Introduction and Roadmap

This section describes the contents and organization of this guide— the *Programming WebLogic Deployment*.

- Document Scope and Audience
- Guide to This Document
- Related Documentation
- Samples for the Deployment API Developer
- Release-Specific WebLogic Deployment API Information
- Summary of WebLogic Deployment API Features
- Unsupported WebLogic Deployment API Features

**Document Scope and Audience**

This document is a resource for software developers who develop a deployment tool using the WebLogic Deployment API. WebLogic provides a packaged deployment tool, WebLogic.Deployer, that serves this function. It is more useful for some development efforts to use the packaged tool. However, if the developer wishes to use their own model implementation (see the J2EE Deployment API standard) and want to interface with the WebLogic SPI, they can use the WebLogic Deployment API deployment factory to build a tool that is documented here. Also, if the developer wants to create an interface that provides more efficient application
configuration options for their work than are available from the WebLogic Server Console, the Deployment API extensions to support one are documented here as well.

It also contains information that is useful for system architects who are evaluating WebLogic Server or considering the use of the WebLogic Deployment API for a particular deployment strategy.

The topics in this document are relevant during the design, development, test, and Pre-production phases of a software project. This document does not directly address production phase administration, monitoring, or performance tuning Deployment API applications topics. The deployment API includes utilities to make software updates during production but it mirrors the functionality of the WebLogic Deployment tools already available. For links to WebLogic Server® documentation and resources for other production topics, see Related Documentation.

It is assumed that the reader is familiar with J2EE concepts, the J2EE Deployment API standard, the Java programming language, Enterprise Java Beans (EJBs), and Web technologies. This document emphasizes the value-added features provided by the WebLogic Deployment API and key information about how to use WebLogic Server features and facilities to use the WebLogic Deployment API to manage application deployment.

Guide to This Document

This document is organized as follows:

- This chapter, Introduction and Roadmap, introduces the organization of this guide and the features of the WebLogic Deployment API.

- Chapter 2, Introducing the WebLogic Server Deployment API, describes the packages, interfaces, and classes of the API, including extensions to the J2EE Deployment API standard, utilities, helper classes, and new concepts for WebLogic Server deployment.

- Chapter 3, Configuring Applications for Deployment, contains instructions on how to configure every aspect of deployment programmatically.

- Chapter 4, Performing Deployment Operations, completes the discussion of the deployment API with the deployment life cycle and controls for a deployed application.

Related Documentation

This document contains Deployment API-specific design and development information. For comprehensive guidelines for developing, deploying, and monitoring WebLogic Server applications, see the following documents:
Samples for the Deployment API Developer

- **Deploying Applications to the WebLogic Server** is a guide to using the deployment tool packaged with weblogic server. Any developer who is unsure of how deployment works should read this document first, before reading the Deployment API developers guide, to understand what is involved in deployment - configuration, deployment, and the deployment life cycle.

- **Developing WebLogic Server Applications** is a guide to developing WebLogic Server components (such as Web applications and EJBs) and applications.

- **Developing Web Applications for WebLogic Server** is a guide to developing Web applications, including servlets and JSPs, that are deployed and run on WebLogic Server.

- **Programming WebLogic Enterprise Java Beans** is a guide to developing EJBs that are deployed and run on WebLogic Server.

- **Programming WebLogic XML** is a guide to designing and developing applications that include XML processing.

- **Overview of WebLogic Server System Administration** provides an overview of administering WebLogic Server and its deployed applications.

**Samples for the Deployment API Developer**

API examples are made available for download at [http://dev2dev.bea.com](http://dev2dev.bea.com). These examples are distributed as zipped files that you can unzip into an existing WebLogic Server samples directory structure.

You build and run the downloadable examples in the same manner as you would an installed WebLogic Server example. See the download pages of individual examples for more information.

**Release-Specific WebLogic Deployment API Information**

For release-specific information, see these sections in *WebLogic Server Release Notes*:

- **WebLogic Server Features and Changes** lists new, changed, and deprecated features.

- **WebLogic Server Known and Resolved Issues** lists known problems by general release, as well as service pack, for all WebLogic Server APIs, including the deployment API.
Summary of WebLogic Deployment API Features

The following list summarizes the main features of WebLogic Deployment API and provides links for additional detailed information:

- Extensions the J2EE Deployment API standard. See the J2EE Deployment API standard on the Sun Microsystems Java support site.

Unsupported WebLogic Deployment API Features

The following list describes the features that are not supported in this release of WebLogic Deployment API:

- The Deployment API does not support an automated fallback procedure for a failed application update. The policy and procedures for this behavior must be defined and configured by the developers and administrators because fallbacks are not trivial operations.
Introducing the WebLogic Server Deployment API

The following sections describes how to:

- **Overview of the Deployment API**
- **J2EE Deployment API Compliance**
- **Deployment API Package Structure**
- **Model**
- **Tools**
- **Shared**
- **SPI**

**Overview of the Deployment API**

The WebLogic Server deployment API implements and extends the J2EE Deployment API deployment specification to provide advanced deployment functionality for WebLogic Server applications. You can use the WebLogic Server API to build a deployment tool that will:

- configure applications in multiple environments while preserving the integrity of packaged applications.
- deploy applications in multiple environments with customized options.

All WebLogic Server deployment tools, such as the Administration Console, weblogic.Deployer tool, and wldeploy Ant tasks, use the deployment API to configure,
Introducing the WebLogic Server Deployment API

deploy, and redeploy applications in a domain. This document and the WebLogic Server Deployment API JavaDocs are intended to be used by developers and Independent Software Vendors (ISVs) who want to perform deployment operations programmatically. It would be useful to examine the existing WebLogic Server Deployer use cases to get a better understanding of what a Deployment Tool can do - it is discussed in the Deploying Applications and Modules documentation for the WebLogic Server.

Note: WebLogic Server 9.0 deprecates the use of the weblogic.management.deploy API used in earlier releases.

J2EE Deployment API Compliance

The WebLogic Server deployment API implements and extends the J2EE Deployment API deployment specification to provide advanced deployment functionality. You can use the WebLogic Server Deployment API to easily configure and deploy applications in multiple environments while preserving the integrity of packaged applications. The functionality described here is in support of a deployer tool's ability to effectively configure and deploy applications. The deployment process has the following phases, all of which are optional:

1) Application evaluation - this phase inspects and evaluates the application files to determine the structure of the application and content of the standard descriptors embedded in it.

2) Front-end configuration - this phase establishes configuration information based on information embedded within the application. This information may be in the form of WebLogic Server descriptors, defaults, and user provided deployment plans.

3) Deployment configuration - this phase involves a conversation with the user to establish desired configuration and tuning for the specific deployment. This phase resolves previously unresolved elements and allows for overriding existing configuration and/or establishment of environment specific information.

4) Deployment preparation - this phase generates the final deployment plan and performs some level of client-side validation of the application.

5) Application deployment - this phase handles the distribution of the application and plan to the admin server for server-side processing and starting the application.

This section introduces the packages necessary to perform these operations. Subsequent sections describe each of the above parts in detail.
J2EE Deployment API Extensions

The WebLogic Deployment API extends the capabilities explicitly described in the J2EE Deployment API standard in several ways. WebLogic supports the “Product Provider” role as described in the standard and thus provides utilities specific to WebLogic server in addition to extensible components for any J2EE network client. These extended features include:

- Finer grain control (module level targeting – not part of J2EE Deployment API)
- Support for WebLogic features (DeploymentOptions – enables you to add optional information which only makes sense to WebLogic server ex start in Admin mode, redeploy with versioning, etc)
- Support of WebLogic module extensions (JMS, JDBC, Interception, Application Specific Configuration[Custom/Config modules]) these are not required by J2EE Deployment API, it is extended for additional configuration
- Remote Operation
- Additional Operations
  - The ‘Deploy’ verb: combines ‘distribute’ and ‘start’
  - Partial Redeployment: redeployment/removal of parts of an application
  - Configuration update: redeployment of a new deployment with only dynamic configuration changes

Deployment API Package Structure

The WebLogic Server 9.0 deployment API is provided in the following packages. These adhere to the J2EE Deployment API standard and extend many of the packages in the javax.enterprise.deploy sub-packages.

weblogic.deploy.api.shared

The weblogic.deploy.api.shared package provides classes that represent the WebLogic Server-specific deployment commands, module types, and target types as classes. These objects can be shared by model and SPI package members.

The definitions of the standard javax.enterprise.deploy.shared classes ModuleType and CommandType are extended in this package to include more specific information that the WebLogic Server can use. The additions provided by the extensions are as follows:
Introducing the WebLogic Server Deployment API

- Module types (JMS, JDBC, Interception, Submodules, Diagnostics, WSEE, Custom)
- Commands (deploy, update)

The new `WebLogicTargetType` class enumerates the different types of deployment targets supported in WebLogic Server. This class does not extend a `javax.deployment` class. It defines the following types:

- Target types (server, cluster, virtual hosts, JMS servers)

**weblogic.deploy.api.model**

`weblogic.deploy.api.model` provides the WebLogic Server implementation of and extensions to the `javax.enterprise.deploy.model` package. This package contains the interfaces used to represent the J2EE configuration of a deployable object (an Enterprise Application or standalone module).

The WebLogic Server implementation of `javax.enterprise.deploy.model` enables you to work with applications that are stored in a WebLogic Server application installation directory, a formal directory structure used for managing application deployment files, deployment s, and external WebLogic Deployment descriptors generated during the configuration process. See **Preparing Applications and Modules for Deployment** for more information about the layout of an application installation directory. It supports any j2ee application, with extensions to support applications residing in an application installation directory.

**Note:** `weblogic.deploy.api.model` does not support dynamic changes to J2EE deployment descriptor elements during configuration and therefore does not support registration and removal of Xpath listeners. `DDBean.addXPathListener` and `removeXPathListener` are not supported.

The `WebLogicDeployableObject` class and `WebLogicDDBean` interface in the `weblogic.deploy.api.model` package represent the standard deployment descriptors in an application.

**weblogic.deploy.api.spi**

`weblogic.deploy.api.spi` provides the interfaces required to configure and deploy applications for deployment to WebLogic Server targets. This package enables a deployment tool to represent the WebLogic Server-specific deployment configuration for an Enterprise Application or standalone module.

`weblogic.deploy.api.spi` includes the `WebLogicDeploymentManager` interface. Deployment tools use the deployment manager to perform all deployment-related operations.
such as distributing, starting, and stopping applications in WebLogic Server. The WebLogicDeploymentManager provides important extensions to the J2EE DeploymentManager interface to support features such as module-level targeting for Enterprise Application modules, production redeployment, application versioning, application staging modes, and constraints on Administrative access to deployed applications.

The WebLogicDeploymentConfiguration and WebLogicDConfigBean classes in the weblogic.deploy.api.spi package represent the deployment and configuration descriptors (WebLogic Server deployment descriptors) for an application. A WebLogicDeploymentConfiguration object is a wrapper for a deployment plan. A WebLogicDConfigBean encapsulates the properties in Weblogic deployment descriptors.

weblogic.deploy.api.spi.factories

This package contains only one interface - WebLogicDeploymentFactory. This is a WebLogic extension to javax.enterprise.deploy.spi.factories.DeploymentFactory. Use this factory interface to select and allocate DeploymentManager objects that have different characteristics. The WebLogicDeploymentManager characteristics are defined by public fields in the WebLogicDeploymentFactory.

weblogic.deploy.api.tools

weblogic.deploy.api.tools provides convenience classes that help you:

- Obtain a WebLogicDeploymentManager
- Populate a configuration for an application
- Create a new or updated deployment plan

Model

These classes are the WebLogic Server extensions to the javax.enterprise.deploy.model interfaces. The model interfaces describes the standard elements, such as deployment descriptors, of a J2EE application.

Accessing Deployment Descriptors

J2EE Deployment API dictates that J2EE deployment descriptors be accessed through a DeployableObject. A DeployableObject represents a module in an application. Elements in the descriptors are represented by DDBeans, one for each element in a deployment descriptor. The
Introducing the WebLogic Server Deployment API

The root element of a descriptor is represented by a DBeanRoot object. All of these interfaces are implemented in corresponding interfaces and classes in this package.

The WebLogicDeployableObject class, which is the weblogic server implementation of DeployableObject, provides the createDeployableObject methods, which create the WebLogicDeployableObject and WebLogicDDBeans for the application's deployment descriptors. Basic configuration tasks are accomplished by associating these WebLogicDDBeans with WebLogicDConfigBeans, which represent the server configuration properties required for deploying the application on a WebLogic Server, are discussed in the SPI section.

Unlike DConfigbeans, which contain configuration information specifically for a server environment (in this case WebLogic server), the DBean objects take in the general deployment descriptor elements for the application. For example, if you were deploying a web application, the deployment descriptors that would end up in WebLogicDDBeans come from WEB-INF/web.xml file in the .war archive. The information for the WebLogicDConfigBeans would come from WEB-INF/weblogic.xml in the .war archive based on the WebLogicDDBeans. Though they serve the same fundamental purpose of holding configuration information, they are logically separate as DBeans describe the application while the DConfigBeans configure the application for a specific environment.

Both of these objects are generated during the initiation of a configuration session. The WebLogicDeployableObject, WebLogicDDBeans, and WebLogicDConfigBeans are all instantiated and manipulated in a configuration session.

Tools

The Tools package provides classes that perform common deployment tool tasks with a minimum of number of controls and explicit object manipulation. This includes controlling DeployableObject and generating deployment plans.

SessionHelper

The SessionHelper views an application and deployment plan artifacts using an “install root” abstraction, which ideally is the actual organization of the application. The install root appears as follows:

install-root (eg myapp)
-- app
----- archive (eg myapp.ear)
-- plan
There is no requirement that the above structure be used for applications, although it is a preferred approach as it serves to keep the application and its configuration artifacts under a common root.

`SessionHelper.getModuleInfo()` returns an object that is useful for understanding the structure of an application without having to work with `DDBeans` and `DeployableObjects`. It provides such information as:

- Names and types of modules and submodules in the application
- Names of web services provided by the application
- Context roots for web applications
- Names of enterprise beans in an EJB

Internally the deployment descriptors are represented as descriptor bean trees, trees of typed Java Bean objects that represent the individual descriptor elements. These bean trees are easier to work with than the more generic `DDBean` and `DConfigBean` objects. The Descriptor bean trees for each module are directly accessible from the associated `WebLogicDDBeanRoot` and `WebLogicDConfigBeanRoot` objects for each module via their `getDescriptorBean` methods.

Modifying the bean trees obtained from a `WebLogicDConfigBean` has the same effect as modifying the associated `DConfigBean`, and therefore the application's deployment plan.

**Helpers for creating and managing a configuration session**

Although configuration sessions can be controlled from a `DeploymentManager` directly, there is a helper class, `SessionHelper`, in the `weblogic.deployer.api.tools` package that simplifies the most common session management operations. These methods include:

- `getDeploymentManager, getDisconnectedDeploymentManager, getRemoteDeploymentManager`: Accessing a DeploymentManager
- `setApplication, setApplicationRoot, setPlan`: identify the application and deployment plan to use in the session
- `initializeConfiguration, inspect`: Initializing a configuration session
- `savePlan`: Saving a deployment
- `getDefaultJMSTargetModuleIDs, getJMSDescriptor`: JMS Submodule targeting
Introducing the WebLogic Server Deployment API

- `getApplication`, `getDescriptorURIs`, `getModuleInfo`, etc: Application inspection - this provides information about the application components.

If your tools code directly to WebLogic Server’s J2EE Deployment API implementation, you should always use `SessionHelper`.

Deployment Plan Creation

`weblogic.PlanGenerator` creates a deployment plan template based on standard and WebLogic Server descriptors included in an application. The resulting plan will describe the app structure, identify all deployment descriptors and will export a subset of the application's configurable properties. Exporting a property exposes it to tools like the WebLogic Server console which can use the plan to assist the administrator in providing appropriate values for those properties. By default, the `PlanGenerator` tool only exports application dependencies; those properties required for a successful deployment. This behavior can be overridden with one of the following options:

- dependencies: export resources referenced by the application (this is the default)
- declarations: export resources defined by the application
- configurables: export non-resource oriented configurable properties
- dynamics: export properties that may be changed in a running application
- all: export all changeable properties
- none: export no properties

Shared

The WebLogic Server 9.0 deployment API extends the `javax.enterprise.deploy.shared` interfaces and provides the types listed below for complete server operability.

Command Types for Deploy and Update

The deploy and update command types were added to the required command types defined in the `javax.enterprise.spi.shared` package. These commands are therefore available to a Deployment Manager for WebLogic Server.
Support for Module Types

Supported module types include JMS, JDBC, Interception, WSEE, Config, and WLDF. These are defined in the weblogic.deploy.api.shared.WebLogicModuleType class as fields.

Support for all WebLogic Server Target Types

Targets, which were not implemented in the J2EE Deployment API specification, is implemented in the WebLogic Deployment API. The valid target values are:

- Cluster
- JMSServer
- SAF Agent
- Server
- Virtual Host

These are enumerated field values in the weblogic.deploy.api.shared.WebLogicTargetType class.

SPI

As a J2EE product provider, BEA extends the javax SPI package to control how configuration and deployment is done to the WebLogic Server specifically. The primary interface for this package is DeploymentManager, from which all other deployment activities can be initiated, monitored, and controlled.

The WebLogicDeploymentManager interface provides WebLogic Server extensions to the javax.enterprise.deploy.spi.DeploymentManager interface. A WebLogicDeploymentManager object is a stateless interface for the Weblogic Server deployment framework. It provides basic deployment features as well as extended WebLogic Server deployment features such as production redeployment and partial deployment for modules in an Enterprise Application. You acquire a WebLogicDeploymentManager object using SessionHelper.getDeploymentManager

Module Targeting

Module targeting is deploying specific modules in an application to different targets (as opposed to always deploying all modules to the same set of targets as dictated by jsr88). The tools
provided in support for module targeting are the
WebLogicDeploymentManager.createTargetModuleID methods.

The WebLogicTargetModuleID class contains the WebLogic Server extensions to the
javax.enterprise.deploy.spi.TargetModuleID interface. The
WebLogicTargetModuleIDs in this class have a close relationship to the configured
TargetInfoMBeans (AppDeploymentMBean and SubDeploymentMBean). The
TargetModuleID's provide a fuller description of the application modules and their relationship
to targets than that represented by MBeans.

Support for Querying WebLogic Target Types

For WebLogic Server, the WebLogicTarget class provides a direct interface for maintaining the
target types available to WebLogic Server. The accessor methods for targets as follows

<table>
<thead>
<tr>
<th>Method</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>isCluster()</td>
<td>Indicates whether this target represents a cluster target.</td>
</tr>
<tr>
<td>isJMServer()</td>
<td>Indicates whether this target represents a JMS server target</td>
</tr>
<tr>
<td>isSAFAgent()</td>
<td>Indicates whether this target represents a SAF agent target</td>
</tr>
<tr>
<td>isServer()</td>
<td>Indicates whether this target represents a server target.</td>
</tr>
<tr>
<td>isVirtualHost()</td>
<td>Indicates whether this target represents a virtual host target</td>
</tr>
</tbody>
</table>

Server Staging Modes

The staging mode of an application affects its deployment behavior. The application's staging
behavior is set using DeploymentOptions.setStageMode(string) and the following values
yielding the following results:

- STAGE - Force copying of files to target servers.
- NO_STAGE - Inhibit copying of files to target servers.
- EXTERNAL_STAGE - files are to be staged manually.
DConfigBean Validation

The property setters in a DConfigBean will reject attempts to set invalid values. This includes property type validation such as attempting to set an integer property to a non-numeric value. Some properties will also do more semantic validation, such as ensuring a maximum value is not smaller than its associated minimum value.
Introducing the WebLogic Server Deployment API
CHAPTER 3

Configuring Applications for Deployment

The term configuration refers to the process of preparing an application or deployable resource for deployment to WebLogic Server. The J2EE Deployment API standard differentiates between a configuration session and deployment. They are distinguished as follows:

- Application Configuration involves: Generation of vendor specific [WebLogic] descriptors, which go into a Deployment Plan
- Deployment involves: Distribute, Start, Stop, Redeploy, Undeploy

The following sections describe how to configure an application for deployment using the WebLogic Server deployment API:

- Overview of the Configuration Process
- Configuring an Application
- Obtaining a Deployment Manager
- Performing Front-End Configuration
- Customizing Deployment Configuration
- Saving a Configuration

Overview of the Configuration Process

One of the tasks handled by deployer tools is configuring an application for a successful deployment. Most configuration information for an application is provided in its deployment
descriptors. The supported descriptors are listed below. Certain elements in these descriptors refer to external objects and/or must be handled in server-specific ways. Different server vendors manage this in different ways. WebLogic Server uses descriptor extensions for this purpose. These are the WebLogic Server specific deployment descriptors. More information on Deployment Descriptors in general can be found in the Overview of Deployment Configuration. The mapping between standard descriptors and WebLogic Server descriptors is managed via DDBeans and DConfigBeans, which are described in this document.

**Types of Configuration Information**

The primary configuration information for an application falls into two distinct but related categories:

- J2EE Configuration
- WebLogic Server Configuration

**J2EE Configuration**

The J2EE configuration for an application defines the basic semantics and runtime behavior of the application, as well as the external resources that are required for the application to function. This configuration information is stored in the standard J2EE deployment descriptor files associated with the application, as listed in Figure 3-1.
Complete and valid J2EE deployment descriptors are a required input to any application configuration session.

Because the J2EE configuration controls the fundamental behavior of an application, the J2EE descriptors are typically defined only during the application development phase, and are not modified when the application is later deployed to a different environment. For example, when deploying an application to a testing or production domain, the application’s behavior (and therefore its J2EE configuration) should remain the same as when application was deployed in the development domain. See Performing Front-End Configuration for more information.

**DDBeans**

DDBeans are described by the javax.enterprise.deploy.model package. These objects provide a generic interface to elements in standard deployment descriptors, but can also be used as an XPath based mechanism to access arbitrary XML files that follow the basic form of the standard descriptors. Examples of such files would be WebLogic Server descriptors and Web Services descriptors.

The DDBean representation of a descriptor is a tree of DDBeans, with a specialized DDBean, a DDBeanRoot, at the root of the tree. DDBeans provide accessors for the element name, id attribute, root, and text of the descriptor element they represent.

The DDBeans for an application are populated by the model plug-in, the tool provider implementation of javax.enterprise.deploy.model. An application is represented by the DeployableObject interface. The WebLogic Server implementation of this interface is a public class, weblogic.deploy.api.model.WebLogicDeployableObject. A WebLogic Server based
deployer tool acquires an instance of `WebLogicDeployableObject` object for an application via the `createDeployableObject` factory methods. This results in the DDBean tree for the application being created and populated by the elements in the J2EE descriptors embedded in the application. If the application is an EAR, multiple `WebLogicDeployableObject` objects are created. The root `WebLogicDeployableObject`, extended as `WebLogicJ2eeApplicationObject`, would represent the EAR module, with its child `WebLogicDeployableObject` instances being the modules contained within the application. These would be WARs, EJBs, RARs and CARs.

**Representing J2EE and WebLogic Server Configuration Information**

Both the J2EE deployment descriptors and any available WebLogic Server descriptors are used as inputs to the application configuration process. You use the deployment API to represent both the J2EE configuration and WebLogic Server configuration as Java objects.

The J2EE configuration for an application is obtained by creating either a `WebLogicJ2eeApplicationObject` for an EAR, or a `WeblogicDeployableObject` for a standalone module. (A `WebLogicJ2eeApplicationObject` contains multiple `DeployableObject` instances to represent individual modules included in the EAR.)

Each `WebLogicJ2eeApplicationObject` or `WeblogicDeployableObject` contains a `DDBeanRoot` to represent a corresponding J2EE deployment descriptor file. J2EE descriptor properties for EARs and modules are represented by one or more `DDBean` objects that reside beneath the `DDBeanRoot`. `DDBean` components provide standard getter methods to access individual deployment descriptor properties, values, and nested descriptor elements.

**The Relationship Between J2EE and WebLogic Server Descriptors**

J2EE descriptors and WebLogic Server descriptors are directly related in the configuration of external resources. A J2EE descriptor defines the types of resources that the application requires to function, but it does not identify the actual resource names to use. The WebLogic Server descriptor binds the resource definition in the J2EE descriptor name to the name of an actual resource in the target domain.

The process of binding external resources is a required part of the configuration process. Binding resources to the target domain ensures that the application can locate resources and successfully deploy.
J2EE descriptors and WebLogic Server descriptors are also indirectly related in the configuration of tuning parameters for WebLogic Server. Although no elements in the standard J2EE descriptors require tuning parameters to be set in WebLogic Server, the presence of individual descriptor files indicates which tuning parameters are of interest during the configuration of an application. For example, although the ejb.xml descriptor does not contain elements related to tuning the WebLogic Server EJB container, the presence of an ejb.xml file in the J2EE configuration indicates that tuning properties can be configured before deployment.

**WebLogic Server Configuration**

The WebLogic Server descriptors provide for enhanced features, resolution of external resources, and tuning associated with application semantics. Applications may or may not have these descriptors embedded in the application. The WebLogic Server configuration for an application:

- Binds external resource names to resource definitions in the J2EE deployment descriptor so that the application can function in a given WebLogic Server domain
- Defines tuning parameters for the application containers
- Provides enhanced features for J2EE applications and standalone modules

The attributes and values of a WebLogic Server configuration are stored in the WebLogic Server deployment descriptor files, as shown in Figure 3-2.
Because different WebLogic Server domains provide different types of external resources and different levels of service for the application, the WebLogic Server configuration for an application typically changes when the application is deployed to a new environment. For example, a production staging domain might use a different database vendor and provide more usable memory than a development domain. Therefore, when moving the application from development to the staging domain, the application’s WebLogic Server descriptor values need to be updated in order to make use of the new database connection and available memory.

The primary job of a deployment configuration tool is to ensure that an application’s WebLogic Server configuration is valid for the selected WebLogic targets.

**DConfigBeans**

DConfigBeans (config beans) are the objects used to convey server configuration requirements to a deployer tool, and are also the primary source of information used to create deployment plans. Config beans are Java Beans and can be introspected for their properties. They also provide basic property editing capabilities.

DConfigBeans are created from information in embedded WebLogic Server descriptors, deployment plans, and input from an IDE style deployer tool.

A DConfigBean is potentially created for every weblogic Descriptor element that is associated with a dependency of the application. Descriptors are entities that describe resources that are available to the application, represented by a JNDI name provided by the server.

Descriptors are parsed into memory as a typed bean tree while setting up a configuration session. The DConfigBean implementation classes delegate to the WebLogic Server descriptor beans. Only beans with dependency properties (e.g. resource references) will have a DConfigBean. The root of descriptor always has a DConfigBeanRoot.

Bean Property accessors return a child DConfigBean for elements that require configuration or a descriptor bean for those that do not. Property accessors return data from the descriptor beans.

Modifications to bean properties result in plan overrides. Plan overrides for existing descriptors are handled via variable assignments. If the application does not come with the relevant WebLogic Server descriptors, they will be automatically created and placed in an external plan directory. For external dd’s, the change is made directly to the descriptor. Embedded descriptors are never modified on disk.

**Configuring an Application**

Taking a look once again at the Deployment phases, those phases that are covered by configuration are the first four:

1) **Application evaluation** - this phase inspects and evaluates the application files to determine the structure of the application and content of the standard descriptors embedded in it.
   
   - Initialize a deployment session by obtaining a WebLogic Deployment Manager.
   - Create a WebLogicJ2eeApplicationObject or WebLogicDeployableObject to represent the J2EE Configuration of an Enterprise Application (EAR) or standalone module (WAR, EAR, RAR, or CAR). If it is an EAR, there will be child objects generated. This is the deployable object as described in the J2EE Deployment API standard.

2) **Front-end configuration** - this phase establishes configuration information based on information embedded within the application. This information may be in the form of WebLogic Server descriptors, defaults, and user provided deployment plans.
   
   - Create a WebLogicDeploymentConfiguration object to represent the WebLogic Server configuration of an Application. This begins a process that result in a Deployment Plan for this deployment of this object.
Configuring Applications for Deployment

- Restore existing WebLogic Server configuration values from an existing deployment plan, if available.

3) Customizing deployment configuration - this phase involves a conversation with the user to establish desired configuration and tuning for the specific deployment. This phase resolves previously unresolved elements and allows for overriding existing configuration and/or establishment of environment specific information.

- Modify individual WebLogic Server configuration values based on user inputs and the selected WebLogic Server targets

4) Deployment preparation - this phase generates the final deployment plan and performs some level of client-side validation of the application.

- Save the modified WebLogic Server configuration information to a new deployment plan or to variable definitions in an existing Deployment Plan.

5) Application deployment - this phases handles the distribution of the application and plan to the administration server for server-side processing and starting the application. (not part of configuration)

Within the first four phases, a deployment configuration tool performs several steps. Each of these steps are described in detail below, but before embarking upon these tasks, it is necessary to take note of the tools WebLogic provides to handle some of the common tasks.

The WebLogic Server SessionHelper Class

SessionHelper simplifies the most common operational patterns such as accessing a DeploymentManager, Initializing a configuration session, saving deployment plans, JMS Submodule targeting, and Inspecting applications.

Tools that code directly to WebLogic J2EE Deployment API implementations are encouraged to use SessionHelper and each of the sections that follow, a subsection devoted to SessionHelper will appear so that you can use it in your implementation. Also see the Javadocs for more information about SessionHelper.
Session Cleanup
Temporary files are created during a configuration session. Archives get exploded into the temp area. They can be removed only after session is complete. There is no standard API defined to close out a session. There are close() methods to WebLogicDeployableObject and WebLogicDeploymentConfiguration. SessionHelper.close() cleans everything up after that. It’s up to the tool programmer to use these methods or the temp directories may fill up over time.

Obtaining a Deployment Manager
A deployment manager provides an interface to the WebLogic Server deployment infrastructure. To initialize a deployment session in a tool, you create a new deployment manager.

The deployment manager is implemented using the factory pattern. You first obtain a deployment factory class by specifying its name, weblogic.deployment.spi.factories.internal.DeploymentFactoryImpl, and then register the factory class with a javax.enterprise.deploy.spi.DeploymentFactoryManager instance. After you have registered the deployment factory, you can use it with a specific URI to obtain a deployment manager that has the functionality you require.

Types of Deployment Managers
WebLogic Server provides a single implementation for javax.enterprise.deploy.spi.DeploymentManager that behaves differently depending on the URI you specify when instantiating the class from a factory. WebLogic Server provides two basic types of deployment manager:

- A disconnected deployment manager has no connection to a WebLogic Server instance. You can use a disconnected deployment manager to configure an application on a remote client machine, but you cannot use it to perform deployment operations. (For example, you cannot use a disconnected deployment manager to distribute an application.)

- A connected deployment manager has a connection to the Administration Server for the WebLogic Server domain, and can be used both to configure and deploy applications. A connected deployment manager can be further classified as being either local to the Administration Server, or running on a remote machine that is connected to the Administration Server. The local or remote classification determines whether file references are treated as being local or remote to the Administration Server.
Figure 3-3 summarizes each basic type of deployment manager.

### Figure 3-3 WebLogic Server Deployment Manager Usage

**Connected and Disconnected Deployment Manage URIs**

All DeploymentManager's obtained from `WebLogicDeploymentFactory` support the WebLogic Server extensions. You obtain a specific type of deployment manager by calling the correct method on the deployment factory instance and supplying a string constant defined in `weblogic.deployer.spi.factories.WebLogicDeploymentFactory` that describes the type of deployment manager you want to obtain. Connected deployment managers require that you pass a valid server URI and credentials to the method in order to obtain a connection to the Administration Server.

Figure 3-4 summarizes the method signatures and constants used to obtain the different types of deployment manager.
The sample code in Listing 3-1 shows how to obtain a disconnected deployment manager.

**Listing 3-1 Obtaining a Disconnected Deployment Manager**

```java
Class WlsFactoryClass =
Class.forName("weblogic.deployer.spi.factories.internal.DeploymentFactoryImpl");
DeploymentFactory myDeploymentFactory = (DeploymentFactory)
WlsFactoryClass.newInstance();
DeploymentFactoryManager.getInstance().registerDeploymentFactory(myDeploymentFactory);
WebLogicDeploymentManager myDisconnectedManager =
(WebLogicDeploymentManager)myDeploymentFactory.getDisconnectedDeploymentManager(
(WebLogicDeploymentFactory.LOCAL_DM_URI);
```
The deployment factory contains a helper method, `createUri()` to help you form the URI argument for creating connected deployment managers. For example, to create a disconnected, remote deployment manager, replace the final line of code with:

```java
(WebLogicDeploymentManager) myDeploymentFactory.getDeploymentManager(myDeploymentFactory.createUri(WebLogicDeploymentFactory.REMOTE_DM_URI, "localhost", "7001", "weblogic", "weblogic"));
```

### Using SessionHelper to Obtain a Deployment Manager

The `SessionHelper` helper class provides several convenience methods to help you easily obtain a deployment manager without manually creating and registering the deployment factories, as in Listing 3-1. The `SessionHelper` code required to obtain a disconnected deployment manager consists of a single line:

```java
DeploymentManager myDisconnectedManager = SessionHelper.getDisconnectedDeploymentManager();
```

Also see the Javadocs for more information about `SessionHelper`.

### Performing Front-End Configuration

A deployment plan is an XML document that contains the environmental configuration for an application, referred to as its front-end configuration. It separates the environment specific details of an application from the logic of the application. A deployment plan is not required for every application. It is required if the application expects specific attributes to be provided by the descriptors, as opposed to the generic values generated automatically. You may have a deployment plan for each environment in which the application will be deployed.

The deployment plan has several purposes:

- It describes the application structure. It will tell you what modules are in the application.
- It allows developers and administrators to update the configuration of an application without modifying the application archive.
- It contains environment specific descriptor override information. By modifying this file, you can override environment variables for the application so that it can be used in a different environment.
DeploymentConfiguration

The server configuration for an application is encapsulated in the
javax.enterprise.deploy.spi.DeploymentConfiguration interface. A
DeploymentConfiguration can also be viewed as the object representation of a deployment
plan. A DeploymentConfiguration is associated with a DeployableObject via the
DeploymentManager.createConfiguration method. Following the creation of the
DeploymentConfiguration, a DConfigBean tree representing the configurable and tunable
elements contained in any and all WebLogic Server descriptors is available. If there are no
WebLogic Server descriptors in the application, then a DConfigBean tree is created using
available default values. Binding properties that have no defaults will be left unset.

It is the responsibility of the deployer tool to ensure the DConfigBean tree is fully populated
before using it to distribute an application. The DConfigBeans are populated from scratch as
shown in the configuration code sample. This example merely iterates through the DDBean tree,
requesting the DConfigBean for each DDBean to be instantiated.

DeploymentConfiguration objects may be persisted as deployment plans via
DeploymentConfiguration.save(). A deployer tool may allow the user to import a saved
deployment plan into the DeploymentConfiguration object instead of populating it from
scratch. DeploymentConfiguration.restore() provides this capability. This supports the
idea of having a repository of deployment plans for an application, with different plans being
applicable to different environments.

Similarly the DeploymentConfiguration may be pieced together via partial plans, which were
presumably saved in a repository from a previous configuration session. A partial plan maps to a
module-root of a DConfigBean tree. DeploymentConfiguration.saveDConfigBean() and
DeploymentConfiguration.restoreDConfigBean() provides this capability.

Parsing of the WebLogic Server descriptors in an application occurs automatically when a
DeploymentConfiguration is created. The descriptors ideally conform to the most current
schema. For older applications that include descriptors based on WebLogic Server 8.1 and earlier
DTDs, a transformation is performed. Old Descriptors are supported but they cannot be modified
using a deployment plan. Therefore, any DOCTYPE declarations must be converted to name
space references, and element specific transformations must be performed.

Reading in Information with SessionHelper

SessionHelper.initializeConfiguration will process all standard and WebLogic Server
descriptors in the application.
Prior to invoking `initializeConfiguration`, you can specify an existing deployment plan to associate with the application using the `SessionHelper.setPlan()` method. With a plan set, you may read in a deployment plan with the `DeploymentConfiguration.restore()` method, in accordance with the J2EE Deployment API standard. In addition, the `DeploymentConfiguration.initializeConfiguration()` method automatically restores configuration information once a plan is set.

When initiating a configuration session with the `SessionHelper` class, you can easily initiate and fill a `deploymentConfiguration` object with deployment plan information as illustrated below:

```java
DeploymentManager dm = SessionHelper.getDisconnectedDeploymentManager();
SessionHelper helper = SessionHelper.getInstance(dm);
// specify location of archive
helper.setApplication(app);
// specify location of existing deployment plan
helper.setPlan(plan);
// initialize the configuration session
helper.initializeConfiguration();
DeploymentConfiguration dc = helper.getConfiguration();
```

**Validating a Configuration**

Validation of the configuration occurs mostly during the parsing of the descriptors, which occurs when the app's descriptors are processed. Validation consists of ensuring the descriptors are valid xml documents and that they abide by their respective schemas.

**Customizing Deployment Configuration**

The configuration at this point is only as good as the descriptors or pre-existing plan associated with the application. The `DConfigBeans` are designed as Java Beans and can be introspected, allowing the tool to present their content in some meaningful way. The properties of a `DConfigBean` are for the most, those that are configurable. Key properties (those that provide uniqueness) are also exposed. Setters are only exposed on those properties that can be safely modified. In general, properties that describe application behavior are not modifiable. All properties are typed as defined by the descriptor schemas.
The property getters return subordinate DConfigBeans, arrays of DConfigBeans, descriptor beans, arrays of descriptor beans, simple values (primitives and java.lang objects), or arrays of simple values. Descriptor beans represent descriptor elements that, while modifiable, do not require DConfigBean features. e.g. there is no standard descriptor element they are directly related to.

Editing a configuration is accomplished by invoking the property setters.

The pure JSR88 DConfigBean class allows the tool to access beans via the getDConfigBean(DDBean) method, or via introspection. The former approach is convenient for tools that present the standard descriptor based on the DDb Bean's in the application's DeployableObject, and then provide direct access to each DDb Bean's configuration (its DConfigBean). This provides configuration of the essential resource requirements an application may have. The latter approach (introspection) allows a tool to present the application's entire configuration, while perhaps highlighting the required resource requirements.

Introspection is, of course, required in both approaches in order to present or modify descriptor properties. The difference is in how the tool presents the information: either driven by standard descriptor content or WebLogic Server descriptor content.

**Targets**

Targets are associated with WebLogic servers, clusters, web servers, virtual hosts and JMS servers. This is captured in the weblogic.deploy.api.spi.WebLogicTarget javadocs.

**Application Naming**

In WebLogic Server, application names are provided by the deployment tool. Names of modules contained within an application are based on the associated archive or root directory name of the modules. These names are persisted in the configuration MBeans constructed for the application.

In J2EE deployment there is no mention of the configured name of an application or its constituent modules, other than in the TargetModuleID object. Yet TargetModuleIDs exist only for applications that have been distributed to a WebLogic Server domain. Hence there is a need to represent application and module names in a deployer tool prior to distribution. This representation should be consistent with the names assigned by the server when the application is finally distributed.

The tool plug-in constructs its view of an application via the DeployableObject and J2eeApplicationObject classes. These represent standalone modules and EARs, respectively. Each of these has a direct relationship to a DDb BeanRoot object. When presented with a
distribution where the name is not configured, one will be derived for it. If the distribution is a File object, the file's name will be used. If the archive is offered as an input stream, a random name will be used for the root module.

**Saving a Configuration**

Committing a configuration is the same as saving the resulting plan from a configuration session. It is handled by the `DeploymentConfiguration.save()` method (another standard J2EE Deployment API method). You can use the `SessionHelper.savePlan()` method to do this; it saves a new copy of deployment plan along with any external documents in the plan directory.

The `DeploymentConfiguration.save` methods will create an XML file based on the deployment plan schema, consisting of a serialization of the current collection of DConfigBeans, along with any variable assignments and definitions. The DConfigBean trees are always saved as external descriptors. These descriptors will only be saved if they do not already exist in the application archive or the external configuration area, i.e., the save operation will not overwrite existing descriptors. The `DeploymentConfiguration.saveDConfigBean` method will, however, overwrite files. This is not to say that any changes made to the configuration are lost. Rather they are handled using variable assignments.

As noted before, the `DeploymentConfiguration.restore` methods are used to create config beans based on a previously saved deployment plan. An entire collection of config beans may be restored or the tool can restore a subset of the config beans. e.g., it is possible to save/restore just the config beans for a specific module in an application. This allows for a degree of flexibility in configuring an application.
Performing Deployment Operations

The second part of the deployer tool actually performs the deployment of the application. The following sections describe how to implement deployment operations for a WebLogic deployment API constructed deployment tool. The operations are as follows:

- Deployment Factories
- Server Connectivity
- Deployment Processing
- Production Redeployment
- Progress Reporting
- Target Objects
- Examples

**Deployment Factories**

A deployer tool must allocate a `DeploymentManager` from a `DeploymentFactory` which is registered with the `DeploymentFactoryManager` class. In addition to configuration (described in *Overview of the Configuration Process*), the `DeploymentManager` is responsible for establishing a connection to a J2EE server. The `DeploymentManager` implementation is accessed via a `DeploymentFactory`.

The deployer tool is responsible for instantiating and registering any `DeploymentFactory` objects it intends to use. The WebLogic factory is advertised via the manifest file in the
Performing Deployment Operations

wldeploy.jar archive. The manifest contains entries defining the fully-qualified class names of
the factories, separated by whitespace. For example:

MANIFEST.MF:

  Manifest-Version: 1.0
  Implementation-Vendor: BEA Systems
  Implementation-Title: WebLogic Server 9.0 Mon Nov 11 08:16:47 PST 2002 221755
  Implementation-Version: 9.0.0.0
  J2EE-DeploymentFactory-Implementation-Class: weblogic.deploy.spi.factories_DeploymentFactoryImpl

The deployer tool is free to define any mechanism for managing the SPI plug-ins it recognizes.
For simplicity’s sake, assume the tool requires that all SPI plug-ins reside in some fixed location,
and that they are also in its classpath. Upon startup, the tool would register the plug-ins as shown
in the example.

The standard DeploymentFactory interface is extended by
weblogic.deploy.api.WebLogicDeploymentFactory. The additional methods provided in
the extension are:

- String[] getUris(): returns an array of URI's that are recognized by
  getDeploymentManager. The first URI in the array is guaranteed to be the default
  DeploymentManager URI, deployer:WebLogic. Only published URI's are returned in
  this array.

- String createUri(String protocol, String host, String port): returns a
  usable URI based on the arguments.

DeploymentManager Behaviors

Only one DeploymentManager implementation is provided. Depending on the URI specified
when allocating the DeploymentManager, it will take on the following characteristics:

- deployer:WebLogic: The DM will assume it is running locally on a WebLogic
  administration server. Thus any files referenced during the deployment session are assumed
  to be local to the admin server.

- deployer:WebLogic.remote: The DM will assume it is running remotely to the
  WebLogic administration server, thus any files referenced during the deployment session
are not assumed to be local to the administration server, i.e. a distribute operation will include uploading the application files to the administration server.

- deployer:WebLogic.authenticated: This is an internal, unpublished URI, usable by applications such as a console servlet that is already authenticated and has access to the domain management information. The DM will assume it is running locally on a WebLogic administration server. Thus any files referenced during the deployment session are assumed to be local to the administration server.

### Server Connectivity

A deployment tool allocates a `DeploymentManager` from a registered `DeploymentFactory` (see above). `DeploymentManagers` can be either connected or disconnected. Connected `DeploymentManagers` imply a connection to a WebLogic administration server. This connection is maintained until it is explicitly disconnected or the connection is lost. If the connection is lost, the `DeploymentManager` will revert to a disconnected state.

Explicitly disconnecting a `DeploymentManager` is accomplished via the `DeploymentManager.release` method. There is no corresponding method for reconnecting the `DeploymentManager`. Instead the deployer tool must allocate a new `DeploymentManager`. This should not affect any configuration information being maintained within the tool through a `DeploymentConfiguration` object.

`DeploymentManagers` are identified by an opaque URI. All `DeploymentManagers` for WebLogic Server have the URI scheme, `deployer:WebLogic<.type>`. The `DeploymentFactory.getDeploymentManager` method takes a URI, userid and password as arguments. In this case the URI must also include the host and port for the admin server, e.g. `deployer:WebLogic:localhost:7001`. When obtaining a disconnected `DeploymentManager`, only the URI is necessary because no actual connection to a server is made. In this case, the URI can simply be `deployer:WebLogic`, although extending the URI with the host and port is allowed.

The userid and password arguments are ignored if the deployer tool uses a pre-authenticated `DeploymentManager`; The factory presumes that the user has already been authenticated.

The URI of any `DeploymentManager` implementation should be accessed using the `DeploymentFactory.getUris()` method. `getUris` is an extension of `DeploymentFactory`.

The behavior of the `DeploymentManager` operations is guided by the URI specified when it is allocated from the factory. These behaviors apply to relevant operations supported by the `DeploymentManager`. They include:
Performing Deployment Operations

- File Upload: determines whether files are uploaded to the admin server. This functionality is automatically enabled for the remote Deployment Managers.

- Authentication Required:

These behaviors also can be explicitly enabled using the WebLogicDeploymentManager methods, enableFileUploads().

Deployment Processing

Most of the functional components of a DeploymentManager are defined in the J2EE Deployment API specification. The specification does not describe a DeploymentManager that is sufficient to support the needs of WebLogic Server customers, hence a number of extensions were introduced. These are documented in the javadocs for weblogic.deploy.api.spi.WebLogicDeploymentManager. The relationship between the SPI operations and WebLogic Server is provided here.

The intent is not to change the programming model defined by the J2EE deployment API specification, but rather to extend the DeploymentManager interface (DM) with the capabilities required and expected by existing WebLogic Server-based deployment tools.

The JSR88 programming model revolves around employing TargetModuleID objects (TargetModuleIDs) and ProgressObject objects. In general, the target modules are specified by a list of TargetModuleIDs which are roughly equivalent to deployable (root modules) and (sub)module level mbeans. The DM applies the TargetModuleIDs to its deployment operations (start, stop, etc) and tracks their progress. The deployer tool queries progress via a ProgressObject returned for each operation. When the ProgressObject indicates the operation is completed or failed, the operation is done.

The following sections describe the different DM operations and their extensions. Full descriptions are provided in the javadocs. This section serves as a general overview. The extensions cover the following features:

- General usability/convenience
- Side-by-side version support
- module level targeting
- partial redeployment
- administration (test) mode applications
DeploymentOptions

The WebLogic Server allows for a DeploymentOptions argument (weblogic.deploy.api.spi.DeploymentOptions), which supports the overriding of certain deployment behaviors. The argument may be null, which provides for standard behaviors. Some of the options supported in this release are:

- administration (test) mode
- Retirement Policy
- Staging

See the DeploymentOptions javadoc for a full list of options.

Distribution

The distribution of new applications results in the application archive and plan being staged on all targets, and the application being configured into the domain. Redistribution will honor the staging mode already configured for the application.

The standard distribute operations do not allow for version naming, leaving this to be generated by the system. WebLogicDeploymentManager extends the standard with a distribute operation that allows the user to specify a version name to associate with the new application.

The ProgressObject returned from a distribute provides a list of TargetModuleIDs representing the application as it exists on the target servers. The targets used in the distribute are any of the supported targets. The TargetModuleID will represent the application's module availability on each target.

For new applications, the resulting TargetModuleIDs represent the top level AppDeploymentMBean objects. The TargetModuleIDs will not have child TargetModuleIDs based on the modules and submodules in the application, since the underlying MBeans would only represent the root module. For pre-existing applications, the TargetModuleIDs are based on the DeployableMBeans and any AppDeploymentMBean and SubAppDeploymentMBean in the configuration.

When using the distribute(Target[], InputStream, InputStream) method to distribute, the archive and plan represented by the input streams will be copied from the streams into a temp area prior to deployment. It is not recommended to use this distribute method for performance reasons.
**Application Start**

The standard start operation only supports root modules; implying only entire applications can be started. Consider the following configuration.

```xml
<AppDeployment Name="myapp">
  <SubDeployment Name="webapp1", Targets="serverx"/>
  <SubDeployment Name="webapp2", Targets="serverx"/>
</AppDeployment>
```

The TargetModuleID returned from `getAvailableModules(ModuleType.EAR)` would look like this:

- myapp on serverx (implied)
- webapp1 on serverx
- webapp2 on serverx

So `start(tmid)` would start webapp1 and webapp2 on serverx.

To just start webapp1, module level control is required. This is achievable as follows by manually creating a TargetModuleID hierarchy.

```java
WebLogicTargetModuleID root =
  dm.createTargetModuleID("myapp", ModuleType.EAR, getTarget(serverx));

WebLogicTargetModuleID web =
  dm.createTargetModuleID(root,"webapp1", ModuleType.WAR);

dm.start(new TargetModuleID[]{web});
```

This approach uses the TargetModuleID creation extension to manually create an explicit TargetModuleID hierarchy. In this case the created TargetModuleID would look like

- myapp on serverx (implied)
- webapp1 on serverx

The start operation does not modify the application configuration. Version support is built into the TargetModuleIDs, allowing the user to start a specific version of an application. Applications may be started in normal or administration (test) mode.
Application Deploy

The deploy operations combine a distribute and start operation, and is provided as a convenience. Web Applications may be deployed in normal or administration (test) mode. Application staging can also be specified via the DeploymentOptions argument on deploy. The deploy operations use TargetModuleIDs instead of Targets for targeting, thus allowing for module level configuration.

The deploy operation may change the application configuration based on the TargetModuleIDs provided.

Application Stop

The standard stop operation only supports root modules; implying only entire applications can be stopped. See the Application Start discussion for more details on module level control.

The stop operation does not modify the application configuration.

Version support is built into the TargetModuleIDs, allowing the user to stop a specific version of an application.

Undeployment

The standard undeploy operation removes an application from the configuration, as specified by the TargetModuleIDs. Individual modules can be undeployed. The result is that the application remains on the target, but certain modules are not actually configured to run on it. See the start operation discussion for more detail on module level control.

The WebLogicDeploymentManager extends undeploy in support of removing files from a distribution. This is a form of in-place redeployment that is only supported in web applications, and is intended to allow for removal of static pages and the like.

Version support is built into the TargetModuleIDs, allowing the user to undeploy a specific version of an application.

Production Redeployment

Standard redeployment support only applies to entire applications and employs side-by-side versioning to ensure uninterrupted session management. The WebLogicDeploymentManager extends the redeploy() method as follows:
Performing Deployment Operations

- Redeploying individual modules in an application. This implies an in-place redeploy (no new version). The version information in the new application must be the same as the old application, but with a different value (e.g. 1.0, 1.1, etc.). Module targeting must be specified.

- Specifying a retirement policy for an old application.

- Partial redeployment - this involves adding or replacing specific files in an existing deployment. This is an in-place redeployment.

- Redeploying applications in administration (test) mode.

- Updating configuration - the redeployment of a deployment plan.

Version support is provided via arguments in the above operations. The version, if relevant, is specified in the `TargetModuleID`.

Retirement Policy

When a new version of an application is redeployed, the old version should eventually be retired and undeployed. There are 2 policies for retiring old versions of applications:

1. (Default) old version is retired when new version is active and old version finishes its in-flight operations.

2. The old version is retired when new version is active, retiring the old after some specified time limit of the new version being active.

Note that the old version will not be retired if the new version is in administration (test) mode.

Module Targeting

DeploymentManager's will honor the JSR88 specification and restrict operations to root modules. Module level control is provided by manually constructing a module specific `TargetModuleID` hierarchy via `WebLogicDeploymentManager.createTargetModuleID`.

Version Support

Side-by-side versioning is used to provide retirement extensions, as suggested in the JSR88 redeployment specification. This ensures that an application can be redeployed with no interruption in service to its current clients. Details on deploying side-by-side versions can be found in the Redeployment Strategies documentation. Briefly, an archive manifest can specify the WebLogic Server application version. The deployment plan also supports a version identifier.
The combination of these 2 version identifiers is used internally to distinguish between versions of applications, and may also be used by developers and administrators to assist in version control.

This provides the basis for production redeployment as it is implemented for the WebLogic Server Deployment Service. Please refer to the Redeployment Strategies documentation for more information.

**Administration (test) Mode**

A web application may be started in normal or administration (test) mode. Normal mode indicates the web app is fully accessible to clients. Administration (test) mode indicates the application only listens for requests via the admin channel. Administration (test) mode is specified via a DeploymentOptions argument on the WebLogic Server extensions for start, deploy and redeploy. See the DeploymentOptions javadoc for more information.

**Progress Reporting**

ProgressObjects are the interface for the deployment state in the SPI. These objects are associated with DeploymentTaskRuntimeMBeans. ProgressObjects support the cancel operation but not the stop operation.

ProgressObjects are associated with one or more TargetModuleIDs, each of which represents an application and its association with a particular target. For any ProgressObject, its associated TargetModuleIDs represent the application that is being monitored.

The ProgressObject maintains a live connection with the deployment framework, allowing it to provide the tools with up-to-date deployment status. Once this status goes to completed, failed or released, the tools should not expect any further changes. Deployment state transitions from running to completed or failed only after all TargetModuleIDs involved have completed their individual deployments. The resulting state is 'completed' only if all TargetModuleIDs were successfully deployed.

The ‘released’ state means that the DeploymentManager was disconnected during the deployment. This may be due to a manual release, a network outage, or similar communication failures.

The following code sample shows how a ProgressObject can be used to wait for a deployment to complete:

```java
package weblogic.deployer.tools;
```
import javax.enterprise.deploy.shared.*;
import javax.enterprise.deploy.spi.*;
import javax.enterprise.deploy.spi.status.*;

/**
 * Example of class that waits for the completion of a deployment
 * using ProgressEvent's.
 */
public class ProgressExample implements ProgressListener {

    private boolean failed = false;
    private DeploymentManager dm;
    private TargetModuleID[] tmids;

    public void main(String[] args) {
        // set up DeploymentManager, TargetModuleIDs, etc
        try {
            wait(dm.start(tmids));
        } catch (IllegalStateException ise) {
            //... dm not connected
        }
        if (failed) System.out.println("oh no!");
    }

    void wait(ProgressObject po) {
        ProgressHandler ph = new ProgressHandler();
    }
}
if (!po.getDeploymentStatus().isRunning()) {
    failed = po.getDeploymentStatus().isFailed();
    return;
}

po.addProgressListener(ph);
ph.start();
while (ph.getCompletionState() == null) {
    try {
        ph.join();
    } catch (InterruptedException ie) {
        if (!ph.isAlive()) break;
    }
}

StateType s = ph.getCompletionState();
failed = (s == null || s.getValue() == StateType.FAILED.getValue());
po.removeProgressListener(ph);

class ProgressHandler extends Thread implements ProgressListener {
    boolean progressDone = false;
    StateType finalState = null;
    public void run(){
        while(!progressDone){
            Thread.currentThread().yield();
        }
    }
}
Performing Deployment Operations

```java
public void handleProgressEvent(ProgressEvent event)
{
    DeploymentStatus ds = event.getDeploymentStatus();
    if (ds.getState().getValue() != StateType.RUNNING.getValue()) {
        progressDone = true;
        finalState = ds.getState();
    }
}

public StateType getCompletionState(){
    return finalState;
}
}
```

### Module Types

The standard module types are defined by `javax.enterprise.deploy.shared.ModuleType`. This is extended to support WebLogic Server-specific module types: JMS, JDBC, INTERCEPT and CONFIG.

### Target Objects

The J2EE Deployment API specification's definition of a target does not include any notion of its type. WebLogic Server recognizes types - servers, clusters, JMS servers and virtual hosts - as valid targets for deployment. These concepts are introduced into the API via the `weblogic.deploy.api.spi.WebLogicTarget` and `weblogic.deploy.api.spi.WebLogicTargetType` classes. `WebLogicTargetType` follows the form of the classes in the `javax.enterprise.deploy.shared` package. It enumerates the known target types.

`WebLogicTarget` and `WebLogicTargetType` are defined in more detail in the javadocs. `WebLogicTarget` extends `javax.enterprise.deploy.spi.Target`.
Target ModuleID Objects

The TargetModuleID objects uniquely identify a module and a target it is associated with. TargetModuleIDs are the objects that specify where modules are to be started and stopped. The object name used to identify the TargetModuleID is of the form:

Application=parent-name,Name=configured-name,Target=target-name,TWebLogicTargeTargetType=target-type

where

- parent-name is the name of the ear this module is part of.
- configured-name is the name used in the WebLogic Server configuration for this application or module
- target-name is the server, cluster or virtual host where the module is targeted
- target-type is the description of the target derived from Target.getDescription.
- module-type is the type of archive (ear, war, ejb, rar, car, jms, jdbc or intercept)
- version-name identifies the version of the application

TargetModuleID.toString() will return this object name.

WebLogic Server TargetModuleID Extensions

TargetModuleID is extended by weblogic.deploy.api.spi.WebLogicTargetModuleID. This class provides the following additional functionality:

- getServers - servers associated with the TargetModuleID's target.
- isOnCluster - whether target is a cluster
- isOnServer - whether target is a server
- isOnHost - whether target is a virtual host
- isOnJMSServer - whether target is a JMS server
- getVersion - the version name
- createTargetModuleID - factory for creating module specific targeting

WebLogicTargetModuleID is defined in more detail in the javadocs.
Performing Deployment Operations

The WebLogicDeploymentManager is also extended with convenience methods that simplify working with TargetModuleIDs. They are:

- **filter** - returns a list of TargetModuleIDs that match on application, module, and version
- **getModules** - creates TargetModuleIDs based on an AppDeploymentMBean

TargetModuleIDs have a hierarchical relationship based on the application upon which they are based. The root TargetModuleID of an application represents an EAR module or a standalone module. Child TargetModuleIDs are modules that are defined by the root module's descriptor. For EARs, these are the modules identified in the application.xml descriptor for the EAR. JMS modules have a notion of sub-module, hence any JMS module may have child TargetModuleIDs as dictated by the JMS deployment descriptor. These may be children of an embedded module or the root module. Therefore, there can be 3 levels of TargetModuleIDs for an application.

TargetModuleIDs are generally acquired via some deployment operation, or one of the DeploymentManager.get*Modules() methods. These will only provide TargetModuleIDs based on existing configuration. In certain scenarios where more specific targeting is desired than is currently defined in the configuration, the createTargetModuleID method is provided. This method will create a root TargetModuleID that is specific to a module or submodule within the application. This TargetModuleID can then be used in any deployment operation. For operations that include the application archive (e.g. deploy()), using one of these TargetModuleIDs may result in the application being reconfigured. For example, given the following configuration:

```
<AppDeployment Name="myapp", Targets="s1,s2"/>
```

the application is currently configured for all modules to run on s1 and s2. To provide more specific targeting, a deployment tool can do the following:

```java
Target s1 = find("s1",dm.getTargets()); // find() is not part of this api
WebLogicTargetModuleID root =
    dm.createTargetModuleID("myapp",ModuleType.EAR,s1);
WebLogicTargetModuleID web =
    dm.createTargetModuleID(root,"webapp1",ModuleType.WAR);
    dm.deploy(new TargetModuleID[]{web},myapp,myplan,null);
```

myapp is reconfigured and webapp is specifically targeted to only run on s1. The new configuration is:

```
<AppDeployment Name="myapp", Targets="s1,s2">
```
<SubDeployment Name="webapp", Targets="sl"/>
</AppDeployment>

Extended Module Support

JSR88 defines a secondary descriptor as additional descriptors that a module can refer to or make use of. These descriptors are linked to the root DConfigBean of a module such that they are visible to a java Beans based tool-- they are child properties of a DConfigBeanRoot object. Secondary descriptors are automatically included in the configuration process for a module.

Web Services

An EJB or Web App may include a webservers.xml descriptor. If present the module will be automatically configured with the WebLogic Server equivalent descriptor for configuring the web services. These are treated as secondary descriptors in jsr88 terminology. The deployment plan includes these descriptors as part of the module, not as a separate module.

CMP

CMP support in EJBs is configured via RDBMS descriptors that are identified for CMP beans in the weblogic-ejb-jar.xml descriptor. The RDBMS descriptors support CMP11 and CMP20 currently. Any number of RDBMS descriptors may be included with an EJB module. These descriptors must be provided in the application archive or configuration area (approot/plan). They are not created by the configuration process, but may be modified as with any other descriptor. RDBMS descriptors are treated as secondary descriptors in the deployment plan.

JDBC

JDBC modules are described by a single deployment descriptor. There is no archive involved. If the module is part of an EAR, the JDBC descriptors are specified in weblogic-application.xml. These are configurable properties. JDBC modules can be deployed to WebLogic servers and clusters. Configuration changes to JDBC descriptors are handled as overrides to the descriptor.

If the JDBC module is part of an EAR its configuration overrides are treated as with secondary descriptors; they are incorporated in the deployment plan as part of the EAR, not as separate modules.
Performing Deployment Operations

**JMS**

JMS modules are described by a single deployment descriptor. There is no archive involved. If part of an EAR the JMS descriptors are specified in `weblogic-application.xml`. These are configurable properties. JMS modules can be deployed to JMS servers. Configuration changes to JMS descriptors are handled as overrides to the descriptor. JMS descriptors may identify “targetable groups”. These groups are treated as sub-modules during deployment.

If the JMS module is part of an EAR its configuration overrides are treated as with secondary descriptors; they are incorporated in the deployment plan as part of the EAR, not as separate modules.

**INTERCEPT**

Intercept modules are described by a single deployment descriptor. There is no archive involved. If part of an EAR the Intercept descriptors are specified in `weblogic-application.xml`. These are configurable properties. Intercept modules can be deployed to WebLogic Server servers and clusters. Configuration changes to Intercept descriptors are handled as overrides to the descriptor.

If the INTERCEPT module is part of an EAR its configuration overrides are treated as with secondary descriptors; they are incorporated in the deployment plan as part of the EAR, not as separate modules.

**Examples**

Consider the deployment of a standalone JMS module, one that employs sub-modules. The module is defined by the file, `jms.xml`, which defines sub-modules, `sub1` and `sub2`. The descriptor is fully configured for the environment hence no deployment plan is required, although the scenario described here would be the same if there was a deployment plan.

The tool to deploy this module performs the following steps:

```java
// init the jsr88 session. This uses a WLS specific helper class,
// which does not employ any WLS extensions
DeploymentManager dm = SessionHelper.getDeploymentManager(host, port, user, pword);

// get list of all configured targets
// The filter method is where the tool might ask the user to select from the
```
// list of all configured targets
Target[] targets = filter(dm.getTargets());

// the module is distributed to the selected targets.
ProgressObject po = dm.distribute(targets, new File("jms.xml"), plan);

// when the wait comes back the task is done
waitForCompletion(po);

// It is assumed here that it worked (there is no exception handling)
// the TargetModuleIDs (tmids) returned from the PO correspond to all the
// configured app/module mbeans for each target the app was distributed to.
// This should include 3 tmids per target: the root module tmid and the
// submodules' tmids.
TargetModuleID[] tmids = po.getResultTargetModuleIDs();

// then to deploy the whole thing everywhere you would do this
po = dm.start(tmids);
// the result is that all sub-modules would be deployed on all the selected
// targets, since they are implicitly targeted wherever the their parent is
// targeted

// To get sub-module level deployment you need to use WebLogic Server
// extensions to create TargetModuleIDs that support module level targeting.
// The following deploys the topic "xyz" on a JMS server
WebLogicTargetModuleID root =
dm.createTargetModuleID(tmids[i].getModuleID(), tmids[i], jmsServer);
Performing Deployment Operations

WebLogicTargetModuleID topic =
dm.createTargetModuleID(root,"xyz",WebLogicModuleType.JMS);

// now we can take the original list of tmids and let the user select
// specific tmids to deploy
po = dm.start(topic);
