlineStyle is a set of CSS styles that are applied to the root DOM element of the component. If the inlineStyle's CSS properties do not affect the DOM element you want affected, then you will have to create a skin and use the skinning keys which are meant to target particular DOM elements, like ::label or ::icon-style.</td>
<td>width:200px;</td>
</tr>
<tr>
<td>UseResetActionListener</td>
<td>Boolean: true / false. True Activates the declarative af:resetActionListener which is associated with the OK and Cancel buttons for each popup in the Attachments component. The resetActionListener resets all of the values submitted to avoid the data in the form from being stale. For more information, see &quot;How to Use a Command Component to Reset Input Fields&quot; in Developing Web User Interfaces with Oracle ADF Faces.</td>
<td>False</td>
</tr>
<tr>
<td>fieldRenderOff</td>
<td>String. A space-separated list of fields that will not be rendered into the page. The fields are Attached By (attachedBy), Attached Date (attachedDate), Description, Shared, and Checked Out By (checkedOutBy).</td>
<td></td>
</tr>
<tr>
<td>carouselItemViewer</td>
<td>String: custom. When the property is set to custom, the Attachments Carousel component will use the customCarouselItem facet for the Carousel Item rather than the default Carousel Item.</td>
<td></td>
</tr>
</tbody>
</table>

A facet (placeholder) is provided on the Attachments Carousel component for product teams to develop their own Carousel Item. The facet customCarouselItem is provided. To enable the facet to be shown instead of the default Carousel Item set the property carouselItemViewer to custom.

The facet tableAppsTableSecondaryToolbar is provided to add toolbar buttons to the Attachments Table toolbar.
## 70.3 About Configuring the Attachment Views Components UI

The default behavior of the Attachment Views component can be changed by setting properties on the component using the Property Inspector.

### Table 70-3  Attachment Views Component Properties

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>actionEntity</td>
<td>String. This must be an Attachment Entity Name. For use when showing the attachments for multiple entities in the Attachments table/popup. Setting this property indicates that update and delete actions will only be possible on this entity.</td>
<td></td>
</tr>
<tr>
<td>actionItemsRendered</td>
<td>String: true / false. Controls whether the Actions menu is rendered in the toolbar.</td>
<td>False</td>
</tr>
<tr>
<td>addAllowed</td>
<td>Boolean: true / false. Enables/disables the Add icon in the toolbar. True: enables the icon in the toolbar. False: disables the icon in the toolbar.</td>
<td>True</td>
</tr>
<tr>
<td>addEnabled</td>
<td>Boolean: true / false. True: shows the icon in the toolbar. False: hides the icon in the toolbar.</td>
<td>True</td>
</tr>
<tr>
<td>additionalListInlineActionItems</td>
<td>Boolean: true / false. True: shows the Inline Action Items facet for the List View. False: hides the facet.</td>
<td>False</td>
</tr>
<tr>
<td>additionalListInlineIconItems</td>
<td>Boolean: true / false. True: shows the Inline Icon Items facet for the List View. False: hides the facet.</td>
<td>False</td>
</tr>
<tr>
<td>additionalTableInlineActionItems</td>
<td>Boolean: true / false. True: shows the Inline Action Items facet for the Table View. False: hides the facet.</td>
<td>False</td>
</tr>
<tr>
<td>additionalTableInlineIconItems</td>
<td>Boolean: true / false. True: shows the Inline Icon Items facet for the Table View. False: hides the facet.</td>
<td>False</td>
</tr>
<tr>
<td>approvalEnabled</td>
<td>Boolean: true / false. True: Adds the Status field to the Detail pane.</td>
<td>False</td>
</tr>
<tr>
<td>attachmentModel</td>
<td>Collection Model. Required.</td>
<td></td>
</tr>
<tr>
<td>binding</td>
<td>Binding (EL only). An EL reference that will store the component instance on a bean. This can be used to give programmatic access to a component from a backing bean, or to move creation of the component to a backing bean.</td>
<td></td>
</tr>
<tr>
<td>confirmDelete</td>
<td>Boolean: true / false. True displays the Delete Attachment Confirmation dialog when the delete icon is used.</td>
<td>True</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>defaultCategory</td>
<td>String. Value selected as the default in the Category poplist when adding new attachments.</td>
<td></td>
</tr>
<tr>
<td>deleteEnabled</td>
<td>Boolean: true / false. Controls show/hide of the Delete icon in the attachments table toolbar. True: shows the icon in the toolbar. False: hides the icon in the toolbar preventing users from deleting attachments.</td>
<td>True</td>
</tr>
<tr>
<td>deleteMessage</td>
<td>String. Message to be displayed on Delete Attachment confirmation page.</td>
<td></td>
</tr>
<tr>
<td>displayViews</td>
<td>String. A space-separated list of views to show. The views are all, table, and list. The default is all, which will show table and list views. It also automatically includes the planned grid and carousel views.</td>
<td>All</td>
</tr>
<tr>
<td>enablePrimaryCategory</td>
<td>String. Users can designate one attachment to be the primary from all of the attachments assigned to a category. Set to true to enable.</td>
<td>False</td>
</tr>
<tr>
<td>fieldRenderOff</td>
<td>String. A space-separated list of fields that will not be rendered into the page. The fields are Attached By (attachedBy), Attached Date (attachedDate), Description, Shared, and checked Out By (checkedOutBy).</td>
<td></td>
</tr>
<tr>
<td>gridItems</td>
<td>Number. Maximum number of cards to display for the grid view.</td>
<td>25</td>
</tr>
</tbody>
</table>
## Table 70-3  (Cont.) Attachment Views Component Properties

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
</table>
| id           | String. The identifier for the component. Every component may be named by a component identifier that must conform to the following rules:
  • They must start with a letter (as defined by the Character.isLetter() method) or underscore ( _ ).
  • Subsequent characters must be letters (as defined by the Character.isLetter() method), digits as defined by the Character.isDigit() method, dashes (-), or underscores ( _ ). To minimize the size of responses generated by JavaServer Faces, it is recommended that component identifiers be as short as possible. If a component has been given an identifier, it must be unique in the namespace of the closest ancestor to that component that is a NamingContainer (if any). | Auto-generated               |
| label        | String. Specifies the title for the Attachment popup.                       | #{applcoreBundle.ATTACHMENT_LABEL} |
| listItems    | Number. Maximum number of rows to display for the List View.                | 10                           |
| listItemViewer | String.                                                                     | Default                      |
| orderingEnabled | String. Provides the end user with the option to control the order the attachment rows are displayed in the table. Set to true to enable. | False                        |
| readOnly     | Boolean: true / false. True disables all creation/update/delete functions in the Attachment component at runtime. | False                        |
| redlineKey   | String. Null, or a comma-separated concatenation of the Entity Name and PK1_VALUE through PK5_VALUEs. Empty tailing PK Values do not need to be included. Supplying a non-null value triggers a comparison of the Attachments for the current record and the record identified by the supplied key. |                              |
| rendered     | Boolean: true / false. True: Component is rendered in the page. False: the component is not rendered. | True                         |
| sortEnabled  | String: true / false. Controls the visibility of the Sort dropdown list in the toolbar. | False                        |
### Table 70-3 (Cont.) Attachment Views Component Properties

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>sortFeaturesOff</td>
<td>String. A space-separated list of fields that will not be included in the Sort dropdown list. The fields are Title, Description, Category, Checked Out By (checkedOutBy), Shared, Last Updated By (lastUpdatedBy), Last Update Date (lastUpdateDate), Status, Size.</td>
<td></td>
</tr>
<tr>
<td>typesEnabled</td>
<td>String. A space-separated list of attachment types that are available for use in the Attachments Views component. The types are – all, file, text, and URL. The default &quot;all&quot; type automatically provides access to all current and any future Attachment types.</td>
<td>All</td>
</tr>
<tr>
<td>updateAllowed</td>
<td>Boolean: true / false. Enables/disables the users' ability to update the Category, Title and Description of the Attachments. True: Makes the Category, Title and Description columns editable for existing attachments. False: Makes the Category, Title and Description columns read-only for existing attachments.</td>
<td>True</td>
</tr>
<tr>
<td>updateCategoryList</td>
<td>String. Stores a comma-separated list of category names that will be used at runtime to populate the category LOV when a user adds new attachments or attempts to update the category of an existing attachment. This list must be a subset of the categories that are assigned to your entity.</td>
<td></td>
</tr>
<tr>
<td>updateEnabled</td>
<td>Boolean: true / false. Controls show/hide of the update icons in the toolbar. These include the &quot;Check In&quot;, &quot;Check Out&quot; and &quot;Cancel Check Out&quot; icons. True: shows the update icons in the toolbar. False: hides the update icons in the toolbar.</td>
<td>True</td>
</tr>
<tr>
<td>visible</td>
<td>Boolean: true / false. True: the component is displayed in the page. False: the component is hidden.</td>
<td>True</td>
</tr>
</tbody>
</table>

The Attachment Views component is a declarative component composed of a number of Oracle Application Development Framework components. The following are the principal components that make up the Attachment Views component:

- List
  - List Item
- Grid
  - Grid Item
• Carousel
  – Carousel Item

• Table
  – Column
    * Category
    * Title
    * Description
    * CheckedOutBy
    * Shared
    * LastUpdatedBy
    * Status
    * Size

Properties for each of these items that are not already used by the Attachments View to provide specific functionality have been exposed. To provide a unique name for common property names, a prefix has been added to the sub-components. This helps to differentiate the InlineStyle property on the Category column and the InlineStyle on the Title column from the InlineStyle of the table itself. For example, tableColumnCategoryInlineStyle, tableColumnTitleInlineStyle and tableInlineStyle are prepended with table.

For consistency, the label and visible properties for the Attachment fields have been consolidated into their own properties. Rather than having to override the label for Title in the table view, list view and Details pane, you can set the property just once and it will display across all of the occurrences.

The following table provides the full set of configuration properties, along with descriptions of what each property does, as found in the Oracle Application Development Framework tag documentation.

---

**Note:**

The properties for the Grid, Grid Item, Carousel and Carousel Item will be used when the Grid and Carousel views become available in the future.

---

<tbody>
<tr>
<td>tableColumnStretching</td>
<td>Indicates what kind of stretching to apply to the columns. For optimal performance, use the &quot;none&quot; (default) option. To stretch the last column to fill up any unused space inside of the viewport, use the &quot;last&quot; option. To automatically insert an empty blank column and have it stretch (so the row background colors will span the entire width of the table), use the &quot;blank&quot; option. To stretch a specific leaf (non-group) column to fill up any unused space inside of the viewport, use the option where you specify &quot;column:&quot; followed by the ID of the column that you want to have stretched, for example, &quot;column:myColId&quot;. To stretch more than one column, use the &quot;multiple&quot; option. When using the &quot;multiple&quot; option, you can set the widths in the columns (non-group) to be percentages. See the column documentation for how percentages are handled. Note that row headers and frozen columns will not be stretched because doing so could easily leave the user unable to access the scrollable data body of the table. Not supported on the following renderkits: org.apache.myfaces.trinidad.core</td>
<td>column:colDesc</td>
</tr>
<tr>
<td>tableContentDelivery</td>
<td>String. Use this property only with the AutoHeightRows property. If AutoHeightRows is not set, this property also should be not be set.</td>
<td>Immediate</td>
</tr>
<tr>

<tr>
<td>tableShortDesc</td>
<td>String. The short description of the component. The shortDesc text may be used in two different ways, depending on the component. For components with images, the shortDesc is often used to render an HTML &quot;Alt&quot; attribute for the image. shortDesc is also commonly used to render an HTML title attribute, which is used by user agents to display &quot;tooltip&quot; help text. In this case, the behavior of the tooltip is controlled by the user agent. For example, Firefox 2 truncates long tooltips. For form components, the shortDesc is displayed in a note window. For components that support the helpTopicId attribute and are not using the shortDesc as image Alt text, it is recommended that helpTopicId is used instead of shortDesc because it is more flexible and provides more accessible descriptive text than the use of the title attribute.</td>
<td>#{applcoreBundle.AA_TABLE_SUMMARY}</td>

### 70.4 About Configuring the Attachment Link Component UI

The default behavior of the Attachment Link Component can be changed by setting properties on the component using the Property Inspector. The majority of the properties available are only used to configure how the Attachment Views component appears in the popup. See Configuring the Attachment Views Component UI (http://aseng-wiki.us.oracle.com/asengwiki/display/ATG/Release+10+Uptake#Release10Uptake-ConfiguringtheAttachmentViewsComponentUI) for more information on these properties. The following table documents the properties that directly affect the Attachment Link component.

**Table 70-5 Attachment Link Component Properties.**

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>attachmentModel</td>
<td>Collection Model. Required.</td>
<td>No default value</td>
</tr>
</tbody>
</table>
### Table 70-5 (Cont.) Attachment Link Component Properties.

<table>
<thead>
<tr>
<th>Property</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>id</td>
<td>String. The identifier for the component. Every component may be named by a component identifier that must conform to the following rules: They must start with a letter (as defined by the Character.isLetter() method) or underscore ( _ ). Subsequent characters must be letters (as defined by the Character.isLetter() method), digits as defined by the Character.isDigit() method, dashes ( - ), or underscores ( _ ). To minimize the size of responses generated by JavaServer Faces, it is recommended that component identifiers be as short as possible. If a component has been given an identifier, it must be unique in the namespace of the closest ancestor to that component that is a NamingContainer (if any).</td>
<td>Auto-generated</td>
</tr>
<tr>
<td>linkMode</td>
<td>String: Classic, Abridged. Required. Specifies how the component should display. Classic will display with information about the last attachment, and action icons. Abridged will display as a single icon.</td>
<td>Classic</td>
</tr>
<tr>
<td>numAttachmentsDisplayed</td>
<td>Number. Maximum number of attachments displayed as links in the hover popup when mode is set to link or columnLink.</td>
<td>3</td>
</tr>
<tr>
<td>linkDeleteAllowed</td>
<td>String. Enables the display of the delete icon. This setting will not override the deleteAllowed or readOnly properties, which will also affect the display of the delete icon.</td>
<td>true</td>
</tr>
<tr>
<td>savepointListener</td>
<td>AttachmentSavepointListener.</td>
<td>No default value</td>
</tr>
<tr>
<td>Property</td>
<td>Description</td>
<td>Default Value</td>
</tr>
<tr>
<td>-------------------------------</td>
<td>-----------------------------------------------------------------------------</td>
<td>---------------</td>
</tr>
<tr>
<td>skipValidationOnPopup</td>
<td>String; default, true, false, skipDataControls, validateCurrentRows. Controls whether the model validation is skipped for the binding container, while the Manage Attachments popup is displayed. The default value does not change the skip validation configuration. Set to false to perform a normal validation. Set to true to skip all validation. Set to skipDataControls to skip only data control validation. Set to validateCurrentRows to validate only the rows modified in the last request.</td>
<td>default</td>
</tr>
</tbody>
</table>
**Glossary**

**all-segment secondary usage**
A type of secondary usage in which the secondary table has all of the key flexfield segment columns that are present in the combinations table.

**application role**
A role specific to applications and stored in the policy store.

**Application Technology Group (ATG)**
Also known as ApplCore for "Applications Core."
A layer of runtime and design time features that deliver functionality targeted specifically for Oracle Fusion Applications.

**autosuggest**
Suggestions that automatically appear for a search field, even before you finish typing your search term. You can select any of the suggestions to run your search.

**business component**
One of a set of cooperating components that are used by ADF Business Components to implement a business service.

**business object**
A resource in an enterprise database, such as an invoice or purchase order.

**CCID**
Code combination ID, the common attribute for key flexfields. Every key flexfield combinations table must have a CCID column, the values of which identify each data row.

**child view object**
A view object that is nested within a master view object.
**code combination ID (CCID)**

See CCID.

**code-combination reference page**

Pages whose underlying entity objects contain a foreign key reference to the combinations table.

**combination maintenance page**

A page whose underlying entity objects use the combinations table itself.

**consumer (of a flexfield)**

The person who incorporates a flexfield into their application, which is typically different from the producer's application. The consumer typically stores the CCID on a transaction table, and works with the structural and seed data and the business components that have been configured by the key flexfield producer.

**context**

A group of attributes. Each context is part of a flexfield, and is comprised of a set of context-sensitive segments that store a particular type of related information.

**context attribute**

The flexfield base view object attribute that contains the context discriminator value.

**context-sensitive segment**

A flexfield segment that is a member of a context.

**custom validation callout**

Callout procedure that is used to enforce custom validation logic for new code combinations beyond what has been defined for cross-validation rules.

**customer flexfield**

A flexfield created for use by the customer.

**cross-validation rule**

A rule that is composed of a condition filter and a validation filter and that specifies when and how to validate a key flexfield code combination.

**data security**

The control of access to data. Data security controls what action a user can take against which data.
**database schema**

A named collection of objects, such as tables, views, clusters, procedures, packages, attributes, object classes, and their corresponding matching rules, which are associated with a particular user.

**derived segment**

A segment whose values automatically change to reflect new reference values.

**descriptive flexfield**

A type of flexfield used to give additional attributes to a data model. Allows customers to add custom attributes to entities, to define how the attributes are validated, and display properties for the attributes. These attributes do not necessarily have anything to do with each other and are not treated together as a combination. A descriptive flexfield can only support a set amount of segments.

**developer (of a flexfield)**

The role to be used if you are incorporating the flexfield into an application.

**developer flexfield**

A flexfield created to support functionality that has been built into the application.

**discriminator**

A common attribute amongst multiple view rows. The discriminator determines which view row type should be used.

**dynamic column**

A method of accessing a flexfield in Excel. Using a dynamic column will enable you to pick flexfield segment values. You can also enter values directly into the segment fields.

**dynamic combination insertion**

The act of end users entering values on an application page that constitute new code combinations (even if the end users are not authorized to perform maintenance tasks directly).

**EAR**

An Enterprise Archive file. A Java EE archive file that is used in deploying applications on a Java EE application server. Framework applications are deployed using both a generic EAR file, which contains the application and the respective runtime customization, and a targeted EAR file, which contains only the application for deployment to the application server.
Enterprise Archive (EAR)

See EAR.

etitlement

Grants of access to functions and data. Oracle Fusion Middleware term for privilege.

descriptive flexfield

A type of flexfield that is similar to a descriptive flexfield, but does not have a fixed number of segments, allows attributes to be grouped, allows entities to inherit segments from their parents, and supports one-to-many relationships between entity and extended attribute rows.

entity object

An object that represents a row in a database table and that simplifies modifying its data by handling all data manipulation language operations for you. Entity objects are ADF Business Components that provide the mapping to underlying data structures.

flexfield

An "expandable" data field that is divided into segments. Flexfields enable you to configure your applications to meet your business needs without having to perform custom development.

flexfield parameter

A declared public variable which can be used to designate which attributes of eligible entity objects that are related to the flexfield can be used to pass external reference data to flexfield segments. These entity objects could, in turn, take their values from column values, constant values, session attributes, and so forth.

form layout

A typical label/prompt and either view-only data or widget (text field, choice list, and so on) that allows a user to enter values.

function security

The control of access to a page or a specific widget or functionality within a page. Function security controls what a user can do.

global

The type of segment label that is used if you want the implementer to tie it to all segments.

globalsearch

The search in the global area that lets you search across many business objects.
global segment
A segment of custom attributes that apply to all entity rows.

hierarchical categories
A feature of extensible flexfields. Extensible flexfields can be configured to enable categories, which can be used to dynamically display different sets of logical pages and contexts based upon a runtime differentiator. The categories can be structured in a hierarchical manner and the children categories inherit all the contexts and logical pages that are configured for the parent categories.

implementor (of a flexfield)
An individual who sets up all or part of a flexfield-enabled application for deployment. Implementors typically work for or on behalf of customers to install, configure, or administer their applications. In the case of developer flexfields that have been created to support functionality that has been built into the application, the developer also plays the role of implementor.

intelligent key
A key composed of business-related values as opposed to an arbitrarily generated sequence.

key flexfield
A type of flexfield in which the segments define a key, or code, that uniquely identifies an object such as an account, an asset, a part, or a job.

maintenance mode
A mode of the key flexfield user interface which allows you to use a code combination maintenance page to manage key flexfield code combinations, including the ability to enter new code combinations and update existing code combinations for a flexfield.

MAR
A Metadata Archive file. A compressed archive of selected metadata used to deploy metadata content to the MDS Repository.

master view object
A view object that has other view objects nested within it.

Metadata Archive (MAR)
See MAR.
owner (of a flexfield)

The developer (or development team) who determines that a particular flexfield is needed or would be useful within a particular Oracle Fusion application, and makes a flexfield of the appropriate design available.

primary key attribute

The attribute of a base view object which links the flexfield view object to the application view object.

primary table

The application table that was used to first register the flexfield. It is the owner of the flexfield.

privilege

A grant or entitlement of access to functions and data.

producer (of a flexfield)

The developer who determines that a particular flexfield is needed or would be useful within a particular application, and makes available a flexfield of the appropriate design. With key flexfields, the producer's product owns the combinations table for that flexfield.

readonly

A boolean property that indicates whether users can modify the value.

rendered

A boolean property that indicates whether the value is visible on the application page.

required

A boolean property that indicates whether the field must have a value.

required (segment label)

The type of segment label that is used if you want the implementors to tie it at least to one segment.

role

Controls access to application functions and data.

secondary table

For descriptive flexfields, a table, other than the primary table, that contains the same set of extension columns as the primary table and that enables the primary table's
**descriptive flexfield** to be reused for that table. For key flexfields, a product table other than the combinations table that contains one or all of the key **flexfield** segments.

**secondary usage**

For descriptive flexfields, the reuse of a **flexfield** on a table other than the **primary table**.

For key flexfields, a type of usage in which there is no direct relationship between the product table and the combinations table.

See also **single-segment secondary usage** and **all-segment secondary usage**.

**security reference implementation**

Predefined function and **data security** in Oracle Fusion Applications, including **role** based access control, and policies that protect functions, data, and segregation of duties. The reference implementation supports identity management, access provisioning, and security enforcement across the tools, data transformations, access methods, and the information life cycle of an enterprise.

**segment label**

A label which identifies the purpose of a particular segment in a key **flexfield**.

**SIN**

Structure instance number. A segment that acts as the **discriminator** attribute for key flexfields.

**single-segment secondary usage**

A type of **secondary usage** in which the **secondary table** has only one **key flexfield** segment column.

**static column**

A method of accessing a **flexfield** in Excel. Used when the flexfield is exposed in an ADF Table component, is **context** sensitive, and the context changes from row to row. A static column should also be used if you do not want flexfield segments to occupy too much space in the worksheet.

**structure code**

A string you provide that individually identifies a structure.

**Structure instance number (SIN)**

See **SIN**.

**tester (of a flexfield)**

The **role** to be used if you are planning to test or share your **flexfield**.
suggestion group
Category of suggestions that appear in the autosuggest for the global search.

transient attribute
An attribute whose value is not stored in a database, and therefore holds a value only for the life of the object. Transient attributes are typically used to display values that are calculated (for example, using Java or Groovy).

unique
The type of segment label that is used if you want the implementer to tie it to at most one segment of the flexfield.

value set
A list of valid values used to specify the validation rules for a flexfield segment.

view accessor
An ADF Business Components object that points from an entity object attribute (or view object) to a destination view object or shared view instance in the same application workspace. The view accessor returns a row set that by default contains all the rows from the destination view object.

WAR
A Web Application Archive file. This file is used in deploying applications on a Java EE application server. WAR files encapsulate in a single module all of the components necessary to run an application. WAR files typically contain an application’s servlet, JSP, and JSF JSP components.

Web Application Archive (WAR)
See WAR.
