4. In the Application Navigator, double-click the name of the called task flow to open its diagram.
5. Click the **Overview** tab for the called task flow.
6. In the overview editor, click the **Parameters** navigation tab and click the **Add** icon to define a new entry in the **Input Parameter Definition** section.
7. In the **Name** field, enter a name for the parameter, for example, `inputParm1`.
8. In the **Value** field, enter an EL expression where the parameter value is stored and referenced, for example, `{pageFlowScope.inputValue}`.
9. In the editor, open the diagram for the calling task flow.
10. In the Application Navigator, drag the called bounded task flow and drop it on top of the task flow call activity that is located on the calling task flow.

Dropping a bounded task flow on top of a task flow call activity in a diagram automatically creates a task flow reference to the bounded task flow. As shown in [Figure 20–4](#), the task flow reference contains the bounded task flow ID and a document name. The bounded task flow ID (`id`) is an attribute of the bounded task flow's `<task-flow-definition>` element. The document name points to the source file for the task flow that contains the ID.

Figure 20–4 Task Flow Reference in Property Inspector

11. In the Property Inspector for the task flow call activity, click **Parameters** and expand the **Input Parameters** section.
12. Enter a name that identifies the input parameter.
Because you dropped the bounded task flow on a task flow call activity having defined input parameters, the name should already be specified. You must keep the same input parameter name.
13. Enter a parameter value, for example, `#{pageFlowScope.parm1}`.
The value on the task flow call activity input parameter specifies where the calling task flow stores parameter values.
The value on the input parameter definition for the called task flow specifies where the value will be retrieved from for use within the called bounded task flow once it is passed.
14. At runtime, the called task flow is able to use the input parameter. Since you specified `pageFlowScope` as the value in the input parameter definition for the called task flow, you can use the parameter value anywhere in the called bounded task flow. For example, you can pass it to a view activity on the called bounded task flow. For more information, see [Section 19.2.1.2, "What Happens When You Pass Control Between View Activities"](#).

20.3.2 What Happens When You Pass an Input Parameter to a Bounded Task Flow

JDeveloper writes entries to the source files for the calling task flow and called task flow based on the values that you select. [Example 20–3](#) shows an input parameter definition specified on a bounded task flow.

Example 20–3 Input Parameter Definition

```
<task-flow-definition id="sourceTaskflow">
...
  <input-parameter-definition>
    <name>inputParameter1</name>
    <value>#{pageFlowScope.parmValue1}</value>
    <class>java.lang.String</class>
  </input-parameter-definition>
...
</task-flow-definition>
```

[Example 20–4](#) shows the input parameter metadata for the task flow call activity that calls the bounded task flow shown in [Example 20–3](#). At runtime, the task flow call activity calls the bounded task flow and passes it the value specified by its `value` element.

Example 20–4 Input Parameter on Task Flow Call Activity

```
<task-flow-call id="taskFlowCall1">
...
  <input-parameter>
    <name>inputParameter1</name>
    <value>#{pageFlowScope.newCustomer}</value>
    <pass-by-value/>
  </input-parameter>
...
</task-flow-call>
```

20.4 Sharing Data Controls Between Task Flows

You can share data controls between task flows. A called bounded task flow can reference and modify the value of the data control owned by its calling task flow. This allows the called task flow to share the same data control instance as its parent. Both task flows look in the same place, the data control frame, to get the data control instance.

In the Fusion Order Demo application, for example, you may have a value that is used to display a row in a product table on a page. Clicking a button on the page updates a shopping cart form in an ADF region. The form updates with the product name, based on the selected value in the table.

A data control frame is the container associated with a task flow that contains data controls. A bounded task flow's transactions operate on data controls in the data control frame. A new `DataControlFrame` is created for each task flow that is entered. This results in each task flow having its own unique instance of any data control it uses.

To specify whether data controls are shared between the calling and called task flows, you must set a `data-control-scope` value of either `shared` or `isolated` on the called bounded task flow. The default value is `shared`.

If `data-control-scope` is set to `shared` on both the calling and called bounded task flow, the data control frame used will be the one for the calling task flow. In [Example 20–5](#), the data control frame for Bounded Task Flow A will also be used by both B and C.

If `data-control-scope` is set to `isolated` on both the calling and called bounded task flow, the task flows both use their own data control frames.

Example 20–5 Sharing Data Controls

```
Bounded Task Flow A - isolated
  Bounded Task Flow B - shared
    Bounded Task Flow C - shared
```

Note: A task flow that is configured to share data controls cannot share data controls with the calling task flow if the calling task flow uses a URL to invoke the called task flow. ADF Controller throws an exception if this scenario occurs.

A caller of a bounded task flow can share its caller's data controls to any depth. For example, Task Flow A can share data controls with called bounded Task Flow B. Called Task Flow C can share the same data controls.

A bounded task flow that specifies `data-control-scope` as `shared` and is used within an ADF region shares the data controls of the task flow in the parent view port. For more information about view ports, see [Section 21.1.2, "About View Ports and ADF Regions"](#).

A new data control frame is created for the unbounded task flow in the call stack of each `RootViewPort`. Each browser window is isolated from all other browser windows within the same HTTP session. The browser windows do not share data controls. However, if an end user opens a new browser window, the two browser windows have the same server-side state and share data controls.

For performance reasons, data controls are not instantiated until needed. For more information about data controls, see [Section 13.3, "Exposing Application Modules with Oracle ADF Data Controls"](#).

20.4.1 How to Share a Data Control Between Task Flows

You share data controls between task flows by specifying a value for the `data-control-scope` element of the called task flow.

Before you begin:

It may be helpful to have an understanding of the properties that determine how you share data controls between task flows. For more information, see [Section 20.4, "Sharing Data Controls Between Task Flows."](#)

You may also find it helpful to understand functionality that can be added using other task flow features and parameters. For more information, see [Section 20.1.2, "Additional Functionality for Task Flows Using Parameters."](#)

To share a data control between task flows:

1. In the Property Inspector for the called task flow, expand the **Behavior** category.
2. Select the **Share data controls with calling task flow** check box.

Note: After you select the **Share data controls with calling task flow** check box, you may need to configure transaction options for the task flow. For more information, see, [Section 20.4.3, "What You May Need to Know About Managing Transactions"](#).

20.4.2 What Happens When You Share a Data Control Between Task Flows

JDeveloper writes an entry in the source file for the called task flow when you select the **Share data controls with calling task flow** check box, as illustrated in [Example 20–6](#).

At runtime, the called task flow shares data controls with the calling task flow.

Example 20–6 Metadata to Share Data Controls Between Task Flows

```
<task-flow-definition id="task-flow-definition">
  ...
  <data-control-scope id="__1">
    <shared/>
  </data-control-scope>
```

...
</task-flow-definition>

20.4.3 What You May Need to Know About Managing Transactions

Data controls cannot be shared across more than one transaction at the same time. If your task flow is involved in managing transactions, the value you select for the `data-control-scope` option may affect the `transaction` option settings for a bounded task flow. [Table 20–1](#) describes how these options interact.

Table 20–1 Interaction of transaction and data-control-scope option settings

transaction Option	data-control-scope Isolated Option	data-control-scope shared Option
<code>requires-existing-transaction</code>	Invalid.	If a transaction is not already open, an exception is thrown. The existing transaction is never committed.
<code>requires-transaction</code>	Always begins a new transaction.	Begins a new transaction if one is not already open.
<code>new-transaction</code>	Always begins a new transaction.	Begins a new transaction if one is not already open. If one is already open, an exception is thrown.
<default> (none)	A new data control frame is created without an open transaction.	The task flow uses the calling task flow’s transaction for shared data controls and for any new data controls it creates. The task flow does not create or require a transaction.

20.5 Specifying a Return Value from a Bounded Task Flow

You can configure a bounded task flow to return a parameter value to the task flow that calls it. The value that the bounded task flow returns is in addition to the outcome that it returns to the caller when the bounded task flow invokes a task flow return activity, as described in [Section 19.7, "Using Task Flow Return Activities."](#) To return a value, you must specify:

- Return value definitions on the called bounded task flow
The return value definition specifies where you store the value that you want to return when the called bounded task flow exits.
- Return values on the task flow call activity in the calling task flow to identify where the calling task flow can find the returned value

You can configure the calling task flow to ignore return value definition from the called task flow by not identifying any return values on the task flow call activity in the calling task flow.

The task flow call activity returns values by reference. For this reason, you do not need to make a copy of the values that you want to return to the calling task flow.

20.5.1 How to Specify a Return Value from a Bounded Task Flow

You specify a return value definition on the called task flow and add a parameter to the task flow call activity in the calling task flow that retrieves the return value at runtime.

Before you begin:

Create a bounded or unbounded task flow (calling task flow) and a bounded task flow (called task flow). For more information, see [Section 18.2, "Creating a Task Flow."](#)

It may be helpful to have an understanding of the interaction between the calling task flow and the called task flow. For more information, see [Section 20.5, "Specifying a Return Value from a Bounded Task Flow."](#)

You may also find it helpful to understand functionality that can be added using other task flow features and parameters. For more information, see [Section 20.1.2, "Additional Functionality for Task Flows Using Parameters."](#)

To specify a return value from a called bounded task flow:

1. In the Application Navigator, double-click the source file for the called task flow.
2. In the overview editor, click the **Parameters** navigation tab.
3. Click the **Add** icon next to the **Return Value Definitions** category and add values as follows to define a return value:
 - **Name:** Enter a name to identify the return value. For example, `returnValue1`.
 - **Class:** Enter a Java class that defines the data type of the return value. The default value is `java.lang.String`.
 - **Value:** Enter an EL expression that specifies where to store the return value when the called task flow exits. For example, enter an EL expression similar to the following:

```
#{pageFlowScope.ReturnValueDefinition}
```
4. In the Application Navigator, double-click the source file for the calling task flow.
5. In the ADF Task Flow page of the Component Palette, from the Component panel, drag and drop a task call activity onto the diagram.
6. In the Property Inspector for the task flow activity, expand the **Parameters** section, click the **Add** icon next to the **Return Values** entry and add values as follows to define a return value:
 - **Name:** Enter a name to identify the return value. For example, `returnValue1`.
The value you enter must match the value you entered for the **Name** field when you defined the return value definition in step 3.
 - **Value:** Enter an EL expression that specifies where to store the return value when the called task flow exits. For example, enter an EL expression similar to the following:

```
#{pageFlowScope.ReturnValueDefinition}
```

 The value you enter must match the value you entered for the **Value** field when you defined the return value definition in step 3.

20.5.2 What Happens When You Specify a Return Value from a Bounded Task Flow

At design time, JDeveloper writes entries to the source files for the task flows that you configured. [Example 20–7](#) shows an example entry that JDeveloper writes to the source file for the calling task flow.

Example 20–7 Metadata in the Calling Task Flow to Specify a Return Value

```
<task-flow-call id="taskFlowCall1">
  <return-value id="__3">
    <name id="__4">returnValue1</name>
    <value id="__2">#{pageFlowScope.ReturnValueDefinition}</value>
  </return-value>
</task-flow-call>
```

[Example 20–8](#) shows an example entry that JDeveloper writes to the source file for the called task flow.

Example 20–8 Metadata in the Called Task Flow to Specify a Return Value

```
<return-value-definition id="__2">
  <name id="__3">returnValue1</name>
  <value>#{pageFlowScope.ReturnValueDefinition}</value>
  <class>java.lang.String</class>
</return-value-definition>
```

At runtime, the called task flow returns a value. If configured to do so, the task flow call activity in the calling task flow retrieves this value.

Using Task Flows as Regions

This chapter describes how to render task flows in pages or page fragments using ADF regions.

This chapter includes the following sections:

- [Section 21.1, "About Using Task Flows in ADF Regions"](#)
- [Section 21.2, "Creating an ADF Region"](#)
- [Section 21.3, "Specifying Parameters for an ADF Region"](#)
- [Section 21.4, "Specifying Parameters for ADF Regions Using Parameter Maps"](#)
- [Section 21.5, "Refreshing an ADF Region"](#)
- [Section 21.6, "Configuring Activation of an ADF Region"](#)
- [Section 21.7, "Navigating Outside an ADF Region's Task Flow"](#)
- [Section 21.8, "Creating ADF Dynamic Regions"](#)
- [Section 21.9, "Adding Additional Task Flows to an ADF Dynamic Region"](#)
- [Section 21.10, "Configuring a Page To Render an Unknown Number of Regions"](#)

21.1 About Using Task Flows in ADF Regions

You can execute a bounded task flow in a JSF page or page fragment (`.jspx`) by using an ADF region. A primary reason for executing a bounded task flow as an ADF region is reuse. You can isolate specific pieces of application functionality in a bounded task flow and an ADF region in order to reuse it throughout the application. You can extract, configure, and package application functionality within a bounded task flow so that it can be added to other pages using an ADF region. ADF regions can be reused wherever needed, which means they are not dependent on a parent page. This also means that you can isolate the presentation of the parent pages from the ADF region; menus, buttons, and navigation areas are not affected by what is displayed in the ADF region. If you modify a bounded task flow, the changes apply to any ADF region that uses the task flow.

An ADF region comprises the following:

- An `af:region` tag that appears in the page or page fragment where you render the region
- An instance object that implements `RegionModel` from the following package:
`oracle.adf.view.rich.model`

For more information about `RegionModel`, see the *Oracle Fusion Middleware Java API Reference for Oracle ADF Faces*

- One or other of the following:
 - A task flow binding (`taskFlow`) in the page definition that identifies the bounded task flow to use in the ADF region
 - A multi task flow binding (`multiTaskFlow`) in the page definition that identifies a list of bounded task flows to use in the ADF region

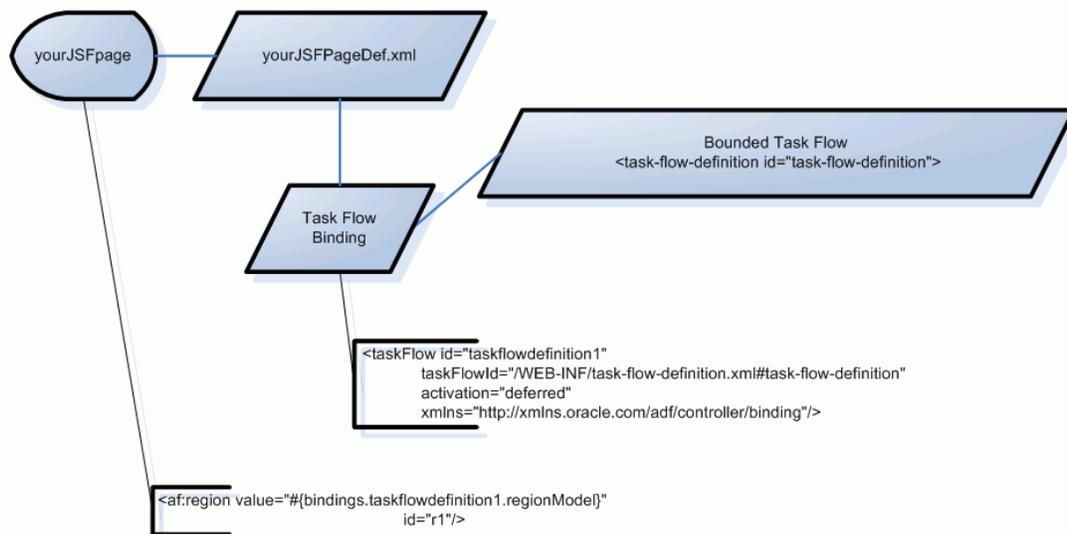

When first rendered, the ADF region's content is that of the first view activity in the bounded task flow. The view activities used in the bounded task flow must be associated with page fragments, not pages.

You can pass values to the ADF region using task flow binding input parameters or contextual events. In addition, you can configure the task flow binding's `parametersMap` property to determine what input parameters the task flow binding passes from the bounded task flow to the ADF region.

ADF regions can be configured so that you determine when the region activates or refreshes. You can also configure an ADF region and a bounded task flow so that navigation control stops in the bounded task flow and passes to the page that contains the ADF region. Finally, you can create dynamic regions (ADF dynamic regions) where the task flow binding determines at runtime what bounded task flow renders in the region and configure a dynamic region link so that end users can change the bounded task flow that renders in the ADF dynamic region at runtime.

Figure 21–1 shows how an ADF region references a bounded task flow using a task flow binding in the page definition file of the page that hosts the ADF region.

Figure 21–1 ADF Region Referencing a Bounded Task Flow

21.1.1 About Page Fragments and ADF Regions

A page fragment is a JSF document (file extension is `.jsff`) that renders as content in another JSF page. A page fragment should not have more than one root component. Wrapping multiple root components in a single root component is recommended so that you optimize the display performance of the page fragment. In addition, if a page

fragment has only one visual root component and a popup component (which is invisible to end users until invoked), it is also recommended to wrap these components in a single root component. For example, place the popup component in a `panelStretchLayout` component's bottom facet with the `bottomHeight` attribute set to 0 pixels.

If a page fragment has more than one root component, the Fusion web application logs a message at runtime, as shown in [Example 21-1](#), where `r1` identifies the ADF region that renders the page fragment.

Example 21-1 Log Message for a Page Fragment with Multiple Root Components

```
<RegionRenderer> <encodeAll> The region component with id: r1 has detected a page
fragment with multiple root components. Fragments with more than one root
component may not display correctly in a region and may have a negative impact
on performance. It is recommended that you restructure the page fragment to have
a single root component.
```

Apart from having only one root component element, a page fragment must not contain any of the following tags:

- `<af:document>`
- `<f:view>`
- `<f:form>`
- `<html>`
- `<head>`
- `<body>`

These tags can only appear once in a document and do not support nesting in a JSF page. For example, a page fragment embedded in a page cannot have an `<html>` tag because the JSF page already has one.

[Example 21-2](#) contains an example of a simple page fragment. Unlike a JSF page, it contains no `<f:view>` or `<f:form>` tags.

Example 21-2 Page Fragment Source Code

```
<?xml version='1.0' encoding='UTF-8'?>
<jsp:root xmlns:jsp="http://java.sun.com/JSP/Page" version="2.1"
          xmlns:af="http://xmlns.oracle.com/adf/faces/rich">
  <af:commandButton text="commandButton 1" id="cb1"/>
</jsp:root>
```

You must nest a page fragment that you include in another JSF page within a region (`af:region` tag). A bounded task flow that you add to a JSF page as a region cannot call pages; it must call page fragments.

21.1.2 About View Ports and ADF Regions

A view port is a display area capable of navigating independently of other view ports. A browser window and an ADF region are both examples of view ports. The root view port displays the main page in a browser window. The root view port may have child view ports, for example, regions on the page, but does not have a parent view port.

Java classes that implement the `ViewPortContext` interface in the `oracle.adf.controller` package get you more information about view ports. For

more information, see the *Oracle Fusion Middleware Java API Reference for Oracle ADF Controller*.

21.1.3 Task Flows and ADF Region Use Cases and Examples

Figure 21–2 shows the Registration page (`register.jspx`) in the Fusion Order Demo application which renders two ADF regions. One of these regions (Registration Help) is static; it appears regardless of actions that an end user invokes elsewhere on the Registration page. It displays help information for the end user by rendering the view activities defined in the Fusion Order Demo application's `help-task-flow.xml` task flow. For more information about creating this type of region, see Section 21.2, "Creating an ADF Region."

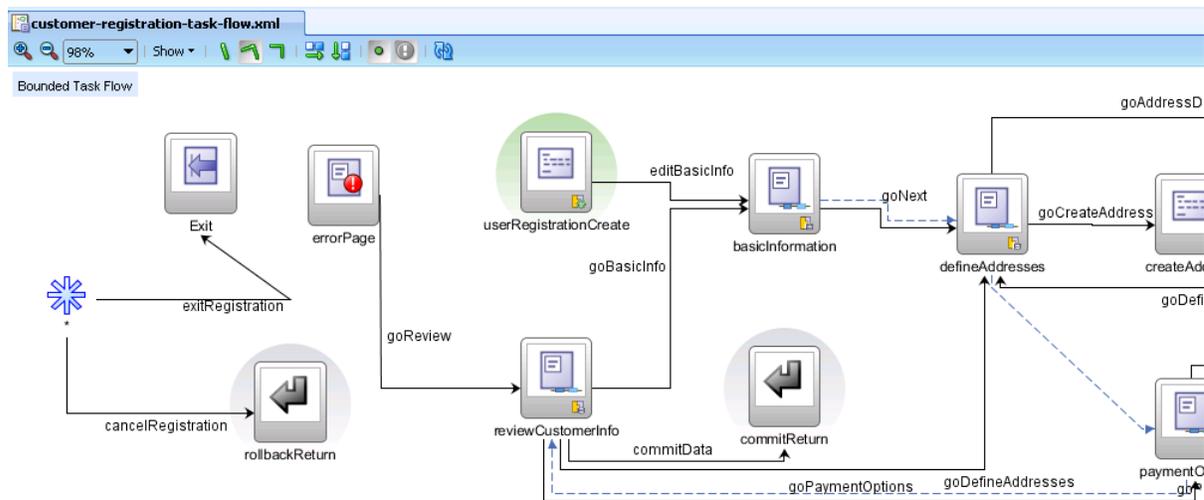

The second region that `register.jspx` renders is a dynamic region (ADF dynamic region). The task flow that it renders depends on the end user's action. If the end user clicks **Register as a customer** on the registration page, the ADF dynamic region renders the customer registration task flow (`customer-registration-task-flow.xml`). Alternatively, if the end user clicks **Register as an employee**, the ADF dynamic region renders the employee registration task flow (`employee-registration-task-flow.xml`). For more information about creating this type of region, see Section 21.8, "Creating ADF Dynamic Regions."

Figure 21–2 ADF Dynamic Region and ADF Region in the Fusion Order Demo Application

The task flows that you render in an ADF region can be simple (for example, the help task flow has one view activity that renders help information) or can involve a number of steps where you guide end users through a process to complete a task, as in the case of the customer registration task flow.

Figure 21–3 shows parts of the customer registration task flow. It contains view activities that allow end users to review information they enter (for example, `reviewCustomerInfo`), an exception handler activity to display a message when an error occurs (`errorPage`), and task flow return activities to cancel or commit the changes that end users make. All these task flow activities can be rendered within an ADF region.

Figure 21–3 Customer Registration Bounded Task Flow in Fusion Order Demo Application

One special case is the task flow return activity. In many cases, you cannot return control when the bounded task flow finishes execution because there is no caller (except the page or page fragment that hosts the bounded task flow) to which you can return control. For this reason, design control flow appropriately in a bounded task flow that you intend to render in an ADF region.

21.1.4 Additional Functionality for Task Flows that Render in ADF Regions

You may find it helpful to understand how a task flow that renders in an ADF region interacts with other task flow and ADF functionality. Following are links to other functionality that may be of interest.

- You can set security on a bounded task flow that displays in an ADF region and associated page definitions. If an end user displays a page that contains an ADF region he or she is not authorized to view, the contents of the ADF region do not display. No authentication mechanism is triggered. For more information, see [Chapter 35, "Enabling ADF Security in a Fusion Web Application"](#).
- Task flows can invoke managed beans. For more information about managed beans, see [Section 24.4, "Using a Managed Bean in a Fusion Web Application."](#)
- You can use contextual events to exchange information with a bounded task flow. For more information, see [Section 34, "Using Contextual Events."](#)

21.2 Creating an ADF Region

You create an ADF region by dragging and dropping a bounded task flow that contains at least one view activity or one task flow call activity to the page where you want to render the ADF region. This makes sure that the ADF region you create has content to display at runtime.

The bound task flow's view activities must be associated with page fragments (.jspx). If you attempt to drag and drop a bounded task flow that is associated with pages rather than page fragments, JDeveloper does not display the context menu that allows you to create an ADF region. You can convert a bound task flow that uses pages to use page fragments. For more information, see [Section 18.6.3, "How to Convert Bounded Task Flows."](#)

The context menu that JDeveloper displays to create an ADF region presents options to create a non-dynamic and a dynamic region. A dynamic region (ADF dynamic region) determines the bounded task flow that it renders at runtime. For more information about creating an ADF dynamic region, see [Section 21.8, "Creating ADF Dynamic Regions."](#) You determine, at design time, the bounded task flow that a non-dynamic region (ADF region) displays.

Before you create an ADF region, you need to do the following:

- Create a bounded task flow with one or more view activities associated with page fragments or one task flow call activity to a task flow with view activities
For more information, see [Section 18.2, "Creating a Task Flow."](#)
- Create a page to host the ADF region

21.2.1 How to Create an ADF Region

Drag a bounded task flow from the Application Navigator to the page where you want to render an ADF region.

Before you begin:

It may be helpful to have an understanding of the requirements for a bounded task flow that you use in an ADF region. For more information, see [Section 21.2, "Creating an ADF Region."](#)

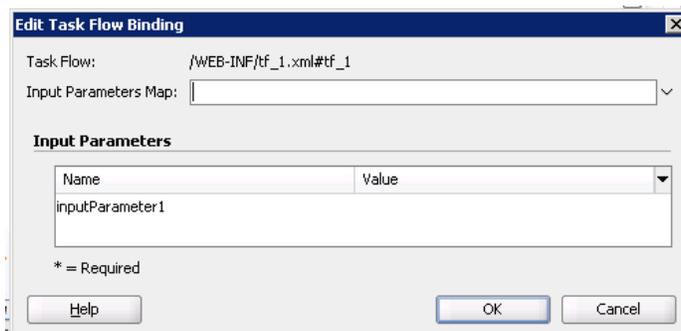

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see [Section 21.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."](#)

To create an ADF region:

1. In the Application Navigator, drag the bounded task flow onto the JSF page and drop it where you want to locate the ADF region.
2. From the context menu that appears, choose **Create > Region**.

The Edit Task Flow Binding dialog appears if the bounded task flow that you drop on the JSF page has an input parameter defined, as described in [Section 20.3, "Passing Parameters to a Bounded Task Flow."](#) For more information about specifying parameters for an ADF region, see [Section 21.3, "Specifying Parameters for an ADF Region."](#)

Figure 21–4 Edit Task Flow Binding Dialog for an ADF Region

3. In the Structure window, right-click the node for the ADF region that you added (**af:region**) and choose **Go to Properties**.

4. Review or modify (as appropriate) the following properties which JDeveloper automatically populates with default values in the Property Inspector for the ADF region:
 - **Id:** An ID that the JSF page uses to reference the ADF region, for example, `r1`.
 - **Value:** An EL reference to the ADF region model, for example, `#{bindings.region1.regionModel}`. This is the region model that describes the behavior of the region.
 - **Rendered:** If `true` (the default value), the ADF region renders when the JSF page renders.
5. For information about how to map parameters between the view activity associated with the JSF page and the ADF region, see [Section 21.3, "Specifying Parameters for an ADF Region"](#).

21.2.2 What Happens When You Create an ADF Region

When you drop a bounded task flow onto a JSF page to create an ADF region, JDeveloper adds an `af:region` tag to the page. The `af:region` tag references an object that implements `RegionModel`. [Example 21-3](#) shows a sample of the metadata that JDeveloper adds to the JSF page.

Example 21-3 Metadata Added to a JSF Page to Create an ADF Region

```
<af:region value="#{bindings.tf_register_employee1.regionModel}"
  id="r1"/>
```

JDeveloper also adds a task flow binding to the page definition file of the page that hosts the ADF region. [Example 21-4](#) shows a sample of the metadata that JDeveloper adds. The task flow binding provides a bridge between the ADF region and the bounded task flow. It binds a specific instance of an ADF region to its associated bounded task flow and maintains all information specific to the bounded task flow. The `taskFlowId` attribute specifies the directory path and the name of the source file for the bounded task flow.

Example 21-4 Metadata Added to Page Definition to Create a Task Flow Binding

```
<taskFlow id="tf_register_employee1"
  taskFlowId="/WEB-INF/tf_register_employee.xml#tf_register_employee"
  activation="deferred"
  xmlns="http://xmlns.oracle.com/adf/controller/binding"/>
```

The bounded task flow preserves all of the data bindings when you drop it on the JSF page. At runtime, a request for a JSF page containing an ADF region initially handles like any other request for a JSF page. As the JSF page definition executes, data loads in to the JSF page. When the component tree for the parent JSF page encounters the `<af:region>` tag, it executes it in order to determine the first page fragment of content to display. Once it determine the first page fragment of content, it adds the appropriate UI components from the page fragment to the component tree for the parent JSF page.

The task flow binding creates an object for its task flow that implements the following interface in order to get the current view activity:

```
oracle.adf.controller.ViewPortContext
```

The task flow binding's `taskFlowId` attribute can also reference an EL expression that evaluates to one of the following:

- `java.lang.String`
- `oracle.adf.controller.TaskFlowId`

You use this capability if you create an ADF dynamic region. For more information, see [Section 21.8, "Creating ADF Dynamic Regions."](#)

21.3 Specifying Parameters for an ADF Region

You can make input parameters that you defined for a bounded task flow available to an ADF region by adding them to the task flow binding that the ADF region references. Use EL expressions to reference input parameters available in memory scopes, managed beans, or the ADF binding layer.

Specifying input parameters is one method of providing information to an ADF region. An alternative method is to use contextual events. The nature of the information that you want to provide to the ADF region determines the method you choose to provide the information. For example, choose:

- Input parameters if the required information is at the beginning of the task flow and a change in the value of this information requires a restart of the task flow.

For example, you have a page that contains a table of employees. An ADF region on that page contains a task flow to enroll a selected employee in a benefits program. A change in the selected employee requires that you restart the benefits enrollment task flow from the beginning for the newly selected employee. Using input parameters to the task flow is the right decision for this use case.

You can pass input parameters by reference or by value. If you pass by reference, an update on the main page for the selected employee's information, such as last name, is automatically reflected in the task flow running in the ADF region without restarting the task flow.

- Contextual events if you can only determine the information to exchange after the start of a task flow and a change in the information does not require a restart of the task flow. For example, the Fusion Order Demo application uses contextual events to display the appropriate help topic when the customer registration task flow renders in the `register.jspx` page. For more information about contextual events, see [Chapter 34, "Using Contextual Events."](#)

For information about creating an ADF region and adding task flow bindings, see [Section 21.2, "Creating an ADF Region."](#) For information about how to define an input parameter for a bounded task flow, see [Section 20.3, "Passing Parameters to a Bounded Task Flow"](#).

21.3.1 How to Specify Parameters for an ADF Region

Use EL expressions to specify parameters available in memory scopes, managed beans, or the ADF binding layer as input for the ADF region.

Before you begin:

It may be helpful to have an understanding of the requirements for specifying parameters for an ADF region. For more information, see [Section 21.3, "Specifying Parameters for an ADF Region."](#)

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see [Section 21.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."](#)

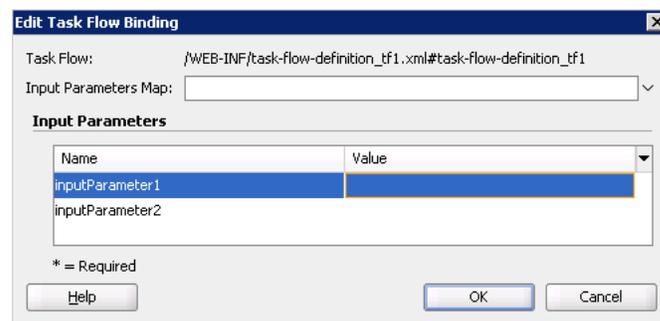

To specify input parameters for an ADF region:

1. In the Application Navigator, right-click the JSF page that holds the ADF region and choose **Go to Page Definition**.
2. In the overview editor for the page definition file, select the task flow binding for which you want to specify parameters.
3. Click the Edit icon to display the Edit Task Flow Binding dialog, as shown in [Figure 21–5](#).

If you defined input parameters for the bounded task flow, as described in [Section 20.3, "Passing Parameters to a Bounded Task Flow"](#), the Edit Task Flow Binding dialog lists these parameters in the Input Parameters section.

Note: You can write an EL expression that references a list of input parameters specified in a managed bean using the Input Parameters Map field of the Edit Task Flow Binding dialog. For more information about implementing this functionality, see [Section 21.4, "Specifying Parameters for ADF Regions Using Parameter Maps."](#)

Figure 21–5 Edit Task Flow Binding Dialog

4. Write an EL expression that retrieves the value of each input parameter you want to specify for the ADF region. Note that you must write an EL expression for parameters that you defined as required. For example, write an EL expression similar to the following:

```
#{pageFlowScope.inputParameter1}
```

5. Click **OK**.

21.3.2 What Happens When You Specify Parameters for an ADF Region

JDeveloper writes entries that are child elements of the `taskFlow` element in the page definition of the JSF page, as illustrated in example [Example 21–5](#).

Example 21–5 Metadata Entries to Specify Input Parameters for an ADF Region

```
<taskFlow id="tflow_tf11"
  taskFlowId="/WEB-INF/tflow_tf1.xml#tflow_tf1"
  activation="deferred"
  xmlns="http://xmlns.oracle.com/adf/controller/binding">
  <parameters>
    <parameter id="inputParameter1"
      value="#{pageFlowScope.inputParameter1}" />
    <parameter id="inputParameter2"
      value="#{pageFlowScope.inputParameter2}" />
  </parameters>
</taskFlow>
```

```
</parameters>  
</taskFlow>
```

At runtime, the values specified by the EL expression in the value attribute are passed to the ADF region.

21.4 Specifying Parameters for ADF Regions Using Parameter Maps

In addition (or as an alternative) to listing all the input parameters on the task flow binding, as described in [Section 21.3, "Specifying Parameters for an ADF Region,"](#) you can use the `parametersMap` property of the task flow binding to specify a parameter map object on a managed bean. The parameter map object that you reference must be of a type that implements the following interface:

```
java.util.Map
```

The parameter map object that you reference specifies keys that map to the values you want to input to the ADF region. Using this approach reduces the number of `parameter` child elements that appear under the task flow binding (`taskFlow`) element or the multi task flow binding (`multiTaskFlow`) in the page definition for the page. This approach also allows you more flexibility in determining what input parameters pass to the ADF region. In particular, it provides a way to pass parameters to ADF dynamic regions as the number of input parameters can differ between the different task flow bindings in an ADF dynamic region. For more information, see [Section 21.8, "Creating ADF Dynamic Regions."](#)

You can configure an ADF region or an ADF dynamic region's task flow binding to reference a parameter map. You can also configure a multi task flow binding to reference a parameter map. Make sure that the name of an input parameter you define for a bounded task flow matches the name of a key that you define in the parameter map object.

If you specify a parameter with the same `id` attribute in a `<parameter>` element and in a `<parametersMap>` element, the `<parametersMap>` element always takes precedence. This is because the `<parametersMap>` element may need to override the static value of the parameter if you create an ADF dynamic region, as described in [Section 21.8, "Creating ADF Dynamic Regions."](#)

21.4.1 How to Create a Parameter Map to Specify Input Parameters for an ADF Region

You configure the task flow binding's `parametersMap` property to reference the parameter map object that defines the key-value pairs you want to pass to the ADF region.

Before you begin:

It may be helpful to have an understanding of the configuration options available to you when passing input parameters to an ADF region. For more information, see [Section 21.4, "Specifying Parameters for ADF Regions Using Parameter Maps."](#)

You may also find it helpful to understand functionality that can be added using other task flow and ADF region features. For more information, [Section 21.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."](#)

To create a parameter map to specify input parameters for an ADF region:

1. Create a managed bean or edit an existing managed bean so that it returns an object that implements the `java.util.Map` interface.

Configure the managed bean so the object returns key-value pairs with the values that you want to pass to the ADF region. For more information about managed beans, see [Section 24.4, "Using a Managed Bean in a Fusion Web Application."](#)

2. In the Application Navigator, right-click the JSF page that holds the ADF region and choose **Go to Page Definition**.
3. In the overview editor for the page definition file, select the task flow binding or multi task flow binding for which you want to specify a parameter map.
4. Click the Edit icon to display the appropriate dialog (Edit Task Flow Binding dialog or the Edit Multi Task Flow Binding).
5. Select **Expression Builder** from the Input Parameters Map dropdown menu.
6. Write or build an EL expression that references a parameter map. For example, write an EL expression similar to the following:

```
#{pageFlowScope.userInfoBean.parameterMap}
```
7. Click **OK**.

21.4.2 What Happens When You Create a Parameter Map to Specify Input Parameters

At runtime, the task flow binding or multi task flow binding evaluates the EL expression specified for its `parametersMap` property. It returns values to the ADF region from the managed bean for keys that match the name of the input parameters defined for the bounded task flow that render in the ADF region.

[Example 21–6](#) shows code snippets from a managed bean that puts two values (`isLoggedIn` and `principalName`) into a parameter map named `parameterMap`.

Example 21–6 *Managed Bean Defining a Parameter Map*

```
import java.util.HashMap;
import java.util.Map;

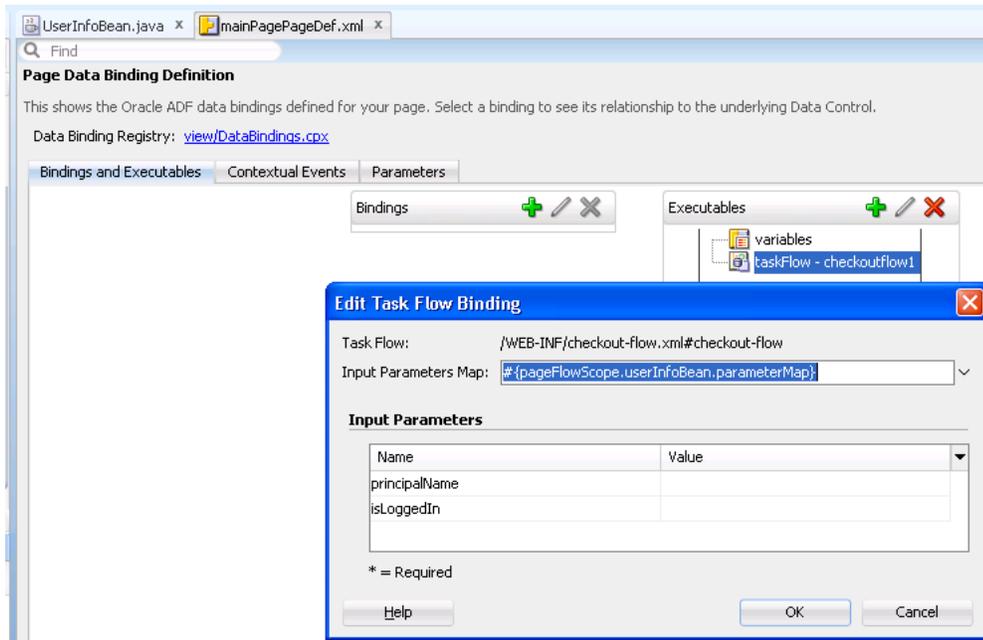

public class UserInfoBean {
    private Map<String, Object> parameterMap = new HashMap<String, Object>();

    public Map getParameterMap() {

        parameterMap.put("isLoggedIn", getSecurity().isAuthenticated());
        parameterMap.put("principalName", getSecurity().getPrincipalName());
        return parameterMap;
    }
}
```

[Figure 21–6](#) shows the Edit Task Flow Binding dialog after you close the Expression Builder dialog, having specified the parameter map object (`parameterMap`) shown in [Example 21–6](#). The **Input Parameters** field in the Edit Task Flow Binding dialog lists the input parameters defined for the bounded task flow associated with this ADF region (`checkout-flow`). The task flow binding retrieves the values for these parameters from the managed bean shown in [Example 21–6](#).

Figure 21–6 EL Expression Referencing Parameter Map on Task Flow Binding

Example 21–7 shows the metadata that appears for the task flow binding in the page definition file of the page that renders the ADF region. The metadata for the task flow binding references both the bounded task flow (`taskFlowId` attribute) and the managed bean (`parametersMap`).

Example 21–7 Task Flow Binding Specifying a Parameter Map

```
<taskFlow id="checkoutflow1"
    taskFlowId="/WEB-INF/checkout-flow.xml#checkout-flow"
    activation="deferred"
    xmlns="http://xmlns.oracle.com/adf/controller/binding"
    parametersMap="#{pageFlowScope.userInfoBean.parameterMap}" />
```

You specify the `<parameterMap>` element in the page definition.

Note: If you specify `Refresh="ifNeeded"`, parameters are not supported in the `<parameterMap>` element. The only condition that determines whether the region need to be refreshed is the boolean value returned by the evaluation of `RefreshCondition`. For more information, see [Section 21.5.2, "What You May Need to Know About Refreshing an ADF Region"](#).

21.5 Refreshing an ADF Region

You can configure when an ADF region refreshes and whether it invokes a task flow. An ADF region can only invoke a task flow when the ADF region is in an active state. An ADF region in an inactive state cannot invoke a task flow and returns a null value for the ID of the referenced task flow to the parent page.

21.5.1 How to Configure the Refresh of an ADF Region

You set values for the task flow binding of the task flow associated with the ADF region to determine when an ADF region switches from an inactive to an active state and to determine when an ADF region refreshes.

Before you begin:

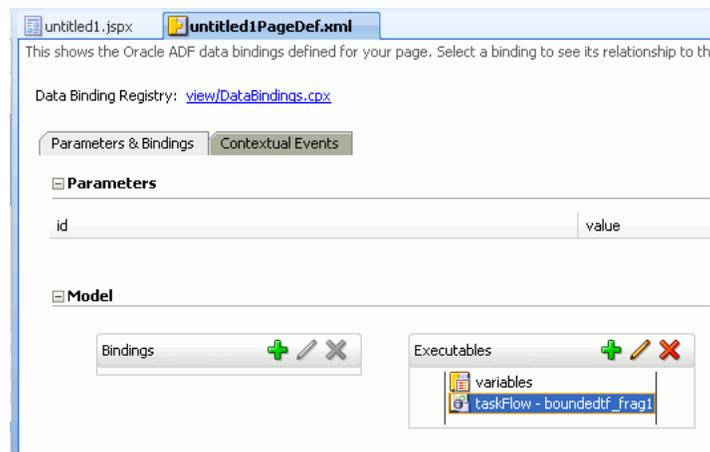

It may be helpful to have an understanding of the requirements for a bounded task flow that you use in an ADF region. For more information, see [Section 21.5, "Refreshing an ADF Region."](#)

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see [Section 21.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."](#)

To configure the refreshing of an ADF Region:

1. In the Application Navigator, select the page that contains the ADF region, right-click and choose **Go to Page Definition**.
2. In the page definition file, select the task flow binding or multi task flowing binding in the **Executables** section, as illustrated in [Figure 21–7](#).

Figure 21–7 Task Flow Binding

3. In the Property Inspector, select a value from the Refresh dropdown menu, as described in the following list:
 - **default:** refresh the ADF region once when the page that hosts the ADF region appears or when the EL expression you set as a value for the RefreshCondition property in step 4 returns `true`.
 - **ifNeeded:** refresh the ADF region if the value of a task flow binding parameter changes. Do not set a value for the RefreshCondition property in step 4 if you select this value.
4. If you selected **default** as the value for the Refresh property, select **Edit** from the RefreshCondition dropdown menu to invoke the Expression Builder and write an EL expression that returns a boolean value at runtime. If the EL expression returns `true`, the ADF region refreshes.
5. In the Property Inspector, select a value from the activation dropdown menu, as described in the following list:

- **conditional**: activates the ADF region if the EL expression set as a value for the task flow binding `active` property returns `true`.
- **deferred**: select this option if your application uses Facelets XHTML pages in the view layer and you want to activate the ADF region when a Facelets XHTML page first requests a `viewID`. If your application uses JSP technology in the view layer, selecting this option has the same effect as selecting **immediate** (the ADF region activates immediately).

This option is recommended if your application uses Facelets XHTML pages. For more information about Facelets with ADF Faces, see the "Getting Started with ADF Faces" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

- **immediate**: activates the ADF region immediately. This is the default value.

The value that you select in the dropdown menu determines when an ADF region switches from an inactive to an active state. An ADF region must have an active state before it can invoke a task flow.

6. If you selected **conditional** as the value for the activation property, select **Edit** from the active dropdown menu to invoke the Expression Builder and write an EL expression that returns a boolean value at runtime. If the EL expression returns `true`, the ADF region invokes the task flow.

21.5.2 What You May Need to Know About Refreshing an ADF Region

An ADF region initially refreshes when the parent JSF page on which the region is located first displays. During the initial refresh, any ADF region task flow binding parameter values are passed in from the parent page. The parameter values are used to display the initial page fragment within the ADF region. If the bounded task flow relies on input parameter values that are not available when the page is first created, make sure that your task flow behaves correctly if the input parameter values are null by, for example, using a `NullPointerException` object. Alternatively (or additionally), make sure that the task flow does not activate until the input parameters become available by configuring the task flow binding's `active` property.

An ADF region task flow binding can be refreshed again based on one of the following task flow binding attributes:

- Neither `Refresh` or `RefreshCondition` attributes are specified (default)

If neither the `Refresh` nor `RefreshCondition` task flow binding attribute is specified, the ADF region is refreshed only once at the time the parent page is first displayed unless you configure a value for the task flow binding's `active` property.
- `RefreshCondition="{EL.expression}"`

The ADF region is refreshed a single time when its `RefreshCondition` evaluates `true`. The `RefreshCondition` must evaluate to a boolean value.

At the time the `RefreshCondition` is evaluated, if the variable `bindings` is used within the EL Expression, the context refers to the binding container of the parent page, not the page fragment displayed within the ADF region.

`RefreshCondition` is independent of the change of value of binding parameters. If the task flow binding parameters do not change, nothing within the ADF region will change.
- `Refresh="ifNeeded"`

Any change to a task flow binding parameter value causes the ADF region to refresh.

If the ADF region task flow binding does not have parameters, `Refresh="ifNeeded"` is equivalent to not specifying the `Refresh` attribute.

If you set `Refresh` to `ifNeeded`, the `RefreshCondition` attribute should not be specified.

`Refresh="ifNeeded"` is not supported if you pass parameters to the task flow binding using a dynamic parameter map. You must instead use the `RefreshCondition="{EL.Expression}"`.

For more information about specifying parameter values using a parameter map, see [Section 21.4, "Specifying Parameters for ADF Regions Using Parameter Maps."](#)

The `RefreshCondition` and `Refresh` properties are mutually exclusive. The `Refresh="ifNeeded"` property takes precedence over `RefreshCondition`. If the bindings variable is used within the EL expression at the time `RefreshCondition` is evaluated, the context refers to the binding container of the parent page, not the page fragment displayed within the ADF region. The expression is evaluated during the `PrepareRender` phase of the ADF page lifecycle. For more information, see [Chapter 25, "Understanding the Fusion Page Lifecycle"](#).

[Example 21–8](#) contains a sample task flow binding located within the page definition of a page on which an ADF region has been added.

Example 21–8 Refresh Option Specified in ADF Region Binding

```
<taskFlow id="Department1" taskFlowId="/WEB-INF/Department#Department"
  Refresh="ifNeeded"
  xmlns="http://xmlns.oracle.com/adf/controller/binding">
  <parameters>
    <parameter id="DepartmentId" value="{bindings.DepartmentId.inputValue}"
      xmlns="http://xmlns.oracle.com/adfm/uimodel"/>
  </parameters>
</taskFlow>
```

You do not need to refresh an ADF region to refresh the data controls inside the ADF region. During the ADF lifecycle, the refresh events telling the iterators to update will be propagated to the binding container of the current page of the ADF region.

21.6 Configuring Activation of an ADF Region

You can configure when an ADF region activates. This has the effect of determining when the task flows contained in ADF regions activate. Configuring the activation of ADF regions can optimize the performance of a Fusion web application's page. For example, a page that contains 5 ADF regions may reference 5 task flows. You may not want these 5 task flows to execute simultaneously when the Fusion web application page loads so you configure an `activation` property to determine when a task flow executes.

21.6.1 How to Configure Activation of an ADF Region

You configure the `activation` property for the task flow binding associated with the ADF region to determine when to activate the ADF region.

Before you begin:

It may be helpful to have an understanding of the configuration options for activating an ADF region. For more information, see [Section 21.6, "Configuring Activation of an ADF Region."](#)

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see [Section 21.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."](#)

To configure the activation of an ADF region:

1. In the Application Navigator, select the page that contains the ADF region(s), right-click and choose **Go to Page Definition**.
2. In the page definition file, select the task flow binding or multi task flow binding in the **Executables** section, as illustrated in [Figure 21–8](#).

Figure 21–8 Task Flow Bindings for ADF Region Configured for Activation

3. In the Property Inspector, select a value from the activation dropdown menu, as described in the following list:
 - **conditional:** activates the ADF region if the EL expression set as a value for the task flow binding `active` property returns `true`.
 - **deferred:** select this option if your application uses Facelets XHTML pages in the view layer and you want to activate the ADF region when a Facelets XHTML page first requests a `viewID`. If your application uses JSP technology in the view layer, selecting this option has the same effect as selecting **immediate** (the ADF region activates immediately).
 This option is recommended if your application uses Facelets XHTML pages. For more information about Facelets with ADF Faces, see the "Getting Started with ADF Faces" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
 - **immediate:** activates the ADF region immediately. This is the default value.

The value that you select in the dropdown menu determines when an ADF region switches from an inactive to an active state. An ADF region must have an active state before it can invoke a task flow.
4. If you selected **conditional** as the value for the `activation` property, select **Edit** from the active dropdown menu to invoke the Expression Builder and write an EL expression that returns a boolean value at runtime. If the EL expression returns

`true`, the ADF region invokes the task flow. If the EL expression returns `false`, the ADF region deactivates a task flow that was active in the ADF region.

21.6.2 What Happens When You Configure Activation of an ADF Region

The behavior of the ADF region at runtime depends on the options that you set for the activation property.

Figure 21–9 shows the default behavior where all task flows in ADF regions execute when the page loads the ADF regions (Tab # 1, Tab # 2, Tab # 3).

Figure 21–9 Default Activation of ADF Regions

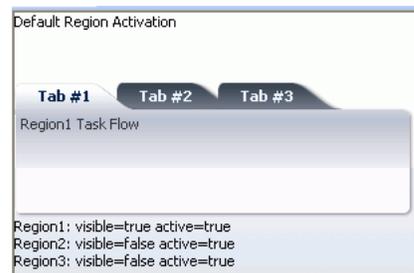

Figure 21–10 shows an example where the activation property was set to deferred and the application uses Facelets. The regions in Tab # 1 and Tab # 2 have an active state because the end user navigated to these regions. The region in Tab # 3 is inactive.

Figure 21–10 Deferred Activation of ADF Regions

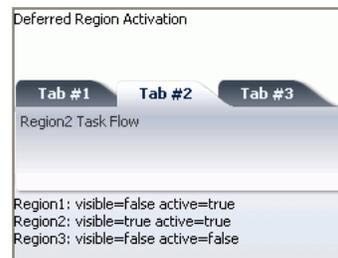

Figure 21–11 shows an example where the activation property was set to conditional and the active property to an EL expression that returns a boolean value at runtime. The region in Tab # 1 is in an active state because the EL expression specified for the active property returns `true`. The regions in Tab # 2 and Tab # 3 are inactive because the EL expression specified for the active property returns `false`.

Note that the following events occur if a region deactivates a task flow (the value returned by the active property changes from `true` to `false`):

- A task flow with an active transaction rolls back the transaction.
For more information about transaction options in task flows, see [Section 22.2, "Managing Transactions in Task Flows."](#)
- If a task flow has a data control frame with a `data-control-scope` value of `isolated`, the task flow releases the data control frame and any data controls in the data control frame.

For more information about data controls, see [Section 20.4, "Sharing Data Controls Between Task Flows"](#) and [Section 22.2.3, "What You May Need to Know About Data Control Scoping with Task Flows."](#)

- ADF Controller releases the view port data structures for the region (including pageFlow and view scopes).
For more information about view ports, see [Section 21.1.2, "About View Ports and ADF Regions."](#) For more information about memory scopes, see [Section 18.2.4, "What You May Need to Know About Memory Scope for Task Flows."](#)

Figure 21-11 Conditional Activation of ADF Regions

21.7 Navigating Outside an ADF Region's Task Flow

A bounded task flow running in an ADF region may need to trigger navigation of its parent view activity or to navigate to the root page of its application. The parent action activity exposes properties (`parent-outcome` and `root-outcome`) that you configure if you want to implement either of these use cases.

For example, you might specify a value for `parent-outcome` if you have a page that displays employee information and an ADF region that contains an enroll button for an employee. After the enroll page completes and the ADF region returns, the employee information page refreshes with the next employee.

Note: An ADF region does not maintain state when you navigate away from the region.

21.7.1 How to Trigger Navigation Outside of an ADF Region's Task Flow

You add a parent action activity to the bounded task that runs in the ADF region and configure it so that it navigates to the parent's view activity.

Before you begin:

It may be helpful to have an understanding of the configuration options for activating an ADF region. For more information, see [Section 21.6, "Configuring Activation of an ADF Region."](#)

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see [Section 21.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."](#)

To trigger navigation outside of an ADF region's task flow:

- In the Application Navigator, double-click the XML file for the bounded task flow that runs in the ADF region.
- In the ADF Task Flow page of the Component Palette, from the Component panel, drag and drop a **Parent Action** onto the diagram.
- Select the parent action activity in the diagram for the bounded task flow.

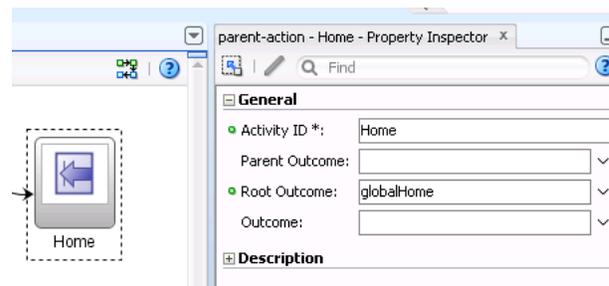

4. In the Property Inspector, choose the appropriate option:
 - **Parent Outcome:** enter a literal value or write an EL expression that returns an outcome so that the parent action activity navigates to the parent view activity. The outcome is then used to navigate the parent view activity's task flow rather than navigating the ADF region's bounded task flow.

The parent view activity's task flow should contain a control flow case or wildcard control flow rule that accepts the value you specify for `parent-outcome`.

- **Root Outcome:** enter a literal value or write an EL expression that returns an outcome so that the parent action activity navigates to the root page of the application.

For example, to navigate from an ADF region to the home page in the Fusion Order Demo application, you specify `globalHome` as the value for **Root Outcome**, as illustrated in [Figure 21–12](#).

Figure 21–12 Navigating to Home Page

Note: **Parent Outcome** and **Root Outcome** are mutually exclusive.

5. (Optional) In the **Outcome** field, enter a literal value that specifies an outcome for control flow within the ADF region after the parent action activity adds `parent-outcome` or `root-outcome` to the appropriate queue.

Specifying an `outcome` element is useful in cases where the parent view activity or root page does not navigate as a result of the `parent-outcome` or `root-outcome` sent by the parent action activity. In addition, the ADF region should not continue to display the same view. If you do not specify a value for `outcome`, the ADF region's `viewId` remains unchanged.

21.7.2 What Happens When You Configure Navigation Outside a Task Flow

At design time, JDeveloper writes entries to the source file for the bounded task flow based on the property values you set for the parent action activity. [Example 21–9](#) shows sample entries that JDeveloper generates when you write a literal value for the Parent Outcome and Outcome properties of the parent action activity.

Example 21–9 Metadata for a Parent Action Activity with a Parent Outcome

```
<parent-action id="parentAction1">
  <parent-outcome>parent_outcome</parent-outcome>
  <outcome id="__2">outcome</outcome>
</parent-action>
```

[Example 21–10](#) shows sample entries that JDeveloper generates when you write a literal value for the Root Outcome and Outcome properties of the parent action activity.

Example 21–10 Metadata for a Parent Action Activity with a Root Outcome

```
<parent-action id="parentAction1">
  <root-outcome>root_outcome</root-outcome>
  <outcome id="__2">outcome</outcome>
</parent-action>
```

At runtime, the bounded task flow navigates to its parent view activity or the root page of the Fusion web application depending on the property that you configured for the parent action activity.

21.7.3 What You May Need to Know About How a Page Determines the Capabilities of an ADF Region

In some cases, a page may need to determine the capabilities currently available within one of the ADF regions that it contains. For example, the page may need to initiate control flow within the ADF region based on its current state using the `queueActionEventInRegion()` method. *Region capabilities* are used by a parent page to identify the current outcomes of one of its regions based on the region's current state. They identify to the parent page whether or not an outcome is possible within the region.

The following scenario describes how region capabilities might typically be used in an application:

1. An ADF region within a page displays its associated page fragment.
2. A user selects a button or performs some other action in the ADF region.
3. The parent page identifies the outcomes (region capabilities) for the ADF region.
4. The parent page updates its buttons based on the ADF region capabilities.

The syntax of an EL expression to determine an ADF region's capabilities is as follows:

```
#{bindings.[regionId].regionModel.capabilities['outcome']}
```

where `regionId` is the ID of the ADF region component on the page and `outcome` is the possible outcome being verified within the ADF region.

Region capabilities require the availability of the specified ADF region's `regionModel` through an EL expression. The EL expression should never access bindings in any other binding container other than the current binding container. Region capabilities cannot be used in some cases. For example, a nested ADF region where a `regionModel` cannot be reached within the current binding container. This is because a nested region's nested binding container might not yet exist or might have already been released.

21.8 Creating ADF Dynamic Regions

An ADF dynamic region is an ADF region where the task flow binding dynamically determines the value of its `taskFlowId` attribute at runtime. This allows the Fusion web application to determine which bounded task flow to execute within the ADF dynamic region based on the result of evaluation of the task flow binding's `taskFlowId` attribute.

Figure 21–13 shows a runtime example from the Fusion Order Demo application where the `register.jspx` page renders a different registration task flow in its center facet in response to the command component button that the end user clicks. For example, if the end user clicks **Register as an employee**, the Fusion Order Demo application renders the `employee-registration-task-flow` in the ADF dynamic region.

At runtime, the ADF dynamic region swaps the task flows that it renders during the Prepare Render lifecycle phase. To give components from a previous task flow the opportunity to participate smoothly in the lifecycle phases, do not navigate off the `regionModel` until the JSF Invoke Application lifecycle phase. It is good practice, therefore, not to navigate a task flow in a dynamic region in response to contextual events. For more information about lifecycle phases, see [Chapter 25, "Understanding the Fusion Page Lifecycle,"](#) and for more information about contextual events, see [Chapter 34, "Using Contextual Events."](#)

Figure 21–13 Customer Registration Task Flow in an ADF Dynamic Region

You create an ADF dynamic region by dragging and dropping a bounded task flow to the page where you want to render the ADF dynamic region. The view activities in the bounded task flow must be associated with page fragments (`.jspx`).

If you attempt to drag and drop a bounded task flow that is associated with pages rather than page fragments, JDeveloper does not display the context menu that allows you to create an ADF dynamic region. You can convert a bound task flow that uses pages to use page fragments. For more information, see [Section 18.6.3, "How to Convert Bounded Task Flows."](#)

After you create an ADF dynamic region, you can add additional bounded task flows to the dynamic region by creating ADF dynamic region links, as described in [Section 21.9, "Adding Additional Task Flows to an ADF Dynamic Region."](#)

21.8.1 How to Create an ADF Dynamic Region

Drag and drop bounded task flows to the page where you want to render the ADF dynamic region.

Before you begin:

It may be helpful to have an understanding of the configuration options available to you when creating an ADF dynamic region. For more information, see [Section 21.8, "Creating ADF Dynamic Regions."](#)

You may also find it helpful to understand other functionality that can be added using other task flow and ADF region features. For more information, see [Section 21.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."](#)

To create an ADF dynamic region:

1. In the Application Navigator, select and open the JSF page where you want to create the ADF dynamic region.
2. Drag and drop the first bounded task flow onto the JSF page.
3. From the context menu that JDeveloper displays, choose **Create > Dynamic Region**.
4. Choose the appropriate option in the Choose Managed Bean for Dynamic Region dialog that JDeveloper displays:
 - If you want an existing managed bean to store the bounded task flow's ID, select an existing managed bean from the **Managed Bean** dropdown list.

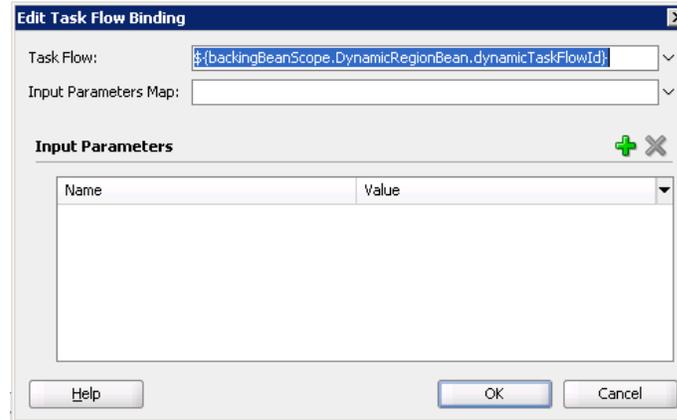

The managed bean passes the value of the bounded task flow's ID into the task flow binding of the ADF dynamic region. Make sure that the managed bean you select is not used by another ADF dynamic region.
 - If no managed bean exists for the page, click the **Add** icon next to the **Managed Bean** dropdown list to create a new one. Enter values in the dialog that appears as follows:
 - a. **Bean Name:** Enter a name for the new managed bean. For example, enter `DynamicRegionBean`.
 - b. **Class Name:** Enter the name of the new managed bean class.
 - c. **Package:** Enter the name of the package that is to contain the managed bean or browse to locate it.
 - d. **Extends:** Enter the name of the Java class that the managed bean extends. The default value is `java.lang.Object`.
 - e. **Scope:** This field is read-only and its value is set to `backingBean`. For more information about the memory scope for managed beans, see [Section 18.2.4, "What You May Need to Know About Memory Scope for Task Flows."](#)
 - f. Click **OK** to close the dialogs where you configure the managed bean.
5. Choose the appropriate option in the Edit Task Flow Binding dialog that JDeveloper displays:
 - Click **OK** if you do not want specify input parameters or an input parameter map for the ADF dynamic region.
 - Specify input parameters for the ADF dynamic region.

For more information, see [Section 21.3, "Specifying Parameters for an ADF Region."](#)

[Figure 21–14](#) shows the Edit Task Flow Binding dialog that JDeveloper displays after you configure a managed bean.

Note: You can write an EL expression that references a list of input parameters specified in a managed bean using the Input Parameters Map field of the Edit Task Flow Binding dialog. For more information about implementing this functionality, see [Section 21.4, "Specifying Parameters for ADF Regions Using Parameter Maps."](#)

Figure 21–14 Edit Task Flow Binding Dialog for an ADF Dynamic Region

6. Click OK.

21.8.2 What Happens When You Create an ADF Dynamic Region

When you drop a bounded task flow onto a JSF page to create an ADF dynamic region, JDeveloper adds an `af:region` tag to the page. The `af:region` tag contains a reference to a task flow binding. [Example 21–11](#) shows a sample of the metadata that JDeveloper adds to the JSF page.

Example 21–11 Metadata Added to a JSF Page to Create an ADF Dynamic Region

```
<af:region value="#{bindings.dynamicRegion1.regionModel}" id="r1"/>
```

JDeveloper also adds a task flow binding to the page definition file of the page that hosts the ADF dynamic region. [Example 21–12](#) shows a sample of the metadata that JDeveloper adds. The task flow binding provides a bridge between the ADF dynamic region and the bounded task flow. It binds the ADF dynamic region to the bounded task flow and maintains all information specific to the bounded task flow.

Example 21–12 Metadata Added to Page Definition to Create a Task Flow Binding

```
<taskFlow id="dynamicRegion1"
  taskFlowId="${backingBeanScope.ManagedBeanName.dynamicTaskFlowId}"
  activation="deferred"
  xmlns="http://xmlns.oracle.com/adf/controller/binding"/>
```

The `taskFlowId` attribute in the task flow binding metadata specifies the managed bean that determines at runtime what bounded task flow to associate with the ADF dynamic region. JDeveloper creates this managed bean or modifies an existing managed bean to store this data. [Example 21–13](#) shows extracts of the code that JDeveloper writes to the managed bean.

Example 21–13 Managed Bean Entries to Retrieve Bounded Task Flow for an ADF Dynamic Region

```
import oracle.adf.controller.TaskFlowId;
...
    private String taskFlowId = "/directoryPath/toTaskFlow";
...
    public TaskFlowId getDynamicTaskFlowId() {
        return TaskFlowId.parse(taskFlowId);
    }
...

```

At runtime, the managed bean stores the value of the bounded task flow's ID (`taskFlowId`) that displays inside the ADF dynamic region. The managed bean swaps the different bounded task flows into the task flow binding of the ADF dynamic region.

When an ADF dynamic region reinitializes, the Fusion web application must reinitialize the task flow binding associated with the ADF dynamic region. This includes evaluating if there are new input parameters and input parameter values to pass to the ADF dynamic region.

21.9 Adding Additional Task Flows to an ADF Dynamic Region

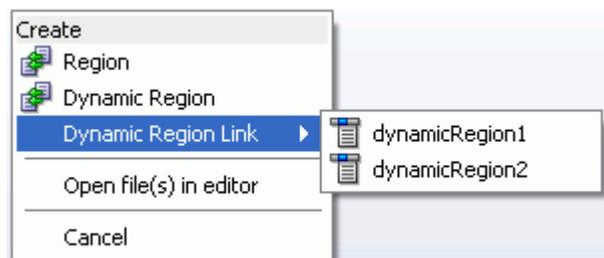

An ADF dynamic region link swaps a bounded task flow for another bounded task flow within an ADF dynamic region. An end user clicks a command component (for example, a button or a link) to update the ADF dynamic region with the new bounded task flow.

For example, a bounded task flow in the ADF dynamic region displays general information about an employee such as an ID and photo. When the end user clicks a link command component labeled **Details**, the ADF dynamic region updates with a table containing more information about the employee from another bounded task flow. The end user's action (clicking the link) invokes a method on the ADF dynamic region's managed bean. The value of the new bounded task flow is passed to the method, and the ADF dynamic region refreshes with the new bounded task flow. The new bounded task flow now displays within the ADF dynamic region.

By default, a ADF dynamic region link swaps another bounded task flow in for the original, but cannot swap back to the original. To toggle back to the original bounded task flow, you could add a second ADF dynamic region link on the page that, when clicked, swaps the current task flow back to the original one.

You can add an ADF dynamic region link if you already have at least one ADF dynamic region on a page and are adding a new bounded task flow as an ADF dynamic region to the same page. After you drop the bounded task flow on the page and choose to create an ADF dynamic region link, a menu displays all of the dynamic regions currently on the page, as shown in [Figure 21–15](#).

JDeveloper displays a list of the current dynamic regions in a document when you choose **Dynamic Region Link** from the menu that appears after you drag and drop a bounded task that you want to add as an option to an existing dynamic region in the document, as shown in [Figure 21–15](#).

Figure 21–15 ADF Dynamic Region Link Menu

Use this menu to select the ADF dynamic region within which you want to display the contents of the bounded task flow.

Tip: You can use the values in the dynamic region link in other UI components. For example, you could create a selection list in which each of the items in the list links to a different bounded task flow. All of the linked bounded task flows would display in the same dynamic region. The links perform a method in the class behind the managed bean created to swap the bounded task flow it displays.

21.9.1 How to Create an ADF Dynamic Region Link

You drag and drop a bounded task flow to a page that already contains an ADF dynamic region and you select **Dynamic Region Link** on the context menu that JDeveloper displays to view a list of ADF dynamic regions to which you can create a link.

Before you begin:

It may be helpful to have an understanding of the configuration required before you attempt to create an ADF dynamic region link. For more information, see [Section 21.9, "Adding Additional Task Flows to an ADF Dynamic Region."](#)

You may also find it helpful to understand functionality that can be added using other task flow and ADF region features. For more information, see [Section 21.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."](#)

To create an ADF dynamic region link:

1. In the Application Navigator, select and open the JSF page where you want to create the ADF dynamic region link.

This procedure assumes that you have already added at least one ADF dynamic region to the JSF page that you open. For information about adding an ADF dynamic region to a JSF page, see [Section 21.8, "Creating ADF Dynamic Regions."](#)

2. Drag a bounded task flow and drop it anywhere on the page.

The view activities of the bounded task flow must be associated with page fragments. You can convert a bounded task flow that uses pages to use page fragments. For more information, see [Section 18.6.3, "How to Convert Bounded Task Flows."](#)

3. From the context menu that JDeveloper displays, choose **Dynamic Region Link**.

A menu displays a list of all ADF dynamic regions that have already been added to the page.

4. Select the name of the ADF dynamic region in which you want to display the contents of the bounded task flow.

5. Click OK.

21.9.2 What Happens When You Create an ADF Dynamic Region

JDeveloper adds a command link to the page, as shown in [Example 21–14](#). JDeveloper also updates the managed bean for the ADF dynamic region and updates the corresponding task flow binding with any new parameters.

Example 21–14 Dynamic Region Link

```
<af:commandLink text="region2" action="#{RegionBean.region2}"
  id="dynamicRegionLink1" />
```

21.10 Configuring a Page To Render an Unknown Number of Regions

You can configure a page at design time when you do not know the number of regions that render in the page at runtime. For example, you want to add or remove regions to tabs using the `panelTabbed` component. Each tab that you add or remove renders a region that references a bounded task flow.

To implement this functionality, you configure the JSF page definition file's `multiTaskFlow` element to reference a list of task flow bindings contained in a managed bean of the following type:

```
oracle.adf.controller.binding.TaskFlowBindingAttributes
```

[Example 21–15](#) shows the code for the class of a managed bean named `MultiBean` that returns a list containing two task flows.

Example 21–15 Managed Bean Returning a List of Task Flow Bindings

```
package view;

import java.util.ArrayList;
import java.util.List;

import oracle.adf.controller.TaskFlowId;
import oracle.adf.controller.binding.TaskFlowBindingAttributes;

public class MultiBean {
    private List<TaskFlowBindingAttributes> mTaskFlowBindingAttrs = new
ArrayList<TaskFlowBindingAttributes>(5);

    public MultiBean() {
        TaskFlowBindingAttributes tfAttr = new TaskFlowBindingAttributes();
        tfAttr.setId("region1");
        tfAttr.setTaskFlowId(new TaskFlowId("/WEB-INF/r1.xml", "r1"));
        mTaskFlowBindingAttrs.add(tfAttr);

        tfAttr = new TaskFlowBindingAttributes();
        tfAttr.setId("region2");
        tfAttr.setTaskFlowId(new TaskFlowId("/WEB-INF/r2.xml", "r2"));
        mTaskFlowBindingAttrs.add(tfAttr);
    }

    public List<TaskFlowBindingAttributes> getTaskFlowList() {
        return mTaskFlowBindingAttrs;
    }
}
```

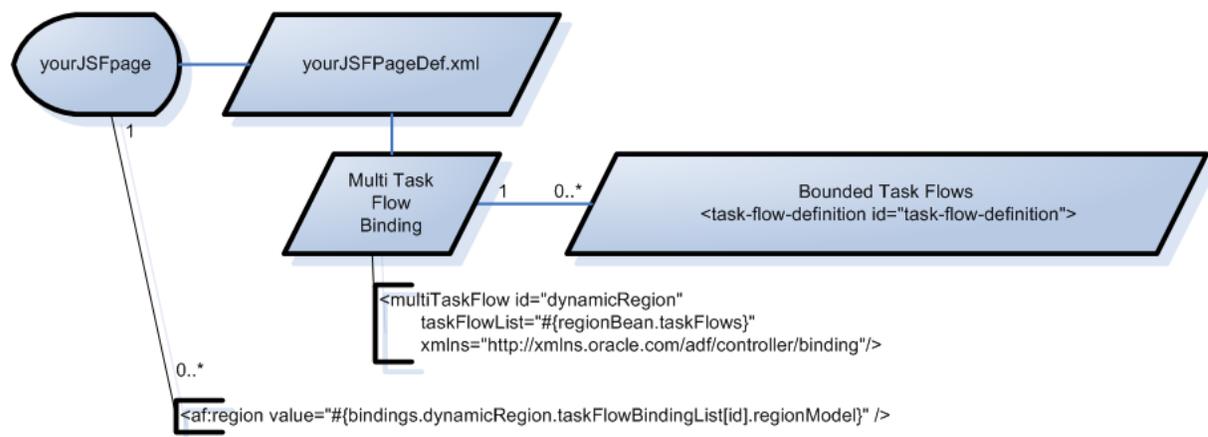

}

For more information about the `TaskFlowBindingAttributes` class, see the *Oracle Fusion Middleware Java API Reference for Oracle ADF Controller*.

At runtime, the `multiTaskFlow` binding references a list of one or more task flows that an end user can add or remove to the page using command components that you also expose. [Figure 21–16](#) shows the relationships between the different parts that make up this use case.

Note: The page fragments that the bounded task flows render must use the Facelets document type.

Figure 21–16 ADF Regions Derived from a Multi Task Flow Binding

21.10.1 How to Configure a Page to Render an Unknown Number of Regions

Configure the JSF page definition file's `multiTaskFlow` element to reference a list of bounded task flows. This list can be modified at runtime by adding or removing elements of type `TaskFlowBindingAttributes`.

Before you begin:

It may be helpful to have an understanding of the configuration options available to you when configuring a page to render an unknown number of ADF regions. For more information, see [Section 21.10, "Configuring a Page To Render an Unknown Number of Regions."](#)

You may also find it helpful to understand other functionality that can be added using other task flow and ADF region features. For more information, see [Section 21.1.3, "Task Flows and ADF Region Use Cases and Examples."](#)

To configure a page to render an unknown number of regions:

1. Create a managed bean with a pageFlow scope. The managed bean that you create returns a list of type `TaskFlowBindingAttributes`. [Example 21–15](#) shows the code for the class of a managed bean that returns such a list.

For more information about how to create a managed bean, see [Section 24.4.1, "How to Use a Managed Bean to Store Information."](#)

2. In the Application Navigator, right-click the JSF page where you want to add or remove ADF regions at runtime and choose **Go to Page Definition** from the context menu.
Click **Yes** if a confirmation dialog appears.
3. In the overview editor for the page definition file, click the **Add** icon in the Executables section to display the Insert Item dialog.
4. Select **ADF Task Flow Bindings** from the dropdown list, then select **multiTaskFlow** as the item to create and click **OK**.
5. In the Insert multiTaskFlow dialog, enter the following values:
 - **id***: Enter a unique ID for the multi task flow binding.
 - **taskFlowList ***: Enter an EL expression that returns the list of TaskFlowBindingAttributes to return at runtime. For example, to return the list in [Example 21–15](#), enter the following EL expression:
`#{pageFlowScope.multiBean.taskFlowList}`
6. In the Application Navigator, select and open the JSF page where you want end users to add or remove ADF regions at runtime.
7. In the ADF Faces page of the Component Palette, from the Operations panel, drag a **For Each** component and drop it on the component in the Structure window that you want to enclose the For Each component.
8. In the Property Inspector for the For Each component, enter values in the following fields:
 - **Items**: Enter an EL expression that references the method that return the list of task flow bindings from the multi task flow binding runtime object.
For example, enter an EL expression similar to the following:
`#{bindings.multiRegion1.taskFlowBindingList}`
 - **Var**: Enter a value to identify the list of task flow bindings.
9. In the JSF page that contains the For Each component, insert a Region component inside the For Each component that references the Region component's region model using an EL expression, as shown in [Example 21–16](#).

Example 21–16 ADF Region Referencing a Region Model

```
<af:forEach var="tf" items="#{bindings.multiRegion1.taskFlowBindingList}">
  <af:panelBox text="#{tf.name}" id="pb1">
    <f:facet name="toolbar"/>
    <af:region value="#{tf.regionModel}" id="r1"/>
  </af:panelBox>
</af:forEach>
```

21.10.2 What Happens When You Configure a Page to Render an Unknown Number of Regions

Metadata similar to that shown in [Example 21–17](#) appears in the JSF page definition file for the multi task flow binding.

Example 21–17 Metadata Added to Page Definition to Create a Multi Task Flow Binding

```
<multiTaskFlow id="multiRegion1"
```

```
taskFlowList="{pageFlowScope.multiBean.taskFlowList}" activation="deferred"  
xmlns="http://xmlns.oracle.com/adf/controller/binding"/>
```

The `taskFlowList` attribute in the multi task flow binding metadata specifies the managed bean. The managed bean stores the list of objects describing the task flows that can be added to the page at runtime.

21.10.3 What You May Need to Know About Configuring a Page to Render an Unknown Number of Regions

- We recommend that you limit the number of ADF regions that you create in a page to 10.
- Each task flow binding inherits attributes defined for the multi task flow binding unless you override this behavior using the methods exposed by `TaskFlowBindingAttributes`.
- Each task flow binding inherits parameters defined in the multi task flow binding in addition to those defined using the `parametersMap` property, as described in [Section 21.4, "Specifying Parameters for ADF Regions Using Parameter Maps."](#)

Creating Complex Task Flows

This chapter describes how to use advanced features of task flows.

This chapter includes the following sections:

- [Section 22.1, "About Creating Complex Task Flows"](#)
- [Section 22.2, "Managing Transactions in Task Flows"](#)
- [Section 22.3, "Reentering Bounded Task Flows"](#)
- [Section 22.4, "Handling Exceptions in Task Flows"](#)
- [Section 22.5, "Configuring Your Application to Use Save Points."](#)
- [Section 22.6, "Using Save Points in Task Flows"](#)
- [Section 22.7, "Using Train Components in Bounded Task Flows"](#)
- [Section 22.8, "Creating Task Flow Templates"](#)
- [Section 22.9, "Creating a Page Hierarchy Using Task Flows"](#)

22.1 About Creating Complex Task Flows

After creating a task flow, adding activities to it, and configuring control flow between the activities, you can extend the task flow's functionality by adding some of the features described in the following list:

- Transaction management can be configured for bounded task flows so that the Fusion web application commits or rolls back the task flow's activities as a group.
- Reentry options can be configured for bounded task flows to determine the response if a user clicks the browser's back button.
- Task flows contain a number of features that allow you to proactively handle exceptions. In addition, you can write custom code to handle exceptions thrown by a task flow
- Task flows can also be configured to capture the state of a Fusion web application at a particular instance using save points. These allow you to save the application's state if, for example, a user leaves a page without finalizing a task.
- Train components are ADF Faces components that render navigation items to guide a user through a multistep process. You can configure a bounded task flow to render these navigation items by default for the view activities in a task flow.
- Task flow templates can serve as a starting point for the creation of task flows that share common elements.

- Create a page hierarchy from the view activities that the default unbounded task flow in your application (and additional task flows in the application) reference.
- Invoke initializers and finalizers when a bounded task flow is entered and exited. An *initializer* is custom code that is invoked when a bounded task flow is entered. A *finalizer* is custom code that is invoked when a bounded task flow is exited via a task flow return activity or because an exception occurred. The finalizer is a method on a managed bean. Common finalizer tasks include releasing all resources acquired by the bounded task flow and performing cleanup before exiting the task flow.

You specify both the initializer and the finalizer as an EL expression for a method on a managed bean, for example:

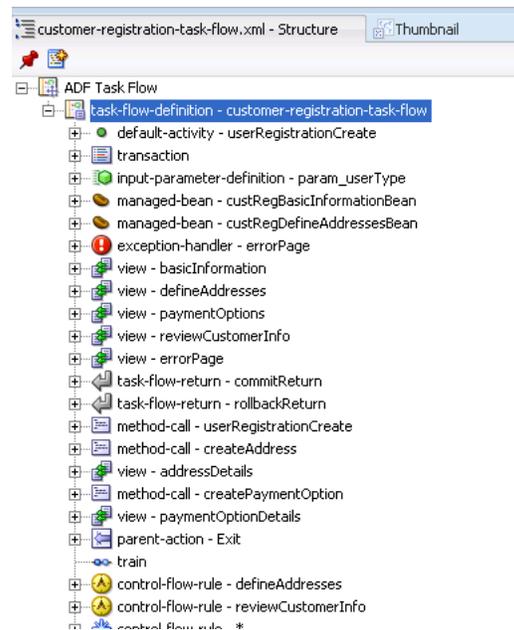

```
#{pageFlowScope.modelBean.releaseResources}
```

There are two techniques for running initializer code at the beginning of the bounded task flow, depending on whether or not the task flow may be reentered via a browser back button:

- No reentry via back button expected: Designate a method call activity as the default activity (first to execute) in the bounded task flow. The method call activity calls a custom method containing the initializer code. For more information, see [Section 19.5, "Using Method Call Activities"](#) and [Section 26.4.4, "What You May Need to Know About the Browser Back Button and Navigating Through Records"](#).
- Back button reentry possible: Specify an initializer method using an option on the bounded task flow metadata. For more information, see [Section 18.2, "Creating a Task Flow"](#). Use this technique if you expect that a user may reenter the task flow using a browser back button. In such a case, the designated default activity for the bounded task flow may never be called, but a method designated using the Initializer method will.

22.1.1 Complex Task Flows Use Cases and Examples

[Figure 22-1](#) shows the Structure window for the customer registration task flow in the Fusion Order Demo application. This task flow implements many of the use cases discussed in [Section 22.1, "About Creating Complex Task Flows."](#) For example, it specifies an error page to handle errors, makes use of the ADF Faces `train` component to render navigation items, and specifies two task flow return activities that either commit or roll back changes that the task flow makes as part of transaction management. For more information about the Fusion Order Demo application that contains this task flow, see [Chapter 2, "Introduction to the ADF Sample Application."](#)

Figure 22–1 Customer Registration Task Flow in the Structure Window

22.1.2 Additional Functionality for Complex Task Flows

You may find it helpful to understand other ADF features before you configure or use task flows. Additionally, you may want to read about what you can do with your task flows. Following are links to other functionality that may be of interest.

- You can specify exception handlers to manage errors that occur during execution of task flows. For more information about error handling, see [Section 16.3, "Customizing Error Handling."](#)
- Task flow save points can save application state. For more information about application state management, see [Section 43, "Application State Management."](#)
- Bounded task flows can be secured by defining the privileges that are required for someone to use them. For more information, see [Section 35, "Enabling ADF Security in a Fusion Web Application."](#)
- You can use Business Process Execution Language (BPEL) with task flows to:
 - Invoke a BPEL process from an unbounded or bounded task flow to perform a function or use services
 - Call a bounded task flow from a BPEL process in order to model user interactions with a web interface

You can use a task flow method call activity to invoke a managed bean method or a web service that interacts with a BPEL process. For more information about the task flow method call activity, see [Section 19.5, "Using Method Call Activities."](#)

- You can write custom code that extends your task flows. For example, you can write custom code to invoke when a task flow throws an exception, as described in [Section 22.4.3, "How to Designate Custom Code as an Exception Handler."](#) For information about the APIs that you can use to write custom code, see the following reference documents:
 - *Oracle Fusion Middleware Java API Reference for Oracle ADF Controller*
 - *Oracle Fusion Middleware Java API Reference for Oracle ADF Faces*

22.2 Managing Transactions in Task Flows

A *transaction* is a persisted collection of work that can be committed or rolled back together as a group. You can use a bounded task flow to represent a transaction and to declaratively manage transaction boundaries. In the Fusion Order Demo application, the customer registration and employee registration task flows are both implemented with the use of task flow return activities. The **Cancel** button implements rollback in the task flows. The **Register** button on the `reviewCustomerInfo.jsff` and `reviewEmployeeInfo.jsff` page fragment files implement commit functionality.

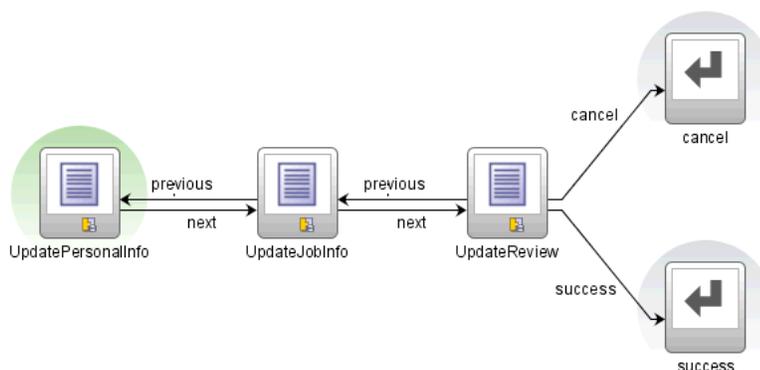

An end user can navigate from the shopping cart to initiate a backorder request for an out-of-stock item. The backorder request application is implemented as a bounded task flow that initiates a new transaction upon entry.

Transaction options on the called bounded task flow specify whether a called bounded task flow should join an existing transaction, create a new one, or create a new one only if there is no existing transaction.

If the called bounded task flow is able to start a new transaction (based on the `transaction` option that you selected), you can specify whether the transaction will be committed or rolled back when the task flow returns to its caller. The commit and rollback options are set on the task flow return activity that returns control back to the calling task flow. The same task flow that starts a transaction must also resolve the transaction.

In a called bounded task flow, you can specify two different return task flow activities that result in either committing or rolling back a transaction in the called bounded task flow. Each of the task flow return activities passes control back to the same calling task flow. The difference is that one task flow return activity specifies the commit option, while the other specifies the rollback option. As shown in [Figure 22–2](#), if transaction processing successfully completes, control flow passes to the success task flow return activity, which specifies options to commit the transaction. If the transaction is cancelled before completion, the cancel task flow activity specifies options to roll back the transaction.

Figure 22–2 Task Flow Return Activities in Called Bounded Task Flow

If no transaction option is specified, a transaction is not started on entry of the called bounded task flow. A runtime exception is thrown if the bounded task flow attempts to access transactional services.

Use the `restore-save-point` option on the task flow return activity if you want to discard the changes an end user makes within a called bounded task flow when the called bounded task flow exits. ADF Controller rolls back to the previous ADF Model save point that was created when the bounded task flow was entered. The

`restore-save-point` option applies only to cases when a bounded task flow is entered by joining an existing transaction (either the `requires-existing-transaction` or `requires-transaction` option is also specified) and a save point is created upon entry.

Tip: You can use a return activity to call the `commit` action or you can use a button bound to the `commit` action. If possible, use a task flow return activity. Using a task flow return activity will commit all data controls used by the ADF task flow. It also makes it easier to see where your application is doing commits and rollbacks, and is therefore easier to maintain.

You must use `invokeAction` if:

- You want to commit before the end of a task flow.
- You are not using ADF Controller.
- The task flow uses multiple data controls and you do not want to commit all of them.

22.2.1 How to Enable Transactions in a Bounded Task Flow

Define transaction options on a bounded task flow that is called by another task flow. Add a task flow return activity on the called bounded task flow that returns control to the task flow that calls the bounded task flow.

Before you begin:

It may be helpful to have an understanding of what a transaction is and how you can configure it. For more information, see [Section 22.2, "Managing Transactions in Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To enable a bounded task flow to run as a transaction:

1. In the Application Navigator, double-click the source file for the called bounded task flow.
2. In the overview editor, click the **Behavior** navigation tab and expand the **Transaction** section.
3. Choose one of the following from the dropdown list:
 - **<No Controller Transaction>**: The called bounded task flow does not participate in any transaction management.

It is recommended that you do not select this option for a bounded task flow that is parent to multiple child bounded task flows that also have the **<No Controller Transaction>** setting. Instead, select **Use Existing Transaction if Possible** for the parent task flow to avoid the creation of multiple database connections by each child bounded task flow.

- **Always Use Existing Transaction**: When called, the bounded task flow participates in an existing transaction already in progress.
- **Use Existing Transaction If Possible**: When called, the bounded task flow either participates in an existing transaction if one exists, or starts a new transaction upon entry of the bounded task flow if one doesn't exist.

- **Always Begin New Transaction:** A new transaction starts when the bounded task flow is entered, regardless of whether or not a transaction is in progress. The new transaction completes when the bounded task flow exits.

Note: After choosing a transaction option, you may also need to select the **Share data controls with calling task flow** option for the bounded task flow to determine whether there are any interactions between the options. For more information, see [Section 20.4.3, "What You May Need to Know About Managing Transactions."](#)

4. Optionally, deselect the **Share data controls with calling task flow** checkbox so that data controls are not shared with the calling task flow if you chose one of the following options in step 3:

- **Use Existing Transaction If Possible**
- **Always Begin New Transaction**

The default behavior is to share data controls. For more information, see [Section 22.2.3, "What You May Need to Know About Data Control Scoping with Task Flows."](#)

5. Optionally, select the **No save point on task flow entry** checkbox to prevent the creation of an ADF Model save point on task flow entry if you chose one of the following options in step 3:

- **Always Use Existing Transaction**
- **Use Existing Transaction If Possible**

An ADF Model save point is a saved snapshot of the ADF Model state. Selecting the **No save point on task flow entry** checkbox means that overhead associated with a save point is not created for the transaction.

6. Select the task flow return activity in the called bounded task flow.
7. In the Property Inspector, expand the **Behavior** section.
8. If the called bounded task flow supports creation of a new transaction (bounded task flow specifies **Use Existing Transaction If Possible** or **Always Begin New Transaction** options), select one of the following in the **End Transaction** dropdown list:
 - **commit:** Select to commit the existing transaction to the database.
 - **rollback:** Select to roll back a new transaction to its initial state on task flow entry. This has the same effect as cancelling the transaction.
9. In the **Restore Save Point** dropdown list, select **true** if you want changes the user makes within the called bounded task flow to be discarded when the task flow exits. The save point that was created upon task flow entry will be restored.

22.2.2 What Happens When You Specify Transaction Options

[Example 22-1](#) shows the metadata for transaction options on a called bounded task flow. The `<new-transaction>` element indicates that a new transaction always starts when the called bounded task flow is invoked.

Example 22-1 Called Bounded Task Flow Metadata

```
<task-flow-definition id="trans-taskflow-definition">
```

```

<default-activity>taskFlowReturn1</default-activity>
<transaction>
  <new-transaction/>
</transaction>
<task-flow-return id="taskFlowReturn1">
  <outcome>
    <name>success</name>
    <commit/>
  </outcome>
</task-flow-return>
</task-flow-definition>

```

[Example 22–1](#) also shows the metadata for transaction options on the task flow return activity on the called task flow. The `<commit/>` element commits the existing transaction to the database. The `<outcome>` element specifies a literal outcome, for example, `success`, that is returned to the caller when the bounded task flow exits. The calling ADF task flow can define control flow rules based on this outcome to For more information about defining control flow upon return, see [Section 19.7, "Using Task Flow Return Activities."](#)

22.2.3 What You May Need to Know About Data Control Scoping with Task Flows

The ADF Model layer exposes the `DataControlFrame` interface to manage a transaction in which the data controls within the frame participate. The `DataControlFrame` interface exposes methods such as:

- `beginTransaction()`
- `commit()`
- `rollback()`

Similarly, ADF Controller allows a task flow to demarcate a transaction boundary, to begin a transaction at task flow entry, and to either commit or roll back the transaction on task flow exit. It does this by invoking methods exposed by the ADF Model layer's `DataControlFrame` interface.

ADF Controller supports the transaction options listed in [Table 22–1](#). The behavior of these transaction options depends on whether you select or deselect the **Share data controls with calling task flow** checkbox (XML element: `<data-control-scope>`) in the overview editor for a task flow.

Table 22–1 Transaction Settings Behavior

Transaction Setting	Share Data Control Scope	Isolate Data Control Scope
<No Controller Transaction>	The <code>DataControlFrame</code> is shared without an open transaction.	A new <code>DataControlFrame</code> is created without an open transaction.
Always Begin New Transaction XML element: <code><new-transaction/></code>	Begins a new transaction if one is not already open and throws an exception if one is already open.	Always begins a new transaction.
Always Use Existing Transaction XML element: <code><requires-existing-transaction/></code>	Throws an exception if the transaction is not already open.	Invalid. The checkbox cannot be deselected.
Use Existing Transaction if Possible XML element: <code><requires-transaction/></code>	Begins a new transaction if one is not already open.	Always begins a new transaction.

22.3 Reentering Bounded Task Flows

To deal with cases in which the end user clicks the back button to navigate back into a bounded task flow that was already exited, you can specify `task-flow-reentry` options for the bounded task flow. These options specify whether a page in the bounded task flow can be reentered.

Upon reentry, bounded task flow input parameters are evaluated using the current state of the application, not the application state existing at the time of the original bounded task flow entry.

Note: Different browsers handle the back button differently. In order to ensure that back button navigation is properly detected across all browsers, the view activities within the task flow need to be properly configured. When a task flows uses the `reentry-not-allowed` or `reentry-outcome-dependent` option, the `redirect` attribute on each view activity within the task flow should be set to `true`. See [Section 19.3, "Using URL View Activities"](#) for more information on how to configure view activities.

22.3.1 How to Set Reentry Behavior

You can set reentry behavior on a bounded task flow by specifying `task-flow-reentry` options.

Before you begin:

It may be helpful to have an understanding of what reentry options you can configure for a bounded task flow. For more information, see [Section 22.3, "Reentering Bounded Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To set reentry behavior:

1. In the Application Navigator, double-click the source file for the bounded task flow.
2. In the overview editor, click the **Behavior** navigation tab.
3. In the **Task Flow Reentry** dropdown list, choose one of the following:
 - **reentry-allowed:** Reentry is allowed on any view activity within the bounded task flow.
 - **reentry-not-allowed:** Reentry of the bounded task flow is not allowed. If you specify `reentry-not-allowed` on a bounded task flow, an end user can still click the browser back button and return to a page within the bounded task flow. However, if the user does anything on the page such as clicking a button, an exception (for example, `InvalidTaskFlowReentry`) is thrown indicating the bounded task flow was reentered improperly. The actual reentry condition is identified upon the submit of the reentered page.

You can set up an exception handler to display the exception and route control flow in order to navigate to the default activity of the called bounded task flow. If the bounded task flow was not called from another bounded task flow, a normal web error is posted and handled as specified in the `web.xml` file.

- **reentry-outcome-dependent:** Reentry of a bounded task flow using the browser back button is dependent on the outcome that was received when the same bounded task flow was previously exited via task flow return activities. If specified, any task flow return activities on the called bounded task flow must also specify either `reentry-allowed` or `reentry-not-allowed` to define outcome-dependent reentry behavior.

If you choose this option, the user can navigate to a task flow using a back button based solely on how the user originally exited the task flow. For example, a task flow representing a shopping cart can be reentered if the user exited by canceling an order, but not if the user exited by completing the order.

22.3.2 How to Set Outcome-Dependent Options

You can set outcome-dependent options on bounded task flows that have specified the `reentry-outcome-dependent` option, as described in [Section 22.3.1, "How to Set Reentry Behavior."](#)

Before you begin:

It may be helpful to have an understanding of what reentry options you can configure for a bounded task flow. For more information, see [Section 22.3, "Reentering Bounded Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To set outcome-dependent options:

1. In the task flow diagram for the bounded task flow, select the task flow return activity.

For information about adding a task flow return activity, see [Section 19.7, "Using Task Flow Return Activities."](#)

2. In the Property Inspector, expand the **General** section.
3. In the **Name** field, enter the name of literal outcome, for example, `success` or `failure`.
4. Expand the **Behavior** section.
5. In the **Reentry** dropdown list, choose one of the following options:
 - **reentry-allowed:** Reentry is allowed on any view activity within the bounded task flow.
 - **reentry-not-allowed:** Reentry of the bounded task flow is not allowed. If you specify `reentry-not-allowed` on a bounded task flow, an end user can still click the browser back button and return to a page within the bounded task flow. However, if the user does anything on the page such as clicking a button, an exception (for example, `InvalidTaskFlowReentry`) is thrown indicating the bounded task flow was reentered improperly. The actual reentry condition is identified upon the submit of the reentered page.

You can set up an exception handler to display the exception and route control flow in order to navigate to the default activity of the called bounded task flow. If the bounded task flow was not called from another bounded task flow, a normal web error is posted and handled as specified in the `web.xml` file.

22.3.3 What You Should Know About Managed Bean Values Upon Task Flow Reentry

When an end user reenters a bounded task flow using a browser's back button, and reentry is allowed, the value of a managed bean is reset to the value of the managed bean before the end user exited the bounded task flow. The managed bean value is reset before a view activity in the reentered bounded task flow renders. Any changes that occur before the reentry of the bounded task flow are lost. To change this behavior, specify the `<redirect>` element on the view activity in the reentered bounded task flow. When the end user reenters the bounded task flow using the back button, the managed bean has the new value from the parent task flow, not the original value from the child task flow that is reentered.

22.4 Handling Exceptions in Task Flows

During execution of a task flow, exceptions can occur that may require some kind of exception handling, for example:

- A method call activity throws an exception.
- A custom method you have written as a task flow initializer or finalizer throws an exception.
- A user is not authorized to execute the activity.

To handle exceptions thrown from an activity or caused by some other type of ADF Controller error, you can designate one activity in a bounded or unbounded task flow as an exception handler.

When a task flow throws an exception, control flow passes to the designated exception handling activity. For example, the exception handling activity might be a view activity that displays an error message. Alternatively, the activity might be a router activity that passes control flow to a method based on an EL expression that evaluates the type of exception. For example:

```
#{controllerContext.currentViewPort.exceptionData.className ==  
'oracle.adf.controller.ControllerException'}
```

After control flow passes to the exception handling activity, flow from the exception handling activity uses standard control flow rules. For example, you designate a router activity as the exception handling activity. At runtime, the task flow passes control to the exception handling activity (in this example, a router activity) in response to an exception. In addition to designating the router activity as an exception handler, you can define task flow control cases that the router invokes based on the type of exception that it has to handle. This allows you to manage your end user's application session gracefully when an exception occurs. For more information, see [Section 18.1.3, "About Control Flows."](#)

You can optionally specify an exception handler for both bounded and unbounded task flows. Each task flow can have only a single exception handler. However, a task flow called from another task flow can have a different exception handler from that of the caller. In addition, a region on a page can have a different exception handler from that of the task flow containing the page. The exception handler activity can be any supported activity type, for example, a view or router activity.

If a bounded task flow does not have a designated exception handler activity, control passes to an exception handler activity in a calling bounded task flow, if there is a calling task flow and if it contains an exception handler activity. The exception is propagated up the task flow stack until either an exception handler activity or the top-level unbounded task flow is reached. If no exception handler is found, the exception is propagated to the web container.

If a bounded task flow does have a designated exception handler activity, make sure the exception handler activity leaves the application in a valid state after it handles an exception. One way to do this is to redirect to a view activity in the same task flow after the exception handler activity.

Other modules, such as the ADF Model, also provide exception handling capabilities. In certain scenarios this can determine the way that your application handles exceptions. For example, a databound method activity is a method activity that has a page definition and an EL expression with the following format:

```
{bindings.somebindingname.execute}
```

where *somebindingname* is a method binding defined in the page definition.

An exception thrown by any type of binding is caught by the ADF Model which calls the `reportException()` method and stores the exception in the binding container. Later, when the page renders, the error displays in the page.

When a method activity invokes a method binding, there is no page to display an error that the exception raises because the exception occurs during navigation between two pages. To make the application aware of an error, Oracle ADF rethrows the exception so that it is caught by the ADF Controller exception handler mechanism that navigates to an exception handler activity if one exists.

Keep this in mind, particularly if you decide to override methods, such as the `reportException()` method, described in [Section 16.3, "Customizing Error Handling,"](#) because in that scenario both the ADF Controller and ADF Model exception handlers will be called.

22.4.1 How to Designate an Activity as an Exception Handler

You can designate an exception handler activity for a bounded task flow running as an ADF Region. If an exception occurs in the bounded task flow and it is not handled by the task flow's exception handler, the exception is not propagated up the task flow stack of the parent page. Instead, it becomes an unhandled exception.

Before you begin:

It may be helpful to have an understanding of what exception handling options you can configure for a task flow. For more information, see [Section 22.4, "Handling Exceptions in Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To designate an activity as an exception handler for a task flow:

1. Right-click the activity in the task flow diagram, and choose **Mark Activity > Exception Handler**.

A red exclamation point is superimposed on the activity in the task flow to indicate that it is an exception handler. [Figure 22-3](#) shows an example.

Figure 22–3 Example of an Activity Designated as an Exception Handler

ex_handler

- To unmark the activity, right-click the activity in the task flow diagram, and choose **Unmark Activity > Exception Handler**.

If you mark an activity as an exception handler in a task flow that already has a designated exception handler, the old handler is unmarked.

22.4.2 What Happens When You Designate an Activity as an Exception Handler

After you designate an activity to be the exception handling activity for a task flow, JDeveloper updates the task flow metadata with an `<exception-handler>` element that specifies the ID of the activity, as shown in [Example 22–2](#).

Example 22–2 `<exception-handler>` element

```
<exception-handler id="__8>activityID</exception-handler>
```

22.4.3 How to Designate Custom Code as an Exception Handler

Rather than designate a task flow activity as the activity to invoke, you can write custom code to invoke when a task flow throws an exception. This requires you to:

- Write a Java class that extends the class `ExceptionHandler` from the following package:

```
oracle.adf.view.rich.context.ExceptionHandler
```
- Register the Java class that you write as a service in the `.adf\META-INF` directory of your Fusion web application

[Example 22–3](#) shows custom code that checks if an exception thrown by a task flow corruptions to a particular type of error message (`ADF_FACES-30108`). If it is, the custom code redirects the task flow to the `faces/SessionExpired.jspx` page.

Example 22–3 Custom Code for an Exception Handler

```
package oracle.fodemo.frmwkext;

import javax.faces.context.ExternalContext;
import javax.faces.context.FacesContext;
import javax.faces.event.PhaseId;
import oracle.adf.view.rich.context.ExceptionHandler;

public class CustomExceptionHandler extends ExceptionHandler {

    public CustomExceptionHandler() {
        super();
    }

    public void handleException(FacesContext facesContext, Throwable throwable,
                               PhaseId phaseId) throws Throwable {
```

```

String error_message;
error_message = throwable.getMessage();

if (error_message != null &&
    error_message.indexOf("ADF_FACES-30108") > -1) {
    ExternalContext ectx = facesContext.getExternalContext();
    ectx.redirect("faces/SessionExpired.jsp");
}

else {
    //Code to execute if the if condition is not met
    throw Throwable
}
}
}

```

For information about the APIs that you can use to write custom code, see the following reference documents:

- *Oracle Fusion Middleware Java API Reference for Oracle ADF Controller*
- *Oracle Fusion Middleware Java API Reference for Oracle ADF Faces*

Before you begin:

It may be helpful to have an understanding of what exception handling options you can configure for a task flow. For more information, see [Section 22.4, "Handling Exceptions in Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To designate custom code as an exception handler:

1. In the `.adf\META-INF` directory of your application, create a directory named **services** so that you have the following directory path:

```
application_root\.adf\META-INF\services
```

where `application_root` refers to the root directory of application.

2. Create a text file named **oracle.adf.view.rich.context.ExceptionHandler** in the **services** folder.
3. Write the package name and class name of the custom code that you wrote to handle exceptions in the text file named **oracle.adf.view.rich.context.ExceptionHandler**.

For example, if you want to register the custom code in [Example 22-3](#), write the following:

```
oracle.fodemo.frmwkext.CustomExceptionHandler
```

4. Save and close the text file.

22.4.4 What Happens When You Designate Custom Code as an Exception Handler

At runtime, the task flow passes control to the custom code that you specified if the task flow throws an exception.

22.4.5 What You May Need to Know About Handling Exceptions During Transactions

Designate an exception handling activity for a bounded task flow that is enabled to run as a transaction. A Fusion web application attempts to commit a transaction if you set `commit` as the value for a task flow return activity's End Transaction property on a bounded task flow that runs as a transaction. If an exception occurs when the Fusion web application attempts to commit a transaction, the exception handling activity receives control and provides the end user with an opportunity to correct the exception. You can use the exception handling activity (for example, a view activity) to display a warning message to an end user with information about how to correct the exception and how to recommit the transaction. For information about enabling a bounded task flow as a transaction and setting `commit` as a value for the End Transaction property, see [Section 22.2.1, "How to Enable Transactions in a Bounded Task Flow."](#)

22.4.6 What You May Need to Know About Handling Validation Errors

For validation errors on a JSF page, you can rely on standard JSF to attach validator error messages to specific components on a page or to the whole page. A component-level validator typically attaches an error message inline with the specific UI component. There is no need to pass control to an exception handler activity.

In addition, your application should define validation logic on data controls that are executed during the Validate Model Updates phase of the JSF lifecycle. In this way, data errors are found as they are submitted to the server without waiting until attempting the final commit.

Validations done during the Validate Model Updates phase typically do not have direct access to the UI components because the intention is to validate the model after the model has been updated. These validations are often things like checking to see whether dependent fields are in sync. In these cases, the error message is usually attached to the whole page, which this logic can access.

You should attach errors detected during the Validate Model Updates phase to the JSF page, and call `FacesContext.renderResponse()`. This signals that following this phase, the current (submitting) page should be rendered showing the attached error messages. There is no need to pass control to an exception handler activity.

For more information, see [Chapter 8, "Implementing Validation and Business Rules Programmatically"](#).

22.5 Configuring Your Application to Use Save Points

Before you can add save points to a task flow, as described in [Section 22.6, "Using Save Points in Task Flows"](#) and configure related functionality, you need to make sure that the Fusion web application allows save points. To do this, you define a value for the `<savepoint-datasource>` element in the `adf-config.xml` file to specify the save points' JNDI name for the database connection.

22.5.1 How to Configure Your Fusion Web Application to Use Save Points

You define a value for the `<savepoint-datasource>` element in your application's `adf-config.xml` file to specify the save points' JNDI name for the database connection.

Before you begin:

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see [Section 22.5, "Configuring Your Application to Use Save Points."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To configure your Fusion web application to allow save points:

1. With the Fusion web application open in JDeveloper, open the Application Resources pane in the Application Navigator.
2. Expand **Descriptors**, then expand **ADF META-INF**.
3. Right-click `adf-config.xml` and choose **Open** from the context menu.
4. On the Controller page of the overview editor, write a value for the Data Source property to specify a JNDI name for the data source.

For example, write the following:

```
java:comp/env/jdbc/Connection1DS
```

where `Connection1` is the JDeveloper connection name.

5. Save the `adf-config.xml` file.

22.5.2 What Happens When You Configure a Fusion Web Application to Use Save Points

JDeveloper generates an entry, similar to that illustrated in [Example 22-4](#), in the `adf-config.xml` file to specify the save points' JNDI name for the database connection.

Example 22-4 Save Point Data Source Definition in adf-config.xml

```
<adf-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
  ...
  <savepoint-datasource>
    java:comp/env/jdbc/Connection1DS
  </savepoint-datasource>
</adf-controller-config>
```

For more information about the `adf-config.xml` file, see [Section A.11, "adf-config.xml"](#).

22.6 Using Save Points in Task Flows

You can configure a task flow to capture the state of a Fusion web application at a particular instance creating what is called a *save point*. This allows you to save application state if, for example, a user leaves a page without finalizing it. The application state can be restored at a later point.

[Table 22-2](#) describes what information a save point captures.

Table 22–2 *Saved Application State Information*

Saved State Information	Description
User Interface State	<p>UI state of the current page, including selected tabs, selected checkboxes, selected table rows, and table column sort order.</p> <p>This state assumes the end user cannot select the browser back button on save point restore.</p>
Managed Beans	<p>State information saved in several possible memory scopes, including session and page flow scope. The managed beans must be serializable in order to be saved. If you have page flow scope beans that are not serializable and you attempt to create a save point, a runtime exception occurs.</p> <p>Request scope is not supported since its lifespan is a single HTTP request and its lifespan can't be used to store cross request application state.</p> <p>Save points will not save and restore application-scoped managed beans since they're not passivated in failover scenarios. Therefore, the application is always responsible for ensuring that all required application-scoped state is available.</p> <p>Potential naming conflicts for managed beans already existing within the session scope at restore time will not occur because multiple managed beans using the same name should not be implemented within an application.</p>
Navigation State	<p>Task flow call stack, which ADF Controller maintains as one task flow calls another at runtime.</p> <p>The task flow call stack tracks where the end user is in the application and the navigation path for getting there. The task flow stack also identifies the starting point of any persisted data transactions originated for the end user.</p>
ADF Model State	<p>Fusion web applications use ADF Model to represent the persisted data model and business logic service providers. The ADF Model holds any data model updates made from when the current bounded task flow begins. The model layer determines any limits on the saved state lifetime. For more information, see Chapter 43, "Application State Management".</p>

You add a method call activity to a bounded task flow that invokes a `createSavePoint` method to create save points. Later, you use a save point restore activity to restore application state and data associated with the created save points.

The same save point can be used if a user repeatedly performs a save for later on a task flow instance that executes in one session within the same browser window. The new save point overwrites the existing save point when a user performs a save for later following navigation from page to page in a task flow. For more information about restoring a save point, see [Section 22.6.3, "How to Restore a Save Point"](#).

You can specify the `createSavePoint` method exposed by the `currentViewPort` node of the ADF Controller Objects in the Expression Builder. Alternatively, you can write a custom method that updates the save point with the values of attributes you specify in your custom method, as illustrated in [Example 22–5](#).

Example 22–5 *Example Custom Method for Creating a Save Point*

```
package viewController;

import java.io.Serializable;

import oracle.adf.controller.ControllerContext;
import oracle.adf.controller.savepoint.SavePointManager;

public class SaveForLater implements Serializable {
    public SaveForLater() {
        super();
    }

    public String saveTaskFlow() {
        ControllerContext cc = ControllerContext.getInstance();
        if (cc != null) {
            SavePointManager mgr = cc.getSavePointManager();
        }
    }
}
```

```

if (mgr != null) {
    String id = mgr.createSavePoint();
    System.out.println("Save point is being set " + id);
    ...
}

```

Note: A database table named ORADFCSAVPT is used to store a save point. If this database table does not exist, it is created the first time that a save point is created. The entry in ORADFCSAVPT for a save point is removed after the save point is restored.

The `SavePointListener` interface exposes methods that notify clients when save point events occur. The following package contains the `SavePointListener` interface:

```
oracle.adf.controller.savepoint
```

Note: All save points created inside a bounded task flow are deleted when the bounded task flow exits.

22.6.1 How to Add a Save Point to a Task Flow

You drag and drop a method call activity to the task flow and configure it to invoke the `createSavePoint` method or to invoke a custom method if you created one.

Before you begin:

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see [Section 22.6, "Using Save Points in Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

Using a save point in a Fusion web application requires that you leave the value of the `jbo.locking.mode` property set to the default value `optimistic`. The value `pessimistic` causes an old session to lock until the session has timed out. In pessimistic mode, if you run an application and change data without committing changes to the database, you may get an error when you create a save point and try to restore it at a later point. For information about the `jbo.locking.mode` property, see [Section 43.11.1, "How to Confirm That Applications Use Optimistic Locking."](#)

To add a save point to a task flow:

1. Open the bounded task flow that you want to configure and navigate to the diagram editor.
2. In the ADF Task Flow page of the Component Palette, from the Component panel, drag and drop a **Method Call** activity onto the diagram.
3. In the Property Inspector, expand the **General** node and write an EL expression for the Method property to specify the save point method that the method call activity invokes.

If you use the Expression Builder to specify the `createSavePoint` method exposed by the `currentViewPort` node of the ADF Controller Objects, the resulting EL expression is similar to the following:

```
#{controllerContext.currentViewPort.createSavePoint}
```

4. Use a control flow to connect the method call activity with other activities in the bounded task flow.

For more information, see [Section 18.4.1, "How to Add a Control Flow Rule to a Task Flow"](#).

5. Optionally, configure save point options in the Fusion web application's `adf-config.xml` file to determine, for example, if implicit save points can be created for the application.

For more information, see [Section 22.6.7, "How to Enable Implicit Save Points"](#).

22.6.2 What Happens When You Add Save Points to a Task Flow

JDeveloper generates entries similar to those shown in [Example 22–6](#) in the task flow's source file when you configure a method call activity to invoke the `createSavePoint` method.

Example 22–6 Method Call Metadata to Invoke the `createSavePoint` Method

```
<method-call id="methodCall1">
  <method id="__3">#{controllerContext.currentViewPort.createSavePoint}</method>
</method-call>
```

22.6.3 How to Restore a Save Point

Use the save point restore activity to restore a previously persisted save point for an application. The save point restore activity uses the save point that was originally created by invoking the `createSavePoint` method to identify the save point to restore.

You can obtain a list of the current persisted save points with `createSavePoint`. However, ADF Controller does not determine which save points to restore. A user must select the save point from a list or the application developer must select it programmatically. The savepoint ID is then passed to a save point restore activity to perform the restore.

Before you begin:

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see [Section 22.6, "Using Save Points in Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To add a save point restore activity to a bounded or unbounded task flow:

1. Open the bounded or unbounded task flow where you want to add the save point restore activity and navigate to the diagram editor.
2. In the ADF Task Flow page of the Component Palette, from the Components panel, drag a **Save Point Restore** activity and drop it on the diagram for the task flow.

3. In the Property Inspector, expand the **General** node and write an EL expression for the **Save Point ID** property that, when evaluated, retrieves the save point that was originally created when the `createSavePoint` method was invoked.

If you use the Expression Builder to specify the `getSavePoint` method of the ADF Controller Objects, the resulting EL expression is similar to the following:

```
#{SessionScope.myBean.savepointID}
```

22.6.4 What Happens When You Restore a Save Point

JDeveloper generates entries similar to [Example 22–7](#) in the task flow’s source file when you add a save point restore activity that gets a save point ID.

Example 22–7 Metadata for a Save Point Restore Activity in a Task Flow

```
<save-point-restore id="savePointRestore1">
  <save-point-id id="__4">#{sessionScope.myBean.savepointID}</save-point-id>
</save-point-restore>
```

22.6.5 How to Use the Save Point Restore Finalizer

When using the save point restore activity, you may need to invoke application-specific logic as part of restoring the application state. You can write an EL expression for the Save Point Restore Finalizer property of a bounded task flow that specifies a finalizer method. The bounded task flow invokes the specified method after the task flow’s state has been restored. It performs any necessary logic to make sure that the application’s state is correct before proceeding with the restore.

Before you begin:

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see [Section 22.6, "Using Save Points in Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To use the save point restore finalizer:

1. In the Structure window, right-click the node for the bounded task flow (`task-flow-definition`) and select **Go to Properties**.
2. In the Property Inspector, expand the **General** tab, and select **Expression Builder** from the **Save Point Restore Finalizer** dropdown menu.
3. Write an EL expression that specifies the finalizer method to invoke.

22.6.6 What Happens When a Task Flow Invokes a Save Point Restore Finalizer

JDeveloper generates entries similar to [Example 22–8](#) in the task flow’s source file when you write an EL expression for the Save Point Restore Finalizer property.

Example 22–8 Metadata to Invoke a Save Point Restore Finalizer

```
<task-flow-definition id="task-flow-definition1">
  <save-point-restore-finalizer id="__2">#{sessionScope.MyBean.invokeFinalizer}
  </save-point-restore-finalizer>
</task-flow-definition>
```

22.6.7 How to Enable Implicit Save Points

A save point in a task flow can be categorized as *implicit* or *explicit*. An explicit save point requires an end user action before a bounded or unbounded task flow creates a save point. For example, an end user clicks a button that invokes a method call activity that, in turn, creates a save point.

An implicit save point can only originate from a bounded task flow. It includes everything from when the originating task flow creates a save point. It occurs when data is saved automatically because:

- A session times out due to end user inactivity
- An end user logs out without saving the data
- An end user closes the only browser window, thus logging out of the application
- An end user navigates away from the current application using control flow rules (for example, uses a `goLink` component to go to an external URL) and having unsaved data.

Enabling implicit save points requires you to add an element to your Fusion web application's `adf-config.xml` file and to make the bounded task flow critical.

You configure the `adf-config.xml` file in your application and the bounded task flow(s) for which you want to create implicit save points. Enabling implicit save points involves a performance cost because your Fusion web application has to do extra work that it would otherwise not do. This is why you have to explicitly enable implicit save points in your application and specify the task flows to which it applies.

Before you begin:

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see [Section 22.6, "Using Save Points in Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To enable implicit save points:

1. In the Application Resources panel of the Application Navigator, expand **Descriptors**, then expand **ADF META-INF**.
2. Right-click `adf-config.xml` and choose **Open** from the context menu.
3. On the Controller page of the overview editor, select the **Enable Implicit Savepoints** checkbox.

JDeveloper generates the following entry in the `adf-config.xml` file:

```
<adf-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
  ...
  <enable-implicit-savepoints>true</enable-implicit-savepoints>
</adf-controller-config>
```

For more information about the `adf-config.xml` file, see [Section A.9, "adfc-config.xml"](#).

4. In the Application Navigator, double-click the source file for the bounded task flow.

5. In the overview editor, click the **Behavior** navigation tab and select the **Critical** checkbox.

22.6.8 What You May Need to Know About Enabling Implicit Save Points

If multiple windows are open when the implicit save point is created, a different save point is created for each browser window. This includes everything from the root view port of the browser window on down. You can write an EL expression for the Method property of a method call activity to retrieve the list of implicit save points using the `savePointManager` node under ADF Controller Objects. The resulting EL expression is similar to the following:

```
ControllerContext.savePointManager.listSavePointIds
```

Implicit save points are generated only if a critical task flow is present in any of the page flow stacks for any view port under the current root view port. An implicit save point is not generated if the request is for an ADF Controller resource, such as:

- Task flow call activity
- Task flow return activity
- Save point restore activity
- A dialog

Implicit save points are deleted when the task flow at the bottom of the stack completes or a new implicit save point is generated, whichever comes earlier.

22.6.9 What You May Need to Know About the Time-to-Live Period for a Save Point

An application-level property (`save-point-expiration`) that is defined in the `adf-config.xml` file determines the period between when a task flow creates a save point and when the save point manager removes it (time-to-live period). The default value is 86400 seconds (24 hours).

You can change the time-to-live period for individual save points by implementing the `setSavePointTimeToLive` method that is defined in the `SavePointManger` interface of the following package:

```
oracle.adf.controller.savepoint
```

[Example 22-9](#) shows the syntax for the `setSavePointTimeToLive` method.

Example 22-9 Syntax for the `setSavePointTimeToLive` Method

```
public void setSavePointTimeToLive(long timeInSeconds) {
}
```

If you supply a value for the `setSavePointTimeToLive` method argument (`timeInSeconds` in [Example 22-9](#)) equal to or less than zero, the default value is used (86400).

Consider implementing the `setSavePointTimeToLive` method at the same time that you implement the method to create save points, as illustrated in [Example 22-5](#).

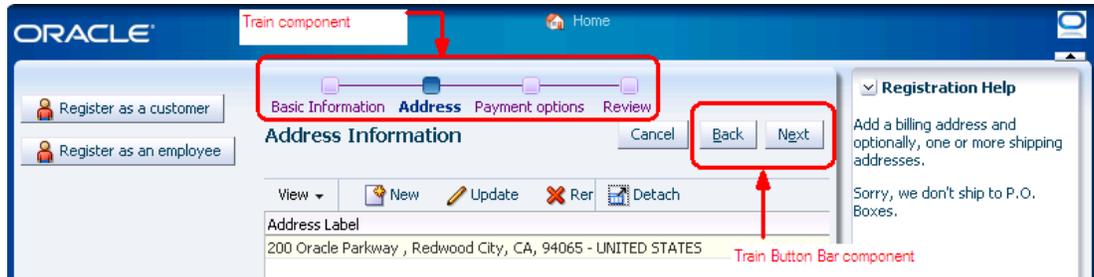

22.7 Using Train Components in Bounded Task Flows

You can create a task flow as a train. This allows you to create a user interface where you navigate end users through a multistep process. For example, the Fusion Order Demo application's customer registration task flow renders a train that navigates end

users through a number of train stops in order to complete the customer registration process, as illustrated in [Figure 22-4](#).

ADF Faces provides the user interface components that render the train functionality in the task flow view activities that appears to the end user. These components are the `train` and `trainButtonBar` components. [Figure 22-4](#) shows the `defineAddresses.jsff` page (a task flow view activity) using the `train` and `trainButtonBar` components to navigate the end user through the address creation step in the customer registration task flow.

Figure 22-4 Train and Train Button Bar Components in the Customer Registration Task Flow

The `train` component in [Figure 22-4](#) renders four train stops. Each stop corresponds to a page fragment in the customer registration task flow where the end user can enter and review information to complete the registration process. [Figure 22-4](#) shows the Address train stop where the end user enters an address for postage. The other stops are:

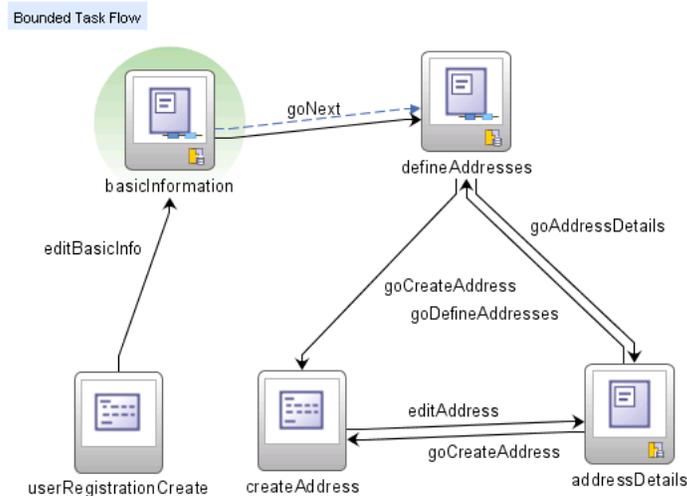

- Basic Information
- Payment Options
- Review

The Train Button Bar component, also shown in [Figure 22-4](#), is optional and provides additional controls to navigate between the train stops. This component can be used in conjunction with the `train` component to provide multiple ways to navigate through train stops.

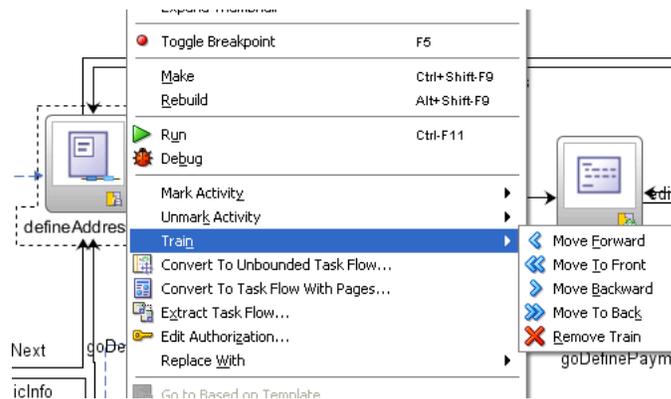

Bounded task flows and task flow templates can make use of these train components if you select the **Create Train** checkbox on the dialogs provided by JDeveloper to create a bounded task flow or a task flow template. A bounded task flow or a task flow template can render one train only. If you want to use multiple trains, create a separate bounded task flow or task flow template for each train.

[Figure 22-5](#) displays an extract from the design time view of the customer registration task flow where you can see the `basicInformation` and `defineAddresses` view activities that render at runtime as the **Basic Information** and **Address** train stops in [Figure 22-4](#).

The dotted line labeled **goNext** connecting the `basicInformation` view activity to the `defineAddresses` view activity indicates the sequence in which the end user navigates between the view activities when the view activities render as train stops.

Figure 22–5 Detail of Customer Registration Task Flow

JDeveloper displays a context menu with options to change the position of the activity when you right-click a view activity or task flow call activity that is configured as a train stop, as illustrated in [Figure 22–6](#).

Figure 22–6 Context Menu to Edit a Train Stop

Configure a task flow call activity as a train stop when you want to group a number of activities as a train stop or call a child train stop. For example, there are cases when other task flow activities, such as router and method call activities, should be considered part of a train stop along with the corresponding view activity. A method call activity might need to precede a view activity for initialization purposes. When grouped this way, the activities can be performed as a set each time the train stop is visited. For more information, see [Section 22.7.3, "Grouping Task Flow Activities to Execute Between Train Stops"](#).

Branching using router activities and control flow cases is supported on the task flow diagram containing the train, as well as in child bounded task flows called from the train.

22.7.1 Creating a Task Flow as a Train

You need to configure a bounded task flow to use train components before you can implement the type of functionality discussed in [Section 22.7, "Using Train"](#)

[Components in Bounded Task Flows.](#)" Use one of the methods outlined in the following list to configure a bounded task flow to use train components:

- Select the **Create Train** checkbox in the dialog that JDeveloper displays when you create a new bounded task flow or task flow template.

For more information, see [Section 18.2, "Creating a Task Flow"](#) or [Section 22.8, "Creating Task Flow Templates."](#)

- Right-click an existing bounded task flow in the diagram and choose **Train > Create Train** from the context menu that JDeveloper displays.
- Open an existing bounded task flow in the overview editor, click the **Behavior** navigation tab and select the **Train** checkbox.

Once you have configured the bounded task flow to use train components, you drag and drop the task flow activities that you want to render in the train to the diagram in the bounded task flow.

22.7.1.1 How to Create a Train in a Bounded Task Flow

You drag and drop the task flow activities that you want to render in the train to the diagram for the bounded task flow.

Before you begin:

Make sure that you configure the bounded task flow to use train components, as described in [Section 22.7, "Using Train Components in Bounded Task Flows."](#)

It may be helpful to have an understanding of the configuration options that you can configure for a train. For more information, see [Section 22.7.1, "Creating a Task Flow as a Train."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To create a train in a bounded task flow:

1. Open the bounded task flow or task flow template where you want to render train stops.
2. Drag each view activity or JSF page you want to include in the train to the diagram for the bounded task flow.
 - If you drag a JSF page, JDeveloper automatically adds a view activity to the diagram.
 - Double-click any view activity that you drag to the diagram to invoke the dialog to create a new JSF page.

You can reorder the train stop sequence at a later point. For more information, see [Section 22.7.4, "Disabling the Sequential Behavior of Train Stops in a Train."](#)

3. In the diagram for the bounded task flow, double-click each view activity that you want to define as a train stop.

JDeveloper displays a dialog to create a new JSF page if the view activity is not yet associated with a JSF page. Use the dialog to create a new JSF page.

If the view activity is already associated with a JSF page, JDeveloper opens the page.

4. In the ADF Faces page of the Component Palette, from the General Controls panel, in the Location group, drag a **Train**, and, optionally, a **Train Button Bar** component and drop it on the JSF page.

You must manually add each Train and Train Button Bar component that you want to appear in a task flow view activity. Consider using a page template. For more information, see [Section 24.2, "Using Page Templates."](#)

22.7.1.2 What Happens When You Create a Task Flow as a Train

JDeveloper writes the `<train/>` element to the source file for the bounded task flow or task flow template that you enable as a train, using one of the methods outlined in [Section 22.7.1, "Creating a Task Flow as a Train."](#)

JDeveloper writes entries to the JSF page where you added `train` and `trainButtonBar` components. [Example 22–10](#) shows code snippets from the `defineAddresses.jsff` page fragment in the Fusion Order Demo application. Both types of train component bind to instances of the train model object (`trainModel`).

Example 22–10 Metadata for Train Components in the Fusion Order Demo Application

```
<af:train value="#{controllerContext.currentViewPort.taskFlowContext.trainModel}"
  id="t1"/>
...
<af:trainButtonBar value="#{controllerContext.currentViewPort.taskFlowContext.trainModel}"
  id="tbb1"/>
```

Dotted lines appear between each view activity that you add to the bounded task flow and define as a train stop, as illustrated in [Figure 22–5](#). The dotted lines indicate the order in which the bounded task flow navigates through the train stops. JDeveloper defines the sequence in the order that you add the view activities to the bounded task flow. You can change the sequence. For more information, see [Section 22.7.4, "Disabling the Sequential Behavior of Train Stops in a Train."](#) You can also skip a train stop. For more information, see [Section 22.7.6, "Configuring a Train to Skip a Train Stop."](#)

22.7.2 Invoking a Child Bounded Task Flow from a Train Stop

An alternative approach to grouping task flow activities in one train stop, as described in [Section 22.7.3, "Grouping Task Flow Activities to Execute Between Train Stops,"](#) is to create another bounded task flow as a train that you invoke from your current bounded task flow. We refer to this bounded task flow as a *child bounded task flow*. You configure the parent bounded task flow to invoke it using a task flow call activity. To implement this functionality, you:

- Create a child bounded task flow as a train
- Add the task flow activities that you want end users to access from the train stop on the parent bounded task flow to the child bounded task flow
- Designate a task flow call activity as a train stop in the parent bounded task flow to invoke the child bounded task flow
- Add a task flow return activity to the child bounded task flow that returns control to the parent bounded task flow once the child bounded task flow finishes execution

Task flow activities in the child bounded task flow execute together regardless of whether the end user visits the train stop for the first time or returns at a later point. Nonview task flow activities in the child bounded task flow typically precede the view

activity in the child bounded task flow's flow control. You can invoke a child bounded task flow from a bounded task flow that itself is a child to another bounded task flow.

22.7.2.1 How to Invoke a Child Bounded Task Flow From a Train Stop

You create a bounded task flow as a train, add task flow activities to it, and configure a task flow call activity on the parent bounded task flow to invoke it.

Before you begin:

It may be helpful to have an understanding of the configuration options that you can configure for a child bounded task flow that you invoke from a train. For more information, see [Section 22.7.2, "Invoking a Child Bounded Task Flow from a Train Stop."](#)

You may also find it helpful to read about the additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To invoke a child bounded task flow from a train stop:

1. Create a child bounded task flow as a train. For more information, see [Section 22.7.1, "Creating a Task Flow as a Train."](#)
2. Add the task flow activities that you want the child bounded task flow to invoke to the child bounded task flow. In particular, make sure that you add a task flow return activity to the child bounded task flow to return control to the parent task flow when the child bounded task flow finishes execution.

For more information, see [Section 19.7, "Using Task Flow Return Activities."](#)

3. Add a task flow call activity to the parent task flow to render as a train stop that invokes the child bounded task at runtime.

For more information, see [Section 19.6, "Using Task Flow Call Activities."](#)

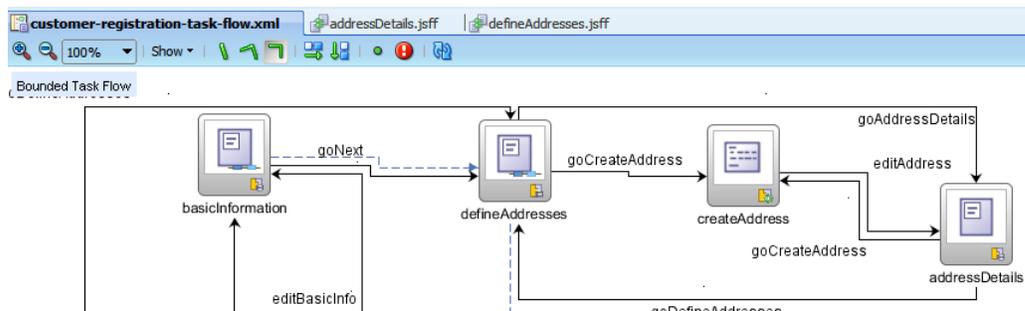

22.7.3 Grouping Task Flow Activities to Execute Between Train Stops

You can group task flow activities together to form a single train stop. For example, the train stop in the Fusion Order Demo application that renders as **Address** at runtime groups together the following task flow activities:

- `defineAddress` view activity
- `createAddress` method call activity
- `addressDetails` view activity

Each time a user visits the runtime **Address** train stop, the customer registration task flow provides access to the task flow activities listed previously. The `defineAddresses` view activity renders the train stop and the associated `defineAddresses.jsff` page fragment. The `defineAddresses.jsff` page fragment, in turn, exposes a command button to invoke the `createAddress` method call activity. This method call activity validates user input in the Address page and defines an outcome that (optionally) passes control to the `addressDetails` view activity. The `addressDetails` view activity renders the Address Information page at runtime where an end user may choose to enter additional addresses.

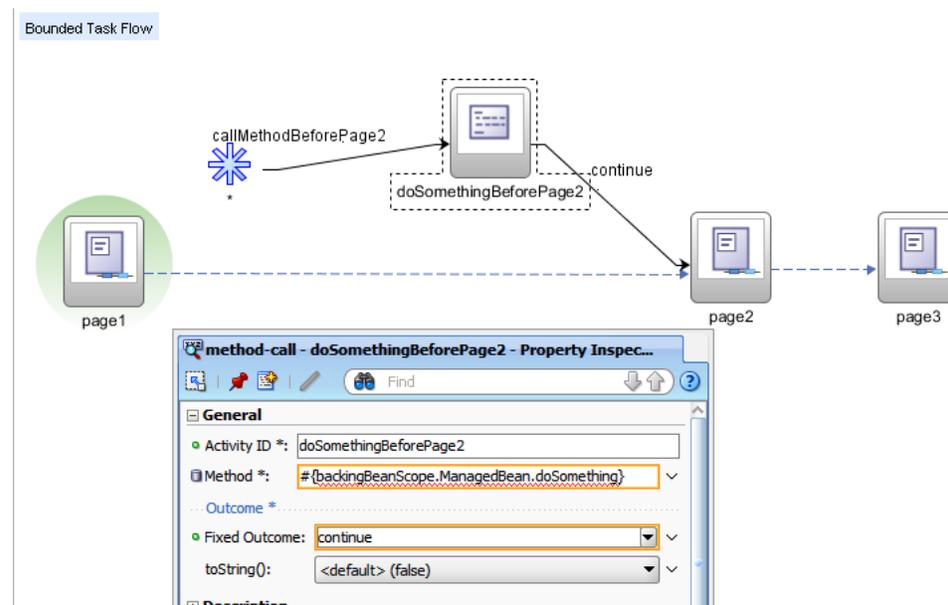

Figure 22–7 Task Flow Activities Grouped into One Train Stop

The train considers all task flow activities that lead from the first nonview activity through the next view activity to be part of the train. Make sure that all task flow activities, except for view and task flow call activities, for the train stop follow the view or task flow call activity that you define as a train stop.

You can also group task flow activities to execute between train stops. Figure 22–8 shows a possible configuration where a method call activity (`doSomethingBeforePage2`) invokes before control flow passes to `page2`. The `callMethodBeforePage2` wildcard control flow rule passes control to the `doSomethingBeforePage2` method call activity. This method call activity defines a fixed outcome (`continue`) that passes control to the next train stop (`page2`) in the train.

Figure 22–8 Method Call Activity Between Train Stops

22.7.4 Disabling the Sequential Behavior of Train Stops in a Train

By default, train stops are sequential. This means end users can select a train stop only after visiting the previous train stop in the train. Figure 22–9 shows the train component that the customer registration task flow renders. End users cannot visit the **Payment** options and **Review** train stops until they first visit the **Address** train stop. All train stops in this train are sequential.

Figure 22–9 Sequential Train Stops in the Customer Registration Task Flow

You can change this default behavior (make a train stop nonsequential) by configuring the view activity that renders the train stop to make it nonsequential.

22.7.4.1 How to Disable the Sequential Behavior of a Train

You write a value for the task flow view activity's `sequential` property that evaluates to `false` at runtime.

Before you begin:

It may be helpful to have an understanding of the configuration options that you can configure for a train. For more information, see [Section 22.7, "Using Train Components in Bounded Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To disable the sequential behavior of a train stop:

1. In the Application Navigator, double-click the source file for the bounded task flow containing the view activity that renders the train stop.
2. In the diagram for the bounded task flow, select the view activity.
3. In the Property Inspector, expand the **Train Stop** and write a value in the **Sequential** field to determine if the train stop is sequential or nonsequential.

Write `false` or write an EL expression that resolves to `false` at runtime to make the train stop nonsequential. For example, write an EL expression similar to the following:

```
{myTrainModel.isSequential}
```

22.7.4.2 What Happens When You Disable the Sequential Behavior a Train Stop

JDeveloper writes an entry to the source file for the bounded task flow, as illustrated in [Example 22–11](#).

Example 22–11 Metadata to Disable the Sequential Behavior of a Train Stop

```
<view id="paymentOptionDetails">
  <page>/account/paymentOptionDetails.jsff</page>
  <train-stop id="__1">
    <sequential>#{myTrainModel.isSequential}</sequential>
  </train-stop>
</view>
```

[Figure 22–10](#) shows the corresponding runtime view when the value specified for `sequential` evaluates to `false`. End users can now navigate directly to payment options by clicking the **Payment options** train stop.

Figure 22–10 Train with a Nonsequential Train Stop

22.7.5 Changing the Label of a Train Stop

You can configure a train stop to display a label that you define. The label that you define can be a static value or a value in a resource bundle that you reference using an EL expression, for example. For more information about using localized strings, see the "Internationalizing and Localizing Pages" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

22.7.5.1 How to Change the Label of a Train Stop

You change the label of a train stop by configuring a value for the view activity's Display Name property.

Before you begin:

It may be helpful to have an understanding of the configuration options that you can configure for a train. For more information, see [Section 22.7, "Using Train Components in Bounded Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To change the label of a train stop:

1. In the Application Navigator, double-click the source file for the bounded task flow containing the view activity that renders the train stop.
2. In the diagram for the bounded task flow, select the view activity.
3. In the Property Inspector, expand the **Description** section and write a value in the **Display Name** to specify the label that the train stop renders at runtime.

Write a literal value or write an EL expression that references a value in a resource bundle to render at runtime.

22.7.5.2 What Happens When You Change the Label of a Train Stop

JDeveloper writes an entry to the source file for the bounded task flow, as illustrated in [Example 22–12](#).

Example 22–12 Metadata to Change the Label of a Train Stop

```
<view id="basicInformation">
  <display-name>Basic Information</display-name>
  <page>/account/basicInformation.jsff</page>
  <train-stop>
    <display-name>Basic Information</display-name>
  </train-stop>
</view>
```

At runtime, the Fusion web application displays the value you specified for the `display-name` property as the label for the train stop.

22.7.6 Configuring a Train to Skip a Train Stop

You can configure a train so that it skips an individual train stop. At runtime, the Fusion web application disables the train stop that you configure to skip. The end user can only navigate to next train stop in the train.

Implement this functionality if you want the train to execute at a train stop other than the first train stop. For example, configure train stops 1 and 2 to skip if you want to execute train stop 3 first. Use this approach rather than defining the view activity associated with the train stop as the default activity, as discussed in [Section 18.2.3, "What You May Need to Know About the Default Activity in a Bounded Task Flow."](#)

22.7.6.1 How to Configure a Train to Skip a Train Stop

You write a value for the view activity's `skip` property that evaluates to `true` at runtime.

Before you begin:

It may be helpful to have an understanding of the configuration options that you can configure for a train. For more information, see [Section 22.7, "Using Train Components in Bounded Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To configure a train to skip a train stop:

1. In the Application Navigator, double-click the source file for the bounded task flow containing the view activity that renders the train stop.
2. In the diagram for the bounded task flow, select the view activity.
3. In the Property Inspector, expand the **Train Stop** and write a value in the **Skip** field to determine if the train navigates to the train stop or skips it.

Write `true` or write an EL expression that resolves to `true` at runtime to make the train skip the train stop. For example, write an EL expression similar to the following:

```
{myTrainModel.shouldSkip}
```

22.7.6.2 What Happens When You Configure a Train to Skip a Train Stop

JDeveloper writes an entry to the source file for the bounded task flow, as illustrated in [Example 22-13](#).

Example 22-13 Metadata to Make a Train Skip a Train Stop

```
<view id="defineAddresses">
  <display-name>Address</display-name>
  <page>/account/defineAddresses.jsff</page>
  <train-stop>
    <display-name>Address</display-name>
    <skip>#{myTrainModel.shouldSkip}</skip>
  </train-stop>
</view>
```

[Example 22–11](#) shows the corresponding runtime view when the value specified for `skip` evaluates to `true`. End users must now navigate to the next train stop in the train (Payment options) if the train is sequential.

Figure 22–11 Train Configured to Skip a Train Stop

22.8 Creating Task Flow Templates

You can create task flow templates for yourself or other application developers to use as a starting point when creating new bounded task flows. Unbounded task flows cannot be created using task flow templates. A bounded task flow created from a task flow template will have definitions for the same set of task flow activities, control flows, input parameters, and managed beans as the task flow template.

An example use case for a task flow template is where you define a task flow activity as an exception handler on a bounded task flow. The task flow activity could be a view activity associated with a page that you display to end users when an exception occurs. Rather than define this view activity in each bounded task flow, you define it in a task flow template and select the task flow template when you create new bounded task flows. For more information about exception handling, see [Section 22.4, "Handling Exceptions in Task Flows."](#)

You can base a new task flow template on an existing task flow template. You can also refactor an existing bounded task flow to create a new task flow template. For more information, see [Section 18.6.3, "How to Convert Bounded Task Flows"](#).

When you create a bounded task flow or another task flow template based on a task flow template, you can specify that subsequent changes you make to a task flow template be automatically propagated to bounded task flows and templates. To do this, you select the **Update the Task Flow When the Template Changes** checkbox in the dialog that you use to create a bounded task flow or a template. Subsequent changes that you make to the task flow template (add new view activities, for example) get propagated to the bounded task flows. You can change, update, or disassociate the parent task flow template of a child bounded task flow or task flow template at any point during development of the child.

At runtime, the contents of a child bounded task flow or a child task flow template combine with the contents of the parent task flow template if you selected the **Update the Task Flow When the Template Changes** checkbox when creating the child. The child task flow and task flow template override the parent task flow template when conflict occurs, even if you selected the **Update the Task Flow When the Template Changes** checkbox when creating the child task flow or task flow template. For example, you create a parent task flow template to use as a train, as described in [Section 22.7, "Using Train Components in Bounded Task Flows,"](#) and then create a bounded task flow based on this task flow template. Later, you disable the train component on the parent task flow template. The child task flow overrides the parent task flow template and continues to execute as a train.

[Table 22–3](#) describes in more detail how ADF Controller resolves conflicts between parent task flow templates and child task flows and child task flow templates.

Table 22–3 Conflict Resolution between Parent Templates and Child Task Flows

Bounded Task Flow Metadata	Combination Algorithm
Default activity	Child bounded task flow or child task flow template overrides parent task flow template.
Transaction	Child bounded task flow or child task flow template overrides parent task flow template as an entire block of metadata, including all subordinate elements.
Task flow reentry	Child bounded task flow or child task flow template overrides parent task flow template as an entire block of metadata, including all subordinate elements.
Control flow rules	<p>Combination algorithm occurs at the control flow case level, not the control flow rule level. Control flow cases fall into the following categories:</p> <ul style="list-style-type: none"> ■ Both from action and from outcome specified ■ Only from action specified ■ Only from outcome specified ■ Neither from action nor from outcome specified <p>Each of these categories is merged additively. The child bounded task flow or template overrides parent task flow template for identical matches within each of the four categories.</p>
Input parameter definitions	Child bounded task flow or child task flow template overrides parent task flow template for identical input parameter definition names.
Return value definitions	Child bounded task flow or child task flow template overrides parent task flow template for identical return value definition names.
Activities	Child bounded task flow or child task flow template overrides parent task flow template for identical activity IDs.
Managed beans	Child bounded task flow or child task flow template overrides parent task flow template for identical managed bean names.
Initializer	Child bounded task flow or child task flow template overrides parent task flow template.
Finalizer	Child bounded task flow or child task flow template overrides parent task flow template.
Critical	Child bounded task flow or child task flow template overrides parent task flow template.
Use page fragments	Child bounded task flow or child task flow template overrides parent task flow template.
Exception handler	Child bounded task flow or child task flow template overrides parent task flow template.
Security - permission	<p>Child bounded task flow or child task flow template overrides parent task flow template.</p> <p>Privilege maps are additive. Child bounded task flow or child task flow template overrides parent task flow template for identical privilege map operations.</p>
Security - transport guarantee	Child bounded task flow or child task flow template overrides parent task flow template.
Train	Child bounded task flow or child task flow template overrides parent task flow template.

Validations at both design time and runtime verify that the resulting parent-child extension hierarchy does not involve cycles of the same task flow template.

22.8.1 How to Create a Task Flow Template

You create a task flow template by selecting ADF Task Flow Template from JDeveloper's New Gallery.

Before you begin:

It may be helpful to have an understanding of what task flow template options you can configure. For more information, see [Section 22.8, "Creating Task Flow Templates."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To create a task flow template:

1. In the Application Navigation, right-click the project where you want to create the task flow and choose **New**.
2. In the New Gallery, expand **Web Tier**, select **JSF/Facelets** and then **ADF Task Flow Template**, and click **OK**.
3. In the Create ADF Task Flow Template dialog, choose the appropriate options:
 - **File Name:** Accept the default value proposed by JDeveloper or enter a new file name. The value is used to name the XML source file for the task flow template you create. The source file includes the activities and control flow rules that are in the task flow template. The default name for the XML source file is `task-flow-template.xml`.
 - **Create with Page Fragments:** Leave this checkbox selected (the default) if you expect that a bounded task flow based on the template will be used as an ADF region. Clear the checkbox if you want to add JSF pages instead of JSF page fragments to a task flow based on the task flow template.
4. Click **OK**.

22.8.2 What Happens When You Create a Task Flow Template

As shown in [Example 22–14](#), an XML file is created each time you create a new task flow template using JDeveloper. You can find the XML file in the Application Navigator in the location that you specified in the **Directory** field of the Create ADF Task Flow Template dialog, for example, `.../WEB-INF`.

The contents of the XML source file for the task flow template can be similar to those of a bounded task flow. One difference is the inclusion of the `<task-flow-template>` tag.

Example 22–14 Task flow template source file

```
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2" id="__
1">
  <task-flow-template id="task-flow-template">
    <default-activity>view1</default-activity>
    <view id="view1">view1.jsff</view>
  </task-flow-template>
</adfc-config>
```

22.8.3 What You May Need to Know About Task Flow Templates

If you use a task flow template that contains bindings, you must change the component IDs of task flows based on the task flow template. Doing this makes sure that the IDs are unique. Task flows generated from the template inherit the same ID as the template. This may cause an exception at runtime. For more information, see [Section 24.2.1, "How to Use ADF Data Binding in ADF Page Templates."](#)

If your Fusion web application has configured ADF security, you have to make grants on both the task flow template and task flows that use the template. Usually, the grant on the task flow template is to the `anonymous-role` application role so that the grant that really matters is on the task flow, but not always. For more information about ADF security, see [Section 35, "Enabling ADF Security in a Fusion Web Application."](#)

22.9 Creating a Page Hierarchy Using Task Flows

Creating a page hierarchy is a useful way of organizing the JSF pages in your Fusion web application so that end users can more easily navigate the application. End users access information on the pages by navigating a path of links. [Figure 22–12](#) shows a sample page hierarchy.

Figure 22–12 Page Hierarchy

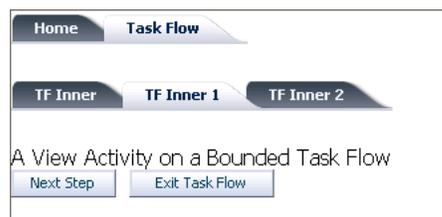

To navigate this hierarchy, an end user clicks links on each page to drill down or up to another level of the hierarchy. For example, clicking **Human Resources** on the Fusion App home page displays the Human Resources page hierarchy shown in [Figure 22–12](#). Clicking the link on the **Benefits** tab displays the page hierarchy shown in [Figure 22–13](#).

Figure 22–13 Benefits Page

The user can click links on the Benefits page to display other pages, for example, the Medical, Dental or Vision pages. The breadcrumbs on each page indicate where the current page fits in the hierarchy. The user can click each node in a breadcrumb to navigate to other pages in the hierarchy. The bold tab labels match the path to the current page shown the breadcrumbs.

Pages referenced by view activities in a bounded task flow can also be included in any page hierarchy that you generate. [Figure 22–14](#) shows the runtime view of a page hierarchy that renders view activities referenced by a bounded task flow.

Figure 22–14 Runtime Menu Hierarchy Including a Bounded Task Flow

You can use ADF Controller with an `XMLMenuModel` implementation to create the previously-discussed page hierarchies. If you do, JDeveloper generates the following for you:

- Control flow metadata that determines the view or page to display when an end user selects a menu item
- An `XMLMenuModel` metadata file
- Default navigation widgets such as **Previous** and **Next** button
- Breadcrumbs
- Managed bean configuration

If you decide not to use ADF Controller, you can create the page hierarchy using an `XMLMenuModel` implementation. For more information about this method of building a page hierarchy, see the "Using a Menu Model to Create a Page Hierarchy" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

22.9.1 How to Create a Page Hierarchy

Create an unbounded task flow or open an existing one. Add view activities or bounded task flows to the unbounded task flow. Each view activity or bounded task

flow that you add to the unbounded task flow contains references to pages to appear in the proposed page hierarchy. Use JDeveloper’s Create ADF Menu Model dialog to generate an XMLMenuModel metadata file. Organize the item nodes in the generated XMLMenuModel metadata file to create the page hierarchy you want. Connect submenus to parent menus to finalize the hierarchy.

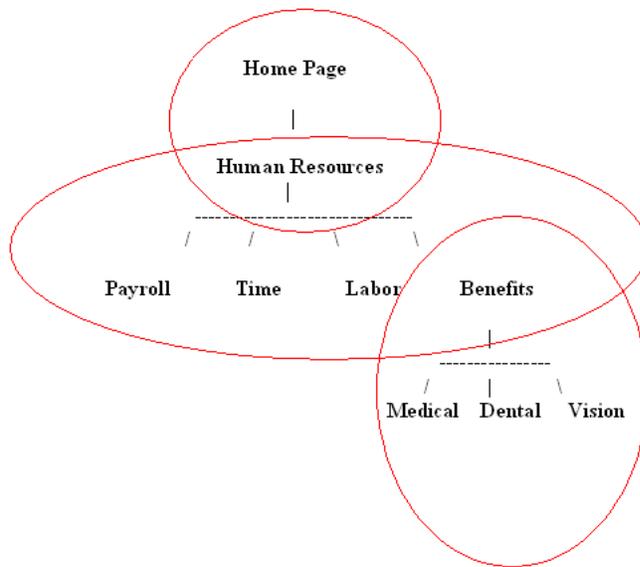

Figure 22–15 shows an example page hierarchy that consists of view activities:

- The top-level menu (**Home Page**) is the root parent page. It contains a single tab that links to the **Human Resources** submenu.

In JDeveloper, **Home Page** page is represented as an item node and **Human Resources** page as a shared node.
- **Human Resources** has four tab links to **Payroll**, **Time**, **Labor**, and **Benefits** pages.

In this menu, **Human Resources** is a group node that references child item nodes (**Payroll**, **Time**, and **Labor**) and a shared node (**Benefits**) that references the Benefits submenu.
- **Benefits** is a group node that references child item nodes (**Medical**, **Dental**, and **Vision**) pages.

Figure 22–15 Menu Hierarchy

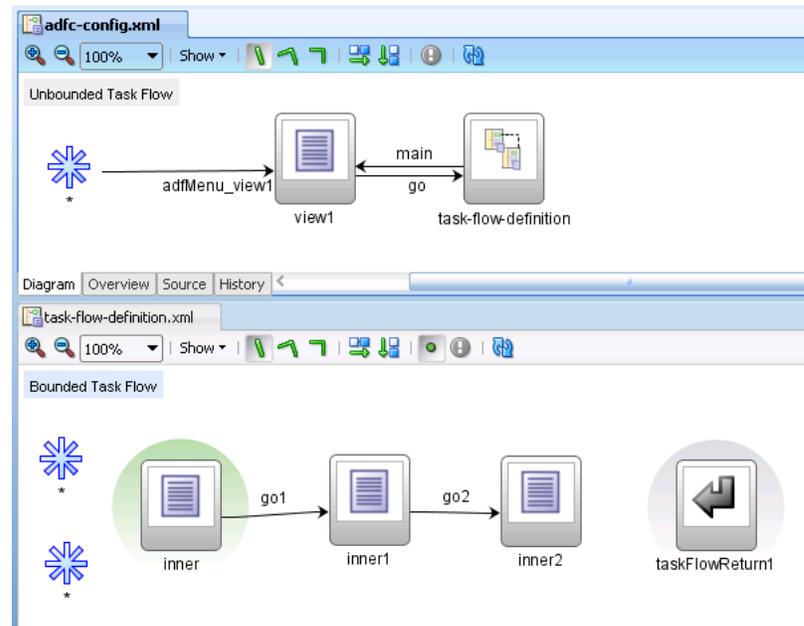

Note: It is possible to create the entire menu hierarchy in one menu model. However, breaking a menu hierarchy into submenus makes maintenance easier. In addition, breaking the menu hierarchy into smaller submenu models enables each separate development organization to develop its own menu. These separate menus can later be combined using shared nodes to create the complete menu hierarchy.

Figure 22–16 shows the corresponding design-time view in JDeveloper of the unbounded and bounded task flows that render the page hierarchy shown in Figure 22–14. The unbounded task flow (`adfc-config.xml`) contains a view activity

(**view1**) and a task flow call activity (**task-flow-definition**) that invokes the bounded task flow (`task-flow-definition.xml`) shown in the lower part of [Figure 22–16](#).

Figure 22–16 Design Time Menu Hierarchy Including a Bounded Task Flow

22.9.1.1 How to Create an XMLMenuModel Metadata File

You use JDeveloper's Create ADF Menu Model dialog to generate an `XMLMenuModel` metadata file once you have defined what menus (unbounded task flows) and nodes (pages) you want to appear in the final page hierarchy.

Before you begin:

It may be helpful to have an understanding of what page hierarchy options you can configure. For more information, see [Section 22.9, "Creating a Page Hierarchy Using Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To create the XMLMenuModel metadata file:

1. Create an unbounded task flow for each menu in the final page hierarchy.

For example, to achieve the page hierarchy illustrated in [Figure 22–15](#), you create two unbounded task flows (Human Resources menu and Benefits menu).

For more information about creating an unbounded task flow, see [Section 18.2.1, "How to Create a Task Flow"](#).

Tip: Prefix the name of the file for unbounded task flows that you create with `adfc-` to help you to identify the file as the source of an unbounded task flow, as opposed to a bounded task flow.

2. Add view activities that reference pages to each unbounded task flow. The pages referenced by the view activities correspond to the menu nodes in the menu.

For example, the Benefits menu contains one group node (benefits) and three item nodes (medical, dental and vision) so you add four view activities to the unbounded task flow for the Benefits menu, as illustrated in [Figure 22–17](#).

Figure 22–17 View Activities on a Task Flow

Do not add view activities for menus that include other menus using shared nodes. For example, the Human Resources menu in [Figure 22–15](#) has a tab called **Benefits** that references the Benefits menu using a shared node. The bounded task flow for the Benefits menu already includes a view activity for Benefits so there is no need to add a view activity to the bounded task flow for the Human Resources menu.

For more information about view activities, see [Section 19.2, "Using View Activities."](#)

Note: If the page hierarchy includes pages referenced by a bounded task flow, add a task flow call activity to the unbounded task flow that calls the bounded task flow.

3. In the Application Navigator, right-click the file(s) for each of the unbounded task flows you created in step 1 and choose **Create ADF Menu Model**.
4. In the Create ADF Menu Model dialog, enter a file name for the `XMLMenuModel` metadata file and a directory to store it.
5. Click **OK**.

22.9.1.2 How to Create a Submenu with a Hierarchy of Group and Child Nodes

You open the `XMLMenuModel` metadata file you created and convert the item nodes that you want to make group nodes to group nodes. You then create a hierarchy where a group node is a parent to one or more item nodes.

Before you begin:

It may be helpful to have an understanding of what page hierarchy options you can configure. For more information, see [Section 22.9, "Creating a Page Hierarchy Using Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To create a submenu with a hierarchy of group and item nodes:

1. In the Application Navigator, select and open the `XMLMenuModel` metadata file.
An item node appears in the Structure window for each view activity in the unbounded task flow. By default, no hierarchy is defined.

2. Drag and drop the item nodes to become child nodes of the item node that you are going to convert to a group node.

Each item node that you convert to a group node must have at least one child item node. For example, to create the menu hierarchy in [Figure 22–15](#), you convert the item node for Benefits to a group node, you drag and drop the item nodes for Medical, Dental, and Vision so that they become child nodes of the Benefit item node.

3. In the Structure window, right-click the parent item node and choose **Convert To groupNode**.

4. Enter a new identifier or accept the default value in the **id** field of the groupNode Properties dialog that appears

The identifier must be unique among all of the nodes in all of the `XMLMenuModel` metadata files. It is good practice to specify a value that identifies the node. For example, if you change the Benefits node to a group node, you can update its default ID, `itemNode_benefits`, to `groupNode_benefits`.

5. In the **idref** field of the groupNode Properties dialog, enter the ID of one of the other nodes in the menu, for example, `itemNode_Medical`.

The value you enter can be an ID of a child item node that is a group node or an item node.

6. Enter or change the existing default value in the **label** field to match what you want to appear at runtime.

For example, you might change `label_benefits` to `Benefits`.

7. Accept the rest of the default values in the fields and click **Finish**

A Confirm Convert dialog asks if you want to delete the `action` and `focusViewID` attributes on the `groupNode` element. Group nodes do not use these attributes, always click **OK**

8. Click **OK**

22.9.1.3 How to Attach a Menu Hierarchy to Another Menu Hierarchy

You use a shared node element to link two menus together. For example, the Human Resources menu illustrated in the menu hierarchy in [Figure 22–15](#) contains four submenus (Payroll, Time, Labor, and Benefits). The Benefits submenu is itself a menu with submenu entries. In the `XMLMenuModel` metadata file for the Human Resources menu, you convert the item node for the Benefits submenu to a shared node. You write an EL expression for an attribute (`ref`) of the newly-created shared node that references the `XMLMenuModel` metadata file for the Benefits menu.

Before you begin:

It may be helpful to have an understanding of what page hierarchy options you can configure. For more information, see [Section 22.9, "Creating a Page Hierarchy Using Task Flows."](#)

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see [Section 22.1.2, "Additional Functionality for Complex Task Flows."](#)

To attach a menu hierarchy to another hierarchy using a shared node:

1. In the Application Navigator, select and open the `XMLMenuModel` metadata file for the menu that is going to reference the other menu.

2. In the Structure window, select a node, right-click and select the appropriate menu options to insert a `sharedNode` element.
3. In the **ref** field of the Insert `sharedNode` dialog that appears, enter an EL expression to reference the `XMLMenuModel` metadata file for the other menu.
4. Click **OK**.

Note: If your page hierarchy has more than one unbounded task flow, ensure that the file name for each additional unbounded task flow appears as a value for the `<metadata-resource>` element in the `adfc-config.xml` file. For more information, see [Section 22.9.2, "What Happens When You Create a Page Hierarchy"](#).

22.9.2 What Happens When You Create a Page Hierarchy

Changes occur in a number of different files when you create a page hierarchy.

Changes to the `adfc-config.xml` File

When you create a new unbounded task flow, JDeveloper automatically adds a reference in the `adfc-config.xml` file to the source file for the newly-created unbounded task flow. In [Example 22–15](#), `adfc-unbounded_tflow.xml` is the name of the source file for a newly-created unbounded task flow.

Example 22–15 Unbounded task flow referenced by `adfc-config.xml`

```
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2"
            id="__1">
  <metadata-resource id="__2">/WEB-INF/adfc-unbounded_
tflow.xml</metadata-resource>
</adfc-config>
```

For more information about `adfc-config.xml`, see [Section A.9, "adfc-config.xml"](#).

At runtime, the Fusion web application loads the `adfc-config.xml` file when it first starts. The `adfc-config.xml` file can contain:

- ADF navigation metadata for an unbounded task flow
- ADF activity metadata for an unbounded task flow
- Managed bean definitions used by ADF activities

XMLMenuModel Metadata File

JDeveloper generates an `XMLMenuModel` metadata file with nodes for each of the view activities that you added to the unbounded task flow, as illustrated in [Example 22–2](#).

Example 22–16 Example `XMLMenuModel` Metadata File

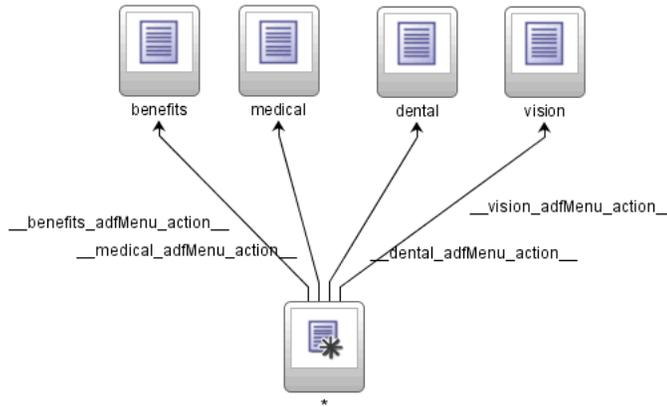

```
<?xml version="1.0" encoding="windows-1252" ?>
<menu xmlns="http://myfaces.apache.org/trinidad/menu">
  <groupNode id="groupNode_benefits" label="Benefits" idref="itemNode_medical">
    <itemNode id="itemNode_medical" label="label_medical"
              action="adfMenu_medical" focusViewId="/medical"/>
    <itemNode id="itemNode_dental" label="label_dental" action="adfMenu_dental"
              focusViewId="/dental"/>
    <itemNode id="itemNode_vision" label="label_vision" action="adfMenu_vision"
              focusViewId="/vision"/>
  </groupNode>
</menu>
```

```
</groupNode>  
</menu>
```

Diagram for an Unbounded Task Flow

JDeveloper updates the file for the unbounded task flow with the control flow rules and managed beans used to navigate the page hierarchy. [Figure 22-18](#) shows the updated unbounded task flow in the diagrammer that corresponds unbounded task flow in [Figure 22-17](#).

Figure 22-18 Updated Unbounded Task Flow

Using Dialogs in Your Application

This chapter describes how to create dialogs in your application. It describes how you can use ADF Controller and task flows to create dialogs or, alternatively, use the ADF Faces dialog framework.

This chapter includes the following sections:

- [Section 23.1, "About Using Dialogs in Your Application"](#)
- [Section 23.2, "Running a Bounded Task Flow in a Modal Dialog"](#)
- [Section 23.3, "Using the ADF Faces Dialog Framework"](#)

23.1 About Using Dialogs in Your Application

Use dialogs if you want to show information to end users in a secondary browser window external to the browser window that displays the end user's current page. For example, you want to display help information to end users to assist them with a task in the primary browser window or you want end users to select a value from a list of values. The help information example is a use case where a modeless dialog is appropriate. A *modeless dialog* allows end users work in both the primary window and the dialog at the same time. For the use case where you want an end user to select a value, a modal dialog is more appropriate. A *modal dialog* prevents an end user accessing the page that invoked the dialog until they execute an action requested by the dialog (for example, select a value).

Use the ADF Faces dialog framework if you want to configure modeless dialogs for your end users. If you plan to configure modal dialogs for your end users, configure an ADF Controller bounded task flow to invoke one or more dialogs.

23.1.1 Using Dialogs in Your Application Use Cases and Examples

[Section 23.2, "Running a Bounded Task Flow in a Modal Dialog"](#) describes how you can run a bounded task flow in a modal dialog to retrieve input from an end user, and return to a view activity that called the bounded task with the retrieved input. If your application does not use ADF Controller task flows or you want to use modeless dialogs, [Section 23.3, "Using the ADF Faces Dialog Framework"](#) describes how you can use the ADF Faces dialog framework to render one or more pages in a dialog.

23.1.2 Additional Functionality for Using Dialogs in Your Application

You may find it helpful to understand other ADF features before you configure or use dialogs in your application. Additionally, you may want to read about what you can do with the dialogs you configure. Following are links to other functionality that may be of interest.

- If your application uses ADF Controller task flows, you may find it helpful to understand more about the features that task flows offer. For more information, see [Chapter 18, "Getting Started with ADF Task Flows."](#)
- For more information about ADF Faces components, see the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- You can also write custom code for your dialogs using the APIs provided by Oracle ADF. Make sure when you write custom code that you do not import packages that are marked internal, as in the following example:

```
import oracle.adfinternal.controller.*;
```

For information about the APIs that you can use to write custom code, see the following reference documents:

- *Oracle Fusion Middleware Java API Reference for Oracle ADF Controller*
- *Oracle Fusion Middleware Java API Reference for Oracle ADF Faces*

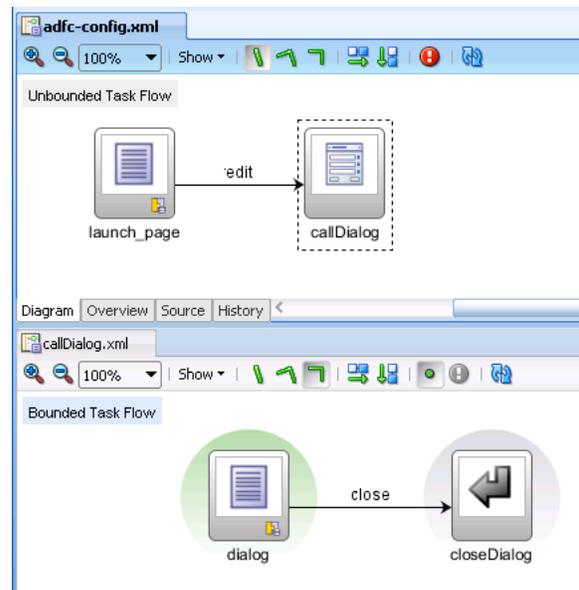

23.2 Running a Bounded Task Flow in a Modal Dialog

You can configure a bounded task flow to run in a modal dialog, retrieve input from an end user, and return to the view activity that called the bounded task flow with the retrieved input. The bounded task flow that you configure must reference pages, not page fragments.

[Figure 23–1](#) shows an example of the configuration required. The task flow in `adfc-config.xml` contains a view activity (**launch_page**) from where the end user invokes the `callDialog.xml` task flow that renders a modal dialog. For more information, see [Section 23.2.1, "How to Run a Bounded Task Flow in a Modal Dialog."](#)

When the end user closes the dialog, control and any modified values return to the launch page in the calling task flow in `adfc-config.xml`. For more information, see [Section 23.2.2, "How to Return a Value From a Modal Dialog."](#)

In addition, you can configure the application to refresh part of the launch page after the modal dialog returns control. For more information, see [Section 23.2.3, "How to Refresh a Page After a Modal Dialog Returns."](#)

Figure 23–1 Task Flow Activities to Invoke a Modal Dialog

23.2.1 How to Run a Bounded Task Flow in a Modal Dialog

You add a view activity and a task flow call activity to an existing task flow. The view activity invokes a page where an end user can invoke an action that, in turn, invokes the bounded task flow to appear in a modal dialog.

Before you begin:

It may be helpful to have an understanding of how the attributes you configure affect the functionality of a bounded task flow in a modal dialog. For more information, see [Section 23.2, "Running a Bounded Task Flow in a Modal Dialog."](#)

You may also find it helpful to understand functionality that can be added using other ADF features. For more information, see [Section 23.1.2, "Additional Functionality for Using Dialogs in Your Application."](#)

To run a bounded task flow in a modal dialog box:

1. In the diagram editor for the existing task flow, double-click the view activity to open the associated page.
2. Select the command component that the end user clicks at runtime to invoke the bounded task flow as a modal dialog box (for example, a `commandButton` component).
3. In the Property Inspector, expand the **Common** section and set the `action` attribute to the control flow case to invoke the bounded task flow.

For example, `edit` in [Figure 23–1](#).

4. Set the `useWindow` attribute to `true` to invoke the bounded task flow in a popup dialog.
5. Return to the diagram editor for the existing task flow and select the task flow call activity.
6. In the Property Inspector, expand the **Behavior** section and set the `run-as-dialog` attribute to `true` to run the bounded task flow as a dialog.

The bounded task flow that the task flow activity calls can now behave as a dialog; it can be invoked by the command component you configured in steps 2 to 4 and can return a value to the view activity that renders the command component, as described in [Section 23.2.2, "How to Return a Value From a Modal Dialog."](#) Note that you need to make these other changes to run a bounded task flow in a modal dialog. Setting the `run-as-dialog` attribute to `true` is not sufficient.

7. For the `display-type` attribute, select `external-window` (the default value) if you want to render the dialog in an external browser window or `inline-popup` if you want to render the dialog in the same browser window.

23.2.2 How to Return a Value From a Modal Dialog

You can configure a bounded task flow that renders in a modal dialog to return a value to the view activity that invoked the bounded task flow when the end user dismisses the modal dialog. The returned value can, for example, be displayed in an input component on the page associated with the view activity.

You must configure the bounded task flow that is called by the task flow call activity to declare input parameters and return values. For more information, see [Section 20.3, "Passing Parameters to a Bounded Task Flow"](#).

You specify a method binding for a method with one argument (a return event) as the value for the `returnListener` attribute of the command component (for example, a `commandButton` component). The `returnListener` attribute sets this value in the input component on the page associated with the view activity. Specify a backing bean for the input component and set the input component's `partialTrigger` attribute to the ID of the command component.

You also need to specify:

- A return value definition on the called bounded task flow to indicate where to take the return value from upon exit of the called bounded task flow.
- Return values on the task flow call activity in the existing task flow to indicate where the existing task flow can find return values.

For more information, see [Section 20.5, "Specifying a Return Value from a Bounded Task Flow"](#).

For more information about creating backing beans, input components, and command components, see the "Using Input Components and Defining Forms" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

Before you begin:

Configure a bounded task flow to run in a modal dialog. For more information, see [Section 23.2.1, "How to Run a Bounded Task Flow in a Modal Dialog"](#).

It may be helpful to have an understanding of how the attributes you configure affect the functionality of bounded task flows in modal dialogs. For more information, see [Section 23.2, "Running a Bounded Task Flow in a Modal Dialog."](#)

You may also find it helpful to understand functionality that can be added using other ADF features. For more information, see [Section 23.1.2, "Additional Functionality for Using Dialogs in Your Application."](#)

To specify a return value:

1. In the diagram editor for the existing task flow, select the task flow call activity.

2. In the Property Inspector, expand the **Behavior** section and set the `run-as-dialog` attribute to `true`.
3. Set the `dialog-return-value` to the name of the return value definition you specified for the target bounded task flow.
5. Select the input component on the page and, in the Property Inspector, expand the **Behavior** section to specify an EL expression for the `partialTriggers` attribute.

For information about how to specify the return value definition on a bounded task flow, see [Section 20.5, "Specifying a Return Value from a Bounded Task Flow"](#).

4. In the Application Navigator, double-click the page that launches the modal dialog.
6. Select the command component and, in the Property Inspector, expand the **Behavior** section.
7. In the **Secondary Window**, enter an EL expression that references a return listener method in the page's backing bean as a value for the `returnListener` attribute.

The EL expression you specify identifies the command component, accepts the return value of the command component, and specifies a backing bean. For example, enter an EL expression with syntax similar to the following:

```
#{pageFlowScope.backingBean.gotoModalDialog}
```

Where `gotoModalDialog` identifies the command component.

The return listener method you specify processes the return event that is generated when an end user dismisses the modal dialog. Enter an EL expression with syntax similar to the following:

```
#{pageBean.listenerMethod}
```

23.2.3 How to Refresh a Page After a Modal Dialog Returns

You can configure the page from where end users invoke a modal dialog to refresh after end users close the modal dialog. You may want to configure this behavior if the modal dialog returns a value or end users edit existing data in the page through controls in the modal dialog.

You implement this functionality by configuring the command component that invokes the modal dialog to listen for a return event. When it receives the return event, it invokes a backing bean method that executes a partial page render event on your page. [Example 23-1](#) shows a `commandButton` component that invokes a modal dialog and listens for a return event.

Example 23-1 ReturnListener Attribute Referencing a Backing Bean Method

```
<af:commandButton text="Edit"
  binding="#{backingBeanScope.backing_launch_page.cb1}"
  id="cb1" action="edit" useWindow="true"
  returnListener="#{backingBeanScope.backing_launch_page.backFromPopup}" />
```

The `commandButton` component's `returnListener` attributes listens for the return event from invoking the modal dialog. When it receives the return event, it invokes a backing bean method similar to the following example:

Example 23-2 Backing Bean Method to Invoke a Partial Page Event

```
public void backFromPopup(ReturnEvent returnEvent) {
    AdfFacesContext adfFacesContext;
```

```

        adfFacesContext = AdfFacesContext.getCurrentInstance();
        adfFacesContext.addPartialTarget(this.getF1());
    }

```

The backing bean method (`backFromPopup`) takes the return event as an argument and, in our example, invokes a partial page render event on a form in the page.

Before you begin:

It may be helpful to have an understanding of how you configure other options for modal dialogs that you invoke from a page associated with a view activity in a task flow. For more information, see [Section 23.2, "Running a Bounded Task Flow in a Modal Dialog."](#)

You may also find it helpful to understand other functionality that can be added using other task flow and dialog framework features. For more information, see [Section 23.1.1, "Using Dialogs in Your Application Use Cases and Examples."](#)

To refresh a page after a modal dialog returns:

1. In the diagram editor for the existing task flow, double-click the view activity that references the page where your end user invokes a command component to launch the modal dialog.
2. Select the command component and, in the **Property Inspector**, expand the **Behavior** section to enter, in the **ReturnListener** field under the **Secondary Window** label, the name of the backing bean method that you want JDeveloper to generate.
3. In the Application Navigator, expand **Application Sources** and then the package that contains the backing bean class where JDeveloper generated a method with the value that you entered in step 2.
4. Write a method body similar to [Example 23–2](#) to invoke a partial page render event on your page.

23.2.4 What You May Need to Know About Dialogs in an Application that Uses Task Flows

If your Fusion web application renders modeless dialogs (non modal dialogs without task flows) and also uses ADF Controller features, such as task flows, you specify the `dialog:syntax` in the control flow rules of the application's `adf-c-config.xml` file rather than the `faces-config.xml` file. Specify `dialog:syntax` in navigation rules within the `faces-config.xml` file if your Fusion web application does not use ADF Controller features.

[Example 23–3](#) shows an example of what you can specify in the `adf-c-config.xml` file.

Example 23–3 `adf-c-config.xml` file with `dialog:syntax`

```

<?xml version="1.0" encoding="windows-1252" ?>
  <adf-c-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2" id="__
1">
    <view id="view1"
      <page>/view1.jsp</page>
    </view>
    <view id="dialog">
      <page>/dialog/untitled1.jsp</page>
    </view>

```

```
<control-flow-rule>
  <from-activity-id>test</from-activity-id>
  <control-flow-case>
    <from-outcome>dialog:test</from-outcome>
    <to-activity-id>dialog</to-activity-id>
  </control-flow-case>
</adfc-config>
```

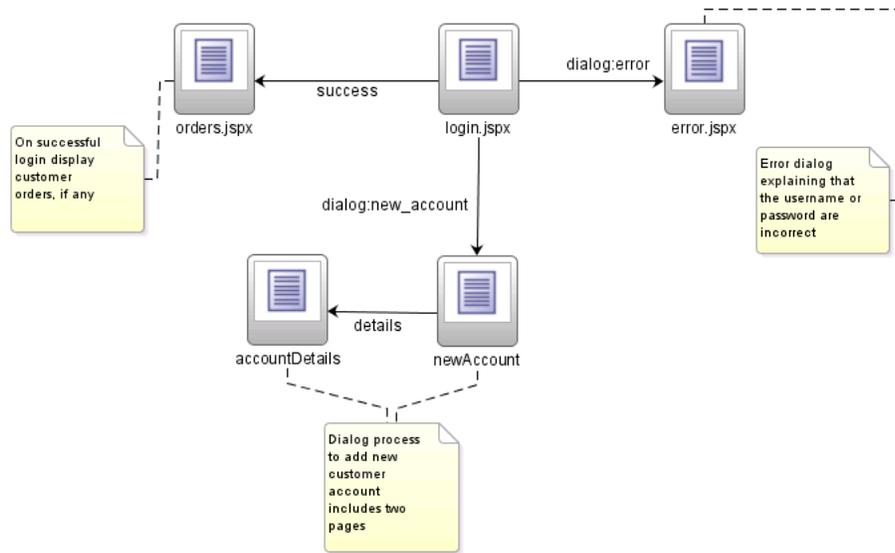

23.3 Using the ADF Faces Dialog Framework

You can use the ADF Faces dialog framework to create modal and modeless dialogs in an application that does not use the ADF Controller and task flows. The dialog framework enables you to display a page or series of pages in a new browser window instead of displaying it in the same window (using the same view ID) as the current page. There may also be cases where you want to use a series of inline dialogs, that is, dialogs that are part of the parent page, but that have a flow of their own, but that do not use a separate view ID. This is important for applications that do not support popups such as, for example, applications that run on client devices or that use the Active Data Service described in [Chapter 45, "Using the Active Data Service."](#) Ordinarily, you would need to use JavaScript to open the dialog and manage the process. With the dialog framework, ADF Faces has made it easy to open a new browser window as well as manage dialogs and processes without using JavaScript.

Note: If your application uses the Fusion technology stack with the ADF Controller, then you should use task flows to create dialogs launched in a separate window, or multiple dialog processes. For more information, see [Section 23.2, "Running a Bounded Task Flow in a Modal Dialog"](#).

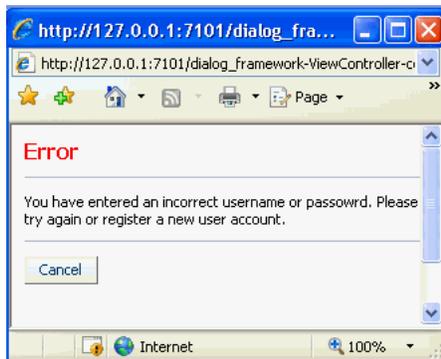

Consider a simple application that requires users to log in to see their orders. [Figure 23-2](#) shows the page flow for the application, which consists of five pages - `login.jspx`, `orders.jspx`, `new_account.jspx`, `account_details.jspx`, and `error.jspx`.

Figure 23–2 Page Flow of an External Dialog Sample Application

When an existing user logs in successfully, the application displays the Orders page, which shows the user's orders, if any. When a user does not log in successfully, the Error page displays in a separate popup dialog window, as shown in [Figure 23–3](#).

Figure 23–3 Error Page Popup

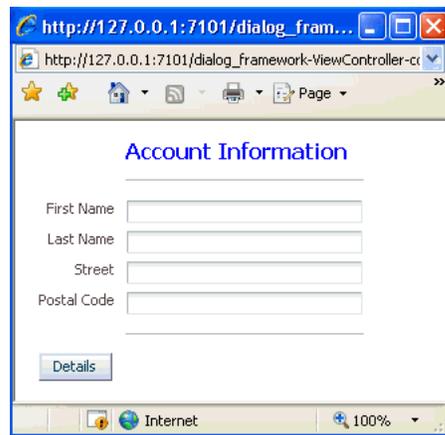

On the Error page there is a **Cancel** button. When the user clicks **Cancel**, the popup dialog closes and the application returns to the Login page and the original flow, as shown in [Figure 23–4](#).

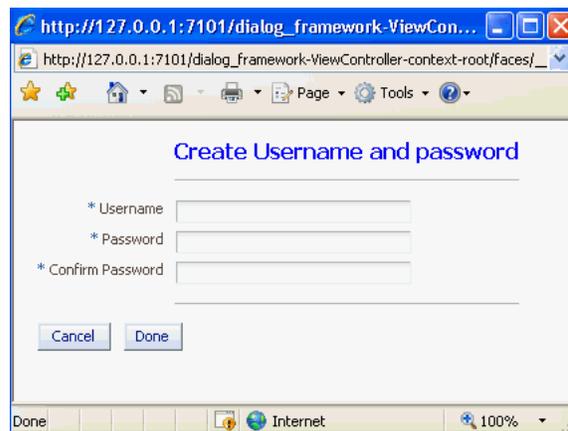

Figure 23–4 Login Page

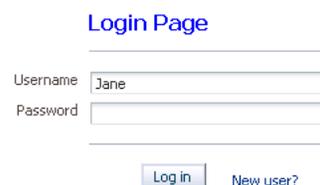

When a new user clicks the **New User** link on the Login page, the New Account page displays in a popup dialog in a new window, as shown in [Figure 23–5](#).

Figure 23–5 New Account Page in a Separate Window

After entering information such as first name and last name, the user then clicks the **Details** button to display the Account Details page in the same popup dialog, as shown in Figure 23–6. In the Account Details page, the user enters other information and confirms a password for the new login account. There are two buttons on the Account Details page - **Cancel** and **Done**.

Figure 23–6 Account Details Page in a Popup Dialog

If the new user decides not to proceed with creating a new login account and clicks **Cancel**, the popup dialog closes and the application returns to the Login page. If the new user clicks **Done**, the popup dialog closes and the application returns to the Login page where the **Username** field is now populated with the user's first name, as shown in Figure 23–7. The new user can then proceed to enter the new password and log in successfully.

Figure 23–7 Login Page with Username Field Populated

Note: The dialog framework should not be used to have more than one dialog open at a time, or to launch dialogs that have a life span outside of the life span of the base page.

To make it easy to support dialog page flows in your applications, ADF Faces has built in the dialog functionality to action components (such as `commandMenuItem` and `commandButton`). For ADF Faces to know whether or not to open a page in a new flow from an action component, the following conditions must exist:

- There must be a JSF navigation rule with an outcome that begins with `dialog:`.
- The command component's action outcome must begin with `dialog:`.
- The `useWindow` attribute on the command component must be `true`.

Note: If the `useWindow` attribute is `false`, or if you configure the popup to be a separate window (and not inline) and the client device does not support popups, ADF Faces automatically shows the page in the current window instead of using a popup window; code changes are not required to facilitate this action.

The page that is displayed in a dialog is an ordinary JSF page, but for purposes of explaining how to implement external dialogs in this chapter, a page that is displayed in a popup dialog is called the *dialog* page, and a page from which the dialog is opened is called the *originating* page. A *dialog process* starts when the originating page opens a dialog (which can contain one dialog page or a series of dialog pages), and ends when the user dismisses the dialog and returns to the originating page.

The tasks for supporting a dialog page flow in an application are:

1. Define a JSF navigation rule for opening a dialog.
2. Create the JSF page from which a dialog is opened.
3. Create the dialog page and return a dialog value.
4. Optional: Pass a value into a dialog.
5. Handle the return value.

The tasks can be performed in any order.

23.3.1 How to Define a JSF Navigation Rule for Opening a Dialog

You manage the navigation into a dialog flow by defining a standard JSF navigation rule with a special `dialog:` outcome.

To define a navigation rule to open a dialog:

1. In the `adfc-config.xml` file, create a page flow for your originating page and dialog pages. For detailed procedures, see [Section 18.4.1, "How to Add a Control Flow Rule to a Task Flow"](#).
2. When creating navigation rules to the dialog pages, the outcome must begin with `dialog:`. For example, in the login sample application shown in [Figure 23–2](#), the outcome from the Login page to the New Account dialog page is `dialog:newAccount`.

At runtime, the dialog navigation rules on their own simply show the specified pages in the originating page. But when used with command components with `dialog:action` outcomes and with `useWindow` attributes set to `true`, ADF Faces knows to open the pages in dialogs.

23.3.2 How to Create the JSF Page That Opens a Dialog

In the originating page, you need to use a command component to launch the dialog. The command component's action value needs to be the outcome to the dialog that is to be launched.

Before you begin:

It may be helpful to have an understanding of how the attributes you configure affect the functionality of the ADF Faces dialog framework. For more information, see [Section 23.1, "About Using Dialogs in Your Application."](#)

You may also find it helpful to understand functionality that can be added using other ADF features. For more information, see [Section 23.1.2, "Additional Functionality for Using Dialogs in Your Application."](#)

To create the JSF Page that opens a dialog

1. Create a JSF page.

For more information, see the "Creating a View Page" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

2. Add a command component to the page.

For more information about adding a command component to a page, see the "Using Buttons and Links for Navigation" section in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

Note the following when setting the attributes on the command component:

- **Action:** Set the action attribute to the outcome that navigates to the dialog, as created in [Section 23.3.1, "How to Define a JSF Navigation Rule for Opening a Dialog."](#)

Tip: The action value can be either a static string or the return of a method on a managed bean.

For example, the action attribute on the command component of the Login page is bound to a method that determines whether to navigate to the Orders page or to the Error dialog page, based on the returned outcome. If the method returns `dialog:error`, the error dialog opens. If the method returns success, the user navigates to the orders page.

- **ActionListener:** As an alternative to setting the action attribute, configure the `actionListener` attribute to invoke the `launchDialog` method from an instance of the following class:

```
oracle.adf.view.rich.context.AdfFacesContext
```

For more information about the `launchDialog` method and the `AdfFacesContext` class, see the *Oracle Fusion Middleware Java API Reference for Oracle ADF Faces*.

- **UseWindow:** Set to `true` to have the dialog open.

Tip: When set to false, ADF Faces shows the dialog page in the current window after preserving all of the state of the current page - you do not have to write any code to facilitate this.

- **WindowHeight** and **WindowWidth:** Set the desired size of the dialog window. These values will set the `contentWidth` and `contentHeight` attributes on the popup component for the dialog.

Tip: While the user can change the values of these attributes at runtime, the values will not be retained once the user leaves the page unless you configure your application to use change persistence. For information about enabling and using change persistence, see the "Allowing User Customization on JSF Pages" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

- **PartialSubmit:** Set to true. This prevents the originating page from reloading (and hence being visible only momentarily) when the popup dialog is displayed.
- **WindowEmbedStyle:** Set to `inlineDocument` if you want the ensuing dialog to open in a popup that belongs to the originating page. Set to `window` if you want the ensuing dialog to open in a separate browser.
- **WindowModalityType:** Set to `applicationModal` if you want the dialog to be modal. Modal dialogs do not allow the user to return to the originating page until the dialog has been dismissed. Set to `modeless` if you want the user to be able to go back and forth between the originating page and the dialog.

When a command component is about to open a dialog, it delivers a `LaunchEvent` event. The `LaunchEvent` event stores information about the component that is responsible for opening a popup dialog, and the root of the component tree to display when the dialog process starts. A `LaunchEvent` can also pass a map of parameters into the dialog. For more information, see [Section 23.3.5, "How to Pass a Value into a Dialog."](#)

23.3.3 How to Create the Dialog Page and Return a Dialog Value

A dialog page is just like any other JSF page, with one exception. In a dialog page, you must provide a way to tell ADF Faces when the dialog process finishes, that is, when the user dismisses the dialog or series of dialogs.

For example, the New Account page and Account Details page belong in the same dialog process. A dialog process can have as many pages as you desire, you only need to notify the framework that the dialog process has ended once.

You do this declaratively using the `returnActionListener` tag as a child to the command component used to close the dialog. However, if you need to provide a return value or other action event processing, you can bind the `actionListener` attribute on the command component to a method that calls the `AdfFacesContext.returnFromDialog()` method. This method lets you send back a return value in the form of a `java.lang.Object` or a `java.util.Map` of parameters. You do not have to know where you are returning the value to - ADF Faces automatically takes care of it.

At runtime, the `AdfFacesContext.returnFromDialog()` method tells ADF Faces when the user dismisses the dialog. This method can be called whether the dialog

page is shown in a popup dialog or in the main window. If a popup dialog is used, ADF Faces automatically closes it.

Before you begin:

It may be helpful to have an understanding of how the attributes you configure affect the functionality of the ADF Faces dialog framework. For more information, see [Section 23.1, "About Using Dialogs in Your Application."](#)

You may also find it helpful to understand functionality that can be added using other ADF features. For more information, see [Section 23.1.2, "Additional Functionality for Using Dialogs in Your Application."](#)

To close a dialog window and optionally return a value:

1. To the dialog page, add a command component. If that component will be used to close the window, set the `immediate` attribute to `true`.

If the button will be used to navigate to another page in the dialog process, configure the button as though it were standard navigation, and set the `useWindow` attribute to `false`, which will cause the next page to display in the same dialog window, preserving the state of the previous page.

2. If you need to end the dialog process and close the dialog, but do not need to return a value, in the Component Palette, from the Operations panel, in the Listeners group, drag a **Return Action Listener** and drop it as a child to the command component.

The `returnActionListener` tag calls the `returnFromDialog` method on the `AdfFacesContext` object - no backing bean code is needed.

No attributes are used with the `af:returnActionListener` tag. The `immediate` attribute on the `af:commandButton` component is set to `true`: if the user clicks **Cancel** without entering values in the required **Password** and **Confirm Password** fields, the default JSF `ActionListener` can execute during the Apply Request Values phase instead of the Invoke Application phase, thus bypassing input validation. For more information, see the "Using the JSF Lifecycle with ADF Faces" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

3. If you need to end the dialog process and do need to return a value, create a method on a managed bean that handles the `action` event and returns the needed values using the `returnFromDialog` method on the current instance of `AdfFacesContext`.

Note: The `AdfFacesContext.returnFromDialog()` method returns `null`. This is all that is needed in the backing bean to handle the Cancel action event.

For example, when the user clicks **Done** on the Account Details page, the process ends and returns the user input values. [Example 23-4](#) shows the code for the event handler method to which **Done** button is bound. The method gets the customer information, then either creates a Faces message for an incorrect password, or sets the values on the new customer object and return that object.

Example 23-4 Action Listener Method for the Done Button in a Managed Bean

```
public void done(ActionEvent e)
{
```

```
AdfFacesContext afContext = AdfFacesContext.getCurrentInstance();
String firstname = afContext.getPageFlowScope().get("firstname").toString();
String lastname = afContext.getPageFlowScope().get("lastname").toString();
String street = afContext.getPageFlowScope().get("street").toString();
String zipCode = afContext.getPageFlowScope().get("zipCode").toString();
String country = afContext.getPageFlowScope().get("country").toString();
String password = afContext.getPageFlowScope().get("password").toString();
String confirmPassword =
    afContext.getPageFlowScope().get("confirmPassword").toString();
if (!password.equals(confirmPassword))
{
    FacesMessage fm = new FacesMessage();
    fm.setSummary("Confirm Password");
    fm.setDetail("You've entered an incorrect password. Please verify that you've
        entered a correct password!");
    FacesContext.getCurrentInstance().addMessage(null, fm);
}
else
{
    //Get the return value
    Customer cst = new Customer();
    cst.setFirstName(firstname);
    cst.setLastName(lastname);
    cst.setStreet(street);
    cst.setPostalCode(zipCode);
    cst.setCountry(country);
    cst.setPassword(password);
    // And return it
    afContext.getCurrentInstance().returnFromDialog(cst, null);
}
}
```

23.3.4 What Happens at Runtime: Raising the Return Event from the Dialog

When the dialog is dismissed, ADF Faces generates a return event (`ReturnEvent`). The `AdfFacesContext.returnFromDialog()` method sends a return value as a property of the return event. The return event is delivered to the return listener (`ReturnListener`) that is registered on the command component that opened the dialog (for example, the **New User** `commandLink` on the Login page). How you would handle the return value is described in [Section 23.3.7, "How to Handle the Return Value."](#)

23.3.5 How to Pass a Value into a Dialog

To pass a value into a dialog, you use a `LaunchListener` listener bound to a handler method for the `LaunchEvent`. You can use the `getDialogParameters()` method to add a parameter to a `Map` using a key-value pair.

Before you begin:

It may be helpful to have an understanding of how the attributes you configure affect the functionality of the ADF Faces dialog framework. For more information, see [Section 23.1, "About Using Dialogs in Your Application."](#)

You may also find it helpful to understand functionality that can be added using other ADF features. For more information, see [Section 23.1.2, "Additional Functionality for Using Dialogs in Your Application."](#)

To Pass a Value into a Dialog:

1. Create a handler method for the `LaunchEvent` that uses the `getDialogParameters` method to get the parameters from a dialog.

For example, in the sample application, a new user can enter a name in the **Username** field on the Login page, and then click the **New User?** link. When the New Account dialog page displays in a popup dialog, the **First Name** input field is automatically populated with the name that was entered in the Login page. To accomplish this, you create a handler that uses the `getDialogParameters` method to put the value of the username field into the dialog, as shown in [Example 23-5](#).

Example 23-5 LaunchEvent Listener Method for the New User Command Link in a Backing Bean

```
public void handleLaunch(LaunchEvent event)
{
    //Pass the current value of the field into the dialog
    Object usr = username;
    event.getDialogParameters().put("firstname", getUsername());
}
// Use by inputText value binding
private String username;
public String getUsername()
{
    return username;
}
public void setUsername(String username)
{
    this.username = username;
}
```

2. Bind the `launchListener` attribute of the command component used to navigate to the next page, to the handler method created in Step 1.

[Example 23-6](#) shows the code for the `commandLink` component, whose `launchListener` attribute is bound to the handler method.

Example 23-6 Input Field and New User Command Link on the Login Page

```
<af:inputText label="Username" value="#{backing_login.username}"/>
<af:commandLink id="cmdLink" text="New User?"
    action="dialog:newAccount"
    useWindow="true" partialSubmit="true"
launchListener="#{backing_login.handleLaunch}"
    returnListener="#{backing_login.handleReturn}"
    windowHeight="200" windowWidth="500" />
```

3. On the resulting page, use the `pageFlowScope` object to retrieve the key and value via a special EL expression in the format `#{pageFlowScope.someKey}`, as shown in [Example 23-7](#)

Example 23-7 Input Field on the New Account Page

```
<af:inputText label="First name" value="#{pageFlowScope.firstname}"/>
```

23.3.6 What Happens at Runtime: Handling the LaunchEvent

In ADF Faces, a process always gets a copy of all the values that are in the `pageFlowScope` of the page from which a dialog is launched. When the `getDialogParameters()` method has added parameters to a `Map`, those parameters also become available in `pageFlowScope`, and any page in the dialog process can get the values out of `pageFlowScope` by referring to the `pageFlowScope` objects via EL expressions.

Note: Unlike `sessionScope`, `pageFlowScope` values are visible only in the current page flow or process. If the user opens a new window and starts navigating, that series of windows has its own process; values stored in each window remain independent. Clicking on the browser's Back button automatically resets `pageFlowScope` to its original state. When you return from a process the `pageFlowScope` is back to the way it was before the process started. To pass values out of a process you would use `AdfFacesContext.returnFromDialog()`, `sessionScope` or `applicationScope`.

23.3.7 How to Handle the Return Value

To handle a return value once the dialog is dismissed, you define a return listener on the command component that launched the dialog. For example, in the sample application, once a new user enters information, that information needs to be handled once the dialog process is complete.

Before you begin:

It may be helpful to have an understanding of how the attributes you configure affect the functionality of the ADF Faces dialog framework. For more information, see [Section 23.1, "About Using Dialogs in Your Application."](#)

You may also find it helpful to understand functionality that can be added using other ADF features. For more information, see [Section 23.1.2, "Additional Functionality for Using Dialogs in Your Application."](#)

To handle the return value:

1. Create a handler method for the `returnEvent`. You use the `getReturnValue()` method to retrieve the return value, because the return value is automatically added as a property of the `ReturnEvent`.

[Example 23-8](#) shows the code for the return listener method that handles the return value.

Example 23-8 Return Listener Method for the New User Link in a Backing Bean

```
public void handleReturn(ReturnEvent event)
{
    if (event.getReturnValue() != null)
    {
        Customer cst;
        String name;
        String psw;
        cst = (Customer)event.getReturnValue();
        name = cst.getFirstName();
        psw = cst.getPassword();
        CustomerList.getCustomers().add(cst);
    }
}
```

```
        inputText1.setSubmittedValue(null);
        inputText1.setValue(name);
        inputText2.setSubmittedValue(null);
        inputText2.setValue(psw);
    }
}
```

2. Bind the `returnListener` attribute on the command component that launched the dialog to the `returnEvent` handler method created in Step 1.

23.3.8 What Happens at Runtime: Handling the ReturnEvent on the Launching Component

At runtime in the sample application, when ADF Faces delivers a `ReturnEvent` to the `ReturnListener` registered on the `commandLink` component, the `handleReturn()` method is called and the return value is processed accordingly. The new user is added to a customer list, and as a convenience to the user any previously submitted values in the Login page are cleared and the input fields are populated with the new information.

Part V

Creating a Databound Web User Interface

Part IV contains the following chapters:

- [Chapter 24, "Getting Started with Your Web Interface"](#)
- [Chapter 25, "Understanding the Fusion Page Lifecycle"](#)
- [Chapter 26, "Creating a Basic Databound Page"](#)
- [Chapter 27, "Creating ADF Databound Tables"](#)
- [Chapter 28, "Command Components to Invoke Functionality in the View Layer"](#)
- [Chapter 29, "Displaying Master-Detail Data"](#)
- [Chapter 30, "Creating Databound Selection Lists and Shuttles"](#)
- [Chapter 31, "Creating ADF Databound Search Forms"](#)
- [Chapter 32, "Using More Complex Databound ADF Faces Components"](#)
- [Chapter 33, "Creating Databound ADF Data Visualization Components"](#)
- [Chapter 34, "Using Contextual Events"](#)

Getting Started with Your Web Interface

This chapter describes the steps you may need to take before using the Data Controls panel to create databound UI components on JSF pages.

This chapter includes the following sections:

- [Section 24.1, "About Developing a Web Application with ADF Faces"](#)
- [Section 24.2, "Using Page Templates"](#)
- [Section 24.3, "Creating a Web Page"](#)
- [Section 24.4, "Using a Managed Bean in a Fusion Web Application"](#)

24.1 About Developing a Web Application with ADF Faces

Most of what you need to know to get started with your web interface is covered in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. However, using the ADF Model layer for data binding instead of JSF managed beans provides additional functionality, such as the ability to declaratively bind components to your business services. For more information on what ADF Model can provide, see [Section 1.2.2, "ADF Model Layer."](#) This chapter provides a high-level overview of the web interface development process as detailed in the Faces guide, and also provides information about the additional functionality available when you use ADF Model data binding.

Following the development process outlined in [Chapter 1, "Introduction to Building Fusion Web Applications with Oracle ADF"](#), developing a web application with ADF Faces and using ADF Model for data binding involves the following steps:

- Creating ADF Faces templates for your pages (optional)
- Creating the individual pages and page fragments for regions to be used within a page
- Creating any needed managed beans

Additionally, the lifecycle of a Fusion web application is different from that of a standard JSF or ADF Faces application. For more information about how the lifecycle works, see [Chapter 25, "Understanding the Fusion Page Lifecycle."](#)

Managed beans are Java classes that give you the flexibility to add UI level code to your pages and task flows. You can use them for functions such as front end data manipulation and event handling.

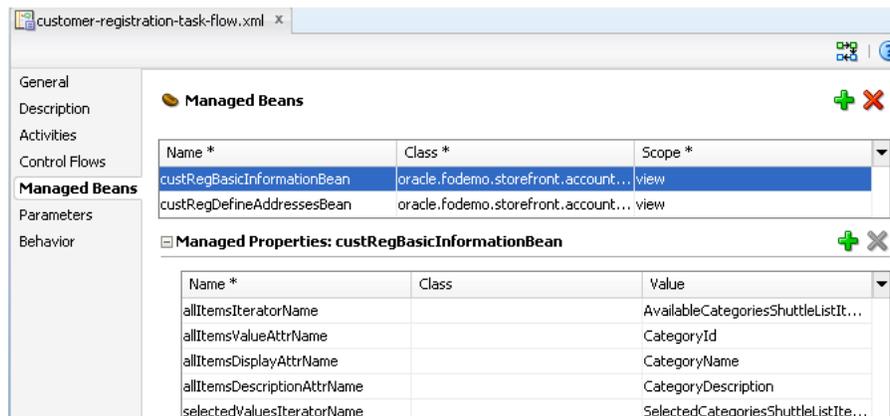

ADF Faces page templates provides structure, consistency, and reusability for building web pages. You can create a page template and apply it to several pages for a

consistent look and feel. It saves you time and effort because you do not need to layout the same elements each time you create a page.

24.1.1 Page Template and Managed Beans Use Cases and Examples

In the customer-registration-task-flow, the `CustRegBasicInformationBean` is used for code to support a shuttle component to shuttle the customers Categories of Interest from the available list to the I am Interested in list. The managed bean contains the code necessary to populate the available list and the selected list. [Figure 24–1](#) shows the managed beans used in the customer-registration-task-flow.

Figure 24–1 Managed Beans in the customer-registration-task-flow

24.1.2 Additional Functionality for Page Templates and Managed Beans

You may find it helpful to understand other ADF features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- For more information about using page templates, see [Chapter 13, "Using ADF Model in a Fusion Web Application,"](#) and the "How to Create a Page Template" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- For more information about managed beans in a standard JSF application, see the Java EE 5 tutorial on Sun's web site (<http://java.sun.com>). For more information about managed beans and scope values, see [Section 25.3, "About Object Scope Lifecycles."](#)

24.2 Using Page Templates

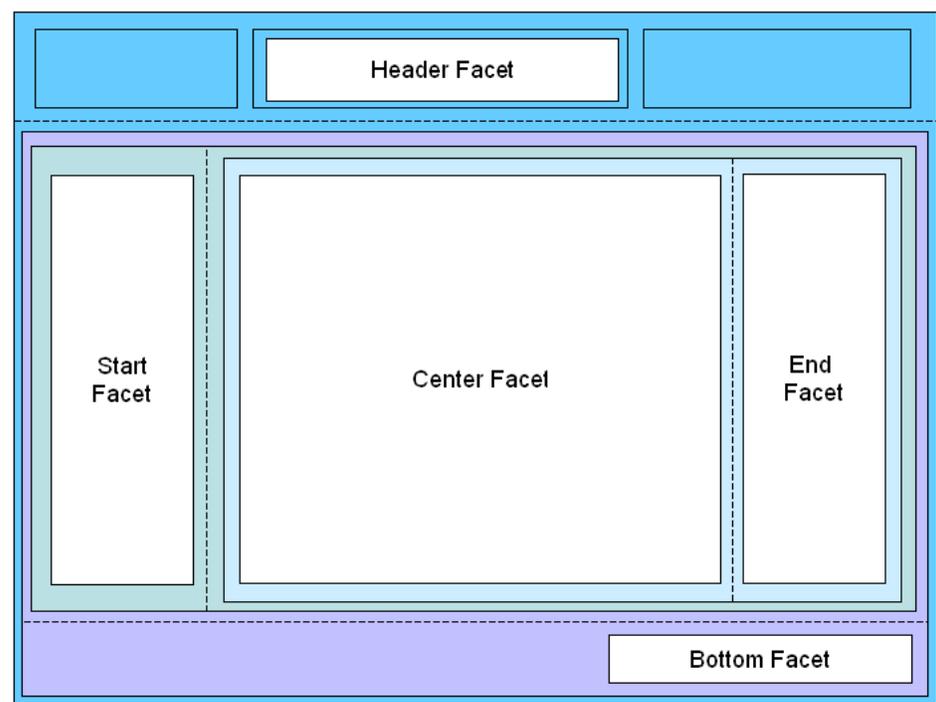

As you design the flow of your application, you can begin to think about the design of your pages. To ensure consistency throughout your application, you use ADF page templates. These page templates provide structure and consistency for other developers building web pages. Page templates typically contain static areas which cannot be changed when they are used, and dynamic areas, where developers can place content specific to the page they are building.

For example, the StoreFront module of the Fusion Order Demo application contains a page template that provides a top area for branding and navigation, a bottom area for copyright information, and a center area for the main content of the page. Page developers do not need to do anything to the branding and copyright information when they use the template. They need only to develop the main content area.

In addition to using ADF Faces components to build a page template, you can add attributes to the template definition. These attributes provide placeholders for specific information that the page developer needs to provide when using the page template. For example, the page template in the StoreFront module application contains an attribute for a welcome message. When page developers use this page template, they can add a different welcome message for each page.

You can also add facet references to the page template. These references act as placeholders for content on the page. [Figure 24–2](#) shows a rendition of how the StoreFrontTemplate template used in the StoreFront module application uses facet references.

Figure 24–2 Facets in the StoreFrontTemplate

In this page template, facet references are used inside four different `panelSplitter` components. When the home page was created using this page template, the navigational links were placed in the Header facet and the accordion panels that hold the navigation trees and search panels were placed in the Start facet. The cart summary was placed in the End facet, and the main portion of the page was placed in the Center facet. The copyright information was placed in the Bottom facet.

When you choose to add databound components to a page template, an associated page definition file and the other metadata files that support ADF Model layer data binding are created. Each component is bound in the same fashion as for standard JSF pages, as described in [Chapter 13, "Using ADF Model in a Fusion Web Application."](#) You can also create model parameters for the page template. The values for these parameter can then be set at runtime by the calling page.

For example, if you wanted a list of products to appear on each page that uses the page template, you could drag and drop the `productName` attribute of the `Products` collection as a list. Or, if you wanted the pages to display the currently selected product ID, you could create a model parameter for the page template that would evaluate to that product's ID.

Note: Page templates are primarily a project artifact. While they can be reused between projects and applications, they are not fully self-contained and will always have some dependencies to external resources, for example, any ADF data binding, `Strings` from a message bundle, images, and managed beans.

If a page template does not contain databound components, it can be referenced dynamically by the calling page using an EL expression. That is, the page template to be used can be determined at runtime. For instance, a page may use `templateA` or `templateB` based on user selection. When you add a page template to a page, an `af:pageTemplate` tag is added to the page. The `af:pageTemplate` tag includes a `viewId` attribute that specifies the page template the page will use. You can set `viewId` with an EL expression to a managed bean method that returns the page template ID, as shown in [Example 24-1](#).

Example 24-1 Page with Dynamic Page Template (not Databound Page Template Only)

```
<af:pageTemplate
  id="pt1"
  viewId="#{myBean.templateViewId}"
```

If the page template has databound components, setting the `viewId` with an EL expression is not enough. Because databound components require access to the binding container, you must specify the page template as well as its associated binding container.

For databound page templates, you use the `pageTemplateModel` to manage both the page template ID and the associated binding container. In the JSF page, instead of using the `viewId` attribute, you set the `value` attribute to the `pageTemplateModel`. You must also modify the page executable section of the calling page's page definition file and create a managed bean with methods to process the page template IDs. For detailed instructions, see [Section 24.2.3, "How to Add a Databound Page Template to a Page Dynamically."](#)

24.2.1 How to Use ADF Data Binding in ADF Page Templates

Creating a page template for use in an application that uses ADF Business Components and ADF Model layer data binding is the same as creating a standard ADF Faces page template, as documented in the "Using Page Templates" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. Once you create the template, you can drag and drop items from the Data Controls panel. JDeveloper automatically adds the page definition file when you drag and drop items from this panel.

The Create JSF Page Template wizard also allows you to create model parameters for use by the template.

Before you begin:

It may help to understand the options that are available to you when you create a basic page template. For more information, see [Section 24.2, "Using Page Templates."](#)

You may also find it useful to understand additional functionality that can be used with page templates. For more information, see [Section 24.1.2, "Additional Functionality for Page Templates and Managed Beans."](#)

You will need to complete this task:

Create a page template that uses ADF Business Components and ADF Model layer databinding.

To add model parameters to a template:

1. Create a page template following the instructions in the "How to Create a Page Template" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. However, do not complete the dialog.
2. In the Create JSF Page Template dialog, select **Create Associated ADFm Page Definition**.

Note: You only need to select this checkbox if you wish to add parameters. JDeveloper automatically adds the page definition file when you drag and drop items from the Data Controls panel.

3. Click the **Model Parameters** tab.
4. Click the **Add** icon.
5. Enter the following for the parameter:
 - **Id:** Enter a name for the parameter.
 - **Value:** Enter a value or an EL expression that can resolve to a value. If needed, click the Invoke Expression Builder (...) button to open the Expression Builder. You can use this to build the expression. For more information about EL expressions and the EL expression builder, see [Chapter 13.8, "Creating ADF Data Binding EL Expressions."](#)
 - **Option:** Select the option that determines how the parameter value will be specified.
 - **optional:** The binding definition's value is used only if the parameter is not specifically set by the caller. This is the default.
 - **final:** The binding definition has the expression to access the value that should be used for this parameter.
 - **mandatory:** The parameter value has to be set by the caller.
 - **Read Only:** Select if the parameter's value is to be read-only and should not be overwritten
6. Create more parameters as needed. Use the order buttons to arrange the parameters into the order in which you want them to be evaluated.

You can now use the Data Controls panel to add databound UI components to the page, as you would for a standard JSF page, as described in the remaining chapters in this part of the book.

Note: If your template contains any method actions bound to a method iterator, you cannot change the value of the `refresh` attribute on the iterator to anything other than `Default`. If set to anything other than `Default`, the method will not execute.

24.2.2 What Happens When You Use ADF Model Layer Bindings on a Page Template

When you add ADF databound components to a template or create model parameters for a template, a page definition file is created for the template, and any model parameters are added to that file.

Note: This section describes what happens for a statically assigned page template. For information about dynamic templates, see [Section 24.2.3, "How to Add a Databound Page Template to a Page Dynamically."](#)

[Example 24–2](#) shows what the page definition file for a template for which you created a `productId` model parameter might look like.

Example 24–2 Model Parameters in a Page Definition for a Template

```
<parameters>
  <parameter id="productId" readonly="true"
    value="#{bindings.productId.inputValue}"/>
</parameters>
<executables/>
<bindings/>
```

Parameter binding objects declare the parameters that the page evaluates at the beginning of a request. For more information about binding objects and the ADF lifecycle, see [Chapter 13, "Using ADF Model in a Fusion Web Application."](#) However, since a template itself is never executed, the page that uses the template (the *calling* page) must access the binding objects created for the template (including parameters or any other type of binding objects created by dragging and dropping objects from the Data Controls panel onto the template).

In order to access the template's binding objects, the page definition file for the calling page must instantiate the binding container represented by the template's page definition file. As a result, a reference to the template's page definition is inserted as an executable into the calling page's page definition file, as shown in [Example 24–3](#).

Example 24–3 Reference to Template's Page Definition as an Executable

```
<executables>
  <page path="oracle.foddemo.storefront.pageDefs.templates_MyTemplatePageDef"
    id="pageTemplateBinding"/>
</executables>
```

In this example, the calling page was built using the `MyTemplate` template. Because the page definition file for the `MyTemplate` template appears as an executable for the calling page, when the calling page's binding container is instantiated, it will in turn instantiate the `MyTemplatePageDef`'s binding container, thus allowing access to the parameter values or any other databound values.

Because there is an ID for this reference (in this case, `pageTemplateBinding`), the calling page can have components that are able to access values from the template.

When you create a JSF page from a template, instead of you having to repeat the code contained within the template, you can use the `af:pageTemplate` tag on the calling page. This tag contains the path to the template JSF page.

Additionally, when the template contains any ADF data binding, the value of that tag is the ID set for the calling page's reference to the template's page definition, as shown in [Example 24-4](#). This binding allows the component access to the binding values from the template.

Example 24-4 Page Template Page Definition Reference

```
<af:pageTemplate viewId="/MyTemplate.jspx"
    value="#{bindings.pageTemplateBinding}".../>
```

24.2.3 How to Add a Databound Page Template to a Page Dynamically

You can dynamically add a page template without databound components by using an EL expression to select the page template. For more information on how to do this, see [Section 24.2, "Using Page Templates."](#)

You can also statically add a page template with databound components. For more information on how to do this, see [Section 24.2.1, "How to Use ADF Data Binding in ADF Page Templates."](#)

This section describes how to dynamically add a page template with databound components to a page. For more information, see [Section 24.2, "Using Page Templates."](#)

You use the `pageTemplateModel` to dynamically manage a page template and its binding container. You use an EL expression in the page definition file to set the page template Id. You create managed bean methods to return the page template Id.

Before you begin:

It may help to understand the options that are available to you when you create a basic page template. For more information, see [Section 24.2, "Using Page Templates."](#)

You may also find it useful to understand additional functionality that can be used with page templates. For more information, see [Section 24.1.2, "Additional Functionality for Page Templates and Managed Beans."](#)

You will need to complete this task:

Create a page template that uses ADF Business Components and ADF Model layer databinding.

To add a databound page template to a page dynamically:

1. Add the page template to the page as described in [Section 24.2.1, "How to Use ADF Data Binding in ADF Page Templates."](#)
2. In the JSF page source editor, remove the `viewId` attribute and change the value attribute to the `pageTemplateModel`. You do not need to create a `pageTemplateModel` explicitly. You can use the `pageTemplateModel` from the corresponding page definition file's page executable binding. For example, for a page executable binding called `pageTemplate1`, you would add the following line under the `af:pageTemplate` tag:

```
value="#{bindings.pageTemplate1.templateModel}"/>
```

3. In the page definition file `<executable>` section, make the following changes to the `<page>` section:

- Remove the `path` attribute. It is no longer needed. The `pageTemplateModel` manages databound components' access to the binding container.
- Change the `id` attribute to the page executable binding. In this example, it is `pageTemplate1`.
- Add a `Refresh` attribute and set it to `ifNeeded`.
- Add a `viewId` attribute and set it to an EL expression with a managed bean method that returns the current page template Id.

For example, for a page executable binding of `pageTemplate1`, the `id` attribute would also be `pageTemplate1`:

```
<executables>
  <page id="pageTemplate1"
        viewId="#{myBean.templateViewId}"
        Refresh="ifNeeded"/>
  ...
</executables>
```

4. Create a `pageFlowScope` managed bean with a method that returns the current page template Id.

The managed bean code should be similar to that of [Example 24–5](#). In this example, `gettemplateViewId()` obtains the user's page template selection and returns the page template Id. `setMDTemplateViewId()` sets the page template to be `MDPageTemplate` and `setPopupTemplateViewId()` sets the page template to be `PopupPageTemplate`.

Example 24–5 Managed Bean Code to Process Page Templates Dynamically

```
public class myClass {
    final private String MDPageTemplate = "/MDPageTemplate.jspx";
    final private String PopupPageTemplate = "/PopupPageTemplate.jspx";
    private String templateViewId;

    public myClass() {
        super();
        templateViewId = MDPageTemplate;
    }
    public String gettemplateViewId() {
        return templateViewId;
    }
    public void setMDTemplateViewId(ActionEvent ae) {
        templateViewId = MDPageTemplate;
    }
    public void setPopupTemplateViewId(ActionEvent ae) {
        templateViewId = PopupPageTemplate;
    }
}
```

24.2.4 What Happens at Runtime: How Pages Use Templates

When a page is created using a template that contains ADF data binding, the following happens:

1. The calling page follows the standard JSF/ADF lifecycle, as documented in [Chapter 25, "Understanding the Fusion Page Lifecycle."](#) As the page enters the Restore View phase, the URL for the calling page is sent to the binding context, which finds the corresponding page definition file.

2. During the Initialize Context phase, the binding container for the calling page is created based on the page definition file.
3. During the Prepare Model phase, the page template executable is refreshed. At this point, the binding container for the template is created based on the template's page definition file, and added to the binding context.
4. The lifecycle continues, with UI components and bindings from both the page and the template being processed.

24.3 Creating a Web Page

Creating a web page for an application that uses ADF Model layer data binding is no different than described in the "Creating a JSF Page" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. You can create pages either by double-clicking a view activity in a task flow or by using the New Gallery. When creating the page (or dropping a view activity onto a task flow), you can choose to create the page as a JSF JSP or as a JSF JSP fragment. JSF fragments provide a simple way to create reusable page content in a project, and are what you use when you wish to use task flows as regions on a page. When you modify a JSF page fragment, the JSF pages that consume the page fragment are automatically updated.

Note: Although JDeveloper supports XHTML files to be used in applications that use Facelets, the `faces-config.xml` and `adfc-config.xml` diagrammers do not support XHTML. In order to add navigation to these files, you have to manually edit the code by clicking the **Source** tab.

When you begin adding content to your page, you typically use the Component Palette and Data Controls panel of JDeveloper. The Component Palette contains all the ADF Faces components needed to declaratively design your page. Once you have the basic layout components placed on the page, you can then drag and drop items from the Data Controls panel to create ADF Model databound UI components. The remaining chapters in this part of the book explain in detail the different types of databound components and pages you can create using ADF Model data binding.

24.4 Using a Managed Bean in a Fusion Web Application

Managed beans are Java classes that you register with the application using various configuration files. When the JSF application starts up, it parses these configuration files, and the beans listed within them are made available. The managed beans can be referenced in an EL expression, allowing access to the beans' properties and methods. Whenever a managed bean is referenced for the first time and it does not already exist, the Managed Bean Creation Facility instantiates the bean by calling the default constructor method on it. If any properties are also declared, they are populated with the declared default values.

Often, managed beans handle events or some manipulation of data that is best handled at the front end. For a more complete description of how managed beans are used in a standard JSF application, see the Java EE 5 tutorial on Sun's web site (<http://java.sun.com>).

Best Practice: Use managed beans to store logic that is related to the UI rendering only. All application data and processing should be handled by logic in the business layer of the application. Similar to how you store data-related logic in the database using PL/SQL rather than a Java class, the rule of thumb in a Fusion web application is to store business-related logic in the middle tier. This way, you can expose this logic as business service methods, which can then become accessible to the ADF Model layer and be available for data binding.

In an application that uses ADF data binding and ADF task flows, managed beans are registered in different configuration files from those used for a standard JSF application. In a standard JSF application, managed beans are registered in the `faces-config.xml` configuration file. In a Fusion web application, managed beans can be registered in the `faces-config.xml` file, the `adfc-config.xml` file, or a task flow definition file. Which configuration file you use to register a managed bean depends on what will need to access that bean, whether or not it needs to be customized at runtime, what the bean's scope is, and in what order all the beans in the application need to be instantiated. [Table 24-1](#) describes how registering a bean in each type of configuration file affects the bean.

Note: Registering managed beans within the `faces-config.xml` file is not recommended in a Fusion web application.

Managed beans accessed within the task flow definition must be registered in that task flow's definition file.

Table 24-1 *Effects of Managed Bean Configuration Placement*

Managed Bean Placement	Effect
<code>adfc-config.xml</code>	<ul style="list-style-type: none"> ■ Managed bean can be of any scope. However, any backing beans for page fragments or declarative components should use <code>BackingBean</code> scope. For more information regarding scope, see Section 25.3, "About Object Scope Lifecycles." ■ When executing within an unbounded task flow, <code>faces-config.xml</code> will be checked for managed bean definitions before the <code>adfc-config.xml</code> file. ■ Lookup precedence is enforced per scope. Request-scoped managed beans take precedence over session-scoped managed beans. Therefore, a request-scoped managed bean named <code>foo</code> in the <code>adfc-config.xml</code> file will take precedence over a session-scoped managed bean named <code>foo</code> in the current task flow definition file. ■ Already instantiated beans take precedence over new instances being instantiated. Therefore, an existing session-scoped managed bean named <code>foo</code> will always take precedence over a request-scoped bean named <code>foo</code> defined in the current task flow definition file.

Table 24–1 (Cont.) Effects of Managed Bean Configuration Placement

Managed Bean Placement	Effect
Task flow definition file	<ul style="list-style-type: none"> ■ Managed bean can be of any scope. However, managed beans of <code>request</code> scope, of <code>pageFlow</code> scope, of <code>view</code> scope, or with the scope set to <code>none</code> that are to be accessed within the task flow definition must be defined within the task flow definition file. Any backing beans for page fragments in a task flow should use <code>BackingBean</code> scope. ■ Managed bean definitions within task flow definition files will be visible only to activities executing within the same task flow. ■ When executing within a bounded task flow, <code>faces-config.xml</code> will be checked for managed bean definitions before the currently executing task flow definition. If no match is found in either location, <code>adfc-config.xml</code> and other bootstrap configuration files will be consulted. However, this lookup in other <code>adfc-config.xml</code> and bootstrap configuration files will only occur for session- or application-scoped managed beans. ■ Lookup precedence is enforced per scope. Request-scoped managed beans take precedence over session-scoped managed beans. Therefore, a request-scoped managed bean named <code>foo</code> in the <code>adfc-config.xml</code> file will take precedence over a session-scoped managed bean named <code>foo</code> in the current task flow definition file. ■ Already instantiated beans take precedence over new instances being instantiated. Therefore, an existing session-scoped managed bean named <code>foo</code> will always take precedence over a request-scoped bean named <code>foo</code> registered in the current task flow definition file. ■ Customizations are allowed.
<code>faces-config.xml</code>	<ul style="list-style-type: none"> ■ Managed beans can be of any scope other than <code>pageFlow</code> scope or <code>view</code> scope. ■ When searching for any managed bean, the <code>faces-config.xml</code> file is always consulted first. Other configuration files will be searched only if a match is not found. Therefore, beans registered in the <code>faces-config.xml</code> file will always win any naming conflict resolution. ■ No customizations can be made.

As a general rule for Fusion web applications, a bean that may be used in more than one page or task flow, or one that is used by pages within the main unbounded task flow (`adfc-config`), should be registered in the `adfc-config.xml` configuration file. A managed bean that will be used only by a specific task flow should be registered in that task flow's definition file. There should be no beans registered in the `faces-config.xml` file.

Note: If you create managed beans from dialogs within JDeveloper, the bean is registered in the `adfc-config.xml` file, if it exists.

For example, in the `StoreFront` module, the `myOrdersBean` managed bean is used by the `myOrders.jspx` page to handle the case where a user decides to cancel editing an order, and the edits have already been committed to the model but have not yet been

persisted to the database. Because this bean is used by a page within the `adfc-config` unbounded task flow, it is registered in the `adfc-config.xml` file. The `custRegBasicInformationBean` is a managed bean used by the `basicInformation` JSF fragment to handle the selections in the shuttle component on that page. Because it is used solely within the `customer-registration` task flow, it is registered in the `customer-registration-task-flow` definition file.

This section describes how to create a managed bean for use within a task flow (either the default `adfc-config` flow or any bounded task flow). For more information regarding managed beans and how they are used as backing beans for JSF pages, see the "Creating and Using Managed Beans" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

24.4.1 How to Use a Managed Bean to Store Information

Within the editors for a task flow definition, you can create a managed bean and register it with the JSF application at the same time.

Before you begin:

It may help to understand the options that are available to you when you create a managed bean. For more information, see [Section 24.4, "Using a Managed Bean in a Fusion Web Application."](#)

You may also find it useful to understand additional functionality that can be used with managed beans. For more information, see [Section 24.1.2, "Additional Functionality for Page Templates and Managed Beans."](#)

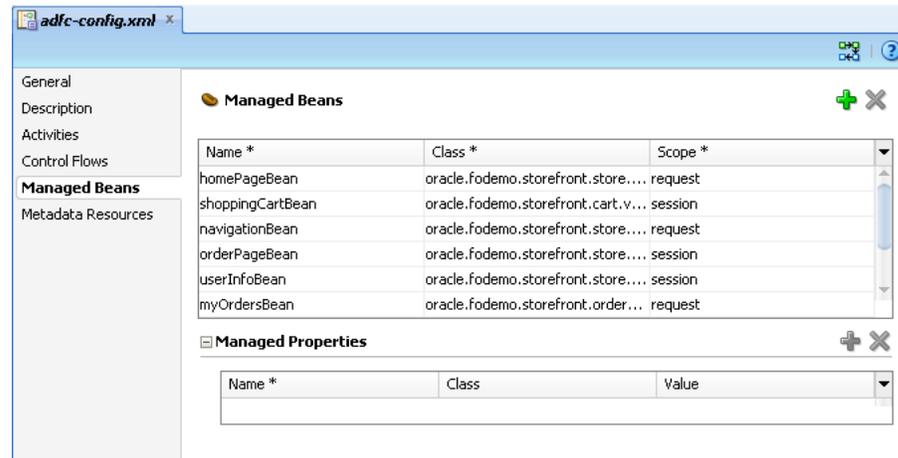

You will need to complete this task:

Create the configuration file (if it doesn't already exist) that you want the managed bean to be associated with. This can be `faces-config.xml`, `adfc-config.xml`, or a bounded task flow definition file.

To create a managed bean for a task flow:

1. In the Application Navigator, double-click either the `adfc-config.xml` file or any other task flow definition file.
2. At the bottom of the window, click the **Overview** tab.
3. In the overview editor, click the **Managed Beans** navigation tab. [Figure 24-3](#) shows the editor for the `adfc-config.xml` file.

Figure 24–3 Managed Beans in the adfc-config.xml File

4. Click the **Add** icon to add a row to the **Managed Beans** table.
5. In the fields, enter the following:
 - **managed-bean-name**: A name for the bean.
 - **managed-bean-class**: If the corresponding class has already been created for the bean, use the browse (...) button for the **managed-bean-class** field to search for and select the class. If a class does not exist, enter the name you'd like to use. Be sure to include any package names as well. You can then use the drop-down menu to choose **Generate Class**, and the Java file will be created for you.
 - **managed-bean-scope**: The bean's scope. For more information about the different object scopes, see [Section 25.3, "About Object Scope Lifecycles."](#)

Note: When determining what scope to register a managed bean with or to store a value in, keep the following in mind:

- Always try to use the narrowest scope possible.
 - If your managed bean takes part in component binding by accepting and returning component instances (that is, if UI components on the page use the binding attribute to bind to component properties on the bean), then the managed bean must be stored in `BackingBean` scope. If it can't be stored in one of those scopes (for example, if it needs to be stored in `sessionScope` for high availability reasons), then instead of using component binding, you need to use the `ComponentReference` API. For more information, see the “What You May Need to Know About Component Bindings and Managed Beans” section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
 - Use the `sessionScope` scope only for information that is relevant to the whole session, such as user or context information. Avoid using the `sessionScope` scope to pass values from one page to another.
 - You can also set the scope to `none`. While not technically a scope, `none` means that the bean will not live within any particular scope, but will instead be instantiated each time it is referenced. You should set a bean's scope to `none` when it is referenced by another bean.
-
-

6. You can optionally add needed properties for the bean. With the bean selected in the **Managed Beans** table, click the **Add** icon for the **Managed Properties** table. Enter a property name (other fields are optional).

Note: While you can declare managed properties using this editor, the corresponding code is not generated on the Java class. You will need to add that code by creating private member fields of the appropriate type and then using the **Generate Accessors** menu item on the context menu of the source editor to generate the corresponding getter and setter methods for these bean properties.

24.4.2 What Happens When You Create a Managed Bean

When you use the configuration editor to create a managed bean and elect to generate the Java file, JDeveloper creates a stub class with the given name and a default constructor. [Example 24-6](#) shows the code added to the `MyBean` class stored in the `view` package.

Example 24-6 Generated Code for a Managed Bean

```
package view;

public class MyBean {
    public MyBean() {
```

```
    }
}
```

You now need to add the logic required by your task flow or page. You can then refer to that logic using an EL expression that refers to the `managed-bean-name` value given to the managed bean. For example, to access the `myInfo` property on the bean, the EL expression would be:

```
#{my_bean.myInfo}
```

JDeveloper also adds a `managed-bean` element to the appropriate task definition file. [Example 24-7](#) shows the `managed-bean` element created for the `MyBean` class.

Example 24-7 Managed Bean Configuration on the `adfc-config.xml` File

```
<managed-bean>
  <managed-bean-name>my_bean</managed-bean-name>
  <managed-bean-class>view.MyBean</managed-bean-class>
  <managed-bean-scope>session</managed-bean-scope>
</managed-bean>
```

24.4.3 How to Set Managed Bean Memory Scopes in a Server-Cluster Environment

Typically, in an application that runs in a clustered environment, a portion of the application's state is serialized and copied to another server or a data store at the end of each request so that the state is available to other servers in the cluster.

Note: If the managed bean will be calling `set` and `get` methods on ADF Faces components, you cannot serialize the managed beans because ADF Faces components are not serializable. You will need to access the ADF Faces components in another way.

When you are designing an application to run in a clustered environment, you must:

- Ensure that all managed beans with a lifespan longer than one request are serializable (that is, they implement the `java.io.Serializable` interface). Specifically, beans stored in session scope, page flow scope, and view scope need to be serializable.

Tip: To identify failures with objects stored in page flow scope and view scope, use `writeObject()`. This method provides additional information in an exception about the object and scope that failed to serialize. Additional information might be a region's page flow scope and the key of the object. :

- Make sure that the framework is aware of changes to managed beans stored in ADF scopes (view scope and page flow scope).

When a value within a managed bean in either view scope or page flow scope is modified, the application needs to notify the framework so that it can ensure that the bean's new value is replicated.

In [Example 24-8](#), an attribute of an object in view scope is modified.

Example 24-8 Code That Modifies an Object in viewScope

```
Map<String, Object> viewScope =
```

```
AdfFacesContext.getCurrentInstance().getViewScope();
MyObject obj = (MyObject)viewScope.get("myObjectName");
Obj.setFoo("newValue");
```

Without additional code, the framework will be unaware of this change and it will not know that a new value needs to be replicated within the cluster. To inform the framework that an object in an ADF scope has been modified and that replication is needed, use the `markScopeDirty()` method, as shown in [Example 24–9](#). The `markScopeDirty()` method accepts only `viewScope` and `pageFlowScope` as parameters.

Example 24–9 Additional Code to Notify Oracle ADF of Changes to an Object

```
ControllerContext ctx = ControllerContext.getInstance();
ctx.markScopeDirty(viewScope);
```

This code is needed for any request that modifies an existing object in one of the ADF scopes. If the scope itself is modified by the scope's `put()`, `remove()`, or `clear()` methods, it is not necessary to notify the framework.

If an application is not deployed to a clustered environment, the tracking of changes to ADF memory scopes is not needed, and by default, this functionality is disabled. To enable ADF Controller to track changes to ADF memory scopes and replicate the page flow scope and view scope within the server cluster, set the `<adf-scope-ha-support>` parameter in the `adf-config.xml` file to `true`. Because scope replication has a small performance overhead, it should be enabled only for applications running in a server-cluster environment.

[Example 24–10](#) shows `adf-scope-ha-support` set to `true` in the `adf-config.xml` file.

Example 24–10 `adf-scope-ha-support` Parameter in the `adf-config.xml` File

```
<?xml version="1.0" encoding="US-ASCII" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
  xmlns:adfc="http://xmlns.oracle.com/adf/controller/config">
  <adfc:adf-controller-config>
  ...
  <adfc:adf-scope-ha-support>true</adfc:adf-scope-ha-support>
  ...
  </adfc:adf-controller-config>
  ...
</adf-config>
```

Understanding the Fusion Page Lifecycle

This chapter describes the ADF page lifecycle, its phases, and how to best use the lifecycle within a Fusion web application.

This chapter includes the following sections:

- [Section 25.1, "About the Fusion Page Lifecycle"](#)
- [Section 25.2, "About the JSF and ADF Page Lifecycles"](#)
- [Section 25.3, "About Object Scope Lifecycles"](#)
- [Section 25.4, "Customizing the ADF Page Lifecycle"](#)

25.1 About the Fusion Page Lifecycle

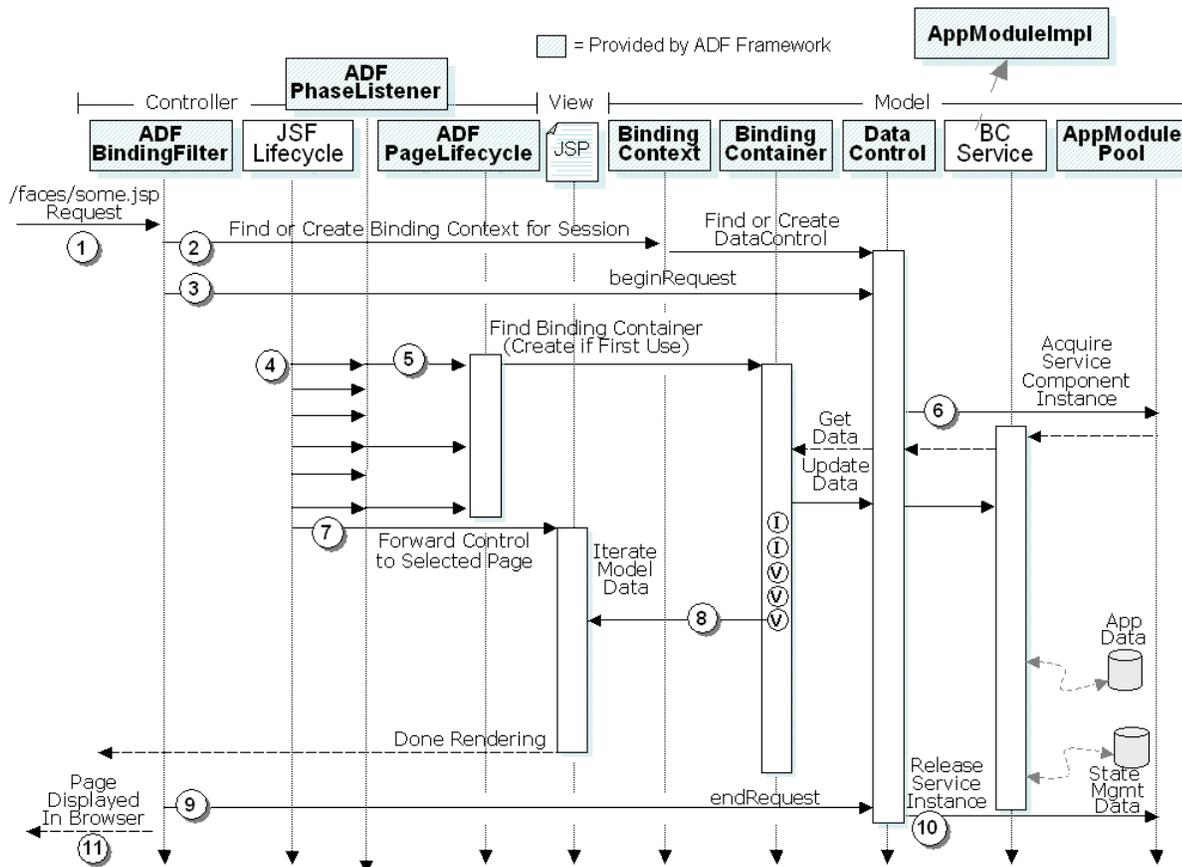

When a page is submitted and a new page requested, the application invokes both the ADF Faces page lifecycle, which extends the standard JSF request lifecycle, and the ADF page lifecycle. The ADF Faces page lifecycle handles submitting the values on the page, validating component values, navigating pages, displaying components on the resulting page, and saving and restoring state. The JSF lifecycle phases use a UI component tree to manage the display of the faces components. This tree is a runtime representation of a JSF page: each UI component tag in a page corresponds to a UI component instance in the tree. The `FacesServlet` servlet manages the request processing lifecycle in JSF applications. `FacesServlet` creates an object called `FacesContext`, which contains the information necessary for request processing, and invokes an object that executes the lifecycle.

For more details about the extended JSF lifecycle, see the "Understanding the JSF and ADF Faces Lifecycles" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

The ADF page lifecycle handles preparing and updating the data model, validating the data at the model layer, and executing methods on the business layer. The ADF page lifecycle uses the binding container to make data available for easy referencing by the page during the current page request.

The combined JSF and ADF page lifecycle is only one sequence within a larger sequence of events that begins when an HTTP request arrives at the application server and continues until the page is returned to the client. This overall sequence of events can be called the *web page lifecycle*. It follows processing through the model, view, and controller layers as defined by the MVC architecture. The page lifecycle is not a rigidly defined set of events, but is rather a set of events for a typical use case. [Figure 25-1](#) shows a sequence diagram of the lifecycle of a web page request using JSF and Oracle ADF in tandem.

Figure 25-1 Lifecycle of a Web Page Request Using JSF and Oracle ADF

The basic flow of processing a web page request using JSF and Oracle ADF happens as follows:

1. A web request for `http://yourserver/yourapp/faces/some.jsp` arrives from the client to the application server.
2. The `ADFBindingFilter` object looks for the ADF binding context in the HTTP session, and if it is not yet present, initializes it for the first time. Some of the functions of the `ADFBindingFilter` include finding the name of the binding context metadata file, and finding and constructing an instance of each data control.
3. The `ADFBindingFilter` object invokes the `beginRequest()` method on each data control participating in the request. This method gives the data control a notification at the start of every request so that it can perform any necessary setup.
4. The `JSF Lifecycle` object, which is responsible for orchestrating the standard processing phases of each request, notifies the `ADFPhaseListener` class during each phase of the lifecycle, so that it can perform custom processing to coordinate the JSF lifecycle with the ADF Model data binding layer. For more information about the details of the JSF and ADF page lifecycle phases, see [Section 25.2, "About the JSF and ADF Page Lifecycles."](#)

Note: The `FacesServlet` class (in `javax.faces.webapp`), configured in the `web.xml` file of a JSF application, is responsible for initially creating the `JSFLifecycle` class (in `javax.faces.lifecycle`) to handle each request. However, since it is the `Lifecycle` class that does all the interesting work, the `FacesServlet` class is not shown in the diagram.

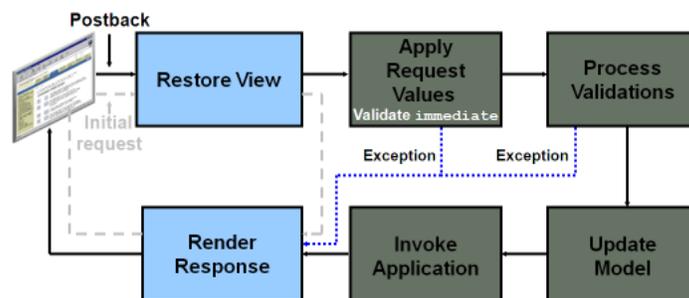

5. The `ADFPhaseListener` object creates an `ADFPagesLifecycle` object to handle each request and delegates the appropriate before and after phase methods to corresponding methods in the `ADFPagesLifecycle` class. If the binding container for the page has never been used before during the user's session, it is created.
6. The first time an application module data control is referenced during the request, it acquires an instance of the application module from the application module pool.
7. The `JSFLifecycle` object forwards control to the page to be rendered.
8. The UI components on the page access value bindings and iterator bindings in the page's binding container and render the formatted output to appear in the browser.
9. The `ADFBindingFilter` object invokes the `endRequest()` method on each data control participating in the request. This method gives a data control notification at the end of every request, so that they can perform any necessary resource cleanup.
10. An application module data control uses the `endRequest` notification to release the instance of the application module back to the application module pool.
11. The user sees the resulting page in the browser.

The ADF page lifecycle also contains phases that are defined simply to notify ADF page lifecycle listeners before and after the corresponding JSF phase is executed (that is, there is no implementation for these phases). These phases allow you to create custom listeners and register them with any phase of both the JSF and ADF page lifecycles, so that you can customize the ADF page lifecycle if needed, both globally or at the page level.

25.2 About the JSF and ADF Page Lifecycles

Figure 25–2 shows a high-level view of the combined JSF and ADF page lifecycles.

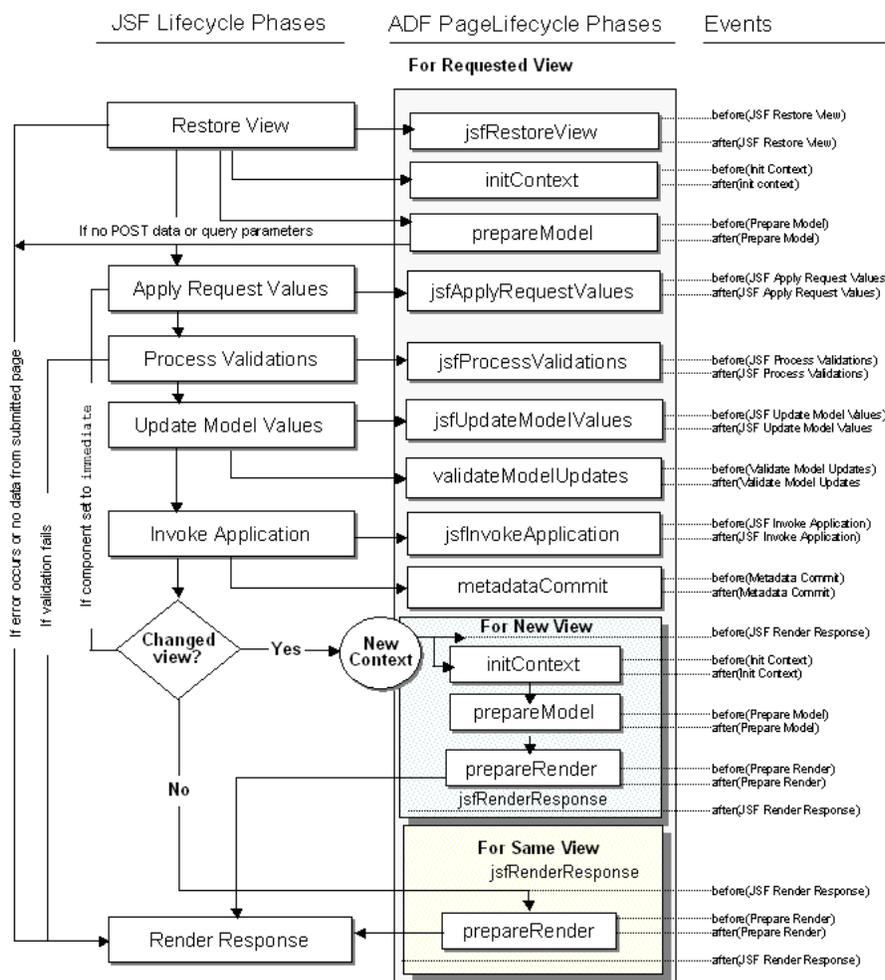

Figure 25–2 JSF and ADF Page Lifecycles

Say for example, you have a page with some text displayed in an input text component and a command button. When that page is first rendered, the component tree is built during the Restore View phase and then the lifecycle goes straight to the Render Response phase, as the components are rendered. When the user clicks the button, the full lifecycle is invoked. The component tree is rebuilt, the input text component extracts any new value during the Apply Request Values phase and Process Validations phase, and if there is an error, for example due to validation, then the lifecycle jumps to the Render Response phase. Otherwise, the model is then updated with the new value during the Update Model phase, and then any application processing associated with the command button (such as navigation), is executed during the Invoke Application phase.

Figure 25-3 shows the details of how the JSF and ADF Faces and ADF model phases integrate in the lifecycle of a page request.

Figure 25-3 Lifecycle of a Page Request in a Fusion Web Application

In a JSF application that uses the ADF Model layer, the phases in the page lifecycle are as follows:

- **Restore View:** The URL for the requested page is passed to the `bindingContext` object, which finds the page definition file that matches the URL. The component tree of the requested page is either newly built or restored. All the component tags, event handlers, converters, and validators on the submitted page have access

to the `FacesContext` instance. If the component tree is empty, (that is, there is no data from the submitted page), the page lifecycle proceeds directly to the Render Response phase.

If any discrepancies between the request state and the server-side state are detected, an error will be thrown and the page lifecycle jumps to the Render Response phase.

- **JSF Restore View:** Provides before and after phase events for the Restore View phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Restore View phase. The Initialize Context phase of the ADF Model page lifecycle listens for the `after(JSF Restore View)` event and then executes. The ADF Controller uses listeners for the before and after events of this phase to synchronize the server-side state with the request. For example, it is in this phase that browser back button detection and bookmark reference are handled. After the before and after listeners are executed, the page flow scope is available.
- **Initialize Context:** The page definition file is used to create the `bindingContainer` object, which is the runtime representation of the page definition file for the requested page. The `LifecycleContext` class used to persist information throughout the ADF page lifecycle phases is instantiated and initialized with values for the associated request, binding container, and lifecycle.
- **Prepare Model:** The ADF page lifecycle enters the Prepare Model phase by calling the `BindingContainer.refresh(PREPARE_MODEL)` method. During the Prepare Model phase, `BindingContainer` page parameters are prepared and then evaluated. If parameters for a task flow exist, they are passed into the flow.

Next, any executables that have their `refresh` property set to `prepareModel` are refreshed based on the order of entry in the page definition file's `<executables>` section and on the evaluation of their `RefreshCondition` properties (if present). When an executable leads to an iterator binding refresh, the corresponding data control will be executed, and that leads to execution of one or more collections in the service objects. If an iterator binding fails to refresh, a JBO exception will be thrown and the data will not be available to display. For more information, see [Section 25.2.2, "What You May Need to Know About Using the Refresh Property Correctly."](#)

If the incoming request contains no `POST` data or query parameters, then the lifecycle forwards to the Render Response phase.

If the page was created using a template, and that template contains bindings using the ADF Model layer, the template's page definition file is used to create the binding container for the template. The container is then added to the binding context.

If any `taskFlow` executable bindings exist (for example, if the page contains a region), the `taskFlow` binding creates an ADF Controller `ViewPortContext` object for the task flow, and any nested binding containers for pages in the flow are then executed.

- **Apply Request Values:** Each component in the tree extracts new values from the request parameters (using its `decode` method) and stores those values locally. Most associated events are queued for later processing. If you have set a component's `immediate` attribute to `true`, then the validation, conversion, and events associated with the component are processed during this phase and the lifecycle skips the Process Validations, Update Model Values, and Invoke Application phases. Additionally, any associated iterators are invoked. For more information about ADF Faces validation and conversion, see the "Validating and

Converting Input" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

- **JSF Apply Request Values:** Provides before and after phase events for the Apply Request Values phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Apply Request Values phase.
- **Process Validations:** Local values of components are converted and validated on the client. If there are errors, the lifecycle jumps to the Render Response phase. At the end of this phase, new component values are set, any validation or conversion error messages and events are queued on `FacesContext`, and any value change events are delivered. Exceptions are also caught by the binding container and cached.
- **JSF Process Validations:** Provides before and after phase events for the Process Validations phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Process Validations phase.
- **Update Model Values:** The component's validated local values are moved to the model and the local copies are discarded. For any updateable components (such as an `inputText` component), corresponding iterators are refreshed, if the refresh condition is set to the default (`deferred`) and the refresh condition (if any) evaluates to `true`.

If you are using a backing bean for a JSF page to manage your UI components, any UI attributes bound to a backing bean property will also be refreshed in this phase.

- **JSF Update Model Values:** Provides before and after phase events for the Update Model Values phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Update Model Values phase.
- **Validate Model Updates:** The updated model is now validated against any validation routines set on the model. Exceptions are caught by the binding container and cached.
- **Invoke Application:** Any action bindings for command components or events are invoked.
- **JSF Invoke Application:** Provides before and after phase events for the Invoke Application phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Invoke Application phase.
- **Metadata Commit:** Changes to runtime metadata are committed. This phase stores any runtime changes made to the application using the Metadata Service (MDS). For more information about using MDS to persist runtime changes, see [Chapter 39, "Customizing Applications with MDS."](#)
- **Initialize Context (only if navigation occurred in the Invoke Application lifecycle):** The Initialize Context phase listens for the `beforeJSFRenderResponse` event to execute. The page definition file for the next page is initialized.
- **Prepare Model (only if navigation occurred in the Invoke Application lifecycle):** Any page parameters contained in the next page's definition are set.
- **Prepare Render:** The binding container is refreshed to allow for any changes that may have occurred in the Apply Request Values or Validation phases. Any iterators that correspond to read-only components (such as an `outputText` component) are refreshed. Any dynamic regions are switched, if needed. The

prepareRender event is sent to all registered listeners, as is the afterJSFRenderResponse event.

Note: Instead of displaying prepareRender as a valid phase for a selection, JDeveloper displays renderModel, which represents the refresh(RENDER_MODEL) method called on the binding container.

- **Render Response:** The components in the tree are rendered as the Java EE web container traverses the tags in the page. State information is saved for subsequent requests and the Restore View phase.

In order to lessen the wait time required to display both a page and any associated data, certain ADF Faces components such as the table component, use data streaming for their initial request. When a page contains one or more of these components, the page goes through the normal lifecycle. However, instead of fetching the data during that request, a special separate request is run. Because the page has just rendered, only the Render Response phase executes for the components that use data streaming, and the corresponding data is fetched and displayed. If the user's action (for example scrolling in a table), causes a subsequent data fetch another request is executed. Tables, trees, tree tables, and data visualization components all use data streaming.

- **JSF Render Response:** Provides before and after phase events for the Render Response phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Render Response phase.

25.2.1 What You May Need to Know About Partial Page Rendering and Iterator Bindings

ADF Faces provides an optimized lifecycle that you can use when you want the page request lifecycle (including conversion and validation) to be run only for certain components on a page, usually for components whose values have changed.

One way to use the optimized lifecycle is to manually set up dependencies so that the events from one component act as triggers for another component, known as the *target*. When any event occurs on the trigger component, the lifecycle is run on any target components, as well as on any child components of both the trigger and the target, causing only those components to be rerendered. This is considered a partial page rendering (PPR)

[Example 25-1](#) shows radio buttons as triggers and a panelGroupLayout component that contains the output text to be the target (the panelGroupLayout component must be the target because the outputText component may not always be rendered).

Example 25-1 Example of Partial Page Rendering

```
<af:form>
  <af:inputText label="Required Field" required="true"/>
  <af:selectBooleanRadio id="show" autoSubmit="true" text="Show"
    value="#{validate.show}"/>
  <af:selectBooleanRadio id="hide" autoSubmit="true" text="Hide"
    value="#{validate.hide}"/>
  <af:panelGroupLayout partialTriggers="show hide" id="panel">
    <af:outputText value="You can see me!" rendered="#{validate.show}"/>
  </af:panelGroupLayout>
</af:form>
```

Because the `autoSubmit` attribute is set to `true` on the radio buttons, when they are selected, a `SelectionEvent` is fired. Because the `panelGroupLayout` component is set to be a target for both radio components, when that event is fired, only the `selectOneRadio` (the trigger), the `panelGroupLayout` component (the trigger's target), and its child component (the `outputText` component) are processed through the lifecycle. Because the `outputText` component is configured to render only when the **Show** radio button is selected, the user is able to select that radio button and see the output text, without having to enter text into the required input field above the radio buttons.

Instead of having to set partial triggers and targets within code manually, the ADF Faces framework provides automatic PPR. Automatic PPR happens when an event has a corresponding event root component, or when the component itself is an event root. An event root component determines the boundaries of PPR. For example, the `attributeChangeEvent` considers the `inputText` component that invokes the event, its event root. Therefore, in the previous example, when the value changes for the `inputText` component, because it is the initial boundary for the PPR, the lifecycle would be run only on that `inputText` component and any child components.

Along with event roots, by default for Fusion web applications, automatic PPR also occurs for all UI components associated with the same iterator binding. All associated components refresh whenever any one of them has a value change event. This functionality is controlled by setting the `changeEventPolicy` attribute for iterators to `ppr`. By default, this is set globally.

For example, say you create a number of `inputText` components using the Data Controls panel (for example, when you create a form). When the `attributeChangeEvent` occurs on one of those `inputText` components, because the other `inputText` components are associated with the same iterator, all those `inputText` components will also be refreshed.

Another example might be a page that contains a `panelSplitter` component, where the left part of the splitter contains a form to create a new customer (created by dropping a form using the `CustomerInfoVO1` collection), and the right part of the splitter contains instructions for using the form. Because the bindings for the `inputText` components that make up the form are all associated with the `CustomerInfoVO1Iterator` iterator, anytime the form is submitted and a value for one of the `inputText` components has changed, only the `inputText` components associated with the `CustomerInfoVO1Iterator` will be processed through the lifecycle. The rest of the page, including the instructions in the right side of the splitter, will not be refreshed.

Note: In order for automatic PPR to happen, the event and event root component must be listed in Table 5-1 of the "Events and Partial Page Rendering" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. If it is not listed, you will need to set up PPR manually, as described in the Enabling Partial Page Rendering Declaratively section of the same guide.

For example, say you create a form and a table from the same data control collection. The form shows the details for a row of data, while the table shows all rows in a collection, with the row currently displayed in the form shown as selected. When you click the **Next** button on the form, you want the table to refresh to show the new row as selected. Because the selection event is not supported by automatic PPR, the table will not refresh, even though the table and form both use the same iterator. You will need to set the **Next** and **Previous** buttons to be triggers of PPR for the target table.

Note: Only UI components that have a control binding defined in the page definition file associated with the configured iterator will be refreshed.

If you directly access the iterator from a managed bean and expose iterator values to UI components through that bean, then automatic PPR will not happen for those UI components. In these cases, you need to configure PPR manually. For more information, see the "Enabling Partial Page Rendering Declaratively" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

Note: The ADF Faces query components do not support automatic PPR. If you set `changeEventPolicy` to be `ppr` globally, any iterators associated with bindings for those components will have the `changeEventPolicy` attribute set to `none`.

By default, all new applications use global PPR. You do not have to set it. You can however, override the setting in the page definition file for a page.

Before you begin:

It may be helpful to have an understanding of partial page rendering. For more information, see [Section 25.2.1, "What You May Need to Know About Partial Page Rendering and Iterator Bindings."](#)

To set iterator bindings to use PPR:

1. To set a specific iterator binding to use or not use PPR, open the associated page definition file, select the iterator, and in the Property Inspector, set **ChangeEventPolicy**.
2. To set all iterator bindings to use PPR:

1. In the Application Navigator, expand the Application Resources panel, expand the **Descriptors** and **ADF META-INF** nodes, and double click **adf-config.xml**.
2. In the overview editor, select the **Model** tab, and then select **Default Change Event Policy is Partial Page Rendering (PPR)**.

For more information about how the ADF Faces framework uses PPR, see the "Rendering Partial Page Content" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

25.2.2 What You May Need to Know About Using the Refresh Property Correctly

For scalability reasons, at runtime the iterator bindings in the binding container release any reference they have to a row set iterator at the end of each request. During the next request, each iterator binding rebinds itself to a "live" row set iterator that is tracking the current row of some data collection. The process of rebinding an ADF iterator binding during the ADF page lifecycle is known as *refreshing* the iterator. By default, this happens only once, on demand, when the iterator is first accessed by the client layer during the lifecycle. This initial access to the iterator typically occurs during page rendering, while EL expressions in the page, which reference the iterator or a control binding related to that iterator, are being evaluated. Alternatively, you can write code that programmatically causes the first access to the iterator to be before the Prepare Render phase. To force the iterator binding to refresh its row set iterator earlier in the lifecycle, you can set the `refresh` attribute on the iterator binding to a value other than the default.

Tip: Refreshing an iterator binding does not forcibly reexecute its query each time. The first time the view object instance's row set iterator is accessed during a particular user's session, it will implicitly execute the view object's query if it was not already executed, as long as a search binding in the page definition related to that iterator has not already cleared the row set in preparation for allowing the user to enter search criteria before executing the query.

Subsequent refreshing of the iterator binding related to that view object instance on page requests that are part of the same logical unit of work will only access the row set iterator again, not forcibly reexecute the query. When you want reexecuting the query to refresh its data, use the `Execute` or `ExecuteWithParams` built-in operation, or programmatically call the `executeQuery()` method on the iterator binding.

The `refresh` and `refreshCondition` attributes are used to determine when and whether to invoke an executable, such as an iterator binding, or an `invokeAction`. The value of the `refresh` attribute determines the lifecycle phase in which to invoke the executable, while the value of the `refreshCondition` attribute provides an optional boolean condition whose outcome determines whether the refresh will occur at the indicated lifecycle phase or not. By default, when JDeveloper adds an executable to a page definition (for example, when you drop an operation as a command component), the `refresh` attribute for the executable binding is set to `deferred`, which enforces execution whenever the binding is accessed the first time. If no `refreshCondition` value exists, the executable is invoked. If a value for `refreshCondition` exists, then that value is evaluated as an EL expression, and if the return value of the evaluation is `true`, then the executable is invoked. If the value evaluates to `false`, the executable is not invoked. For details about the `refresh` attribute, see [Section A.8.1, "PageDef.xml Syntax"](#).

For most cases in a Fusion web application, you should not need to change the `refresh` or `refreshCondition` values on an iterator binding. These values are set to ensure that the correct data is displayed.

While the `invokeAction` executable continues to be supported for upward compatibility from previous releases, in Oracle ADF 11g you use a method activity in a task flow to call an action binding (or any backing bean method) to perform some application behavior before the page is rendered. For example, for a page used to create an object, you might have a task flow that begins with a method activity that calls the `CreateInsert` operation. The task flow then proceeds to the view activity for the page where the user inputs data. Modeling this behavior as discreet method call activities provides a much cleaner separation of application logic and data bindings, making applications both self-documenting and easier to maintain. For more information, see [Section 26.6, "Creating an Input Form."](#)

However, for completeness' sake, in case you encounter situations where you decide to change the `refresh` attribute for iterator bindings or for `invokeAction` (for example, if you have programmatic code that runs after the Prepare Model phase and needs to access the iterator programmatically), you should do so, informed of the following information regarding the valid values:

- `deferred` (the default): On demand

Tip: Any `invokeAction` executable in a page definition file must have a value other than the default (`deferred`) for its `refresh` attribute, or it will not be refreshed and invoked.

- `prepareModel`: During the Prepare Model phase.
- `renderModel`: During the Prepare Render phase.

Tip: Notice in [Figure 25-3](#) that the key distinction between the Prepare Model phase and the Prepare Render phase is that one comes before JSF's Invoke Application phase, and one after. Since JSF's Invoke Application phase is when action listeners fire, if you need your iterator refreshed or the method or operation associated with the `invokeAction` to execute after these action listeners have performed their processing, you'll want to set the `refresh` attribute to `renderModel`.

- `ifNeeded`: During the Prepare Model and Prepare Render phases, only if needed. For iterators, the refresh is considered needed if the binding has not yet been refreshed. To determine if the execution is needed for an `invokeAction`, the framework compares the current set of evaluated parameter values with the set that was used to invoke the method action binding previously. If the parameter values for the current invocation are exactly the same as those used previously, the `invokeAction` does not invoke its bound method action binding. Use this setting if the `invokeAction` executable binds to a method action binding that accepts parameters.

Tip: For `invokeAction` executables bound to methods that do not take parameters, the `invokeAction` executable will be called twice. To use the `invokeAction` executable with parameterless methods, you should use ensure that the condition associated with the `refreshCondition` attribute evaluates to invoke the method only if the value has changed. This will prevent multiple invocations.

- `prepareModelIfNeeded` and `renderModelIfNeeded`: Same as `ifNeeded`, except that it is executed during the named phase.
- `never`: Not valid for `invokeAction` executables. For iterators, the iterator will never be refreshed. Use when your own code calls `getRowSetIterator()` on the iterator binding.
- `always`: Not valid for `invokeAction` executables. For iterators, the iterator will always be refreshed (potentially multiple times) during both the Prepare Model and Prepare Render phases, as well as during the Update Model phase.
- `refreshAfter`: Use to handle dependencies between executables. For example, you can set the condition so that this executable refreshes after another executable.

Tip: You can determine the order of executable invocation using the `refreshAfter` attribute. For example, suppose you have two `invokeAction` elements—one with an ID of `myAction` and another with an ID of `anotherAction`—and you want `myAction` to fire after `anotherAction`. You would set the `refreshAfter` condition on `myAction` to `anotherAction`.

25.2.3 What You May Need to Know About Task Flows and the Lifecycle

Task flows are initially refreshed when the parent binding container (the one associated with the page) is refreshed. This happens in the Prepare Model phase. On a subsequent request, the task flow will be refreshed during the Prepare Render phase, depending on its `refresh` and `refreshCondition` attributes and its parameter value.

Note: Any child page fragment's page definition still handles the refresh of the bindings of the child page fragments.

Tip: If you have a region on a page that is not initially disclosed (for example, a popup dialog), the parameters still need to be available when the parent page is rendered, even though the region might not be displayed. If a region requires parameters, but those parameter values will not be available when the parent page is rendered, then you should use dynamic regions. If the parameters are null, an empty task flow can be used until the parameters for the region are ready and that region can display. To swap in an empty task flow, you set the dynamic region's `taskFlowId` attribute to an empty string.

If you set an EL expression as the value of the `refreshCondition` attribute, it will be evaluated during the Prepare Render phase of the lifecycle. When the expression evaluates to `true`, the task flow will be refreshed again. When `refreshCondition` evaluates to `false`, the behavior is the same as if the `refreshCondition` had not been specified.

Note: If the variable `bindings` is used within the EL expression, the context refers to the binding container of the parent page, not the page fragment displayed within the region.

The valid values for the `refresh` property of a task flow executable are as follows:

- `default`: The region will be refreshed only once, when the parent page is first displayed.
- `ifNeeded`: Refreshes the region only if there has been a change to `taskFlow` binding parameter values. If the `taskFlow` binding does not have parameters, then `ifNeeded` is equivalent to the default. When `ifNeeded` is used, the `refreshCondition` attribute is not considered.

Note: Setting the `refresh` attribute to `ifNeeded` takes precedence over any value for the `refreshCondition` attribute. Also note that `ifNeeded` is not supported when you pass parameters to the `taskFlow` binding using a dynamic parameter Map. Instead, use `refreshCondition="{EL.Expression}"`.

Because the only job of the `taskFlow` binding is to refresh its parameters, setting `Refresh` to `always` does not make sense. If the `taskFlow` binding's parameters don't change, there is no reason to refresh the ADF region.

Note that the child page fragment's page definition still handles the refresh of the bindings of the child page fragments.

25.3 About Object Scope Lifecycles

At runtime, ADF objects such as the binding container and managed beans are instantiated. Each of these objects has a defined lifespan set by its scope attribute. You can access a scope as a `java.util.Map` from the `RequestContext` API. For example, to access an object named `foo` in the request scope, you would use the expression `{requestScope.foo}`.

There are six types of scopes in a Fusion web application:

- Application scope: The object is available for the duration of the application.
- Session scope: The object is available for the duration of the session.

Note: There's no window uniqueness for session scope, all windows in the session share the same session scope instance. If you are concerned about multiple windows being able to access the same object (for example to ensure that managed beans do not conflict across windows), you should use a scope that is window-specific, such as page flow or view scope.

- Page flow scope: The object is available for the duration of a bounded task flow.

Note: Because this is not a standard JSF scope, EL expressions must explicitly include the scope to reference bean. For example, to reference the `MyBean` managed bean from the `pageFlowScope` scope, your expression would be `{pageFlowScope.MyBean}`.

- Request scope: The object is available from the time an HTTP request is made until a response is sent back to the client.
- Backing bean scope: Used for managed beans for page fragments and declarative components only, the object is available from the time an HTTP request is made

until a response is sent back to the client. This scope is needed for fragments and declarative components because there may be more than one page fragment or declarative component on a page, and to prevent collisions, any values must be kept in separate scope instances. Therefore, any managed bean for a page fragment or declarative component must use backing bean scope.

Note: Because this is not a standard JSF scope, EL expressions must explicitly include the scope to reference bean. For example, to reference the `MyBean` managed bean from the backing bean scope, your expression would be `#{backingBeanScope.MyBean}`.

- View scope: The object is available until the view ID for the current view activity changes. This scope can be used to hold values for a given page. However, unlike request scope, which can be used to store a value needed from one page to the next, anything stored in view scope will be lost once the view ID changes.

Note: Both JSF and ADF Faces have an implementation of view scope. Only the ADF Faces view scope survives page redirects and refreshes. In a Fusion web application, when you use `viewScope` in an expression, it resolves to the ADF Faces view scope.

Because this view scope is not a standard JSF scope, EL expressions must explicitly include the scope to reference bean. For example, to reference the `MyBean` managed bean from the view scope, your expression would be `#{viewScope.MyBean}`.

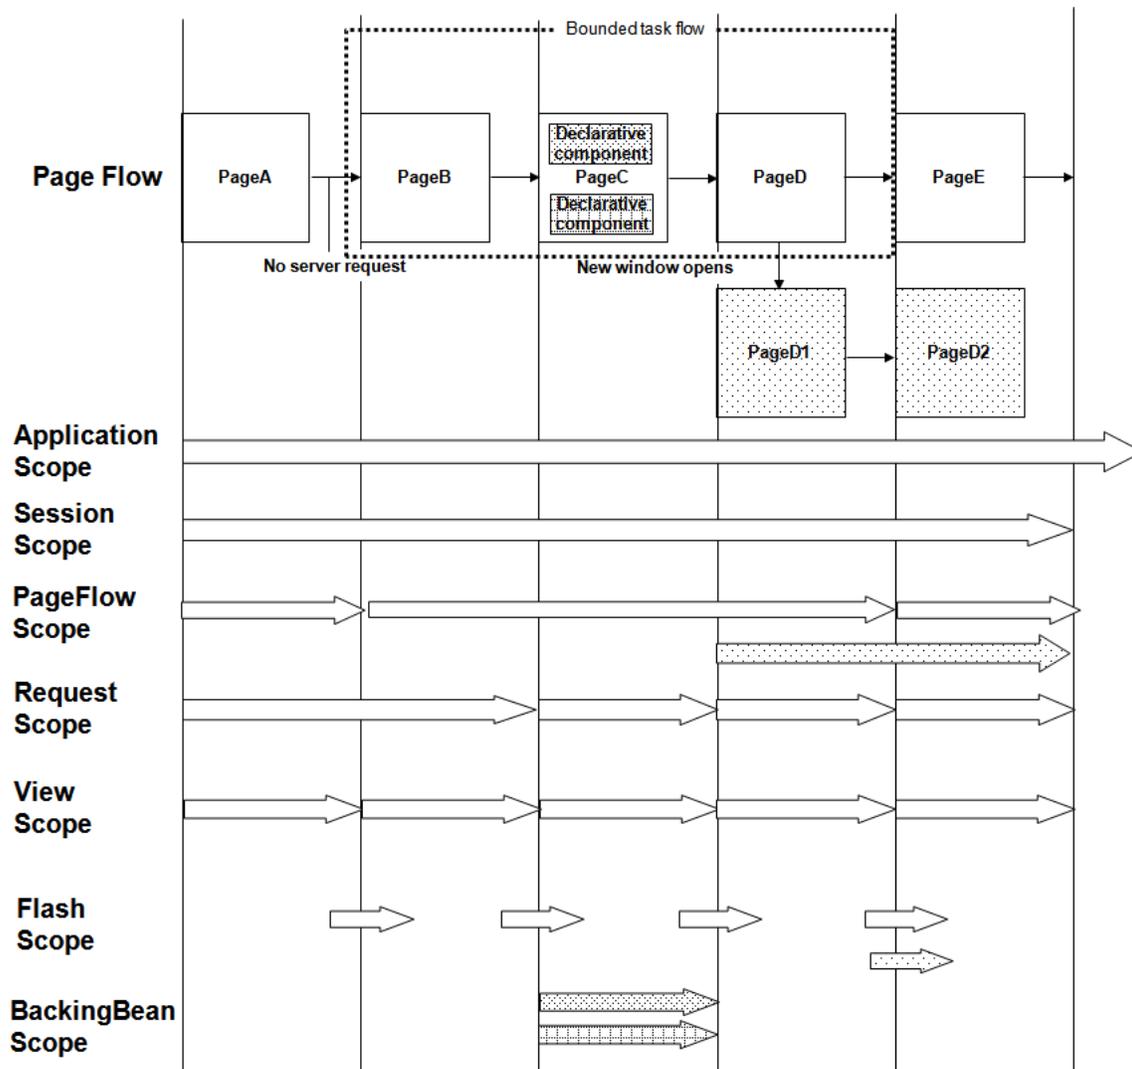

Note: When you create objects (such as a managed bean) that require you to define a scope, you can set the scope to `none`, meaning that it will not live within any particular scope, but will instead be instantiated each time it is referenced.

Object scopes are analogous to global and local variable scopes in programming languages. The wider the scope, the higher availability of an object. During their life, these objects may expose certain interfaces, hold information, or pass variables and parameters to other objects. For example, a managed bean defined in session scope will be available for use during multiple page requests. However, a managed bean defined in request scope will only be available for the duration of one page request.

By default, the binding container and the binding objects it contains are defined in session scope. However, the *values* referenced by value bindings and iterator bindings are undefined between requests and for scalability reasons do not remain in session scope. Therefore, the values that binding objects refer to are valid only during a request in which that binding container has been prepared by the ADF lifecycle. What stays in session scope are only the binding container and binding objects themselves.

[Figure 25-4](#) shows the time period during which each type of scope is valid.

Figure 25–4 Relationship Between Scopes and Page Flow

When determining what scope to register a managed bean with, always try to use the narrowest scope possible. Only use the session scope for information that is relevant to the whole session, such as user or context information. Avoid using session scope to pass values from one task flow to another. When creating a managed bean for a page fragment or a declarative component, you must use backing bean scope.

Managed beans can be registered in either the `adfc-config.xml` or the configuration file for a specific task flow. For more information about using managed beans in a Fusion application, see [Section 24.4, "Using a Managed Bean in a Fusion Web Application."](#)

Note: Registering managed beans within the `faces-config.xml` file is not recommended in a Fusion web application.

25.3.1 What You May Need to Know About Object Scopes and Task Flows

When determining what scope to use for variables within a task flow, you should use any of the scope options other than application or session scope. These two scopes will persist objects in memory beyond the life of the task flow and therefore compromise

the encapsulation and reusable aspects of a task flow. In addition, application and session scopes may keep objects in memory longer than needed, causing unneeded overhead.

When you need to pass data values between activities within a task flow, you should use page flow scope. View scope is recommended for variables that are needed only within the current view activity, not across view activities. Request scope should be used when the scope does not need to persist longer than the current request. It is the only scope that should be used to store UI component information. Lastly, backing bean scope must be used for backing beans in your task flow if there is a possibility that your task flow will appear in two region components or declarative components on the same page and you would like to achieve region instance isolations.

25.4 Customizing the ADF Page Lifecycle

The ADF lifecycle contains clearly defined phases that notify ADF lifecycle listeners before and after the corresponding JSF phase is executed. You can customize this lifecycle by creating a custom phase listener that invokes your needed code, and then registering it with the lifecycle to execute during one of these phases.

For example, if you do not want to use the default "Managed State" release level for application modules, you can set the release level from the after-prepareRender phase of the ADF lifecycle using a custom ADF page phase-listener class (for more information, see [Section 43.4.5, "How to Set Release Level in an ADF PagePhaseListener"](#)).

Note: An application cannot have multiple phase listener instances. An initial `ADFPhaseListener` instance is, by default, registered in the `META-INF/faces-config.xml` configuration file. Registering, for example, a customized subclass of the `ADFPhaseListener` creates a second instance. In this scenario, only the instance that was most recently registered is used.

The following warning message indicates when an instance has been replaced by a newer one: "ADFc: Replacing the ADF Page Lifecycle implementation with *class name of the new listener*."

25.4.1 How to Create a Custom Phase Listener

To create a custom phase listener, you must create a listener class that implements the `PagePhaseListener` interface. You then add methods that execute code either before or after the phase that the code needs to execute.

[Example 25-2](#) contains a template that you can modify to create a custom phase listener. See [Section 4.13.1, "How to Generate Custom Classes,"](#) for more information about creating a class in JDeveloper.

Example 25-2 Example Custom Phase Listener

```
public class MyPagePhaseListener implements PagePhaseListener
{
    public void afterPhase(PagePhaseEvent event)
    {
        System.out.println("In afterPhase " + event.getPhaseId());
    }
}
```

```

public void beforePhase(PagePhaseEvent event)
{
    System.out.println("In beforePhase " + event.getPhaseId());
}
}

```

Once you create the custom listener class, you need to register it with the phase in which the class needs to be invoked. You can either register it globally (so that the whole application can use it), or you can register it only for a single page.

25.4.2 How to Register a Listener Globally

To customize the ADF lifecycle globally, register your custom phase listener by editing the `adf-settings.xml` configuration file. The `adf-settings.xml` file is shared by several ADF components, including ADF Controller, to store configuration information.

To register the listener in `adf-settings.xml`:

1. In the Application Navigator, beneath the **META-INF** node, double-click the **adf-settings.xml** file.

2. In the editor window, click the **Source** tab

3. In the source editor, scroll down to

```

<adfc-controller-config xmlns=
"http://xmlns.oracle.com/adf/controller/config">

```

If this entry does not exist, add it to the file.

4. Enter the remaining elements shown in italics:

```

<?xml version="1.0" encoding="US-ASCII" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config">
.
.
.
    <adf-controller-config
xmlns="http://xmlns.oracle.com/adf/controller/config">
        <lifecycle>
            <phase-listener>
                <listener-id>MyPagePhaseListener</listener-id>
                <class>mypackage.MyPagePhaseListener</class>
            </phase-listener>
        </lifecycle>
    </adf-controller-config>
.
.
</adf-config>

```

5. Add values for the following elements:

- `<listener-id>` A unique identifier for the listener (you can use the fully qualified class name)
- `<class>` The class name of the listener

25.4.3 What You May Need to Know About Listener Order

You can specify multiple phase listeners in the `adf-settings.xml` and, optionally, the relative order in which they are called. When registering a new listener in the file, you determine the position in the list of listeners using two parameters:

- `beforeIdSet`: The listener is called before any of the listeners specified in `beforeIdSet`
- `afterIdSet`: The listener is called after any of the listeners specified in `afterIdSet`

[Example 25-3](#) contains an example configuration file in which multiple listeners have been registered for an application.

Example 25-3 *adf-settings.xml Configuration File with Multiple Listener Registration*

```
<lifecycle>
  <phase-listener>
    <listener-id>MyPhaseListener</listener-id>
    <class>view.myPhaseListener</class>
    <after-id-set>
      <listener-id>ListenerA</listener-id>
      <listener-id>ListenerC</listener-id>
    </after-id-set>
    <before-id-set>
      <listener-id>ListenerB</listener-id>
      <listener-id>ListenerM</listener-id>
      <listener-id>ListenerY</listener-id>
    </before-id-set>
  </phase-listener>
</lifecycle>
```

In the example, `MyPhaseListener` is a registered listener that executes after listeners A and C but before listeners B, M, and Y. To execute `MyPhaseListener` after listener B, move the `<listener-id>` element for listener B under the `<after-id-set>` element.

25.4.4 How to Register a Lifecycle Listener for a Single Page

To customize the lifecycle of a single page, you set the `ControllerClass` attribute on the page definition file. This listener will be valid only for the lifecycle of the particular page described by the page definition. For more information about the page definition file and its role in a Fusion web application, see [Section 13.7, "Working with Page Definition Files."](#)

You specify a different controller class depending on whether it is for a standard JSF page or a page fragment:

To customize the ADF Lifecycle for a single page or page fragment:

1. In the Application Navigator, right-click the page or page fragment and choose **Go To Page Definition**.
2. In the Structure window, select the page definition node.
3. In the Property Inspector, click the dropdown menu next to **ControllerClass** and choose **Edit**.
4. Click the **Hierarchy** tab and navigate to the appropriate controller class for the page or page fragment. Following are the controller classes to use for different types of pages:

- Standard JSF page - specify
`oracle.adf.controller.v2.lifecycle.PageController`
 If you need to receive afterPhase/beforePhase events, specify
`oracle.adf.controller.v2.lifecycle.PagePhaseListener`
- Page fragment - specify
`oracle.adf.model.RegionController`

Tip: You can specify the value of the page definition's `ControllerClass` attribute as a fully qualified class name or you can enter an EL expression that resolves to a class directly in the **ControllerClass** field.

When using an EL expression for the value of the `ControllerClass` attribute, the Structure window may show a warning indicating that `"#{YourExpression}"` is not a valid class. You can safely ignore this warning.

25.4.5 What You May Need to Know About Extending RegionController for Page Fragments

Bindings inside page fragments used as regions are refreshed through the `refreshRegion` and `validateRegion` events of the `RegionController` interface. These events are available if you specify `oracle.adf.model.RegionController` in the **ControllerClass** field as described in [Section 25.4.4, "How to Register a Lifecycle Listener for a Single Page."](#)

As shown in [Example 25–4](#), you can use the `refreshRegion` event to add custom code that executes before the region is refreshed. For example, you may want to refresh the bindings used by the page fragment in the region so that the refreshed binding values are propagated to the inner binding container.

To do this, create a new class that implements the `RegionController` interface. Then, write the following `refreshRegion` method, including your custom code that you want to execute before the Prepare Model phase.

Example 25–4 *regionRefresh Method*

```
public boolean refreshRegion(RegionContext regionCtx)
{
    int refreshFlag = regionCtx.getRefreshFlag();
    if (refreshFlag == RegionBinding.PREPARE_MODEL)
    {
        // Execute some code before
    }
    // Propagate the refresh to the inner binding container
    regionCtx.getRegionBinding().refresh(refreshFlag);

    return false;
}

public boolean validateRegion(RegionContext regionCtx)
{
    // Propagate the validate to the inner binding container
    regionCtx.getRegionBinding().validate();

    return false;
}
```

As shown in [Example 25-4](#), the refresh flag value can be:

- `RegionBinding.PREPARE_MODEL` - corresponds to the event occurring during the ADF Lifecycle `prepareModel` phase
- `RegionBinding.RENDER_MODEL` - corresponds to the event occurring during the ADF Lifecycle `prepareRender` phase

Creating a Basic Databound Page

This chapter describes how to use the Data Controls panel to create databound forms using ADF Faces components.

This chapter includes the following sections:

- [Section 26.1, "About Creating a Basic Databound Page"](#)
- [Section 26.2, "Using Attributes to Create Text Fields"](#)
- [Section 26.3, "Creating a Basic Form"](#)
- [Section 26.4, "Incorporating Range Navigation into Forms"](#)
- [Section 26.5, "Creating a Form to Edit an Existing Record"](#)
- [Section 26.6, "Creating an Input Form"](#)
- [Section 26.7, "Using a Dynamic Form to Determine Data to Display at Runtime"](#)
- [Section 26.8, "Modifying the UI Components and Bindings on a Form"](#)

26.1 About Creating a Basic Databound Page

You can create UI pages that allow you to display and collect information using data controls created for your business services. For example, using the Data Controls panel, you can drag an attribute for an item, and then choose to display the value either as read-only text or as an input text field with a label. JDeveloper creates all the necessary JSF tag and binding code needed to display and update the associated data. For more information about the Data Controls panel and the declarative binding experience, see [Chapter 13, "Using ADF Model in a Fusion Web Application."](#)

Instead of having to drop individual attributes, JDeveloper allows you to drop all attributes for an object at once as a form. The actual UI components that make up the form depend on the type of form dropped. You can create forms that display values, forms that allow users to edit values, and forms that collect values (input forms).

Once you drop the UI components, you can then drop built-in operations as command UI components that allow you to navigate through the records in a collection or that allow users to operate on the data, such as committing, deleting, or creating a record. For example, you can create a button that allows users to delete data objects displayed in the form. You can also modify the default components to suit your needs.

26.1.1 ADF Databound Forms Use Cases and Examples

You use forms when you need to collect or display a row of data or related data. For example, the StoreFront module contains a page that allows users to register information about themselves, as shown in [Figure 26-1](#). This form was created by

dragging and dropping the CustomerRegistration collection from the Data Controls panel.

Figure 26–1 Register Customer Form in the StoreFront Module

The screenshot shows a web form titled "Basic Information" with tabs for "Address", "Payment options", and "Review". The form includes the following fields and sections:

- Basic Information:**
 - * User Name (text input)
 - Title (<No Selection> dropdown)
 - First Name (text input)
 - Last Name (text input)
 - Person Type (Customer dropdown)
 - * Email Address (text input)
 - * Confirmed Email Address (text input)
 - Phone (text input)
 - Mobile Phone (text input)
 - * Gender (<No Selection> dropdown)
 - Date of Birth (text input with calendar icon)
 - Contact Method (<No Selection> dropdown)
 - * Marital Status (<No Selection> dropdown)
 - Income (text input)
- Categories of interest:** A list of categories including Audio and Video, Books, Camera and Photo, Cell Phones, DVDs, Electronics, Games, Hardware, Media, Music, and Office.
- I am interested in...:** A section for selecting categories of interest, with a "Description" field below it.

Navigation buttons "Cancel" and "Next" are located in the top right corner.

When you create a form, you can also choose to add navigation, so that the user can navigate quickly between records, as shown in [Figure 26–2](#).

Figure 26–2 Navigate Between Records in a Form

The screenshot shows a record display form with the following fields and navigation buttons:

- Person Id 109
- First Name Daniel
- Last Name Faviet
- Confirmed Email Address DFAVIET
- Mobile Phone
- Membership Id
- Navigation buttons: First, Previous, Next, Last

You can also add command buttons that invoke processing on the row displayed in the form. For example, you can change values for a record and save those changes in an edit form, as shown in [Figure 26–1](#), or you can create an input form that allows users to create a new record. [Figure 26–3](#) shows an input form where a user can create a new address.

Figure 26–3 Input Form

The screenshot shows a web form with a breadcrumb trail: Basic Information > **Address** > Payment options > Review. Below the breadcrumb are three buttons: 'Address Del...' (disabled), 'Cancel', and 'Save & Add Another'. To the right are 'Save & Return' and 'Save & Add Another' buttons. The form fields include:

- * Address Line 1 (text input)
- Address Line 2 (text input)
- * City (text input)
- * State / Province (text input)
- Postal Code or ZIP (text input)
- * Country (dropdown menu, currently showing '<No Selection>')
- Address Usage Type (dropdown menu, currently showing 'Invoice Address')

 Asterisks (*) indicate required fields.

When the attributes to display in a form are only available at runtime, you can create a dynamic form.

26.1.2 Additional Functionality for Databound Forms

You may find it helpful to understand other ADF Faces features before you implement your forms. Additionally, once you have added a form to your page, you may find that you need to add functionality such as security. Following are links to other functionality that you may find useful.

- **ADF view objects:** Much of how the components display and function in the form is controlled by the corresponding view objects. For more information, see [Chapter 5, "Defining SQL Queries Using View Objects."](#)
- **ADF Model and data binding:** When you create forms in an ADF Web application, you use ADF Model and data binding. For more information, see [Appendix 13, "Using ADF Model in a Fusion Web Application."](#)
- **ADF Faces:** You also use ADF Faces UI components. For detailed information about developing with ADF Faces, see the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- **Advanced UI controls:** Basic forms use input and output components. You can also use more advanced components, such as lists, tables trees, and search forms. For more information, see the remaining chapters in [Part V, "Creating a Databound Web User Interface"](#).
- **Task flows:** If your form takes part in a transaction, for example an input form, then you may need to use an ADF task flow to invoke certain operations before or after the form is rendered. For more information, see [Part IV, "Creating ADF Task Flows"](#).
- **Page lifecycle:** For information about how forms works with the page lifecycle, see [Chapter 25, "Understanding the Fusion Page Lifecycle."](#)
- **Validation:** You may want certain fields to be validated before they are submitted to the data store. For more information, see [Chapter 7, "Defining Validation and Business Rules Declaratively"](#) and [Chapter 16, "Using Validation in the ADF Model Layer."](#)
- **Active data:** If your application uses active data, then you can have the data in your UI components update automatically, whenever the data in the data source changes. For more information, see [Chapter 45, "Using the Active Data Service."](#)

26.2 Using Attributes to Create Text Fields

JDeveloper allows you to create text fields declaratively in a WYSIWYG development environment for your JSF pages, meaning you can design most aspects of your pages without needing to look at the code. When you drag and drop items from the Data Controls panel, JDeveloper declaratively binds ADF Faces text UI components to attributes on a data control using an attribute binding.

26.2.1 How to Create a Text Field

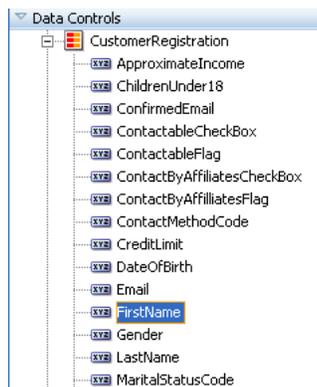

To create a text field that can display or update an attribute, you drag and drop an attribute of a collection from the Data Controls panel.

To create a bound text field:

1. From the Data Controls panel, select an attribute for a collection. For a description of the icons that represent attributes and other objects in the Data Controls panel, see [Section 13.4, "Using the Data Controls Panel."](#)

For example, [Figure 26–4](#) shows the `FirstName` attribute under the `CustomerRegistration` collection of the `StoreServiceAMDataControl` data control in the `StoreFront` module. This is the attribute to drop to display or enter the customer's first name.

Figure 26–4 Attributes Associated with a Collection in the Data Controls Panel

2. Drag the attribute onto the page, and from the context menu choose the type of widget to display or collect the attribute value. For an attribute, you are given the following choices:

- **Text:**

- **ADF Input Text w/ Label:** Creates an ADF Faces `inputText` component with a nested `validator` component. The `label` attribute is populated.

Tip: For more information about validators and other attributes of the `inputText` component, see the "Using Input Components and Defining Forms" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

- **ADF Input Text:** Creates an ADF Faces `inputText` component with a nested `validator` component. The `label` attribute is not populated.

- **ADF Output Text w/ Label:** Creates a `panelLabelAndMessage` component that holds an ADF Faces `outputText` component. The `label` attribute on the `panelLabelAndMessage` component is populated.
- **ADF Output Text:** Creates an ADF Faces `outputText` component. No label is created.
- **ADF Output Formatted w/Label:** Same as ADF Output Text w/Label, but uses an `outputFormatted` component instead of an `outputText` component. The `outputFormatted` component allows you to add a limited amount of HTML formatting. For more information, see the "Displaying Output Text and Formatted Output Text" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*
- **ADF Output Formatted:** Same as ADF Output Formatted w/Label, but without the label.
- **ADF Label:** An ADF Faces `outputLabel` component.
- **List of Values:** Creates ADF LOV lists. For more information about how these lists work, see [Section 5.12, "Working with List of Values \(LOV\) in View Object Attributes."](#) For more information about using the lists on a JSF page, see [Section 30.3, "Creating a Selection List."](#)
- **Single selections:** Creates single selection lists. For more information about creating lists on a JSF page, see [Section 30.3, "Creating a Selection List."](#)

Note: These selections are your choices by default. However, the list of components available to use for an attribute can be configured as a control hint on the associated entity or view object. For more information, see [Section 4.6, "Defining Attribute Control Hints for Entity Objects"](#) and [Section 5.13, "Defining Attribute UI Hints for View Objects."](#)

For the purposes of this chapter, only the text components (and not the lists) will be discussed.

26.2.2 What Happens When You Create a Text Field

When you drag an attribute onto a JSF page and drop it as a UI component, among other things, a page definition file is created for the page (if one does not already exist). For a complete account of what happens when you drag an attribute onto a page, see [Section 13.4.2, "What Happens When You Use the Data Controls Panel."](#) Bindings for the iterator and attributes are created and added to the page definition file. Additionally, the necessary JSPX page code for the UI component is added to the JSF page.

26.2.2.1 Creating and Using Iterator Bindings

Whenever you create UI components on a page by dropping an item that is part of a collection from the Data Controls panel (or you drop the whole collection as a form or table), JDeveloper creates an iterator binding if it does not already exist. An iterator binding references an iterator for the data collection, which facilitates iterating over its data objects. It also manages currency and state for the data objects in the collection. An iterator binding does not actually access the data. Instead, it simply exposes the object that can access the data and it specifies the current data object in the collection.

Other bindings then refer to the iterator binding in order to return data for the current object or to perform an action on the object's data. Note that the iterator binding is not an iterator. It is a binding to an iterator. In the case of ADF Business Components, the actual iterator is the default row set iterator for the default row set of the view object instance in the application module's data model.

For example, if you drop the `FirstName` attribute under the `CustomerRegistration` collection, JDeveloper creates an iterator binding for the `CustomerRegistration` collection.

Tip: There is one iterator binding created for each collection. This means that when you drop two attributes from the same collection (or drop the collection twice), they use the same binding. This is fine, unless you need the binding to behave differently for the different components. In that case, you will need to manually create separate iterator bindings.

The iterator binding's `rangeSize` attribute determines how many rows of data are fetched from a data control each time the iterator binding is accessed. This attribute gives you a relative set of 1-*n* rows positioned at some absolute starting location in the overall row set. By default, it is set to 25. For more information about using this attribute, see [Section 26.4.2.2, "Iterator RangeSize Attribute."](#) [Example 26-1](#) shows the iterator binding created when you drop an attribute from the `CustomerRegistration` collection.

Example 26-1 Page Definition Code for an Iterator Binding for an Attribute Dropped from a Collection

```
<executables>
  <iterator Binds="CustomerRegistration" RangeSize="25"
    DataControl="StoreServiceAMDataControl"
    id="CustomerRegistrationIterator"/>
</executables>
```

For information regarding the iterator binding element attributes, see [Appendix B, "Oracle ADF Binding Properties."](#)

This metadata allows the ADF binding container to access the attribute values. Because the iterator binding is an executable, by default, it is invoked when the page is loaded, thereby allowing the iterator to access and iterate over the `CustomerRegistration` collection. This means that the iterator will manage all the `CustomerRegistration` objects in the collection, including determining the current `CustomerRegistration` or range of `CustomerRegistration` objects.

26.2.2.2 Creating and Using Value Bindings

When you drop an attribute from the Data Controls panel, JDeveloper creates an attribute binding that is used to bind the UI component to the attribute's value. This type of binding presents the value of an attribute for a single object in the current row in the collection. Value bindings can be used both to display and to collect attribute values.

For example, if you drop the `PrincipalName` attribute under the `CustomerRegistration` collection as an ADF Output Text w/Label widget onto a page, JDeveloper creates an attribute binding for the `PrincipalName` attribute. This allows the binding to access the attribute value of the current record. [Example 26-2](#) shows the attribute binding for `PrincipalName` created when you drop the attribute

from the `CustomerRegistration` collection. Note that the attribute value references the iterator named `CustomerRegistrationIterator`.

Example 26–2 Page Definition Code for an Attribute Binding

```
<bindings>
...
  <attributeValues IterBinding="CustomerRegistrationIterator"
    id="PrincipalName">
    <AttrNames>
      <Item Value="PrincipalName" />
    </AttrNames>
  </attributeValues>
</bindings>
```

For information regarding the attribute binding element properties, see [Appendix B, "Oracle ADF Binding Properties."](#)

26.2.2.3 Using EL Expressions to Bind UI Components

When you create a text field by dropping an attribute from the Data Controls panel, JDeveloper creates the UI component associated with the widget dropped by writing the corresponding tag to the JSF page.

For example, when you drop the `PrincipalName` attribute as an Output Text w/Label widget, JDeveloper inserts the tags for a `panelLabelAndMessage` component and an `outputText` component. It creates an EL expression that binds the `label` attribute of the `panelLabelAndMessage` component to the `label` property of hints created for the `PrincipalName`'s binding. This expression evaluates to the label hint set on the view object (for more information about hints, see [Section 5.13, "Defining Attribute UI Hints for View Objects"](#)). It creates another expression that binds the `outputText` component's `value` attribute to the `inputValue` property of the `PrincipalName` binding, which evaluates to the value of the `PrincipalName` attribute for the current row. An ID is also automatically generated for both components.

Tip: JDeveloper automatically generates IDs for all ADF Faces components. You can override these values as needed.

[Example 26–3](#) shows the code generated on the JSF page when you drop the `PrincipalName` attribute as an Output Text w/Label widget.

Example 26–3 JSF Page Code for an Attribute Dropped as an Output Text w/Label

```
<af:panelLabelAndMessage label="#{bindings.PrincipalName.hints.label}" id="plam1">
  <af:outputText value="#{bindings.PrincipalName.inputValue}" id="ot1"/>
</af:panelLabelAndMessage>
```

If instead you drop the `PrincipalName` attribute as an Input Text w/Label widget, JDeveloper creates an `inputText` component. As [Example 26–4](#) shows similar to the output text component, the value is bound to the `inputValue` property of the `PrincipalName` binding. Additionally, the following properties are also set:

- `label`: Bound to the `label` property of the control hint set on the object.
- `required`: Bound to the mandatory property of the control hint.
- `columns`: Bound to the `displayWidth` property of the control hint, which determines how wide the text box will be.

- `maxLength`: Bound to the precision property of the control hint. This control hint property determines the maximum number of characters per line that can be entered into the field.

In addition, JDeveloper adds a validator component.

Example 26–4 JSF Page Code for an Attribute Dropped as an Input Text w/Label

```
<af:inputText value="#{bindings.PrincipalName.inputValue}"
  label="#{bindings.PrincipalName.hints.label}"
  required="#{bindings.PrincipalName.hints.mandatory}"
  columns="#{bindings.PrincipalName.hints.displayWidth}"
  maxLength="#{bindings.PrincipalName.hints.precision}">
  shortDesc="#{bindings.PrincipalName.hints.tooltip}" id="it1">
  <f:validator binding="#{bindings.PrincipalName.validator}" />
</af:inputText>
```

You can change any of these values to suit your needs. For example, the `mandatory` control hint on the view object is set to `false` by default, which means that the `required` attribute on the component will evaluate to `false` as well. You can override this value by setting the `required` attribute on the component to `true`. If you decide that all instances of the attribute should be mandatory, then you can change the control hint on the view object, and all instances will then be required. For more information about these properties, see [Appendix B, "Oracle ADF Binding Properties."](#)

26.3 Creating a Basic Form

Instead of dropping each of the individual attributes of a collection to create a form, you can create a complete form that displays or collects data for all the attributes on an object.

For example, you could create a page that displays basic information about registered users in the StoreFront module by dragging and dropping the `CustomerInfoVO1` collection.

You can also create forms that provide more functionality than simply displaying data from a collection. For information about creating a form that allows a user to update data, see [Section 26.5, "Creating a Form to Edit an Existing Record."](#) For information about creating forms that allow users to create a new object for the collection, see [Section 26.6, "Creating an Input Form"](#). You can also create search forms. For more information, see [Chapter 31, "Creating ADF Databound Search Forms."](#)

26.3.1 How to Create a Form

To create a form using a data control, you bind the UI components to the attributes on the corresponding object in the data control. JDeveloper allows you to do this declaratively by dragging and dropping a collection or a structured attribute from the Data Controls panel.

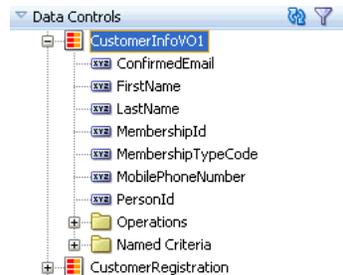

Before you begin:

It may be helpful to have an understanding of basic databound forms. For more information, see [Section 26.3, "Creating a Basic Form."](#)

You may also find it helpful to understand other ADF functionality and features. For more information, see [Section 26.1.2, "Additional Functionality for Databound Forms."](#)

To create a basic form:

1. From the Data Controls panel, select the collection that represents the data you wish to display. [Figure 26–5](#) shows the `CustomerInfoVO1` collection for the `StoreServiceAMDataControl` data control.

Figure 26–5 CustomerInfo View Object in the Data Controls Panel

2. Drag the collection onto the page, and from the context menu choose the type of form that will be used to display or collect data for the object. For a form, you are given the following choices:

- **ADF Form:** Launches the Edit Form Fields dialog that allows you to select individual attributes instead of having JDeveloper create a field for every attribute by default. It also allows you to select the label and UI component used for each attribute. By default, ADF `inputText` components are used for most attributes. Each `inputText` component has the `label` attribute populated.

Attributes that are dates use the `InputDate` component. Additionally, if a control type control hint has been created for an attribute, or if the attribute has been configured to be a list, then the component set by the hint is used instead. `InputText` components contain a `validator` tag that allows you to set up validation for the attribute, and if the attribute is a number or a date, a converter is also included.

Tip: For more information about validators, converters, and other attributes of the `inputText` component, see the "Using Input Components and Defining Forms" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

- **ADF Read-Only Form:** Same as the ADF Form, but only read-only `outputText` components are used. Since the form is meant to display data, no `validator` tags are added (converters are included). Attributes of type `Date` use the `outputText` component when in a read-only form. All components are placed inside `panelLabelAndMessage` components, which have the `label` attribute populated, and are placed inside a `panelFormLayout` component.
 - **ADF Search Form:** Creates a form that can be used to execute a Query-by-Example (QBE) search. For more information, see [Chapter 31](#), "Creating ADF Databound Search Forms."
3. In the Edit Form Fields dialog, configure your form.

You can elect to include navigational controls that allow users to navigate through all the data objects in the collection. For more information, see [Section 26.4](#), "Incorporating Range Navigation into Forms." You can also include a **Submit**

button used to submit the form. This button submits the HTML form and applies the data in the form to the bindings as part of the JSF/ADF page lifecycle. For additional help in using the dialog, click **Help**. All UI components are placed inside a `panelFormLayout` component.

4. If you are building a form that allows users to update data, you now need to drag and drop an operation that will perform the update. For more information, see [Section 26.5, "Creating a Form to Edit an Existing Record."](#)

26.3.2 What Happens When You Create a Form

Dropping an object as a form from the Data Controls panel has the same effect as dropping a single attribute, except that multiple attribute bindings and associated UI components are created. The attributes on the UI components (such as `value`) are bound to properties on that attribute's binding object (such as `inputValue`) or to the values of control hints set on the corresponding business object. [Example 26–5](#) shows some of the code generated on the JSF page when you drop the `CustomerInfoVO1` collection as a default ADF Form.

Note: If an attribute is marked as hidden on the associated view or entity object, then no corresponding UI is created for it.

Example 26–5 Code on a JSF Page for an Input Form

```
<af:panelFormLayout id="pf11">
  <af:inputText value="#{bindings.PersonId.inputValue}"
    label="#{bindings.PersonId.hints.label}"
    required="#{bindings.PersonId.hints.mandatory}"
    columns="#{bindings.PersonId.hints.displayWidth}"
    maximumLength="#{bindings.PersonId.hints.precision}"
    shortDesc="#{bindings.PersonId.hints.tooltip}" id="it2">
    <f:validator binding="#{bindings.PersonId.validator}"/>
  </af:inputText>
  <af:inputText value="#{bindings.FirstName.inputValue}"
    label="#{bindings.FirstName.hints.label}"
    required="#{bindings.FirstName.hints.mandatory}"
    columns="#{bindings.FirstName.hints.displayWidth}"
    maximumLength="#{bindings.FirstName.hints.precision}"
    shortDesc="#{bindings.FirstName.hints.tooltip}"
    id="it1">
    <f:validator binding="#{bindings.FirstName.validator}"/>
  </af:inputText>
  <af:inputText value="#{bindings.LastName.inputValue}"
    label="#{bindings.LastName.hints.label}"
    required="#{bindings.LastName.hints.mandatory}"
    columns="#{bindings.LastName.hints.displayWidth}"
    maximumLength="#{bindings.LastName.hints.precision}"
    shortDesc="#{bindings.LastName.hints.tooltip}" id="it7">
    <f:validator binding="#{bindings.LastName.validator}"/>
  </af:inputText>
  . . .
</af:panelFormLayout>
```

Note: For information regarding the validator and converter tags, see the "Validating and Converting Input" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

When you choose to create an input form using an object that contains a defined list of values (LOV), then a `selectOneChoice` component is created instead of an `inputText` component. For example, the `PersonsVO` view object contains a defined LOVs for the `Title`, `Gender`, `MaritalStatusCode`, and `PersonTypeCode` attributes. When you drop the `Persons` data control object as an ADF Form, instead of as an empty input text field, a dropdown list showing all values is created. For more information about how these lists work, see [Section 5.12, "Working with List of Values \(LOV\) in View Object Attributes."](#) For more information about using the lists on a JSF page, see [Section 30.3, "Creating a Selection List."](#)

Note: If the object contains a structured attribute (an attribute that is neither a Java primitive type nor a collection), that attribute will not appear in the dialog, and it will not have a corresponding component in the form. You will need to create those fields manually.

26.4 Incorporating Range Navigation into Forms

When you create an ADF Form, if you choose to include navigational controls, JDeveloper includes ADF Faces command components bound to existing navigational logic on the data control. This built-in logic allows the user to navigate through all the data objects in the collection. For example, [Figure 26–6](#) shows a form that would be created if you drag the `CustomerInfoVO1` collection and drop it as an ADF Form that uses navigation.

Figure 26–6 *Navigation in a Form*

The screenshot shows a form with the following text labels: Person Id 109, First Name Daniel, Last Name Faviet, Confirmed Email Address DFAVIET, Mobile Phone, and Membership Id. Below these labels is a row of four buttons: First, Previous, Next, and Last.

26.4.1 How to Insert Navigation Controls into a Form

By default, when you choose to include navigation when creating a form using the Data Controls panel, JDeveloper creates **First**, **Last**, **Previous**, and **Next** buttons that allow the user to navigate within the collection.

You can also add navigation buttons to an existing form manually.

Before you begin:

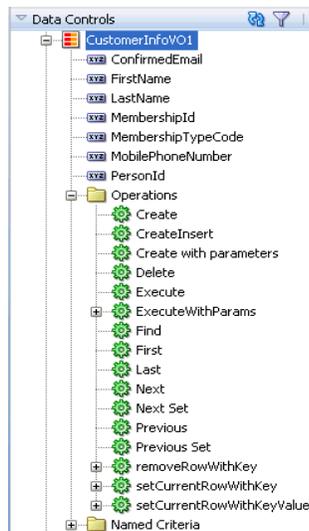

It may be helpful to have an understanding of navigation controls. For more information, see [Section 26.4, "Incorporating Range Navigation into Forms."](#)

You may also find it helpful to understand other ADF functionality and features. For more information, see [Section 26.1.2, "Additional Functionality for Databound Forms."](#)

To manually add navigation buttons:

1. From the Data Controls panel, select the operation associated with the collection of objects on which you wish the operation to execute, and drag it onto the JSF page.

For example, if you want to navigate through a collection of persons, you would drag the **Next** operation associated with the `Persons` collection. [Figure 26–7](#) shows the operations associated with the `CustomerInfoVO1` collection.

Figure 26–7 Operations Associated with a Collection

- From the ensuing context menu, choose either **ADF Button** or **ADF Link**.

Tip: You can also drop the **First**, **Previous**, **Next**, and **Last** buttons at once. To do so, drag the corresponding collection, and from the context menu, choose **Navigation > ADF Navigation Buttons**.

26.4.2 What Happens When You Create Command Buttons

When you drop any operation as a command component, JDeveloper:

- Defines an action binding in the page definition file for the associated operations
- Configures the iterator binding to use partial page rendering for the collection
- Inserts code in the JSF page for the command components

26.4.2.1 Action Bindings for Built-in Navigation Operations

Action bindings execute business logic. For example, they can invoke built-in methods on the action binding object. These built-in methods operate on the iterator or on the data control itself, and are represented as operations in the Data Controls panel. JDeveloper provides navigation operations that allow users to navigate forward, backwards, to the last object in the collection, and to the first object.

Like value bindings, action bindings for operations contain a reference to the iterator binding when the action binding is bound to one of the iterator-level actions, such as `Next` or `Previous`. These types of actions are performed by the iterator, which determines the current object and can therefore determine the correct object to display when a navigation buttons is clicked. Action bindings to other than iterator-level actions, for example for a custom method on an application module, or for the commit or rollback operations, will not contain this reference.

Action bindings use the `RequiresUpdateModel` property, which determines whether or not the model needs to be updated before the action is executed. In the case of navigation operations, by default this property is set to `true`, which means that any changes made at the view layer must be moved to the model before navigation can occur. [Example 26–6](#) shows the action bindings for the navigation operations.

Example 26–6 Page Definition Code for an Operation Action Binding

```

<action IterBinding="CustomerInfoVO1Iterator" id="First"
    RequiresUpdateModel="true" Action="first"/>
<action IterBinding="CustomerInfoVO1Iterator" id="Previous"
    RequiresUpdateModel="true" Action="previous"/>
<action IterBinding="CustomerInfoVO1Iterator" id="Next"
    RequiresUpdateModel="true" Action="next"/>
<action IterBinding="CustomerInfoVO1Iterator" id="Last"
    RequiresUpdateModel="true" Action="last"/>

```

26.4.2.2 Iterator RangeSize Attribute

Iterator bindings have a `rangeSize` attribute that the binding uses to determine the number of data objects to make available for the page for each iteration. This attribute helps in situations when the number of objects in the data source is quite large. Instead of returning all objects, the iterator binding returns only a set number, which then become accessible to the other bindings. Once the iterator reaches the end of the range, it accesses the next set. [Example 26–7](#) shows the default range size for the `CustomerInfoVO` iterator.

Example 26–7 RangeSize Attribute for an Iterator

```

<iterator Binds="CustomerInfoVO" RangeSize="25"
    DataControl="StoreServiceAMDataControl"
    id="CustomerInfoVO1Iterator"
    ChangeEventPolicy="ppr"/>

```

Note: This `rangeSize` attribute is not the same as the `rows` attribute on a table component. For more information, see [Table 27–1, "ADF Faces Table Attributes and Populated Values"](#).

By default, the `rangeSize` attribute is set to 25. This means that a user can view 25 objects, navigating back and forth between them, without needing to access the data source. The iterator keeps track of the current object. Once a user clicks a button that requires a new range (for example, clicking the **Next** button on object number 25), the binding object executes its associated method against the iterator, and the iterator retrieves another set of 25 records. The bindings then work with that set. You can change this setting as needed. You can set it to -1 to have the full record set returned.

Note: When you create a navigateable form using the Data Controls panel, the `CacheResults` property on the associated iterator is set to `true`. This ensures that the iterator's state, including currency information, is cached between requests, allowing it to determine the current object. If this property is set to `false`, navigation will not work.

[Table 26–1](#) shows the built-in navigation operations provided on data controls and the result of invoking the operation or executing an event bound to the operation. For more information about action events, see [Section 26.4.3, "What Happens at Runtime: How Action Events and Action Listeners Work."](#)

Table 26–1 Built-in Navigation Operations

Operation	When invoked, the associated iterator binding will...
First	Move its current pointer to the beginning of the result set.
Last	Move its current pointer to the end of the result set.
Previous	Move its current pointer to the preceding object in the result set. If this object is outside the current range, the range is scrolled backward a number of objects equal to the range size.
Next	Move its current pointer to the next object in the result set. If this object is outside the current range, the range is scrolled forward a number of objects equal to the range size.
Previous Set	Move the range backward a number of objects equal to the range size attribute.
Next Set	Move the range forward a number of objects equal to the range size attribute.

26.4.2.3 EL Expressions Used to Bind to Navigation Operations

When you create command components using navigation operations, the command components are placed in a `panelGroupLayout` component. JDeveloper creates an EL expression that binds a navigational command button's `actionListener` attribute to the `execute` property of the action binding for the given operation.

At runtime an action binding will be an instance of the `FacesCtrlActionBinding` class, which extends the core `JUCtrlActionBinding` implementation class. The `FacesCtrlActionBinding` class adds the following methods:

- public void execute(ActionEvent event):** This is the method that is referenced in the `actionListener` property, for example `{bindings.First.execute}`.
 This expression causes the binding's operation to be invoked on the iterator when a user clicks the button. For example, the **First** command button's `actionListener` attribute is bound to the `execute` method on the `First` action binding.
- public String outcome():** This can be referenced in an `Action` property, for example `{bindings.Next.outcome}`.

This can be used for the result of a method action binding (once converted to a `String`) as a JSF navigation outcome to determine the next page to navigate to.

Note: Using the `outcome` method on the action binding implies tying the view-controller layer too tightly to the model, so it should be rarely used.

Every action binding for an operation has an `enabled` boolean property that Oracle ADF sets to `false` when the operation should not be invoked. By default, JDeveloper binds the UI component's `disabled` attribute to this value to determine whether or not the component should be enabled. For example, the UI component for the **First** button has the following as the value for its `disabled` attribute:

```
{!bindings.First.enabled}
```

This expression evaluates to `true` whenever the binding is not enabled, that is, when operation should not be invoked, thereby disabling the button. In this example,

because the framework will set the `enabled` property on the binding to `false` whenever the first record is being shown, the **First** button will automatically be disabled because its `disabled` attribute is set to be `true` whenever `enabled` is `False`. For more information about the `enabled` property, see [Appendix B, "Oracle ADF Binding Properties."](#)

[Example 26–8](#) shows the code generated on the JSF page for navigation operation buttons. For more information about the `partialSubmit` attribute on the button, see the "Enabling Partial Page Rendering Declaratively" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

Example 26–8 JSF Code for Navigation Buttons Bound to ADF Operations

```
<f:facet name="footer">
  <af:panelGroupLayout>
    <af:commandButton actionListener="#{bindings.First.execute}"
      text="First"
      disabled="#{!bindings.First.enabled}"
      partialSubmit="true" id="cb1"/>
    <af:commandButton actionListener="#{bindings.Previous.execute}"
      text="Previous"
      disabled="#{!bindings.Previous.enabled}"
      partialSubmit="true" id="cb2"/>
    <af:commandButton actionListener="#{bindings.Next.execute}"
      text="Next"
      disabled="#{!bindings.Next.enabled}"
      partialSubmit="true" id="cb3"/>
    <af:commandButton actionListener="#{bindings.Last.execute}"
      text="Last"
      disabled="#{!bindings.Last.enabled}"
      partialSubmit="true" id="cb4"/>
  </af:panelGroupLayout>
</f:facet>
```

26.4.3 What Happens at Runtime: How Action Events and Action Listeners Work

An action event occurs when a command component is activated. For example, when a user clicks a **Submit** button, the form is submitted and, subsequently, an action event is fired. Action events might affect only the user interface (for example, a link to change the locale, causing different field prompts to display), or they might involve some logic processing in the back end (for example, a button to navigate to the next record).

An action listener is a class that wants to be notified when a command component fires an action event. An action listener contains an action listener method that processes the action event object passed to it by the command component.

In the case of the navigation operations, when a user clicks, for example, the **Next** button, an action event is fired. This event object stores currency information about the current data object, taken from the iterator. Because the component's `actionListener` attribute is bound to the `execute` method of the `Next` action binding, the `Next` operation is invoked when the event fires. This method takes the currency information passed in the event object to determine what the next data object should be.

In addition, when a user clicks a navigation button, only those components associated with the same iterator as the button's action binding are processed through the

lifecycle. For more information, see [Section 25.2.1, "What You May Need to Know About Partial Page Rendering and Iterator Bindings."](#)

26.4.4 What You May Need to Know About the Browser Back Button and Navigating Through Records

You must use the navigation buttons to navigate through the records displayed in a form; you cannot use the browser's back or forward buttons. Because navigation forms automatically use PPR, only part of the page goes through the lifecycle, meaning that when you click a navigation button, the components displaying the data are refreshed and display new data, and you actually remain on the same page. Therefore, when you click the browser's back button, you will be returned to the page that was rendered before the page with the form, instead of to the previous record displayed in the form.

For example, say you are on a page that contains a link to view all current orders. When you click the link, you navigate to a page with a form and the first order, Order #101, is displayed. You then click **Next** and Order #102 is displayed. You click **Next** again, and Order #103 is displayed. If you click the browser's back button, you will not be shown Order #102. Instead, you will be returned to the page that contained the link to view all current orders.

26.5 Creating a Form to Edit an Existing Record

You can create a form that allows a user to edit the current data, and then commit those changes to the data source. To do this, you use operations that can modify data records associated with the collection or the data control itself to create command buttons. For example, you can use the `Delete` operation to create a button that allows a user to delete a record from the current range. Or you can use the built-in **Submit** button to submit changes.

Tip: While you can use the `Create` operation on a form to create a new object, using the ADF Creation Form instead provides additional built-in functionality. See [Section 26.6, "Creating an Input Form"](#) for more information.

It is important to note that these operations are executed only against objects in the ADF cache. You need to use the `Commit` operation on the root data control to actually commit any changes to the data source. You use the data control's `Rollback` operation to roll back any changes made to the cached object. If the page is part of a transaction within a bounded task flow, you would most likely use these operations to resolve the transaction in a task flow return activity. For more information, see [Section 22.2, "Managing Transactions in Task Flows."](#)

26.5.1 How to Create Edit Forms

To use the operations on a form, you follow the same procedures as with the navigation operations.

Before you begin:

It may be helpful to have an understanding of creating edit forms. For more information, see [Section 26.5, "Creating a Form to Edit an Existing Record."](#)

You may also find it helpful to understand other ADF functionality and features. For more information, see [Section 26.1.2, "Additional Functionality for Databound Forms."](#)

To create an edit form:

1. From the Data Controls panel, drag the collection for which you wish to create the form, and select **ADF Form** from the context menu.

This creates a form using `inputText` components, which will allow the user to edit the data in the fields.

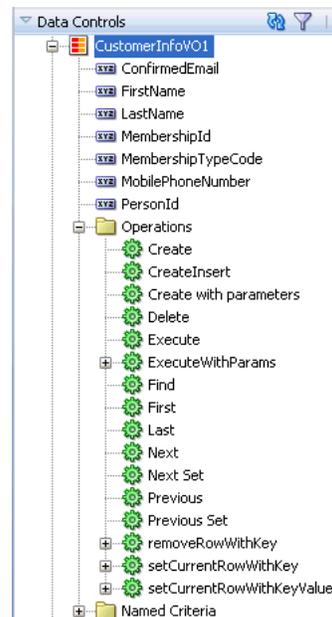

2. In the Edit Form Fields dialog, select **Include Submit Button** and click **OK**.
3. You can either create new buttons for the operations you want to include, or you can rebind the **Submit** button so that it invokes another operation. To keep the **Submit** button as is and create new buttons for the operations, continue with this step. To rebind the **Submit** button, see Step 5.

From the Data Controls panel, select the operation associated with the collection of objects on which you wish the operation to execute, and drag it onto the JSF page. If you simply want to be able to edit the data, then the **Submit** button is all that is required.

For example, if you want to be able to delete a customer record, you would drag the **Delete** operation associated with the `CustomerInfoVO1` collection.

[Figure 26–8](#) shows the operations associated with a collection.

Figure 26–8 Operations Associated with a Collection

4. From the ensuing context menu, choose either **ADF Button** or **ADF Link**.
5. To rebind the Submit button, right-click the button in the Structure window, and choose **Bind to ADF Control**. In the Bind to ADF Control dialog, select the operation to which you want the button bound. Ensure that the operation you select is associated with the collection on which the form is based.

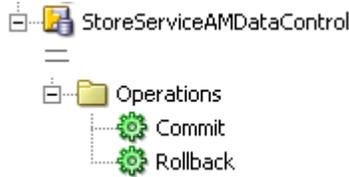

For example, if you want to be able to delete a customer record, you would select the **Delete** operation associated with the `CustomerInfoVO1` collection.

[Figure 26–8](#) shows the operations associated with a collection.

6. If the page is not part of a transaction within a bounded task flow, then you need to create buttons that allow the user either to commit or roll back the changes. From the Data Controls panel, drag the **Commit** and **Rollback** operations

associated with the root-level data control, and drop them as either a command button or a command link. [Figure 26–9](#) shows the commit and rollback operations for the `StoreServiceAMDataControl` data control (note that for viewing simplicity, the figure omits details in the tree that appear for each view object).

Figure 26–9 Commit and Rollback Operations for a Data Control

If the page is part of a transaction within a bounded task flow, then you can simply enter `Commit` and `Rollback` as the values for the transaction resolution when creating the task flow return activity. For more information, see [Section 22.2, "Managing Transactions in Task Flows."](#)

26.5.2 What Happens When You Use Built-in Operations to Change Data

Dropping any data control operation as a command button causes the same events as does dropping navigation operations. For more information, see [Section 26.4.2, "What Happens When You Create Command Buttons."](#)

The only difference is that the action bindings for the `Commit` and `Rollback` operations do not require a reference to the iterator, because they execute a method on the application module (the data control itself), as opposed to the iterator. Note that the `Rollback` action has the `RequiresUpdateModel` property set to `false`. This is because the model should not be updated before the operation is executed, since all changes need to be discarded. [Example 26–9](#) shows the action bindings generated in the page definition file for these operations.

Example 26–9 Action Bindings for Commit and Rollback Operations

```
<action id="Commit" RequiresUpdateModel="true" Action="commitTransaction"
    DataControl="StoreServiceAMDataControl" />
<action id="Rollback" RequiresUpdateModel="false"
    Action="rollbackTransaction"
    DataControl="StoreServiceAMDataControl" />
```

[Table 26–2](#) shows the built-in non-navigation operations provided on data controls and data control objects, along with the result of invoking the operation or executing an event bound to the operation. For more information about action events, see [Section 26.4.3, "What Happens at Runtime: How Action Events and Action Listeners Work."](#)

Table 26–2 More Built-in Operations

Operation	When invoked, the associated iterator binding will...
<code>CreateInsert</code>	Creates a row directly before the current row, inserts the new record into the row set, then moves the current row pointer to the new row. Note that the range does not move, meaning that the last row in the range may now be excluded from the range. For more information about using the <code>CreateInsert</code> operation to create objects, see Section 26.6, "Creating an Input Form."

Table 26-2 (Cont.) More Built-in Operations

Operation	When invoked, the associated iterator binding will...
Create	Creates a row directly before the current row, then moves the current row pointer to the new row. Note that the range does not move, meaning that the last row in the range may now be excluded from the range. Also note that the record will not be inserted into the row set, preventing a blank row should the user navigate away without actually creating data. The new row will be created when the user submits the data. For more information, see Section 27.4.5, "What You May Need to Know About Create and CreateInsert."
CreateWith Parameters	Same as the CreateInsert operation (the new record is inserted into the row set), however uses named parameters to create the object.
Delete	Deletes the current row from the cache and moves the current row pointer to the next row in the result set. Note that the range does not move, meaning that a row may be added to the end of the range. If the last row is deleted, the current row pointer moves to the preceding row. If there are no more rows in the collection, the enabled attribute is set to disabled.
RemoveRowWithKey	Uses the row key as a String converted from the value specified by the input field to remove the data object in the bound data collection.
SetCurrentRowWith Key	Sets the row key as a String converted from the value specified by the input field. The row key is used to set the currency of the data object in the bound data collection. For an example of when this is used, see Section 27.2.3, "What You May Need to Know About Setting the Current Row in a Table."
SetCurrentRowWith KeyValue	Sets the current object on the iterator, given a key's value. For more information, see Section 27.2.3, "What You May Need to Know About Setting the Current Row in a Table."
ExecuteWithParams	Refreshes the data collection by first assigning new values to the named bind variables passed as parameters, then (re)executing the view object's query. You would use this operation in the same manner as you would use the CreateInsert operation to create an input form. For more information, see Section 26.6, "Creating an Input Form." This operation appears only for view objects that have defined one or more named bind variables at design time. For more information, see Section 5.10, "Working with Bind Variables."
Commit	Causes all items currently in the cache to be committed to the database.
Rollback	Clears the cache and returns the transaction and iterator to the initial state. Resets the ActionListener method.
Execute and Find	These operations are used only in search forms. See Chapter 31, "Creating ADF Databound Search Forms" for more information.

26.6 Creating an Input Form

You can create a form that allows a user to enter information for a new record and then commit that record to the data source. You need to use a task flow that contains a method activity that will call the `CreateInsert` operation before the page with the input form is displayed. This method activity causes a blank row to be inserted into the row set which the user can then populate using a form.

For example, in the `StoreFront` module, the `customer-registration-task-flow` task flow contains the `createAddress` method activity, which calls the `CreateInsert` operation on the `CustomerAddress` view object. Control is then

passed to the `addressDetails` view activity, which displays a form where the user can enter a new address, as shown in [Figure 26–10](#).

Figure 26–10 *Create an Address*

Note: If your application does not use task flows, then the calling page should invoke the `createInsert` operation similar to the way in which a task flow's method activity would. For example, you could provide application logic within an event handler associated with a command button on the calling page.

26.6.1 How to Create an Input Form Using a Task Flow

Instead of using command components to create new objects, you use a method activity in a task flow.

Before you begin:

Before you create the input form, you need to create a bounded task flow that will contain both the form and the method activity that will execute the `CreateInsert` operation. For more information, see [Section 18.2, "Creating a Task Flow."](#)

It may be helpful to have an understanding of input forms. For more information, see [Section 26.6, "Creating an Input Form."](#)

You may also find it helpful to understand other ADF functionality and features. For more information, see [Section 26.1.2, "Additional Functionality for Databound Forms."](#)

To create an input form:

1. To the bounded task flow, add a method call activity. Have this activity execute the `CreateInsert` operation associated with the collection for which you are creating the form. For procedures on using method activities, see [Section 19.5, "Using Method Call Activities."](#)
2. In the Property Inspector, enter a string for the **fixed-outcome** property. For example, the `createAddress` method activity in the `customer-registration-task-flow` task flow has `editAddress` as the `fixed-outcome` value.
3. Add a view activity that represents the page for the input form. For information on adding view activities, see [Section 18.3, "Adding Activities to a Task Flow."](#)

4. Add a control flow case from the method activity to the view activity. In the Property Inspector, enter the value of the **fixed-outcome** property of the method activity set in Step 2 as the value of the `from-outcome` of the control flow case.
5. Open the page for the view activity in the design editor, and from the Data Controls panel, drag the collection for which the form will be used to create a new record, and choose **ADF Form** from the context menu.

Tip: If you want the user to be able to create multiple entries before committing to the database, do the following:

1. In the task flow, add another control flow case from the view activity back to the method activity, and enter a value for the `from-outcome` method. For example, you might enter `createAnother`.
 2. Drag and drop a command component from the Component Palette onto the page, and set the `action` attribute to the `from-outcome` just created. This will cause the task flow to return to the method activity and reinvoke the `CreateInsert` operation.
6. Because you need to commit the new data, the application needs to execute the `commit` operation of the data control. To do this, you can add a button that navigates to a return activity that calls the `commit` operation. For procedures for using a return activity, see [Section 19.7, "Using Task Flow Return Activities."](#)

Best Practice: Use the return activity unless the task flow contains data managed by more than one data control, or you need to commit the data before the end of the flow. In those cases, you can add a button to the page bound to the `commit` button.

If you need to add a `commit` button to the page, do the following:

1. In the Data Controls panel, drag the `commit` operation associated with the data control that contains the collection associated with the input form, and drop it as a command button.
2. In the Structure window, select the command button for the `commit` operation.
3. In the Property Inspector, set the action to the outcome String that will navigate back to the method activity. You then need to add a control flow case from the page back to the activity, using the same outcome value.
4. Set the command button's `disabled` property to `false`.

By default, JDeveloper binds the `disabled` attribute of the button to the `enabled` property of the binding, causing the button to be disabled when the `enabled` property is set to `false`. For this binding, the `enabled` property is `false` until an update has been posted. For the purposes of an input form, the button should always be enabled, since there will be no changes posted before the user needs to create the new object.

26.6.2 What Happens When You Create an Input Form Using a Task Flow

When you use an ADF Form to create an input form, JDeveloper:

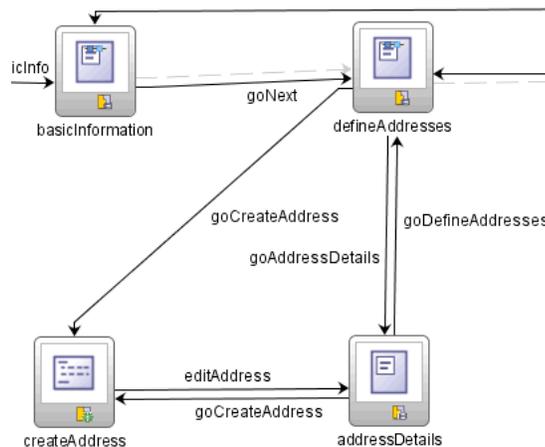

- Creates an iterator binding for the collection and an action binding for the `CreateInsert` operation in the page definition for the method activity. The `CreateInsert` operation is responsible for creating a row in the row set and populating the data source with the entered data. In the page definition for the page, JDeveloper creates an iterator binding for the collection and attribute bindings for each of the attributes of the object in the collection, as for any other

form. If you created command buttons or links using the Commit and Rollback operations, JDeveloper also creates an action bindings for those operations.

- Inserts code in the JSF page for the form using ADF Faces `inputText` components, and in the case of the operations, `commandButton` components.

For example, the StoreFront module contains a page that displays all the addresses for a customer in a table. The table includes an **Add** button that navigates to a form where you can input data for a new address. Once the address is created, you return to the page with the table and the new address is displayed. [Figure 26-11](#) shows the customer-registration-task-flow task flow with the `createAddress` method activity.

Figure 26-11 Task Flow for an Input Form

[Example 26-10](#) shows the page definition file for the method activity.

Example 26-10 Page Definition Code for a Creation Method Activity

```
<executables>
  <iterator id="CustomerAddressIterator" RangeSize="25"
    Binds="CustomerAddress" DataControl="StoreServiceAMDataControl" />
</executables>
<bindings>
  <action id="CreateInsert" IterBinding="CustomerAddressIterator"
    InstanceName="StoreServiceAMDataControl.CustomerAddress"
    DataControl="StoreServiceAMDataControl" RequiresUpdateModel="true"
    Action="createInsertRow" />
</bindings>
```

26.6.3 What Happens at Runtime: CreateInsert Action from the Method Activity

When the `createMethodCall` activity is accessed, the `CreateInsert` action binding is invoked, which executes the `CreateInsertRow` operation, and a new blank instance for the collection is created. Note that during routing from the method activity to the view activity, the method activity's binding container skips validation for required attributes, allowing the blank instance to be displayed in the form on the page.

26.6.4 What You May Need to Know About Displaying Sequence Numbers

Because the `Create` action is executed before the page is displayed, if you are populating the primary key using sequences, the next number in the sequence will appear in the input text field, unlike the rest of the fields, which are blank. The sequence number is displayed because the associated entity class contains a method that uses an eager fetch to generate a sequence of numbers for the primary key attribute. The eager fetch populates the value as the row is created. Therefore, using sequences works as expected with input forms.

However, if instead you've configured the attribute's type to `DBSequence` (which uses a database trigger to generate the sequence), the number would not be populated until the object is committed to the database. In this case, the user would see a negative number as a placeholder. To avoid this, you can use the following EL expression for the `Rendered` attribute of the input text field:

```
#{bindings.EmployeeId.inputValue.value > 0}
```

This expression will display the component only when the value is greater than zero, which will not be the case before it is committed. Similarly, you can simply set the `Rendered` attribute to `false`. However, then the page will never display the input text field component for the primary key.

26.7 Using a Dynamic Form to Determine Data to Display at Runtime

ADF Faces offers a library of dynamic components that includes dynamic form and dynamic table widgets that you can drop from the Data Controls panel. Dynamic components differ from standard components in that all the binding metadata is created at runtime. This dynamic building of the bindings allows you set display information using control hints on a view object instead of configuring the information in the Edit Form Fields dialog as you drop the control onto the page. Then if you want to change how the data displays, you need only change it on the view object, and all dynamic components bound to that view object will change their display accordingly. With standard components, if you want to change any display attributes (such as the order or grouping of the attributes) you would need to change each page on which the data is displayed.

For example, in the `StoreFront` module, you could set the `Category` and `Field Order` attribute hints on the `CustomerInfoVO` view object that groups the `FirstName` and `LastName` attributes together and at the top of a form (or at the leftmost columns of a table), the `ConfirmedEmail` and `MobilePhoneNumber` together and at the bottom of a form (or the rightmost columns of a table), and the `MembershipID` and `MembershipType` together and at the middle of a form or table. You could make it so that the `PersonId` does not display at all. For more information about control hints on view objects, see [Section 5.13, "Defining Attribute UI Hints for View Objects."](#)

[Figure 26–12](#) shows a dynamic form at runtime created by dragging and dropping the `CustomerInfoVO` view object with control hints set as described previously, as a dynamic form. Note that the input fields are grayed out because the view object is nonupdateable.

Figure 26–12 Dynamic Form Displays Based on Hints Set on the View Object

FirstName	John
LastName	Chen
MembershipId	1
MembershipTypeCode	PERS
MobilePhoneNumber	
ConfirmedEmail	JCHEN

26.7.1 How to Use Dynamic Forms

To use dynamic forms you first need to set control hints (especially the order and grouping hints) on any corresponding view objects. Next you import the libraries for the dynamic components. You can then drop the dynamic form or table widgets onto your page.

Before you begin:

It may be helpful to have an understanding of dynamic forms. For more information, see [Section 26.7, "Using a Dynamic Form to Determine Data to Display at Runtime."](#)

You may also find it helpful to understand other ADF functionality and features. For more information, see [Section 26.1.2, "Additional Functionality for Databound Forms."](#)

To use dynamic components:

1. Set UI hints on the corresponding view objects. For the Category hint, enter a string that can be used to group attributes together. For example, in the CustomerInfoVO hints, the `FirstName` and `LastName` attributes both have name as the value for the Category UI hint. The Field Order hint determines the order the attributes are displayed within a category. For example, in the CustomerInfoVO hints, the `FirstName` attribute has a Field Order value of 1 and the `LastName` attribute has a Field Order value of 2.

For procedures on creating UI hints, see [Section 5.13, "Defining Attribute UI Hints for View Objects."](#)
2. If not already included, import the dynamic component library.
 1. In the Application Navigator, right-click the view project in which the dynamic components will be used, and from the context menu, choose **Project Properties**.
 2. In the tree, select **JSP Tag Libraries**.
 3. On the JSP Tag Libraries page, click **Add**.
 4. In the Choose Tag Libraries dialog, select **ADF Dynamic Components**, and click **OK**.
 5. On the JSP Tag Libraries page, click **OK**.
3. From the Data Controls panel, select the collection that represents the view object.
4. Drag the collection onto the page, and from the context menu, choose **Forms > ADF Dynamic Form**.

Tip: If dynamic components are not listed, then the library was not imported into the project. Repeat Step 2.

5. In the Property Inspector, enter the following: for the **Category** field:

- **Category:** Enter the string used as the value for the Category UI hint for the first group you'd like to display in your form. For example, in [Figure 26–12](#), the Category value would be name.
 - **Editable:** Enter `true` if you want the data to be editable (the default). Enter `false` if the data should be read-only.
6. Repeat Steps 4 and 5 for each group that you want to display on the form. For example, the form in [Figure 26–12](#) is actually made up of three different forms: one for the category name, one for the category membership, and one for the category contact.

26.7.2 What Happens When You Use Dynamic Components

When you drop a dynamic form, only a binding to the iterator is created.

[Example 26–11](#) shows the page definition for a page that contains one dynamic form component created by dropping the `CustomerInfoVO` collection. Note that no attribute bindings are created.

Example 26–11 Page Definition Code for a Dynamic Form

```
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
  version="11.1.1.53.2" id="DynamicFormPageDef"
  Package="package.pageDefs">
  <parameters/>
  <executables>
    <iterator Binds="CustomerInfoV01" RangeSize="25"
      DataControl="StoreServiceAMDDataControl"
      id="CustomerInfoV01Iterator"/>
  </executables>
  <bindings/>
</pageDefinition>
```

JDeveloper inserts a `form` tag which contains a dynamic form tag for each of the forms dropped. The form tag's value is bound to the iterator binding, as shown in [Example 26–12](#). This binding means the entire form is bound to the data returned by the iterator. You cannot set display properties for each attribute individually, nor can you rearrange attributes directly on the JSF page.

Example 26–12 JSF Page Code for a Dynamic Form

```
<af:document>
  <af:messages/>
  <af:form>
    <dynamic:form value="#{bindings.CustomerInfoV01Iterator}"
      category="name" id="f1"/>
    <dynamic:form value="#{bindings.CustomerInfoV01Iterator}"
      category="member" id="f2"/>
    <dynamic:form value="#{bindings.CustomerInfoV01Iterator}"
      category="contact" id="f3"/>
  </af:form>
</af:document>
```

Tip: You can set certain properties that affect the functionality of the form. For example, you can make a form available for upload, set the rendered property, or set a partial trigger. To do this, select the `af:form` tag in the Structure window, and set the needed properties using the Property Inspector.

26.7.3 What Happens at Runtime: How Attribute Values Are Dynamically Determined

When a page with dynamic components is rendered, the bindings are created just as they are when items are dropped from the Data Controls panel at design time, except that they are created at runtime. For more information, see [Section 26.3.2, "What Happens When You Create a Form."](#)

Tip: While there is a slight performance hit because the bindings need to be created at runtime, there is also a performance gain because the JSF pages do not need to be regenerated and recompiled when the structure of the view object changes.

26.8 Modifying the UI Components and Bindings on a Form

Once you use the Data Controls panel to create any type of form (except a dynamic form), you can then delete attributes, change the order in which they are displayed, change the component used to display data, and change the attribute to which the components are bound.

Note: You cannot change how a dynamic form displays using the following procedures. You must change display information on the view object or entity object instead.

26.8.1 How to Modify the UI Components and Bindings

You can modify certain aspects of the default components dropped from the Data Controls panel. You can use the Structure window to change the order in which components are displayed, to add new components or change existing components, or to delete components. You can use the Property Inspector to change or delete bindings, or to change the label displayed for a component.

To modify default components and bindings:

1. Use the Structure window to do the following:
 - Change the order of the UI components by dragging them up or down the tree. A black line with an arrowhead denotes where the UI component will be placed.
 - Add a UI component. Right-click an existing UI component in the Structure window and choose to place the new component before, after, or inside the selected component. You then choose from a list of UI components.
 - Bind a UI component. Right-click an existing UI component in the Structure window and choose **Bind to ADF Control**. You can then select the object to which you want your component bound.
 - Rebind a UI component. Right-click an existing UI component in the Structure window and choose **Rebind to another ADF Control**. You can then select the new control object to which you want your component bound.
 - Delete a UI component. Right-click the component and choose **Delete**. If you wish to keep the component, but delete the binding, you need to use the Property Inspector. See the second bullet point in Step 2.
2. With the UI component selected in the Structure window, you can then do the following in the Property Inspector:

- Add a non-ADF binding for the UI component. Enter an EL expression in the **Value** field, or use the dropdown menu and choose **Edit**.
- Delete a binding for the UI component by deleting the EL expression.
- Change the label for the UI component. By default, the label is bound to the binding's `label` property of its hint. This property allows your page to use the UI control hints for labels that you have defined for your entity object attributes or view object attributes. The UI hints allow you to change the value once and have it appear the same on all pages that display the label.

You can change the label just for the current page. To do so, select the `label` attribute. You can enter text or an EL expression to bind the label value to something else, for example, a key in a properties or resource file.

For example, the `inputText` component used to display the name of a product might have the following for its `Label` attribute:

```
#{bindings.ProductName.hints.label}
```

However, you could change the expression to instead bind to a key in a properties file, for example:

```
#{properties['productName']}
```

In this example, `properties` is a variable defined in the JSF page used to load a properties file.

26.8.2 What Happens When You Modify Attributes and Bindings

When you modify how an attribute is displayed by moving or changing the UI component, JDeveloper changes the corresponding code on the JSF page. When you use the binding editors to add or change a binding, JDeveloper adds the code to the JSF page, and also adds the appropriate elements to the page definition file.

Creating ADF Databound Tables

This chapter describes how to use the Data Controls panel to create data bound tables using ADF Faces components.

This chapter includes the following sections:

- [Section 27.1, "About Creating ADF Databound Tables"](#)
- [Section 27.2, "Creating a Basic Table"](#)
- [Section 27.3, "Creating an Editable Table"](#)
- [Section 27.4, "Creating an Input Table"](#)
- [Section 27.5, "Modifying the Attributes Displayed in the Table"](#)

27.1 About Creating ADF Databound Tables

Unlike forms, tables allow you to display more than one data object from a collection at a time.

You can create tables that simply display data, or you can create tables that allow you to edit or create data. Once you drop a collection as a table, you can add command buttons bound to actions that execute some logic on a selected row. You can also modify the default components to suit your needs.

27.1.1 ADF Databound Tables Use Cases and Examples

[Figure 27-1](#) shows the Items Ordered tab of the My Orders page in the StoreFront module application, which uses a browse table to display the items for a given order.

Figure 27–1 The Orders Table

Item(s) Summary		
Product Id	Name	List Price
 See Larger Image@	LCD HD Television [Audio and Video] The sleekly styled 32-inch Nexus HD-ready monitor features the company's latest LCD panel technology—Cinespeed—and an expanded viewing angle of 176 degrees. With no internal tuner (either standard NTSC or digital ATSC), the 32HLC56 requires an optional tuner or cable/satellite set-top box to receive standard- and high-definition television programming. The smaller, sleeker design makes it easy to carry around and enjoy games any time, anywhere. It ...	List Price 199.95 ShippingCost 14.99 Quantity 1

Unlike a form that may display information for one row, a table displays information for all (or a set) of rows.

You can create a table that simply displays information, as shown in [Figure 27–1](#), or you can allow the user to edit the information, as shown in [Figure 27–2](#).

Figure 27–2 Edit Table

No.	Name	Size	Date Modified	A Spinbox
0	.	0 B	7/12/2004	1979
1	..	0 B	7/12/2004	1979
2	admin.jar	1 KB	5/11/2004	1979
3	applib	0 B	7/12/2004	1979
4	applications	0 B	7/12/2004	1979
5	config	0 B	7/12/2004	1979
6	connectors	0 B	7/12/2004	1979

You can also use a table with a button to create new records, which are then inserted into the data collection.

27.1.2 Additional Functionality for Databound Tables

You may find it helpful to understand other ADF Faces features before you implement your table and tree components. Additionally, once you have added a tree or table component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that table and tree components can use.

- **ADF view objects:** Much of how the components display and function in the table is controlled by the corresponding view objects. For more information, see [Chapter 5, "Defining SQL Queries Using View Objects."](#)
- **ADF Model and data binding:** When you create tables in an ADF Web application, you use ADF Model and data binding. For more information, see [Appendix 13, "Using ADF Model in a Fusion Web Application."](#)
- **ADF Faces:** For detailed information about developing with ADF Faces, see the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

- **Command buttons:** You may want to add command button or links that invoke some functionality against the data set. For more advanced functionality than what is covered in this chapter, see [Chapter 28, "Command Components to Invoke Functionality in the View Layer."](#)
- **Filtered tables:** You can create tables that provide filtering, in effect executing a query-by-example search against the data in the table. For more information, see [Section 31.5, "Creating Standalone Filtered Search Tables from Named View Criteria."](#)
- **Task flows:** If your table takes part in a transaction, for example an input table, then you may need to use an ADF task flow to invoke certain operations before or after the table is rendered. For more information, see [Part IV, "Creating ADF Task Flows"](#).
- **Validation:** You may want certain fields to be validated before they are submitted to the data store. For more information, see [Appendix 7, "Defining Validation and Business Rules Declaratively"](#) and [Appendix 16, "Using Validation in the ADF Model Layer."](#)
- **Active data:** If your application uses active data, then you can have the data in your tables and trees update automatically, whenever the data in the data source changes. For more information, see [Chapter 45, "Using the Active Data Service."](#)

Note: If you wish to use active data, and your application uses ADF Business Components, then your tables must conform to the following:

- The binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
 - The binding rule contains a single attribute.
 - The table does not use filtering.
 - The tree component's `nodeStamp` facet contains a single `outputText` tag and contains no other tags.
-
-

27.2 Creating a Basic Table

Unlike with forms where you bind the individual UI components that make up a form to the individual attributes on the collection, with a table you bind the ADF Faces `table` component to the complete collection or to a range of n data objects at a time from the collection. The individual components used to display the data in the columns are then bound to the attributes. The iterator binding handles displaying the correct data for each object, while the `table` component handles displaying each object in a row. JDeveloper allows you to do this declaratively, so that you don't need to write any code.

27.2.1 How to Create a Basic Table

To create a table using a data control, you bind the `table` component to a collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

Tip: You can also create a table by dragging a table component from the Component Palette.

Before you begin:

It may be helpful to have an understanding of ADF Faces databound tables. For more information, see [Section 27.2, "Creating a Basic Table."](#)

You may also find it helpful to understand other ADF functionality and features. For more information, see [Section 27.1.2, "Additional Functionality for Databound Tables."](#)

To create a databound table:

1. From the Data Controls panel, select a collection.

For example, to create a simple table in the StoreFront module that displays products in the system, you would select the `Products` collection.

2. Drag the collection onto a JSF page, and from the context menu, choose the appropriate table.

When you drag the collection, you can choose from the following types of tables:

- **ADF Table:** Allows you to select the specific attributes you wish your editable table columns to display, and what UI components to use to display the data. By default, ADF `inputText` components are used for most attributes, thus enabling the table to be editable. Attributes that are dates use the `inputDate` component. Additionally, if a control type control hint has been created for an attribute, or if the attribute has been configured to be a list, then the component set by the hint is used instead.
 - **ADF Read-Only Table:** Same as the **ADF Table**; however, each attribute is displayed in an `outputText` component.
 - **ADF Dynamic and ADF Read-Only Dynamic Table:** Allows you to create a table when the attributes returned and displayed are determined dynamically at runtime. This component is helpful when the attributes for the corresponding object are not known until runtime, or you do not wish to hardcode the column names in the JSF page. For more information about working with dynamic components, see [Section 26.7, "Using a Dynamic Form to Determine Data to Display at Runtime."](#)
3. The Edit Table Columns dialog shows each attribute in the collection, and allows you to determine how these attributes will behave and appear as columns in your table.

Note: If the collection contains a structured attribute (an attribute that is neither a Java primitive type nor a collection), the attributes of the structured attributes will also appear in the dialog.

Using this dialog, you can do the following:

- Allow the ADF Model layer to handle selection by selecting the **Row Selection** checkbox. Selecting this option means that the iterator binding will access the iterator to determine the selected row or rows. Select this option unless you do not want the table to allow selection.
- Allow the ADF Model layer to handle column sorting by selecting the **Enabling Sorting** checkbox. Selecting this option means that the iterator binding will access the iterator, which will perform an order-by query to determine the order. Select this option unless you do not want to allow column sorting.

- Allow the columns in the table to be filtered using entered criteria by selecting the **Enabling Filtering** checkbox. Selecting this option allows the user to enter criteria in text fields above each column. That criteria is then used to build a Query-by-Example (QBE) search on the collection, so that the table will display only the results returned by the query. For more information, see [Section 31.5, "Creating Standalone Filtered Search Tables from Named View Criteria."](#)
- Group columns for selected attributes together under a parent column, by selecting the desired attributes (shown as rows in the dialog), and clicking the **Group** button. [Figure 27-3](#) shows how three grouped columns appear in the visual editor after the table is created.

Figure 27-3 Grouped Columns in an ADF Faces Table

Group			Name
Product Id	Supplier Id	Category Id	
#{...ProductId}	#{...SupplierId}	#{...CategoryId}	#{...ProductName}
#{...ProductId}	#{...SupplierId}	#{...CategoryId}	#{...ProductName}
#{...ProductId}	#{...SupplierId}	#{...CategoryId}	#{...ProductName}

- Change the display label for a column. By default, the label is bound to the `labels` property for any control hint defined for the attribute on the table binding. This binding allows you to change the value of a label text once on the view object, and have the change appear the same on all pages that display the label.

Instead of using this default, you can enter text or an EL expression to bind the label value to something else, for example, a key in a resource file.

- Change the value binding for a column. You can change the column to be bound to a different attribute. If you simply want to rearrange the columns, you should use the order buttons. If you do change the attribute binding for a column, the label for the column also changes.
- Change the UI component used to display an attribute. The UI components are set based on the table you selected when you dropped the collection onto the page, on the type of the corresponding attribute (for example, `inputDate` components are used for attributes that are dates), and on whether or not default components were set as control hints on the corresponding view object. You can change to another component using the dropdown menu.

Tip: If one of the attributes for your table is also a primary key, you may want to choose a UI component that will not allow a user to change the value.

Tip: If you want to use a component that is not listed in the dropdown menu, use this dialog to select the `outputText` component, and then manually add the other tag to the page.

- Change the order of the columns using the order buttons.
- Add a column using the **Add** icon. There's no limit to the number of columns you can add. When you first click the icon, JDeveloper adds a new column line at the bottom of the dialog and populates it with the values from the first attribute in the bound collection; subsequent new columns are populated with values from the next attribute in the sequence, and so on.

- Delete a column using the **Delete** icon.
4. Once the table is dropped on the page, you can use the Property Inspector to set other display properties of the table. For example, you may want to set the width of the table to a certain percentage or size. For more information about display properties, see the "Using Tables and Trees" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

Tip: When you set the table width to 100%, the table will not include borders, so the actual width of the table will be larger. To have the table set to 100% of the container width, expand the **Style** section of the Property Inspector, select the **Box** tab, and set the `Border Width` attribute to 0 pixels.
 5. If you want the user to be able to edit information in the table and save any changes, you need to provide a way to submit and persist those changes. For more information, see [Section 27.3, "Creating an Editable Table."](#) For procedures on creating tables that allow users to input data, see [Section 27.4, "Creating an Input Table."](#)

27.2.2 What Happens When You Create a Table

Dropping a table from the Data Controls panel has the same effect as dropping a text field or form. Briefly, JDeveloper does the following:

- Creates the bindings for the table and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

For more information, see [Section 26.2.2, "What Happens When You Create a Text Field."](#)

27.2.2.1 Iterator and Value Bindings for Tables

When you drop a table from the Data Controls panel, a tree value binding is created. A tree consists of a hierarchy of nodes, where each subnode is a branch off a higher level node. In the case of a table, it is a flattened hierarchy, where each attribute (column) is a subnode off the table. Like an attribute binding used in forms, the tree value binding references the iterator binding, while the iterator binding references an iterator for the data collection, which facilitates iterating over the data objects in the collection. Instead of creating a separate binding for each attribute, only the tree binding to the table node is created. In the tree binding, the `AttrNames` element within the `nodeDefinition` element contains a child element for each attribute that you want to be available for display or reference in each row of the table.

The tree value binding is an instance of the `FacesCtrlHierBinding` class that extends the core `JUCtrlHierBinding` class to add two JSF specific properties: `collectionModel`.

- `collectionModel`: Returns the data wrapped by an object that extends the `javax.faces.model.DataModel` object that JSF and ADF Faces use for collection-valued components like tables.
- `treeModel`: Extends `collectionModel` to return data that is hierarchical in nature. For more information, see [Chapter 29, "Displaying Master-Detail Data."](#)

[Example 27-1](#) shows the value binding for the table created when you drop the `Products` collection.

Example 27–1 Value Binding Entries for a Table in the Page Definition File

```

<bindings>
  <tree IterBinding="ProductsIterator" id="Products">
    <nodeDefinition DefName="oracle.fodemo.storefront.store.queries.ProductsVO">
      <AttrNames>
        <Item Value="ProductId" />
        <Item Value="SupplierId" />
        <Item Value="CategoryId" />
        <Item Value="ProductName" />
        <Item Value="CostPrice" />
        <Item Value="ListPrice" />
        .
        .
        .
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>

```

Only the table component needs to be bound to the model (as opposed to the columns or the text components within the individual cells), because only the table needs access to the data. The tree binding for the table drills down to the individual structure attributes in the table, and the table columns can then derive their information from the table component.

27.2.2.2 Code on the JSF Page for an ADF Faces Table

When you use the Data Controls panel to drop a table onto a JSF page, JDeveloper inserts an ADF Faces `table` component, which contains an ADF Faces `column` component for each attribute named in the table binding. Each column then contains another component (such as an `inputText` or `outputText` component) bound to the attribute's value. Each column's heading is bound to the `labels` property for the control hint of the attribute.

Tip: If an attribute is marked as hidden on the associated view or entity object, no corresponding UI is created for it.

[Example 27–2](#) shows a simplified code excerpt from a table created by dropping the `Products` collection as a read only table.

Example 27–2 Simplified JSF Code for an ADF Faces Table

```

<af:table value="#{bindings.Products.collectionModel}" var="row"
  rows="#{bindings.Products.rangeSize}"
  emptyText="#{bindings.Products.viewable ? 'No data to display.' :
    'Access Denied.'}"
  fetchSize="#{bindings.Products.rangeSize}"
  selectedRowKeys="#{bindings.Products.collectionModel.selectedRow}"
  selectionListener="#{bindings.Products.collectionModel.makeCurrent}"
  rowSelection="single" id="t1">
  <af:column sortProperty="#{bindings.Products.hints.ProductId.name}"
    sortable="true"
    headerText="#{bindings.Products.hints.ProductId.label}" id="c1">
    <af:outputText value="#{row.ProductId}" id="ot1"/>
    <af:convertNumber groupingUsed="false" Cos
      pattern="#{bindings.Products.hints.ProductId.format}"/>
  </af:column>
  <af:column sortProperty="#{bindings.Products.hints.SupplierId.name}"
    sortable="true"

```

```

        headerText="#{bindings.Products.hints.SupplierId.label}" id="c2">
<af:outputText value="#{row.SupplierId}" id="ot2">
    <af:convertNumber groupingUsed="false"
        pattern="#{bindings.Products.hints.SupplierId.format}"/>
</af:outputText>
</af:column>
<af:column sortProperty="#{bindings.Products.hints.CostPrice.name}"
    sortable="true"
    headerText="#{bindings.Products.hints.CostPrice.label}" id="c3">
<af:outputText value="#{row.CostPrice}" id="ot3">
    <af:convertNumber groupingUsed="false"
        pattern="#{bindings.Products.hints.CostPrice.format}"/>
</af:outputText>
</af:column>
.
.
.
</af:table>

```

The tree binding iterates over the data exposed by the iterator binding. Note that the table's value is bound to the `collectionModel` property, which accesses the `collectionModel` object. The table wraps the result set from the iterator binding in a `collectionModel` object. The `collectionModel` allows each item in the collection to be available within the table component using the `var` attribute.

In the example, the table iterates over the rows in the current range of the `Products` iterator binding. The iterator binding binds to a row set iterator that keeps track of the current row. When you set the `var` attribute on the table to `row`, each column then accesses the current data object for the current row presented to the table tag using the row variable, as shown for the value of the `af:outputText` tag:

```
<af:outputText value="#{row.ProductId}"/>
```

When you drop an ADF Table (as opposed to an ADF Read Only Table), instead of being bound to the row variable, the value of the input component is implicitly bound to a specific row in the binding container through the `bindings` property, as shown in [Example 27-3](#). Additionally, JDeveloper adds validator and converter components for each input component. By using the `bindings` property, any raised exception can be linked to the corresponding binding object or objects. The controller iterates through all exceptions in the binding container and retrieves the binding object to get the client ID when creating `FacesMessage` objects. This retrieval allows the table to display errors for specific cells. This strategy is used for all input components, including selection components such as lists.

Example 27-3 Using Input Components Adds Validators and Converters

```

<af:table value="#{bindings.Products.collectionModel}" var="row"
    rows="#{bindings.Products.rangeSize}"
    emptyText="#{bindings.Products.viewable ? 'No data to display.':
        'Access Denied.'}"
    fetchSize="#{bindings.Products.rangeSize}"
    selectedRowKeys="#{bindings.Products.collectionModel.selectedRow}"
    selectionListener="#{bindings.Products.collectionModel.makeCurrent}"
    rowSelection="single" id="t1">
<af:column sortProperty="bindings.Products.hints.ProductId.name" sortable="true"
    headerText="#{bindings.Products.hints.ProductId.label}" id="c1">
    <af:inputText value="#{row.bindings.ProductId.inputValue}"
        label="#{bindings.Products.hints.ProductId.label}"
        required="#{bindings.Products.hints.ProductId.mandatory}"
        columns="#{bindings.Products.hints.ProductId.displayWidth}"

```

```

        maximumLength="#{bindings.Products.hints.ProductId.precision}"
        shortDesc="#{bindings.Products.hints.ProductId.tooltip}"
        id="it1">
    <f:validator binding="#{row.bindings.ProductId.validator}"/>
    <af:convertNumber groupingUsed="false"
        pattern="#{bindings.Products.hints.ProductId.format}"/>
</af:inputText>
</af:column>

```

For more information about using ADF Faces validators and converters, see the "Validating and Converting Input" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

Table 27-1 shows the other attributes defined by default for ADF Faces tables created using the Data Controls panel.

Table 27-1 ADF Faces Table Attributes and Populated Values

Attribute	Description	Default Value
rows	Determines how many rows to display at one time.	An EL expression that, by default, evaluates to the <code>rangeSize</code> property of the associated iterator binding, which determines how many rows of data are fetched from a data control at one time. Note that the value of the <code>rows</code> attribute must be equal to or less than the corresponding iterator's <code>rangeSize</code> value, as the table cannot display more rows than are returned.
first	Index of the first row in a range (based on 0).	An EL expression that evaluates to the <code>rangeStart</code> property of the associated iterator binding.
emptyText	Text to display when there are no rows to return.	An EL expression that evaluates to the <code>viewable</code> property on the iterator. If the table is viewable, the attribute displays No data to display when no objects are returned. If the table is not viewable (for example, if there are authorization restrictions set against the table), it displays Access Denied .
fetchSize	Number of rows of data fetched from the data source.	An EL expression that, by default, evaluates to the <code>rangeSize</code> property of the associated iterator binding. For more information about the <code>rangeSize</code> property, see Section 26.4.2.2, "Iterator RangeSize Attribute." This attribute can be set to a larger number than the <code>rows</code> attribute. Note that to improve scrolling behavior in a table, when the table's iterator binding is expected to manage a data set consisting of over 200 items, and the view object is configured to use range paging, the iterator actually returns a set of ranges instead of just one range. For more information about using range paging, see Section 42.1.5, "Efficiently Scrolling Through Large Result Sets Using Range Paging."
selectedRowKeys	The selection state for the table.	An EL expression that by default, evaluates to the selected row on the collection model.
selectionListener	Reference to a method that listens for a selection event.	An EL expression that by default, evaluates to the <code>makeCurrent</code> method on the collection model.

Table 27–1 (Cont.) ADF Faces Table Attributes and Populated Values

Attribute	Description	Default Value
<code>rowSelection</code>	Determines whether rows are selectable.	Set to <code>single</code> to allow one row to be selected at a time. Set to <code>multiple</code> to allow more than one row to be selected.
Column Attributes		
<code>sortProperty</code>	Determines the property on which to sort the column.	Set to the columns corresponding attribute binding value.
<code>sortable</code>	Determines whether a column can be sorted.	Set to <code>false</code> . When set to <code>true</code> , the iterator binding will access the iterator to determine the order.
<code>headerText</code>	Determines the text displayed at the top of the column.	An EL expression that, by default, evaluates to the label control hint set on the corresponding attribute.

27.2.3 What You May Need to Know About Setting the Current Row in a Table

When you use tables in an application and you allow the ADF Model layer to manage row selection, the current row is determined by the iterator. When a user selects a row in an ADF Faces table, the row in the table is shaded, and the component notifies the iterator of the selected row. To do this, the `selectedRowKeys` attribute of the table is bound to the collection model's selected row, as shown in [Example 27–4](#).

Example 27–4 Selection Attributes on a Table

```
<af:table value="#{bindings.Products1.collectionModel}" var="row"
.
.
.
    selectedRowKeys="#{bindings.Products.collectionModel.selectedRow}"
    selectionListener="#{bindings.Products.collectionModel.
                                                makeCurrent}"
    rowSelection="single">
```

This binding binds the selected keys in the table to the selected row of the collection model. The `selectionListener` attribute is then bound to the collection model's `makeCurrent` property. This binding makes the selected row of the collection the current row of the iterator.

Note: If you create a custom selection listener, you must create a method binding to the `makeCurrent` property on the collection model (for example `#{binding.Products.collectionModel.makeCurrent}`) and invoke this method binding in the custom selection listener before any custom logic.

Although a table can handle selection automatically, there may be cases where you need to programmatically set the current row for an object on an iterator.

You can call the `getKey()` method on any view row to get a `Key` object that encapsulates the one or more key attributes that identify the row. You can also use a `Key` object to find a view row in a row set using the `findByKey()`. At runtime, when either the `setCurrentRowWithKey` or the `setCurrentRowWithKeyValue` built-in

operation is invoked by name by the data binding layer, the `findByKey()` method is used to find the row based on the value passed in as a parameter before the found row is set as the current row.

The `setCurrentRowWithKey` and `setCurrentRowWithKeyValue` operations both expect a parameter named `rowKey`, but they differ precisely by what each expects that `rowKey` parameter value to be at runtime:

setCurrentRowWithKey Operation

`setCurrentRowWithKey` expects the `rowKey` parameter value to be the *serialized string representation* of a view row key. This is a hexadecimal-encoded string that looks like this:

```
000200000002C20200000002C102000000010000010A5AB7DAD9
```

The serialized string representation of a key encodes all of the key attributes that might comprise a view row's key in a way that can be conveniently passed as a single value in a browser URL string or form parameter. At runtime, if you inadvertently pass a parameter value that is not a legal serialized string key, you may receive exceptions like `oracle.jbo.InvalidParamException` or `java.io.EOFException` as a result. In your web page, you can access the value of the serialized string key of a row by referencing the `rowKeyStr` property of an ADF control binding (for example, `#{bindings.SomeAttrName.rowKeyStr}`) or the row variable of an ADF Faces table (e.g. `#{row.rowKeyStr}`).

setCurrentRowWithKeyValue Operation

The `setCurrentRowWithKeyValue` operation expects the `rowKey` parameter value to be the literal value representing the key of the view row. For example, its value would be simply "201" to find product number 201.

Note: If you write custom code in an application module class and need to find a row based on a serialized string key passed from the client, you can use the `getRowFromKey()` method in the `JboUtil` class in the `oracle.jbo.client` package:

```
static public Row getRowFromKey(RowSetIterator rsi, String sKey)
```

The first parameter is the view object instance in which you'd like to find the row. The second parameter is the serialized string format of the key.

27.3 Creating an Editable Table

You can create a table that allows the user to edit information within the table, and then commit those changes to the data source. To do this, you use operations that can modify data records associated with the collection (or the data control itself) to create command buttons, and place those buttons in a toolbar in the table. For example, you might use the `Delete` operation to create a button that allows a user to delete a record from the current range. Or you can use the built-in **Submit** button to submit changes.

Tip: To create a table that allows you to insert a new record into the data store, see [Section 27.4, "Creating an Input Table."](#)

It is important to note that these operations are executed only against objects in the ADF cache. You need to use the `Commit` operation on the root data control to actually commit any changes to the data source. You use the data control's `Rollback`

operation to roll back any changes made to the cached object. If the page is part of a transaction within a bounded task flow, you would most likely use these operations to resolve the transaction in a task flow return activity. For more information, see [Section 22.2, "Managing Transactions in Task Flows."](#)

When you decide to use editable components to display your data, you have the option of the table displaying all rows as editable at once, or displaying all rows as read-only until the user double-clicks within the row. [Figure 27-4](#) shows a table whose rows all have editable fields. The page renders using the components that were added to the page (for example, `inputText`, `inputDate`, and `inputNumberSpinbox` components).

Figure 27-4 Table with Editable Fields

No.	Name	Size	Date Modified	A Spinbox
0	.	0 B	7/12/2004	1979
1	..	0 B	7/12/2004	1979
2	admin.jar	1 KB	5/11/2004	1979
3	applib	0 B	7/12/2004	1979
4	applications	0 B	7/12/2004	1979
5	config	0 B	7/12/2004	1979
6	connectors	0 B	7/12/2004	1979

[Figure 27-5](#) shows the same table, but configured so that the user must double-click (or single-click if the row is already selected) a row in order to edit or enter data. Note that `outputText` components are used to display the data in the non-selected rows, even though the same input components as in [Figure 27-4](#) were used to build the page. The only row that actually renders those components is the row selected for editing.

Figure 27-5 Click to Edit a Row

No.	Name	Size	Date Modified	A Spinbox
0	.	0 B	7/12/2004	1979
1	..	0 B	7/12/2004	1979

4	applications	0 B	7/12/2004	1979
5	config	0 B	7/12/2004	1979
6	connectors	0 B	7/12/2004	1979

For more information about how ADF Faces table components handle editing, see the "Editing Data in Tables, Trees, and Tree Tables" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

27.3.1 How to Create an Editable Table

To create an editable table, you follow similar procedures to creating a basic table, then you add command buttons bound to operations. However, in order for the table to contain a toolbar, you need to add an ADF Faces component that associates the toolbar with the items in the collection used to build the table.

Before you begin:

It may be helpful to have an understanding of editable databound tables. For more information, see [Section 27.3, "Creating an Editable Table."](#)

You may also find it helpful to understand other ADF functionality and features. For more information, see [Section 27.1.2, "Additional Functionality for Databound Tables."](#)

To create an editable table:

1. From the Data Controls panel, select a collection.

For example, to create a simple table in the StoreFront module that will allow you to edit products in the system, you would select the `Products` collection.

2. Drag the collection onto a JSF page, and from the context menu, choose **ADF Table**.

This creates an editable table using input components.

3. Use the ensuing Edit Table Columns dialog to determine how the attributes should behave and appear as columns in your table. Be sure to select the **Row Selection** checkbox, which will allow the user to select the row to edit.

For more information about using this dialog to configure the table, see [Section 27.2.1, "How to Create a Basic Table."](#)

4. With the table selected in the Structure window, expand the **Behavior** section of the Property Inspector and set the **EditingMode** attribute. If you want all the rows to be editable select **editAll**. If you want the user to click into a row to make it editable, select **clickToEdit**.

5. From the Structure window, right-click the table component and select **Surround With** from the context menu.

6. In the Surround With dialog, ensure that **ADF Faces** is selected in the dropdown list, select the **Panel Collection** component, and click **OK**.

The `panelCollection` component's toolbar facet will hold the toolbar which, in turn, will hold the command components used to update the data.

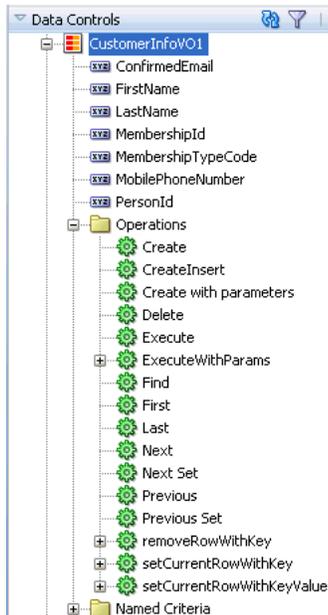

7. In the Structure window, right-click the `panelCollection`'s **toolbar** facet folder and from the context menu, choose **Insert inside toolbar > Toolbar**.

This creates a toolbar that already contains a default menu that allows users to change how the table is displayed and a **Detach** link that detaches the entire table and displays it such that it occupies the majority of the space in the browser window. For more information about the `panelCollection` component, see the "Displaying Table Menus, Toolbars, and Status Bars" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

8. From the Data Controls panel, select the operation associated with the collection of objects on which you wish the operation to execute, and drag it onto the `toolbar` component in the Structure window. This will place the databound command component inside the toolbar.

For example, if you want to be able to delete a product record, you would drag the `Delete` operation associated with the `Products` collection. [Figure 27-6](#) shows the operations associated with a collection.

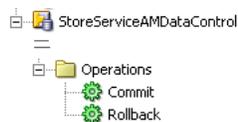

Figure 27–6 Operations Associated with a Collection

9. Choose **Operations > ADF Toolbar Button** from the context menu.
10. To create a **Submit** button that submits changes to the cache, right-click the **toolbar** component in the Structure window and choose **Insert inside af:toolbar > Toolbar Button**.
11. If the page is not part of a transaction within a bounded task flow, then you need to create buttons that allow the user to either commit or rollback the changes. From the Data Controls panel, drag the **Commit** and **Rollback** operations associated with the root-level data control, and drop them as either a command button or command link into the toolbar.

Figure 27–7 shows the commit and roll back operations for the `StoreServiceAMDataControl` data control.

Figure 27–7 Commit and Rollback Operations for a Data Control

If the page is part of a transaction within a bounded task flow, then you can simply enter `Commit` and `Rollback` as the values for the transaction resolution when creating the task flow return activity. For more information, see [Section 22.2, "Managing Transactions in Task Flows."](#)

27.3.2 What Happens When You Create an Editable Table

Creating an editable table is similar to creating a form used to edit records. Action bindings are created for the operations dropped from the Data Controls panel. For details on what happens when you create an editable table, see [Section 26.4.2, "What Happens When You Create Command Buttons."](#)

27.4 Creating an Input Table

You can create a table that allows users to insert a new blank row into a table and then add values for each column (any default values set on the corresponding entity or view object will be automatically populated).

27.4.1 How to Create an Input Table

When you create an input table, you want the user to see the new blank row in the context of the other rows within the current row set. To allow this insertion, you need to use the `CreateInsert` operation instead of the `Create` operation (as you would use with forms). The `CreateInsert` operation actually creates the new row within the row set instead of only in the cache.

ADF Faces components can be set so that one component refreshes based on an interaction with another component, without the whole page needing to be refreshed. This is known as *partial page rendering*. When the user clicks a button to create the new row, you want the table to refresh to display that new row. To have that happen, you need to configure the table to respond to that user action.

Before you begin:

It may be helpful to have an understanding of ADF Faces input tables. For more information, see [Section 27.4, "Creating an Input Table."](#)

You may also find it helpful to understand other ADF functionality and features. For more information, see [Section 27.1.2, "Additional Functionality for Databound Tables."](#)

You must do the following in JDeveloper before you create an input table.

1. Create an editable table, as described in [Section 27.3, "Creating an Editable Table."](#)
2. If your table is not part of a bounded task flow, be sure to include buttons bound to the `Commit` and `Rollback` operations.

To create an input table:

1. From the Data Controls panel, drag the `CreateInsert` operation associated with the dropped collection and drop it as a toolbar button into the toolbar. You may want to change the ID to something more recognizable, such as `CreateInsert`. This will make it easier to identify when you need to select it as the partial trigger.

Note: If the collection is a child to another collection (for example, the `OrderItems` collection is a child to the `Orders` collection), then instead of using the `CreateInsert` operation, you need to use the `Create with Parameters` operation. This is because the record to create for the child collection must first be associated with

2. In the Structure window, select the table component. In the Property Inspector, expand the **Behavior** section.
3. In the Property Inspector, click the dropdown menu for the **PartialTriggers** attribute, and select **Edit**.
4. In the Edit Property dialog, expand the toolbar facet for the `panelCollection` component and then expand the toolbar that contains the `CreateInsert` command component. Select that component and shuttle it to the **Selected** panel. Click **OK**. This sets that component to be the trigger that will cause the table to refresh.

27.4.2 What Happens When You Create an Input Table

When you use the `CreateInsert` operation to create an input table, JDeveloper:

- Creates an iterator binding for the collection, an action binding for the `CreateInsert` operation, and attribute bindings for the table. The `CreateInsert` operation is responsible for creating the new row in the row set. If you created command buttons or links using the `Commit` and `Rollback` operations, JDeveloper also creates an action bindings for those operations.
- Inserts code in the JSF page for the table using ADF Faces `table`, `column`, and `inputText` components, and in the case of the operations, `commandButton` components.

[Example 27-5](#) shows the page definition file for an input table created from the `Products` collection (some attributes were deleted in the `Edit Columns` dialog when the collection was dropped).

Example 27-5 Page Definition Code for an Input Table

```
<executables>
  <iterator Binds="Products" RangeSize="25"
    DataControl="StoreServiceAMDataControl" id="ProductsIterator" />
</executables>
<bindings>
  <tree IterBinding="ProductsIterator" id="Products">
    <nodeDefinition DefName="oracle.fodemo.storefront.store.queries.ProductsVO">
      <AttrNames>
        <Item Value="ProductId" />
        <Item Value="ProductName" />
        <Item Value="CostPrice" />
        <Item Value="ListPrice" />
        <Item Value="Description" />
        <Item Value="CategoryName" />
        <Item Value="CategoryDescription" />
        <Item Value="ProductImageId" />
      </AttrNames>
    </nodeDefinition>
  </tree>
  <action IterBinding="ProductsIterator" id="CreateInsert"
    RequiresUpdateModel="true" Action="createInsertRow" />
  <action id="Commit" RequiresUpdateModel="true" Action="commitTransaction"
    DataControl="StoreServiceAMDataControl" />
  <action id="Rollback" RequiresUpdateModel="false"
    Action="rollbackTransaction"
    DataControl="StoreServiceAMDataControl" />
</bindings>
```

[Example 27-6](#) shows the code added to the JSF page that provides partial page rendering, using the `CreateInsert` command toolbar button as the trigger to refresh the table.

Example 27-6 Partial Page Trigger Set on a Command Button for a Table

```
<af:form>
  <af:panelCollection id="pcl">
    <f:facet name="menus" />
    <f:facet name="toolbar">
      <af:toolbar id="tbl">
        <af:commandToolbarButton actionListener="#{bindings.CreateInsert.execute}"
          text="CreateInsert" />
      </af:toolbar>
    </f:facet>
  </af:panelCollection>
</af:form>
```

```

                disabled="#{!bindings.CreateInsert.enabled}"
                id="CreateInsert"/>
<af:commandToolbarButton actionListener="#{bindings.Commit.execute}"
    text="Commit"
    disabled="false" id="ctb2"/>
<af:commandToolbarButton actionListener="#{bindings.Rollback.execute}"
    text="Rollback"
    disabled="#{!bindings.Rollback.enabled}"
    immediate="true" id="ctb3">
    <af:resetActionListener/>
</af:commandToolbarButton>
</af:toolbar>
</f:facet>
<f:facet name="statusbar"/>
<af:table value="#{bindings.Products.collectionModel}" var="row"
    rows="#{bindings.Products.rangeSize}"
    emptyText="#{bindings.Products.viewable ? \'No data to display.\' :
        \'Access Denied.\'}"
    fetchSize="#{bindings.Products.rangeSize}"
    rowSelection="single" partialTriggers="CreateInsert" id="t1">
<af:column sortProperty="ProductId" sortable="false"
    headerText="#{bindings.Products.hints.ProductId.label}" id="c1">
<af:inputText value="#{row.ProductId}" simple="true"
    required="#{bindings.Products.hints.ProductId.mandatory}"
    columns="#{bindings.Products.hints.ProductId.displayWidth}"
    maximumLength="#{bindings.Products.hints.
        productId.precision}" id="it1"/>
</af:column>
.
.
.
</af:table>
</af:panelCollection>
</af:form>

```

27.4.3 What Happens at Runtime: How CreateInsert and Partial Page Refresh Work

When the button bound to the `CreateInsert` operation is invoked, the action executes, and a new instance for the collection is created and inserted as the page is rerendered. Because the button was configured to be a trigger that causes the table to refresh, the table redraws with the new empty row shown at the top. When the user clicks the button bound to the `Commit` action, the newly created rows in the row set are inserted into the database. For more information about partial page refresh, see the "Rendering Partial Page Content" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

27.4.4 What You May Need to Know About Creating a Row and Sorting Columns

If your table columns allow sorting, and the user has sorted on a column before inserting a new row, then that new row will not be sorted. To have the column sort with the new row, the user must first sort the column opposite to the desired sort, and then resort. This is because the table assumes the column is already sorted, so clicking on the desired sort order first will have no effect on the column.

For example, say a user had sorted a column in ascending order, and then added a new row. Initially, that row appears at the top. If the user first clicks to sort the column again in ascending order, the table will not resort, as it assumes the column is already in ascending order. The user must first sort on descending order and then ascending order.

If you want the data to automatically sort on a specific column in a specific order after inserting a row, then programmatically queue a `SortEvent` after the commit, and implement a handler to execute the sort.

27.4.5 What You May Need to Know About Create and CreateInsert

When you use the `Create` or `CreateInsert` operation to declaratively create a new row, it performs the following lines of code:

```
// create a new row for the view object
Row newRow = yourViewObject.createRow();
// mark the row as being "initialized", but not yet new
newRow.setNewRowState(Row.STATUS_INITIALIZED);
```

However, if you are using the `CreateInsert` operation, it performs the additional line of code to insert the row into the row set:

```
// insert the new row into the view object's default rowset
yourViewObject.insertRow(newRow);
```

When you create a row in an entity-based view object, the `Transaction` object associated with the current application module immediately takes note of the fact. The new entity row that gets created behind the view row is already part of the `Transaction`'s list of pending changes. When a newly created row is marked as having the *initialized* state, it is removed from the `Transaction`'s pending changes list and is considered a blank row in which the end user has not yet entered any data values. The term *initialized* is appropriate since the end user will see the new row initialized with any default values that the underlying entity object has defined. If the user never enters any data into any attribute of that initialized row, then it is as if the row never existed. At transaction commit time, since that row is not part of the `Transaction`'s pending changes list, no `INSERT` statement will be attempted for it.

As soon as at least one attribute in an initialized row is set, it automatically transitions from the initialized status to the new status (`Row.STATUS_NEW`). At that time, the underlying entity row is enrolled in the `Transaction`'s list of pending changes, and the new row will be permanently saved the next time you commit the transaction.

Note: If the end user performs steps that result in creating many initialized rows but never populating them, it might seem like a recipe for a slow memory leak. However, the memory used by an initialized row that never transitions to the new state will eventually be reclaimed by the Java virtual machine's garbage collector.

27.5 Modifying the Attributes Displayed in the Table

Once you use the Data Controls panel to create a table, you can then delete attributes, change the order in which they are displayed, change the component used to display them, and change the attribute binding for the component. You can also add new attributes, or rebind the table to a new data control.

27.5.1 How to Modify the Displayed Attributes

You can modify the following aspects of a table that was created using the Data Controls panel:

- Change the binding for the label of a column

- Change the UI component bound to an attribute
- Add or delete columns that represent the attributes
- Reorder the columns in the table
- Enable selection and sorting

To change the attributes for a table:

1. In the Structure window, select the table component.
2. In the Property Inspector, expand the Columns section to change, add, or delete the attributes that are displayed as columns. You can also change the UI component used within the column to display the data.
3. Expand other sections of the Property Inspector to change the display and behavior of the table, such as filtering and sorting.

27.5.2 How to Change the Binding for a Table

Instead of modifying a binding, you can completely change the object to which the table is bound.

To rebind a table:

1. Right-click the table in the Structure window and choose **Rebind to Another ADF Control**.
2. In the Bind to ADF Control dialog, select the new collection to which you want to bind the table. Note that changing the binding for the table will also change the binding for all the columns. You can then use the procedures in [Section 27.5.1, "How to Modify the Displayed Attributes"](#) to modify those bindings.

Tip: You can also rebind a table by dragging a different view object on top of the existing table.

27.5.3 What Happens When You Modify Bindings or Displayed Attributes

When you simply modify how an attribute is displayed by moving the UI component or changing the UI component, JDeveloper changes the corresponding code on the JSF page. When you use the binding editors to add or change a binding, JDeveloper adds the code to the JSF page, and also adds the appropriate elements to the page definition file.

Command Components to Invoke Functionality in the View Layer

This chapter describes how to add more complex bindings to your pages. It describes how to use methods that take parameters for creating forms and command components.

This chapter includes the following sections:

- [Section 28.1, "About Command Components"](#)
- [Section 28.2, "Creating Command Components to Execute Methods"](#)
- [Section 28.3, "Setting Parameter Values Using a Command Component"](#)
- [Section 28.4, "Overriding Declarative Methods"](#)

Note: Some of the implementation methods in this chapter are intended for page-level designs. If you are using task flows, you may be able to perform many of the same functions. For more information, see [Chapter 18, "Getting Started with ADF Task Flows."](#)

28.1 About Command Components

Once you create a basic page and add navigation capabilities, you may want to add more complex features, such as passing parameters between pages or providing the ability to override declarative actions. Oracle ADF provides many features that allow you to add this complex functionality using very little actual code.

Some of the functions described in this chapter may be performed using other methodology. For example, if you are using task flows instead of individual page flows, you should use the task flow parameter passing mechanism. Or, if you are using ADF Business Components, you should use the validation rules on entity objects in the data model project, rather than using ADF Model validation rules. For more information about validation rules for Business Components, see [Chapter 7, "Defining Validation and Business Rules Declaratively."](#)

28.1.1 Command Component Use Cases and Examples

You can use command components to perform an action, such as passing parameters, overriding declarative actions, or perform some logic. You can bind a command component to a custom method in the Data Control panel. For example, if you have a custom method called `updateItemInCart(Integer, Integer, Boolean)`, you can create a button bound to this method so when the user presses this button, the shopping cart will be updated.

You can also use the `setPropertyListener` tag within a command component to assign values when an event fires. For example, you have a button that initiates a search and displays the results on another page depending on a parameter value stored in a managed bean. You use the `setPropertyListener` property to pass this parameter value to the method that checks this value.

You can add code to a declarative method that is bound to a command component. For example, after you have created a declarative `Commit` button, you can add code to a managed bean and then override the `Commit` operation for additional processing

28.1.2 Additional Functionality for Command Components

You may find it helpful to understand other ADF features before you work with command components. Following are links to other functionality that may be of interest.

- For information about creating custom methods that can be added to the page as a command component, see [Section 9.7, "Customizing an Application Module with Service Methods,"](#) and [Section 9.9, "Publishing Custom Service Methods to UI Clients."](#)
- For information about creating command components from operations, see [Section 26.4.2, "What Happens When You Create Command Buttons."](#)
- If you want to use EL expressions in your methods, see [Section 26.4.2.3, "EL Expressions Used to Bind to Navigation Operations."](#)
- For more information about the command button's `actionListener` attribute, see [Section 26.4.3, "What Happens at Runtime: How Action Events and Action Listeners Work."](#)
- For more information about ADF bindings, see [Section 13, "Using ADF Model in a Fusion Web Application."](#)
- If you are using task flows, you can use the task flow parameter passing mechanism. For more information, see [Chapter 20, "Using Parameters in Task Flows."](#)
- If you are considering using task flow call methods, see [Section 19.5, "Using Method Call Activities."](#)
- If you are using managed beans, see [Section 24.4, "Using a Managed Bean in a Fusion Web Application."](#)

28.2 Creating Command Components to Execute Methods

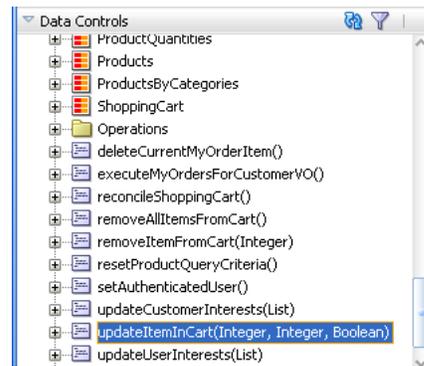

When your application contains custom methods, these methods appear in the Data Controls panel. You can then drag these methods and drop them as command buttons. When a user clicks the button, the method is executed.

For more information about creating custom methods, see [Section 9.7, "Customizing an Application Module with Service Methods,"](#) and [Section 9.9, "Publishing Custom Service Methods to UI Clients."](#)

Note: If you are using task flows, you can call methods directly from the task flow definition. For more information, see [Section 19.5, "Using Method Call Activities."](#)

For example, the application module in the StoreFront module of the Fusion Order Demo application contains the `updateItemInCart(Integer, Integer, Boolean)` method. This method updates the items in the shopping cart. To allow the user to execute this method, you drag the `updateItemInCart(Integer, Integer, Boolean)` method from the Data Controls panel, as shown in [Figure 28-1](#).

Figure 28-1 *Methods in the Data Controls Panel*

28.2.1 How to Create a Command Component Bound to a Custom Method

In order to perform the required business logic, many methods require a value for their parameter or parameters. This means that when you create a button bound to the method, you need to specify where the value for the parameter(s) is to be retrieved from. For example, if you use the `updateItemInCart(Integer, Integer, Boolean)` method, you need to specify the items to be updated.

Before you begin:

It may be helpful to have an understanding of custom methods. For more information, see [Section 28.2, "Creating Command Components to Execute Methods."](#)

You may also find it helpful to understand functionality that can be added using other command components. For more information, see [Section 28.1.2, "Additional Functionality for Command Components."](#)

To create a command component bound to a custom method:

1. From the Data Controls panel, drag the method onto the page.

Tip: If you are dropping a button for a method that needs to work with data in a table or form, that button must be dropped inside the table or form.

2. From the context menu, choose **Create > Methods > ADF Button**.

If the method takes parameters, the Edit Action Binding dialog opens. In the Edit Action Binding dialog, enter values for each parameter or click the **Show EL Expression Builder** menu selection in the **Value** column of **Parameters** to launch the EL Expression Builder.

28.2.2 What Happens When You Create Command Components Using a Method

When you drop a method as a command button, JDeveloper:

- Defines a method action binding for the method.

- If the method takes any parameters, JDeveloper creates `NamedData` elements that hold the parameter values.
- Inserts code in the JSF page for the ADF Faces command component.
- Binds the button to the method using `actionListener`.
- Uses the return value from the method call.

28.2.2.1 Defining Method Action Binding

JDeveloper adds an action binding for the method. Action bindings use the `RequiresUpdateModel` property, which determines whether or not the model needs to be updated before the action is executed. For command operations, this property is set to `true` by default, which means that any changes made at the view layer must be moved to the model before the operation is executed.

28.2.2.2 Using Parameters in a Method

When you drop a method that takes parameters onto a JSF page, JDeveloper creates a method action binding. This binding is what causes the method to be executed when a user clicks the command component. When the method requires parameters to run, JDeveloper also creates `NamedData` elements for each parameter. These elements represent the parameters of the method.

For example, the `updateItemInCart(Integer, Integer, Boolean)` method action binding contains `NamedData` elements for the parameter. This element is bound to the value specified when you created the action binding. [Example 28–1](#) shows the method action binding created when you drop the `updateItemInCart(Integer, Integer, Boolean)` method, and bind the `Integer` parameter (named `productId`) and the other `Integer` parameter (named `quantity`) and the `Boolean` parameter (named `isSet`) to the appropriate variables.

Example 28–1 Method Action Binding for a Parameter Method

```
<methodAction id="updateItemInCart"
    InstanceName="StoreServiceAMDataControl.dataProvider"
    DataControl="StoreServiceAMDataControl"
    RequiresUpdateModel="true" Action="invokeMethod"
    MethodName="updateItemInCart" IsViewObjectMethod="false">
    <NamedData NDName="productId" NDType="java.lang.Integer"/>
    <NamedData NDName="quantity" NDType="java.lang.Integer"/>
    <NamedData NDName="isSet" NDType="java.lang.Boolean"/>
</methodAction>
```

28.2.2.3 Adding ADF Faces Component Code to JSF Page

JDeveloper adds code for the ADF Faces component to the JSF page. This code is the same as code for any other command button, as described in [Section 26.4.2.3, "EL Expressions Used to Bind to Navigation Operations."](#) However, instead of being bound to the `execute` method of the action binding for a built-in operation, the button is bound to the `execute` method of the method action binding for the method that was dropped.

28.2.2.4 Using EL Expressions to Bind to Methods

Like creating command buttons using operations, when you create a command button using a method, JDeveloper binds the button to the method using the

`actionListener` attribute. The button is bound to the `execute` property of the action binding for the given method using an EL expression. This EL expression causes the binding's method to be invoked on the application module. For more information about the command button's `actionListener` attribute, see [Section 26.4.3, "What Happens at Runtime: How Action Events and Action Listeners Work."](#)

Tip: Instead of binding a button to the `execute` method on the action binding, you can bind the button to the method in a backing bean that overrides the `execute` method. Doing so allows you to add logic before or after the original method runs. For more information, see [Section 28.4, "Overriding Declarative Methods."](#)

Like navigation operations, the `disabled` property on the button uses an EL expression to determine whether or not to display the button. [Example 28–2](#) shows the EL expression used to bind the command button to the `updateItemInCart(Integer, Integer, Boolean)` method.

Example 28–2 JSF Code to Bind a Command Button to a Method

```
<af:commandButton actionListener="#{bindings.updateItemInCart.execute}"
    text="updateItemInCart"
    disabled="#{!bindings.updateItemInCart.enabled}"/>
```

Tip: When you drop a command button component onto the page, JDeveloper automatically gives it an ID based on the number of the same type of component that was previously dropped. For example, `commandButton1`, `commandButton2`. If you change the ID to something more descriptive, you must manually update any references to it in any EL expressions in the page.

28.2.2.5 Using the Return Value from a Method Call

You can also use the return value from a method call. [Example 28–3](#) shows a custom method that returns a string value.

Example 28–3 Custom Method That Returns a Value

```
/**
 * Custom method.
 */
public String getHelloString() {
    return ("Hello World");
}
```

[Example 28–4](#) shows the code in the JSF page for the command button and an `outputText` component.

Example 28–4 Command Button to Call the Custom Method

```
<af:commandButton actionListener="#{bindings.getHelloString.execute}"
    text="getHelloString"
    disabled="#{!bindings.getHelloString.enabled}"
    id="helloButtonId"/>
<af:outputText value="#{bindings.return.inputValue}"
    id="helloOutputId"/>
```

When the user clicks the command button, it calls the custom method. The method returns the string "Hello World" to be shown as the value of the `outputText` component.

28.2.3 What Happens at Runtime: Command Button Method Bindings

When the user clicks the button, the method binding causes the associated method to be invoked, passing in the value bound to the `NamedData` element as the parameter. For example, if a user clicks a button bound to the `updateItemInCartItem(Integer, Integer, Boolean)` method, the method takes the values of the product `Id` and quantity and updates the shopping cart.

28.3 Setting Parameter Values Using a Command Component

There may be cases where an action on one page needs to set parameters that will be used to determine application functionality. For example, you can create a search command button on one page that will navigate to a results table on another page. But the results table will display only if a parameter value is `false`.

You can use a managed bean to pass this parameter between the pages, and to contain the method that is used to check the value of this parameter. The managed bean is instantiated as the search page is rendered, and a method on the bean checks that parameter. If it is `null` (which it will be the first time the page is rendered), the bean sets the value to `true`.

For more information about creating custom methods, see [Section 9.7, "Customizing an Application Module with Service Methods,"](#) and [Section 9.9, "Publishing Custom Service Methods to UI Clients."](#)

Note: If you are using task flows, you can use the task flow parameter passing mechanism. For more information, see [Chapter 20, "Using Parameters in Task Flows."](#)

A `setPropertyListener` component with `type` property set to `action`, which is nested in the command button that executed this search, is then used to set this flag to `false`, thus causing the results table to display once the search is executed. For information about using managed beans, see [Section 24.4, "Using a Managed Bean in a Fusion Web Application."](#)

28.3.1 How to Set Parameters Using `setPropertyListener` Within a Command Component

You can use the `setPropertyListener` component to set values on other objects. This component must be a child of a command component.

Before you begin:

It may be helpful to have an understanding of how `setPropertyListener` and managed bean can be used to set a value. For more information, see [Section 28.3, "Setting Parameter Values Using a Command Component."](#)

You may also find it helpful to understand functionality that can be added using other command components. For more information, see [Section 28.1.2, "Additional Functionality for Command Components."](#)

You will need to complete this task:

Create a command component on the page.

To use the `setPropertyListener` component:

1. In the Component Palette, from the Operations panel, drag a `setPropertyListener` component and drop it as a child to the command component.

Or right-click the component and select **Insert inside Button > ADF Faces > `setPropertyListener`**.

2. In the Insert Set Property Listener dialog, enter the parameter value in the **From** field.
3. Enter the parameter target in the **To** field.

Tip: Consider storing the parameter value on a managed bean or in scope instead of setting it directly on the resulting page's page definition file. By setting it directly on the next page, you lose the ability to easily change navigation in the future. For more information, see [Section 24.4, "Using a Managed Bean in a Fusion Web Application."](#) Additionally, the data in a binding container is valid only during the request in which the container was prepared. The data may change between the time you set it and the time the next page is rendered.

4. From the **Type** dropdown menu, select **Action**.
5. Click **OK**.

28.3.2 What Happens When You Set Parameters

The `setPropertyListener` component lets the command component set a value before it navigates to the next page. When you set the `from` attribute either to the source of the value you need to pass or to the actual value, the component will be able to access that value. When you set the `to` attribute to a target, the command component is able to set the value on the target. [Example 28–5](#) shows the code on the JSF page for a command component that takes the value `false` and sets it as the value of the `initialSearch` flag on the `searchResults` managed bean.

Example 28–5 JSF Page Code for a Command Button Using a `setPropertyListener` Component

```
<af:commandButton actionListener="#{bindings.Execute.execute}"
  text=Search>
  <af:setPropertyListener from="#{false}"
    to="#{searchResults.initialSearch}"/>
  type="action"/>
</af:commandButton>
```

28.3.3 What Happens at Runtime: `setPropertyListener` for a Command Component

When a user clicks the command component, before navigation occurs, the `setPropertyListener` component sets the parameter value. In [Example 28–4](#), the `setPropertyListener` takes the value `false` and sets it as the value for the `initialSearch` attribute on the `searchResults` managed bean. Now, any component that needs to know this value in determining whether or not to render can access it using the EL expression `#{searchResults.initialSearch}`.

28.4 Overriding Declarative Methods

When you drop an operation or method as a command button, JDeveloper binds the button to the `execute` method for the operation or method. However, there may be occasions when you need to add logic before or after the existing logic.

Note: If you are using task flows, you can call custom methods from the task flow. For more information, see [Section 18, "Getting Started with ADF Task Flows."](#)

JDeveloper allows you to add logic to a declarative operation by creating a new method and property on a managed bean that provides access to the binding container. By default, this generated code executes the operation or method. You can then add logic before or after this code. JDeveloper automatically binds the command component to this new method, instead of to the `execute` property on the original operation or method. Now when the user clicks the button, the new method is executed.

For example, in the Fusion Order Demo application Orders page, the `Commit` operation requires additional processing. The **Commit** button is renamed to **Submit Orders** and logic is added to the `submitOrders` method in the `orderPageBean` managed bean.

In order to override a declarative method, you must have a managed bean to hold the new method to which the command component will be bound. If your page has a backing bean associated with it, JDeveloper adds the code needed to access the binding object to this backing bean. If your page does not have a backing bean, JDeveloper asks you to create one.

28.4.1 How to Override a Declarative Method

You can add a command component and override its declarative methods using a managed bean.

Before you begin:

It may be helpful to have an understanding of how to override declarative methods. For more information, see [Section 28.4, "Overriding Declarative Methods."](#)

You may also find it helpful to understand functionality that can be added using other command components. For more information, see [Section 28.1.2, "Additional Functionality for Command Components."](#)

You will need to complete this task:

Create the method that will override the declarative method in a managed bean. Operations are available by default.

Note: You cannot override the declarative method if the command component currently has an EL expression as its value for the `Action` attribute, because JDeveloper will not overwrite an EL expression. You must remove this value before continuing.

To override a declarative method:

1. Drag the operation or method to be overridden onto the JSF page and drop it as a UI command component.

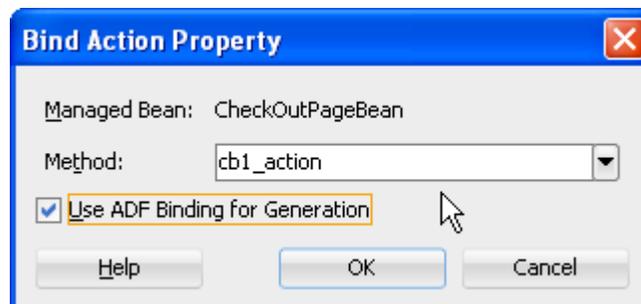

The component is created and bound to the associated binding object in the ADF Model layer with the `ActionListener` attribute.

For more information about creating command components using methods on the Data Controls panel, see [Section 28.2, "Creating Command Components to Execute Methods."](#)

For more information about creating command components from operations, see [Section 26.4.2, "What Happens When You Create Command Buttons."](#)

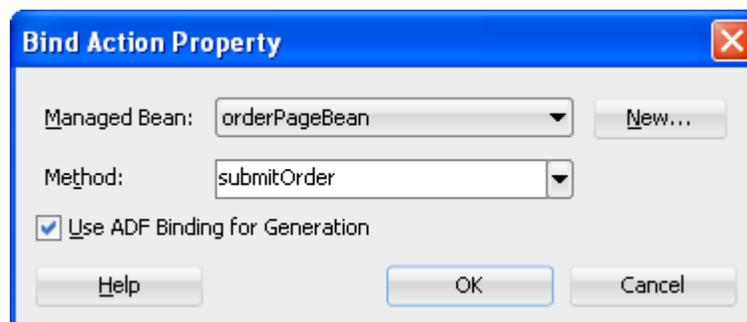

2. On the JSF page, double-click the component.
3. In the Bind Action Property dialog, identify the backing bean and the method to which you want to bind the component, using one of the following techniques:
 - If auto-binding has been enabled on the page, the backing bean is already selected for you, as shown in [Figure 28–2](#).

Figure 28–2 Bind Action Property Dialog for a Page with Auto-Binding Enabled

- To create a new method, enter a name for the method in the **Method** field, which initially displays a default name.
- or
- To use an existing method, select a method from the dropdown list in the **Method** field.
- Select **Use ADF Binding for Generation**.
- If the page is not using auto-binding, you can select from an existing backing bean or create a new one, as shown in [Figure 28–3](#).

Figure 28–3 Bind Action Property Dialog for a Page with Auto-Binding Disabled

- Click **New** to create a new backing bean. In the Create Managed Bean dialog, name the bean and the class, and set the bean's scope.
- or

- Select an existing backing bean and method from the dropdown lists.

Note: Whenever there is a value for the `ActionListener` attribute on the command component, JDeveloper understands that the button is bound to the `execute` property of a binding. If you have removed that binding, you will not be given the choice to generate the ADF binding code. You will need to insert the code manually, or to set a dummy value for the `ActionListener` before double-clicking the command component.

4. After identifying the backing bean and method, click **OK** in the Bind Action Property dialog

JDeveloper opens the managed bean in the source editor. [Example 28–6](#) shows the code inserted into the bean. In this example, a command button is bound to the `Commit` operation.

Example 28–6 Generated Code in a Backing Bean to Access the Binding Object

```
public String submitOrder() {
    BindingContainer bindings = getBindings();
    OperationBinding operationBinding =
        bindings.getOperationBinding("Commit");
    Object result = operationBinding.execute();
    if (!operationBinding.getErrors().isEmpty()) {
        return null;
    }
}
```

5. You can now add logic either before or after the binding object is accessed, as shown in [Example 28–7](#).

Example 28–7 Code Added to the Overridden Method

```
public String submitOrder() {
    DCBindingContainer bindings =
        (DCBindingContainer)JSFUtils.resolveExpression("#{bindings}");
    OperationBinding operationBinding =
        bindings.getOperationBinding("Commit");
    JUCtrlAttrsBinding statusCode =
        (JUCtrlAttrsBinding)bindings.findNamedObject("OrderStatusCode");
    statusCode.setAttribute("OrderStatusCode", "PENDING");
    JUCtrlAttrsBinding orderDate =
        (JUCtrlAttrsBinding)bindings.findNamedObject("OrderDate");
    orderDate.setAttribute("OrderDate", new Date());
    JUCtrlAttrsBinding orderId =
        (JUCtrlAttrsBinding)bindings.findNamedObject("OrderId");
    JSFUtils.storeOnSession("orderId", orderId.getAttribute("OrderId"));
    JUCtrlAttrsBinding invoiceTotal =
        (JUCtrlAttrsBinding)bindings.findNamedObject("InvoiceTotal");
    JUCtrlAttrsBinding orderTotal =
        (JUCtrlAttrsBinding)bindings.findNamedObject("OrderTotal");
    orderTotal.setAttribute("OrderTotal",
        invoiceTotal.getAttribute("InvoiceTotal"));
    Object result = operationBinding.execute();
    ShoppingCartBean shoppingCartBean =
        (ShoppingCartBean)JSFUtils.resolveExpression("#{shoppingCartBean}");
    shoppingCartBean.removeAllItems();
}
```

```

        return "orderSummary";
    }

```

The code in [Example 28–7](#) uses the FOD utility method `JSFUtils.resolveExpression` to resolve EL expressions. The code for such a method would be similar to the code in [Example 28–8](#).

Example 28–8 Utility Method to Solve EL Expressions

```

public static Object resolveExpression(String expression) {
    FacesContext facesContext = getFacesContext();
    Application app = facesContext.getApplication();
    ExpressionFactory elFactory = app.getExpressionFactory();
    ELContext elContext = facesContext.getELContext();
    ValueExpression valueExp =
        elFactory.createValueExpression(elContext, expression, Object.class);
    return valueExp.getValue(elContext);
}

```

In addition to any processing logic, you may also want to write conditional logic to return one of multiple outcomes. For example, you might want to return `null` if there is an error in the processing, or another outcome value if the processing was successful. A return value of `null` causes the navigation handler to forgo evaluating navigation cases and to immediately redisplay the current page.

Tip: To trigger a specific navigation case, the outcome value returned by the method must exactly match the outcome value in the navigation rule, including case.

The command button is now bound to this new method using the `Action` attribute instead of the `ActionListener` attribute. If a value had previously existed for the `Action` attribute (such as an outcome string), that value is added as the return for the new method. If there was no value, the return is kept as `null`.

28.4.2 What Happens When You Override a Declarative Method

When you override a declarative method, JDeveloper adds a managed property to your backing bean with the managed property value of `#{bindings}` (the reference to the binding container), and it adds a strongly typed bean property to your class of the `BindingContainer` type, which the JSF runtime will then set with the value of the managed property expression `#{bindings}`. JDeveloper also adds logic to the UI command action method. This logic includes the strongly typed `getBindings()` method used to access the current binding container.

The code does the following:

- Accesses the binding container.
- Finds the binding for the associated method, and executes it.
- Adds a return for the method that can be used for navigation. By default, the return is `null`. If an outcome string had previously existed for the button's `Action` attribute, that attribute is used as the return value. You can change this code as needed.

JDeveloper automatically rebinds the UI command component to the new method using the `Action` attribute, instead of the `ActionListener` attribute. [Example 28–9](#) shows the code when a `Commit` operation is declaratively added to a page.

Example 28–9 JSF Page Code for a Command Button Bound to a Declarative Method

```
<af:commandButton actionListener="#{bindings.Commit.execute}"
    text="Commit"
    disabled="#{!bindings.Commit.enabled}"/>
```

[Example 28–10](#) shows the code after the method on the page's backing bean is overridden. Note that the `action` attribute is now bound to the backing bean's method.

Example 28–10 JSF Page Code for a Command Button Bound to an Overridden Method

```
<af:commandButton text="#{res['order.cart.submit']}"
    action="#{orderPageBean.submitOrder}"/>
```

Tip: If when you click the button that uses the overridden method you receive this error:

```
SEVERE: Managed bean main_bean could not be created
The scope of the referenced object: '#{bindings}' is
shorter than the referring object
```

it is because the managed bean that contains the overriding method has a scope that is greater than `request` (that is, either `session` or `application`). Because the data in the binding container referenced in the method has a scope of `request`, the scope of this managed bean must be set to the same or a lesser scope.

Displaying Master-Detail Data

This chapter describes how to create various types of pages that display master-detail related data.

This chapter includes the following sections:

- [Section 29.1, "About Displaying Master-Detail Data"](#)
- [Section 29.2, "Common Functionality for Master-Detail Tables, Forms, and Trees"](#)
- [Section 29.3, "Using Tables and Forms to Display Master-Detail Objects"](#)
- [Section 29.4, "Using Trees to Display Master-Detail Objects"](#)
- [Section 29.5, "Using Tree Tables to Display Master-Detail Objects"](#)
- [Section 29.6, "Using Selection Events with Trees and Tables"](#)

For information about using a selection list to populate a collection with a key value from a related master or detail collection, see [Chapter 30, "Creating Databound Selection Lists and Shuttles"](#).

29.1 About Displaying Master-Detail Data

In ADF Business Components, a master-detail relationship refers to two view object instances that are related by a view link. As described in [Section 5.1, "About View Objects"](#), a view link represents the relationship between two view objects, which is usually, but not necessarily, based on a foreign-key relationship between the underlying data tables. The view link associates a row of one view object instance (the master object) with one or more rows of another view object instance (the detail object).

To display master-detail data on a page using ADF data binding, you exclusively use data model view link instances, which support master-detail coordination. When using ADF Business Components in combination with the ADF Model layer and ADF Faces UI components, the data model automatically updates to reflect any changes to the row sets of these business objects.

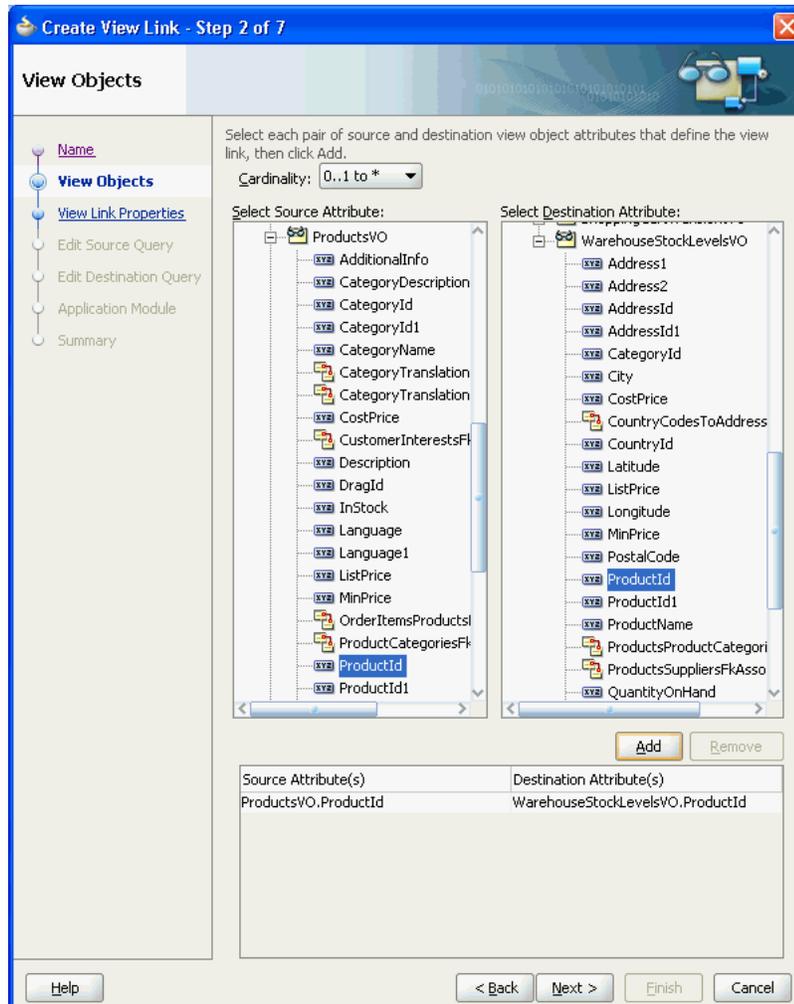

There are many instances where data needs to be presented in a hierarchical manner. In a master-detail relationship, when the user changes the selected item in the master object, the data set displayed in the detail object changes with it. For example, selecting the television categories in the master object would display all the models of televisions in the detail object.

Master-detail tables, forms, trees, and tree tables provide an excellent way to display hierarchical data.

29.1.1 Master-Detail Tables, Forms, and Trees Use Cases and Examples

To enable master-detail coordination, you must add both the master view object and the detail view object instances to the application module data model. For example, in the Fusion Order Demo application, there is a view link from the `ProductsVO` view object to the `WarehouseStockLevelsVO` view object based on the `ProductId` attribute, both contained in the application module data model, as shown in [Figure 29–1](#). A change in the current row of the master view object instance causes the row set of the detail view object instance to refresh to include the details for the current master.

Figure 29–1 View Link between Products and WarehouseStockLevels View Objects

When objects have a master-detail relationship, you can declaratively create pages that display the data from both objects simultaneously. For example, the page shown in [Figure 29–2](#) displays a country code in a form at the top of the page and its related states and provinces in a table at the bottom of the page. This is possible because the objects have a master-detail relationship. In this example, the `Country Code` is the master object and `States` is the detail object. ADF iterators automatically manage the synchronization of the detail data objects displayed for a selected master data object. Iterator bindings simplify building user interfaces that allow scrolling and paging through collections of data and drilling-down from summary to detail information.

You display master and detail objects in forms and tables. The master-detail form can display these objects on separate pages. For example, you can display the master object in a table on one page and detail objects in a read-only form on another page.

Note: There are some cases when the master-detail UI components that JDeveloper provides cannot provide the functionality you require. For example, you may need to bind components programatically instead of using the master-detail UI components.

A master object can have many detail objects, and each detail object can in turn have its own detail objects, down to many levels of depth. If one of the detail objects in this hierarchy is dropped from the Application Navigator as a master-detail form on a page, only its immediate parent master object displays on the page. The hierarchy will not display all the way up to the topmost parent object.

If you display the detail object as a tree or tree table object, it is possible to display the entire hierarchy with multiple levels of depth, starting with the topmost master object, and traversing detail children objects at each node.

Figure 29–3 shows an example of a master form with detail table. When the user navigates through the departments using the command buttons, the table lists the employees in that department.

Figure 29–3 Master Form Detail Table

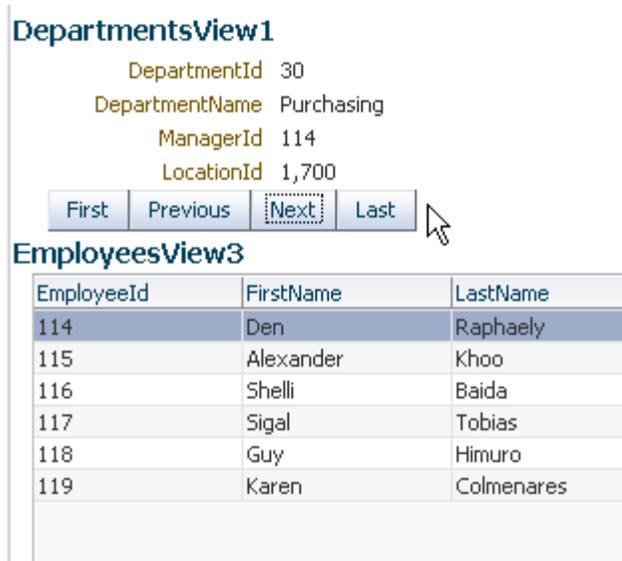

Figure 29–4 shows a tree that has multiple levels of nodes. You can use trees to display hierarchical information. In this example, a tree is used to display the folders and items in file system. The user can expand nodes to traverse down a branch of the tree to access the leaf items.

Figure 29–4 Multi-level Tree

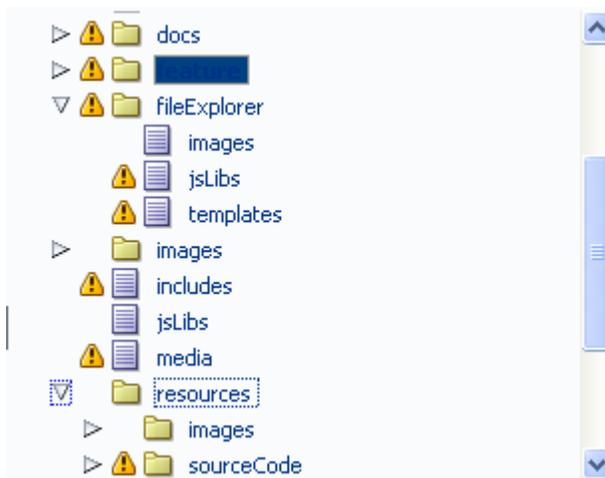

Figure 29–5 show the same file structure displayed using a tree table instead of a tree. In addition to the hierarchical node levels of a tree, a tree table can also display column information for each node. You can also focus on subtrees as well as collapsing and expanding the elements.

Figure 29–5 Tree Table

29.1.2 Additional Functionality for Master-Detail Tables, Forms, and Trees

You may find it helpful to understand other ADF features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- For information about adding master-detail objects to the data model, see [Section 5.6.4, "How to Enable Active Master-Detail Coordination in the Data Model."](#)
- For information about the icons displayed on the Data Controls panel, see ["Section 13.4.1, "How to Use the Data Controls Panel."](#)
- If you want to modify the default forms or tables, see [Section 26.3, "Creating a Basic Form"](#) or [Section 27.2, "Creating a Basic Table."](#)
- For more information about creating view links, see [Section 5.6.6, "How to Access the Detail Collection Using the View Link Accessor."](#)
- For more information about creating and using managed beans, see [Section 24.4, "Using a Managed Bean in a Fusion Web Application."](#)
- For more information about creating listener methods, see the "Using ADF Faces Server Events" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- For more information about finding the event source component, see the "How to Return the Original Source of the Event" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

29.2 Common Functionality for Master-Detail Tables, Forms, and Trees

Master-Detail tables, forms, trees, and tree tables requires a master-detail relationship to be established in the model. When a master-detail relationship is present, it is reflected in the Data Controls panel.

29.2.1 Identifying Master-Detail Objects on the Data Controls Panel

You can declaratively create pages that display master-detail data using the Data Controls panel. The Data Controls panel displays master-detail related objects in a hierarchy that mirrors the one you defined in the application module data model, where the detail objects are children of the master objects. For information about adding master-detail objects to the data model, see [Section 5.6.4, "How to Enable Active Master-Detail Coordination in the Data Model."](#)

To display master-detail objects as form or table objects, drag the detail object from the Data Controls panel and drop it on the page. Its master object is automatically created on the page.

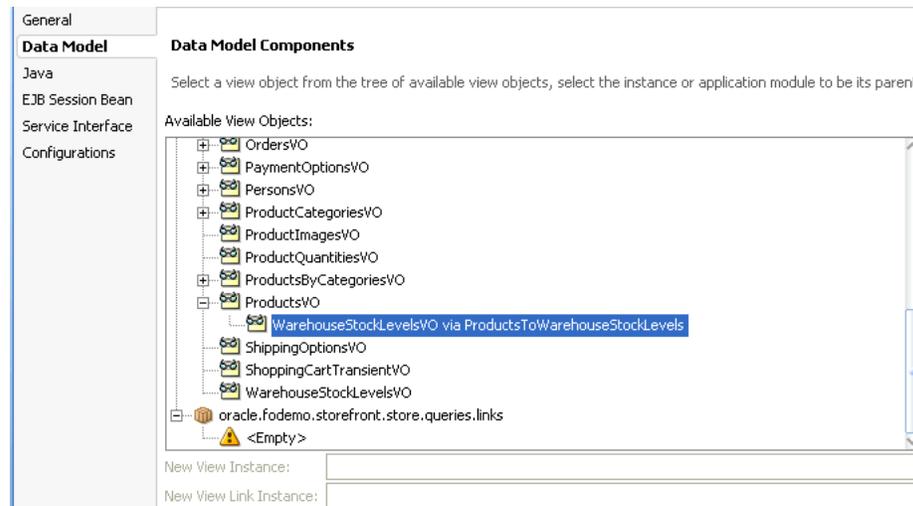

[Figure 29–6](#) shows two master-detail related collections in the Data Controls panel of the Fusion Order Demo application. The `Products` collection is an instance of the `ProductsVO` view object, and the `WarehouseStockLevels` collection, which appears as a child of the `Products` collection, is an instance of the `WarehouseStockLevelsVO` view object.

Note: The master-detail hierarchy displayed in the Data Controls panel does not reflect the cardinality of the relationship (that is, one-to-many, one-to-one, many-to-many). The hierarchy simply shows which collection (the master) is being used to retrieve one or more objects from another collection (the detail).

Figure 29–6 Master-Detail Objects in the Data Controls Panel

The master-detail hierarchy on the Data Controls panel reflects the hierarchy defined in the application module data model, as shown in [Figure 29–7](#). The hierarchy was established by creating a view link from the `ProductsVO` view object to the `WarehouseStockLevelsVO` view object. Next, an instance of the resulting detail view object, `WarehouseStockLevelsVO` via `ProductsToWarehouseStockLevels`, was added to the application module data model shown in [Figure 29–7](#).

Figure 29–7 Master-Detail Hierarchy Defined in the Application Module Data Model

In the Fusion Order Demo application, the view link between the `ProductsVO` view object and `WarehouseStockLevelsVO` view object is a one-way relationship. If the view link were bidirectional and both sets of master and detail view objects were added to the application module data model, then the Data Controls panel would also display the `WarehouseStockLevelsVO` collection at the same node level as the `Products` collection, and the detail instance of the `Products` collection as a child of the `WarehouseStockLevelsVO` collection.

Tip: By default, when you define a view link using the Create View Link wizard, the source view object is the master and the destination view object is the detail. However, if you choose to generate accessors in both the source and the destination view objects, then the master-detail relationship is bidirectional. If both sets of master-detail view objects resulting from a bidirectional view link are added to the application module data model, then instances of both sets of view objects will appear independently on the Data Controls panel.

For more information about the icons displayed on the Data Controls panel, see ["Section 13.4.1, "How to Use the Data Controls Panel."](#)

29.3 Using Tables and Forms to Display Master-Detail Objects

You can create a master-detail browse page in a single declarative action using the Data Controls panel. All you have to do is drop the detail collection on the page and choose the type of widget you want to use.

The prebuilt master-detail widgets available from the Data Controls panel include range navigation that enables the end user to scroll through the data objects in collections. You can delete unwanted attributes by removing the text field or column from the page.

[Figure 29–8](#) shows an example of prebuilt master-detail widget, which displays products information in a form at the top of the page and stock levels in a table at the bottom of the page. When the user clicks the **Next** button to scroll through the records in the master data at the top of the page, the page automatically displays the related detail data.

29.3.1 How to Display Master-Detail Objects in Tables and Forms

If you do not want to use the prebuilt master-detail widgets, you can drag and drop the master and detail objects individually from the Data Controls panel as tables and forms on a single page or on separate pages.

The Data Controls panel enables you to create both the master and detail widgets on one page with a single declarative action using prebuilt master-detail forms and tables. For information about displaying master and detail data on separate pages, see [Section 29.3.4, "What You May Need to Know About Displaying Master-Detail Widgets on Separate Pages."](#)

Before you begin:

It may help to understand the options that are available to you when you create a master-detail table and form. For more information, see [Section 29.3, "Using Tables and Forms to Display Master-Detail Objects."](#)

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see [Section 29.1.2, "Additional Functionality for Master-Detail Tables, Forms, and Trees."](#)

To create a master-detail page using the prebuilt ADF master-detail forms and tables:

1. From the Data Controls panel, locate the detail object, as described in [Section 29.2.1, "Identifying Master-Detail Objects on the Data Controls Panel."](#)
2. Drag and drop the detail object onto the JSF page.

Note: If you want to create an editable master-detail form, drop the master object and the detail object separately on the page.

3. In the context menu, choose one of the following **master-detailsUI** components:

- **ADF Master Table, Detail Form:** Displays the master objects in a table and the detail objects in a read-only form under the table.

When a specific data object is selected in the master table, the first related detail data object is displayed in the form below it. The user must use the form navigation to scroll through each subsequent detail data object.

- **ADF Master Form, Detail Table:** Displays the master objects in a read-only form and the detail objects in a read-only table under the form.

When a specific master data object is displayed in the form, the related detail data objects are displayed in a table below it.

- **ADF Master Form, Detail Form:** Displays the master and detail objects in separate forms.

When a specific master data object is displayed in the top form, the first related detail data object is displayed in the form below it. The user must use the form navigation to scroll through each subsequent detail data object.

- **ADF Master Table, Detail Table:** Displays the master and detail objects in separate tables.

When a specific master data object is selected in the top table, the first set of related detail data objects is displayed in the table below it.

If you want to modify the default forms or tables, see [Section 26.3, "Creating a Basic Form"](#) or [Section 27.2, "Creating a Basic Table."](#)

29.3.2 What Happens When You Create Master-Detail Tables and Forms

When you drag and drop a collection from the Data Controls panel, JDeveloper does many things for you, including adding code to the JSF page and the corresponding entries in the page definition file. For a full description of what happens and what is created when you use the Data Controls panel, see [Section 13.4.1, "How to Use the Data Controls Panel."](#)

29.3.2.1 Code Generated in the JSF Page

The JSF code generated for a prebuilt master-detail widget is similar to the JSF code generated when you use the Data Controls panel to create a read-only form or table. If you are building your own master-detail widgets, you might want to consider including similar components that are automatically included in the prebuilt master-detail tables and forms.

The tables and forms in the prebuilt master-detail widgets include a `panelHeader` tag that contains the fully qualified name of the data object populating the form or table. You can change this label as needed using a string or an EL expression that binds to a resource bundle.

If there is more than one data object in a collection, a form in a prebuilt master-detail widget includes four `commandButton` tags for range navigation: `First`, `Previous`, `Next`, and `Last`. These range navigation buttons enable the user to scroll through the data objects in the collection. The `actionListener` attribute of each button is bound to a data control operation, which performs the navigation. The `execute` property used in the `actionListener` binding, invokes the operation when the button is clicked. (If the form displays a single data object, JDeveloper automatically omits the range navigation components.) For more information about range navigation, see [Section 26.4, "Incorporating Range Navigation into Forms."](#)

Tip: If you drop an **ADF Master Table, Detail Form** or **ADF Master Table, Detail Table** widget on the page, the parent tag of the detail component (for example, `panelHeader` tag or `table` tag) automatically has the `partialTriggers` attribute set to the `id` of the master component (see [Section 27.4.1, "How to Create an Input Table"](#) for more information about partial triggers). At runtime, the `partialTriggers` attribute causes only the detail component to be rerendered when the user makes a selection in the master component, which is called *partial rendering*. When the master component is a table, ADF uses partial rendering, because the table does not need to be rerendered when the user simply makes a selection in the facet. Only the detail component needs to be rerendered to display the new data.

29.3.2.2 Binding Objects Defined in the Page Definition File

[Example 29–1](#) shows the page definition file created for a master-detail page that was created by dropping the `WarehouseStockLevels` collection, which is a detail object under the `Products` object, on the page as an **ADF Master Form, Detail Table**.

The `executables` element defines two iterators: one for the product (the master object) and one for the `WarehouseStockLevels` (the detail object). The underlying view link from the master view object to the detail view object establishes the relationship between the two iterators. At runtime, the ADF data model and the row set iterator for the detail view object instance keep the row set of the detail view object refreshed to the correct set of rows for the current master row as that current row changes (for more information, see [Section 29.3.3, "What Happens at Runtime: ADF Iterator for Master-Detail Tables and Forms"](#)).

The `bindings` element defines the value bindings for the form and the table. The attribute bindings that populate the text fields in the form are defined in the `attributeValues` elements. The `id` attribute of the `attributeValues` element contains the name of each data attribute, and the `IterBinding` attribute references an iterator binding to display data from the master object in the text fields.

The attribute bindings that populate the text fields in the form are defined in the `attributeValues` elements. The `id` attribute of the `attributeValues` element contains the name of each data attribute, and the `IterBinding` attribute references an iterator binding to display data from the master object in the text fields.

The range navigation buttons in the form are bound to the action bindings defined in the `action` elements. As in the attribute bindings, the `IterBinding` attribute of the action binding references the iterator binding for the master object.

The table, which displays the detail data, is bound to the table binding object defined in the `table` element. The `IterBinding` attribute references the iterator binding for the detail object.

For more information about the elements and attributes of the page definition file, see [Section A.8, "pageNamePageDef.xml."](#)

Example 29–1 Binding Objects Defined in the Page Definition for a Master-Detail Page

```
<executables>
  <iterator Binds="Products" RangeSize="25"
    DataControl="StoreServiceAMDataControl" id="ProductsIterator"/>
  <iterator Binds="WarehouseStockLevels" RangeSize="25"
    DataControl="StoreServiceAMDataControl"
    id="WarehouseStockLevelsIterator"/>
</executables>
```

```

<bindings>
  <methodAction id="findHelpTextById" RequiresUpdateModel="true"
    Action="invokeMethod" MethodName="findHelpTextById"
    IsViewObjectMethod="false"
    DataControl="LookupServiceAMDataControl"
    InstanceName="LookupServiceAMDataControl.dataProvider"
    ReturnName="LookupServiceAMDataControl.methodResults.
      findHelpTextById_LookupServiceAMDataControl_
      dataProvider_findHelpTextById_result">
    <NamedData NDName="helpId" NDType="java.lang.Long"
      NDOption="2"/>
  </methodAction>
  <tree IterBinding="ProductsIterator" id="Products">
    <nodeDefinition DefName="oracle.fodemo.storefront.store.queries.ProductsVO">
      <AttrNames>
        <Item Value="ProductId"/>
        <Item Value="SupplierId"/>
        <Item Value="CategoryId"/>
        <Item Value="ProductName"/>
        ...
        <Item Value="CostPrice"/>
        <Item Value="DragId"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
  <tree IterBinding="WarehouseStockLevelsIterator" id="WarehouseStockLevels">
    <nodeDefinition DefName="oracle.fodemo.storefront.store.
      queries.WarehouseStockLevelsVO">
      <AttrNames>
        <Item Value="ProductId"/>
        <Item Value="WarehouseId"/>
        ...
        <Item Value="ShippingClassCode"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>

```

29.3.3 What Happens at Runtime: ADF Iterator for Master-Detail Tables and Forms

At runtime, an ADF iterator determines which row from the master table object to display in the master-detail form. When the form first displays, the first master table object row appears highlighted in the master section of the form. Detail table rows that are associated with the master row display in the detail section of the form.

As described in [Section 29.3.2.2, "Binding Objects Defined in the Page Definition File,"](#) ADF iterators are associated with underlying `row setIterator` objects. These iterators manage which data objects, or rows, currently display on a page. At runtime, the row set iterators manage the data displayed in the master and detail components.

Both the master and detail row set iterators listen to row set navigation events, such as the user clicking the range navigation buttons, and display the appropriate row in the UI. In the case of the default master-detail components, the row set navigation events are the command buttons on a form (**First, Previous, Next, Last**).

The row set iterator for the detail collection manages the synchronization of the detail data with the master data. Because of the underlying view link from the master view

object to the detail view object, the detail row set iterator listens for row navigation events in both the master and detail collections. If a row set navigation event occurs in the master collection, the detail row set iterator automatically executes and returns the detail rows related to the current master row.

29.3.4 What You May Need to Know About Displaying Master-Detail Widgets on Separate Pages

The default master-detail components display the master-detail data on a single page. However, using the master and detail objects on the Data Controls panel, you can also display the collections on separate pages, and still have the binding iterators manage the synchronization of the master and detail objects.

For example, in the Fusion Order Demo application, a product table and product details are displayed on the home page. However, the page could display the product table only. It could provide a button called **Details**. If the user clicked the **Details** button, the application would navigate to a new page that displays all the related details in a list. A button on the list's page would enable the user to return to the service request page.

To display master-detail objects on separate pages, create two pages, one for the master object and one for the detail object, using the individual tables or forms available from the Data Controls panel. Remember that the detail object iterator manages the synchronization of the master and detail data. Be sure to drag the appropriate detail object from the Data Controls panel when you create the page to display the detail data. For more information, see [Section 29.2.1, "Identifying Master-Detail Objects on the Data Controls Panel."](#)

To handle the page navigation, create an ADF task flow, and then add two view activities to it, one for the master page and one for the detail page. (See [Section 18.2, "Creating a Task Flow"](#) for information about associating a View activity with an existing JSF page). Add command buttons or links to each page, or use the default **Submit** button available when you create a form or table using the Data Controls panel. Each button must specify a navigation rule outcome value in the `action` attribute. In the `task-flow-definition.xml` file, add a navigation rule from the master data page to the detail data page, and another rule to return from the detail data page to the master data page. The `from-outcome` value in the navigation rules must match the outcome value specified in the action attribute of the buttons. For information about adding navigation between pages, see [Section 18.2, "Creating a Task Flow."](#)

29.4 Using Trees to Display Master-Detail Objects

In addition to tables and forms, you can also display master-detail data in hierarchical trees. The ADF Faces `tree` component is used to display hierarchical data. It can display multiple root nodes that are populated by a binding on a master object. Each root node in the tree may have any number of branches, which are populated by bindings on detail objects. A tree can have multiple levels of nodes, each representing a detail object of the parent node. Each node in the tree is indented to show its level in the hierarchy.

The `tree` component includes mechanisms for expanding and collapsing the tree nodes; however, it does not have focusing capability. If you need to use focusing, consider using the ADF Faces `treeTable` component (for more information, see [Section 29.5, "Using Tree Tables to Display Master-Detail Objects"](#)). By default, the icon for each node in the tree is a folder; however, you can use your own icons for each level of nodes in the hierarchy.

Figure 29–9 shows an example of a tree located on the home . j s p x page of the Fusion Order Demo application. The tree displays two levels of nodes: root and branch. The root node displays parent product categories such as Media, Office, and Electronics. The branch nodes display and subcategories under each parent category, such as Hardware, Supplies, and Software under the Office parent category.

Figure 29–9 Databound ADF Faces Tree

29.4.1 How to Display Master-Detail Objects in Trees

A *tree* consists of a hierarchy of nodes, where each subnode is a branch off a higher level node. Each node level in a databound ADF Faces `tree` component is populated by a different data collection. In JDeveloper, you define a databound tree using the Edit Tree Binding dialog, which enables you to define the rules for populating each node level in the tree. There must be one rule for each node level in the hierarchy. Each rule defines the following node-level properties:

- The data collection that populates that node level
- The attributes from the data collection that are displayed at that node level
- A view link accessor attribute that returns a detail object to be displayed as a branch of the current node level (for information about view link accessors, see [Section 5.6.6.2, "Programmatically Accessing a Detail Collection Using the View Link Accessor"](#))

To create the Browse tree on the Fusion Order Demo home page shown in [Figure 29–9](#), a view object, `ParentProductCategories` was created to return a list of parent categories. Another view object, `ProductCategories` was created to return subcategories of products. A view link was created from the `ParentProductCategories` view object to the `ProductCategories` view object, thus establishing a master-detail relationship.

To add a third-level node, for example, a list of products under each subcategory, a view link would need to exist from the `ProductCategories` object to the `Products` view object. For more information about creating view links, see [Section 5.6.6, "How to Access the Detail Collection Using the View Link Accessor."](#)

In the case where a branch of the tree is recursive, a single view object accompanied by a self-referential view link must be defined in the data model project. For example, in a collection defined by `EmployeesView`, the root node of each branch is specified by the `ManagerId` attribute and the child nodes of the same branch are the employees (also known as "direct reports") who are related to the `ManagerId`. The source and destination view object named by the self-referential view link are both defined as `EmployeesView` with the destination renamed to `DirectReports` for clarify. For more information about creating self-referential view links, see [Section 5.7.1, "How to Create a Recursive Master-Detail Hierarchy for an Entity-Based View Object."](#)

Before you begin:

It may help to understand the options that are available to you when you create a master-detail table and form. For more information, see [Section 29.4, "Using Trees to Display Master-Detail Objects."](#)

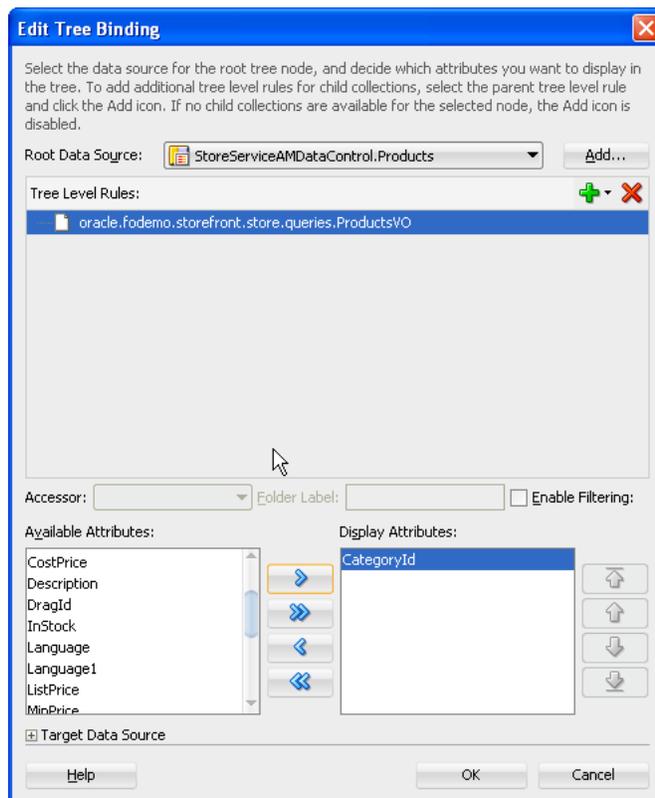

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see [Section 29.1.2, "Additional Functionality for Master-Detail Tables, Forms, and Trees."](#)

To display master-detail objects in a tree:

1. Drag the master object from the Data Controls panel, and drop it onto the page. This should be the master data that will represent the root level of the tree.
2. In the context menu, choose **Trees > ADF Tree**.

JDeveloper displays the Edit Tree Binding dialog, as shown in [Figure 29–10](#). You use the binding editor to define a rule for each level that you want to appear in the tree.

Figure 29–10 Edit Tree Binding Dialog

3. In the **Root Data Source** dropdown list, select the data collection that will populate the root node level. This will be the master data collection. By default, this is the same collection that you dragged from the Data Controls panel to create the tree, which was a master collection.

Tip: If you don't see the data collection you want in the **Root Data Source** list, click the **Add** button. In the Add Data Source dialog, select a data control and an iterator name to create a new data source.

4. Click the + icon to add the root data source you selected to the **Tree Level Rules** list.
5. In the **Tree Level Rules** list, select the data source you just added.
6. In the **Accessor** dropdown list, select a view link accessor attribute.

The list displays only the accessor attributes that return the detail collections for the master collection you selected. For example, if you are defining the `ParentProductCategories` node level and you want to add a detail level that displays all subcategories under each parent category, you would select the accessor attribute that returns the `ProductCategories` collection.

If you select `<none>`, the node will not expand to display any detail collections, thus ending the branch.

View link accessor attributes, which return data collections, are generated when you create a view link. The **Accessor** field displays all accessor attributes that return detail collections for the master collection selected in the **Tree Level Rules** list. For more information about view objects, view links, and view link accessors, see [Section 5.6.6, "How to Access the Detail Collection Using the View Link Accessor."](#)

7. Select an attribute in the **Available Attributes** list and move it to the **Display Attributes** list.

The attribute will be used to display nodes at the master level. For example, for the Parent Product Categories level, you might select the `Categories` attribute.

When you are finished, the Tree Binding Editor should contain values similar to those in [Figure 29–10](#).

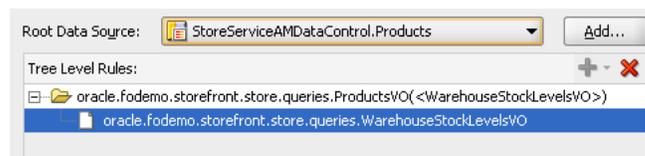

After defining a rule for the master level, you must next define a second rule for the detail level that will appear under the master level in the tree.

For example, in the sample tree shown in [Figure 29–9](#), the first rule added to the tree binding editor populates the parent category nodes (Media, Office, and Electronics). The detail level rule populates the product category nodes (for example, Hardware, Supplies, and Software under the Media parent category).'

8. To add a second rule, click the **Add** icon above the **Tree Level Rules** list.

A detail data source should appear automatically under the master data source, as shown in [Figure 29–11](#).

Figure 29–11 Master-Detail Tree Level Rules

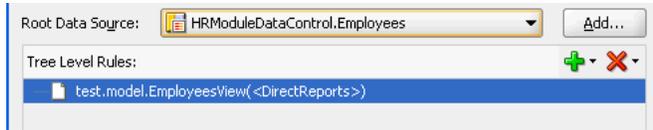

For example, if you specified `Products` as the master Root Data Source, `WarehouseStockLevels` will automatically appear underneath in the **Tree Level Rules** list, because the two data sources share a master-detail relationship.

If you are creating a tree with a recursive master-detail hierarchy, then you only need to define a rule that specifies a data source with a self accessor. A recursive tree displays root nodes based on a single collection and displays the child nodes from the attributes of a self accessor that recursively fetches data from that collection. The recursive tree differs from a typical master-detail tree because it

requires only a single rule to define the branches of the tree. A recursive data source should display the data source followed by the name of the self accessor in brackets, as shown in [Figure 29–12](#).

Figure 29–12 Recursive Tree Level Rule

For example, in a collection defined by `EmployeesView`, the root node of each branch could be specified by the `ManagerId` for the employee and the child nodes of the same branch are the employees who are related to the `ManagerId`, as specified by the self accessor `DirectReports`.

9. Click **OK**.
10. You can add data sources to the **Tree Level Rules** list to increase the number of nodes that display in the tree. The order of the remaining data sources should follow the hierarchy of the nodes you want to display in the tree.

29.4.2 What Happens When You Create an ADF Databound Tree

When you drag and drop from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see [Section 13.4.1, "How to Use the Data Controls Panel."](#)

When you create a databound tree using the Data Controls panel, JDeveloper adds binding objects to the page definition file, and it also adds the tree tag to the JSF Page. The resulting UI component is fully functional and does not require any further modification.

29.4.2.1 Code Generated in the JSF Page

[Example 29–2](#) shows the code generated in a JSF page when you use the Data Controls panel to create a tree. This sample tree displays two levels of nodes: parent product categories and product categories. The `ParentProductCategories` collection was used to populate the root node.

Example 29–2 Code Generated in the JSF Page for a Databound Tree

```
<af:tree id="productCategoriesTree" contentDelivery="immediate"
  selectionListener="#{homePageBean.
    productCategoriesTreeSelectionListener}"
  rowSelection="single"
  value="#{bindings.ParentProductCategories.treeModel}"
  var="node" initiallyExpanded="true">
  <f:facet name="nodeStamp">
    <af:panelGroupLayout>
      <af:outputText rendered="#{node.ParentCategoryId eq null}"
        value="#{node.CategoryName}"
        inlineStyle="color:#FF8000;font-weight:bold;"/>
      <af:outputText rendered="#{node.ParentCategoryId ne null}"
        value="#{node.CategoryName}"/>
    </af:panelGroupLayout>
  </f:facet>
</af:tree>
```

By default, the `af:tree` tag is created inside a form. The `value` attribute of the `tree` tag contains an EL expression that binds the `tree` component to the `ParentProductCategories` tree binding object in the page definition file. The `treeModel` property in the binding expression refers to an ADF class that defines how the `tree` hierarchy is displayed, based on the underlying data model. The `var` attribute provides access to the current node.

In the `f:facet` tag, the `nodeStamp` facet is used to display the data for each node. Instead of having a component for each node, the `tree` repeatedly renders the `nodeStamp` facet, similar to the way rows are rendered for the ADF Faces table component.

The ADF Faces `tree` component uses an instance of the `oracle.adf.view.faces.model.PathSet` class to display expanded nodes. This instance is stored as the `treeState` attribute on the component. You may use this instance to programmatically control the expanded or collapsed state of an element in the hierarchy. Any element contained by the `PathSet` instance is deemed expanded. All other elements are collapsed.

29.4.2.2 Binding Objects Defined in the Page Definition File

[Example 29-3](#) shows the binding objects defined in the page definition file for the ADF databound tree.

Example 29-3 Binding Objects Defined in the Page Definition File for a Databound Tree

```
<executables>
  <iterator Binds="ParentProductCategories" RangeSize="25"
    DataControl="StoreServiceAMDDataControl"
    id="ParentProductCategoriesIterator"/>
</executables>
<bindings>
  <tree IterBinding="ParentProductCategoriesIterator"
    id="ParentProductCategories">
    <nodeDefinition
      DefName="oracle.fodemo.storefront.store.queries.ProductCategoriesVO">
      <AttrNames>
        <Item Value="CategoryId"/>
      </AttrNames>
      <Accessors>
        <Item Value="ProductCategoriesVO"/>
        <Item Value="ParentCategoryIdProductCategoriesVO"/>
      </Accessors>
    </nodeDefinition>
  </tree>
</bindings>
```

The page definition file contains the rule information defined in the Tree Binding Editor. In the `executables` element, notice that although the tree displays two levels of nodes, only one iterator binding object is needed. This iterator iterates over the master collection, which populates the root nodes of the tree. The accessor you specified in the node rules returns the detail data for each branch node.

The `tree` element is the value binding for all the attributes displayed in the tree. The `iterBinding` attribute of the `tree` element references the iterator binding that populates the data in the tree. The `AttrNames` element within the `tree` element

defines binding objects for *all* the attributes in the master collection. However, the attributes that you select to appear in the tree are defined in the `AttrNames` elements within the `nodeDefinition` elements.

The `nodeDefinition` elements define the rules for populating the nodes of the tree. There is one `nodeDefinition` element for each node, and each one contains the following attributes and subelements:

- `DefName`: An attribute that contains the fully qualified name of the data collection that will be used to populate the node.
- `id`: An attribute that defines the name of the node.
- `AttrNames`: A subelement that defines the attributes that will be displayed in the node at runtime.
- `Accessors`: A subelement that defines the accessor attribute that returns the next branch of the tree.

The order of the `nodeDefinition` elements within the page definition file defines the order or level of the nodes in the tree, where the first `nodeDefinition` element defines the root node. Each subsequent `nodeDefinition` element defines a sub-node of the one before it.

For more information about the elements and attributes of the page definition file, see [Appendix A.8, "pageNamePageDef.xml."](#)

29.4.3 What Happens at Runtime: Displaying an ADF Databound Tree

Tree components use `org.apache.myfaces.trinidad.model.TreeModel` to access data. This class extends `CollectionModel`, which is used by the ADF Faces table component to access data. For more information about the `TreeModel` class, refer to the ADF Faces Javadoc.

When a page with a `tree` is displayed, the iterator binding on the tree populates the root nodes. When a user collapses or expands a node to display or hide its branches, a `DisclosureEvent` event is sent. The `isExpanded` method on this event determines whether the user is expanding or collapsing the node. The `DisclosureEvent` event has an associated listener.

The `DisclosureListener` attribute on the `tree` is bound to the accessor attribute specified in the node rule defined in the page definition file. This accessor attribute is invoked in response to the `DisclosureEvent` event; in other words, whenever a user expands the node the accessor attribute populates the branch nodes.

29.5 Using Tree Tables to Display Master-Detail Objects

Use the ADF Faces `treeTable` component to display a hierarchy of master-detail collections in a table. The advantage of using a `treeTable` component rather than a `tree` component is that the `treeTable` component provides a mechanism that enables users to focus the view on a particular node in the tree.

For example, you can create a tree table that displays three levels of nodes: countries, states or provinces, and cities. Each root node represents an individual country. The branches off the root nodes display the state or provinces in the country. Each state or province node branches to display the cities contained in it.

As with trees, to create a tree table with multiple nodes, it is necessary to create view links between the view objects. The view links establish the master-detail relationships. For example, to create a tree table with three levels of country, state, and city, it was

necessary to create view links from the `CountryCodes` object to the `StatesandProvinces` view object, and another view link from the `StatesandProvinces` view object to the `Cities` view object. For more information about creating view links, see [Section 5.6, "Working with Multiple Tables in a Master-Detail Hierarchy."](#)

A databound ADF Faces `treeTable` displays one root node at a time, but provides navigation for scrolling through the different root nodes. Each root node can display any number of branch nodes. Every node is displayed in a separate row of the table, and each row provides a focusing mechanism in the leftmost column.

You can edit the following `treeTable` component properties in the Property Inspector:

- Range navigation: The user can click the **Previous** and **Next** navigation buttons to scroll through the root nodes.
- List navigation: The list navigation, which is located between the **Previous** and **Next** buttons, enables the user to navigate to a specific root node in the data collection using a selection list.
- Node expanding and collapsing mechanism: The user can open or close each node individually or use the **Expand All** or **Collapse All** command links. By default, the icon for opening and closing the individual nodes is an arrowhead with a plus or minus sign. You can also use a custom icon of your choosing.
- Focusing mechanism: When the user clicks on the focusing icon (which is displayed in the leftmost column) next to a node, the page is redisplayed showing only that node and its branches. A navigation link is provided to enable the user to return to the parent node.

29.5.1 How to Display Master-Detail Objects in Tree Tables

The steps for creating an ADF Faces databound tree table are exactly the same as those for creating an ADF Faces databound tree, except that you drop the data collection as an **ADF Tree Table** instead of an **ADF Tree**.

29.5.2 What Happens When You Create a Databound Tree Table

When you drag and drop from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see [Section 13.4.1, "How to Use the Data Controls Panel."](#)

When you create a databound tree table using the Data Controls panel, JDeveloper adds binding objects to the page definition file, and it also adds the `treeTable` tag to the JSF Page. The resulting UI component is fully functional and does not require any further modification.

29.5.2.1 Code Generated in the JSF Page

[Example 29–4](#) shows the code generated in a JSF page when you use the Data Controls panel to create a tree table. This sample tree table displays two levels of nodes: products and stock levels.

By default, the `treeTable` tag is created inside a form. The `value` attribute of the tree table tag contains an EL expression that binds the tree component to the binding object that will populate it with data. The `treeModel` property refers to an ADF class that defines how the tree hierarchy is displayed, based on the underlying data model. The `var` attribute provides access to the current node.

Example 29–4 Code Generated in the JSF Page for a Databound ADF Faces Tree Table

```

<af:form>
  <af:treeTable value="#{bindings.Products.treeModel}" var="node"
    selectionListener="#{bindings.Products.treeModel.makeCurrent}"
    rowSelection="single">
    <f:facet name="nodeStamp">
      <af:column customizationId="column1">
        <af:outputText value="#{node}" />
      </af:column>
    </f:facet>
    <f:facet name="pathStamp">
      <af:outputText value="#{node}" />
    </f:facet>
  </af:treeTable>
</af:form>

```

In the `facet` tag, the `nodeStamp` facet is used to display the data for each node. Instead of having a component for each node, the tree repeatedly renders the `nodeStamp` facet, similar to the way rows are rendered for the ADF Faces `table` component. The `pathStamp` facet renders the column and the path links above the table that enable the user to return to the parent node after focusing on a detail node.

29.5.2.2 Binding Objects Defined in the Page Definition File

The binding objects created in the page definition file for a tree table are exactly the same as those created for a tree.

29.5.3 What Happens at Runtime: Events

Tree components use `oracle.adf.view.faces.model.TreeModel` to access data. This class extends `CollectionModel`, which is used by the ADF Faces `table` component to access data. For more information about the `TreeModel` class, refer to the ADF Faces Javadoc.

When a page with a tree table is displayed, the iterator binding on the `treeTable` component populates the root node and listens for a row navigation event (such as the user clicking the **Next** or **Previous** buttons or selecting a row from the range navigator). When the user initiates a row navigation event, the iterator displays the appropriate row.

If the user changes the view focus (by clicking on the component's focus icon), the `treeTable` component generates a focus event (`FocusEvent`). The node to which the user wants to change focus is made the current node before the event is delivered. The `treeTable` component then modifies the `focusPath` property accordingly. You can bind the `FocusListener` attribute on the tree to a method on a managed bean. This method will then be invoked in response to the focus event.

When a user collapses or expands a node, a disclosure event (`DisclosureEvent`) is sent. The `isExpanded` method on the disclosure event determines whether the user is expanding or collapsing the node. The disclosure event has an associated listener, `DisclosureListener`. The `DisclosureListener` attribute on the tree table is bound to the accessor attribute specified in the node rule defined in the page definition file. This accessor attribute is invoked in response to a disclosure event (for example, the user expands a node) and returns the collection that populates that node.

The `treeTable` component includes **Expand All** and **Collapse All** links. When a user clicks one of these links, the `treeTable` sends a `DisclosureAllEvent` event. The `isExpandAll` method on this event determines whether the user is expanding or collapsing all the nodes. The table then expands or collapses the nodes that are children of the root node currently in focus. In large trees, the expand all command will not expand nodes beyond the immediate children. The ADF Faces `treeTable` component uses an instance of the `oracle.adf.view.faces.model.PathSet` class to determine expanded nodes. This instance is stored as the `treeState` attribute on the component. You can use this instance to programmatically control the expanded or collapsed state of a node in the hierarchy. Any node contained by the `PathSet` instance is deemed expanded. All other nodes are collapsed. This class also supports operations like `addAll()` and `removeAll()`.

Like the ADF Faces `table` component, a `treeTable` component provides for range navigation. However, instead of using the `rows` attribute, the `treeTable` component uses a `rowsByDepth` attribute whose value is a space-separated list of non-negative numbers. Each number defines the range size for a node level on the tree. The first number is the root node of the tree, and the last number is for the branch nodes. If there are more branches in the tree than numbers in the `rowsByDepth` attribute, the tree uses the last number in the list for the remaining branches. Each number defines the limit on the number items displayed at one time in each branch. If you want to display all items in a branch, specify 0 in that position of the list.

For example, if the `rowsByDepth` attribute is set to 0 0 3, all root nodes will be displayed, all direct children of the root nodes will be displayed, but only three nodes will display per branch after that. The `treeTable` component includes links to navigate to additional nodes, enabling the user to display the additional nodes.

For more information about the ADF Faces `treeTable` component, refer to the `oracle.adf.view.faces.component.core.data.CoreTreeTable` class in the ADF Faces Javadoc.

29.5.4 How to Use the `TargetIterator` Property

You can expand a node binding in the page definition editor to view the page's `nodeDefinition` elements. These are the same tree binding rules that you can configure in the tree binding dialog.

For each node definition (rule), you can specify an optional `TargetIterator` property. Its value is an EL expression that is evaluated at runtime when the user selects a row in the tree. The EL expression evaluates an iterator binding in the current binding container. The iterator binding's view row key attributes match (in order, number, and data type) the view row key of the iterator from which the `nodeDefinition` type's rows are retrieved for the tree.

At runtime, when the tree control receives a `selectionChanged` event, it passes in the list of keys for each level of the tree. These keys uniquely identify the selected node.

The tree binding starts at the top of the tree. For each tree level whose key is present in the `Currently Selected Tree Node Keys` list, if there is a `TargetIterator` property configured for that `nodeDefinition`, the tree binding performs a `setCurrentRowWithKey()` operation on the selected target iterator. It uses the key from the appropriate level of the `Currently Selected Tree Node Keys` list.

For example, you may have created `DeptEO` and `EmpEO` entity objects, and created view links based on these entity objects. The view link accessor in the `DeptVO` object that returns the linked collection of employees in that department is named `EmployeesInDepartment`. The application module will have a `DepartmentsTree`

view object instance of type `DeptVO`. It will also have an `EditDepartment` view object instance of type `DeptVO`, and a view link for the `EditEmployees` view object instance of type `EmpVO`.

Before you begin:

It may help to understand the options that are available to you when you create a tree table. For more information, see [Section 29.5, "Using Tree Tables to Display Master-Detail Objects."](#)

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see [Section 29.1.2, "Additional Functionality for Master-Detail Tables, Forms, and Trees."](#)

To use the property:

1. Drag the **DepartmentsTree** data collection from the Data Controls panel onto the page and choose **Create > Trees > ADF Tree**.
2. Configure tree binding rules to navigate the `EmployeesInDepartment` view link accessor attribute.

This will access the children employee rows of the current department row.

3. Drag the **EditEmployees** detail view object instance to the page, and choose **Create > Master-Detail > ADF Master Form, Detail Form**.

This creates a form to edit a department and a form to edit an employee in that department.

4. For the `DeptVO` node definition of the tree binding, configure the `TargetIterator` property to be `#{bindings.EditDepartmentIterator}`.
5. For the `EmpVO` node definition of the tree binding, configure the `TargetIterator` property to be `#{bindings.EditEmployeesIterator}`.

When you run the master-detail form, clicking on an employee in any department in the tree will first set the current department row in the target iterator for the department of that selected employee. Then it will set the current employee row in the target iterator for the selected employee.

29.6 Using Selection Events with Trees and Tables

There may be cases when you need to determine which node in a tree or tree table has been selected in order to handle some processing in your application. For example, on the home page of the `StoreFront` module, when a user selects a category node in the **Browse** tree, a selection event is fired. The listener associated with this event needs to determine the product category of the node selected, and then to return all products whose category attribute matches that value.

Selection changes in a tree or table will also trigger contextual events for communicating between regions within a page. For more information, see [Chapter 34, "Using Contextual Events."](#)

29.6.1 How to Use Selection Events with Trees and Tables

To programmatically use selection events, you need to create a listener in a managed bean that will handle the selection event and perform the needed logic. You then need to bind the `selectionListener` attribute of the tree or table to that listener.

Before you begin:

It may help to understand the options that are available to you when you create a master-detail table and form. For more information, see [Section 29.6, "Using Selection Events with Trees and Tables."](#)

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see [Section 29.1.2, "Additional Functionality for Master-Detail Tables, Forms, and Trees."](#)

To use selection events with trees and tables:

1. If one does not already exist, create a managed bean to contain the needed listener. For more information about creating and using managed beans, see [Section 24.4, "Using a Managed Bean in a Fusion Web Application."](#)
2. Create a listener method on the managed bean. For more information about creating listener methods, see the "Using ADF Faces Server Events" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. Your listener should do the following:
 - a. Access the component using the event source. [Example 29–5](#) shows how the `productCategoriesTreeSelectionListener` method on the `HomeBean` managed bean accesses the tree that launched the selection event.

Example 29–5 Getting the Source of an Event

```
public void productCategoriesTreeSelectionListener(SelectionEvent evt) {
    RichTree tree = (RichTree)evt.getSource();
```

For more information about finding the event source component, see the "How to Return the Original Source of the Event" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

- b. Access the tree model to get the value of the model, use the `RowKeySet` object to get the currently selected node, and then set that as the current row on the model, as shown in [Example 29–6](#). For more information about `RowKeySet` objects, see [Section 29.6.2, "What Happens at Runtime: RowKeySet Objects and SelectionEvent Events."](#)

Example 29–6 Setting the Current Row on a Tree Model

```
TreeModel model = (TreeModel)tree.getValue();
RowKeySet rowKeySet = evt.getAddedSet();
Object key = rowKeySet.iterator().next();
model.setRowKey(key);
```

- c. You can now add logic to execute against the currently selected row. For example, the `productCategoriesTreeSelectionListener` method uses the value binding of the selected row to determine the category ID, and then uses that value as the parameter for another method that when executed, returns all products with that category ID, as shown in [Example 29–7](#).

Example 29–7 Returning Objects that Match a Given Attribute Value

```
JUCtrlValueBinding nodeBinding =
    (JUCtrlValueBinding)model.getRowData();
Number catId = (Number)nodeBinding.getAttribute("CategoryId");
_selectedCategory = (String)nodeBinding.getAttribute("CategoryName");
```

```
OperationBinding ob =  
    ADFUtils.findOperation("ProductsByCategoriesExecuteWithParams");  
ob.getParamsMap().put("category", catId);  
ob.execute();
```

3. On the associated JSF page, select the tree or table component. In the Property Inspector, expand the **Behavior** section and set the value of the `SelectionListener` attribute to the listener method just created. You can use the **Edit** option from the dropdown method to declaratively select the bean and the method.

29.6.2 What Happens at Runtime: RowKeySet Objects and SelectionEvent Events

Whenever a user selects a node in a tree (or a row in a table), the component triggers selection events. A `selectionEvent` event reports which rows were just deselected and which rows were just selected. The current selection, that is, the selected row or rows, is managed by the `RowKeySet` object, which keeps track of all currently selected nodes by adding and deleting the associated key for the row into or out of the key set. When a user selects a new node, and the tree or table is configured for single selection, then the previously selected key is discarded and the newly selected key is added. If the tree or table is configured for multiple selection, then the newly selected keys are added to the set, and the previously selected keys may or may not be discarded, based on how the nodes were selected. For example, if the user pressed the `CTRL` key, then the newly selected nodes would be added to the current set.

Creating Databound Selection Lists and Shuttles

This chapter describes how to add selection lists and shuttle components to pages.

This chapter includes the following sections:

- [Section 30.1, "About Selection Lists and Shuttles"](#)
- [Section 30.2, "Creating List of Values \(LOV\) Components"](#)
- [Section 30.3, "Creating a Selection List"](#)
- [Section 30.4, "Creating a List with Navigation List Binding"](#)
- [Section 30.5, "Creating a Databound Shuttle"](#)

30.1 About Selection Lists and Shuttles

Selection list components present the user with a list of choices as input values. The selection list may be model-driven, obtained from a fixed list, or dynamically created at runtime. Selection list components can be rendered as lists, radio buttons, checkboxes, and list boxes. Some selection types can also be singular (select one) or multiple (select many).

Selection lists and shuttles work the same way as do standard JSF list components. ADF Faces list components, however, provide extra functionality such as support for label and message display, automatic form submission, and partial page rendering. When you present users with a list, they can readily see the available choices and make a selection. Picking from a list also eliminates typing errors that may occur.

List of values (LOV) components are UI components that allow the user to enter values by picking from a list that is generated by a query. The LOV displays inside a modal popup dialog that typically includes search capabilities. The `af:inputListOfValues` and `af:inputComboboxListOfValues` components, for example, offer additional features that are not available in selection lists, such as search fields inside the LOV modal dialog and queries based on multiple table columns. For more information, see [Section G.2.6, "How to Create a Popup List of Values"](#) and the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

List of values components offer more complex search and input capabilities by using the query component to create a popup search panel with a results table. The query component also has features such as auto-suggestion, smart list filtering, and custom facets for additional functionality.

When the user selects an item from a navigation list, a corresponding component bound to the list also changes its value in response to the selection. For example, when the user selects a product from a shopping list, the table that is bound to the products list updates to display the details of the selected product.

A shuttle allows the user to easily see the available items on an available list and the selected items in the selected list and to quickly move those items back and forth between the lists.

Shuttles provide a visual way to select items from an available list and at the same time see those selected items. ADF Faces provides the `selectManyShuttle` component and the `selectOrderShuttle` component, which allow reordering of the selected list. Both components can be implemented by adding code in a managed bean to populate the lists.

30.1.1 Selection Lists and Shuttles Use Cases and Examples

You can use a selection list component such as `selectOneChoice` for a single value input selection situation in which the list is relatively small. For example, you can use a `selectOneChoice` to select from a list of product colors or the type of credit card being used.

For larger lists and with more complex filtering, use an `af:inputListOfValues` or `af:inputComboboxListOfValues` component. These components use the query component to perform a transactional search to populate the list. For instance, you can use the `af:inputComboboxListOfValues` to select from a list of countries in an address input page.

Use the `selectShuttle` components when you want the user to be able to assemble a list of items and be able to select and unselect them. You should use the shuttle components when the number of items is large but not overwhelming to display. The user can review the selection and be able to iteratively select and unselect the items until the user is satisfied with the final selection. For instance, the available list could be the options available for a particular automobile and the user can shuttle the options he like to the selected list.

30.1.2 Additional Functionality for Selection Lists and Shuttles

You may find it helpful to understand other ADF features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- For more information about using LOV components with search forms and the `af:query` component, see [Section 31.1.2, "List of Values \(LOV\) Input Fields."](#)
- You can use the LOV in a task flow that uses an isolated data control. For more information about shared and isolated data controls, see [Section 20.4, "Sharing Data Controls Between Task Flows."](#)
- LOVs are associated with a named view criteria. For more information about setting view criteria options, see [Section 5.11.1, "How to Create Named View Criteria Declaratively."](#)
- LOV components uses the `af:query` component to populate the selection list. For more information about the `af:query` component, see [Chapter 31, "Creating ADF Databound Search Forms."](#)

30.2 Creating List of Values (LOV) Components

List of values (LOV) components are input components that allow the user to enter values by picking from a list that is generated by a query. ADF Faces provides the `af:inputListOfValues` and `af:inputComboboxListOfValues` components. If you are creating a fully-featured LOV component, you must define the LOV in the view object as described in [Section 5.12, "Working with List of Values \(LOV\) in View Object Attributes."](#)

If you are using dependent LOVs as part of your search form, you must use them with the `af:query` component. For more information about using LOV components with search forms, see [Section 31.1.2, "List of Values \(LOV\) Input Fields."](#)

The `af:inputListOfValues` component has a search icon next to the search criteria field, as shown in [Figure 30-1](#).

Figure 30-1 Search Criteria Input Field Defined as an `inputListOfValues`

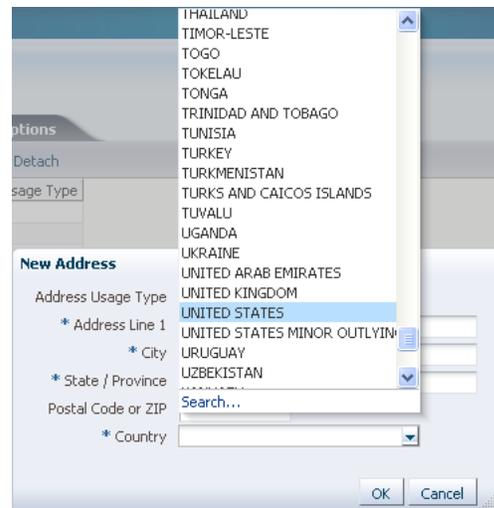

The `af:inputComboboxListOfValues` component has a dropdown icon next to the field, as shown in [Figure 30-2](#) for the `PaymentOptionId` attribute.

Figure 30-2 Search Criteria Input Field Defined as an `inputComboboxListOfValues`

For `af:inputComboboxListOfValues`, clicking the dropdown icon displays the LOV dropdown list and either a **More** or a **Search** command link, as shown in [Figure 30-3](#). A **Search** link appears when the LOV Search and Select popup dialog contains a search panel to refine the search. A **More** link appears when the popup dialog contains only the list-of-values table.

Figure 30-3 LOV Dropdown List with Search Link for `inputComboboxListOfValues`

The user can select any of the items in the dropdown list to populate the input field. The dropdown list includes a filtered list of values and an optional list of most recently used items. The width of each attribute in the dropdown list can be configured using the `DisplayWidth` UI hint for that attribute in the view object definition. The width of

the dropdown list will be the sum of the widths of all the attributes in the dropdown list.

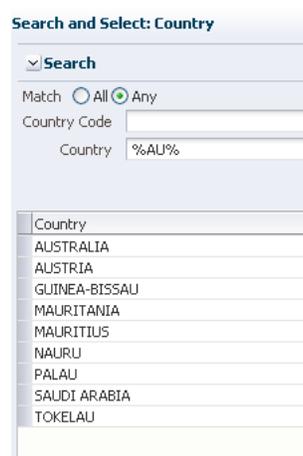

You can create custom content to be rendered in the Search and Select dialog using the `searchContent` facet. You can add components such as input text, tables, and trees to display the custom content. You will need to define the `returnPopupDataValue` attribute and implement a `returnPopupListener`. When you want to add the auto-complete feature with your custom popup, you can disable the popup by adding `launchPopupEvent.setLaunchPopup(false)` to your `LaunchPopupListener()` code. However, clicking on the **Search** link will still launch the Search and Select dialog. For more information about adding custom content, see the "Using List-of-Values Components" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

If the component's `readOnly` attribute is set to `true`, then the input field will not be rendered and the value cannot be changed. By default, the `readOnly` attribute is set to `false`, which also enables the `editMode` attribute to determine whether the user is permitted only to select a value from the list (`editMode` set to `select`) or whether the user can also enter a value into the input field (`editMode` set to `input`).

You can also set up the LOV component to display a list of selectable suggested items when the user types in a partial value. For example, when the user types in `Ca`, then a suggested list which partially matches `Ca` is displayed as a suggested items list. The user can select an item from the list to be entered into the input field. If there are no matches, a "No results found" message will be displayed. You add the `af:autoSuggestBehavior` tag from the Component Palette into the LOV and set the `selectedItem` attribute to the `suggestedItems` method implemented in ADF Model.

When the user clicks the **Search** or **More** link (or for `af:inputListOfValues`, the search icon), the LOV Search and Select dialog displays with the full list of values in a table format. The LOV Search and Select dialog launched from a **More** link is shown in [Figure 30-4](#).

Figure 30-4 LOV Search and Select Dialog

The Search and Select popup dialog also presents a create function that allows the user to add a new row. Be aware that if you are creating a new record using the LOV Search and Select dialog, the new row will appear as an empty row in the table if the LOV has the **Query Automatically** control hint set to `false`. The content of the row will appear

when you perform a query using the **Search** button. [Example 30–1](#) shows a code sample that uses a `commandLink` to invoke the create function.

Example 30–1 Create Function Sample Code

```
<f:facet name="customActions">
  <af:commandLink id="createLink" text="Create..."
    partialSubmit="true">
    <af:showPopupBehavior popupId="createSLPopup"
      alignId="createLink"/>
  </af:commandLink>
</f:facet>
```

If the LOV is part of a task flow that is using an isolated data control, and you use the create function to add a new record, the newly added record will not be displayed in the parent page. This is because the search region is also using an isolated data control scope, so the underlying view object updates are not displayed. For more information about shared and isolated data controls, see [Section 20.4, "Sharing Data Controls Between Task Flows."](#)

To programmatically refresh the LOV and display the view object updates, add a `returnListener` to the **Create** link with code similar to that shown in [Example 30–2](#).

Example 30–2 Code to Refresh the LOV

```
public void refreshLOV() {
    BindingContainer bindings = this.getBindings();
    oracle.jbo.uicli.binding.JUCtrlListBinding lovBinding =
        (oracle.jbo.uicli.binding.JUCtrlListBinding)
        bindings.get("Description1");
    JUIteratorBinding lovIter = lovBinding.getIteratorBinding();
    RowSet rs = lovIter.getRowSetIterator().getRowSet();
    rs.executeQuery();

    //Add LOV as the partialTrigger

    AdfFacesContext.getCurrentInstance().addPartialTarget(this.getPlatformDesc());
}
```

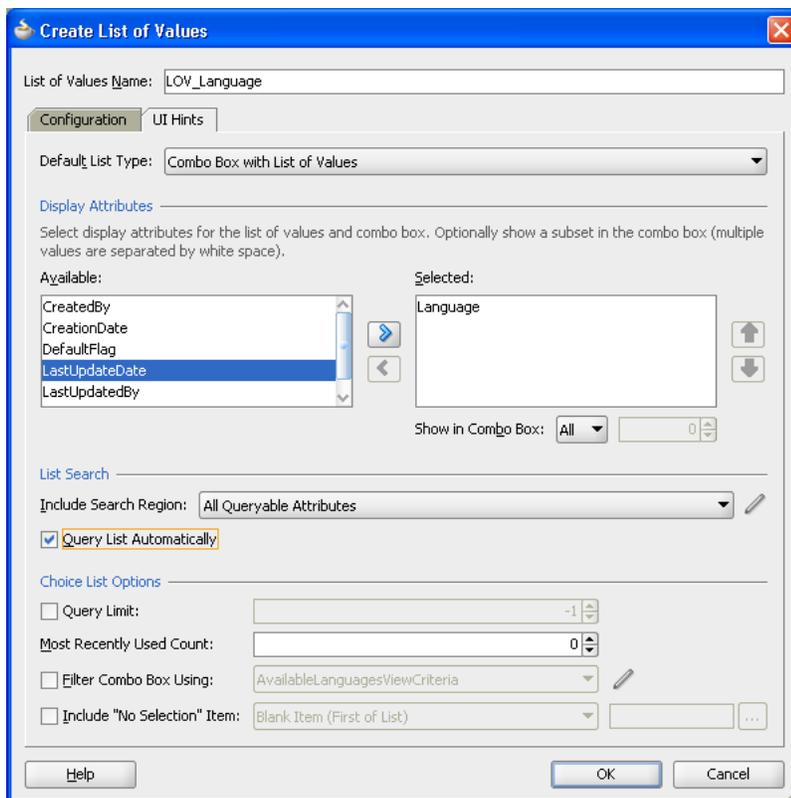

An LOV is associated with a data source via the view accessor. You can apply one or more view criteria to the view accessor associated with the LOV. The view accessor provides permanent filtering to the LOV data source. In addition to this permanent filtering, you may be able to apply other filters.

The LOV dialog may include a query panel to allow the user to enter criteria to search for the list of values, or it may contain only a table of results. When you define the LOV in the view object, you can use the UI hints to specify whether a search region should be displayed, which view criteria should be used as the search to populate the list of values, and which LOV component to use. [Figure 30–5](#) shows the Create List of Values dialog and some of its options. In this example, the search region will be made available with the `AvailableLanguages1ViewCriteria` view criteria used for the query, and `af:inputComboboxListOfValues` as the component. Another useful option for the `af:inputComboboxListOfValues` is the **Show in Combo Box** option, which allows you to select the number of attributes to display in the dropdown list and in the Search and Select dialog. For more information on LOV UI hints, see [Section 5.12.5, "How to Set User Interface Hints on a View Object LOV-Enabled Attribute."](#)

For both `af:inputListOfValues` and `af:inputComboboxListOfValues`, if the user enters a partial match in the input search field and presses the Tab or Enter key, the LOV automatically launches the LOV Search and Select dialog and executes the query after applying an auto-generated view criteria with a single item representing the partial match value entered by the user. If there are matches, the Search and Select dialog displays all the entries matching the partially entered criteria. If there are no entries that match the entered partial match, then the dialog displays all the entries.

By default, in the `af:inputComboboxListOfValues` component *auto-complete* feature, the search is case-sensitive. If you want the search to be case-insensitive, create a view criteria to be associated with that LOV attribute. In the Create View Criteria dialog, deselect the **Ignore Case** checkbox for that view criteria item before you apply that view criteria to the LOV definition. For more information about setting view criteria options, see [Section 5.11.1, "How to Create Named View Criteria Declaratively."](#)

Figure 30–5 List of Values Dialog UI Hints Tab

You can also set up the LOV component to display a list of selectable suggested items when the user types in a partial value. For example, when the user types in *Ca*, then a suggested list which partially matches *Ca* is displayed as a suggested items list. The user can select an item from the list to be entered into the input field. You add this *auto-suggest behavior* feature by including an `af:autoSuggestBehavior` tag from the Component Palette in the LOV and set the `selectedItem` attribute to the `suggestedItems` method implemented in ADF Model.

If the LOV is an `af:inputComboboxListOfValues`, you can apply an additional view criteria to further filter the values in the dropdown list to create a *smart list*. If the **Filter Combo Box Using** UI hint is not applied, the dropdown list is filtered by the view criteria applied to the view accessor. Note that this smart list filter applies only to

the dropdown list. The full list is still used for validation and for searching from the LOV Search and Select popup dialog.

If both the auto-suggest behavior and smart list filter are enabled for an LOV, auto-suggest will search from the smart list first. If the user waits for two seconds without clicking, then auto-suggest will also search from the full list and append the results. You can also specify the number of suggested items returned by setting the `maxSuggestedItems` attribute (-1 indicates a complete list). If `maxSuggestedItems > 0`, a **More** link is rendered for the user to click on to launch the LOV's Search and Select dialog. [Example 30-3](#) shows the code from an LOV with both auto-suggest behavior and a smart list.

Example 30-3 Auto-Suggest Behavior and Smart List

```
af:autoSuggestBehavior
  suggestItems="#{bindings.CountryName.suggestItems}"
  smartList="#{bindings.CountryName.smartList}"/>
  maxSuggestedItems="5"
```

You can define an attribute in the view object to be one or more LOVs. If multiple LOVs are defined on an attribute, each LOV has its own name, view accessor, data mappings, validator, and UI hints (except for the **Default List Type** hint, which is defined once for the attribute). To switch between LOVs to be used at runtime, an LOV switcher is used. The LOV switcher can be based on an existing attribute of type `String`, or created as a new `String` attribute solely for switching between LOVs. The LOV switcher returns the name of the LOV to use at runtime. For instance, you can create three LOVs for the price attribute, and designate the `CountryCode` attribute as the LOV switcher. At runtime, the value of `CountryCode` will switch the price attribute to use the LOV that reflects the country's price and currency.

If an attribute is defined as an LOV, you can set the **Support Multiple Value Selection** control hint in its view criteria to enable users to make multiple selections in the search criteria field. If multiple selection is enabled on an LOV attribute, and the `Equal to` or `Not equal to` operator is chosen, a `selectManyChoice` component will render in the query panel. The user can select multiple items as the search criteria.

If the value of an LOV depends on the value of another LOV, then the two LOVs are called *cascading* LOVs. For instance, the list of values for the City LOV depends on the value of the Country LOV that was selected. If the LOV is defined as a named bind variable, or if validation is enabled, the LOV query may behave differently depending on such conditions as whether null values for the named bind variable are acceptable. If the bind variable is null, you may want the LOV query to return an empty list. The view criteria's **Ignore Null Values** and **Validation** options can be used to define LOV query behavior.

If the view object has an LOV with a bind variable, you should set that view object bind variable's control hint to **Hide**. Otherwise, the bind variable will be displayed in the LOV Search and Select popup dialog. In the view object overview editor's **Query** tab, double-click the bind variable, click the **Control Hints** tab and select **Hide** from the **Display Hint** dropdown list.

Best Practice: An attribute that has been enabled as an LOV should not be used as search criteria in a manually created search form using the "Find Mode" iterator. Creating a search form in this way could result in SQL exception: `java.sql.SQLException: Attempt to set a parameter name that does not occur in the SQL.` It is best practice to use the query and quick query components for creating search forms. For more information, see [Chapter 31, "Creating ADF Databound Search Forms."](#)

Displaying an LOV list for a name attribute when the view object's key attribute is a numerical value requires mapping supplemental attributes on the LOV-enabled attribute. For example, to display a list of credit cards by name instead of by their payment option ID value, you can create an LOV on the name reference attribute and define the primary key attribute as a supplemental attribute to the LOV. For details about creating an LOV-enabled reference attribute, see [Section 5.12.4, "How to Define an LOV to Display a Reference Attribute."](#)

For more information about different usage scenarios and other view criteria options, see [Section 5.11.1, "How to Create Named View Criteria Declaratively,"](#) and [Section 5.11.3, "What You May Need to Know About Bind Variable Options."](#)

30.2.1 How to Create an LOV

You can create the LOV using either the `af:inputListOfValues` or the `af:inputComboboxListOfValues` component. You can add auto-suggest behavior to the component to display a list of possible matches from user input.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an LOV. For more information, see [Section 30.2, "Creating List of Values \(LOV\) Components."](#)

You may also find it helpful to understand functionality that can be used with LOVs. For more information, see [Section 30.1.2, "Additional Functionality for Selection Lists and Shuttles."](#)

You will need to complete this task:

Define the attribute to be an LOV in the view object by following the procedure described in [Section 5.12, "Working with List of Values \(LOV\) in View Object Attributes."](#)

To create an LOV:

1. From the Data Controls panel, drag and drop the attribute onto the JSF page and choose **Create > List of Values > ADF LOV Input** or **Create > List of Values > ADF LOV Choice List**.
2. In the Operations page of the Component Palette, from the ADF Faces panel, drag and drop **Auto Suggest Behavior** as a child to the LOV component.
3. In the Property Inspector, for each of the auto-suggest attributes, enter the:
 - EL expression that resolves to the `suggestItems` method.
 - EL expression that resolves to the `smartList` method.
 - Number of items to be displayed in the auto-suggest list. Enter -1 to display the complete list.

[Example 30–4](#) shows an `inputListOfValues` component with the auto-suggest behavior and smart list features.

Example 30–4 LOV Component with Auto-Suggest Behavior

```
<af:inputListOfValues id="ProductsId"
    popupTitle="Search and Select: #{bindings.Products.hints.label}"
    value="#{bindings.Products.inputValue}"
    label="#{bindings.Products.hints.label}"
    model="#{bindings.Products.listOfValuesModel}"
    required="#{bindings.Products.hints.mandatory}"
    columns="#{bindings.Products.hints.displayWidth}"
    shortDesc="#{bindings.Products.hints.tooltip}" />
<f:validator binding="#{bindings.Products.validator}" />
<af:autoSuggestBehavior suggestItems="#{bindings.Products.suggestedItems}"
    smartList="#{bindings.Products.smartList}"
    maxSuggestedItems="5" />
</af:inputListOfValues>
```

4. If you added the auto-suggest behavior, you must set the component's `autoSubmit` property to `true`.

30.2.2 What Happens When You Create an LOV

When you drag and drop an attribute from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see [Section 26.2.2, "What Happens When You Create a Text Field."](#)

When you drag and drop an attribute defined as an LOV from the Data Controls panel onto a JSF page as an `inputListOfValues` or `inputComboboxListOfValues` component, JDeveloper adds code to the page similar to that shown in [Example 30–5](#). The language attribute in the `CountryCodes` view object has been defined as an LOV and its default component is set to be an `inputComboboxListOfValues`. The component gets its properties from the control hints defined declaratively in the view object. If you want to include the auto-suggest behavior, you must manually add that tag from the Component Palette.

Example 30–5 `inputComboboxListOfValues` Component Code in a JSF Page

```
<af:inputComboboxListOfValues id="languageId"
    popupTitle="Search and Select: #{bindings.Language.hints.label}"
    value="#{bindings.Language.inputValue}"
    label="#{bindings.Language.hints.label}"
    model="#{bindings.Language.listOfValuesModel}"
    required="#{bindings.Language.hints.mandatory}"
    columns="#{bindings.Language.hints.displayWidth}"
    shortDesc="#{bindings.Language.hints.tooltip}"
    readOnly="false">
    <f:validator binding="#{bindings.Language.validator}" />
</af:inputComboboxListOfValues>
```

In the page definition file, JDeveloper adds code as shown in [Example 30–6](#). The bindings section of the page definition specifies that the LOV is for the language attribute and the name of the LOV is `LOV_language`. JDeveloper adds the definitions for the iterator binding objects into the `executables` element, and the list of values binding object into the `bindings` element.

Example 30–6 inputComboboxListOfValues Component Code in Page Definition

```
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="CountryCodesView1" RangeSize="25"
    DataControl="AppModuleDataControl"
    id="CountryCodesView1Iterator"/>
</executables>
<bindings>
  <listOfValues StaticList="false" IterBinding="CountryCodesView1Iterator"
    Uses="LOV_Language" id="Language"/>
</bindings>
```

For more information about the page definition file and ADF data binding expressions, see [Section 13.7, "Working with Page Definition Files,"](#) and [Section 13.8, "Creating ADF Data Binding EL Expressions."](#)

30.3 Creating a Selection List

ADF Faces Core includes components for selecting a single value and multiple values from a list. For example, `selectOneChoice` allows the user to select an item from a dropdown list, and `selectManyChoice` allow the user to select several items from a list of checkboxes. Selection lists are described in [Table 30–1](#).

Table 30–1 ADF Faces Single and Multiple List Components

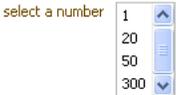

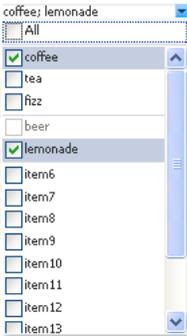

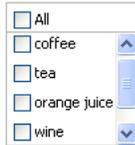

ADF Faces component	Description	Example
<code>SelectOneChoice</code>	Select a single value from a list of items.	
<code>SelectOneRadio</code>	Select a single value from a set of radio buttons.	
<code>SelectOneListbox</code>	Select a single value from a scrollable list of items.	
<code>SelectManyChoice</code>	Select multiple values from a scrollable list of checkboxes. Each selection displays at the top of the list.	
<code>SelectManyCheckbox</code>	Select multiple values from a group of checkboxes.	

Table 30–1 (Cont.) ADF Faces Single and Multiple List Components

ADF Faces component	Description	Example
SelectManyListbox	Select multiple values from a scrollable list of checkboxes,	

You can create selection lists using the `SelectOneChoice` ADF Faces component. The steps are similar for creating other single-value selection lists, such as `SelectOneRadio` and `SelectOneListbox`.

A databound selection list displays values from a data control collection or a static list and updates an attribute in another collection or a method parameter based on the user's selection. When adding a binding to a list, you use an attribute from the data control that will be populated by the selected value in the list.

Note: By default, ADF Model list binding passes the index to the component. If you set `valuePassThru=true`, then you should set the list binding entry in the corresponding page definition file `Mode` attribute to `Object`. When `Mode=Object`, the list binding will pass an object instead of an index to the component. For more information, see [Section 30.3.5, "What Happens When You Create a Fixed Selection List."](#)

To create a selection list, you choose a base data source and a list data source in the Edit List Binding dialog:

- Base data source: Select the data collection that you want to bind to your control and that contains the attributes to be updated from user selections.
- List data source: Select the data collection that contains the attributes to display.

The data collection is based on the view object. For more information about creating a view object, see [Section 5.2.1, "How to Create an Entity-Based View Object."](#)

You can create three types of selection lists in the Edit List Binding dialog:

- Model-driven list: List selections are based on a list of values bound to a data collection. This type of selection list offers significant advantages over the other two, as described in [Section 30.3.1, "How to Create a Model-Driven List."](#)
- Static list: List selections are based on a fixed list that you create manually by entering values one at a time into the editor. For more information, see [Section 30.3.2, "How to Create a Selection List Containing Fixed Values."](#)
- Dynamic list: List selections are generated dynamically based on one or more databound attribute values. For more information, see [Section 30.3.3, "How to Create a Selection List Containing Dynamically Generated Values."](#)

30.3.1 How to Create a Model-Driven List

A model-driven list is based on a list of values that is bound to a view data object. Lists of Values are typically used in forms to enable an end user to select an attribute value from a dropdown list instead of having to enter it manually. When the user submits

the form with the selected values, ADF data bindings in the ADF Model layer update the value on the view object attributes corresponding to the databound fields.

Note: One way to create a model-driven list is to drag a collection from the Data Controls panel onto a JSF page, choose one of the ADF Forms in the popup menu, and accept the defaults. The advantage is that if there are LOVs defined on the underlying view object attributes, all the LOVs on the entire form will be configured automatically. For more information, see [Section 5.12.1, "How to Define a Single LOV-Enabled View Object Attribute."](#)

You can also use the list of values as the basis for creating a selection list. The advantages of creating a model-driven list based on a list of values are:

- **Reuse:** The list of values is bound to a view data collection. Any selection list that you create based on the data collection can use the same list of values. Because you define the LOV on the individual attributes of view objects in a data model project with ADF Business Components, you can customize the LOV usage for an attribute once and expect to see the changes anywhere that the business component is used in the user interface.
- **Translation:** Values in the list of values can be included in resource bundles used for translation.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an selection list component. For more information, see [Section 30.3, "Creating a Selection List."](#)

You may also find it helpful to understand functionality that can be used with selection lists. For more information, see [Section 30.1.2, "Additional Functionality for Selection Lists and Shuttles."](#)

You will need to complete these tasks:

1. Create a view object.
2. Create a view accessor on the object.
3. Create a list of values that is bound to an attribute on the base data source for the selection list. For example, you can create a list of values bound to the `CountryId` attribute of the `Addresses` view data object.

For more information, see [Section 5.12.1, "How to Define a Single LOV-Enabled View Object Attribute."](#)

To create a model-driven selection list:

1. From the Data Controls panel, drag and drop the attribute onto the JSF page and choose **Create > Single Selections > ADF Select One Choice**.

The Edit List Binding dialog displays. The view object collection containing the attribute you dropped on the JSF page is selected by default in the **Base Data Source** list.

To select a different view data collection, click the **Add** icon next to the list.

2. Click the **Model Driven List** radio button.

3. In the **Base Data Source Attribute** list, select an attribute on which you based a list of values, for example, `CountryId`.

The list contains all the attributes for the view data collection selected in the **Base Data Source** list.

4. If a list of values was created for the attribute you selected, it will be listed in the **Server List Binding Name** list.

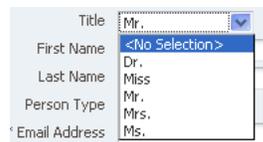

For example, you could select `LOV_CountryId` in the **Server List Binding Name** list because a list of values was created for the `CountryId` attribute.

5. Click **OK**.

30.3.2 How to Create a Selection List Containing Fixed Values

You can create a selection list containing selections that you code yourself, rather than retrieving the values from another data source. See [Section 30.3.3, "How to Create a Selection List Containing Dynamically Generated Values,"](#) for information about populating selection lists with values that are dynamically generated from another data source.

Figure 30–6 Selection List Bound to a Fixed List of Values

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a selection list component. For more information, see [Section 30.3, "Creating a Selection List."](#)

You may also find it helpful to understand functionality that can be used with selection lists. For more information, see [Section 30.1.2, "Additional Functionality for Selection Lists and Shuttles."](#)

You will need to complete this task:

Prepare a list of values that you will enter into the component as a fixed list.

To create a list bound to a fixed list of values:

1. From the Data Controls panel, drag and drop the attribute onto the JSF page and choose **Create > Single Selections > ADF Select One Choice**.

The Edit List Binding dialog displays. The view object collection containing the attribute you dropped on the JSF page is selected by default in the **Base Data Source** list.

To select a different view data collection, click the **Add** icon next to the list.

2. Click the **Fixed List** radio button.

The **Fixed List** option lets end users choose a value from a static list that you define.

3. In the **Base Data Source Attribute** list, choose an attribute.

The **Base Data Source Attribute** list contains all of the attributes in the view data collection you selected in the **Base Data Source** list. For example, if you selected `CountryCodes` as the base data source, you can choose `CountryName` in the list.

4. In the **Set of Values** box, enter each value you want to appear in the list. Press the Enter key to set a value before typing the next value. For example, you could add the country codes `India`, `Japan`, and `Russia`.

The order in which you enter the values is the order in which the list items are displayed in the `SelectOneRadio` control at runtime.

The `SelectOneRadio` component supports a `null` value. If the user has not selected an item, the label of the item is shown as blank, and the value of the component defaults to an empty string. Instead of using blank or an empty string, you can specify a string to represent the `null` value. By default, the new string appears at the top of the list.

5. Click **OK**.

30.3.3 How to Create a Selection List Containing Dynamically Generated Values

You can populate a selection list component with values dynamically at runtime.

Tip: Another option is to create a static view object or a database view object within a shared application module. Then use a model-driven LOV to create the list. This provides caching and translatability.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a selection list component. For more information, see [Section 30.3, "Creating a Selection List."](#)

You may also find it helpful to understand functionality that can be used with selection lists. For more information, see [Section 30.1.2, "Additional Functionality for Selection Lists and Shuttles."](#)

You will need to complete these tasks:

1. Define a data source for the list data source that provides the dynamic list of values.
2. Define a data source for the base data source that is to be updated based on the user's selection.

To create a selection list bound containing dynamically generated values:

1. From the Data Controls panel, drag and drop the attribute onto the JSF page and choose **Create > Single Selections > ADF Select One Choice**.

The Edit List Binding dialog displays. The view object collection containing the attribute you dropped on the JSF page is selected by default in the **Base Data Source** list.

To select a different view data collection, click the **Add** icon next to the list.

2. Click the **Dynamic List** radio button.

The **Dynamic List** option lets you specify one or more base data source attributes that will be updated from another set of bound values.

3. Click the **Add** button next to **List Data Source**.

4. In the Add Data Source dialog, select the view data collection that will populate the values in the selection list.

In the Fusion Order Demo application, for example, you could select `ProductQuantities`.

Note: The list and base collections do not have to form a master-detail relationship, but the attribute in the list collection must have the same type as the base collection attributes.

5. Accept the default iterator name and click **OK**.

The **Data Mapping** section of the Edit List Binding dialog updates with a default data value and list attribute. The **Data Value** control contains the attribute on the data collection that is updated when the user selects an item in the selection list. The **List Attribute** control contains the attribute that populates the values in the selection list.

6. You can accept the default mapping or select different attributes items from the **Data Value** and **List Attribute** lists to update the mapping.

To add a second mapping, click **Add**.

7. Click **OK**.

30.3.4 What Happens When You Create a Model-Driven Selection List

When you drag and drop an attribute from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see [Section 26.2.2, "What Happens When You Create a Text Field."](#)

[Example 30–7](#) shows the page source code after you add a model-driven `SelectOneChoice` component to it.

Example 30–7 Model-Driven SelectOneChoice List in JSF Page Source Code

```
<af:selectOneChoice value="#{bindings.CountryId1.inputValue}"
                    label="#{bindings.CountryId1.label}">
    <f:selectItems value="#{bindings.CountryId1.items}" />
</af:selectOneChoice>
```

The `f:selectItems` tag, which provides the list of items for selection, is bound to the `items` property on the `CountryId1` list binding object in the binding container. For more information about ADF data binding expressions, see [Section 13.6, "Configuring the ADF Binding Filter."](#)

In the page definition file, JDeveloper adds the list binding object definitions in the bindings element, as shown in [Example 30–8](#).

Example 30–8 List Binding Object for the Model-Driven List in the Page Definition File

```
<bindings>
  <list IterBinding="AddressesView1Iterator" id="CountryId"
        Uses="LOV_AddressId" StaticList="false" ListOperMode="0">
    <AttrNames>
      <Item Value="AddressId" />
    </AttrNames>
  </list>
```

```

<list IterBinding="AddressesView1Iterator" id="CountryId1"
      Uses="LOV_CountryId" StaticList="false" ListOperMode="0">
  <AttrNames>
    <Item Value="CountryId"/>
  </AttrNames>
</list>
</bindings>

```

In the `list` element, the `id` attribute specifies the name of the list binding object. The `IterBinding` attribute references the variable iterator, whose current row is a row of attributes representing each variable in the binding container. The variable iterator exposes the variable values to the bindings in the same way as do other collections of data. The `AttrNames` element specifies the attribute value returned by the iterator.

For more information about the page definition file and ADF data binding expressions, see [Section 13.7, "Working with Page Definition Files,"](#) and [Section 13.8, "Creating ADF Data Binding EL Expressions."](#)

30.3.5 What Happens When You Create a Fixed Selection List

When you add a fixed selection list, JDeveloper adds source code to the JSF page and list and iterator binding objects to the page definition file.

[Example 30–9](#) shows the page source code after you add a fixed `SelectOneChoice` component to it.

Example 30–9 Fixed SelectOneChoice List in JSF Page Source Code

```

<af:selectOneChoice value="#{bindings.CountryIdStatic.inputValue}"
                   label="#{bindings.CountryIdStatic.label}">
  <f:selectItems value="#{bindings.CountryIdStatic.items}"/>
</af:selectOneChoice>

```

The `f:selectItems` tag, which provides the list of items for selection, is bound to the `items` property on the `CountryId` list binding object in the binding container. For more information about ADF data binding expressions, see [Section 13.8, "Creating ADF Data Binding EL Expressions."](#)

In the page definition file, JDeveloper adds the definitions for the iterator binding objects into the `executables` element, and the list binding object into the `bindings` element, as shown in [Example 30–10](#).

Example 30–10 List Binding Object for the Fixed Selection List in the Page Definition File

```

<executables>
  <iterator Binds="Addresses1" RangeSize="10"
           DataControl="StoreFrontModuleDataControl"
           id="Addresses1Iterator"/>
</executables>
<bindings>
  <list IterBinding="Addresses1Iterator" id="CountryIdStatic" ListOperMode="0"
        StaticList="true">
    <AttrNames>
      <Item Value="CountryIdStatic"/>
    </AttrNames>
    <ValueList>
      <Item Value="India"/>
      <Item Value="Japan"/>
      <Item Value="Russia"/>
    </ValueList>
  </list>
</bindings>

```

```

    </ValueList>
  </list>
</bindings>

```

For complete information about page definition files, see [Section 13.7, "Working with Page Definition Files."](#)

30.3.6 What You May Need to Know About Values in a Selection List

Once you have created a list binding, you may want to access a value in the list. You can set the component's `valuePassThru` attribute to `true` either in the visual editor or in the Property Inspector. [Example 30–11](#) shows the code for a `selectOneChoice` component.

Example 30–11 *valuePassThru Attribute Set to true in selectOneChoice*

```

<af:selectOneChoice value="#{bindings.Language.inputValue}"
  label="#{bindings.Language.label}"
  required="#{bindings.Language.hints.mandatory}"
  shortDesc="#{bindings.Language.hints.tooltip}"
  valueChangeListener="#{myBean.valueChanged}"
  id="soc1" valuePassThru="true">
  <f:selectItems value="#{bindings.Language.items}" id="si1"/>
</af:selectOneChoice>

```

Only when the `valuePassThru` attribute is set to `true` and the `Mode` attribute in the corresponding page definition file is set to `Object` can the value passed to the `valueChangeListener` be of type `Object` (which is the actual value). By default, `Mode` is set to `Index`. [Example 30–12](#) shows the `Mode` attribute in the page definition file.

Example 30–12 *Mode Attribute Set to Object in the Page Definition File*

```

<list IterBinding="AvailableLanguagesView1Iterator" id="Language"
  DTSupportsMRU="true" StaticList="false"
  ListIter="CountryCodesView1Iterator"
  Mode="Object"/>

```

30.3.7 What Happens When You Create a Dynamic Selection List

When you add a dynamic selection list to a page, JDeveloper adds source code to the JSF page and list and iterator binding objects to the page definition file.

[Example 30–13](#) shows the page source code after you add a dynamic `SelectOneChoice` component to it.

Example 30–13 *Dynamic SelectOneChoice List in JSF Page Source Code*

```

<af:selectOneChoice value="#{bindings.Quantity.inputValue}"
  label="#{bindings.Quantity.label}">
  <f:selectItems value="#{bindings.Quantity.items}" />
</af:selectOneChoice>

```

The `f:selectItems` tag, which provides the list of items for selection, is bound to the `items` property on the `Quantity` list binding object in the binding container. For more information about ADF data binding expressions, see [Section 13.8, "Creating ADF Data Binding EL Expressions."](#)

In the page definition file, JDeveloper adds the definitions for the iterator binding objects into the `executables` element, and the list binding object into the `bindings` element, as shown in [Figure 30-14](#).

Example 30-14 List Binding Object for the Dynamic Selection List in the Page Definition File

```
<executables>
  <iterator Binds="OrderItems" RangeSize="-1"
    DataControl="StoreFrontModuleDataControl1"
    id="OrderItemsIterator" />
  <iterator Binds="ProductQuantities" RangeSize="10"
    DataControl="StoreFrontModuleDataControl1"
    id="ProductQuantitiesIterator" />
</executables>
<bindings>
  <list IterBinding="AddressesView1Iterator" id="CountryId"
    Uses="LOV_AddressId" StaticList="false" ListOperMode="0">
    <AttrNames>
      <Item Value="AddressId" />
    </AttrNames>
  </list>
  <list IterBinding="ProductQuantities1Iterator" id="Quantity"
    StaticList="false" ListOperMode="0" ListIter="OrderItems1Iterator">
    <AttrNames>
      <Item Value="Quantity" />
    </AttrNames>
    <ListAttrNames>
      <Item Value="Quantity" />
    </ListAttrNames>
    <ListDisplayAttrNames>
      <Item Value="OrderId" />
    </ListDisplayAttrNames>
  </list>
</bindings>
```

By default, JDeveloper sets the `RangeSize` attribute on the `iterator` element for the `OrderItems` iterator binding to a value of `-1` thus allowing the iterator to furnish the full list of valid products for selection. In the `list` element, the `id` attribute specifies the name of the list binding object. The `IterBinding` attribute references the iterator that iterates over the `ProductQuantities` collection. The `ListIter` attribute references the iterator that iterates over the `ProductList` collection. The `AttrNames` element specifies the base data source attributes returned by the base iterator. The `ListAttrNames` element defines the list data source attributes that are mapped to the base data source attributes. The `ListDisplayAttrNames` element specifies the list data source attribute that populates the values users see in the list at runtime.

For complete information about page definition files, see [Section 13.7, "Working with Page Definition Files."](#)

30.4 Creating a List with Navigation List Binding

Navigation list binding lets users navigate through the objects in a collection. As the user changes the current object selection using the navigation list component, any other component that is also bound to the same collection through its attributes will display from the newly selected object. In addition, if the collection whose current row you change is the master view object instance in a data model master-detail

relationship, the row set in the detail view object instance is automatically updated to show the appropriate data for the new current master row.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a navigation list. For more information, see [Section 30.4, "Creating a List with Navigation List Binding."](#)

You may also find it helpful to understand functionality that can be used with navigation lists. For more information, see [Section 30.1.2, "Additional Functionality for Selection Lists and Shuttles."](#)

To create a list that uses navigation list binding:

1. From the Data Controls panel, drag and drop a collection to the page and choose **Create > Navigation > ADF Navigation Lists**.
2. In the Edit List Binding dialog, from the **Base Data Source** dropdown list, select the collection whose members will be used to create the list.

This should be the collection you dragged from the Data Controls panel. If the collection does not appear in the dropdown menu, click the **Add** button to select the collection you want.

3. From the **Display Attribute** dropdown list, select the attribute that will display in the list. You can choose the selection that includes all the attributes, and you can choose **Select Multiple** to launch a selection dialog.

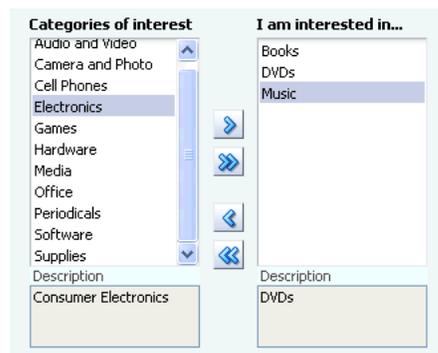

In the Select Multiple Display Attributes dialog, shuttle the attributes you want to display from the **Available Attributes** list to the **Attributes to Display** list. Click **OK** to close the dialog.

4. Click **OK**.

30.5 Creating a Databound Shuttle

The `selectManyShuttle` and `selectOrderShuttle` components render two list boxes and buttons that allow the user to select multiple items from the leading (or available) list box and to move or shuttle those items over to the trailing (or selected) list box, and vice versa. You can also double-click an item to move it to the other list box. [Figure 30–10](#) shows an example of a rendered `selectManyShuttle` component. You can specify any text you want for the headers that display above the list boxes.

Figure 30–7 *SelectManyShuttle Component*

The only difference between `selectManyShuttle` and `selectOrderShuttle` is that in the `selectOrderShuttle` component, the user can reorder the items in the trailing list box by using the up and down arrow buttons on the side.

The Fusion Order Demo application uses a `selectManyShuttle` component to select customer interest categories from a **Categories of Interest** list box to an **I am interested in** list box. The leading list box on the left displays all the categories. The trailing list box on the right displays the categories the customer has selected.

Like other ADF Faces selection list components, the `selectManyShuttle` component can use the `f:selectItems` tag to provide the list of items available for display and selection in the leading list.

Before you can bind the `f:selectItems` tag, create a generic class that can be used by any page that requires a shuttle. In the class, declare and include getter and setter methods for the properties that describe the view object instance names that should be used for the list of all available choices (leading list or available product categories) and the list of selected choices (trailing list or assigned product categories).

[Example 30–15](#) shows the `CustRegBasicInformationBean` class that is created to manage the population and selection state of the shuttle component on the `basicInformation.jsff` page.

Example 30–15 CustRegBasicInformationBean Class

```
package oracle.fodemo.storefront.account.view.managed;
import java.io.Serializable;
import java.util.List;
import javax.faces.application.FacesMessage;
import javax.faces.context.FacesContext;
import oracle.binding.OperationBinding;
import oracle.binding.BindingContainer;
import oracle.fodemo.storefront.adf.util.ADFUtils;
import javax.faces.event.ValueChangeEvent;
import oracle.fodemo.storefront.jsf.util.JSFUtils;
public class CustRegBasicInformationBean implements Serializable {
    String allItemsIteratorName;
    String allItemsValueAttrName;
    String allItemsDisplayAttrName;
    String allItemsDescriptionAttrName;
    String selectedValuesIteratorName;
    String selectedValuesValueAttrName;
    List selectedValues;
    List allItems;
    private boolean refreshSelectedList = false;
    public CustRegBasicInformationBean() {
    }

    public void setAllItemsIteratorName(String allItemsIteratorName) {
        this.allItemsIteratorName = allItemsIteratorName;
    }
    public String getAllItemsIteratorName() {
        return allItemsIteratorName;
    }

    // other getter and setter methods are omitted
    public void setSelectedValues(List selectedValues) {
        this.selectedValues = selectedValues;
    }
    public void refreshSelectedList(ValueChangeEvent event) {
        refreshSelectedList = true;
    }
}
```

```

    }
    public List getSelectedValues() {
        if (selectedValues == null || refreshSelectedList) {
            selectedValues =
                ADFUtils.attributeListForIterator(selectedValuesIteratorName,
                                                selectedValuesValueAttrName);
        }
        return selectedValues;
    }
    public void setAllItems(List allItems) {
        this.allItems = allItems;
    }

    public List getAllItems() {
        if (allItems == null) {
            allItems =
                ADFUtils.selectItemsForIterator(allItemsIteratorName,
                                                allItemsValueAttrName,
                                                allItemsDisplayAttrName,
                                                allItemsDescriptionAttrName);
        }
        return allItems;
    }
}

```

The `getAllItems()` method populates the shuttle's leading list. The `getSelectedValues()` method also returns a `List`, but the list defines the items in the shuttle's trailing list. The values returned by `getSelectedValues()` are a subset of the values returned by `getAllItems()`. Values that are in `getAllItems()` but not in `getSelectedValues()` will be ignored (and will generate an error in the server log). Note that the `CustRegBasicInformationBean` class calls several utility methods in the `ADFUtils` class. Also note that this class uses values for several properties of the base bean. [Example 30-16](#) shows the managed bean and managed properties configured in `customer-registration-task-flow.xml` for working with the shuttle component.

Example 30-16 Managed Bean for the Shuttle Component in the customer-registration-task-flow File

```

<managed-bean>
  <managed-bean-name>

```

The `basicInformation.jsff` page uses the following iterator objects:

- `CustomerRegistrationIterator`: Iterates over the `CustomerRegistration` collection, which provides the context for the form above the shuttle.
- `SelectedCategoriesShuttleListIterator`: Iterates over the `SelectedCategoriesShuttleList` collection, which provides the list of categories assigned to the current customer.
- `AvailableCategoriesShuttleListIterator`: Iterates over the `AvailableCategoriesShuttleList` collection, which provides the list of product categories.

All the bindings of the `basicInformation.jsff` page are defined in the file `account_basicInformationPageDef.xml`. [Example 30–17](#) shows part of the page definition file for the `basicInformation.jsff` page.

Example 30–17 Page Definition File for the `basicInformation` Page

```

<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uiamodel"
    version="11.1.1.48.68" id="account_basicInformationPageDef"
    Package="oracle.fodemo.storefront.pageDefs">
    <parameters/>
    <executables>
        <page path="oracle.fodemo.storefront.pageDefs.
            templates_StoreFrontTemplatePageDef"
            id="pageTemplateBinding"/>
        <iterator Binds="CustomerRegistration" RangeSize="25"
            DataControl="StoreServiceAMDDataControl"
            id="CustomerRegistrationIterator" Refresh="ifNeeded"/>
        <iterator id="SelectedCategoriesShuttleListIterator"
            Binds="SelectedCategoriesShuttleList" RangeSize="-1"
            DataControl="StoreServiceAMDDataControl"/>
        <iterator id="AvailableCategoriesShuttleListIterator"
            Binds="AvailableCategoriesShuttleList" RangeSize="-1"
            DataControl="StoreServiceAMDDataControl"/>
        <invokeAction Binds="setHelpId" id="invokeSetHelpId" Refresh="ifNeeded"/>
    </executables>

```

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a shuttle. For more information, see [Section 30.5, "Creating a Databound Shuttle."](#)

You may also find it helpful to understand functionality that can be used with selection lists. For more information, see [Section 30.1.2, "Additional Functionality for Selection Lists and Shuttles."](#)

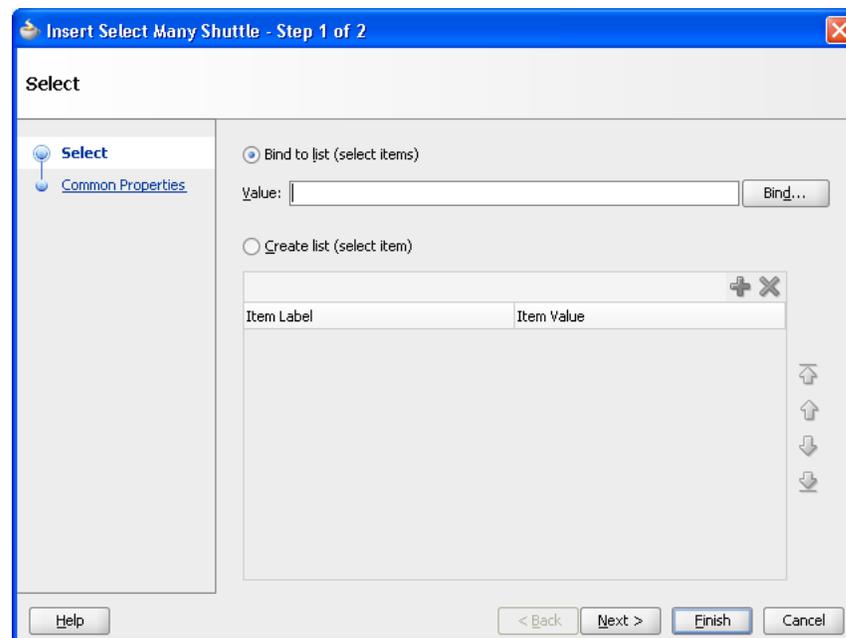

You will need to complete these tasks:

1. Create the relevant iterator bindings in the page definition file. Use [Example 30–17](#) as a guide.
2. Create a class similar to the `CustRegBasicInformationBean` class. Use [Example 30–15](#) as a guide.
3. Configure the required managed bean and managed properties in the task flow definition or, in the case of an unbounded task flow, the `adf-config.xml` file. Use [Example 30–16](#) as a guide.

To create a shuttle component:

1. In the Common Components page of the Component Palette, from the Common panel, drag and drop **SelectManyShuttle** onto the page. JDeveloper displays the Insert SelectManyShuttle wizard, as illustrated in [Figure 30–8](#).

Figure 30–8 Insert SelectManyShuttle Wizard

2. Select **Bind to list (select items)** and click **Bind** to open the Expression Builder.
3. In the Expression Builder, expand **ADF Managed Beans > pageFlowScope > CustRegBasicInformationBean > allItems** to build the expression `{pageFlowScope.custRegBasicInformationBean.allItems}` and click **Next**.

This binds the `f:selectItems` tag to the `getAllItems()` method that populates the shuttle's leading list.

4. In the Common Properties page, click **Bind** next to the **Value** field to open the Expression Builder again.
5. In the Expression Builder, expand **ADF Managed Beans > pageFlowScope > CustRegBasicInformationBean > selectedValues** to build the expression

`#{pageFlowScope.custRegBasicInformationBean.selectedValues}` and click **Finish**.

This binds the value attribute of the `selectManyShuttle` component to the `getSelectedValues()` method that populates the shuttle's trailing list.

[Example 30–18](#) shows the code for the `selectManyShuttle` component after you complete the Insert `SelectManyShuttle` dialog.

Example 30–18 *SelectManyShuttle* Component in *basicInformation.jsff* File

```
<af:selectManyShuttle
    value="#{pageFlowScope.custRegBasicInformationBean.selectedValues}"
    leadingHeader="#{res['basicinfo.leadingHeader']}"
    trailingHeader="#{res['basicinfo.trailingHeader']}"
    leadingDescShown="true" size="8"
    trailingDescShown="true"
    inlineStyle="background-color:transparent;"
    id="sms1">
    <f:selectItems
        value="#{pageFlowScope.custRegBasicInformationBean.allItems}"/>
</af:selectManyShuttle>
```

Creating ADF Databound Search Forms

This chapter describes how to create search forms to perform complex searches on multiple attributes and search forms to search on a single attribute. It also includes information on using named bind variables and using filtered table searches.

This chapter includes the following sections:

- [Section 31.1, "About Creating Search Forms"](#)
- [Section 31.2, "Creating Query Search Forms"](#)
- [Section 31.3, "Setting Up Search Form Properties"](#)
- [Section 31.4, "Creating Quick Query Search Forms"](#)
- [Section 31.5, "Creating Standalone Filtered Search Tables from Named View Criteria"](#)

31.1 About Creating Search Forms

You can create search forms that allow users to enter search criteria into input fields for known attributes of an object. The search criteria can be entered via input text fields or selected from a list of values in a popup list picker or dropdown list box. The entered criteria is constructed into a query to be executed. *Named bind variables* can be used to supply attribute values during runtime for the query. The results of the query can be displayed as a table, a form, or another UI component.

Oracle ADF supports two types of search forms: query and quick query. The *query search form* is a full-featured search form. The *quick query search form* is a simplified form with only one search criteria. Each of these search forms can be combined with a filtered table to display the results, thereby enabling additional search capabilities. You can also create a standalone filtered table to perform searches without the query or quick query search panel.

Search forms are based either on view criteria defined in view objects or on implicit view criteria defined by JDeveloper. Search forms are region-based components that are reusable and personalizable. They encapsulate and automate many of the actions and iterator management operations required to perform a query. You can create several search forms on the same page without any need to change or create new iterators.

A *filtered table* is a table that has additional Query-by-Example (QBE) search criteria fields above each searchable column. When the filtering option of a table is enabled, you can enter QBE-style search criteria for each column to filter the query results. For more information about tables, see [Chapter 27, "Creating ADF Databound Tables."](#)

For more information about individual query and table components, see the "Using Query Components" and the "Using Tables and Trees" chapters of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

31.1.1 Implicit and Named View Criteria

When you create data controls, all data collections will automatically include a Named Criteria node with an All Queriable Attributes criteria. This is the default view criteria that includes all the searchable attributes or columns of the data collection. You cannot edit or modify this view criteria. These implicit view criteria can be used in the same way as declaratively created (or named) view criteria during the creation of query and quick query search forms. For more information about creating named view criteria, see [Section 5.11, "Working with Named View Criteria."](#)

When you add additional named view criteria for that view object or collection, the new view criteria will be added to the Named Criteria node.

Note: Query search forms have certain restrictions for working with expressions that have nested view criteria and may not work with all types of nested expressions. For more information about the nested expressions supported by search forms, see [Section 5.11.4, "What You May Need to Know About Nested Expressions."](#)

In the Data Controls panel, a data collection's Named Criteria node will always include the implicit view criteria, regardless of whether any named view criteria were defined. The implicit view criteria is always available for every data collection.

31.1.2 List of Values (LOV) Input Fields

List of values (LOV) components are input components that allow the user to enter values by picking from a list that is generated by a query. ADF Faces provides the `af:inputListOfValues` and `af:inputComboboxListOfValues` components. If you are using dependent LOVs as part of your search form, you must use them with the `af:query` component. For more information about LOV components, see [Section 30.2, "Creating List of Values \(LOV\) Components."](#)

If an attribute is defined as an LOV, you can set the **Support Multiple Value Selection** control hint in its view criteria to enable users to make multiple selections in the search criteria field. If multiple selection is enabled on an LOV attribute, and the `Equal to` or `Not equal to` operator is chosen, a `selectManyChoice` component will render in the query panel. The user can select multiple items as the search criteria.

When the LOV is in a query component, if the **Support Multiple Value Selection** hint is not set and the `Equal to` or `Not equal to` operator is chosen, the query component will render a search criteria component according to the **Default List Type** control hint for the corresponding attribute in the view object.

The quick query component does not support multiple selection. It will always render the component specified by the **Default List Type** control hint. [Table 31–1](#) shows the control hint selection and the default list component.

Table 31–1 Query and Quick Query Search Criteria Field Input Components

Default List Type Control Hint	Component
Input Text with List of Values	<code>af:inputListOfValues</code>

Table 31–1 (Cont.) Query and Quick Query Search Criteria Field Input Components

Default List Type Control Hint	Component
Combo Box with List of Values	<code>af:inputComboboxListOfValues</code>
Choice List, Combo Box, List Box, Radio Group	<code>af:selectOneChoice</code>

For more information about view criteria options, see [Section 5.11.1, "How to Create Named View Criteria Declaratively,"](#) and [Section 5.11.3, "What You May Need to Know About Bind Variable Options."](#)

31.1.3 Search Form Use Cases and Examples

The search forms are based on the model-driven `af:query` and `af:quickQuery` components. Because these underlying components are model-driven, the search form will change automatically to reflect changes in the model. The view layer does not need to be changed. For example, if you define a list of values (LOV) on an attribute in the view object or entity object, the LOV will automatically show up in the search form as an LOV component. Or, if you modify a view criteria to include a new attribute for the `WHERE` clause, the search panel using this view criteria will automatically reflect that change by adding a search field for that attribute.

In the StoreFront module of the Fusion Order Demo application, a quick query is used to allow the user to perform a simple search among several attributes that can be used to find a product. For instance, user can select to search on product id and then entering a code, or search on product name and entering a name, as shown in [Figure 31–1](#).

Figure 31–1 Quick Query

For more complex searches, such as including criteria for product name, price ranges, and availability, a query component is used. You can create the query component in several different modes to give the user different capabilities, as shown in [Figure 31–2](#). The user can even add their own search criteria using the **Add Fields** button. The user can save the searches that were created to be used later.

Figure 31–2 Query Component

For simple searches, you can use the filtered table to provide Query-by-Example (QBE) searches, as shown in [Figure 31–3](#).

Figure 31–3 Filtered Table Searches

31.1.4 Additional Functionality for Search Forms

You may find it helpful to understand other ADF features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- Both the query and quick query components are based on the view criteria defined in a view object. You use the view criteria to set up the initial search fields and search criteria. You use control hints to further define the query component. For more information about creating named view criteria, see [Section 5.11, "Working with Named View Criteria."](#)
- Since filtered tables also provide search functions, you should consider them for simple searches. For more information about tables, see [Chapter 27, "Creating ADF Databound Tables."](#)
- List of value components use the query component in their search panel for creating the list of values selection list. For more information about LOV components, see [Section 30.2, "Creating List of Values \(LOV\) Components."](#)
- If your application is set up with a Metadata Storage (MDS), you can persist saved searches across transactions and personalize your searches. For more information about using MDS, see [Chapter 39, "Customizing Applications with MDS."](#)

31.2 Creating Query Search Forms

The query search form is the standard form for complex transactional searches. You can build complex search forms with multiple search criteria fields each with a dropdown list of built-in operators. You can also add custom operators and customize the list. The query search form supports lists of values, AND and OR conjunctions, and saving searches for future use.

A query search form has a basic mode and an advanced mode. The user can toggle between the two modes using the basic/advanced button. At design time, you can declaratively specify form properties (such as setting the default state) to be either

basic or advanced. [Figure 31–4](#) shows an advanced mode query search form with three search criteria.

Figure 31–4 Advanced Mode Query Search Form

The advanced mode query form features are:

- Selecting search criteria operators from a dropdown list
- Adding custom operators and deleting standard operators
- Selecting WHERE clause conjunctions of either AND or OR (match all or match any)
- Dynamically adding and removing search criteria fields at runtime
- Saving searches for future use
- Personalizing saved searches

Typically, the query search form in either mode is used with an associated results table or tree table. For example, the query results for the search form in [Figure 31–4](#) may be displayed in a table, as shown in [Figure 31–5](#).

Figure 31–5 Results Table for a Query Search

The basic mode has all the features of the advanced mode except that it does not allow the user to dynamically add search criteria fields. [Figure 31–6](#) shows a basic mode query search form with one search criteria field. Notice the lack of a dropdown list next to the **Save** button used to add search criteria fields in the advanced mode.

Figure 31–6 Basic Mode Query Form with One Search Criteria Field

In either mode, each search criteria field can be modified by selecting operators such as *Greater Than* and *Equal To* from a dropdown list, and the entire search panel can be modified by the **Match All/Any** radio buttons. Partial page rendering is also supported by the search forms in almost all situations. For example, if a *Between* operator is chosen, another input field will be displayed to allow the user to select the upper range.

A *Match All* selection implicitly uses AND conjunctions between the search criteria in the WHERE clause of the query. A *Match Any* selection implicitly uses OR conjunctions in the WHERE clause. [Example 31–3](#) shows how a simplified WHERE clause may appear (the real WHERE in the view criteria is different) when *Match All* is selected for the search criteria shown in [Figure 31–4](#).

Example 31–1 Simplified WHERE Clause Fragment When "Match All" Is Selected

```
WHERE (ProductId=4) AND (InStock > 2) AND (ProductName="Ipod")
```

[Example 31–1](#) shows a simplified WHERE clause if **Match Any** is selected for the search criteria shown in [Example 31–2](#).

Example 31–2 Simplified WHERE Clause Fragment When "Match Any" Is selected

```
WHERE (ProductId=4) OR (InStock > 2) OR (ProductName="Ipod")
```

If the view criteria for the query has mixed AND and OR conjunctions between the criteria items, then neither **Match All** nor **Match Any** will be selected when the component first renders. However, the user can select **Match All** or **Match Any** to override the conjunctions defined as the initial state in the view criteria.

Advanced mode query forms allow users to dynamically add search criteria fields to the query panel to perform more complicated queries. These user-created search criteria fields can be deleted, but the user cannot delete existing fields. [Figure 31–7](#) shows how the **Add Fields** dropdown list is used to add the **CategoryId** criteria field to the search form.

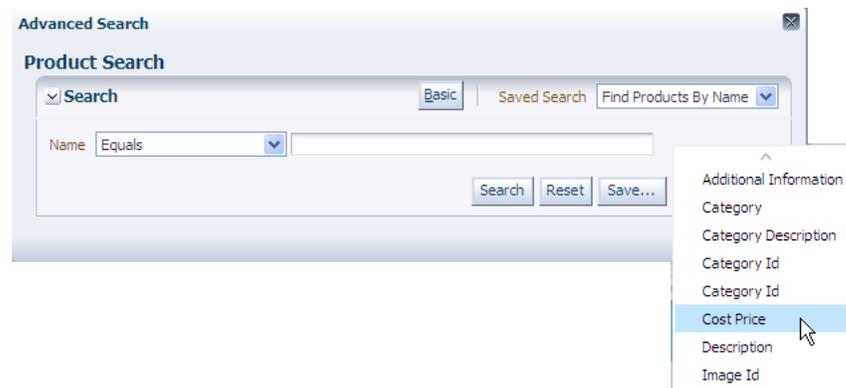

Figure 31–7 Dynamically Adding Search Criteria Fields at Runtime

Figure 31–8 shows a user-added search criteria with the delete icon to its right. Users can click the delete icon to remove the criteria.

Figure 31–8 User-Added Search Criteria with Delete Icon

If either **Match All** or **Match Any** is selected and then the user dynamically adds the second instance of a search criterion, then both **Match All** and **Match Any** will be deselected. The user must reselect either **Match All** or **Match Any** before clicking the **Search** button.

If you intend for a query search form to have both a basic and an advanced mode, you can define each search criteria field to appear only for basic, only for advanced, or for both. When the user switches from one mode to the other, only the search criteria fields defined for that mode will appear. For example, suppose three search fields for basic mode (A, B, C) and three search fields for advanced mode (A, B, D) are defined for a query. When the query search form is in basic mode, search criteria fields A, B, and C will appear. When it is in advanced mode, then fields A, B, and D will appear. Any search data that was entered into the search fields will also be preserved when the form returns to that mode. If the user entered 35 into search field C in basic mode, switched to advanced mode, and then switched back to basic, field C would reappear with value 35.

Along with using the basic or advanced mode, you can also determine how much of the search form will display. The default setting displays the whole form. You can also configure the query component to display in compact mode or simple mode. The compact mode has no header or border, and the **Saved Search** dropdown lists moves next to the expand/collapse icon. Figure 31–9 shows a query component set to compact mode.

Figure 31–9 Query Component in Compact Mode

The simple mode displays the component without the header and footer, and without the buttons normally displayed in those areas. Figure 31–10 shows the same query component set to simple mode.

Figure 31–10 Query Component in Simple Mode

A query is associated with the view object that it uses for its query operation. In particular, a query component is the visual representation of the view criteria defined for that view object. If there are multiple view criteria defined, each can be selected from the **Saved Search** dropdown list. These saved searches are created at design time and are called *system searches*. For example, in the StoreFront module of the Fusion Order Demo application, there are two view criteria defined on the `ProductsVO` view object. When the query associated with that view criteria is run, both view criteria are available for selection, as shown in Figure 31–11.

Note: Be aware that opening and closing the query panel by clicking the panel expansion/collapse icon does not reset the applied view criteria. You can click the **Reset** button to reset the applied view criteria.

Figure 31–11 Query Form Saved Search Dropdown List

If there are no explicitly defined view criteria for a view object, you can use the default implicit view criteria.

Users can also create saved searches at runtime to save the state of a search for future use. The entered search criteria values, the basic/advanced mode state, and the layout of the results table/component can be saved by clicking the **Save** button to open a Save Search dialog, as shown in Figure 31–12. User-created saved searches persist for the session. If they are intended to be available beyond the session, you must configure a persistent data store to store them. For Oracle ADF, you can use an access-controlled

data source such as MDS. For more information about using MDS, see [Chapter 39, "Customizing Applications with MDS."](#)

Figure 31–12 Runtime Saved Search Dialog Window

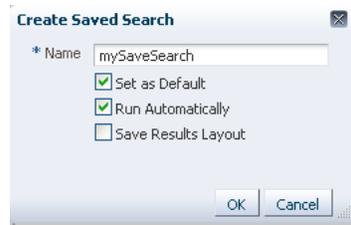

Table 31–1 lists the possible scenarios for creators of saved searches, the method of their creation, and their availability.

Table 31–2 Design Time and Runtime Saved Searches

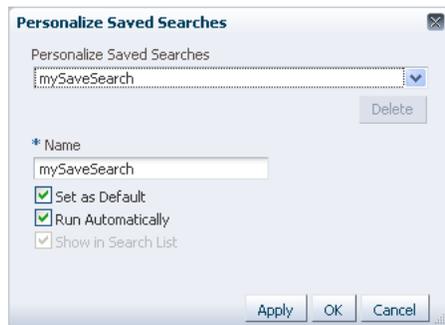

Creator	Created at Design time as View Criteria	Created at Runtime with the Save Button
Developer	Developer-created saved searches (system searches) are created during application development and typically are a part of the software release. They are created at design time as view criteria. They are usually available to all users of the application and appear in the lower part of the Saved Search dropdown list.	
Administrator		Administrator-created saved searches are created during predeployment by site administrators. They are created before the site is made available to the general end users. Administrators can create saved searches (or view criteria) using the JDeveloper design time when they are logged in with the appropriate role. These saved searches (or view criteria) appear in the lower part of the Saved Search dropdown list.
End User		End-user saved searches are created at runtime using the query form Save button. They are available only to the user who created them. End-user saved searches appear in the top part of the Saved Search dropdown list.

End users can manage their saved searches by using the Personalize function in the **Saved Search** dropdown list to bring up the Personalize Saved Searches dialog, as shown in [Figure 31–13](#).

End users can use the Personalize function to:

- Update a saved search. Users can add and/or remove search criterion, update operators, update values, modify conjunctions and save it using the existing saved search name. In other words, overriding an existing saved search.
- Delete a saved search (including the currently active Saved Search)
- Set a saved search as the default
- Set a saved search to run automatically
- Set the saved search to show or hide from the **Saved Search** dropdown list

Figure 31–13 Personalize Saved Searches Dialog

Note: If in you are changing the value of a view criteria item programmatically, you must invoke the `ViewCriteria.saveState()` method to prevent the `searchRegion` binding from resetting the value of the view criteria item to the value that was specified at design time.

You create a query search form by dropping a named view criteria item from the Data Controls panel onto a page. You have a choice of dropping only a search panel, dropping a search panel with a results table, or dropping a search panel with a tree table.

If you choose to drop the search panel with a table, you can select the filtering option in the dialog to turn the table into a filtered table.

Typically, you would drop a query search panel with the results table or tree table. JDeveloper will automatically create and associate a results table or tree table with the query panel.

If you drop a query panel by itself and want a results component or if you already have an existing component for displaying the results, you will need to match the query panel's `ResultsComponentId` with the results component's `Id`.

Note: When you drop a named view criteria onto a page, that view criteria will be the basis for the initial search form. All other view criteria defined against that data collection will also appear in the **Saved Search** dropdown list. Users can then select any of the view criteria search forms, and also any end-user created saved searches.

31.2.1 Named Bind Variables in Query Search Forms

Instead of specifying a literal operand in a view criteria to be used in a search form, you have the option of specifying a named bind variable. The named bind variable performs like a parameter whose value can change at runtime without the need to change the SQL statement. It must be defined in the view object before it can be used in a view criteria.

If you specify a literal operand in the view criteria and leave the value blank, it will not appear in the SQL preview. When the view criteria is applied as a search form at runtime, that attribute is rendered as a blank input search field. If a value is specified for the literal operand, then the SQL preview will generate a SQL clause for it. When the view criteria is applied as a search form at runtime, the SQL statement is not automatically applied even though the value specified in the view criteria appears in the input search field. The SQL statement won't get applied until the user clicks **Search** (or when auto-execute is set to true).

If a named bind variable is used in the query defined in the view criteria, the SQL preview will display the `WHERE` clause with the bind variable. When the view criteria is applied as a search form at runtime, the bind variable will be rendered with a prompt and an input search field based on the name of the attribute (not on the name of the bind variable). The named bind variable input field may be `NULL`, it may contain the default value, or it may contain a value that has loaded from previous processing, such as from another page. The user can enter values for the named bind variable as in any other search criteria. When the search is executed, the value of the named bind variable will be evaluated with the other criteria, as defined by the SQL query statement.

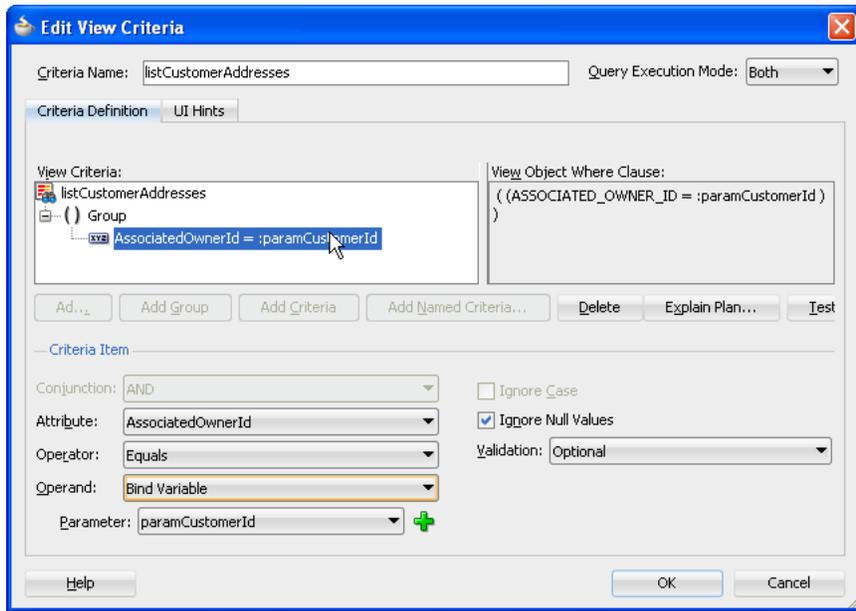

If the bind variable is used more than once in the same view criteria, each occurrence of the bind variable will be rendered as an individual input field. Because there is only one bind variable backing all the input fields, the value of all the fields will be synchronized. For instance, if you specify a view criteria that uses the same bind variable three times, then three input fields will be rendered. When the user enters a value into one input field, the other two input fields will have the same value. Using bind variables in this way eliminates the need for the user to enter the same value multiple times.

Another use of the bind variable is to pass a value from the base row into a search for an LOV search form.

Bind variables can also be used to pass parameter values from one page to another, such as when a customer ID is passed to another page for more detail processing. And, depending on the construct of the SQL statement, using the named bind variable may speed up the query because it may lessen the need to prepare a new statement, which means that the database does not need to reparse. For more information about creating and using named bind variables, see [Section 5.10, "Working with Bind Variables."](#)

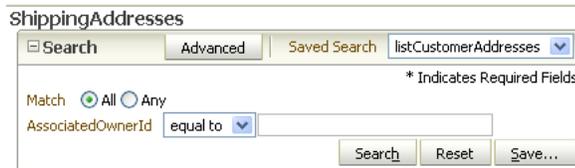

For example, in the StoreFront module of the Fusion Order Demo application, in the `listCustomerAddresses` view criteria, the `WHERE` clause checks to see whether the `AssociatedOwnerId` is the same as the value of the `paramCustomerId` named bind variable. This view criteria is in the `AddressesLookupVO` view object. The `listCustomerAddresses` view criteria as defined in the Edit View Criteria dialog is shown in [Figure 31-14](#).

Figure 31–14 View Criteria with Named Bind Variable

A query search form for a view criteria with a named bind variable will render with a search field for the variable using the `inputText` component. Figure 31–15 shows the `AssociatedOwnerId` search field displayed as an `inputText` component.

Figure 31–15 Query Search Form with Named Bind Variable

31.2.2 How to Create a Query Search Form with a Results Table or Tree Table

You create a search form by dragging and dropping a view criteria from the Data Controls panel onto the page. You have the option of having a results table or only the query panel.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see [Section 31.2, "Creating Query Search Forms."](#)

You may also find it useful to understand functionality that can be used with query search forms. For more information, see [Section 31.1.4, "Additional Functionality for Search Forms."](#)

You will need to complete these tasks:

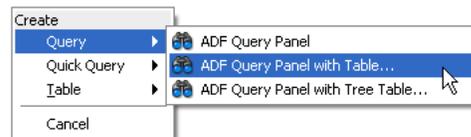

1. Create a view object.

2. Create view criteria if you intend to create search forms based on view criteria. You can also use the default implicit view criteria, which would include all queryable attributes in the collection.
3. Set the search form default properties. For more information about setting the default state of the search form, see [Section 31.3.1, "How to Set Search Form Properties on the View Criteria."](#) For information on how to create view criteria, see [Section 5.11, "Working with Named View Criteria."](#)

To create a query search form with a results table or tree table:

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the named view criteria item and drop it onto the page or onto the Structure window.
3. From the context menu, choose **Create > Query > ADF Query Panel with Table** or **Create > Query > ADF Query Panel with Tree Table**, as shown in [Figure 31–16](#).

Figure 31–16 Data Controls Panel with Query Context Menu

4. In the Edit Table Columns dialog, you can rearrange any column and select table options. If you choose the filtering option, the table will be a filtered table.

After you have created the form, you may want to set some of its properties or add custom functions. For more information on how to do this, see [Section 31.3, "Setting Up Search Form Properties."](#)

31.2.3 How to Create a Query Search Form and Add a Results Component Later

You create a search form by dragging and dropping a view criteria from the Data Controls panel onto the page. You have the option of having a results table or only the query panel.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see [Section 31.2, "Creating Query Search Forms."](#)

You may also find it useful to understand functionality that can be used with query search forms. For more information, see [Section 31.1.4, "Additional Functionality for Search Forms."](#)

You will need to complete these tasks:

1. Create a view object.
2. Create view criteria if you intend to create search forms based on view criteria. You can also use the default implicit view criteria, which would include all queryable attributes in the collection.
3. Set the search form default properties. For more information about setting the default state of the search form, see [Section 31.3.1, "How to Set Search Form](#)

[Properties on the View Criteria.](#) For information on how to create view criteria, see [Section 5.11, "Working with Named View Criteria."](#)

To create a query search form and add a results component in a separate step:

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the named view criteria item and drop it onto the page or onto the Structure window.
3. Choose **Create > Query > ADF Query Panel** from the context menu, as shown in [Figure 31-16](#).
4. If you do not already have a results component, then drop the data collection associated with the view criteria as a component.
5. In the Property Inspector for the table, copy the value of the **Id** field.
6. In the Property Inspector for the query panel, paste the value of the table's ID into the query's **ResultsComponentId** field.

After you have created the search form, you may want to set some of its properties or add custom functions. See [Section 31.3, "Setting Up Search Form Properties,"](#) for more information.

31.2.4 How to Persist Saved Searches into MDS

If you want saved searches to be persisted to MDS, you need to define the `/persdef` namespace in the `adf-config.xml` file. In addition, you need to perform the regular MDS configuration, such as specifying `metadatapath`. [Example 31-3](#) shows an `adf-config.xml` file with the `/persdef` namespace defined.

Example 31-3 Sample `adf-config.xml` with `/persdef` Namespace

```
<persistence-config>
  <metadata-namespaces>
    <namespace path="/persdef" metadata-store-usage="mdsstore"/>
  </metadata-namespaces>
  <metadata-store-usages>
    <metadata-store-usage id="mdsstore" deploy-target="true"
      default-cust-store="true">
    </metadata-store-usage>
  </metadata-store-usages>
</persistence-config>
```

In order for the added saved searches to be available the next time the user logs in, `cust-config` needs to be defined as part of the MDS configuration. For more information about setting `cust-config` and MDS, see [Section 39.2.1, "How to Create Customization Classes."](#)

If you are also saving the layout of the results component, the application must have the ADF PageFlow Runtime and ADF Controller Runtime libraries installed. Set the project's technology scope to include **ADF Page Flow** or automatically include these libraries by using the Fusion Web Application (ADF) application template.

31.2.5 How to Set Default Search Binding Behavior

A *search binding* provides the model-driven behavior for a search form at runtime. The search binding is related to a particular iterator and the view criteria on that iterator, whose runtime defaults are specified by the `Binds` and `Criteria` properties of the search

binding, respectively. The behavior of the search binding depends on the **Query Automatically** control hint. For more information about creating named view criteria, see [Section 5.11, "Working with Named View Criteria."](#)

The first time a search form is rendered in a task flow, the search binding's runtime behavior, also known as the initial AutoQuery-or-ClearRowSet behavior, is as follows:

- If **Query Automatically** is set to `true`: The search binding automatically executes the iterator when the search binding is initialized in a task flow. The user will be presented with the results of the search based on the view criteria.
- If **Query Automatically** is set to `false`: The search binding clears the row set related to its iterator. The user will be presented with an empty search results component, which allows the user to enter search criteria and click the **Search** button to execute the search.

The **Query Automatically** control hint is available declaratively only for named view criteria. For the All Queriable Attributes view criteria, you can use the `setProperty()` method on the view criteria API interface to configure the hint at runtime. You can also use this method to set the hint on named view criteria. In the method, set the `ViewCriteriaHints.CRITERIA_AUTO_EXECUTE` property to `true`.

If the user changes the search form by selecting a different view criteria from the dropdown **Saved Search** list, the runtime behavior is as follows:

- If **Query Automatically** is set to `true`: The search binding automatically executes the iterator after applying the new view criteria. The user will be presented with the results of the newly selected saved search.
- If **Query Automatically** is set to `false`: The search binding applies the new view criteria only, leaving any existing search results intact. The user is presented with the results of the previous search.

The search binding's `queryPerformed` property evaluates to `true` if the search binding has performed the query, either automatically or by the user clicking the **Search** button. Clicking the **Reset** button in the search form resets the view criteria and sets the `queryPerformed` property to `false`.

The search binding offers two properties that allow you to customize its default behavior: `TrackQueryPerformed` and `InitialQueryOverridden`. You can set the `TrackQueryPerformed` and the `InitialQueryOverridden` properties in the Property Inspector.

A search binding's `TrackQueryPerformed` property controls whether it manages its `queryPerformed` property during runtime at the page flow level or at the individual page or page fragment level. The valid values for `TrackQueryPerformed` are `pageFlow` and `page`, and the default is `pageFlow`. The search binding's behavior is as follows:

- If `TrackQueryPerformed` is set to `pageFlow`, then `queryPerformed` is initialized once per page flow and tracked at the page flow level. The user can navigate away from the search form page, return to the page within the life of the page flow, and the value of the `queryPerformed` flag will remain the same.
- If `TrackQueryPerformed` is set to `page`, then `queryPerformed` is initialized each time the user navigates to the page or page fragment. This happens when the page is navigated to for the first time and when the page is returned from another page within the page flow.

When `TrackQueryPerformed` of a search binding is set to `pageFlow`, its initial AutoQuery-or-ClearRowSet behavior is performed once during the page flow. In

contrast, when `TrackQueryPerformed` is set to `page`, the initial `AutoQuery-or-ClearRowSet` behavior is performed each time the user visits the page or page fragment.

A search binding's `InitialQueryOverridden` property controls whether it should suppress its initial `AutoQuery-or-ClearRowSet` behavior the first time the search binding is used in a page flow. If `InitialQueryOverridden` is `true`, then all valid values, including `true`, `false`, or a boolean-valued EL expression, are suppressed. The default value is `false`.

When you set the `InitialQueryOverridden` property to `true`, you are responsible for writing custom application logic to execute the query. Typically, the query should execute after the code applies some view criteria, sets some bind variables, or performs some other programmatic query setup. If your custom code fails to execute the query as expected with `InitialQueryOverridden` set to `true`, unless **Query Automatically** is set to `false`, the framework will still implicitly execute your query the first time during a user session in which there is an iterator binding reference. This occurs because when **Query Automatically** is not set to `false`, the iterator binding's default `executeQueryIfNeeded` behavior takes effect and executes the query.

When `InitialQueryOverridden` evaluates to `true` or boolean `true`, then the initial `AutoQuery-or-ClearRowSet` behavior is suppressed the first time the search binding is used in a page flow. If `TrackQueryPerformed` is set to `pageFlow`, then only the initial `AutoQuery-or-ClearRowSet` behavior (that would have occurred for this search binding) is suppressed.

In contrast, if a search binding's `TrackQueryPerformed` property is set to `page`, then only the initial `AutoQuery-or-ClearRowSet` behavior is suppressed. Subsequent initial `AutoQuery-or-ClearRowSet` behaviors that occur due to the user's navigating back to the same page (or page fragment) are not affected by the `InitialQueryOverridden` property.

If you want to avoid the search binding's performing any initial `AutoQuery-or-ClearRowSet` behavior, then leave the `TrackQueryPerformed` set to `pageFlow` and set `InitialQueryOverridden` to `true`.

You should not use the `RefreshCondition` property of an iterator to reference the `queryPerformed` property of a search binding. Doing so will inadvertently prevent new rows from being created in that iterator's row set until after the search binding's query has been performed.

31.2.6 What You May Need to Know About Dependent Criterion

There are situations when one search criteria is dependent on the value of another criteria. For example, a bug database has a search form with a `Component` and a `Subcomponent` search criteria, both defined as LOVs. When the user selects a value from the `Component` search criteria, that value must be submitted to the model so that `Subcomponent` can be filtered and populated with the appropriate search list for the user to choose from.

If you have a search criteria that has dependents, you must set the root and dependent criteria's underlying view attribute's **Auto Submit** control hint to `true`. You can create a custom listener to trigger a partial submit to update the model and refresh the search panel when the query component detects a value change for the root criteria. You need to create a custom listener because the standard `QueryOperationListener` does not handle this event type. You can create a custom `QueryOperationListener` class using the `QueryOperationListener` interface. You then register this class by implementing it in a managed bean or by directly setting it in the JSF page.

31.2.7 What Happens When You Create a Query Form

When you drop a query search form onto a page, JDeveloper creates an `af:query` tag on the page. If you drop a query with table or tree table, then an `af:table` tag or `af:treeTable` tag will follow the `af:query` tag.

Under the `af:query` tag are several attributes that define the query properties. They include:

- The `id` attribute, which uniquely identifies the query.
- The `resultsComponentId` attribute, which identifies the component that will display the results of the query. Typically, this will be the table or tree table that was dropped onto the page together with the query. You can change this value to be the `id` of a different results component. For more information, see [Section 31.2.3, "How to Create a Query Search Form and Add a Results Component Later."](#)

In the page definition file, JDeveloper creates an iterator and a `searchRegion` entry in the `executables` section. [Example 31–4](#) shows the sample code for a page definition file.

In the page definition file `executable` section:

- The iterator `binds` property is set to the name of the data collection. In the example, the value is set to `Products`.
- The iterator `id` property is set to a data collection iterator. In the example, the value is set to `SearchProductsIterator`
- If there is more than one view criteria defined for that data collection, the `searchRegion Criteria` property is set to the name of the view criteria that was dropped. In the example, the value is set to `FindByProductNameCriteria`. If there is only one view criteria defined, then there will not be a `Criteria` property.
- The `searchRegion Binds` property is set to the same value as the iterator `id` property. In the example, the value is set to `SearchProductsIterator`
- The `searchRegion id` property is set to the name of the view criteria concatenated with `Query`. In the example, the value is set to `FindByProductNameCriteriaQuery`.

If the query was dropped onto the page with a table or tree, then in the page definition file `bindings` section, a tree element is added with the `Iterbinding` property set to the search iterator. In this example, the value is set to `SearchProductsIterator`. This should be the same iterator defined in the `executable` section.

Example 31–4 Search Form Code in the Page Definition File

```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
  version="11.1.1.52.34" id="homePageDef"
  Package="oracle.fodemo.storefront.pageDefs"
  EnableTokenValidation="false">
  <parameters/>
<executables>
  ...
  <iterator Binds="Products" RangeSize="25"
    DataControl="StoreServiceAMDataControl"
    id="SearchProductsIterator"/>
  ...
<searchRegion Criteria="FindByProductNameCriteria"
```

```

        Customizer="oracle.jbo.uicli.binding.JUSearchBindingCustomizer"
        Binds="SearchProductsIterator"
        id="FindByProductNameCriteriaQuery" />
    ...
</executables>
<bindings>
    <tree IterBinding="SearchProductsIterator"
        id="SearchProducts">
        <nodeDefinition DefName="oracle.fodemo.storefront.store.queries.ProductsVO"
            Name="SearchProducts">
            <AttrNames>
                <Item Value="ProductId" />
                <Item Value="ProductName" />
                <Item Value="ListPrice" />
                <Item Value="MinPrice" />
            ...
            </AttrNames>
        </nodeDefinition>
    </tree>
    ...
</bindings>

```

31.2.8 What Happens at Runtime: Search Forms

At runtime, the search form displays as a search panel on the page. The search panel will display in either basic mode or advanced mode, depending on the mode control hint when its corresponding view criteria was created. The **Saved Search** dropdown list will contain all the view criteria that are enabled (**Show in List** control hint enabled). The **Match All/Any** conjunction radio button may be enabled.

A search criteria field will be rendered for each search criteria defined in the view criteria. If the **Default List Type** control hint in the view object has been declared as an LOV or a selection list component, the search criteria field component is as shown in [Table 31-1](#).

After the user enters the search criteria and clicks **Search**, a query against the view criteria is executed and the results are displayed in the associated table, tree table, or component.

31.3 Setting Up Search Form Properties

A query search form is based on a view criteria defined in a view object. When you create the view criteria, you also specify some of the search form properties. Later on, when you drop the named criteria onto the page to create a query component, you can specify other search form properties.

Search form properties that can be set on the view object include grouping related and dependent fields together in the query panel. For more information on setting hints in the view object, see [Section 5.13.3, "How to Define UI Category Hints."](#)

Search form properties that can be set when the view criteria is being created include:

- Default mode in basic or advanced mode
- Automatic query execution when the page loads
- Rendering of the search criteria field
- Enabling multiple selections for attributes defined as an LOV

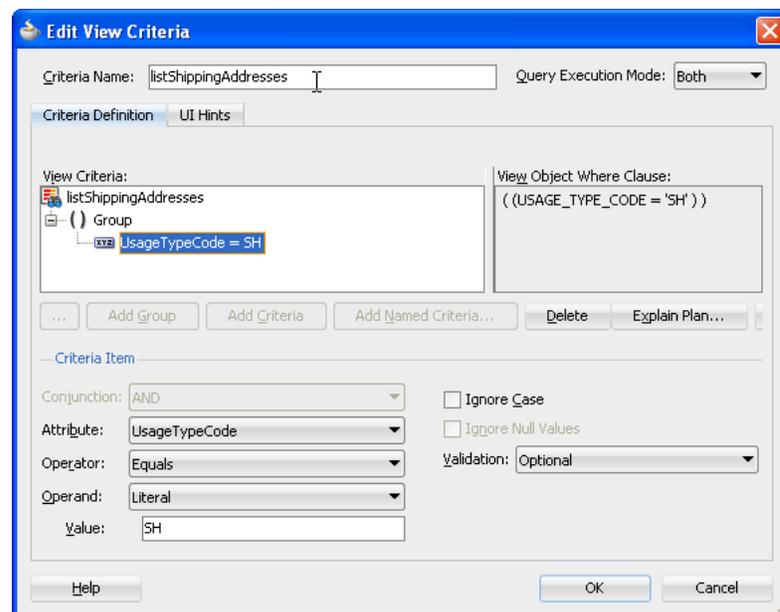

Search form properties that can be set after the query component has been added to the JSF page include:

- id of the results table or results component
- Show or hide of the basic/advanced button
- Position of the mode button
- Default, simple, or compact mode for display

31.3.1 How to Set Search Form Properties on the View Criteria

When you are creating a view criteria, you can declaratively set the initial state of several properties. [Figure 31–17](#) shows the Edit View Criteria dialog for setting default options. For more information about view criteria, see [Section 5.11, "Working with Named View Criteria."](#)

Figure 31–17 Edit View Criteria Dialog

You must select the default mode of the query search form as either basic or advanced. The default is basic.

You also must declare whether each individual search criteria field will be available only in basic mode, only in advanced mode, available in both modes, or never displayed. If a search criteria field is declared only for basic mode, it will not appear when the user switches to advanced mode, and the reverse is true. If the field is declared for all, then it will appear in all modes. The default for search criteria field rendering is all modes.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see [Section 31.3, "Setting Up Search Form Properties."](#)

You may also find it useful to understand functionality that can be used with query search forms. For more information, see [Section 31.1.4, "Additional Functionality for Search Forms."](#)

To set the default mode and search criteria field display option:

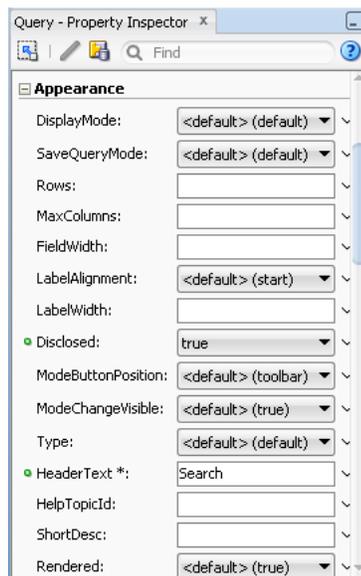

1. While creating a view criteria, in the Edit View Criteria dialog, click **UI Hints**.
2. From the **Search Region Mode** dropdown list, select either **Basic** or **Advanced**.
3. In the **Criteria Item UI Hints** section, select the criteria item you want to set.
4. In the **Rendered Mode** dropdown list, select **All**, **Basic**, **Advanced**, or **Never**.

31.3.2 How to Set Search Form Properties on the Query Component

After you have dropped the query search form onto a page, you can edit other form properties in the Property Inspector, as shown in [Figure 31–18](#). Some of the common properties you may set are:

- Enabling or disabling the basic/advanced mode button
- Setting the ID of the query search form
- Setting the ID of the results component (for example, a results table)
- Selecting the default, simple, or compact mode for display
- Setting the `criteriaFeatures` to `matchCaseDisplayed` to require all string-based search criterion to be case-sensitive or to `requiredDisplayed` to require all the criterion to be displayed.

Figure 31–18 *Property Inspector for a Query Component*

One common option is to show or hide the basic/advanced button. For more information on some of the other properties, see the "How to Add the Query Component" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see [Section 31.3, "Setting Up Search Form Properties."](#)

You may also find it useful to understand functionality that can be used with query search forms. For more information, see [Section 31.1.4, "Additional Functionality for Search Forms."](#)

To enable or hide the basic/advanced button in the query form:

1. In the Structure window, double-click `af:query`.
2. In the Property Inspector, click the **Appearance** tab.
3. To enable the basic/advanced mode button, select **true** from the `ModeChangeVisible` field. To hide the basic/advance mode button, select **false** from the `ModeChangeVisible` field.

31.3.3 How to Create Custom Operators or Remove Standard Operators

You can create custom operators for each view criteria item by adding code to the view object XML file. For example, you can create a new operator called `more than a year`, which operates on a date attribute (greater than 365 days from the current date).

You can also remove standard operators from a view criteria item. For example, you can remove the standard operator `before` from the list.

For a list of standard operators, see the "Using Query Components" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see [Section 31.3, "Setting Up Search Form Properties."](#)

You may also find it useful to understand functionality that can be used with query search forms. For more information, see [Section 31.1.4, "Additional Functionality for Search Forms."](#)

To add a custom operator:

1. In the Application Navigator, select the view object for the view criteria in which you want to add a custom operator.
2. In the editor window, click the **Source** tab.
3. In the XML editor, locate the code for the view criteria attribute, and add the `CompOper` code statements after the last item within the `ViewCriteriaItem` group.

In [Example 31–5](#), the `CompOper` code statements appear in bold.

Example 31–5 Adding the Custom Operator Code to the View Object XML

```
<ViewCriteriaRow
  Name="vcrow50"
  UpperColumns="1">
  <ViewCriteriaItem
    Name="LastUpdateDate"
    ViewAttribute="LastUpdateDate"
    Operator="="
    Conjunction="AND"
    Required="Optional">
    <CompOper
      Name="LastUpdateDate"
```

```

        ToDo="1"
        OperDescStrCode="LastUpdateDate_custOp_grt_year"
        Oper=">Y"
        MinCardinality="0"
        MaxCardinality="0" >
        <TransientExpression><![CDATA[ return " < SYSDATE - 365"
        ]]></TransientExpression>
    </CompOper>
</ViewCriteriaItem>

```

The CompOper properties are:

- Name: Specify an id for the operation.
 - ToDo: Set to 1 to add this custom operator. Set to -1 to remove an operator.
 - OperDescStrCode: Specify the id used in the message bundle to map to the description string, as described in Step 4.
 - Oper: Set to a value that will be used programmatically to denote this operation in the SQL statement. In [Example 31-5](#), Oper was set to >Y to denote greater than 1 year.
 - MinCardinality: If there is an input range, set this property to the minimum value for the range. For example, if the range is months in a year, this value should be set to 1. If there is no range, set it to 0.
 - MaxCardinality: If there is an input range, set this property to the maximum value for the range. For example, if the range is months in a year, this value should be set to 12. If there is no range, set it to 0.
 - TransientExpression: Set the expression to perform the custom operator function. In [Example 31-5](#), the expression is ! [CDATA[return " > SYSDATE -365"]], which returns the string " > SYSDATE -365".
4. Open the message bundle file for the view object and add an entry for the custom operator, using the OperDescStrCode identifier defined in the view object XML in Step 3.

[Example 31-6](#) shows the message bundle code for the LastUpdateDate custom operator described in [Example 31-5](#).

Example 31-6 Adding the Custom Operator Entry for LastUpdateDate to the Message Bundle

```

public class AvailLangImplMsgBundle extends JboResourceBundle {
    static final Object[][] sMessageStrings =
    {
        { "LastUpdateDate_custOp_grt_year", "more than a year old"
        },
    },

```

To remove a standard operator:

1. In the Application Navigator, select the view object for the view criteria in which you want to remove a standard operator.

Note: Before you attempt to remove the standard operator, make sure you do not remove the default operator for that view criteria item.

2. In the editor window, click the **Source** tab.
3. In the XML editor, locate the code for the view criteria attribute, and add the `CompOper` code statements after the last item within the `ViewCriteriaItem` group.

In [Example 31–7](#), the `CompOper` code statements appear in bold. The code in this example removes the `BEFORE` operator from the list of operators for the `LastUpdateDate` attribute.

Example 31–7 Removing a Standard Operator Code in the View Object XML

```
<ViewCriteriaRow
  Name="vcrow50"
  UpperColumns="1">
  <ViewCriteriaItem
    Name="LastUpdateDate"
    ViewAttribute="LastUpdateDate"
    Operator="="
    Conjunction="AND"
    Required="Optional">
    <CompOper
      Name="LastUpdateDate"
      ToDo="-1"
      Oper="BEFORE"
    </CompOper>
  </ViewCriteriaItem>
```

The `CompOper` properties are:

- **Name:** Specify an id for the operation.
- **ToDo:** Set to `-1` to remove an operator. Set to `1` to add an operator. Do not set `ToDo` to `-2`, which would remove all the operators.
- **Oper:** Set to the standard operator you want to remove from the list.

31.4 Creating Quick Query Search Forms

A quick query search form is intended to be used in situations where a single search will suffice or as a starting point to evolve into a full query search. Both the query and quick query search forms are ADF Faces components. A quick query search form has one search criteria field with a dropdown list of the available searchable attributes from the associated data collection. Typically, the searchable attributes are all the attributes in the associated view object. You can exclude attributes by setting the attribute's **Display Hint** property in the Control Hints page of the Edit Attribute dialog to **Hide**. The user can search against the selected attribute or search against all the displayed attributes. The search criteria field type will automatically match the type of its corresponding attribute. An **Advanced** link built into the form offers you the option to create a managed bean to control switching from quick query to advanced mode query search form. For more information, see the "Using Query

Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

You can configure the form to have a horizontal layout, as shown in [Figure 31–19](#).

Figure 31–19 Quick Query Search Form in Horizontal Layout

You can also choose a vertical layout, as shown in [Figure 31–20](#).

Figure 31–20 Quick Query Search Form in Vertical Layout

You can use quick query search forms to let users search on a single attribute of a collection. Quick query search form layout can be either horizontal or vertical. Because they occupy only a small area, quick query search forms can be placed in different areas of a page. You can create a managed bean to enable users to switch from a quick query to a full query search. For more information about switching from quick query to query using a managed bean, see the "Using Query Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

If you drop a quick query panel with a results table or tree, JDeveloper will automatically create the results table, as described in [Section 31.4.1, "How to Create a Quick Query Search Form with a Results Table or Tree Table."](#) If you drop a quick query panel by itself and subsequently want a results table or component or if you already have one, you will need to match the quick query `id` with the results component's `partialTrigger` value, as described in [Section 31.4.2, "How to Create a Quick Query Search Form and Add a Results Component Later."](#)

Note: A quick query search creates a dropdown list of all searchable attributes defined in the underlying view object. If you want to show only a subset of those attributes, you can set the attribute's **Display** control hint to **Hide** for those attributes you want to exclude. For more information about setting control hints on view objects, see [Chapter 5, "Defining SQL Queries Using View Objects."](#)

31.4.1 How to Create a Quick Query Search Form with a Results Table or Tree Table

You can create quick query searches using the full set of searchable attributes and simultaneously add a table or tree table as the results component.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see [Section 31.4, "Creating Quick Query Search Forms."](#)

You may also find it useful to understand functionality that can be used with query search forms. For more information, see [Section 31.1.4, "Additional Functionality for Search Forms."](#)

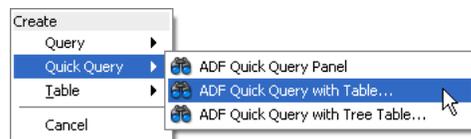

You will need to complete this task:

Create a view object to be the basis of the search form.

To create a quick query search form with a results table:

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the **All Queriable Attributes** item and drop it onto the page or onto the Structure window.
3. From the context menu, choose **Create > Quick Query > ADF Quick Query Panel with Table** or **Create > Quick Query > ADF Quick Query Panel with Tree Table**, as shown in [Figure 31–21](#).
4. In the Edit Table Columns dialog, you can rearrange any column and select table options. If you choose the filtering option, the table will be a filtered table.

Figure 31–21 Data Control Panel with Quick Query Context Menu

31.4.2 How to Create a Quick Query Search Form and Add a Results Component Later

You can create quick query searches using the full set of searchable attributes and add a table or tree table as the results component later.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see [Section 31.4, "Creating Quick Query Search Forms."](#)

You may also find it useful to understand functionality that can be used with query search forms. For more information, see [Section 31.1.4, "Additional Functionality for Search Forms."](#)

You will need to complete this task:

Create a view object to be the basis of the search form.

To create a quick query search form and add a results component in a separate step:

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the **All Queriable Attributes** item and drop it onto the page or onto the Structure window.
3. From the context menu, choose **Create > Quick Query > ADF Quick Query Panel**.
4. If you do not already have a results component, then drop the data collection associated with the view criteria as a component.

5. In the Property Inspector for the quick query panel, copy the value of the **Id** field.
6. In the Property Inspector for the results component (for example, a table), paste or enter the value into the **PartialTriggers** field.

31.4.3 How to Set the Quick Query Layout Format

The default layout of the form is horizontal. You can change the layout option using the Property Inspector.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see [Section 31.4, "Creating Quick Query Search Forms."](#)

You may also find it useful to understand functionality that can be used with query search forms. For more information, see [Section 31.1.4, "Additional Functionality for Search Forms."](#)

To set the layout:

1. In the Structure window, double-click **af:quickQuery**.
2. In the Property Inspector, on the Commons page, select the **Layout** property using the dropdown list to specify **default**, **horizontal**, or **vertical**.

31.4.4 What Happens When You Create a Quick Query Search Form

When you drop a quick query search form onto a page, JDeveloper creates an `af:quickQuery` tag. If you have dropped a quick query with table or tree table, then an `af:table` tag or `af:treeTable` tag is also added.

Under the `af:quickQuery` tag are several attributes and facets that define the quick query properties. Some of the tags are:

- The `id` attribute, which uniquely identifies the quick query. This value should be set to match the results table or component's `partialTriggers` value. JDeveloper will automatically assign these values when you drop a quick query with table or tree table. If you want to change to a different results component, see [Section 31.4.2, "How to Create a Quick Query Search Form and Add a Results Component Later."](#)
- The `layout` attribute, which specifies the quick query layout to be default, horizontal, or vertical.
- The `end` facet, which specifies the component to be used to display the **Advanced** link (that changes the mode from quick query to the query). For more information about creating this function, see the "Using Query Components" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

31.4.5 What Happens at Runtime: Quick Query

At runtime, the quick query search form displays a single search criteria field with a dropdown list of selectable search criteria items. If there is only one searchable criteria item, then the dropdown list box will not be rendered. An input component that is compatible with the selected search criteria type will be displayed, as shown in [Table 31-3](#). For example, if the search criteria type is date, then `inputDate` will be rendered.

Table 31–3 Quick Query Search Criteria Field Components

Attribute Type	Rendered Component
DATE	af:inputDate
VARCHAR	af:inputText
NUMBER	af:inputNumberSpinBox

If the **Default List Type** control hint in the view object has been declared as an LOV or a selection list component, the search criteria field component appears as shown in [Table 31–1](#) in [Section 31.1.2, "List of Values \(LOV\) Input Fields."](#)

In addition, a **Search** button is rendered to the right of the input field. If the end facet is specified, then any components in the end facet are displayed. By default, the end facet contains an **Advanced** link.

31.5 Creating Standalone Filtered Search Tables from Named View Criteria

A filtered table can be created standalone or as the results table of a query or quick query search form. Filtered table searches are based on Query-by-Example and use the QBE text or date input field formats. The input validators are turned off to allow for entering characters such as > and <= to modify the search criteria. For example, you can enter >1500 as the search criteria for a number column. Wildcard characters may also be supported. If a column does not support QBE, the search criteria input field will not render for that column.

The filtered table search criteria input values are used to build the query WHERE clause with the AND operator. If the filtered table is associated with a query or quick query search panel, the composite search criteria values are also combined to create the WHERE clause.

Note: If the filtered table is used with a query component in a search form and the search region is using an existing named criteria, the results of the query will be filtered by all the view criteria rows in an iterative manner. For example, a filtered table has two view criteria rows: `PersonId` and `DeptId`. The first view criteria row has `PersonId > 1`. When the user enters > 100 in the filter field, then the second view criteria row `DeptId` is used to accept input to further filter the results. This process iterates through all the view criteria rows until the final query result is reached.

[Figure 31–22](#) shows a query search form with a filtered results table. When the user enters a QBE search criteria, such as >100 for the `PersonId` field, the query result is the AND of the query search criteria and the filtered table search criteria.

Figure 31–22 Query Search Form with Filtered Table

Table 31–4 lists the acceptable QBE search operators that can be used to modify the search value.

Table 31–4 Query-by-Example Search Criteria Operators

Operator	Description
>	Greater than
<	Less than
>=	Greater than or equal to
<=	Less than or equal to
AND	And
OR	Or

You use query search forms for complex searches, but you can also perform simple QBE searches using the filtered table. You can create a standalone ADF-filtered table without the associated search panel and perform searches using the QBE-style search criteria input fields. For more information about filtered tables, see [Section 31.5.1, "How to Create Filtered Table and Query-by-Example Searches."](#)

You can set the QBE search criteria for each filterable column to be a case-sensitive or case-insensitive search using the `filterFeature` attribute of `af:column` in the `af:table` component. For more information, see the "Enable Filtering in Tables" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

31.5.1 How to Create Filtered Table and Query-by-Example Searches

When creating a table, you can make almost any table a filtered table by selecting the filtering option if the option is enabled. There are three ways to create a standalone filtered table:

- You can drop a table onto a page from the Component Palette, bind it to a data collection, and set the filtering option. For more information, see the "Using Query Components" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- You can create a filtered table by dragging and dropping a data collection onto a page and setting the filtering option. For more information, see [Section 27.2.1, "How to Create a Basic Table."](#)
- You can also create a filtered table or a read-only filtered table by dropping named criteria onto a page. You can use either the implicitly created named criteria **All Queriable Attributes** or any declaratively created named view criteria. The resulting filtered table will have a column for each searchable attribute and an input search field above each column.

Before you begin:

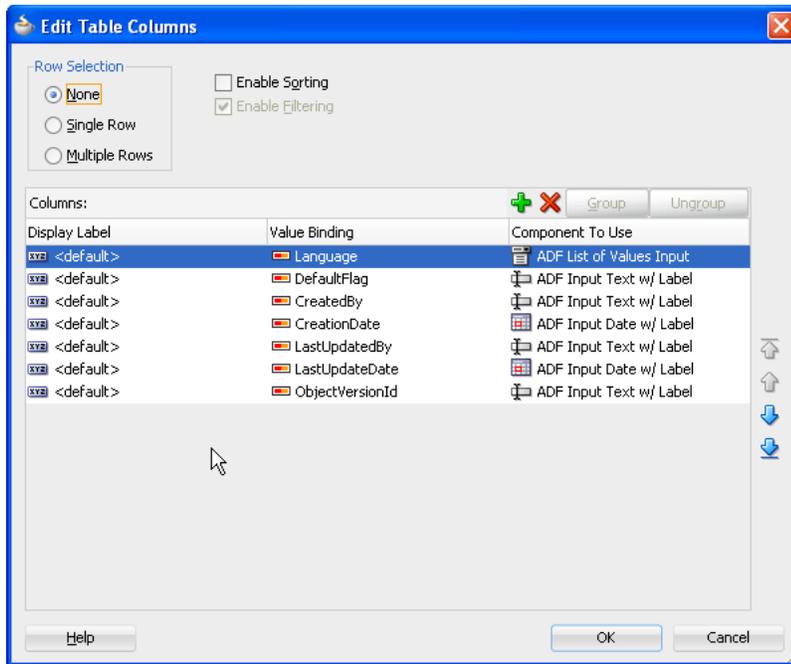

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see [Section 31.5, "Creating Standalone Filtered Search Tables from Named View Criteria."](#)

You may also find it useful to understand functionality that can be used with query search forms. For more information, see [Section 31.1.4, "Additional Functionality for Search Forms."](#)

To create a filtered table using named view criteria:

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the named view criteria item and drop it onto the page or onto the Structure window.
3. From the context menu, choose **Create > Tables > ADF Filtered Table** or **Create > Tables > ADF Read-Only Filtered Table**.
4. In the Edit Table Columns dialog, you can rearrange any column and select table options. Because the table is created by JDeveloper during quick query creation, the filtering option is automatically enabled and not user-selectable, as shown in [Figure 31–23](#).

Figure 31–23 Edit Table Columns Dialog for Filtered Table

Using More Complex Databound ADF Faces Components

This chapter describes how to add the ADF Faces Calendar and Carousel components to your pages.

This chapter includes the following sections:

- [Section 32.2, "Using the ADF Faces Calendar Component"](#)
- [Section 32.3, "Using the ADF Faces Carousel Component"](#)

32.1 About More Complex Databound ADF Faces Components

ADF Faces calendar and ADF Faces carousel are complex components that you can use to include calendar functions or display rotating images in your application. The ADF Faces calendar displays activities in daily, weekly, monthly, or list views for a given provider. The calendar is configurable to only display some of the views. The calendar includes a toolbar with built-in functionality that allows a user to change the view (between daily, weekly, monthly, or list), go to the previous or next day, week, or month, and return to today. The toolbar is customizable and allows you to choose which buttons and text to display, and you can also add buttons or other components.

The ADF Faces carousel displays images in revolving loop that the user can select by using the slider or clicking another image. It can be configured to have either a horizontal or vertical orientation. You can use other components in conjunction with the carousel. You can add a toolbar or menu bar, and then add buttons or menu items that allow users to perform actions on the current object.

32.1.1 Complex Databound ADF Faces Components Use Cases and Examples

The ADF Faces calendar can be used whenever you want to add a calendar feature to your application. You will need to have the relevant data in your data store that represents the content provided by the calendar, such as the date, time, title, location, and owner. You can use the familiar patterns of entity objects and view objects to model the data and then use drag and drop from the Data Controls panel to create the calendar.

The carousel component gives the user the ability to view an image from a series of images. The user can see partial views of the images before and after the image being viewed and can scroll through each image in the sequence. The user can do so using a slider or navigation buttons. The carousel is useful for showing objects that require a highly visual presentation. For example, it can be used to display a photographic collection or merchandise in a catalog.

32.1.2 Additional Functionality of Complex Databound ADF Faces Components

You may find it helpful to understand other ADF features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- You can customize the calendar for individual users so that the calendar appears in the selected configuration when that user accesses the calendar. For more information, see [Section 40, "Allowing User Customizations at Runtime."](#)
- Calendars are based on entity objects. For information on creating entity objects, see [Chapter 4, "Creating a Business Domain Layer Using Entity Objects."](#)
- For more information about partial page rendering and the `partialTriggers` attribute, see the "Rendering Partial Page Content" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- The carousel component uses a tree binding to iterate over the data. For more information about the tree binding, see [Section 27.2.2.1, "Iterator and Value Bindings for Tables."](#)

32.2 Using the ADF Faces Calendar Component

ADF Faces includes a calendar component that displays created activities in daily, weekly, or monthly views. [Figure 32–1](#) shows an ADF Faces calendar in weekly view mode with some sample activities.

Figure 32–1 ADF Faces Calendar

The calendar component also includes the following functionality:

- A toolbar that allows users to switch between monthly, weekly, daily, and list views.

Tip: When these toolbar buttons are used, attribute values on the calendar are changed. You can configure these values to be persisted so that they remain for a particular user whenever they access the calendar. For more information, see [Section 40, "Allowing User Customizations at Runtime."](#)

- Configurable start of the week days and start of the day hours. For example, a calendar's week might start on Sunday and the day might show 8:00 am at the top.
- Configurable styles using skinning keys.

Additionally, you can implement the following functionality using other ADF Faces components and the rich client framework:

- Popup functionality. Components placed in supported faces that respond to certain events and allow the user to act on activities or the calendar. For example, when a user clicks an activity in the calendar, the `CalendarActivityEvent` is invoked and any popup component in the `ActivityDetail` facet is displayed. You might use a dialog component that contains a form where users can view and edit the activity, as shown in [Figure 32–2](#).

Figure 32–2 *Edit Dialog for ActivityDetail Facet*

- Drag and drop capability: You can add the `calendarDropTarget` tag that allows a user to drag an activity to another place on the calendar. You then implement the functionality so that the time is actually changed on the activity and persisted to the data store.
- Toolbar customization: By default, the toolbar contains buttons that allow the user to switch between the different views, along with previous and next buttons and a button that returns to the current date. The toolbar also displays the current date range (or the date when in day view). You can customize the toolbar by adding facets that contain additional buttons of your choosing.
- Skinning: The calendar uses skinning keys to determine things like colors and icons used. You can extend the skin to change the appearance of the calendar.

Details for configuring the built-in functionality or for implementing additional functionality can be found in the "Creating a Calendar" chapter of the *Oracle Fusion*

Middleware Web User Interface Developer's Guide for Oracle Application Development Framework.

An ADF Faces Calendar component must be bound to a `CalendarModel` class. This class can be created for you when you use ADF Business Components to manage your calendar's data. For example, say you have data in your data store that represents the details of an activity, such as the date, time, title, location, and owner. When you create an entity object to represent that data, and then a view object to display the data, you can drag and drop the associated collection from the Data Controls panel to create the calendar. JDeveloper will declaratively create the model and bind the view to that model so that the correct data will display when the calendar is launched. However, in order for the model to be created, your entity objects in the data model project with ADF Business Components and your view objects in the same project must contain date-effective attributes. Additionally, the view objects must contain variables that will be used to modify the query to return the correct activities for the given date range.

32.2.1 How to Use the ADF Faces Calendar

Before you can create a calendar on a JSF page, you must first create an entity object with specific attributes that represent attributes on a calendar. You then must create a view object from that entity object, and modify the query to use named bind variables that represent the date range and current time zone to display. This will allow the query to return only the activities that should be displayed in the given view on the calendar.

For example, say you have a database table that represents an activity. It has a column for title, start time, end time, and a reference to a provider object that represents the owner. You would create an entity object and a view object based on that table (ensuring that it meets the requirements, as described in the following steps). To the view object, you would then add named bind variables for the start and end times currently displayed on the calendar, along with the time zone currently in use by the calendar, so that the query returns only those activities that fall within that time range.

Once you add the calendar component to a JSF page, you can configure it, and add further needed functionality.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a calendar. For more information, see [Section 32.2, "Using the ADF Faces Calendar Component."](#)

You may also find it useful to understand functionality that can be used with LOVs. For more information, see [Section 32.1.2, "Additional Functionality of Complex Databound ADF Faces Components."](#)

To create an ADF Faces calendar:

1. Create an entity object based on your data source. The entity object must include the attributes shown in [Table 32-1](#). The attributes do not have to use the names shown in the table; they can be named anything. However, they must be of one of the types noted. You will map these attributes to attributes in the `CalendarModel` in a later step.

Table 32–1 Required Attributes for a Calendar

Attribute	Valid Types	Description
Start time	java.util.Date, java.sql.Date, oracle.jbo.domain.Date, oracle.jbo.domain.TimeStamp	Start time for the activity
End time	java.util.Date, java.sql.Date, oracle.jbo.domain.Date, oracle.jbo.domain.TimeStamp	End time for the activity
ID	String	Unique ID
Provider ID	String	ID of the provider object that represents the owner of the activity
Title	String	Short description of the activity

The entity object can also contain the known (but not required) attributes shown in [Table 32–2](#):

Table 32–2 Optional Attributes for a Calendar

Attribute	Type	Description
Recurring	String or CalendarActivity.Recurring	Status of recurrence for the activity. Valid values are SINGLE (does not recur), RECURRING, or CHANGED (this activity was part of the recurring activity but has been modified to be different from parent activity).
Reminder	String or CalendarActivity.Reminder	Whether or not the activity has an associated reminder. Valid values are ON or OFF.
Time Type	String or CalendarActivity.TimeType	Type of time associated with the activity. Valid values are ALLDAY and TIME. Activities that have a value of ALLDAY do not have any time associated with them. They are considered to span the entire day. Activities with a value of TIME have a specific time duration.
Location	String	Location of an activity.
Tags	Set of Strings or a semicolon separated list of Strings.	Keywords for the activity.

Your entity objects can also contain other attributes that the `CalendarModel` has no knowledge of. You will be able to add these to the model as custom properties in a later step.

For information on creating entity objects, see [Chapter 4, "Creating a Business Domain Layer Using Entity Objects."](#)

2. Create an associated view object. In the Query page of the overview editor, create named bind variables for the following:
 - A string that represents the time zone
 - A date that represents the start time for the current date range shown on the calendar.

- A date that represents the end time for the current date range shown on the calendar.

Tip: Dates in an ADF Faces calendar are "half-open," meaning that the calendar will return all activities that start on or after the start time and before (but not on) the end time.

For more information about creating named bind variables, see [Section 5.10, "Working with Bind Variables."](#)

3. Create an entity object that represents the provider (owner) of activities. The entity object must include the attributes shown in [Table 32–3](#). The attributes do not have to use the names shown in the table; they can be named anything. However, they must be of the type noted. You will map these attributes to attributes in the `CalendarProvider` class in a later step.

Table 32–3 *Attributes for a CalendarProvider Class*

Attribute	Type	Description
Id	String	Unique ID.
Display Name	String	The name of the provider that can be displayed in the calendar.

4. Create a view object for the provider.
5. Ensure that the new view objects are part of the application module, and if needed, refresh the Data Controls panel.
6. Create your JSF page, as documented in [Section 24.3, "Creating a Web Page."](#)
7. From the Data Controls panel, drag the collection that represents the view object for the activity created in Step 2 and drop it as a **Calendar**.

Tip: The Calendar option will display in the context menu only if the view object contains the required attributes documented in [Table 32–1](#) and the bind variables described in Step 2.

8. Complete the Calendar Bindings dialog to map the bind variables and attributes to the `CalendarModel` and the `CalendarProvider` classes. For additional help, click **Help** or press **F1**.
9. By default, the calendar will be read-only and will return only those activities currently in the data store. You will need to configure the calendar and implement additional functionality as described in the "Creating a Calendar" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

For example, to allow creation of a new activity, you might create an input form in a dialog (as described in the "How to Create a Dialog" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*) using the same data control collection used to create the calendar. For more information about creating input forms, see [Section 26.6, "Creating an Input Form."](#)

32.2.2 What Happens When You Create a Calendar

When you drop a collection as a calendar, JDeveloper:

- Defines an iterator binding to the collection of activities, and another iterator binding to the collection of providers.
- Defines an action binding to the `executeWithParams` operation on the activities collection. It is this operation that will be invoked to execute the query to return the activities to display. Because the operation requires parameters to determine the date range and time zone, `NamedData` elements are also created for each of the parameters (created as named bind variables on the view object). For more information about `NamedData` elements, see [Section 28.2.2.2, "Using Parameters in a Method."](#)
- Defines a calendar binding. This binding contains a `node` element that represents a row in the collection and maps the data control attributes to the calendar activity's attributes, as defined when using the wizard. The `value` is the data control attribute and the `type` is the calendar attribute. For any custom defined attributes, the `type` will be `custom` and `value` will be the data control attribute. Each row (node) is represented by a `rowKey`, which is the activity ID.

There is also a `providerDefinition` element that determines the source and mapping of available providers. This mapping allows the calendar model to filter activities based on the state of the provider (either enabled or disabled).

Tip: To access a custom attribute, use the `CalendarActivity.getCustomAttributes()` method, passing in the name of the attribute as defined by the `value` element.

[Example 32-1](#) shows the page definition code for a calendar.

Example 32-1 Page Definition Code for a Calendar Binding

```
<executables>
  <iterator Binds="ActivityView1" RangeSize="-1"
    DataControl="AppModuleDataControl" id="ActivityView1Iterator" />
  <iterator Binds="EmployeesView1" RangeSize="25"
    DataControl="AppModuleDataControl" id="EmployeesView1Iterator" />
</executables>
<bindings>
  <action IterBinding="ActivityView1Iterator" id="ExecuteWithParams"
    RequiresUpdateModel="true" Action="executeWithParams">
    <NamedData NDName="startTime"
      NDValue="#{bindings.ActivityView1.startDate}"
      NDType="oracle.jbo.domain.Date" />
    <NamedData NDName="endTime" NDValue="#{bindings.ActivityView1.endDate}"
      NDType="oracle.jbo.domain.Date" />
    <NamedData NDName="timeZone"
      NDValue="#{bindings.ActivityView1.timeZoneId}"
      NDType="java.lang.String" />
  </action>
  <calendar IterBinding="ActivityView1Iterator" id="ActivityView1"
    xmlns="http://xmlns.oracle.com/adf/faces/binding"
    ActionBindingName="ExecuteWithParams">
    <nodeDefinition DefName="model.ActivityView">
      <AttrNames>
        <Item Type="id" Value="Id" />
        <Item Type="providerId" Value="ProviderId" />
        <Item Type="title" Value="Title" />
        <Item Type="startTime" Value="StartTime" />
        <Item Type="endTime" Value="EndTime" />
      </AttrNames>
    </nodeDefinition>
  </calendar>
</bindings>
```

```
<providerDefinition IterBindingName="EmployeesView1Iterator">
  <AttrNames>
    <Item Type="id" Value="EmployeeId"/>
    <Item Type="displayName" Value="FirstName"/>
  </AttrNames>
</providerDefinition>
</calendar>
</bindings>
```

JDeveloper inserts code onto the JSF page that binds the calendar value to the `CalendarModel` class, as shown in [Example 32-2](#).

Example 32-2 JSF Page Code for a Calendar

```
<af:form>
  <af:calendar value="#{bindings.ActivityView1.calendarModel}"/>
</af:form>
```

The `CalendarModel` class uses `CalendarActivityDefinition` class to access the calendar binding.

32.2.3 What Happens at Runtime: How the Calendar Binding Works

When the calendar is accessed, the `executeWithParams` operation is invoked, with the value of the `startDate` and `endDate` parameters determined by the value of the calendar component's `view` and `activeDay` attributes. For example, if the `view` attribute is set to `month` and the `activeDay` is set to the current date (say, February 6, 2009), then the value for the `startDate` would be February 1, 2009 and the `endDate` value would be February 28, 2009. By default, the time zone value is taken from the `time-zone` setting in the `trinidad-config.xml` file (for more information, see the "Configuration in `trinidad-config.xml`" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*). Therefore, the query would be restricted to return only activities that fall within that date range.

When the query returns data, because the calendar component is bound to the `CalendarModel`, the `CalendarModel` uses the `CalendarActivityDefinition` class to access the calendar binding class and map the values from the data source to the calendar, using the mappings provided by the binding.

32.3 Using the ADF Faces Carousel Component

You can display images in a revolving carousel, as shown in [Figure 32-3](#). Users can change the image at the front by using either the slider at the bottom or by dragging another image to the front.

Figure 32–3 Carousel Component

Instead of containing a child `carouselItem` component for each image to be displayed, and then binding these components to the individual images, the `carousel` component is bound to a complete collection and repeatedly renders one `carouselItem` component by stamping the value for each item, similar to the way a tree stamps out each row of data. As each item is stamped, the data for the current item is copied into a property that can be addressed using an EL expression using the `carousel` component's `var` attribute. Once the carousel has completed rendering, this property is removed or reverted back to its previous value. Carousels contain a `nodeStamp` facet, which is a holder for the `carouselItem` component used to display the text and short description for each item, and is also the parent component to the image displayed for each item. For more information about the carousel component, see the "Displaying Images in a Carousel" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

32.3.1 How to Create a Databound Carousel Component

When using a carousel component in a Fusion web application, you create the component using the Data Controls Panel. You also use a managed bean to handle the carousel spin event, and for other logic you may need to display your items.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a calendar. For more information, see [Section 32.3, "Using the ADF Faces Carousel Component."](#)

You may also find it useful to understand functionality that can be used with LOVs. For more information, see [Section 32.1.2, "Additional Functionality of Complex Databound ADF Faces Components."](#)

You will need to complete these tasks:

1. Create a view object for the collection to be displayed in the carousel.
2. Define the view object with the following minimum set of attributes:
 - Title, which will be displayed below the image in the carousel
 - Short description used for text displayed when the user mouses over the image.

To create a databound carousel component:

1. From the Data Controls panel, drag the collection for the view object on to the page and select **Carousel** from the context menu.
2. In the Property Inspector, in the Behavior section, bind the **CarouselSpinListener** to a handler method that handles the spinning of the carousel when you need logic to be executed when the carousel spin is executed. [Example 32–3](#) shows the handler methods that might be used to handle the display of product images for the Products view object used to create the carousel:

Example 32–3 Handler for the CarouselSpinEvent

```
public void handleCarouselSpin(CarouselSpinEvent event)
{
    RichCarousel carousel = getCarousel();
    carousel.setRowKey(event.getNewItemKey());
    detailNodeItem = (JUCtrlHierNodeBinding) carousel.getRowData();
}
public JUCtrlHierNodeBinding getDetailNodeItem()
{
    // Get the initial item
    if(detailNodeItem == null)
    {
        RichCarousel carousel = getCarousel();

        Object oldKey = carousel.getRowKey();
        try
        {
            Object key = carousel.getCurrentItemKey();
            getCarousel().setRowKey(key);
            detailNodeItem = (JUCtrlHierNodeBinding) carousel.getRowData();
        }
        finally
        {
            carousel.setRowKey(oldKey);
        }
    }

    return detailNodeItem;
}
```

3. In the Advanced section of the Property Inspector, click the dropdown menu for the **Bindings** attribute and select Edit. In the Edit Property: Binding dialog, select the managed bean used in Step 2. Create a new property called `carousel`. This will allow the handler methods to access the carousel object.
4. In the Structure window, expand the `carousel` component and the `nodeStamp` facet, and select the `carouselItem` component.
5. Bind the `CarouselItem` component's `text` attribute to the associated property in the data model using variable value set on the carousel's `var` attribute, which by default is set to `item`. So the value of the `carouselItem`'s `text` attribute

would be `item.title` (given that `title` is the property used to access the text used for the carousel items on the data model).

If you were using the `Products` view object, the value would be `{item.ProductName}`.

6. In the Advanced section of the Property Inspector, click the dropdown menu for the **Bindings** attribute and select Edit. In the Edit Property: Binding dialog, select the managed bean used in Step 2. Create a new property called `carouselItem`.
7. In the ADF Faces page of the Component Palette, from the Common Components panel, drag an **Image** and drop it as a child to the `carouselItem`.

In the Insert Image dialog, enter the path to the source for the images, being sure to use the variable for the item in the carousel. For example, the path to the image files for the products would normally be:

```
/imageservlet?detail=#{Products.ProductId}
```

For an image in the carousel, you would use:

```
/imageservlet?detail=#{item.ProductId}
```

For information about setting other attributes of the `carousel` and `carouselItem` components, see the "How to Create a Carousel" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

8. If you want to provide additional information about the items in the carousel, you can drag and drop the same view object onto the page, for example, as a form. For the components in the form to redisplay the information for the current item displayed once the carousel is spun, you need to set the `partialTrigger` attribute of the component containing the form to the carousel component's ID.

For example, the form that displays the information for each item in [Figure 32–3](#) is contained in a `panelBox` component. The `partialTrigger` attribute for the `panelBox` component is set to `c1`, which is the carousel component's ID. This means that whenever the `carouselItem` invokes the `CarouselSpinEvent`, the `panelBox` will be refreshed, causing it to display information about the item that was just made current. For more information about partial page rendering and the `partialTriggers` attribute, see the "Rendering Partial Page Content" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

[Example 32–4](#) shows the page code for the carousel displayed in [Figure 32–3](#).

Example 32–4 Partial Trigger Updates the Form to Match the Displayed Carousel Item

```
<af:carousel
    currentItemKey=#{bindings.Products.treeModel.rootCurrencyRowKey} "
    value=#{bindings.Products.treeModel} var="item"
    id="c1"
    carouselSpinListener=#{carBean.handleCarouselSpin}">
  <f:facet name="nodeStamp">
    <af:carouselItem id="ci1" text=#{item.ProductName}"
      binding=#{carBean.carouselItem}">
      <af:image source="/imageservlet?detail=#{item.ProductId}"
        id="i1"/>
    </af:carouselItem>
  </f:facet>
</af:carousel>
<af:panelBox text="PanelBox1" id="pb1" partialTriggers="c1">
```

```

<af:panelFormLayout id="pf11">
  <af:panelLabelAndMessage label="#{bindings.ProductName.hints.label}"
    id="plam2">
    <af:outputText value="#{bindings.ProductName.inputValue}"
      id="ot4"/>
  </af:panelLabelAndMessage>
  .
  .
  .
</af:panelBox>

```

32.3.2 What Happens When You Create a Carousel

When you drop a collection from the Data Controls panel as a carousel, a tree value binding is created. A tree consists of a hierarchy of nodes, where each subnode is a branch off a higher level node.

The tree binding iterates over the data exposed by the iterator binding. The carousel wraps the result set from the iterator binding in a `treeModel` object, which is an extension of the `collectionModel`. The `collectionModel` allows each item in the collection to be available within the carousel component using the `var` attribute. For more information about the tree binding, see [Section 27.2.2.1, "Iterator and Value Bindings for Tables."](#)

JDeveloper adds both a carousel component and its child `carouselItem` component onto the page, as shown in [Example 32-5](#).

Example 32-5 Page Code for a Carousel Component

```

<af:carousel
  currentItemKey="#{bindings.Products.treeModel.rootCurrencyRowKey}"
  value="#{bindings.Products.treeModel}" var="item"
  id="c1"
  carouselSpinListener="#{carBean.handleCarouselSpin}">
  <f:facet name="nodeStamp">
    <af:carouselItem id="cil" text="#{item.ProductName}"/>
  </f:facet>
</af:carousel>

```

The carousel value is bound to the `treeModel` for the associated collection, and the `currentItemKey` attribute of the carousel is bound to the `rootCurrencyRowKey` of the binding object. In this example, the carousel iterates over the items in the `Products` iterator binding. The iterator binding binds to a `rowKeySet` that keeps track of the current product. By default, the `currentItemKey` attribute of the carousel is bound to the `rootCurrencyRowKey` of the binding object, which causes the product currently displayed at the front of the carousel to be the root and the current item. The `carouselItem` component accesses the current data object for the current item presented to the carousel tag using the `item` variable.

Creating Databound ADF Data Visualization Components

This chapter describes how to use ADF data controls to create ADF Data Visualization components that visually represent business data. Data visualization components allow you to display and analyze data through a wide variety of graphs, several kinds of gauges, a pivot table and pivot filter bar, geographic and thematic maps with multiple layers of information, several kinds of Gantt charts, and a hierarchy viewer.

This chapter includes the following sections:

- [Section 33.1, "About ADF Data Visualization Components"](#)
- [Section 33.2, "Creating Databound Graphs"](#)
- [Section 33.3, "Creating Databound Gauges"](#)
- [Section 33.4, "Creating Databound Pivot Tables"](#)
- [Section 33.5, "Creating Databound Geographic Maps"](#)
- [Section 33.6, "Creating Databound Thematic Maps"](#)
- [Section 33.7, "Creating Databound Gantt Charts"](#)
- [Section 33.8, "Creating Databound Hierarchy Viewers"](#)

33.1 About ADF Data Visualization Components

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component needs to be bound to data before it can be rendered since the appearance of the components is dictated by the data that is displayed. This chapter describes how to bind each component to a data source

Both graph and gauge components render graphical representations of data. However, graphs, which support more than 50 types of charts, allow you to evaluate multiple data points on multiple axes in a variety of ways. Many graph types assist in the comparison of results from one group with the results from another group. In contrast, gauges focus on a single data point and examine that point relative to minimum, maximum, and threshold indicators to identify problems.

The pivot table component produces a grid that supports multiple layers of data labels on the row edge or the column edge of the grid. An optional pivot filter bar represents a page edge that filters the available pivot table data. This component also provides the option of automatically generating subtotals and totals for grid data. Pivot tables let you pivot data layers from one edge to another to obtain different views of your data. For example, a pivot table might initially display total sales data for products

within regions on the row edge, broken out by years on the column edge. If you pivot region and year at runtime, then you end up with total sales data for products within years, broken out by region. At runtime, end users can click buttons that appear in the inner column labels to sort rows in ascending or descending order.

The geographic map component represents business data spatially, enabling you to superimpose multiple layers, also referred to as *themes*, of information on a single map. For example, a map of the United States might use a color theme that provides varying color intensity to indicate the popularity of a product within each state, a pie chart theme that shows sales within product category, and a point theme that identifies the exact location of each warehouse. When all three themes are superimposed on the United States map, you can easily evaluate whether there is sufficient inventory to support the popularity level of a product in specific locations. Geographic maps require a connection to an Oracle MapViewer service, and optionally, a geocoder service to display geographical and political detail.

Thematic map components represents business data as patterns in stylized areas or associated markers and does not require a connection to an Oracle MapViewer service. Thematic maps focus on data without the geographic details in a geographic map. The thematic map is packaged with prebuilt base maps including a USA base map, a world base map, and base maps for continents and regions of the world including EMEA and APAC. Each base map includes several sets of regions and one fixed set of cities. A set of regions or cities is referred to as a layer. Each layer can be bound to a data collection and stylized to represent the data with color and pattern fills, or a data marker, or both. At runtime, only one map layer and its associated data can be displayed at a time, unless the thematic map has been enabled for drilling.

There are three types of ADF Gantt chart components: the project Gantt chart (which focuses on project management), the scheduling Gantt chart, and the resource utilization Gantt chart (both of which focus on resource management). Each Gantt chart displays the following regions combined with a splitter:

- **List region content:** The left side of the splitter provides a list of tasks (for the project Gantt chart) or a list of resources (for the resource utilization and scheduling Gantt charts). This region can display any number of additional columns of related information, using a tree table model.
- **Chart region content:** The right side of the splitter consists of an area in which task progress, resource utilization, or resource progress is graphed over time. The ability of the Gantt chart to zoom in or out on its time axis lets you view management information across the desired time period.

The ADF hierarchy viewer component produces an interactive graphic that displays hierarchical data as a set of linked shapes. The shapes and links correspond to the elements and relationships in the data. For example, a hierarchy viewer component might be used to generate an organizational chart based on employee data. At runtime, end users can pan and zoom the graphic and expand, select, and navigate the management hierarchy that the graphic displays.

Each Data Visualization component needs to be bound to data before it can be rendered since the appearance of the components is dictated by the data that is displayed. This chapter describes how to bind each component to a data source.

The prefix `dvt:` occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.

33.1.1 End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for each component, see the following:

- Graph components: "End User and Presentation Features of Graphs" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- Gauge components: "End User and Presentation Features of Gauges" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- Pivot table and pivot filter bar components: "End User and Presentation Features of Pivot Tables" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- Geographic and thematic map components: "End User and Presentation Features of Maps" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- Gantt chart components: "End User and Presentation Features of Gantt Charts" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- Hierarchy view components: "End User and Presentation Features of Hierarchy Viewers" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

33.1.2 Data Visualization Components Use Cases and Examples

For detailed descriptions of each data visualization use cases and examples, see the following:

- Graph components: "Graph Component Use Cases and Examples" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- Gauge components: "Gauge Component Use Cases and Examples" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- Pivot table and pivot filter bar components: "Pivot Table and Pivot Filter Bar Component Use Cases and Examples" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- Geographic and thematic map components: "Map Component Use Cases and Examples" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- Gantt chart components: "Gantt Chart Component Use Cases and Examples" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- Hierarchy view components: "Hierarchy Viewer Component Use Cases and Examples" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

33.1.3 Additional Functionality for Data Visualization Components

You may find it helpful to understand other ADF Faces features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- **Partial page rendering:** You may want a DVT component to refresh to show new data based on an action taken on another component on the page. For more information, see the "Rerendering Partial Page Content" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- **Personalization:** Users can change the way the DVT components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see the "Allowing User Customization on JSF Pages" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- **Accessibility:** You can make your DVT components accessible. For more information, see the "Developing Accessible ADF Faces Pages" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- **Skins and styles:** You can customize the appearance of DVT components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (`styleClass` or `inlineStyle`). For more information, see the "Customizing the Appearance Using Styles and Skins" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- **Placeholder data controls:** If you know the DVT components on your page will eventually use ADF data binding, but you need to develop the pages before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see [Chapter 17, "Designing a Page Using Placeholder Data Controls."](#)

33.2 Creating Databound Graphs

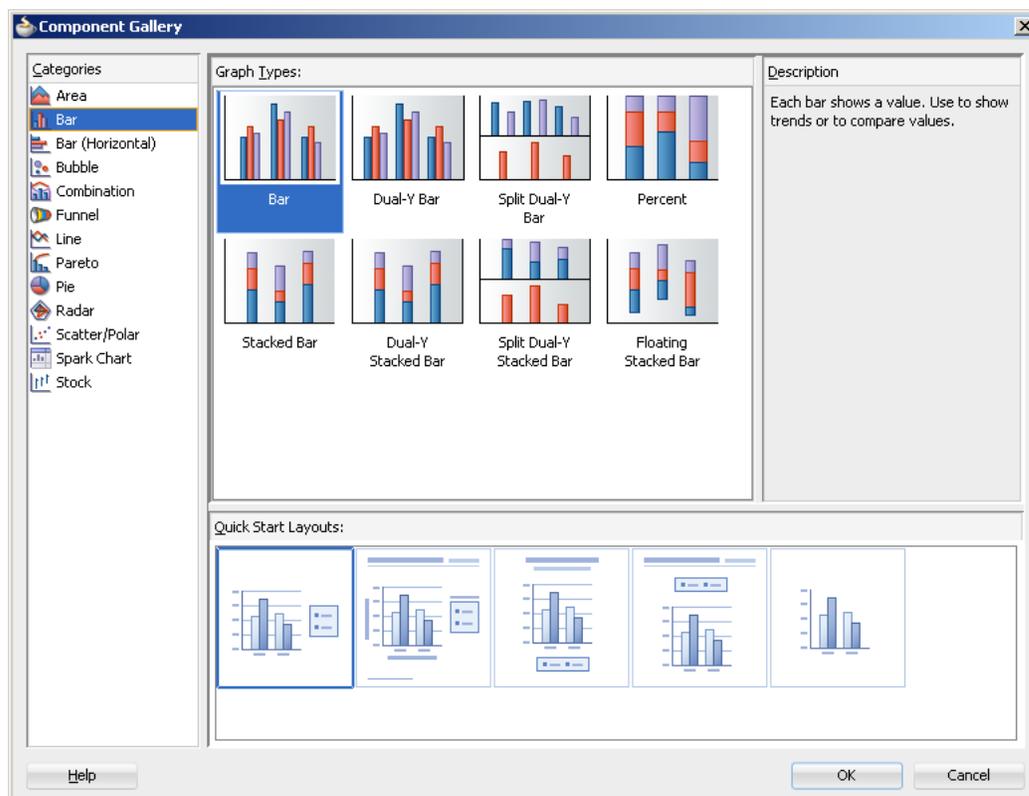

When you create a graph using a data collection inserted from the Data Controls panel, a Component Gallery allows you to choose from a wide number of graph categories, graph types, and layout options. Graph categories group together one or more types of graph. For example, the Bar category includes the following types of graphs:

- Bar
- Dual-Y Bar
- Split Dual-Y Bar
- Percent
- Stacked Bar
- Dual-Y Stacked Bar

- Split Dual-Y Stack Bar
- Floating Stacked Bar

Explore the Component Gallery that appears when you create a graph to view available graph categories, types, and descriptions for each one. [Figure 33-1](#) shows the Component Gallery that appears for ADF graphs when you use the Data Controls panel.

Figure 33-1 ADF Graphs Component Gallery from Data Controls Panel

Note: Some graph types require very specific kinds of data. If you bind a graph to a data collection that does not contain sufficient data to display the graph type requested, then the graph is not displayed and a message about insufficient data appears.

You can also create a graph by dragging a graph component from the Component Palette. This approach allows you the option of designing the graph user interface before binding the component to data. A Component Gallery appears to view graph types, descriptions, and quick layout options.

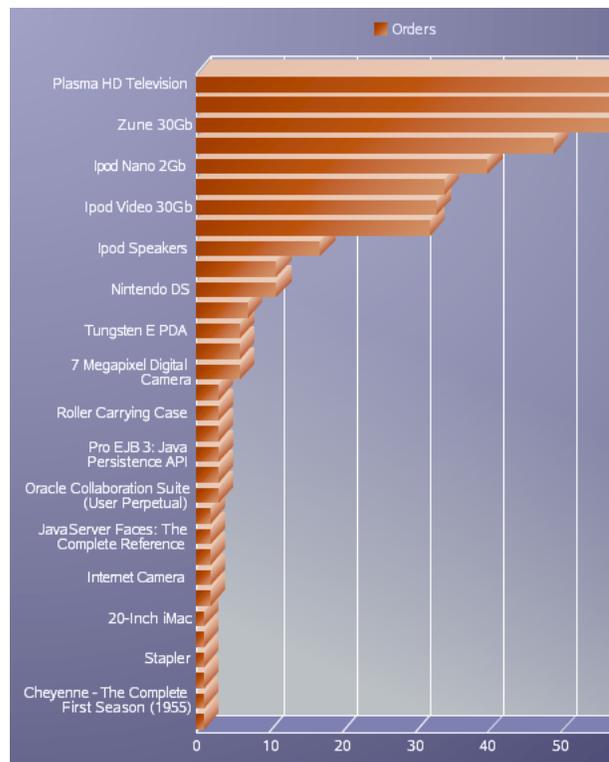

[Table 33-1](#) lists the categories that appear in the Component Gallery for graphs. Each category has one or more graph types associated with it.

Table 33–1 ADF Graph Categories in the Component Gallery

Category	Description
Area	Creates a graph in which data is represented as a filled-in area. Use area graphs to show trends over time, such as sales for the last 12 months. Area graphs require at least two groups of data along an axis. The axis is often labeled with time periods such as months.
Bar	Creates a graph in which data is represented as a series of vertical bars. Use to examine trends over time or to compare items at the same time, such as sales for different product divisions in several regions.
Bar (Horizontal)	Creates a graph that displays bars horizontally along the y-axis. Use to provide an orientation that allows you to show trends or compare values.
Bubble	Creates a graph in which data is represented by the location and size of round data markers (bubbles). Use to show correlations among three types of values, especially when you have a number of data items and you want to see the general relationships. For example, use a bubble graph to plot salaries (x-axis), years of experience (y-axis), and productivity (size of bubble) for your work force. Such a graph allows you to examine productivity relative to salary and experience.
Combination	Creates a graph that uses different types of data markers (bars, lines, or areas) to display different kinds of data items. Use to compare bars and lines, bars and areas, lines and areas, or all three.
Funnel	Creates a graph that is a visual representation of data related to steps in a process. The steps appear as vertical slices across a horizontal cylinder. As the actual value for a given step or slice approaches the quota for that slice, the slice fills. Typically a funnel graph requires actual values and target values against a stage value, which might be time. For example, use this component to watch a process (such as a sales pipe line) move towards a target across the stage of the quarters of a fiscal year.
Line	Creates a graph in which data is represented as a line, as a series of data points, or as data points that are connected by a line. Line graphs require data for at least two points for each member in a group. For example, a line graph over months requires at least two months. Typically a line of a specific color is associated with each group of data such as the Americas, Europe, or Asia. Use to compare items over the same time.
Pareto	Creates a graph in which data is represented by bars and a percentage line that indicates the cumulative percentage of bars. Each set of bars identifies different sources of defects, such as the cause of a traffic fatality. The bars are arranged by value, from the largest number to the lowest number of incidents. A pareto graph is always a dual-y graph in which the first y-axis corresponds to values that the bars represent and the second y-axis runs from 0 to 100% and corresponds to the cumulative percentage values. Use the pareto graph to identify and compare the sources of defects.
Pie	Creates a graph in which one group of data is represented as sections of a circle causing the circle to look like a sliced pie. Use to show relationship of parts to a whole such as how much revenue comes from each product line.
Radar	Creates a graph that appears as a circular line graph. Use to show patterns that occur in cycles, such as monthly sales for the last three years.
Scatter/Polar	Creates a graph in which data is represented by the location of data markers. Use to show correlation between two different kinds of data values such as sales and costs for top products. Scatter graphs are especially useful when you want to see general relationships among a number of items.
Sparkchart	Creates a simple, condensed graph that displays trends or variations, often in the column of a table, or inline with text.
Stock	Creates a graph in which data shows the high, low, and closing prices of a stock. Each stock marker displays three separate values.

Figure 33–2 shows the horizontal bar graph that appears in the Hot Items Statistics page of the `StoreFrontModule` application. This graph displays the quantity of orders for each product so that you can easily identify the items that have been ordered most frequently.

Figure 33–2 Hot Items Statistics Graph

For information about customizing graphs after the data binding is completed, see the "Using ADF Graph Components" chapter in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

33.2.1 How to Create a Graph

Graphs are based on data collections. Using data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop a collection from the Data Controls panel onto the JSF page and use a dialog to bind the data collection attributes in the graph.

The attributes in a data collection can be data values or categories of data values. Data values are numbers represented by markers, like bar height, or points in a scatter graph. Categories of data values are members represented as axis labels, or appear as additional properties in a tooltip. The role that an attribute plays in the bindings (either data values, or identifiers) is determined by both its data type (Graph requires numeric data values) and where it gets mapped (e.g., Bars vs. X Axis).

To create a databound graph:

1. From the Data Controls panel, select a collection.

For example, to create the bar graph that displays the order count for each product in the Hot Items Statistics page of the `StoreFrontModule` application, select the

ProductOrdersCount collection. [Figure 33–3](#) shows the ProductOrdersCount collection in the Data Controls panel.

Figure 33–3 Data Collection for Counting Product Orders

2. Drag the collection onto a JSF page and, from the context menu, choose **Graphs** to display the Component Gallery.
3. Select a graph category and a graph type from the Component Gallery and click **OK**.

For information about the graph categories and graph types that appear in the Component Gallery, see [Table 33–1](#).

The name of the dialog and the input field labels that appears depends on the category and type of graph that you select. For example, if you select **Bar (Horizontal)** as the category and **Bar** as the type, then the name of the dialog that appears is Create Horizontal Bar Graph and the input field is labeled **Bars**.

4. Do the following in the dialog to configure the graph to display data:
 - Drag attributes from the **Available** list to the **Bars** or **X Axis** input fields, depending on where you want the values for the attributes to appear at runtime.
 - In the **Attribute Labels** table, accept the default value or select a value from the dropdown list in the **Label** field to specify the label that appears at runtime.

If an attribute represents data values, then the choices in the **Label** field determine how that attribute's label is rendered in the graph:

- **Use Attribute Name:** Select to render the value as a string using the label from the UIHints for that attribute in the underlying `ViewObject`. This is the default selection.
- **No Label:** Select to render no label. This choice is useful if there is a single metric and you want to provide your own descriptive text on the page to describe the resulting graph.
- **Select Text Resource:** Select to open a Select Text Resource dialog to select or add a text resource to use for the label. The text resource is a translatable string from an application resource bundle. If you need help, press **F1** or click **Help**.
- **Expression Builder:** Select to open the Expression Builder dialog to create an expression to be executed at runtime for the label. If you need help, press **F1** or click **Help**.

If the attribute represents a category of data values, then the choices are:

- **Use Attribute Name:** Select to render the value as a string using the label from the UIHints for that attribute in the underlying `ViewObject`. This is the default selection.
- From the dropdown list, choose an alternate attribute for the label. For example, use Employee Names for labels instead of Employee IDs.
- If you want to change the display of the data represented in the bars to the Y-Axis, click the **Swap Bars with Y-Axis** button. This action switches the hidden data layer between the graph series and groups, not a simple manual swap of the bars and y-axis attributes.
- If you want to change from the default selection of **Typed Attributes** to **Name-Value Pairs** to configure how data points are stored in a collection, then click the **Change Data Shape** button. A dialog appears that presents you with the following options:
 - Typed Attributes

Each kind of data point in the collection is represented by a different attribute. This option is also valid when there is only a single kind of data point in the graph.

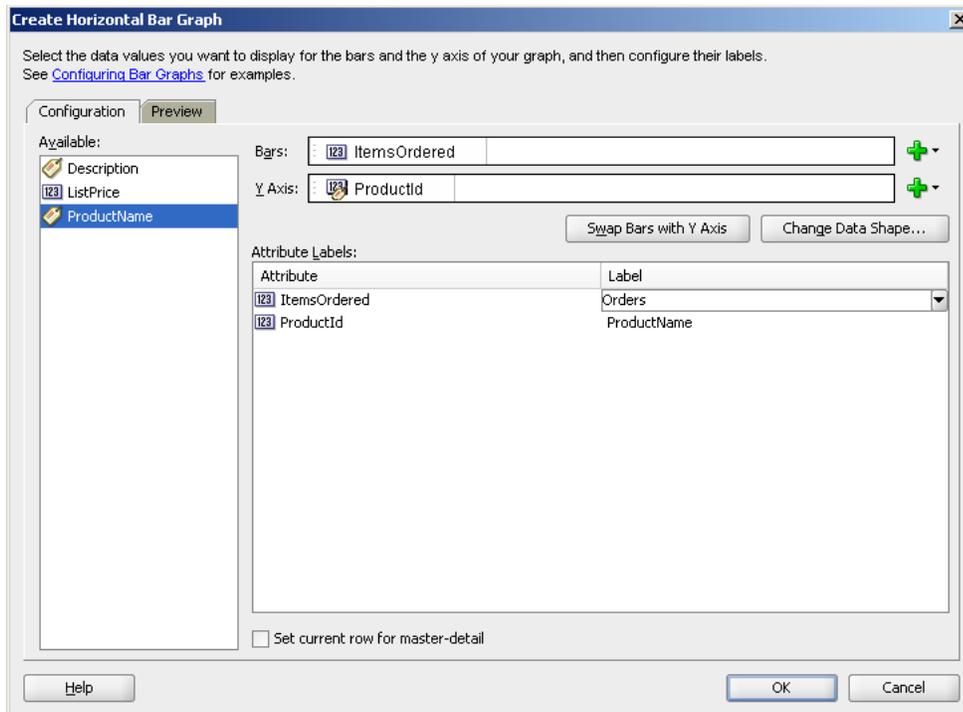

For example, if you have data points for **Estimated Value** and **Actual Value**, then select **Typed Attributes** only if you have one attribute for the estimated value and a second attribute for the actual value.
 - Name-Value Pairs

Indicates that there are two or more kinds of data points represented by exactly two attributes; a `Name` attribute that specifies the kind of data point, and a `Value` attribute that specifies the data value.

For example, the `Name` attribute might have the value `EST` for a `Value` attribute that represents an estimated value, or the `Name` attribute might have a value `ACT` for a `Value` attribute that represents an actual value.
- Select **Set the current row for master-detail** to use the graph's row selection listener to enable clicks on a bar, slice, or other graph data element to update the data in another ADF component. For more information see [Section 33.2.3, "What You May Need to Know About Using a Graph's Row Selection Listener for Master-Detail Processing."](#)

Figure 33–4 shows the Create Horizontal Bar Graph dialog that generates a graph using data from the `ItemsOrdered` attribute in the `ProductOrdersCount` data collection. The `ProductName` attribute provides labels for the displayed data.

Figure 33–4 Create Horizontal Bar Graph Dialog for ProductOrdersCount

5. Optionally, click the **Preview** tab to display a live preview of the bar graph and its data. If necessary, go back to the **Configuration** tab so that you can adjust the bar graph specifications.
6. Click **OK**.

After completing the data binding dialog, you can use the Property Inspector to specify settings for the graph attributes and you can also use the child tags associated with the graph tag to customize the graph further.

Note: Use the `emptyText` attribute to specify the text to display when there is no data to return in the graph. The default message is **No data to display**. The attribute accepts HTML for formatting the message and an EL expression that evaluates to the viewable property of the data. If the graph is not viewable (for example, if there are authorization restrictions set against the graph), it displays **Access Denied**.

33.2.2 What Happens When You Use the Data Controls Panel to Create a Graph

Dropping a graph from the Data Controls panel has the following effect:

- Creates the bindings for the graph and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

The data binding XML that JDeveloper generates varies depending on the type of graph you select. The XML represents the physical model of the specific graph type you create. [Example 33–1](#) shows the bindings that JDeveloper generated in the page definition file where a horizontal bar graph was created using data from the `ItemsOrdered` attribute in the `ProductOrdersCount` data collection.

Example 33–1 Binding XML for an ADF Bar (Horizontal) Graph

```
<graph IterBinding="ProductOrdersCountIterator" id="ProductOrdersCount"
  xmlns="http://xmlns.oracle.com/adfm/dvt" type="BAR_HORIZ_CLUST">
  <graphDataMap convert="false" leafOnly="true">
    <series>
      <data>
        <item value="ItemsOrdered"/>
      </data>
    </series>
    <groups>
      <item value="ProductName"/>
    </groups>
  </graphDataMap>
</graph>
```

Example 33–2 shows the code generated for a horizontal bar graph when you drag the ProductOrdersCount data collection onto a JSF page.

Example 33–2 JSF Code for an ADF Bar (Horizontal) Graph

```
<dvt:horizontalBarGraph id="horizontalBarGraph1"
  value="#{bindings.ProductOrdersCount.graphModel}"
  subType="BAR_HORIZ_CLUST"
  threeDEffect="true"
  imageHeight="450" imageWidth="500">
  <dvt:background>
    <dvt:specialEffects/>
  </dvt:background>
  <dvt:graphPlotArea/>
  <dvt:seriesSet>
    <dvt:series/>
  </dvt:seriesSet>
  <dvt:olAxis/>
  <dvt:y1Axis/>
  <dvt:legendArea automaticPlacement="AP_NEVER"
    position="LAP_BOTTOM"/>
</dvt:horizontalBarGraph>
```

33.2.3 What You May Need to Know About Using a Graph's Row Selection Listener for Master-Detail Processing

You can use the row selection listener of a graph (which serves as a master view) to enable clicks on a bar, slice, or other graph data element to update the data in another ADF component (which serves as a detail view). For example, a click on a bar that represents sales for a given product in a graph might cause the display of the detailed sales data for that product in a pivot table.

The following requirements must be met to achieve this master-detail processing declaratively:

1. You must use the same data control to provide data for both views as follows:
 - a. Bind the graph as a row set to the parent collection in the data control, for example, DepartmentsView.
 - b. Bind the other ADF view (such as a table or pivot table) to the dependent detail collection in the data control, for example EmployeesView.

2. Select **Set the current row for master-detail** in the Create <type> Graph dialog to automatically set a value for the `clickListener` attribute of the graph tag and use the `processClick` method that is already part of the graph binding.

For example, if the value attribute of the graph tag is `value="#{bindings.myGraph.graphModel}"`, then the `clickListener` attribute is set to `clickListener="#{bindings.myGraph.graphModel.processClick}"`.

You do not have to write Java code for handling clicks on data elements in the graph. The `processClick` event on the graph binding recognizes click events on data component in a graph and performs the necessary processing.

33.2.4 What You May Need to Know About Using Name-Value Pairs

When you configure a graph using data controls, by default the data binding dialog supports typed attributes, where each kind of data point in the collection is represented by a different attribute. For example, if you have data points for the sales and costs of multiple products, use typed attributes only if you have one attribute for the sales data of each product, and a second attribute for the cost of each product in the data collection.

Typed attributes data shape is also valid when there is only a single kind of data point in the graph. [Figure 33-5](#) shows a typed attribute data shape.

Figure 33-5 Typed Attribute Data Shape

Product	Sales	Costs
A	10	80
B	20	120
C	30	150
D	40	200

You can select **Change Data Shape** in the data binding dialog to change the dialog to support name-value pairs, where there are two or more kinds of data points represented by exactly two attributes; a `Name` attribute that specifies the kind of data point, and a `Value` attribute that specifies the data value. In this case, each dedicated attribute has values that identify each kind of data point. For example, the `Metrics` attribute might have values for `Sales` and `Costs` for each product in a data collection. [Figure 33-6](#) shows a data collection in a name-value pairs data shape.

Figure 33-6 Name-Value Pairs Data Shape

Product	Metric	Value
A	Sales	100
A	Costs	80
B	Sales	200
B	Costs	120

When using a name-value pairs data shape, specify these values in the graph data binding dialog:

- **Name Attribute:** the attribute in the data collection representing the `Name` attribute, when its unique values categorize data points into different metrics.
- **Value Attribute:** the attribute in the data collection representing the numeric data points plotted on the graph. Each data point is categorized as belonging to a particular metric by the corresponding `Name` attribute value.
- Specify the values for the `Value` attribute in the relevant fields for the graph type as defined in the dialog, for example, **Bubble Colors** and **Bubble Tootips** for a

bubble graph. Values can be attributes in the data collection, or data values, representing a unique value of the Name attribute to be used at runtime to categorize data points into specific metrics. You must specify one or more data values, although you are not required to select all the metrics available in the Name attribute.

You must add one or more data values by selecting **Data Value** from the field **Add** dropdown list. Each data value represents a unique value of the Name Attribute to be used at runtime to categorize data points into specific metrics. You are not required to select all the metrics available in the Name Attribute.

After specifying attributes or data values for the input field, you can right click on any attribute to display a context menu for actions such as **Move Right**, **Move Left**, **Delete**, or **Edit Data Value**.

For example, you can create a stock graph that displays open, high, low, and close stock values bound to a data collection with a single numeric column of data in a name-value pairs shape as displayed in [Figure 33-7](#).

33.2.5 How to Create a Graph Using Name-Value Pairs

You can create a graph where the data collection is arranged in a name-value pairs data shape. For example, stock values may be arranged in a single numeric column of data with multiple data points and multiple attributes to designate these points as displayed in the data collection in [Figure 33-7](#).

Figure 33-7 Stock Values in Name-Value Pairs Data Shape

Symbol	MarketDate	Measure	Data
ORCL	2/12/2007	OPEN	16.65
ORCL	2/12/2007	HIGH	16.71
ORCL	2/12/2007	LOW	16.51
ORCL	2/12/2007	CLOSE	16.65
ORCL	2/12/2007	VOLUME	31930300
ORCL	2/13/2007	OPEN	16.71
ORCL	2/13/2007	HIGH	16.74
ORCL	2/13/2007	LOW	16.53
ORCL	2/13/2007	CLOSE	16.62
ORCL	2/13/2007	VOLUME	27438100
ORCL	2/14/2007	OPEN	16.74
ORCL	2/14/2007	HIGH	16.94
ORCL	2/14/2007	LOW	16.68
ORCL	2/14/2007	CLOSE	16.77
ORCL	2/14/2007	VOLUME	42296000
ORCL	2/15/2007	OPEN	16.84
ORCL	2/15/2007	HIGH	16.92

Before You Begin:

What you may need to know about n-v pairs

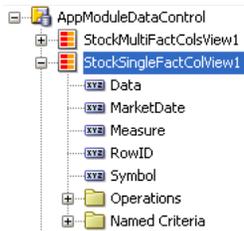

To create a graph using a name-value pairs data shape:

1. From the Data Controls panel, select a collection.

In the example to create a graph that displays the open, high, low, and close stock values over a week's time, select the collection `StockSingleFactColView1`.

[Figure 33-8](#) shows the `StockSingleFactColView1` collection in the Data Controls panel.

Figure 33–8 Data Collection for Stock Values in Single Column

2. Drag the collection onto a JSF page and, from the context menu, choose **Graphs** to display the Component Gallery.
3. In the Component Gallery, select the Stock graph category, then the Open-Hi-Lo-Close Candle with Volume graph type, and click **OK**.
4. Do the following to change the dialog to support a name-value pairs data shape:
 - Click **Change Data Shape**.
 - In the Change Chart Data Shape dialog, select **Name-Value Pairs**, and click **OK**.
 - If prompted, confirm your selection.
5. Do the following in the modified dialog to configure the graph to display data:
 - For Name Attribute, select the attribute category **Measures** from the dropdown list.
 - For Value Attribute, specify the exact Name Attribute values corresponding to the **Open, Hi, Lo, and Close** data attribute from the dropdown list.
 - In the **Chart Values** table, accept the default value or select a value from the dropdown list in the **Label** field to specify the label that appears at runtime.

If an attribute represents data values, then the choices in the **Label** field determine how that attribute's label is rendered in the graph:

- **Use Attribute Name:** Select to render the value as a string using the label from the UIHints for that attribute in the underlying `ViewObject`. This is the default selection.
- **No Label:** Select to render no label. This choice is useful if there is a single metric and you want to provide your own descriptive text on the page to describe the resulting graph.
- **Select Text Resource:** Select to open a Select Text Resource dialog to select or add a text resource to use for the label. The text resource is a translatable string from an application resource bundle. If you need help, press **F1** or click **Help**.
- **Expression Builder:** Select to open the Expression Builder dialog to create an expression to be executed at runtime for the label. If you need help, press **F1** or click **Help**.

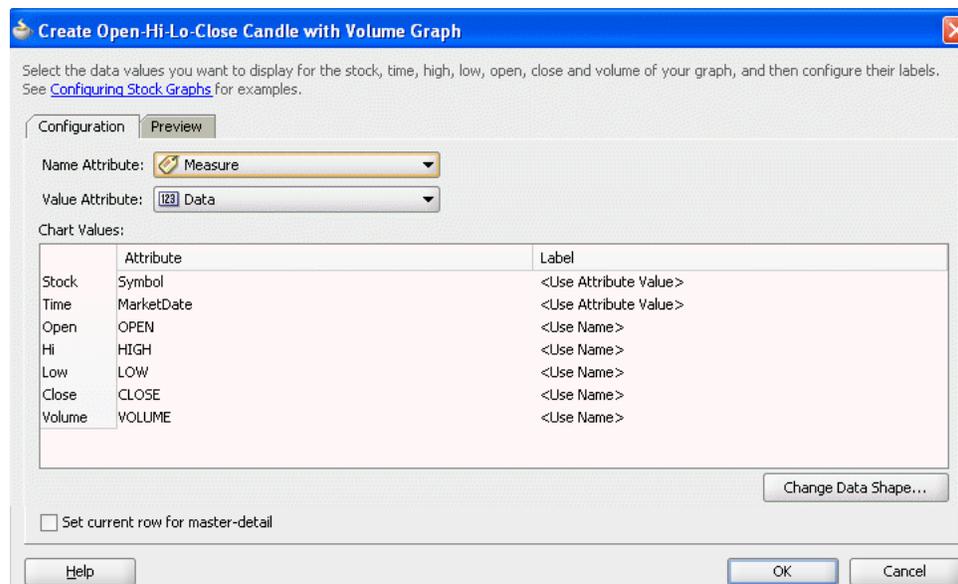

If the attribute represents a category of data values, then the choices

- **Use Attribute Name:** Select to render the value as a string using the label from the UIHints for that attribute in the underlying `ViewObject`. This is the default selection.
- From the dropdown list, choose an alternate attribute for the label. For example, use Employee Names for labels instead of Employee IDs.

- Set the current row for master-detail:** Select to use the graph's row selection listener to enable clicks on a bar, slice, or other graph data element to update the data in another ADF component. For more information see [Section 33.2.3, "What You May Need to Know About Using a Graph's Row Selection Listener for Master-Detail Processing."](#)

Figure 33–9 shows the Create Stock Graph dialog that generates a graph using the attribute in the collection.

Figure 33–9 Create Stock Graph for StockSingleFactColView1

- Optionally, click the **Preview** tab to display a live preview of the stock graph and its data. If necessary, go back to the **Configuration** tab so that you can adjust the stock graph specifications.
- Click **OK**.

33.2.6 How to Create a Databound Spark Chart

Spark charts are simple, condensed graphs that display trends or variations, often in the column of a table, or inline with text. Line, bar, and area spark charts require a single series of data values. Figure 33–10 shows an example of a line spark chart in a table column.

Figure 33–10 Line Spark Chart in Table of Stock Prices

Stock Symbol	Prices for 2008
ORCL	
AAPL	
MSFT	
YHOO	
CSCO	
PALM	

Floating bar spark charts require two series of data values, one for the float offset, and one for the bar value. Figure 33–11 shows an example of a floating bar sparkchart.

Figure 33–11 Floating Bar Spark Chart

In a simple UI-first development scenario you can insert a sparkchart using the Component Palette and bind it to data afterwards.

You can provide data to sparkcharts in any of the following ways:

- Specify data statically in child `dvt:sparkItem` tags. [Example 33–3](#) shows an example of providing static data to a sparkchart.

Example 33–3 Static Data in Sparkchart

```
<dvt:sparkChart>
  <dvt:sparkItem value="20"/>
  <dvt:sparkItem value="15"/>
  <dvt:sparkItem value="30"/>
</dvt:sparkChart>
```

- Specify data using EL Expression in child `dvt:sparkItem` tags. [Example 33–4](#) shows an example of providing data using EL Expressions.

Example 33–4 EL Expression Data in Sparkchart

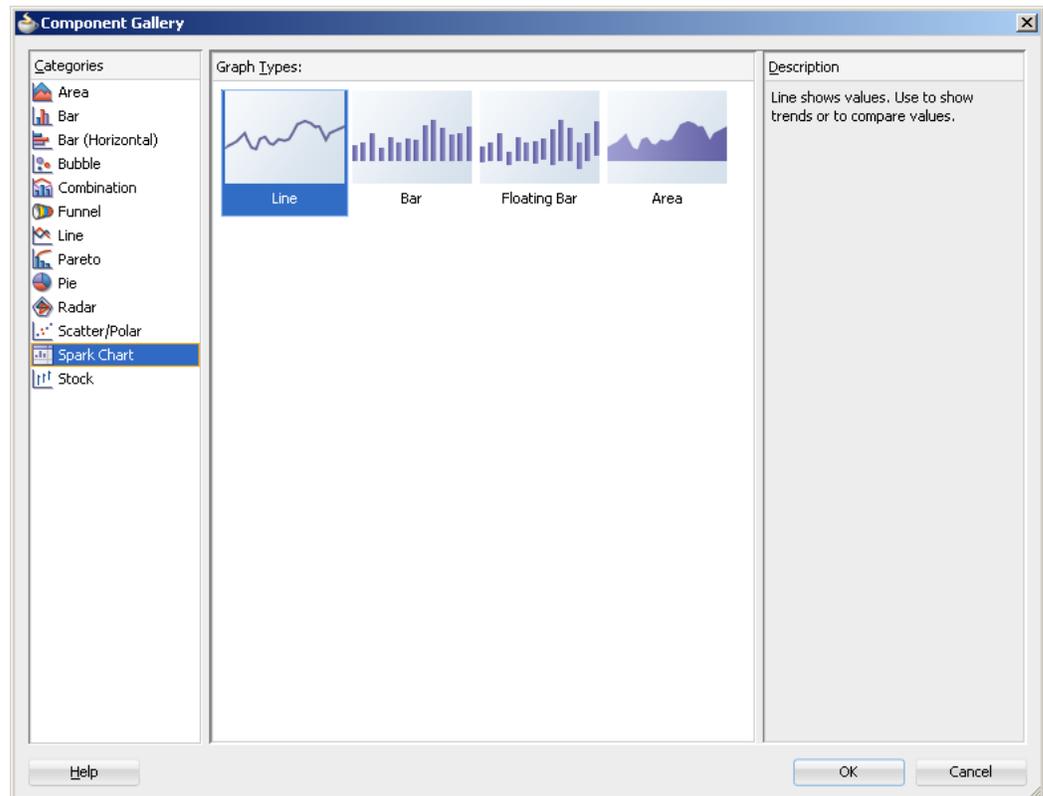

```
<af:table value="#{sample.tableModel}" var="row">
  <af:column>
    <dvt:sparkChart>
      <dvt:sparkItem value="#{row.col1}"/>
      <dvt:sparkItem value="#{row.col2}"/>
      <dvt:sparkItem value="#{row.col3}"/>
    </dvt:sparkChart>
  </af:column>
</af:table>
```

- Specify data using a child accessor in a table. [Example 33–5](#) shows an example of using `af:iterator` to provide sparkchart data from the data collection model, `row.stockValues`.

Example 33–5 Sparkchart Data in Table Child Accessor

```
<af:table value="#{sample.tableModel}" var="row">
  <af:column>
    <dvt:sparkChart>
      <af:iterator value="#{row.stockValues}" var="data">
        <dvt:sparkItem value="#{data.closeValue}"/>
      </af:iterator>
    </dvt:sparkChart>
  </af:column>
</af:table>
```

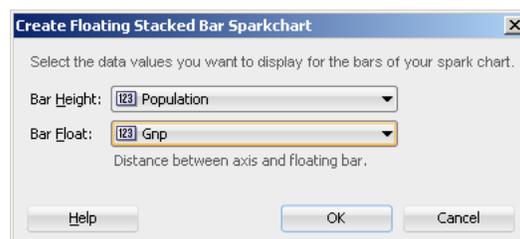

You can also create a sparkchart by inserting a data control from the Data Controls Panel. [Figure 33–12](#) shows the Component Gallery that displays when you drag a sparkchart component onto your page from the Data Controls panel.

Figure 33–12 Create Sparkchart Component Gallery

A binding dialog prompts you to specify the value you wish to display for the selected sparkchart type. Line, bar, and area spark charts require a single series of data values, for example the changing value of a stock. Floating bar sparkcharts require two series of data values, one for the float offset, and one for the bar value. For example, in the Create Floating Stacked Bar Sparkchart dialog you specify:

- **Bar Height:** Use to select the data value to use for the bar value.
- **Bar Float:** Use to select the data value to use for the float offset, the distance between the axis and the floating bar.

Figure 33–13 shows a completed Create Floating Stacked Bar Sparkchart dialog.

Figure 33–13 Sparkchart Binding Dialog

33.3 Creating Databound Gauges

A gauge plots one data point with indication of whether the data point falls in an acceptable or unacceptable range. One databound gauge component can create a

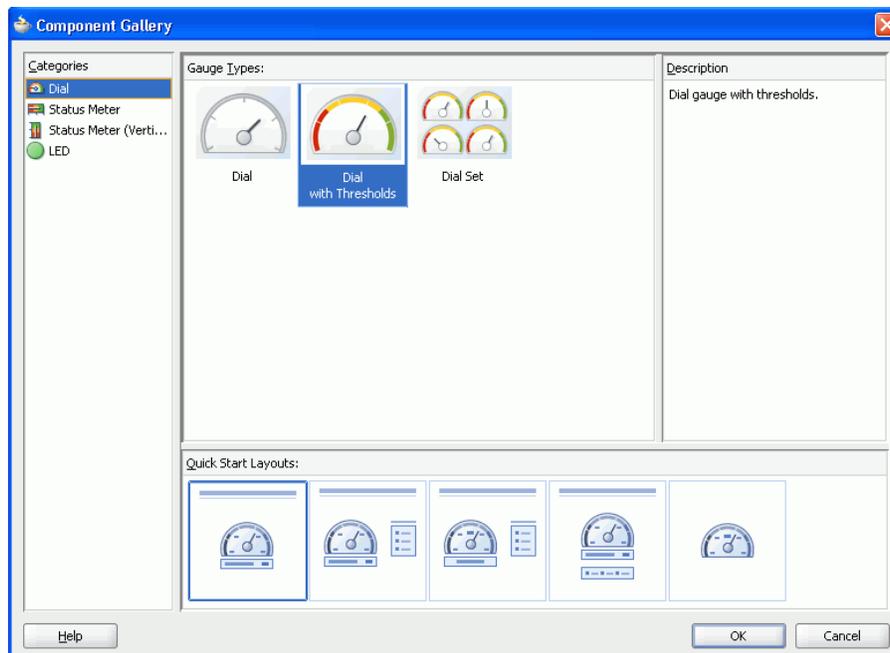

single gauge or an entire set of gauges, depending on the number of rows in the data collection used. In a collection, each row contains the values for a single gauge.

The Component Gallery for gauges allows you to choose from the following categories of gauges:

- Dial: Indicates the metric value of a task along a configurable arc.
- Status Meter: Indicates the progress of a task or the level of some measurement along a rectangular bar.
- Status Meter (Vertical): Indicates the progress of a task or the level of some measurement along a rectangular bar.
- LED: Depicts graphically a measurement such as a key performance indicator (KPI). Several styles of graphics are available for LED gauges such as arrows that indicate good (up arrow), fair (left- or right-pointing arrow), and poor (down arrow).

Each of these categories contains a number of different types of gauge. Explore the Component Gallery that appears when you create a gauge to view all available gauge and category types, and descriptions for each one. [Figure 33–14](#) shows the Component Gallery that appears for ADF gauges.

Figure 33–14 ADF Gauges Component Gallery

The data binding process is essentially the same regardless of which type of gauge you create. Only the metric value (that is, the measurement that the gauge is to indicate) is required. However, if a row in a data collection contains range information such as maximum, minimum, and thresholds, then these values can be bound to the gauge to provide dynamic settings. If information that you want to use in a gauge’s upper or lower labels is available in the data collection, then you can bind these values to the gauge also.

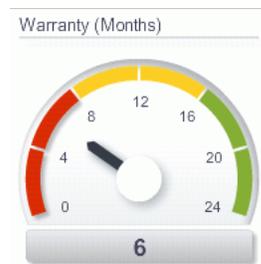

For information about customizing a gauge after the data binding is completed, see the "Using ADF Gauge Components" chapter in *Oracle Fusion Middleware Web User Interface Developer’s Guide for Oracle Application Development Framework*.

33.3.1 How to Create a Databound Dial Gauge

You can use the ADF gauge component to create a dial gauge against a background that specifies ranges of values (also called *thresholds*) that vary from poor to excellent. The gauge indicator specifies the current value of the metric while the graphic allows you to evaluate the status of that value easily.

Figure 33–15 shows a single dial gauge that appears if you create a gauge from the collection that stores `WarrantyPeriodMonths` data. Because only one gauge appears, this data collection must contain only a single row of data. The value of the metric (which is 6) appears in a label below the gauge. The range of values in the gauge is displayed as 0 to 24. Threshold ranges are identified at 8, 16, and 24 and are filled with the colors red for poor (below 8), yellow for adequate (from 8 to 16), and green for superior (above 16).

Figure 33–15 The Warranty in Months Dial Gauge

To create a dial gauge using a data control, you bind the gauge component to a collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

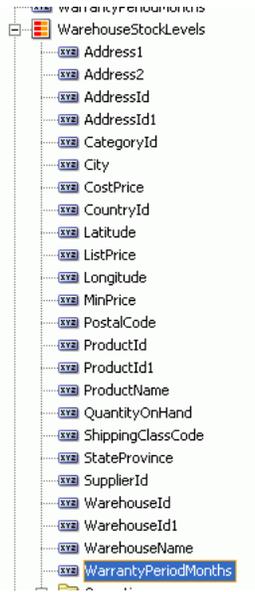

To create a databound dial gauge:

1. From the Data Controls panel, select a collection.

For example, to create a dial gauge in the `StoreFrontModule` application to display the current warranty period in months for a product in a particular warehouse, you would select the `WarehouseStockLevels` collection.

Figure 33–16 shows the `WarehouseStockLevels` collection in the Data Controls panel.

Figure 33–16 Data Collection with Warranty Period for a Product

2. Drag the collection onto a JSF page and, from the context menu, choose **Gauges**.
3. In the Component Gallery dialog, choose the category, type of gauge, and quick start layout, and then click **OK**.
4. In the Configuration tab of the dialog, do the following:
 - In the **Metric** box, select the column in your data collection that contains the actual value that the gauge is to plot. This is the only required value in the dialog.
 - In the **Minimum** box, if your data collection stores a minimum value for the gauge range, select the column that contains this value.
 - In the **Maximum** box, if your data collection stores a maximum value for the gauge range, select the column that contains this value.
 - In the **Top Label** box, if your data collection stores a value that you want to display in the top label of the gauge, select the column that contains this value.
 - In the **Bottom Label** box, if your data collection stores a value that you want to display in the bottom label of the gauge, then select the column that contains this value.
 - In the **Threshold Attributes** list, if you want to specify threshold values, click the **Add icon** to insert a row for each threshold and specify the value in that row. Do not create a threshold equal to the maximum value for the gauge because the gauge automatically treats the maximum value as a threshold setting.

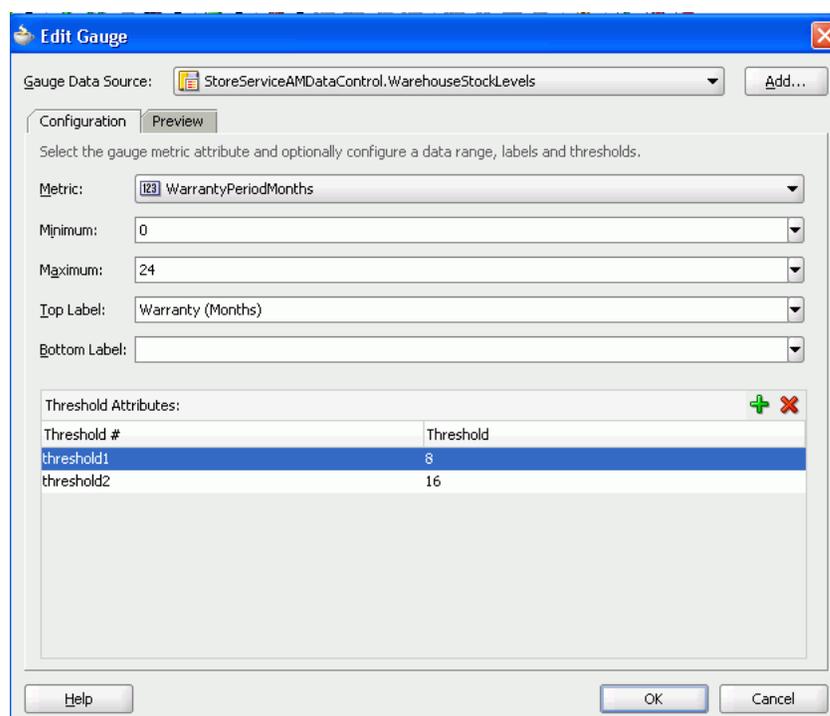

Note: Gauge Top, Bottom, and Threshold labels can be configured to specify a text resource from a resource bundle using the Select Text Resource dialog, or use the EL Expression builder to evaluate the label text at runtime. Use the dropdown menu for the label field to open both dialogs.

5. Optionally, click the **Preview** tab to display a live preview of the gauge and its data. If necessary, go back to the **Configuration** tab so that you can adjust the gauge specifications.
6. Click **OK**.

You can examine and adjust the gauge bindings for `WarehouseStockLevels` in the Edit Gauge dialog. [Figure 33–17](#) shows the dialog that appears when you click the **Edit** icon in the Property Inspector for the gauge component.

Note: The data source and metric data values are required. Other data values in the dialog are optional and can be specified in the gauge component through the Property Inspector.

Figure 33–17 Edit Gauge Dialog

In the Property Inspector, after you complete the binding of the gauge, you can set values for additional attributes in the gauge tag and its child tags to customize the component.

33.3.2 What Happens When You Create a Dial Gauge from a Data Control

Dropping a gauge from the Data Controls panel has the following effect:

- Creates the bindings for the gauge and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

[Example 33–6](#) shows the bindings that JDeveloper generated for the dial gauge that displays warranty in months for a product in a warehouse. This code example shows that the gauge metric receives its value dynamically from the

WarrantyPeriodMonths column in the data collection and that the remaining data values have static settings.

Example 33–6 Bindings for a Dial Gauge

```
<gauge IterBinding="WarehouseStockLevelsIterator" id="WarehouseStockLevels"
    xmlns="http://xmlns.oracle.com/adfm/dvt">
  <gaugeDataMap>
    <item type="threshold" value="8" valueType="literal"/>
    <item type="threshold" value="16" valueType="literal"/>
    <item type="metric" value="WarrantyPeriodMonths"/>
    <item type="minimum" value="0" valueType="literal"/>
    <item type="maximum" value="24" valueType="literal"/>
    <item type="topLabel"
        value="{adfBundle['view.ViewControllerBundle'].
            WARRANTY_(MONTHS)}" valueType="literal"/>
  </gaugeDataMap>
</gauge>
```

Example 33–7 shows the code that JDeveloper generated in the JSF page for a dial gauge. The `<dvt:thresholdSet>` element specifies one `<dvt:threshold>` element for each threshold. Colors for the threshold ranges default to red, yellow, and green as specified by the values for the `fillColor` attributes. The `<dvt:indicator>` element specifies `IT_NEEDLE` as the indicator to use. This renders a needle at runtime. The default value for `<dvt:indicator>` renders a line (`IT_LINE`).

Example 33–7 Code on the JSF Page for an ADF Dial Gauge

```
<dvt:gauge id="gauge1"
    value="{bindings.WarehouseStockLevels.gaugeModel}"
    gaugeType="DIAL" imageFormat="FLASH">
  <dvt:gaugeBackground>
    <dvt:specialEffects fillType="FT_GRADIENT">
      <dvt:gradientStopStyle/>
    </dvt:specialEffects>
  </dvt:gaugeBackground>
  <dvt:thresholdSet>
    <dvt:threshold text="Low" fillColor="#d62800"/>
    <dvt:threshold text="Medium" fillColor="#ffc21"/>
    <dvt:threshold text="High" fillColor="#84ae31"/>
  </dvt:thresholdSet>
  <dvt:gaugeFrame/>
  <dvt:indicator type="IT_NEEDLE"/>
  <dvt:indicatorBase/>
  <dvt:gaugePlotArea/>
  <dvt:tickLabel/>
  <dvt:tickMark/>
  <dvt:topLabel/>
  <dvt:bottomLabel/>
  <dvt:metricLabel position="LP_WITH_BOTTOM_LABEL"/>
</dvt:gauge>
```

33.3.3 How to Create a Databound Status Meter Gauge Set

You can use the ADF gauge component to create a status meter gauge where the inner rectangle shows the current level of a measurement against the ranges marked in the

outer rectangle. The graphic of the status meter gauge allows you to evaluate the condition or progress of a measurement easily.

Figure 33–18 shows a set of status meter gauges that represent the inventory levels in a number of warehouses. This set of gauges results from binding one gauge component to a data collection (`WarehouseStockLevels`). This data collection contains a row of data for each warehouse. Each row produces one gauge in the set. Notice that all gauges in the set share the same range values of minimum (0) and maximum (1500) with thresholds set at 500 and 1000 and 1500. Each gauge in the set displays the name of the warehouse that it represents and the stock metric for that warehouse in its bottom label.

Figure 33–18 The Warehouse Inventory Status Meter Gauge Set

To create a status meter gauge set using a data control, you bind the gauge component to a data collection that contains multiple rows of data. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

To create a databound status meter gauge:

- From the Data Controls panel, select a collection.
For example, to create a status meter gauge in the `StoreFrontModule` application that displays the quantity of stock on hand in a warehouse, you select the `WarehouseStockLevels` collection.
- Drag the collection onto a JSF page and, from the context menu, choose **Gauges**.
- In the Component Gallery, choose the following:
 - Status Meter** or **Status Meter (Vertical)** in the **Categories** list
 - The type of gauge that you want to create
 - The quick start layout for the gauge at runtime
- Click **OK**.
- In the Create Gauge dialog that appears, select values as described in the following list:
 - Select an attribute binding from the **Metric** dropdown list. This attribute binding contains the actual value that the gauge is to plot.
 - Input a minimum value in the **Minimum** field if your data collection stores a minimum value for the gauge range.
 - Input a maximum value in the **Maximum** field if your data collection stores a maximum value for the gauge range.

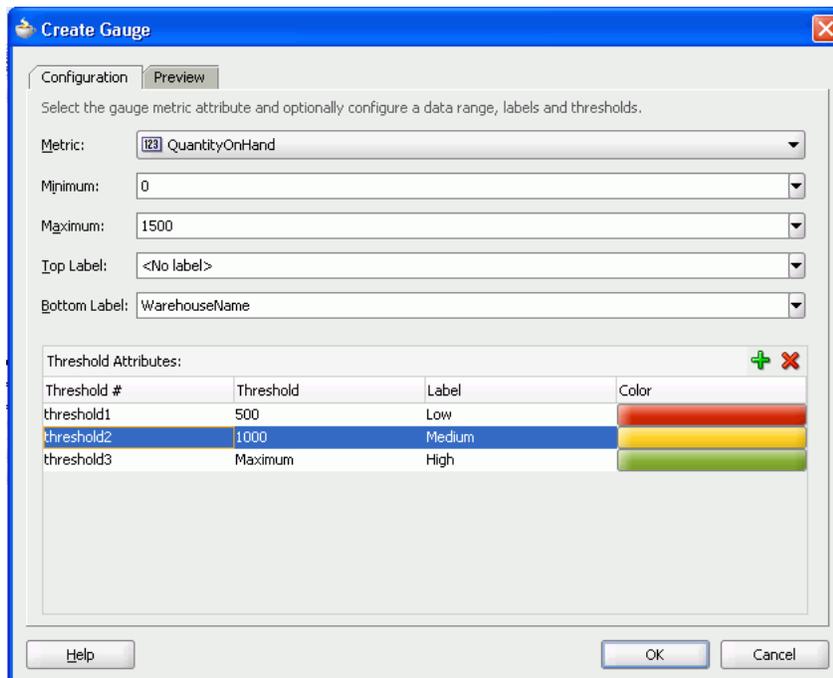

- Write or select a value in the **Top Label** field if you want to display a label on top of the gauge at runtime.
- Write or select a value in the **Bottom Label** field if you want to display a label below the gauge at runtime.
- Click the **Add** icon to insert a row for each threshold and specify the value for that threshold if you want to specify threshold values in the **Threshold Attributes** list. Do not create a threshold equal to the maximum value for the gauge because the gauge automatically treats the maximum value as a threshold setting.

Note: Gauge Top, Bottom, and Threshold labels can be configured to specify a text resource from a resource bundle using the Select Text Resource dialog, or use the EL Expression builder to evaluate the label text at runtime. Use the dropdown menu for the label field to open both dialogs.

6. Optionally, click the **Preview** tab to display a live preview of the gauge and its data. If necessary, click the **Configuration** tab so that you can adjust the gauge specifications.

Figure 33–19 shows the settings for the set of status meter gauges that appears in Figure 33–18. In addition to setting values for the required metric value, this dialog sets values for thresholds and for the name of the warehouse to appear in the gauge’s bottom label.

Figure 33–19 Create Gauge Dialog for Warehouse Inventory Gauge Set

7. Click **OK**.

In the Property Inspector, after you complete the binding of the gauge, you can set values for additional attributes in the gauge tag and its child tags to customize the component as needed.

33.3.4 What Happens When You Create a Status Meter Gauge from a Data Control

Dropping a gauge from the Data Controls panel has the following effect:

- Creates the bindings for the gauge and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

[Example 33–8](#) shows the row set bindings that were generated for the status meter gauge set that displays inventory levels for each warehouse as illustrated in [Figure 33–19](#). This example shows the value binding created between the gauge metric attribute and the `QuantityOnHand` value in the data collection. It also shows the value binding between the `Bottom Label` attribute and the `WarehouseName` value in the data collection.

Example 33–8 Bindings Code for the ADF Status Meter Gauge Set

```
<gauge IterBinding="WarehouseStockLevelsIterator" id="WarehouseStockLevels"
  xmlns="http://xmlns.oracle.com/adfm/dvt">
  <gaugeDataMap>
    <item type="threshold" value="500" valueType="literal"/>
    <item type="threshold" value="1000" valueType="literal"/>
    <item type="metric" value="QuantityOnHand"/>
    <item type="minimum" value="0" valueType="literal"/>
    <item type="maximum" value="1500" valueType="literal"/>
    <item type="bottomLabel" value="WarehouseName"/>
  </gaugeDataMap>
</gauge>
```

[Example 33–9](#) shows the code generated on the JSF page for the status meter gauge set that shows inventory levels for warehouses. The `gaugeSetColumnCount` attribute specifies that gauges should be displayed in two columns. The code also specifies three thresholds: Low, Medium, and High. For brevity, the value of the `inlineStyle` attribute has been omitted.

Example 33–9 Code on the JSF Page for the ADF Status Meter Gauge Set

```
<dvt:gauge id="gauge1"
  value="#{bindings.WarehouseStockLevels.gaugeModel}"
  gaugeType="STATUSMETER" imageFormat="FLASH">
  <dvt:gaugeBackground>
    <dvt:specialEffects fillType="FT_GRADIENT">
      <dvt:gradientStopStyle/>
    </dvt:specialEffects>
  </dvt:gaugeBackground>
  <dvt:thresholdSet>
    <dvt:threshold text="Low" fillColor="#d62800"/>
    <dvt:threshold text="Medium" fillColor="#ffcf21"/>
    <dvt:threshold text="High" fillColor="#84ae31"/>
  </dvt:thresholdSet>
  <dvt:indicatorBar/>
  <dvt:gaugePlotArea/>
  <dvt:tickLabel/>
  <dvt:tickMark/>
  <dvt:topLabel/>
```

```

<dvt:bottomLabel />
<dvt:metricLabel position="LP_WITH_BOTTOM_LABEL" />
</dvt:gauge>

```

33.4 Creating Databound Pivot Tables

The ADF pivot table displays data in a grid layout with unlimited layers of nested rows and columns. The pivot table supports an optional pivot filter bar, representing a page edge that filters the available pivot table data. The pivot table has the following structure:

- Column edge: The horizontal axis above the pivot table containing one or more layers of information in the pivot table.
- Row edge: The vertical axis to the left of the pivot table containing one or more layers of information in the pivot table.
- Page edge: The optional pivot filter bar containing zero or more layers of information for filtering the display of data in the pivot table.
- Data body: One or more measures, or data values, displayed in the cells of the pivot table.

Figure 33–20 shows a Sales pivot table that displays data values for sales and units in the data body, a geography data layer on the column edge, and year and product data layers on the row edge. A pivot filter bar displays a channel filter on the page edge.

Figure 33–20 Sales Pivot Table

		World		Boston		Total Geography	
		Sales	Units	Sales	Units	Sales	Units
>	2005	8750	35	500	9	9250	44
∇	2006	17500	70	1000	15	18500	85
	Tents	10000	100	250	25	10250	125
	Canoes	7500	40	750	4	8250	44
∇	2007	15000	28	900	11	15900	39
	Canoes	10000	50	500	2	10500	52
	Tents	5000	5	400	20	5400	25
Total Across Years		41250	265	2400	68	43650	333

The pivot table example aggregates data based on a CSV file of data shown in Figure 33–21.

Figure 33–21 Pivot Table CSV Data

Year	Product	Channel	Geography	Sales	Units
2007	Tents	Direct	World	5000	5
2007	Tents	Indirect	World	20000	200
2007	Tents	Direct	Boston	400	20
2007	Tents	Indirect	Boston	100	50
2007	Canoes	Direct	World	10000	50
2007	Canoes	Direct	Boston	500	2
2007	Canoes	Indirect	World	15000	75
2007	Canoes	Indirect	Boston	1500	8
2006	Tents	Direct	World	10000	100
2006	Tents	Direct	Boston	250	25
2006	Tents	Indirect	World	20000	200
2006	Tents	Indirect	Boston	500	50
2006	Canoes	Direct	World	7500	40
2006	Canoes	Direct	Boston	750	4
2006	Canoes	Indirect	World	15000	80
2006	Canoes	Indirect	Boston	150	8
2005	Tents	Direct	World	5000	50

A Create Pivot Table wizard provides declarative support for data-binding and configuring the pivot table. In the wizard pages you can:

- Specify the initial layout of the pivot table
- Associate and configure a pivot filter bar
- Specify alternative labels for the data layers
- Configure insert or filter drilling
- Define aggregation of data values
- Configure category and data sorting
- View a live data preview of the pivot table

As you lay out the pivot table in the first page of the wizard, corresponding entries are initialized in the following wizard pages. You can use the **Back** and **Next** buttons to adjust the pivot table as you go through the wizard pages. You can also skip configuration options in later wizard pages by clicking **Finish**.

For information about customizing a pivot table after data binding is completed, see the "Using ADF Pivot Table Components" chapter in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

33.4.1 How to Create a Pivot Table

To create a pivot table using a data control, you bind the pivot table component to a collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

Tip: You can also create a pivot table by dragging a pivot table component from the Component Palette. This approach allows you the option of designing the pivot table user interface before binding the component to data.

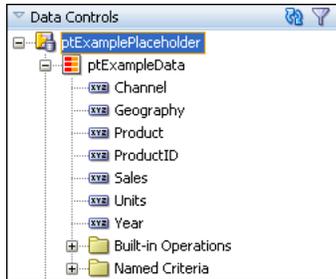

To demonstrate the creation of the sample Sales pivot table shown in [Figure 33–20](#), a placeholder data control was created and data types defined for the CSV file shown in [Figure 33–21](#). For more information, see [Section 17.4, "Using Placeholder Data Controls."](#)

To create a databound pivot table:

1. From the Data Controls panel, select a collection.

For example, to create a pivot table that displays sales and units sold by year for each product, you could select the `ptExampleData` defined for the `ptExamplePlaceholder` collection in the Data Controls panel, as shown in [Figure 33–22](#).

Figure 33–22 Data Collection for Product Sales by Year

2. Drag the data collection onto a JSF page and, from the context menu, choose **Tables > ADF Pivot Table**.
3. In the Select Display Attributes page of the Create Pivot Table wizard, specify the initial layout of the pivot table by doing the following:
 - a. If you want to associate a pivot filter bar with your pivot table, select **Create Pivot Filter Bar**. Optionally, you can drag attributes from the **Available Attributes** list to the page edge to configure the initial display of filters; otherwise, an empty pivot filter bar is created.

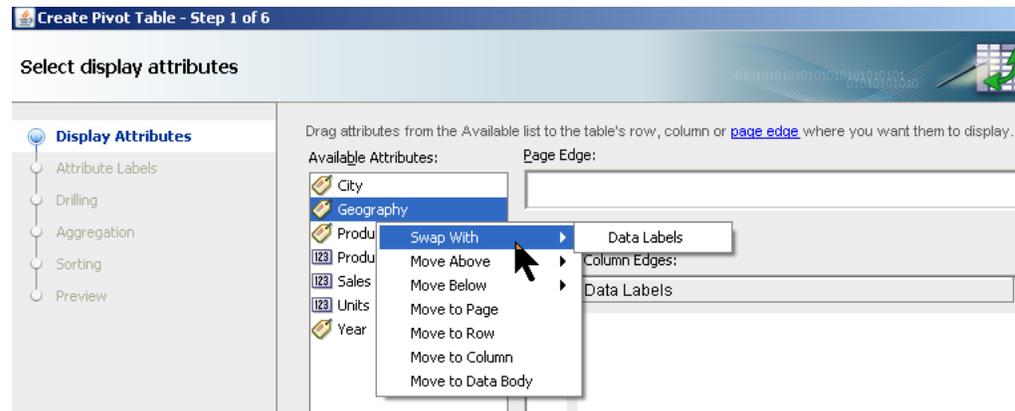

Note: You can add or remove a pivot filter bar after completing the wizard by selecting the `pivotTable` component in the Property Inspector, clicking the **Edit** icon, and checking or unchecking the **Create Pivot Filter Bar** option. You can also drag and drop a `pivotFilterBar` component from the Component Palette adjacent to a pivot table and the bindings will be done for you.

- b. For the initial layout, select the attributes for the pivot table’s columns, rows, page edge, and data body by dragging the attributes from the **Available Attributes** list to the pivot table layout.

In the pivot table layout, **Data Labels** refers to a layer of the pivot table that identifies the data in the cells (data values), and that appears as header labels in the row, column, or page edge. Labels for attributes that you drag to the data body of the pivot table appear in the data labels layer.

You can drag data labels to any location on the row, column, or page edge. You can also drag attributes to different locations on the same edge or on another edge.

As an alternative to using a drag operation to place or move attributes in the layout, you can right-click the attribute or use **Shift+F10** to display a context menu of options. [Figure 33–23](#) shows the context menu options for the Geography attribute.

Figure 33–23 Display Attributes Context Menu

Note: Potential drill paths between attributes are defined as you lay out multiple attributes on the row, column, and page edges. These drill paths can later be enabled to support pivot table drilling at runtime.

- c. If you want to change from the default selection of **Typed Attributes** to **Name-Value Pairs** to configure how data points are stored in a collection, then click the **Change Data Shape** button. A dialog appears that presents you with the following options:

– **Typed Attributes**

Each kind of data point in the collection is represented by a different attribute. This option is also valid when there is only a single kind of data point in the pivot table.

For example, if you have data points for **Estimated Value** and **Actual Value**, then select **Typed Attributes** only if you have one attribute for the estimated value and a second attribute for the actual value.

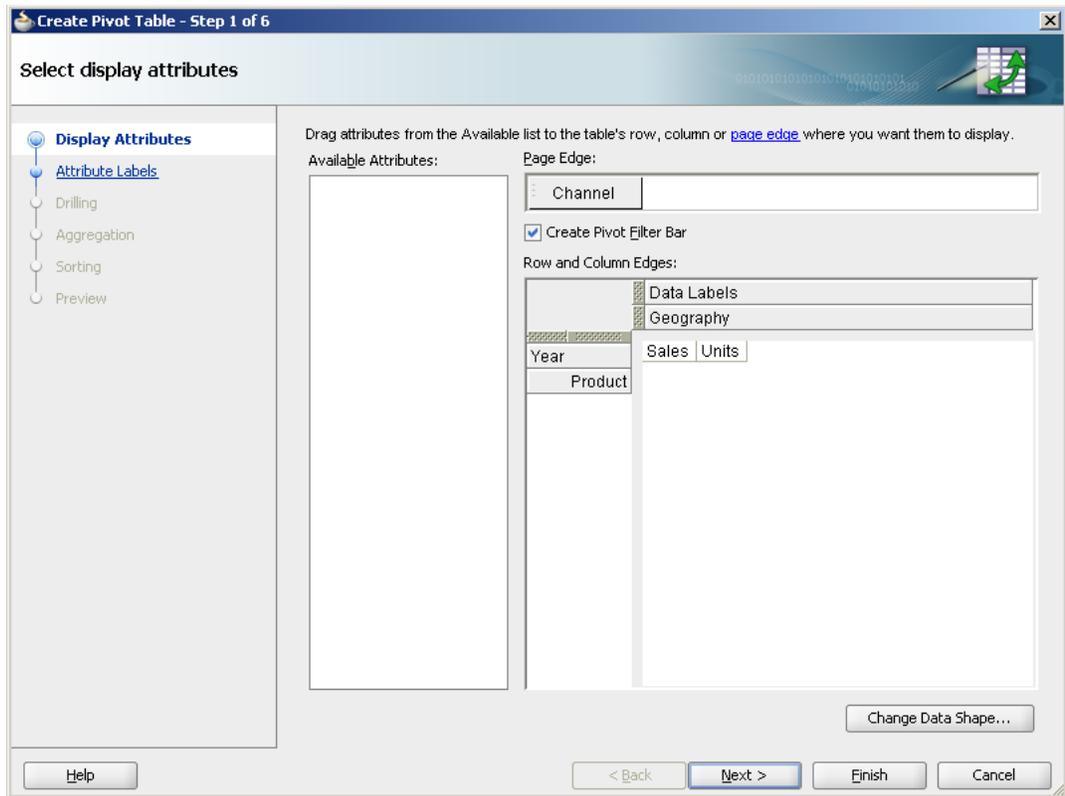

– **Name-Value Pairs**

Indicates that there are two or more kinds of data points represented by exactly two attributes; a **Name** attribute that specifies the kind of data point, and a **Value** attribute that specifies the data value.

For example, the **Name** attribute might have the value **EST** for a **Value** attribute that represents an estimated value, or the **Name** attribute might have a value **ACT** for a **Value** attribute that represents an actual value.

For example, to specify the initial layout of the Sales pivot table shown in [Figure 33–20](#), you would drag the Channel attribute to the page edge, Year and Product attributes to the row edge, Sales and Units attributes to the data body (Data Labels), Geography to the column edge, and select **Create Pivot Filter Bar**, as shown in [Figure 33–24](#).

Figure 33–24 Select Display Attributes Page of Create Pivot Table Wizard

4. If you want to specify alternative labels or values for the attributes laid out in the Select Display Attributes page of the wizard, use the Specify Attribute Labels page to do the following:
 - a. To specify alternative labels for data values in the **Data Values** area, change the default `Use Data Attribute Name` text label stamped in the header cell for the attribute at runtime. You can enter the text directly, select `No Label` to suppress the header cell as in the case of using a single data value for the pivot table, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime.

Note: If you configured **Project Properties > Resource Bundle** page to **Automatically Synchronize Bundle**, then you can type an alternate label string, and the design time code will create a translatable Text Resource for you.

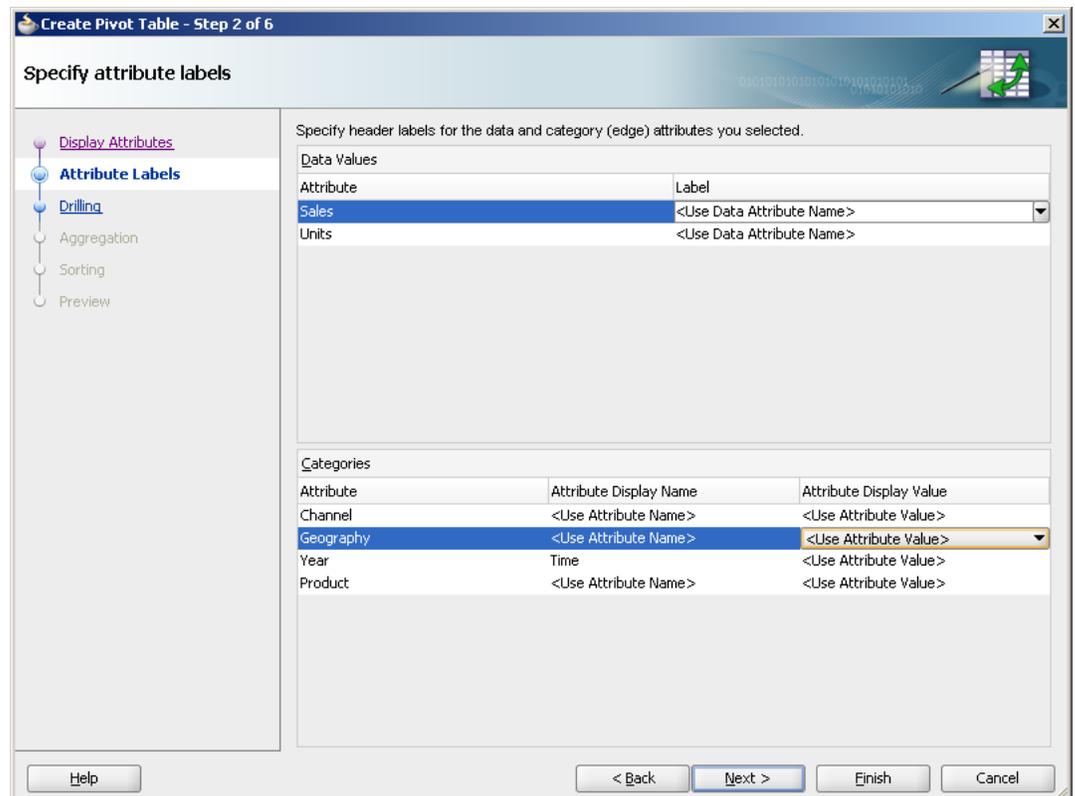

- b. To specify alternative labels for attribute categories in the **Categories** area, change the default `Use Attribute Name` text label stamped in the header cell for the attribute at runtime in the **Attribute Display Name** column. You can enter the text directly, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime. The label displays in the pivot handle at runtime.

Note: If you configured **Project Properties > Resource Bundle** page to **Automatically Synchronize Bundle**, then you can type an alternate label string, and the design time code will create a translatable Text Resource for you.

You can also specify an alternative value for an attribute category by selecting a different attribute in the **Attribute Display Value** column. For example, you might use a `ProductId` attribute in the data collection to lay out the pivot table, but you want the `ProductName` attribute values to appear in the pivot table header at runtime to make the information more readable.

For example, to specify an alternate label for the `Year` attribute of the `Sales` pivot table shown in [Figure 33–20](#), you would enter text (Time) in the **Attribute Display Name** field, as shown in [Figure 33–25](#).

Figure 33–25 Specify Attribute Labels Page of Create Pivot Table Wizard

- If you want to expose drill operations in the pivot table at runtime, use the Configure Drilling page of the Create Pivot Table wizard to enable one of the following options:
 - Select **Insert Drilling** to provide a collapsed or expanded view of the detail data while preserving the sibling and aggregate data. At runtime, a drill icon is displayed in the parent attribute display label.

Use **Insert Parent Row** to specify whether the aggregate total for the parent attribute will be displayed before or after the child attributes in the expanded view.

To enable insert drilling you must also:

- Select the drill paths to enable. Drill paths are configured based upon the layout of the attributes in the Select Display Attributes page of the wizard.
- Configure aggregation in the Configure Aggregation page of the wizard.

For example, [Figure 33–26](#) shows a pivot table using insert drilling to expand the view for the Year data layer. The aggregated value of Sales (52,500 in 2007, 544,150 in 2006) and Units (410 in 2007, 507 in 2006) for each year is displayed in the row above the products.

Figure 33–26 Pivot Table with Insert Drilling Enabled

	Sales	Units		Sales	Units
TOTAL	128,172	1,135			
> 2007	52,500	410			
> 2006	54,150				
> 2005	21,522				
			TOTAL	128,172	1,135
			▼ 2007	52,500	410
			Tents	25,500	275
			Canoes	27,000	135
			▼ 2006	54,150	507
			Tents	30,750	375
			Canoes	23,400	132
			> 2005	21,522	218

- Select **Filter Drilling** to provide a collapsed or expanded view of the detail data without preserving the sibling or aggregate data. At runtime, a drill icon is enabled in the parent attribute display label.

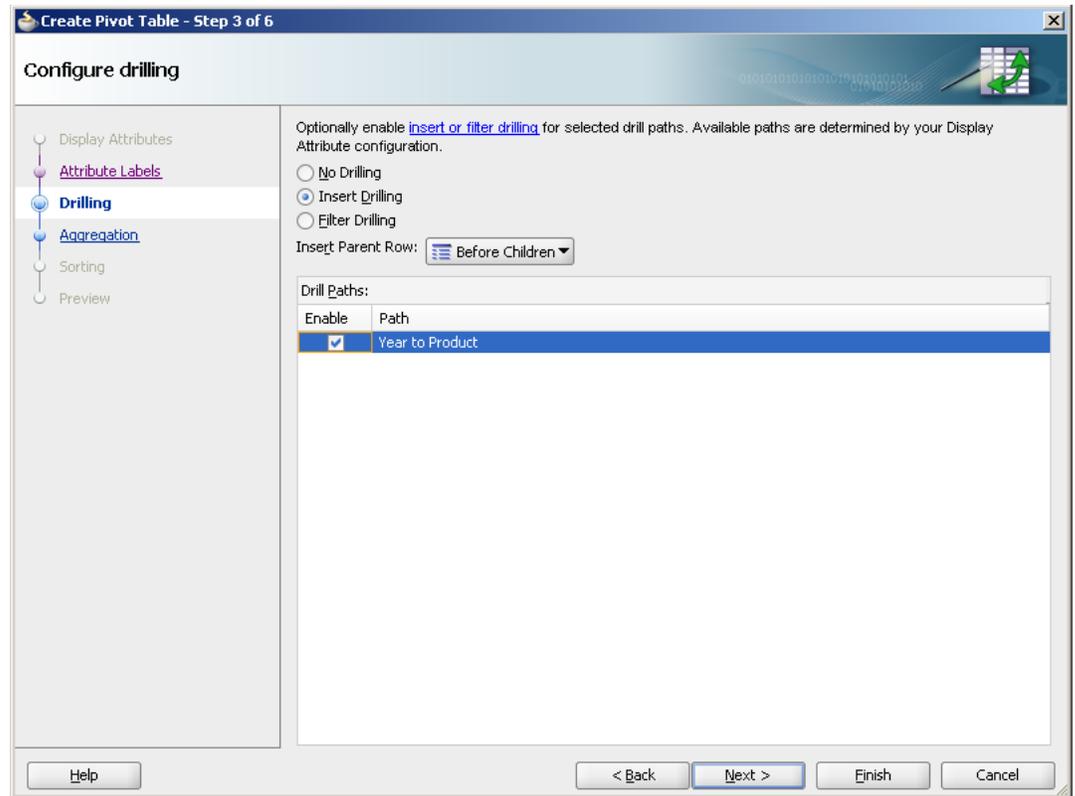

Filter drilling focuses the view on the details of the data layer attribute. For example, [Figure 33–27](#) shows a pivot table using filter drilling to expand the view of the Year (2007) data layer, displaying the total Sales (52,500) and Units (410), while filtering out both the data for the other years and the aggregated total for all the years.

Figure 33–27 Pivot Table with Filter Drilling Enabled

	Sales	Units		Sales	Units
TOTAL	128,172	1,135			
> 2007	52,500	410			
> 2006	54,150				
> 2005	21,522				
			TOTAL	52,500	410
			▼ 2007	25,500	275
			Canoes	27,000	135

To enable filter drilling you must select the drill paths to enable. Drill paths are configured based upon the layout of the attributes in the Select Display Attributes page of the wizard.

For example, to enable the insert drilling for the Sales pivot table shown in [Figure 33–20](#), complete the Configure Drilling page of the wizard, as shown in [Figure 33–28](#).

Figure 33–28 Configure Drilling Page of Create Pivot Table Wizard

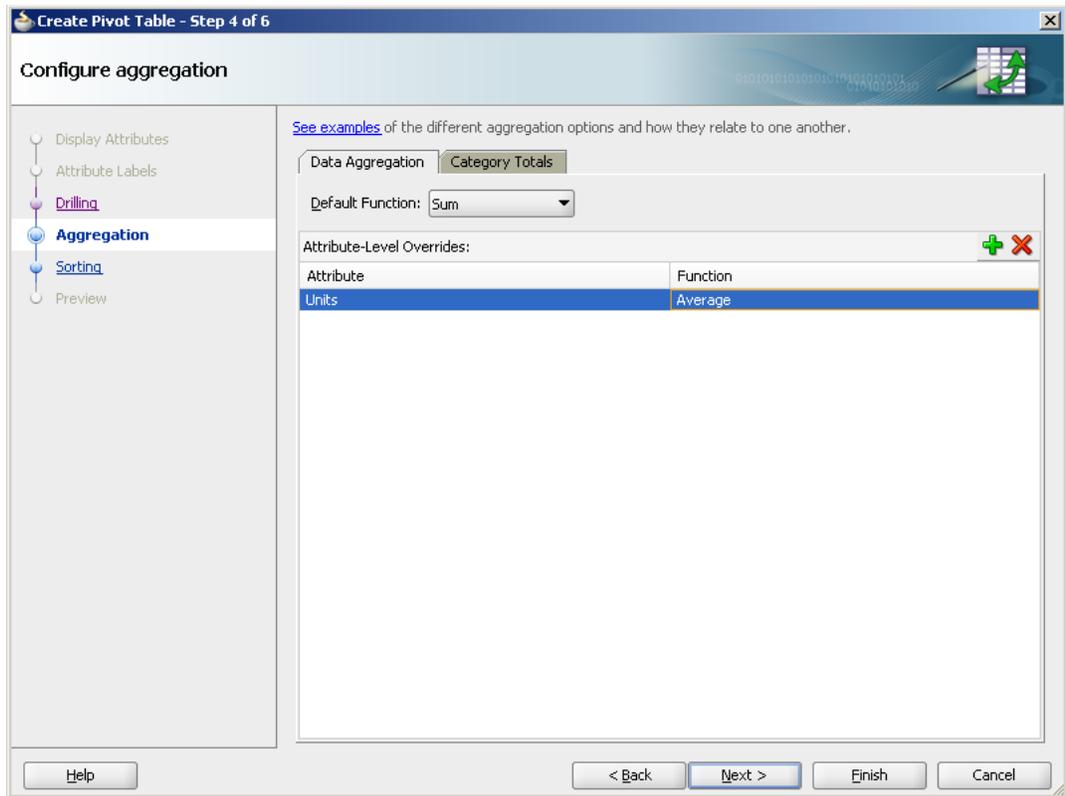

6. If you want to define how data is aggregated in totals and subtotals for the pivot table, use one or both of the Configure Aggregation pages of the Create Pivot Table wizard.

By default, if the attributes displayed in the pivot table do not uniquely identify each row in the data collection, the data from duplicate rows is aggregated to collapse that data into a single pivot table cell. You can also override the default aggregate type for a particular data item.

- If you want to specify how data is aggregated in the pivot table, in the Data Aggregation page, do the following:
 - If you want to change the default aggregation method for handling duplicate rows, use the **Default Function** dropdown list to specify the value. Valid values are Sum, Average, Count, Maximum, Minimum, Standard Deviation, Median, and Variance.
 - If you want to override the default aggregate type for a specific data value, click the **Add** icon to insert a row for the available attributes. Then, in the **Function** column for each attribute, select the mathematical operation that you want to use for the aggregation. Available options are Sum, Average, Count, Maximum, Minimum, Standard Deviation, Median, and Variance. This attribute is useful only when you have multiple data values (such as Sales and Units) bound to your pivot table.

For example, to override the default aggregation type for the Units data value in the Sales pivot table shown in [Figure 33–20](#), use the **Add** icon to add the Units attribute and select Average in the **Function** column in the Data Aggregation page, as shown in [Figure 33–29](#).

Figure 33–29 Data Aggregation Page of Create Pivot Table Wizard

- You can also define totals and subtotals for attribute categories added to the column, row, or page edges in the pivot table. In the Categories Totals page, use the **Add** icon to insert each attribute or select **Aggregate All** to add all available attributes, and do the following:
 - In the **Attribute** column, select the attribute that you want to total.
 - In the **Function** column, select the mathematical operation that you want to use for the aggregation. Available options are Sum, Average, Count, Maximum, Minimum, Standard Deviation, Median, and Variance.
 - In the **Insert Total** column, select the value that indicates where you want the aggregate display to appear relative to the item referenced in the **Attribute** column. Valid values are: Before, After, or Replace.
 - In the **Total Label** column, enter the text that you want to use as a label for the aggregation. You can enter the text directly, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime.

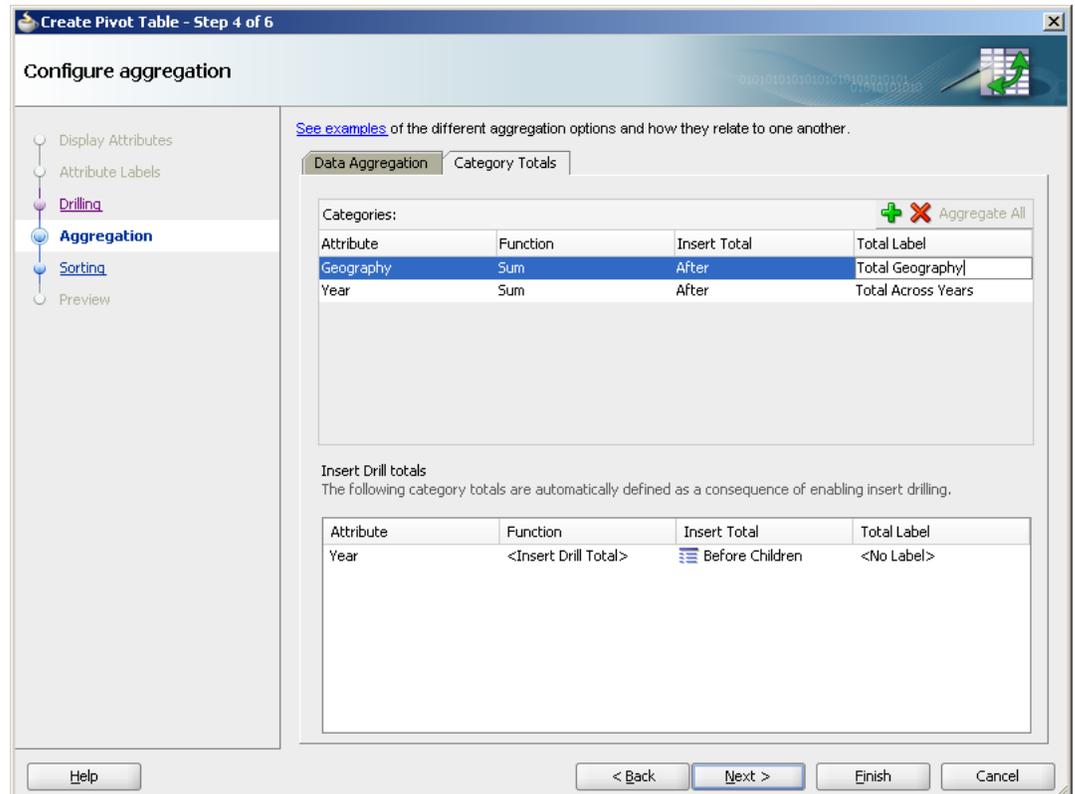

Note: If you configured **Project Properties > Resource Bundle** page to **Automatically Synchronize Bundle**, then you can type an alternate label string, and the design time code will create a translatable Text Resource for you.

Note: The read-only **Insert Drill Totals** table displays the category totals automatically defined as a consequence of enabling insert drilling on the pivot table.

For example, to define totals for the Geography and Year data layers in the Sales pivot table shown in [Figure 33–20](#), select **Sum** in the **Function** column and **After** in the **Insert Total** column, and enter text (Total Geography and Total Year) in the **Total Labels** column respectively for each attribute in the **Categories Totals** page, as shown in [Figure 33–30](#).

In the resulting pivot table at runtime, expanding a particular Year value will automatically preserve the aggregate total computed from its child value based on the layout and configuration of the insert drill option in the previous wizard page.

Figure 33–30 Categories Totals Page of the Create Pivot Table Wizard

7. If you want to configure sorting in the pivot table, use one or both of the Configure Sorting pages in the Create Pivot Table wizard.

By default, a pivot table initially sorts data based on values in the outer row data layer. You can specify sort order on the data layer of any row, column, or page edge, called a *category sort*. At runtime, when the data layer is pivoted to a different edge, the specified category sort order is honored.

You cannot specify a category sort of data labels (data values), although you can order the attributes mapped to the data body in the Select Display Attributes page of the wizard. For example, [Figure 33–24](#) shows a pivot table layout with data values for Sales and Units. While you cannot specify a category sort of these

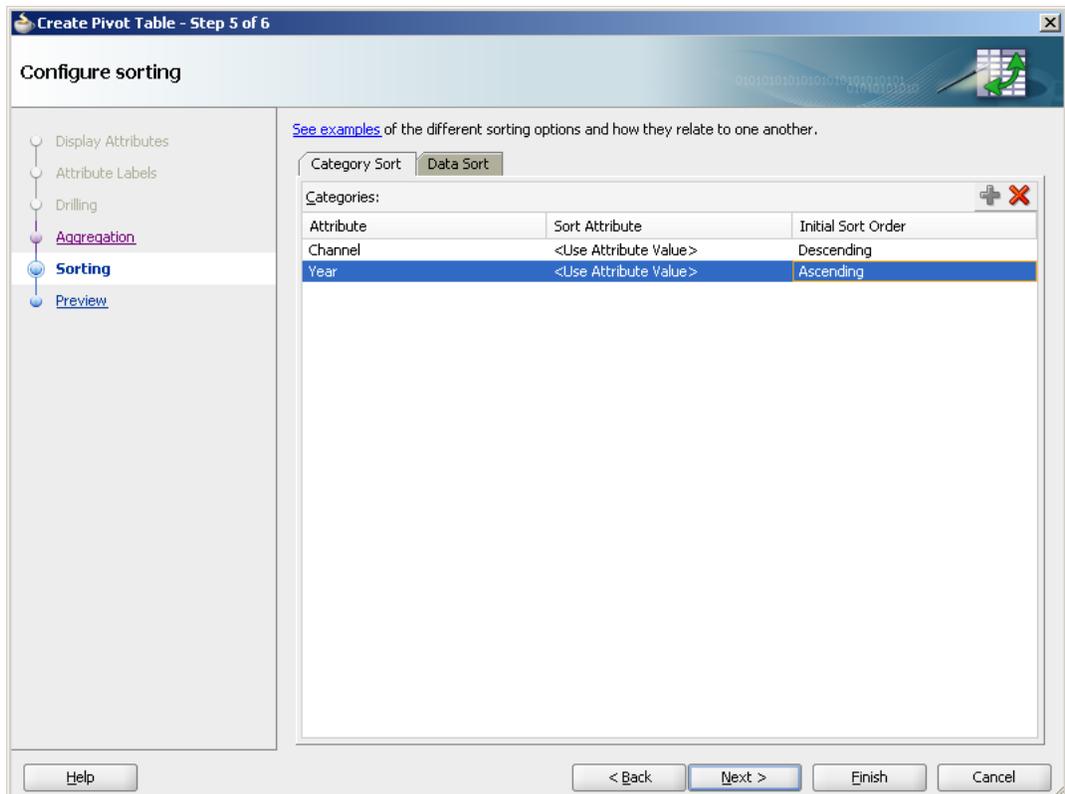

measures, you can specify the order in which the values will appear in the data body of the pivot table at runtime, shown in [Figure 33–20](#).

You can also specify an initial sort order of the data values in the data body when the pivot table is rendered, called a *data sort*.

- To configure sorting by category, in the Category Sort page, use the **Add** icon to add the attribute for each row, column, or page edge you wish to configure, and do the following:
 - In the **Sort Attribute** column, accept the default `Use Attribute Value` to specify an alphabetical sort based on the actual values in the pivot table header, or customize the sort order by specifying an alternate sort order attribute from the dropdown list. For example, if the underlying query included a rank calculation for ranking products by profitability, you could choose to see products ordered by `(ProductRank, Descending)`.
 - In the **Initial Sort Order** column, select the initial direction of the sort. Valid values are `ASCENDING` or `DESCENDING`.

For example, [Figure 33–31](#) shows the Category Sort page of the wizard configured to display the Channel data layer descending on the column edge and the Year data layer ascending on the row edge.

Figure 33–31 Category Sort Page of Create Pivot Table Wizard

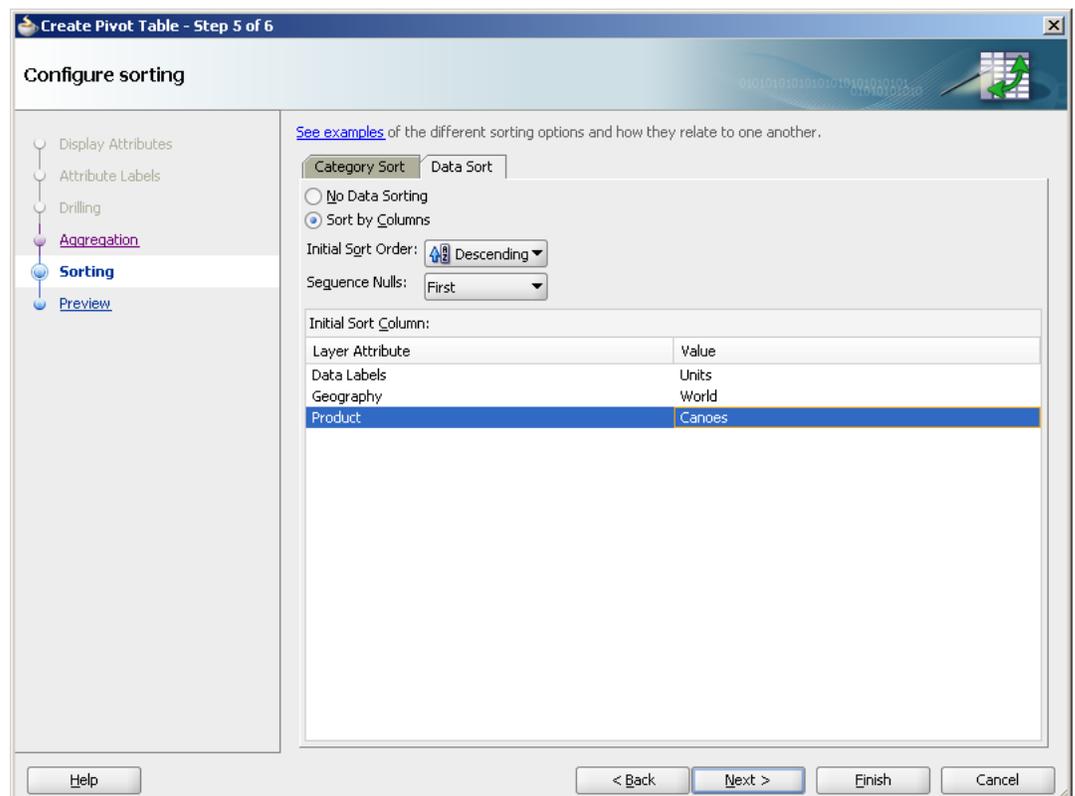

At runtime, the pivot table displays as shown in [Figure 33–32](#).

Figure 33–32 Category Sort Example

	Sales		Units	
	Indirect	Direct	Indirect	Direct
2005	12272	9250	131	87
2006	35650	18500	338	169
2007	36600	15900	333	77

- To configure data sorting, in the Data Sort page, do the following:
 - Select **Sort by Columns** to specify an initial sort order of the data when the pivot table is rendered.
 - In the **Initial Sort Order** dropdown list select the initial direction of the sort. Valid values are ASCENDING and DESCENDING.
 - In the **Sequence Nulls** dropdown list, select **First** if you want the null values to appear at the beginning of a sort and select **Last** if you want the null values to appear at the end of the sort.
 - In the **Initial Sort Column** table, specify a data value in the **Value** column for each data layer displayed in the **Layer Attribute** column.

For example, [Figure 33–33](#) shows the Data Sort page configured to sort the Channel data layer grouped by Year, based upon Units/World/Canoes data values.

Figure 33–33 Data Sort Page of the Create Pivot Table Wizard

At runtime, the pivot table initially renders as shown in [Figure 33–34](#).

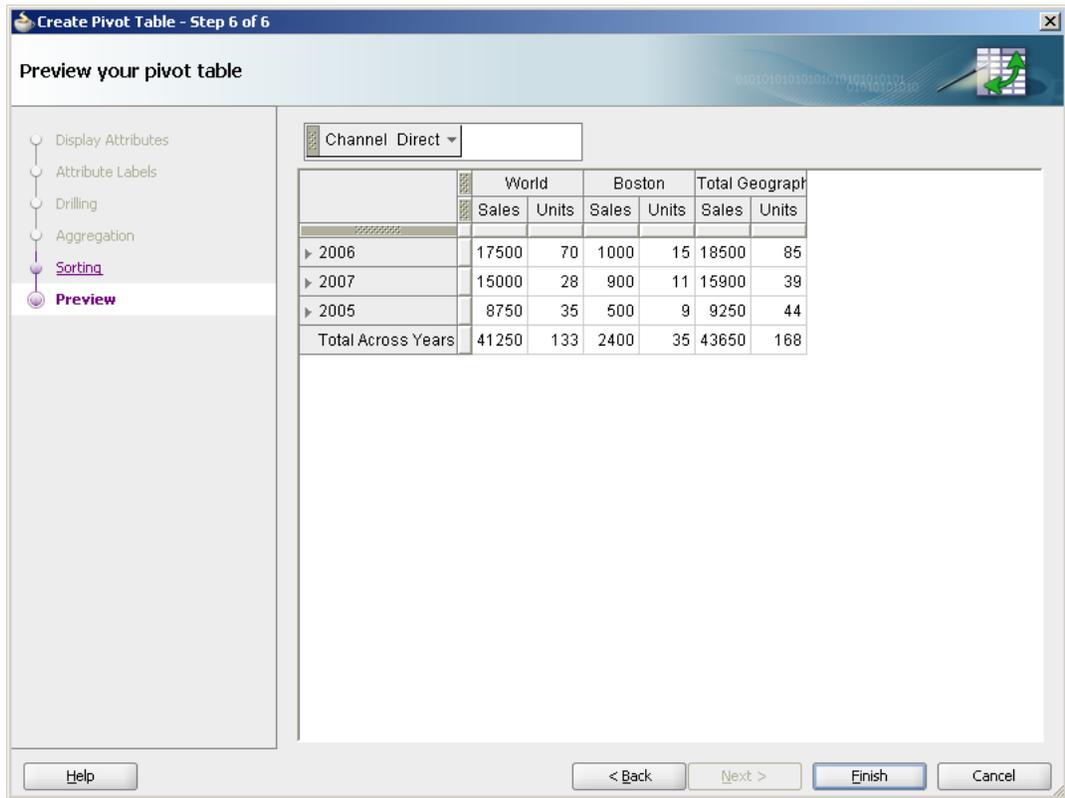

Figure 33–34 Data Sort Example

		Units			
		World		Boston	
		Tents	Canoes	Tents	Canoes
2007	Indirect	200	75	50	8
	Direct	5	50	20	2
2006	Indirect	200	80	50	8
	Direct	100	40	25	4
2005	Direct	50	20	15	2
	Indirect	100	10	20	1

- In the Preview Your Pivot Table page of the Create Pivot Table wizard, see a live preview of the data that will be displayed in the pivot table. The preview does not require that you compile and run code. If you are not satisfied with the preview, alter the settings in the binding wizard pages and return again to the preview page to verify that your data looks as desired.

Figure 33–35 shows the Preview Your Pivot Table page of the wizard for the Sales pivot table shown in Figure 33–20.

Figure 33–35 Live Data Preview of Pivot Table

33.4.2 What Happens When You Use the Data Controls Panel to Create a Pivot Table

Dropping a pivot table from the Data Controls panel has the following effect:

- Creates the bindings for the pivot table and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

33.4.2.1 Bindings for Pivot Tables

When you create a pivot table from the Data Controls panel, the page definition file is updated with the bindings. [Example 33–10](#) shows the row set bindings that were generated for the pivot table that displays product sales and units sold within geography by year. The pivot table data map contains the following elements:

- `<columns>`: Defines each column item in the appropriate sequence
- `<rows>`: Defines each row item in the appropriate sequence
- `<pages>`: Defines the items to be included in the pivot filter bar
- `<aggregatedItems>`: Defines the totals and subtotals of items
- `<hierarchies>`: Defines the potential drill paths between two items
- `<sorts>`: Defines category sorts and the initial sort order of pivot table data

The default data aggregation method for duplicate rows is specified in the `<data>` element. For more information about aggregating duplicates, see [Section 33.4.3, "What You May Need to Know About Aggregating Attributes in the Pivot Table."](#)

For more information about sorting operations, see [Section 33.4.4, "What You May Need to Know About Specifying an Initial Sort for a Pivot Table."](#)

Example 33–10 Binding XML for the ADF Pivot Table

```
<pivotTable IterBinding="ptExampleDataIterator" id="ptExampleData"
  xmlns="http://xmlns.oracle.com/adfm/dvt"
  ChangeEventPolicy="ppr">
  <pivotTableDataMap>
    <columns>
      <item value="Geography"
        itemLabel="{adfBundle['view.ViewControllerBundle']}.
        LOCATION" />
      <data aggregateDuplicates="true" defaultAggregateType="SUM">
        <item value="Sales" />
        <item value="Units" aggregateType="AVERAGE" />
      </data>
    </columns>
    <rows>
      <item value="Year" />
    </rows>
    <pages>
      <item value="Channel" />
    </pages>
    <aggregatedItems>
      <item aggregateLocation="AFTER" aggregateType="SUM" value="Geography"
        aggregateLabel="{adfBundle['view.ViewControllerBundle']}.
        TOTAL_GEOGRAPHY" />
      <item aggregateLocation="AFTER" aggregateType="SUM" value="Year"
        aggregateLabel="{adfBundle['view.ViewControllerBundle']}.
        TOTAL_ACROSS_YEARS" />
    </aggregatedItems>
    <drills type="INSERT" />
    <hierarchies>
      <item value="Year" location="BEFORE">
        <child value="Product"
          label="{adfBundle['view.ViewControllerBundle']}.PRODUCT" />
      </item>
    </hierarchies>
    <sorts>
```

```

        <categorySort item="Channel" direction="DESCENDING"/>
        <categorySort item="Year" direction="ASCENDING"/>
        <qdrSliceSort direction="DESCENDING" edge="rows" grouped="true"
            nullsFirst="true">
            <item name="Geography" value="World"/>
        </qdrSliceSort>
    </sorts>
</pivotTableDataMap>
</pivotTable>

```

33.4.2.2 Code on the JSF Page for a Pivot Table and Pivot Filter Bar

When the pivot table is created using the Data Controls panel, the necessary code is added to the page. [Example 33–11](#) shows the code generated on the JSF page for the sales pivot table and associated pivot filter bar.

Example 33–11 XML Code on a JSF Page for the Pivot Table and Pivot Filter Bar

```

<dvt:pivotFilterBar id="pt1pivotFilterBar"
    value="#{bindings.ptExampleData.pivotFilterBarModel}"
    modelName="pt1Model"/>
<dvt:pivotTable id="pt1" value="#{bindings.ptExampleData.pivotTableModel}"
    modelName="pivotTableModel"
    var="cellData" varStatus="cellStatus">
    <dvt:headerCell>
        <af:switcher facetName="#{cellData.layerName}" defaultFacet="Default" id="s1">
            <f:facet name="DataLayer">
                <af:outputText value="#{cellData.label}" id="ot1"/>
            </f:facet>
            <f:facet name="Year">
                <af:outputText value="#{cellData.dataValue}" id="ot2">
                    <af:convertNumber groupingUsed="false"
                        pattern="#{bindings.ptExampleData.
                            hints.Gnp.format}"/>
                </af:outputText>
            </f:facet>
            <f:facet name="Product">
                <af:outputText value="#{cellData.dataValue}" id="ot3"/>
            </f:facet>
            <f:facet name="Default">
                <af:outputText value="#{cellData.dataValue}" id="ot4"/>
            </f:facet>
        </af:switcher>
    </dvt:headerCell>
    <dvt:dataCell>
        <af:switcher facetName="#{cellStatus.members.DataLayer.value}"
            defaultFacet="Default" id="s2">
            <f:facet name="Sales">
                <af:outputText value="#{cellData.dataValue}" id="ot5">
                    <af:convertNumber groupingUsed="false"
                        pattern="#{bindings.ptExampleData.
                            hints.Population.format}"/>
                </af:outputText>
            </f:facet>
            <f:facet name="Default">
                <af:outputText value="#{cellData.dataValue}" id="ot6"/>
            </f:facet>
        </af:switcher>
    </dvt:dataCell>

```

```
</dvt:pivotTable>
```

33.4.3 What You May Need to Know About Aggregating Attributes in the Pivot Table

If the attributes that you choose to display in your pivot table do not uniquely identify each row in your data collection, then you can aggregate the data from duplicate rows to collapse that data into a single pivot table cell.

For example, if the rows in the data collection shown in [Figure 33–20](#) also contained a store identification, then the data rows from all stores in a given combination of Product, Channel, and Geography would have to be collapsed into a single cell in the pivot table.

The pivot table has the following optional data binding attributes available for controlling the calculation of duplicate data rows:

- `aggregateDuplicates`: Boolean property of the `<data>` element that determines whether special processing is enabled at binding runtime to aggregate data values in duplicate rows. If this attribute is not specified, then `false` is assumed.
- `defaultAggregateType`: String property of the `<data>` element that specifies a default aggregation method for handling duplicates. Valid values are `SUM`, `AVERAGE`, `COUNT`, `MIN`, `MAX`, `STDDEV`, `MEDIAN`, `VARIANCE`. If `aggregateDuplicates` is `true` and `defaultAggregateType` is unspecified, then `SUM` is assumed.
- `aggregateType`: String property of an `<item>` element that enables you to override the default aggregate type for a particular data item. This attribute is useful only when you have multiple data values (such as Sales and Units) bound to your pivot table.

33.4.3.1 Default Aggregation of Duplicate Data Rows

By default, the pivot table uses the `SUM` operation to aggregate the data values of duplicate data rows in a data collection to produce a single cell value in the pivot table. This means that the `aggregateDuplicates` attribute is set to `true` and the `defaultAggregateType` is assumed to be `SUM`.

The `<data>` element shown in [Example 33–10](#) is an example of such default aggregation.

33.4.3.2 Custom Aggregation of Duplicate Rows

If you want the pivot table to use a different mathematical operation to aggregate the data values of duplicate rows, then you set the `defaultAggregateType` to the desired operation.

[Example 33–12](#) shows a data element with the `defaultAggregateType` set to `SUM`. This operation would be appropriate if you want to see the total of sales from all stores for each unique combination of Product, Channel, and State.

Example 33–12 Binding XML for Custom Aggregation of Duplicate Rows

```
<pivotTable IterBinding="SalesPivotTable1Iterator" id="SalesPivotTable11"
  xmlns="http://xmlns.oracle.com/adfm/dvt">
  <pivotTableDataMap>
    <columns>
      <data aggregateDuplicates="true" defaultAggregateType="SUM">
        <item value="Sales"/>
      </data>
    </columns>
  </pivotTableDataMap>
</pivotTable>
```

```

        </data>
        <item value="Geography" />
    </columns>
    <rows>
        <item value="Channel" />
        <item value="Product" />
    </rows>
    <aggregatedItems>
        <item aggregateLocation="After" aggregateType="AVERAGE"
            value="Product" aggregateLabel="Average" />
    </aggregatedItems>
</pivotTableDataMap>
</pivotTable>

```

If you have a pivot table with multiple data values (such as sales and the average size of a store in square feet) and you want to sum the sales data values in duplicate rows, but you want to average the square feet data values, then do the following:

- On the `<data>` element, set the `defaultAggregateType` to `SUM`.
- On the `<item>` element for the square feet attribute, set the `aggregateType` to `AVERAGE`.

[Example 33–13](#) shows the `<columns>` elements wrapped by a `PivotTableDataMap` element. The `<data>` element contains the default attributes for aggregation. These apply to all data items that do not have a specific custom `aggregateType` attribute specified.

Example 33–13 Data and Item Elements for Multiple Custom Aggregations

```

<columns>
  <data aggregateDuplicates="true" defaultAggregateType="SUM">
    <item value="Sales" label="Total Sales" />
    <item value="StoreSqFeet" label="Avg Sq Feet" aggregateType="AVERAGE" />
  </data>
  <item value="State" />
</columns>

```

33.4.4 What You May Need to Know About Specifying an Initial Sort for a Pivot Table

By default, a pivot table initially sorts data based on values in the outer row data layer. You can specify sort order on the data layer of any row, column, or page item, called a *category sort*. At runtime, when the data layer is pivoted to a different edge, the specified category sort order is honored. Insert a `categorySort` element inside the `sorts` element and set values for the attributes as described in [Table 33–2](#).

Table 33–2 Attribute Values for categorySort Element

Attribute	Description
item	Specify the column, row, or page item for which you are setting the category sort. A value for this attribute is required.
direction	Specify the initial direction of the sort. Valid values are <code>ASCENDING</code> and <code>DESCENDING</code> . A value for this attribute is required.

You can also specify the initial sort order of the data values in the data body when the pivot table is rendered, called a *data sort*. You can change the default behavior by inserting a `sorts` element inside the `pivotTableDataMap` element of a pivot table

binding in the page definition file. Insert a `qdrSliceSort` element inside the `sorts` element and set values for the attributes as described in [Table 33–3](#).

Table 33–3 Attribute Values for `qdrSliceSort` Element

Attribute	Description
<code>direction</code>	Specify the initial direction of the sort. Valid values are <code>ASCENDING</code> and <code>DESCENDING</code> . A value for this attribute is required.
<code>edge</code>	Specify columns or rows to determine which edge sorts data. A value for this attribute is required.
<code>grouped</code>	Specify <code>true</code> if you want to sort slices within their parent or <code>false</code> if you want to sort across the entire edge. A value for this attribute is optional. The default value is <code>false</code> .
<code>nullsFirst</code>	Specify <code>true</code> if you want null values to appear at the beginning of a sort and <code>false</code> if you want null values to appear at the end of a sort. The default value is <code>false</code> . A value for this attribute is optional.

Insert one or more `item` tags inside the `qdrSliceSort` tag. An `item` tag specifies the slice on the opposite edge from which the values to be sorted should be obtained. For example, if sorting rows based upon the data, then you must specify an `item` tag for each layer on the column edge. Set values for the attributes as described in [Table 33–4](#).

Table 33–4 Attribute Values for `item` Tag

Attribute	Description
<code>name</code>	Specify the name of the layer to sort on. Typically, this is the column name in the row set. Specify <code>DataLayer</code> to identify the layer that contains the data columns in a row set (for example, <code>Sales</code> , <code>Costs</code> , and so on).
<code>value</code>	Specify the value of the specified layer on the desired slice.

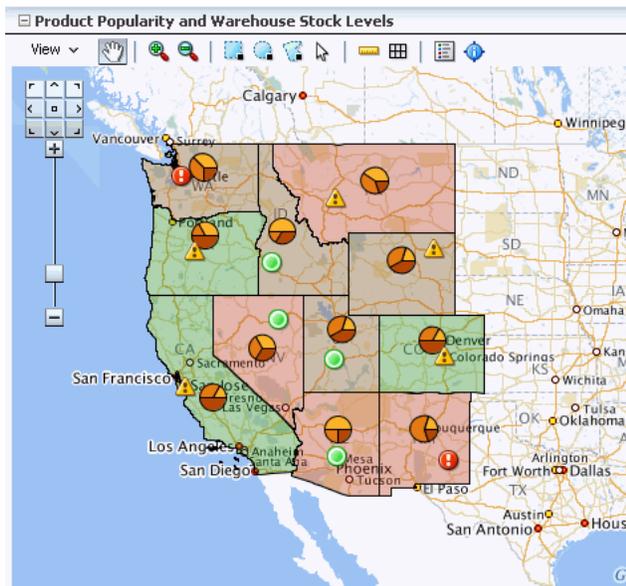

33.5 Creating Databound Geographic Maps

An ADF geographic map is an ADF Data Visualization component that provides the functionality of Oracle Spatial within Oracle ADF. This component allows users to represent business data on a geographic map and to superimpose multiple layers of information (known as *themes*) on a single map. These layers can be represented as any of the following themes: bar graph, pie graph, color, point, and predefined theme.

[Figure 33–36](#) shows a geographic map component that uses a base map for a region in the United States with the following themes:

- **Color theme:** For the selected product, this theme colors states based on product popularity. The colors range from green (which represents the highest popularity for that product) to red (which represents the lowest popularity for that product).
- **Pie graph theme:** This theme displays a pie graph in each state to indicate the popular product categories in that state. In this example, the pie graph shows the following product categories as pie slices: Media, Office, and Electronics.
- **Point theme:** This theme identifies warehouses as points. For each point, it displays an icon to indicate the inventory level at that warehouse for the selected product. A separate icon is displayed for each of the following ranges of inventory: low inventory, medium inventory, and high inventory.

Figure 33–36 Geographic Map with Color Theme, Pie Graph Theme, and Point Theme for a Product

A geographic map component differs from other ADF Data Visualization components as you do not need to put multiple maps on a page to display multiple sets of data. This contrasts to components such as graphs where you can put multiple graphs on a page. Instead, you show how multiple sets of data relate to each other spatially or, for a specific point, you display different attributes layered in separate themes.

The geographic map component itself is not bound to data. However, each map *theme* has its own data bindings.

A base map forms the background on which the ADF geographic map component layers the themes that developers create.

In Oracle Spatial, administrators create base maps that consist of one or more themes. The administrator controls the visibility of the base map themes. When you zoom in and out on a base map, various base map themes are hidden or displayed. At the ADF geographic map component level, you cannot use zoom factor to control the display of the themes created by the administrator on the base map.

When you overlay themes on the ADF geographic map, you can control the visibility of your themes by setting the `maxZoom` and `minZoom` properties of the components related to these themes. At runtime, you can also hide or display your custom themes by using the View menu of the Map toolbar or by using other ADF components that you create on the page.

For information about customizing a geographic map after data-binding is completed, see the "Using ADF Geographic Map Components" chapter in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

33.5.1 How to Create a Geographic Map with a Point Theme

To create a geographic map, you first configure the map (that is, select a base map and provide URLs for processing) and then bind a theme of the map to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel for the theme that you want to create.

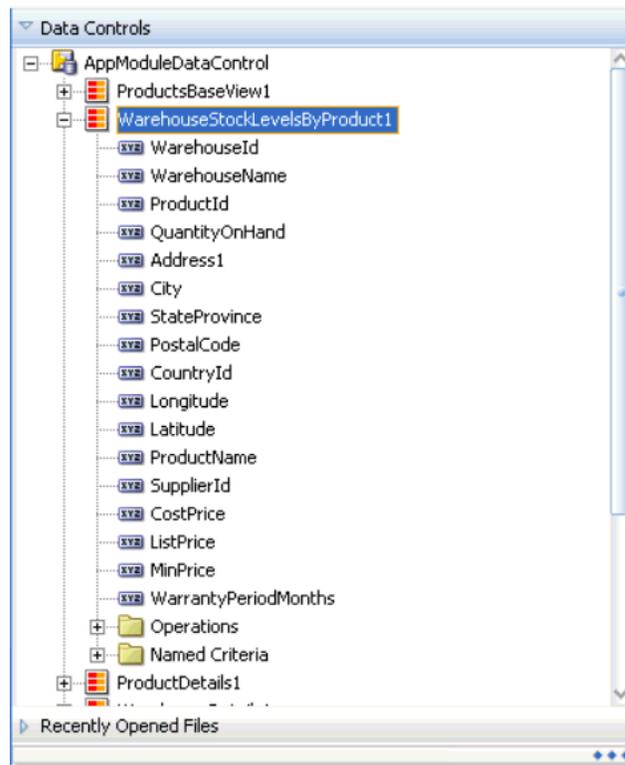

When you create a map point theme, you have the option of customizing the style of the points that appear in the map. For each different point style, you can use a `mapPointStyleItem` tag.

To create a geographic map with a databound point theme:

1. From the Data Controls panel, select a collection.

Figure 33–37 shows an example where you could select the `WarehouseStockLevelsByProduct1` collection in the Data Controls panel to create a geographic map with a point theme that displays an image to represent the quantity on hand for each warehouse point.

Figure 33–37 Data Collection for Warehouse Stock Levels

2. Drag the collection onto a JSF page and, from the context menu, choose **Geographic Map > Map and Point Theme**.
3. If you have not yet configured a map on the page, then in the ensuing Create Geographic Map dialog, click the **New** icon to display the Create Geographic Map Configuration dialog and do the following:
 - a. In the **Id** field enter the unique identifier for the map configuration.
 - b. In the **MapViewer URL** field enter the URL for the Oracle MapViewer service.
 - c. In the **Geocoder URL** field select the URL for the Geocoder Web service that converts street addresses into latitude and longitude coordinates for mapping.

Note: The Geocoder URL is needed only if you do *not* already have longitude and latitude information for addresses.

- d. Click **OK** to dismiss the dialog and return to the Create Geographic Map dialog.
4. In the Maps page, you select the base map for the geographic map component and provide other settings to use with the map by doing the following:
 - a. From the **Data Source** list select the collection of maps from which you will choose a base map.
 - b. From the **Base Map** list select the map that will serve as the background for the geographic map component.
 - c. To specify values for the **StartingX** field and the **StartingY** field click on the image of the map to center it within the Preview window.

You can use the arrows in the map navigator in the upper left-hand corner to move the map in the appropriate direction.
 - d. Optionally use the sliding arrow in the Preview window to adjust the zoom factor of the map.
 - e. Click **OK** to dismiss the dialog and to display the Create Point Map Theme dialog.
5. In the **Theme Id** field enter the unique identifier for the point map theme.
6. In the **Location** section, specify whether the point location is to be specified by **Address** or by a pair of x and y coordinates (Longitude and Latitude).

The choice you select for location will determine which controls appear in the Location section.

Tip: Using x and y coordinates is a more efficient way to present data on the map rather than using the Address controls, which must be converted by a Geocoder to x and y coordinates. If the data collection has more than 100 rows, use x and y coordinates for better performance.

7. For the x and y point location, select attributes from the data collection that represents the following items:
 - **X (Longitude):** The horizontal location of the point on the map.
 - **Y (Latitude):** The vertical location of the point on the map.
 - **Label:** The labels for the points in the top section of the information window, which is displayed when you click a point.
8. In the Point Data section, provide the following information that identifies the data associated with the point, its label, and optionally the style for the point:
 - In the **Data** field, select the data column that is associated with the point, such as `QuantityOnHand`.
 - In the **Label** field, enter the text that will appear in the information window before the data value when you click a point. You can enter a text resource to use for the label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press **F1** or click **Help**.
 - Optionally, in the **Category** field, select a data column to use for finding the appropriate style for a point. If you select a value for Category, that value is stored in the binding for this point theme and then matched against the

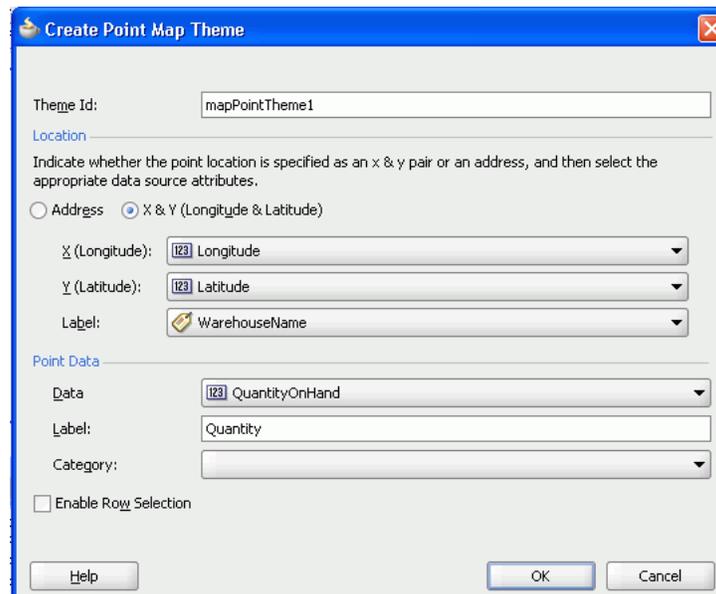

itemValue attribute of the mapPointStyleItem tags that you create for this point theme.

Note: If your data does not have a column that you want to use as a category for finding the style of a point, you can also use mapPointStyleItem tags to define styles related to data ranges (such as high, medium, and low) that are matched to the values in the column that you select in the Data field. For more information, see [Section 33.5.2, "How to Create Point Style Items for a Point Theme"](#).

9. Select the **Enable Row Selection** Select if you want to enable master-detail relationships. This is useful when the data collection for the geographic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. Selecting this options enables both selectionListener and clickListener attributes.
10. Click OK.

Figure 33–38 shows the Create Point Map Theme dialog for a geographic map with a point theme that displays an image representing quantity on hand for each warehouse point.

Figure 33–38 Create Point Map Theme Dialog for Warehouse Inventory Levels

33.5.2 How to Create Point Style Items for a Point Theme

There are a variety of options available for creating point style items for use in a given map point theme. These are:

- A single image for all data points
- Separate images for each data point category
- Images that represent low, medium, and high data value ranges

After you create the data binding for a map point theme, you have the option of selecting a single built-in image that should be used for all points in that map theme.

In the Property Inspector, you can make this selection in the `builtInImage` attribute of the `mapPointTheme` tag. The default value for this attribute is an orange ball.

Alternatively, if you specify a value for `Category` in the Create Point Map Theme dialog, then you should also create a set of point style items to determine a separate image that represents data points in each category. In this case, you do not use the minimum and maximum values in the point style item tags. Instead, you set the `itemValue` attribute of point style item tags to a value that matches entries in the data column that you specified for `Category`.

In a point theme for a geographic map, if you do not specify a value for `Category`, you can still use the `mapPointStyleItem` child tags of the `mapPointTheme` tag to specify ranges of values (such as low, medium, and high) and the images that are to represent these ranges. If you do this, then each point will be represented by an image that identifies the range in which the data value for that point falls.

The following procedure assumes that you have already created a geographic map with a point theme.

To add point style items to a map point theme to represent low, medium, and high data value ranges:

1. In the Structure window, right-click the `dvt:mapPointTheme` tag and choose **Insert inside the dvt:mapPointTheme > Point Style Item**.
2. In the Point Style Item Property Inspector, set values as described [Table 33–5, "Properties for Point Style Item"](#).

Table 33–5 Properties for Point Style Item

For this property	Set this value
<code>Id</code>	Specify a unique ID for the point style item.
<code>MinValue</code>	Specify the minimum value in a data range that you define.
<code>MaxValue</code>	Specify the maximum value in a data range that you define.
<code>ShortLabel</code>	Specify text to appear when a user hovers over the point item. For example, if you define a point item for low inventory, then enter <code>Low Inventory</code> as the value for this property.
<code>ImageUrl</code>	Specify the URL to the image file or select it from the dropdown list. At runtime, the image you specify appears on the map to represent the data range identified by the MinValue and MaxValue properties. Alternatively, you can select one of a number of predefined images referenced by the BuiltInImage dropdown list that appears in the Other section.
<code>HoverImageUrl</code>	Specify the URL to the image file or select it from the dropdown list. At runtime, the image you specify appears when a user hovers over the point item.
<code>SelectedImageUrl</code>	Specify the URL to the image file or select it from the dropdown list. At runtime, the image you specify appears when a user selects the point item.

3. If you defined a data value range for a low data value range in Steps 1 and 2, then repeat Steps 1 and 2 to define medium and high data value ranges with appropriate values.

Note: The use of `mapPointStyleItem` child tags to customize the style of points is a declarative approach that lets you provide custom point images. For information about using a callback to provide not only custom images but also custom HTML, see [Section 33.5.4, "What You May Need to Know About Adding Custom Point Style Items to a Map Point Theme"](#).

33.5.3 What Happens When You Create a Geographic Map with a Point Theme

Dropping a geographic map and a point theme (which in this case would be the initial theme added to the map) from the Data Controls panel has the following effect:

- Creates the bindings for the point theme and adds the bindings to the page definition file
- Adds the necessary tags to the JSF page for the geographic map component
- Adds the necessary point theme child tags within the geographic map tag to the JSF page

33.5.3.1 Binding XML for a Point Theme

[Example 33–14](#) shows the row set bindings that were generated for the point theme of the geographic map.

Example 33–14 Point Theme Binding XML

```
<mapTheme IterBinding="WarehouseStockLevelsByProduct1Iterator"
          id="WarehouseStockLevelsByProduct1"
          xmlns="http://xmlns.oracle.com/adfm/dvt">
  <mapThemeDataMap convert="false" mapThemeType="point">
    <data>
      <item value="QuantityOnHand"
            label="${adfBundle['view.ViewControllerBundle'].PRODUCT_QUANTITY}"/>
    </data>
    <item type="lat_long" latitude="Latitude"
          longitude="Longitude"
          label="${adfBundle['view.ViewControllerBundle'].WAREHOUSE_NAME}"/>
  </mapThemeDataMap>
</mapTheme>
```

33.5.3.2 XML Code on the JSF Page for a Geographic Map and Point Theme

[Example 33–15](#) shows the XML code generated on the JSF page for the geographic map and its point theme. Notice the code for the three kinds of point style settings based on data value.

The initial point style setting (`ps0`) applies to values that do not exceed 500. This point style displays an image for very low inventory and provides corresponding tooltip information.

The second point style setting (`ps1`) applies to values between 500 and 1000. This point style displays an image for low inventory and provides corresponding tooltip information.

The final point style setting (`ps2`) applies to values between 1000 and 1600. This point style displays an image for high inventory and provides corresponding tooltip information.

Example 33–15 Geographic Map and Point Theme XML Code on the JSF Page

```

<dvt:map id="map1"
  mapServerConfigId="mapConfig1"
  inlineStyle="width:850px;height:490px"
  startingX="-96.0"
  baseMapName="ELOCATION_MERCATOR.WORLD_MAP"
  startingY="37.0" zoomBarPosition="WEST"
  showScaleBar="false"
  <dvt:mapPointTheme id="mapPointTheme1"
    shortLabel="#{viewControllerBundle.WAREHOUSE_STOCK_LEVELS}"
    value="#{bindings.WarehouseStockLevelsByProduct1.geoMapModel}"
    rendered="#{AppState.showPointTheme}">
    <dvt:mapPointStyleItem id="ps0"
      minValue="0"
      maxValue="500"
      imageURL="/images/low.png"
      selectedImageURL="/images/lowSelected.png"
      shortLabel="#{viewControllerBundle.VERY_LOW_
        INVENTORY}"/>
    <dvt:mapPointStyleItem id="ps1"
      minValue="500"
      maxValue="1000"
      imageURL="/images/medium.png"
      selectedImageURL="/images/mediumSelected.png"
      shortLabel="#{viewControllerBundle.LOW_INVENTORY}"/>
    <dvt:mapPointStyleItem id="ps2"
      minValue="1000"
      maxValue="1600"
      imageURL="/images/regularGreen.png"
      selectedImageURL="/images/regularGreenSelected.png"
      shortLabel="#{viewControllerBundle.HIGH_INVENTORY}"/>
  </dvt:mapPointTheme>
</dvt:map>

```

33.5.4 What You May Need to Know About Adding Custom Point Style Items to a Map Point Theme

If you want to provide custom HTML as well as custom images for map points, then you can use the `customPointCallback` attribute of the `dvt:mapPointTheme` tag to accomplish this customization.

Important: If you set the `customPointCallback` attribute for a map point theme, the map ignores any `dvt:mapPointStyleItem` child tags because the callback overrides these tags.

To use a callback to customize the style of map points:

1. Write a method in Java to perform the desired point customization.
2. Store this method in a managed bean for the map.

For more information about managed beans, see the "Creating and Using Managed Beans" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

3. After you finish data-binding the map point theme, use the Property Inspector to specify a reference to the managed bean method in the `customPointCallback` attribute of the `dvt:mapPointTheme` tag.

For example, if the managed bean is named `MapSampleBean` and the method is named `setCustomPointStyle`, then the reference becomes `{mapSampleBean.CustomPointStyle}`.

33.5.5 How to Add a Databound Color Theme to a Geographic Map

When you create a geographic map, you can choose to create themes (point, color, and graph) in any sequence that you wish.

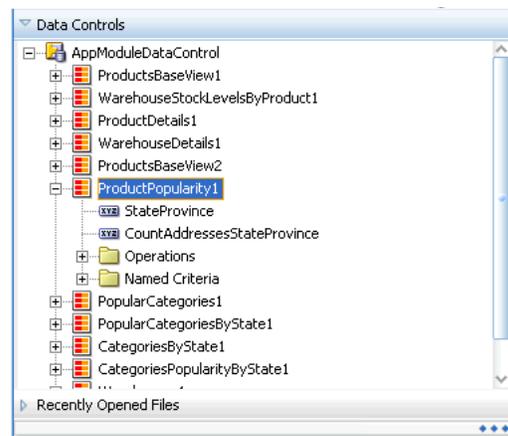

The following procedure assumes that a geographic map has already been configured and, therefore, the map component does not display the dialog for configuring the map. Instead, only the dialog for creating the color theme appears.

To add a databound color theme to a geographic map:

1. From the Data Controls panel, select a collection.

Figure 33–39 shows an example where you could select the `ProductPopularity1` collection in the Data Controls panel to create a color map theme that shows product popularity by the color of regions (for example, states).

Figure 33–39 Data Collection for Product Popularity by State

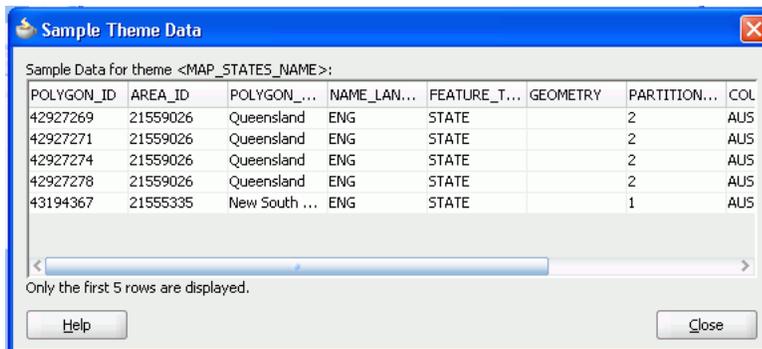

2. Drag the collection onto a JSF page which already contains a geographic map component and, from the context menu, choose **Geographic Map > Color Theme**.
3. In the ensuing Create Color Map Theme dialog, enter a unique identifier for the map theme in the **Id** field.
4. In the **Base Map Theme** section, identify the base map color theme to use for the geographic map by doing the following:
 - a. In the **Name** field, select the name of the base map theme.
 - b. For **Location**, select the location column in the data collection that should be matched to the location column in the base map theme that you selected.
 - c. Optionally, click **View Sample Theme Data** to display the Sample Theme Data dialog, in which you can examine the first several rows of the actual data so that you can identify the appropriate location column.

For example, if you want to view the data for a region that consists of states in the United States map, you might select `MAP_STATES_NAME` as shown in Figure 33–40.

Note: It is possible for an administrator of Oracle Spatial to disable the display of sample data. If this button is not available, then consult the administrator for guidance.

Figure 33–40 Sample Theme Data for Regions or States

5. In the **Appearance** section, specify the look of the color theme as follows:
 - a. In **Data Bucket Count**, enter the number of groups for the data in this geographic map. Each group is coded with a color. After specifying this number, you can provide colors for the minimum value and the maximum value. The colors for the other values are chosen automatically using an RGB algorithm.
 - b. In **Minimum Value Color**, select the color for the minimum value.
 - c. In **Maximum Value Color**, select the color for the maximum value.

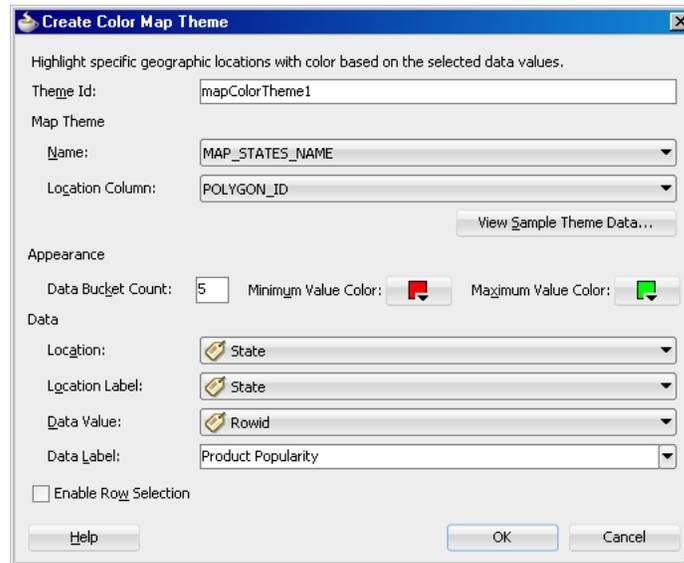

Note: If you want to specify an exact color for each data bucket, see [Section 33.5.7, "What You May Need to Know About Customizing Colors in a Map Color Theme"](#).

6. In the **Data** section, provide the following information about the data in the collection:
 - a. For **Location**, select the column in the data collection that should match the values in the location column that you selected from the base map theme.
 - b. For **Location Label**, select the column in the data collection that contains the labels associated with the values in the location column. These labels are shown in the information window that is displayed when you click or hover over a color.
 - c. For **Data Label**, enter the label to use for describing the data in the information window and the tooltip that is displayed when you click or hover over a color. For example, the information window might include a label before the data value, such as **Product Popularity**. You can also enter a text resource to use for the data label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime for a dynamic label. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press **F1** or click **Help**.
7. Use **Enable Row Selection** only if you want to enable master-detail relationships. This is useful when the data collection for the map theme is a master in a

master-detail relationship with a detail view that is displayed in another UI component on the page.

Figure 33–41 shows the Create Color Map Theme dialog for the product popularity by state color theme.

Figure 33–41 Create Color Map Theme for Product Popularity By State

33.5.6 What Happens When You Add a Color Theme to a Geographic Map

Dropping a color theme from the Data Controls panel to an existing geographic map has the following effect:

- Creates the bindings for the color theme and adds the bindings to the page definition file
- Adds the necessary color theme child tags within the geographic map tag to the JSF page

33.5.6.1 Binding XML for a Color Theme

Example 33–16 shows the row set bindings that were generated for the color theme of the geographic map.

Example 33–16 Color Theme Binding XML

```
<mapTheme IterBinding="ProductPopularity1Iterator" id="ProductPopularity1"
  xmlns="http://xmlns.oracle.com/adfm/dvt">
  <mapThemeDataMap mapThemeType="color">
    <data>
      <item value="CountAddressesStateProvince"
        label="${adfBundle['view.ViewControllerBundle'].POPULARITY"/>
    </data>
    <item type="location" value="StateProvince"
      label="${adfBundle['view.ViewControllerBundle'].STATE_PROVINCE"/>
  </mapThemeDataMap>
</mapTheme>
```

33.5.6.2 XML Code on the JSF Page for a Color Theme

[Example 33–17](#) shows the XML code generated on the JSF page for a color theme that represents product popularity in different states on the United States map.

Example 33–17 Color Theme XML Code on the JSF Page

```
<dvt:mapColorTheme id="mapColorTheme1"
  themeName="MAP_STATES_NAME"
  shortLabel="#{viewControllerBundle.PRODUCT_POPULARITY}"
  value="#{bindings.ProductPopularity1.geoMapModel}"
  locationColumn="POLYGON_NAME"
  minColor="#ff0000"
  maxColor="#008200"
  bucketCount="5"/>
</dvt:mapColorTheme>
```

33.5.7 What You May Need to Know About Customizing Colors in a Map Color Theme

While you are data-binding a map color theme, you can specify only a minimum color and a maximum color for the data buckets. The map uses an algorithm to determine the colors of the buckets between the minimum and maximum. However, after the data-binding is finished, you have the option of specifying the exact color to be used for each data bucket.

In the Object Inspector, for the `dvt:mapColorTheme` tag you can use the `colorList` attribute to specify the color for each bucket. You can either bind a color array to this attribute or you can specify a string of colors using a semicolon separator.

For example, if the value of this attributes is set to: `#ff0000;#00ff00;#0000ff`, then the color of the first bucket is red, the second bucket is green, and the third bucket is blue.

33.5.8 How to Add a Databound Pie Graph Theme to a Geographic Map

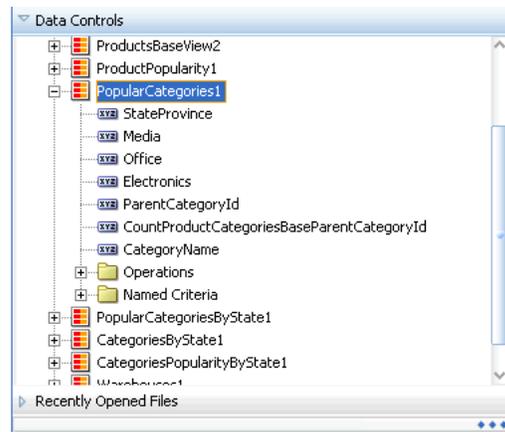

When you create a geographic map, you can choose to create themes (point, color, and graph) in any sequence that you wish. However, only one graph theme (pie or bar) can be visible at a time on the ADF geographic map component.

The following procedure assumes that a geographic map has already been configured and, therefore, the map component does not display the dialog for configuring the map. Instead, only the dialog for creating the pie graph theme appears.

To add a databound pie graph theme to a geographic map:

1. From the Data Controls panel, select a collection.

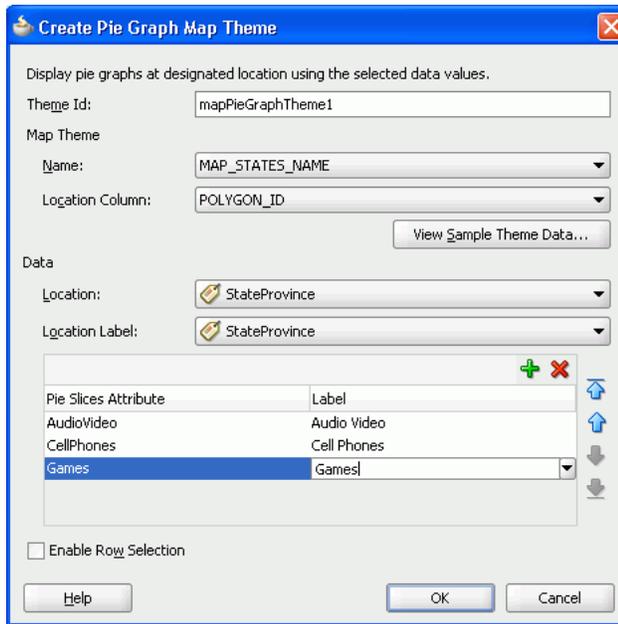

[Figure 33–42](#) shows an example where you could select the `PopularCategories1` collection to create a pie bar theme in an existing geographic map component to represent the popular product categories within a state.

Figure 33–42 Data Collection for Popular Product Categories by State

2. Drag the collection onto a JSF page and, from the context menu, choose **Create > Pie Graph Theme**.
3. In the ensuing Create Pie Graph Theme Binding dialog, do the following to identify the new theme and the base map theme elements that you want to work with:
 - a. For **Theme Id**, enter a unique identifier for the pie graph theme that you are creating.
 - b. In the **Base Map Theme** section, select the name of the base map and the region in which you want to place the pie graphs.
4. In the **Appearance** section, under **Data**, do the following:
 - a. For **Location**, select the location column in the data collection that should be matched to the location column in the base map theme that you selected.
If needed, click **View Sample Theme Data** to examine the first several rows of the actual data so that you can identify the appropriate location column.
 - b. For **Location Label**, select the column in the data collection that contains labels for the locations in the data collection.
 - c. In the grid for **Series Attributes**, enter each attribute that contains values that you want represented in the pie graph that you are creating.
 - d. Beside each series attribute, enter text that should be used as a label for the data values in the series attribute.
5. Select **Enable Row Selection** only if you want to enable the selection of rows in a related component. You select this component when the page contains a component that is linked to a data collection that is related to the geographic map that you are creating.
6. Click **OK**.

Figure 33–43 shows the completed Create Pie Graph Map Theme dialog for the product popularity by state pie graph theme.

Figure 33–43 Create Pie Graph Map Theme for Product Popularity by State

33.5.9 What Happens When You Add a Pie Graph Theme to a Geographic Map

Dropping a pie graph theme from the Data Controls panel to an existing geographic map has the following effect:

- Creates the bindings for the pie graph theme and adds the bindings to the page definition file
- Adds the necessary pie graph theme code to the JSF page within the map XML

33.5.9.1 Binding XML for a Pie Graph Theme

Example 33–18 shows the row set bindings that were generated for the pie graph theme of the geographic map.

Example 33–18 Pie Graph Theme Binding XML

```
<mapTheme IterBinding="PopularCategoriesByState1Iterator"
  id="PopularCategoriesByState1"
  xmlns="http://xmlns.oracle.com/adfm/dvt">
  <mapThemeDataMap mapThemeType="pieChart">
    <item type="location" value="StateProvince" label="StateProvince"/>
    <data>
      <item value="AudioVideo"
        label="{adfBundle['view.ViewControllerBundle'].AUDIO_VIDEO}"/>
      <item value="CellPhones"
        label="{adfBundle['view.ViewControllerBundle'].CELL_PHONES}"/>
      <item value="Games"
        label="{adfBundle['view.ViewControllerBundle'].GAMES}"/>
    </data>
  </mapThemeDataMap>
</mapTheme>
```

33.5.9.2 Code on the JSF Page for a Pie Graph Theme

[Example 33–19](#) shows the XML code generated on the JSF page for the pie graph theme of the geographic map.

Example 33–19 Pie Graph Theme Code on the JSF Page

```
<dvt:mapPieGraphTheme id="mapPieGraphTheme1"
  themeName="MAP_STATES_NAME"
  shortLabel="#{viewControllerBundle.POPULAR_CATEGORIES}"
  pieRadius="10"
  styleName="comet"
  value="#{bindings.PopularCategoriesByState1.geoMapModel}"
  locationColumn="POLYGON_ID" />
</dvt:mapPieGraphTheme>
```

33.6 Creating Databound Thematic Maps

A thematic map represents business data as patterns in stylized areas or associated markers and does not require a connection to a remote Oracle MapViewer service. Thematic maps focus on data without the geographic details in a geographic map.

The thematic map is packaged with prebuilt base maps including a USA base map, a world base map, and base maps for continents and regions of the world including EMEA and APAC. Each base map includes several sets of regions and one fixed set of cities. A set of regions or cities is referred to as a layer. Each layer can be bound to a data collection and stylized to represent the data with color and pattern fills, or a data marker, or both. At runtime, only one map layer and its associated data can be displayed at a time, unless the thematic map has been enabled for drilling.

The data displayed in a thematic map is based on data collections. Using ADF data controls, JDeveloper makes data binding a declarative task. You drag and drop a collection from the Data Controls panel onto the JSF page and use a Component Gallery to select the base map and map layers on which to display the data. You can then use a Layer Browser and binding dialogs to bind data collection attributes to the data layers in the thematic map.

Stamping is used to associate map layers with a row of data in a data collection. Using stamping, each row of data in the data model can be identified by a style, for example a color or pattern; a marker, for example a circle or square; or an image. When you use stamping, child components are not created for every area, marker, or image in a thematic map. Rather, the content of the component is repeatedly rendered, or stamped, once per data attribute, such as the rows in a data collection.

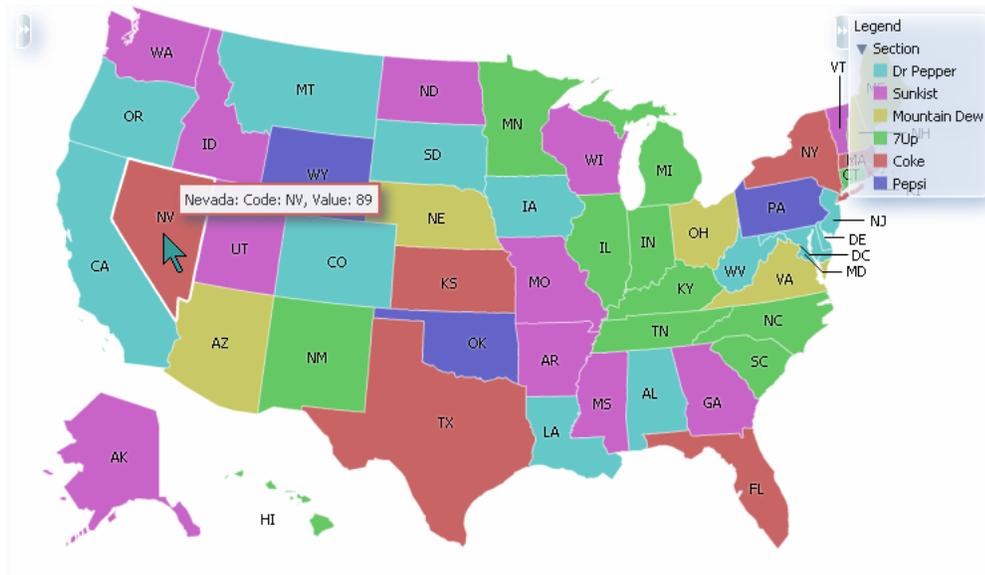

For detailed information about thematic map end user and presentation features, use cases, tag structure, and adding special features to thematic maps, see the "Using Thematic Map Components" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

33.6.1 How to Create a Thematic Map Using ADF Data Controls

You can create a thematic map that displays business data associated with a regional layer in the base map, stylizing the map areas to visually illustrate the data.

For example, you could use a USA base map with a states map layer to display the preferences in each state for a particular brand of soft drink using colors as displayed in [Figure 33–44](#). The example illustrates thematic map default features including a data bound legend and labels associated with the stylized areas when you use the Data Controls panel and thematic map binding dialogs.

Figure 33–44 Thematic Map Displaying Product Preference by US State

The thematicMap component uses a model to access the data in the underlying list. The specific model class is `oracle.adf.view.rich.model.CollectionModel`. You can also use other model instances, for example, `java.util.List`, `java.util.Array`, and `javax.faces.model.DataModel`. The data layer will automatically convert the instance into a `CollectionModel`.

Before you begin:

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

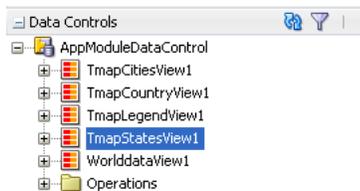

You should already have an ADF data control or ADF managed bean that represents the data you wish to display on the thematic map.

To create a thematic map using the Data Controls panel:

1. From the Data Controls panel, select a data collection.

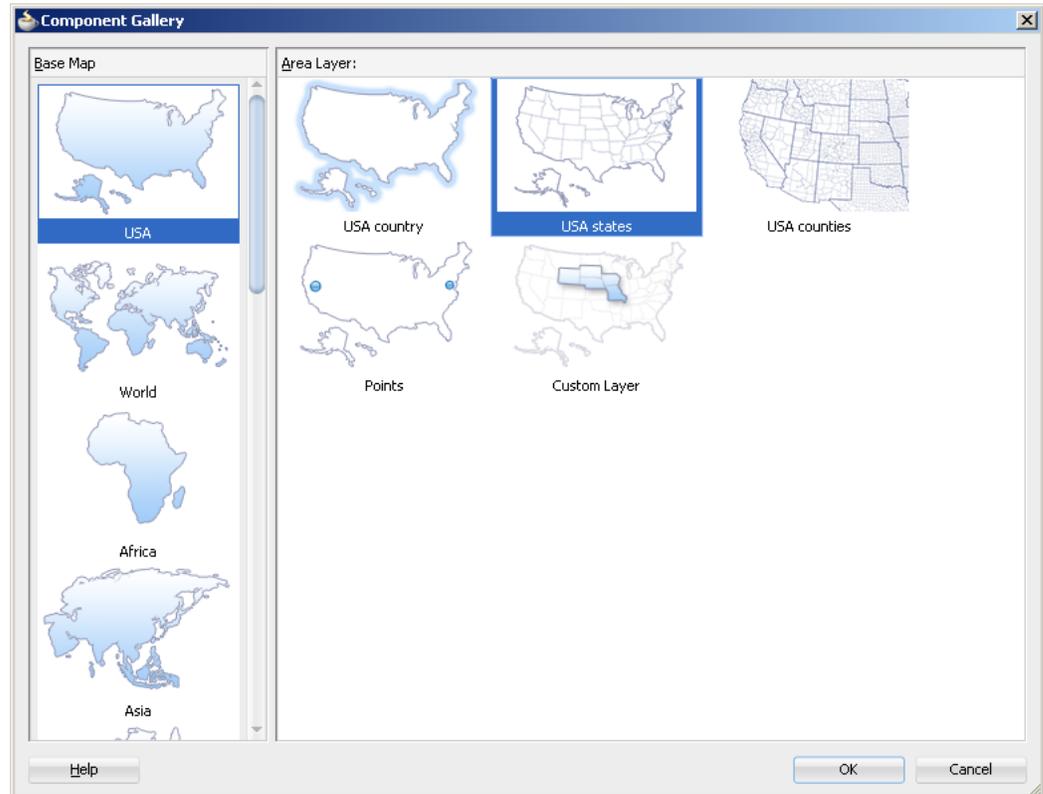

Figure 33–45 shows an example where you could select the `TmapStatesView1` collection in the Data Controls panel to create a thematic map using colors to represent the preference in each state for a particular product.

Figure 33–45 Data Collection for Product Preference by State

2. Drag the collection onto a JSF page and, from the context menu, choose **Thematic Map**.
3. In the Component Gallery, select the map layer associated with the base map you want to configure for displaying data. In the example, a states map layer in the US base map is selected. [Figure 33–46](#) shows the Component Gallery with the USA states map layer selected.

Figure 33–46 Thematic Map Component Gallery

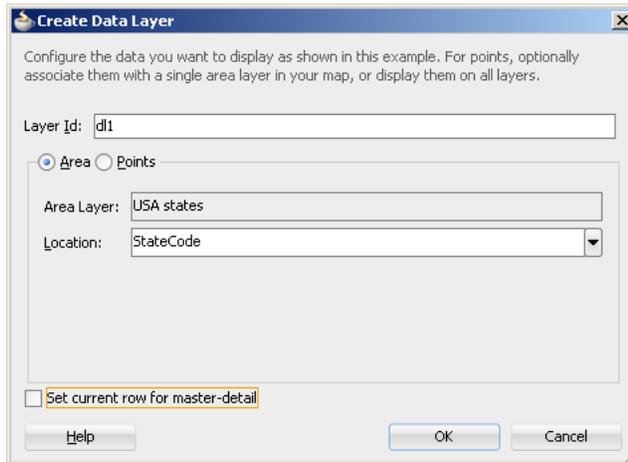

By default, the Create Data Layer dialog opens for adding an area or point data layer to the selected map layer. In the example, an area data layer is configured. For information about adding and configuring point data layers, see [Section 33.6.4, "How to Add Data Layers to Thematic Maps."](#)

4. In the Create Data Layer dialog, enter the following:
 - **Layer Id:** Enter a unique name for the data layer you are defining. By default, a unique, consecutively numbered id is entered, d11, d12, and so on.
 - **Area:** Select to add an area data layer to the map layer.
 - **AreaLayer:** References the map layer to which you are adding a data layer. In the example, a **USA States** map layer.
 - **Location:** Select the attribute that represents the column in the data model that determines the location of the data for the areas in the data layer. The locations are Ids of the regions from the base map for which the data is being displayed. For more information, see [Section 33.6.3, "What You May Need to Know About Base Map Location Ids."](#)
 - **Set current row for master-detail:** Select if you want to enable master-detail relationships. This is useful when the data collection for the thematic map is a

master in a master-detail relationship with a detail view that is displayed in another UI component on the page. For more information, see [Section 33.6.6, "What You May Need to Know About Configuring Master-Detail Relationships."](#)

Figure 33–47 shows the completed Create Data Layer dialog.

Figure 33–47 Create Area Data Layer Dialog

An area data layer representing the `areaDataLayer` component, and an area, representing the `area` component is added in the Layer Browser hierarchy. [Figure 33–48](#) shows the expanded Layer Browser after adding an area data layer and area to the map layer.

Figure 33–48 Thematic Map Layer Browser

5. In the Layer Browser, expand the area data layer, select the area to be stylized, and click the **Edit** icon to open the Configure Area dialog.

Note: You configure an area with a default stamp across all areas in the thematic map layer, or you can use a child `attributeGroups` tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the area tag, and by an `attributeGroups` tag, the `attributeGroups` style type will take precedence. For more information, see [Section 33.6.7, "Styling Areas, Markers, and Images to Display Data."](#)

6. In the Configure Area dialog, Attribute Groups page, enter the following:

- Grouping Rules:** Use this table to specify the styling of categorical groups of data in a data collection. Use the **Add** icon to add a row to the table for configuring rules for a categorical group and use the **Delete** icon to remove any row selected in the table. Each grouping rule is represented as a `attributeGroups` component, and assigned a unique, consecutively numbered `Id`, `ag1`, `ag2`, and so on.

For each row added to the table, enter the following:

- Group by Value:** Enter or use the dropdown list to select the attribute representing the column in the data set by which you wish to group the data values. For example, `Category` represents the product preference by state of the different soft drinks.

Note: The selected attribute should consist of discrete values that can be categorized. For example, a range of numeric values between 40 and 45, are not automatically grouped.

- Area Properties:** Use the dropdown list to select the property to use for styling that area. Areas can be styled using **color**, **pattern**, **opacity**, or any combination of these valid values. Choose **Select multiple attributes** from the dropdown list for a dialog to specify any combination of values.

The default style values that are generated for each property are defined using CSS style properties in the ADF skin. Each `attributeGroups` type has a default ramp defined in the skin, and these can be customized by setting the index-based properties to the desired values. For more information, see [Section 33.6.7.4, "What You May Need to Know About Default Style Values for Attribute Groups."](#)

- Legend Label:** Enter text or use the dropdown list to select the attribute representing the text to use for the categorical group in the thematic map legend. You can also select **Expression Builder** from the dropdown list to create an EL expression to specify the legend text. For more information, see [Section 33.6.8, "Creating Databound Legends."](#)
- Value-Specific Rules:** Click to open the **Match Rules** and **Exception Rules** tables used to specify a finer detail for one or more data values in categorical groups in a data set. For example, use a match rule to style every state with a preference of Dr Pepper with an aqua, `#00ffff`, color, instead of a predefined range of colors.

Note: Any match or exception rule specified in these tables will override the settings defined in the **Grouping Rules** table.

- Match Rules:** Use to specify the style rule matched to one or more data values in a group of data in a data collection. Use the **Add** icon to add a row to the table for configuring a match rule for a categorical group and use the **Delete** icon to remove any row selected in the table. Each match rule is represented as a `attributeMatchRule` component, and assigned a unique, consecutively numbered `Id`, `amr1`, `amr2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

```
<dvt:attributeMatchRule id="amr1" group="Mountain Dew">
  <f:attribute name="color" value="#ffff00"/>
</dvt:attributeMatchRule>
```

For each row added to the table, enter the following:

- **Group Value:** Enter the exact value for a **Group By Value** attribute that will trigger this Match Rule to execute. In the example, soft drink preference data collection attribute, values include Dr Pepper, 7 Up, and so on.
- **Property:** Use the dropdown list to select the property to use for styling that data value. Areas can be styled using **color**, **pattern**, or **opacity** values. The property selected here must match one of the property types listed in the **Area Properties** for the attribute **Grouping Rules**.
- **Property Value:** Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp.

Valid values for **color** are RGB hexadecimal colors.

Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **large-Crosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

Valid values for **opacity** range from **0.0** for transparent to **1.0** for opaque.

- **Exception Rules:** Use to specify one or more exception to the style rules for categorical groups in the data set. Use the **Add** icon to add a row to the table for configuring an exception rule and use the **Delete** icon to remove any row selected in the table. Each exception rule is represented as an `attributeExceptionRule` component, and assigned a unique, consecutively numbered `id`, `aer1`, `aer2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

```
<dvt:attributeExceptionRule id="aer1" condition="{row.name=='TX'}"
    label="Texas">
  <f:attribute name="color" value="#ff00ff"/>
</dvt:attributeExceptionRule>
```

For each row added to the table, enter the following:

- **Condition:** Enter an EL expression, or use the dropdown list to open an Expression Builder dialog to create an EL expression that replaces the style property value with another when certain conditions are met. For example:
- ```
{row.Sales gt 100000}
```
- **Property:** Use the dropdown list to select the property to use for styling that data value. Areas can be styled using **color**, **pattern**, or **opacity** values. The property selected here must match one of the property types listed in the **Area Properties** for the attribute **Grouping Rules**.
  - **Property Value:** Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp.

Valid values for **color** are RGB hexadecimal colors.

Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **large-Crosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

Valid values for **opacity** range from **0.0** for transparent to **1.0** for opaque.

- **Legend Label:** Enter a text resource to use for the legend label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press **F1** or click **Help**.

---

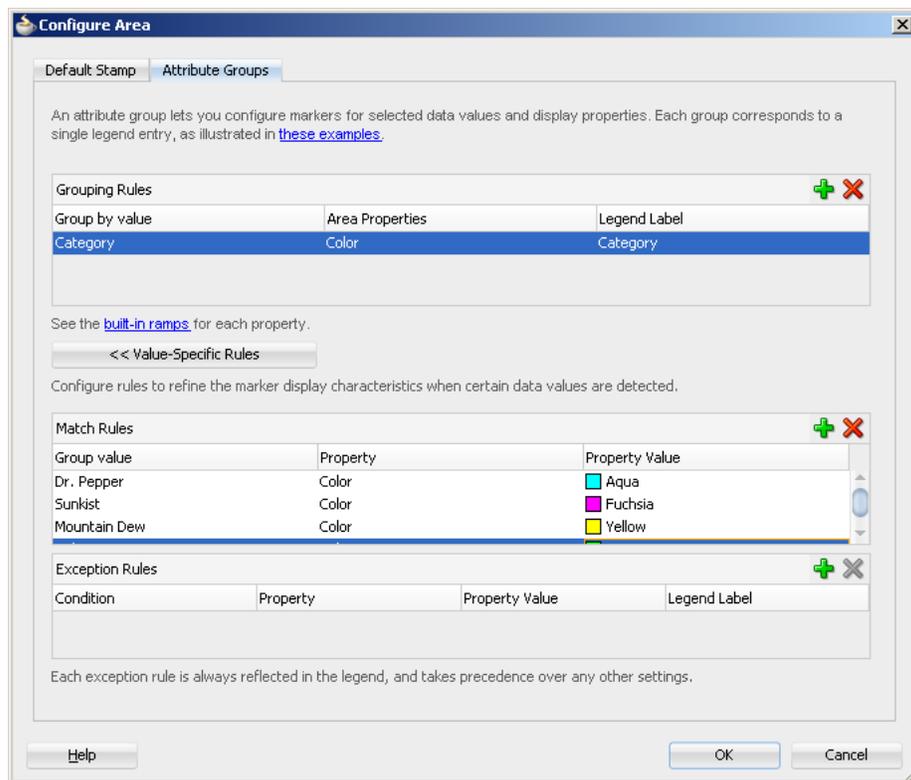

**Note:** the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

```
{viewController.ResourceBundle[row.label]}
```

- **Messages:** Review and clear as necessary any alerts related to the configuration of the area.

Figure 33–49 shows the completed Configure Area dialog. The warning in the message pane alerts the user that the default area color specified in the Default Stamp page of the dialog will be overwritten by the color specified in the Grouping Rules and any value-specific overrides specified in the Attribute Groups page.

**Figure 33–49** Configure Area Dialog Attribute Groups Page

You can add additional map layers representing available regions in the geographical hierarchy of the base map, and associate area or point data layers using the same data collection you used to create the thematic map. The Layer Browser represents the logical structure of the map layers, area and point data layers, and stylized areas and markers. Use the Layer Browser to:

- Add additional map layers in the base map geographical hierarchy to the thematic map.
- Define a custom map layer in the geographical hierarchy of the base map, using lower level regions to aggregate the regions in the custom layer. For more information, see [Section 33.6.9, "How to Define a Custom Map Layer."](#)
- Add, edit, or delete area or point (global or map layer specific) data layers. For more information, see [Section 33.6.4, "How to Add Data Layers to Thematic Maps."](#)
- Add, edit, or delete stylized areas or markers. For more information, see [Section 33.6.7, "Styling Areas, Markers, and Images to Display Data."](#)

After creating a thematic map using data controls, you can customize the default map labels, legend display, and add interactivity and animation effects. For more information, see in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

## 33.6.2 What Happens When You Use Data Controls to Create a Thematic Map

When you use ADF data controls to create a thematic map, JDeveloper:

- Defines the bindings for the thematic map in the page definition file of the JSF page, and
- Inserts code in the JSF page for the DVT thematic map components.

[Example 33–20](#) shows the bindings defined in the page definition file of the JSF page for the example thematic map in [Figure 33–44](#).

### **Example 33–20 XML Bindings in Page Definition File**

```
<bindings>
 <tree IterBinding="TmapStatesView1Iterator" id="TmapStatesView1">
 <nodeDefinition DefName="model.TmapStatesView">
 <AttrNames>
 <Item Value="Abbrev"/>
 <Item Value="Category"/>
 <Item Value="Color"/>
 <Item Value="Data"/>
 <Item Value="Id"/>
 <Item Value="Name"/>
 </AttrNames>
 </nodeDefinition>
 </tree>
</bindings>
```

[Example 33–21](#) shows the code inserted in the JSF page for the example thematic map in [Figure 33–44](#).

### **Example 33–21 JSF Code for Thematic Map Components**

```
<dvt:thematicMap id="tm1" basemap="usa">
 <dvt:areaLayer layer="states" id="all">
 <dvt:areaDataLayer id="dl1"
```

```

 value="#{bindings.TmapStatesView1.collectionModel}" var="row">
<dvt:areaLocation name="#{row.Name}" id="al2">
 <dvt:area id="a1">
 <dvt:attributeGroups id="ag1" value="#{row.Category}" type="color"
 label="#{row.Category}">
 <dvt:attributeMatchRule id="amr1" group="Mountain Dew">
 <f:attribute name="color" value="#ffff00"/>
 </dvt:attributeMatchRule>
 <dvt:attributeMatchRule id="amr2" group="Sunkist">
 <f:attribute name="color" value="#ff00ff"/>
 </dvt:attributeMatchRule>
 <dvt:attributeMatchRule id="amr3" group="Dr Pepper">
 <f:attribute name="color" value="#00ffff"/>
 </dvt:attributeMatchRule>
 <dvt:attributeMatchRule id="amr4" group="7 Up">
 <f:attribute name="color" value="#00ff00"/>
 </dvt:attributeMatchRule>
 <dvt:attributeMatchRule id="amr5" group="Pepsi">
 <f:attribute name="color" value="#0000ff"/>
 </dvt:attributeMatchRule>
 <dvt:attributeMatchRule id="amr6" group="Coke">
 <f:attribute name="color" value="#ff0000"/>
 </dvt:attributeMatchRule>
 </dvt:attributeGroups>
 </dvt:area>
</dvt:areaLocation>
</dvt:areaDataLayer>
</dvt:areaLayer>
<dvt:legend id="l1">
 <dvt:legendSection source="a1:dl1:ag1" id="ls1"/>
</dvt:legend>
</dvt:thematicMap>

```

### 33.6.3 What You May Need to Know About Base Map Location Ids

Each base map provided for the thematic map component has two or more prebuilt map layers that represent a set of regions. For example, the `world` base map includes a map layer for `continents` and another layer for `countries`. The regions in the lower level map layers are aggregated to make up the next level in the geographical hierarchy. The map layer is specified in the `layer` attribute of the `areaLayer` component.

When you are binding your data collection to a thematic map, you must provide a column in the data model that specifies the location of the area or point data using the map location Ids of the regions from the base map for which the data is being displayed. Area locations are specified in the `name` attribute of the `areaLocation` component, and point locations are specified in the `pointName` attribute for the `pointLocation` component when its `type` attribute is set to `pointName`.

For the United States base map, the locations Ids are determined by the following naming rules:

- `country` layer: USA
- `states` layer: Use the two-letter postal abbreviation. For example, the location Id for Massachusetts is MA, and the location Id for Texas is TX.
- `counties` layer: Use the `states` layer location Id, followed by an underscore, and then the name of the county, all in capital letters with underscores replacing

characters that are not letters. For example, the location Id for Middlesex county in Massachusetts is MA\_MIDDLESEX, and the location Id for Red River county in Texas is TX\_RED\_RIVER.

- `cities` layer: Use the `states` layer location Id, followed by an underscore, and then the name of the city, all in capital letters with underscores replacing characters that are not letters. For example, the location Id for the id for Boston, Massachusetts is MA\_BOSTON, and the location Id for San Antonio, Texas is TX\_SAN\_ANTONIO.

For all other base maps, location Ids are determined by the following naming rules:

- `continents` layer: AF (Africa), AS (Asia), AU (Australia), EU (Europe), NA (North America), and SA (South America) for the `world`, `africa`, `asia`, `australia`, `europe`, `northAmerica`, and `southAmerica` base maps.
- `worldRegions` layers: APAC (Asia-Pacific), EMEA (Europe and the Middle East), LAT (Latin America), NA (United States and Canada) for the `worldRegions`, `apac`, `emea`, `latinAmerica`, and `usaAndCanada` base maps.
- `countries` layer: Use the ISO 3166-1 alpha-3 country codes. For example, the location Id for Canada is CAN, and the location Id for China is CHN.
- `cities` layer: Use the three-letter `countries` location ID, followed by an underscore, and then the name of the city, all in capital letters with underscores replacing characters that are not letters. For example, the location Id for Toronto, Canada is CAN\_TORONTO, and the location Id for Los Angeles, United States is USA\_LOS\_ANGELES.

You can download a comma-separated value (CSV) file for each of the prebuilt map layers with a complete listing of all the thematic map base map location Ids. Find these links in the tag documentation for the `areaLocation` component, `name` attribute. To access tag documentation for the data visualization components, select the component in the Structure window and click the help button in the Property Inspector.

### 33.6.4 How to Add Data Layers to Thematic Maps

You use data layers to associate map layers with a data collection. Using stamping, each row of data in the data model can be identified by a style, for example a color or pattern; a marker, for example a circle or square; or an image. When a map layer is displayed at runtime, the data appears as stylized areas, markers, or images.

Map layers can display data using an area data layer and/or one or more point data layers. Area data layers can be styled using areas, markers, or images. Point data layers can be styled using markers or images.

When a point data layer is associated with the base map as a direct child of `thematicMap` instead of as a child of a specific map layer, the data displays at all times and is called a *global point layer*.

#### **Before you begin:**

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see [Section 33.6.1, "How to Create a Thematic Map Using ADF Data Controls."](#)

**To add an area data layer to a map layer:**

1. Select the thematic map in the Visual Editor.
2. In the Layer Browser, select the map layer to which you wish to bind a row in the data collection. If the Layer Browser is not open in the Visual Editor, right-click inside the map and choose **Open Layer Browser**.
3. From the **Add** icon dropdown list, choose **Add Data Layer** to open the Create Data Layer dialog.
4. In the Create Data Layer dialog, enter the following:
  - **Layer Id:** Enter a unique name for the data layer you are defining. By default, a unique, consecutively numbered id is entered, d11, d12, and so on.
  - **Bind Data Now:** Select and click **Browse** to open the Picker dialog > Data Controls Definitions page. Select the data collection in the ADF data controls you are using to data bind your data layer.

---

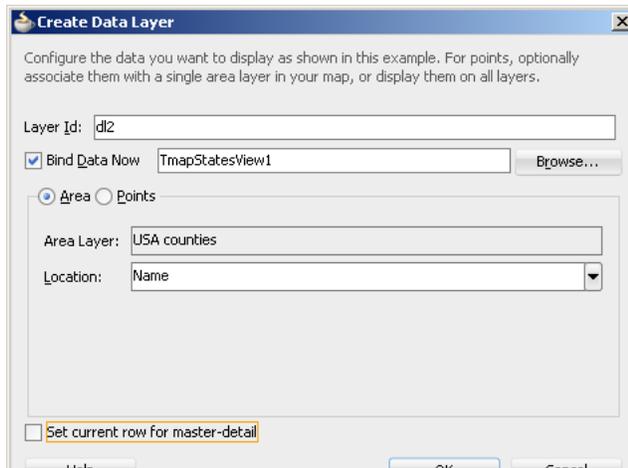

**Note:** Alternatively, you can use the Expression Builder page to select an ADF managed bean you are using to databind your area data layer and areas. You can also use the Expression Builder dialog in each remaining field.

---

- **Area:** Select to add an area data layer to the map layer.
- **AreaLayer:** References the map layer to which you are adding a data layer.
- **Location:** Select attribute that represents the column in the data model that determines the location of the data for the areas in the data layer. The locations are Ids of the regions from the base map for which the data is being displayed. For more information, see [Section 33.6.3, "What You May Need to Know About Base Map Location Ids."](#)
- **Set current row for master-detail:** Select if you want to enable master-detail relationships. This is useful when the data collection for the thematic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. For more information, see [Section 33.6.6, "What You May Need to Know About Configuring Master-Detail Relationships."](#)

Figure 33–50 shows the completed Create Area Data Layer dialog.

**Figure 33–50 Create Area Data Layer Dialog**

By default, an area data layer representing the `areaDataLayer` component, and an area, representing the `area` component is added in the Layer Browser hierarchy. [Example 33–22](#) shows the code added to the JSF page when you add an area data layer to a map layer.

**Example 33–22 Area Data Layer Code in JSF Page**

```
<dvt:thematicMap id="tm1" basemap="usa">
 <dvt:areaLayer layer="counties" id="al1">
 <dvt:areaDataLayer id="dl2"
 value="#{bindings.TmapStatesView1.collectionModel}"
 var="row">
 <dvt:areaLocation name="#{row.Name}" id="al2">
 <dvt:area id="a1"/>
 </dvt:areaLocation>
 </dvt:areaDataLayer>
 </dvt:areaLayer>
 ...
</dvt:thematicMap>
```

**To add a point data layer to a map layer:**

1. Select the thematic map in the Visual Editor.
2. In the Layer Browser, select the map layer to which you wish to bind a data layer. If the Layer Browser is not open in the Visual Editor, right-click inside the map and choose **Open Layer Browser**.
3. From the **Add** icon dropdown list, choose **Add Data Layer** to open the Create Data Layer dialog.

---

**Note:** If you wish to create a global point layer that displays at all times on the thematic map, choose **Create Global Point Layer**.

---

4. In the Create Data Layer dialog, enter the following:
  - **Layer Id:** Enter a unique ID for the data layer you are defining. By default, a unique, consecutively numbered id is entered, `dl1`, `dl2`, and so on.

- **Bind Data Now:** Select and click **Browse** to open the Picker dialog > Data Controls Definitions page. Select the data collection in the ADF data controls you are using to data bind your data layer.

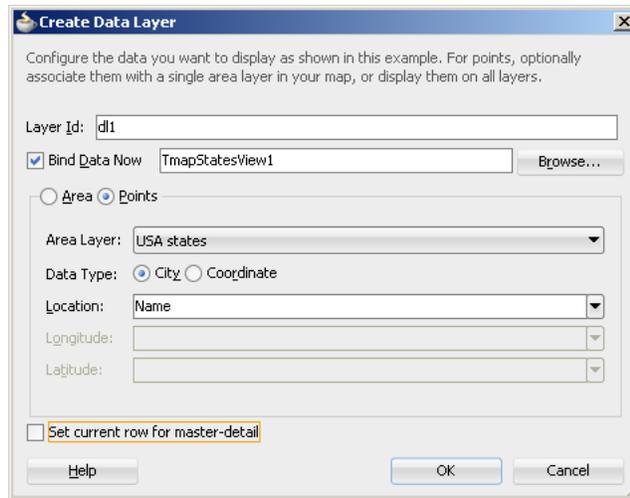

---

**Note:** Alternatively, you can use the Expression Builder page to select an ADF managed bean you are using to databind your point data layer and markers. You can also use the Expression Builder dialog in each remaining field.

---

- **Points:** Select to add a point data layer to the map layer.
- **AreaLayer:** Use the dropdown list to select the map layer to which you are associating a data layer. If you select **All**, the point data layer will be configured as a global point layer and display at all times. If you select an available map layer, the point data layer will only display with that map layer is displayed.
- **Data Type:** Choose one of the following:
  - **City:** Select to use a `pointName` data type representing the named points, such as cities, in the data collection that map to named points in the base map.
  - **Coordinates:** Select to use a `pointXY` data type representing the columns in the data collection that join `pointX` and `pointY` to define the point locations.
- **Location:** Available if a City Data Type is specified. Use the dropdown list to select the attribute that represents the column in the data model that determines the location of the data for the points in the data layer. The locations are IDs of the points from the base map for which the data is being displayed. For more information, see [Section 33.6.3, "What You May Need to Know About Base Map Location Ids."](#)
- **Longitude:** Available if a Coordinates Data Type is specified. Use the dropdown list to select the attribute in the data collection that represents the longitude, or `pointX` of the marker.
- **Latitude:** Available if a Coordinates Data Type is specified. Use the dropdown list to select the attribute in the data collection that represents the latitude, or `pointY` of the markers.
- **Set current row for master-detail:** Select if you want to enable master-detail relationships. This is useful when the data collection for the thematic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. For more information, see [Section 33.6.6, "What You May Need to Know About Configuring Master-Detail Relationships."](#)

Figure 33–51 shows the completed Create Point Data Layer dialog for a `pointName` data type.

**Figure 33–51 Create Point Data Layer Dialog**

By default, a point data layer representing the `pointDataLayer` component, and a marker, representing the `marker` component is added in the Layer Browser hierarchy. [Example 33–23](#) shows the code added to the JSF page when you add a point data layer to a map layer.

**Example 33–23 Point Data Layer Code in JSF Page**

```
<dvt:thematicMap id="tm1" basemap="usa">
 <dvt:areaLayer layer="states" id="all">
 <dvt:pointDataLayer id="dl1"
 value="#{bindings.TmapCitiesView1.collectionModel}"
 var="row">
 <dvt:pointLocation type="pointName" pointName="#{row.City}" id="pl1">
 <dvt:marker id="m2"/>
 </dvt:pointLocation>
 </dvt:pointDataLayer>
 </dvt:areaLayer>
 ...
</dvt:thematicMap>
```

[Example 33–24](#) shows the code added to the JSF page when you add a global point data layer to a thematic map.

**Example 33–24 Global Point Data Layer Code in JSF Page**

```
<dvt:thematicMap>
 <areaLayer layer="states" id="all"/>
 <dvt:pointDataLayer id="dl2"
 value="#{bindings.TmapCitiesView12.collectionModel}"
 var="row">
 <dvt:pointLocation type="pointXY" pointX="#{row.Longitude}"
 pointY="#{row.Latitude}" id="pl2">
 <dvt:marker id="m3"/>
 </dvt:pointLocation>
 </dvt:pointDataLayer>
 ...
</dvt:thematicMap>
```

After adding the area or point data layer to the thematic map, you style the data using areas, markers, or images. For more information, see [Section 33.6.7, "Styling Areas, Markers, and Images to Display Data."](#)

### 33.6.5 How to Configure Drilling in Thematic Maps

A thematic map with related data views in different map layers can be configured for drilling between the higher and lower level data views. For example, a thematic map can display data for sales category by USA state drilled down to USA county data as illustrated in [Figure 33–62](#). When a state or county is selected, drilling up or down is initiated through a context menu choice or the Control Panel.

The following requirements must be met to achieve thematic map area drilling declaratively:

- For each map layer (`areaLayer`) in the drilling hierarchy, you must bind its child `areaDataLayer` with a data control that defines the related data for that map layer.
- Each `areaDataLayer` in the map layer drill hierarchy must have its `selectionMode` attribute set to `single` or `multiple`.
- You must configure the area in the lower level map layer drill hierarchy to display data using the same default stamp or categorical attribute style used in the higher level map layer area component.
- The `thematicMap` component `drilling` attribute must be set to `on`.

---

---

**Note:** If drilling is enabled for the thematic map, drilling between a custom layer and the map layer used to aggregate the custom layer is available.

---

---

#### Before you begin:

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see [Section 33.6.1, "How to Create a Thematic Map Using ADF Data Controls."](#)

You should already have data controls that define the data model for each of the map layers in the drill hierarchy.

#### To configure a thematic map area for drilling:

1. In the Structure window, select the `dvt:thematicMap` component.
2. In the Property Inspector, expand the **Behavior** section. Use this section to set the following attributes:
  - **Drilling:** Use to enable drilling the area data view between thematic map layers. From the dropdown list select **on** to enable drilling. The default value is **off**.
  - **MaintainDrill:** Optionally, use to specify an optional **true** value for maintaining the drilled state of a previously drilled area when a new area is drilled. The default value is **false**.

- **DrillBehavior:** Optionally, use to specify an optional **zoomToFit** effect on the area being drilled. The default value is **none**.
3. In the Layer Browser, select each **Area Layer** component in the desired drilling hierarchy and do the following:
    - Select the **Add icon** and choose **Add Data Layer** to open the Create Data Layer dialog. Complete the dialog to add an area data layer and bind the data layer to the data control for that map layer. If you need help, press **F1** or click **Help**.

---

**Note:** If the **Area Data Layer** is already present, select the **Edit icon** to confirm binding to the data control.

---

- In the Property Inspector, expand the **Behavior** section and set the **SelectionMode** attribute to **single** or **multiple**.
4. In the Layer Browser, select each **Area Data Layer** component in the desired drilling hierarchy and do the following:
    - Select the **Add icon** and choose **Add Area** to open the Configure Area dialog. Complete the dialog to define a default stamp or use attribute groups to style the area for that map layer. If you need help, press **F1** or click **Help**.

---

**Note:** If the **Area** is already present, select the **Edit icon** to confirm the styling of the area.

---

Figure 33–25 shows sample code for drilling enabled for USA states and counties map layers with an area styled to display data about sales categories.

**Example 33–25 Sample Code for Configuring Drilling**

```
<dvt:thematicMap id="thematicMap"
 basemap="usa"
 drilling="on"
 maintainDrill="true"
 drillBehavior="zoomToFit"
 animationOnDisplay="none"
<dvt:areaLayer id="a1" layer="states">
 <dvt:areaDataLayer id="ad1"
 selectionMode="single"
 contentDeliver="immediate"
 value="{row.state}"
 var="row"
 varStatus="rowStatus">
 <dvt:areaLocation id="areaLocS" name="{row.stname}">
 <dvt:area id="a1" fillColor="{row.state}"/>
 </dvt:areaLocation>
 </dvt:areaDataLayer>
</dvt:areaLayer>
<dvt:areaLayer id="a2" layer="counties">
 <dvt:areaDataLayer id="ad2"
 selectionMode="single"
 contentDelivery="immediate"
 value="{row.county}"
 var="row"
 varStatus="rowStatus">
 <dvt:areaLocation id="areaLocC" name="{row.coname}">
```

```

 <dvt:area id="a2" fillColor="#{row.county}"/>
 </dvt:areaLocation>
</dvt:areaDataLayer>
</dvt:areaLayer>
...
</dvt:thematicMap>

```

### 33.6.6 What You May Need to Know About Configuring Master-Detail Relationships

You can configure a thematic map to display its associated data in another UI component on the page such as a table. In this configuration the data collection for the thematic map is a master in a master-detail relationship with a detail view in another UI component. [Figure 33–52](#) shows a thematic map displaying unemployment rates by state. Users can select one or multiple states to display the data detail view in the table.

**Figure 33–52** Thematic Map Master and Detail Table View

The following requirements must be met to achieve this master-detail processing declaratively:

- You must use the same data collection to provide data for both views as follows:
  - Bind the thematic map `areaDataLayer` or `pointDataLayer` to the data collection whose attributes represent the data to be styled by areas or markers in the thematic map layer.
  - Bind the other ADF component (such as a table) to same data collection.
- Select **Set the current row for master-detail** in the Create Data Layer dialog to automatically set a value for the `selectionListener` attribute of the thematic map `areaLayer` component and use the `processSelection` method that is already part of the thematic map binding.

For example, if the value attribute of the thematic map area data layer component is `value="#{stateData.employmentData}"`, then the `selectionListener` attribute is set to:

```
selectionListener="#{stateData.employmentData.processSelection}";
```

- Ensure that the `selectionMode` attribute on the `areaDataLayer` or `pointDataLayer` component is set to `single` or `multiple`, depending on the requirements for the thematic map.

### 33.6.7 Styling Areas, Markers, and Images to Display Data

An area data layer is used to associate map layers with a data collection. Using stamping, each row of data in the data model can be identified by a style, for example a color or pattern; a marker, for example a circle or square; or an image.

A point data layer is used to associate a set of points on a map with a data collection. The data point can be specified by a named point in a map layer, for example, cities in the US map, or by longitude and latitude. Using stamping, each row of data in the data model can be identified by a marker, for example a circle or square, or an image.

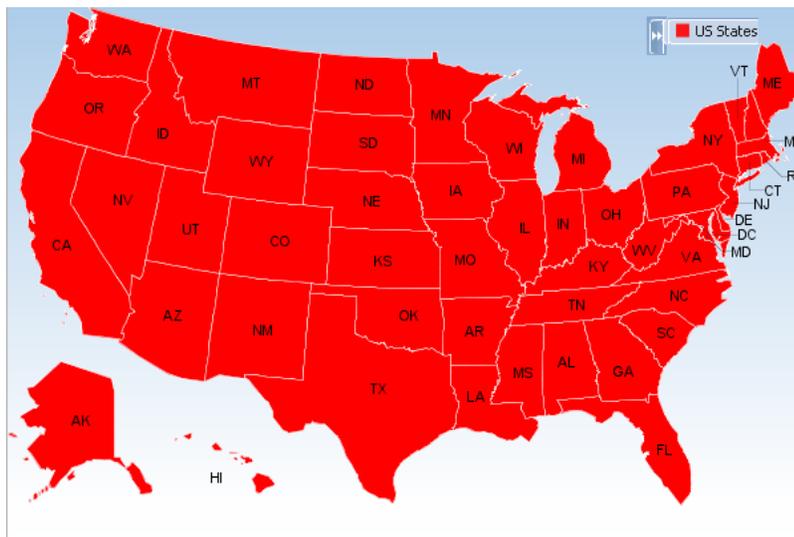

#### 33.6.7.1 How to Style Areas to Display Data

You configure an area with a default stamp across all areas in the thematic map `areaLayer`, or you can use a child `attributeGroups` tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the `area` tag, and by an `attributeGroups` tag, the `attributeGroups` style type will take precedence.

By default, when you add an area data layer, a configurable area is added to the Layer Browser. You can use the Layer Browser to add additional areas or markers to an area data layer, or markers to a point data layer. The Layer Browser reflects the logical structure of the map layers, area or point data layers, and areas or markers configured in the thematic map.

For example, using the default stamp, you can style all the states in the `states` layer of the `usa` base map with the color red as illustrated in [Figure 33–53](#).

**Figure 33–53** Thematic Map with Area Default Stamp Configured

#### Before you begin:

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see [Section 33.6.1, "How to Create a Thematic Map Using ADF Data Controls."](#)

**To style areas using a default stamp:**

1. In the Layer Browser, select the area at the area location inside the map layer you are configuring.
2. Choose the **Edit** icon to open the Configure Area dialog.
3. In the Configure Area dialog, Default Stamp page, enter the following:
  - **Location:** By default, the attribute that represents the column in the data model that determines the location of the data for the areas in the data layer. The locations are Ids of the regions from the base map for which the data is being displayed. This read-only field displays the EL expression that maps the stamped area to a region in the base map. For more information, see [Section 33.6.3, "What You May Need to Know About Base Map Location Ids."](#)
  - **Color:** Optionally, from the dropdown list select the fill color for the area. Valid values are RGB hexadecimal. Choose **Custom Color** from the dropdown list to open a Color Picker dialog
  - **Pattern:** Optionally, from the dropdown list select one of twelve prebuilt patterns to style the area, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **largeCrosshatch**. If fill color is specified, the pattern displays in that color on the default white background.
  - **Opacity:** Optionally, specify the opacity of the fill color of the area. Valid values range from **0.0** for transparent to **1.0** for opaque.
  - **Include in Legend:** Select and use the search icon to open a Select Text Resource dialog to select or create an application text resource to use for the legend text. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. If you need help, press **F1** or click **Help**.

---

**Note:** the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

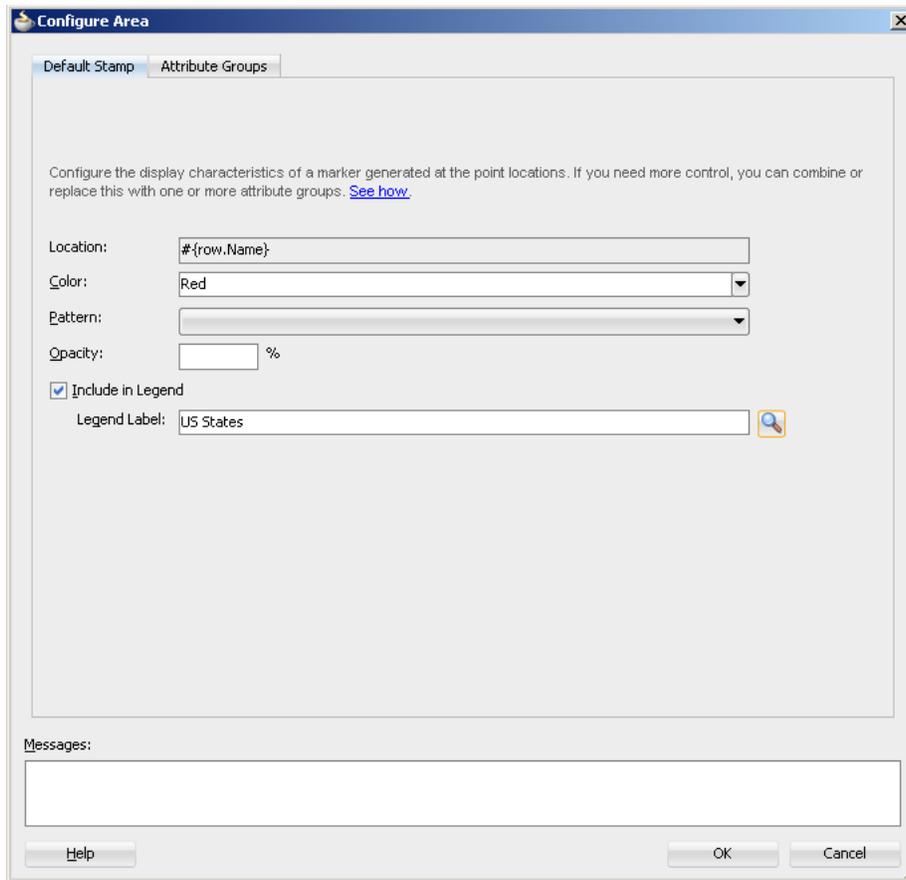

```
#{viewController.ResourceBundle[row.label]}
```

---

- **Messages:** Review and clear as necessary any alerts related to the configuration of the area.

[Figure 33-54](#) shows the Configure Area dialog for the Default Stamp page.

**Figure 33–54 Configure Area Dialog Default Stamp Page**

Example 33–26 shows the code inserted in the JSF page for the configured area.

**Example 33–26 Sample Code for Area Default Stamp Configuration**

```
<dvt:thematicMap id="tm1" basemap="usa">
 <dvt:areaLayer layer="states" id="a1">
 <dvt:areaDataLayer id="dl1"
 value="#{bindings.TmapStatesView1.collectionModel}"
 var="row">
 <dvt:areaLocation name="#{row.Name}" id="a12">
 <dvt:area id="a1" fillColor="#ff0000">
 <f:attribute name="legendLabel"
 value="#{Bundle.US_STATES}" />
 </dvt:area>
 </dvt:areaLocation>
 </dvt:areaDataLayer>
 </dvt:areaLayer>
</dvt:thematicMap>
```

If you wish to style areas using categorical groups of data in the data collection, use the Attribute Groups page of the Configure Area dialog. For details about using the Attribute Groups page including sample code, see the use case described in [Section 33.6.1, "How to Create a Thematic Map Using ADF Data Controls."](#)

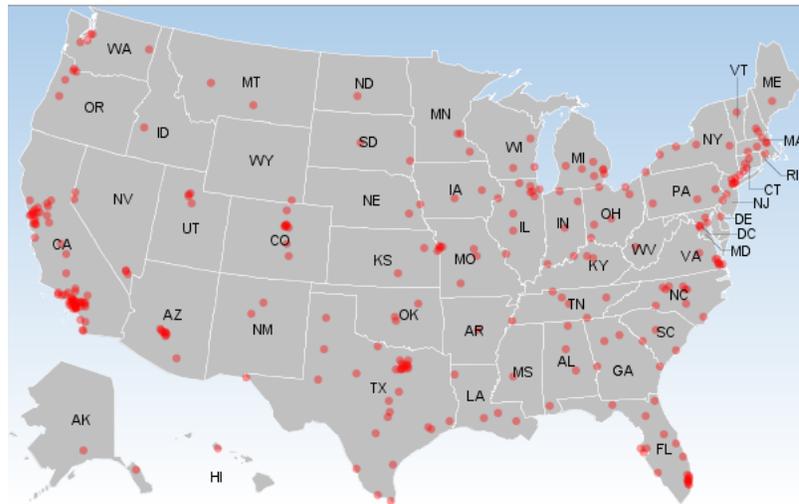

### 33.6.7.2 How to Style Markers to Display Data

You configure a marker with a default stamp across all markers in the thematic map layer, or you can use a child `attributeGroups` tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the marker tag, and by an `attributeGroups` tag, the `attributeGroups` style type will take precedence.

By default, when you add a point data layer, a configurable marker element is added to the Layer Browser. You can use the Layer Browser to add additional areas or markers to an area data layer, or markers to a point data layer. The Layer Browser reflects the logical structure of the map layers, area or point data layers, and areas or markers configured in the thematic map.

For example, using the default stamp, you can identify all the predefined cities in the states layer of the USA base map with a red circle as illustrated in [Figure 33–55](#). In the example, markers are styled on a point data layer. Styling markers on an area data layer is similar.

**Figure 33–55 Thematic Map with Marker Default Stamp Configured**

#### Before you begin:

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see [Section 33.6.1, "How to Create a Thematic Map Using ADF Data Controls."](#)

#### To style markers using a default stamp:

1. In the Layer Browser, select the marker at the point location inside the map layer you are configuring
2. Select the **Edit** icon to open the Configure Marker dialog.
3. In the Configure Marker dialog, Default Stamp page, enter the following:

- **Location:** By default, the attribute that represents the column in the data model that determines the location of the data for the markers in the data layer. The locations are Ids of the points from the base map for which the data is being displayed. This read-only field displays the EL expression that maps the stamped marker to a point in the base map. For more information, see [Section 33.6.3, "What You May Need to Know About Base Map Location Ids."](#)
- **Color:** Optionally, from the dropdown list select the fill color for the marker. Valid values are RGB hexadecimal. Choose **Custom Color** from the dropdown list to open a Color Picker dialog.
- **Pattern:** Optionally, from the dropdown list select one of twelve prebuilt patterns to style the marker, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **largeCrosshatch**. If fill color is specified, the pattern displays in that color on the default white background.
- **Opacity:** Optionally, specify the opacity of the fill color of the marker. Valid values range from **0.0** for transparent to **1.0** for opaque.
- **Shape:** Optionally, select the shape of the marker. Valid values are **circle** (default), **square**, **plus**, **diamond**, **triangleUp**, **triangleDown**, and **human**.  
Optionally, use the **Custom Shape** field to specify the `shapePath` value to a Scalable Vector Graphics (SVG) file to use for the marker. Enter the path or use the **Search** icon to open the Select SVG File dialog and navigate to the file location. This option is only available if the default shape is selected in the **Shape** field.  
  
Shapes can also be specified using CSS style properties. Predefined marker shapes can be overwritten, and the paths to SVG files for custom markers can also be defined without using the `shapePath` attribute. For more information, see [Section 33.6.7.3, "What You May Need to Know About Styling Markers."](#)
- **Size:** Optionally, enter a percentage by which to scale the marker from its default size for **ScaleX** (horizontal), and **ScaleY** (vertical). The percentages are then scaled to a float. For example, you can double the marker width by setting **ScaleX** to 200, written to the tag as `2.0`, and halve the height by setting **ScaleY** to 50, written to the tag as `0.5`.
- **Include in Legend:** Enter a text resource to use for the legend label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press **F1** or click **Help**.

---

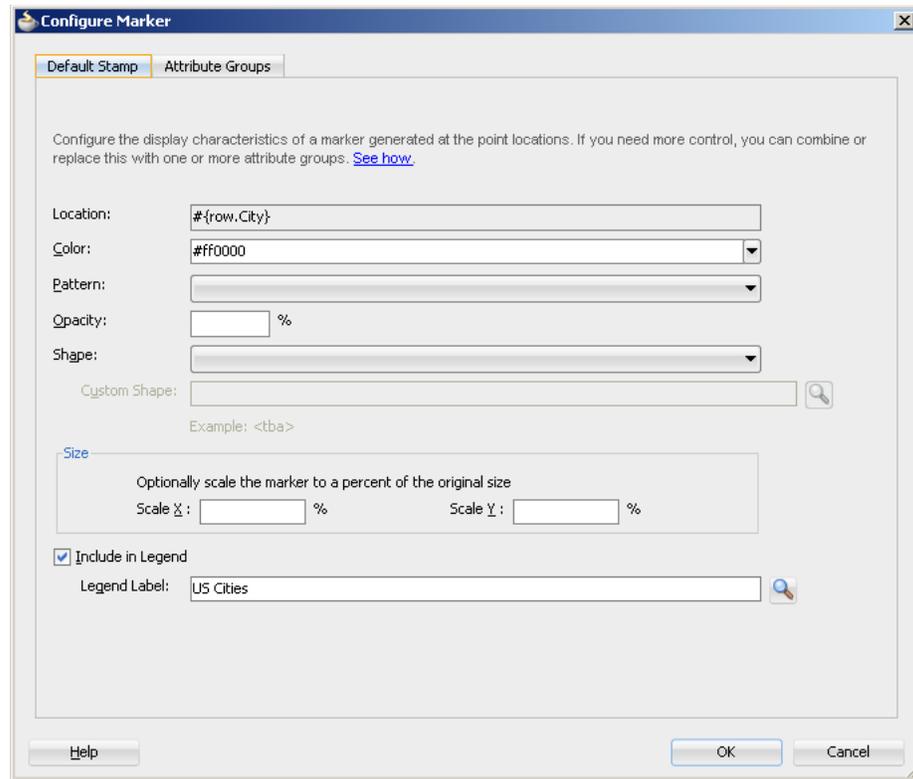

**Note:** the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

```
#{viewController.ResourceBundle[row.label]}
```

---

- **Messages:** Review and clear any messages related to the configuration of the marker.

Figure 33–56 shows the Configure Marker dialog, Default Stamp page.

**Figure 33–56 Configure Marker Dialog Default Stamp Page**

Example 33–27 shows the code inserted in the JSF page for the configured marker.

#### **Example 33–27 Sample Code for Marker Default Stamp Configuration**

```
<dvt:thematicMap id="tm1" basemap="usa">
 <dvt:areaLayer layer="states" id="all">
 <dvt:pointDataLayer id="dl2"
 value="#{bindings.TmapCitiesView1.collectionModel}"
 var="row">
 <<dvt:pointLocation type="pointName" pointName="#{row.City}" id="pl1">
 <dvt:marker id="m2" fillColor="#ff0000">
 <f:attribute name="legendLabel"
 value="#{Bundle.US_CITIES}"/>
 </dvt:marker>
 </dvt:pointLocation>
 </dvt:pointDataLayer>
 </dvt:areaLayer>
</dvt:thematicMap>
```

If you wish to style markers using categorical groups of data in the data collection, use the Attribute Groups page of the Configure Marker dialog. You can configure markers for a point data layer or an area data layer.

#### **To style markers using categorical groups of data:**

1. In the Layer Browser, select the marker at the marker location inside the map layer you are configuring.
2. Select the **Edit** icon to open the Configure Marker dialog.
3. In the Configure Marker dialog, Attribute Groups page, enter the following:

- **Grouping Rules:** Use this table to specify the styling of categorical groups of data in a data collection. Use the **Add** icon to add a row to the table for configuring rules for a categorical group and use the **Delete** icon to remove any row selected in the table. Each grouping rule is represented as a `attributeGroups` component, and assigned a unique, consecutively numbered Id, `ag1`, `ag2`, and so on.

For each row added to the table, enter the following:

- **Group by Value:** Enter or use the dropdown list to select the attribute representing the column in the data set by which you wish to group the data values.

---

**Note:** The selected attribute should consist of discrete values that can be categorized. For example, a range of numeric values between 40 and 45, are not automatically grouped.

---

- **Marker Properties:** Use the dropdown list to select the property to use for styling that marker. Markers can be styled using **color**, **pattern**, **opacity**, **scaleX**, **scaleY**, or any combination of these valid values. Choose **Select multiple attributes** from the dropdown list for a dialog to specify any combination of values.

The default style values that are generated for each property are defined using CSS style properties in the ADF skin. Each `attributeGroups` type has a default ramp defined in the skin, and these can be customized by setting the index-based properties to the desired values. For more information, see [Section 33.6.7.4, "What You May Need to Know About Default Style Values for Attribute Groups."](#)

- **Legend Label:** Enter text or use the dropdown list to select the attribute representing the text to use for the categorical group in the thematic map legend. You can also select **Expression Builder** from the dropdown list to create an EL expression to specify the legend text. For more information, see [Section 33.6.8, "Creating Databound Legends."](#)

- **Value-Specific Rules:** Click to open the **Match Rules** and **Exception Rules** tables used to specify a finer detail for one or more data values for categorical groups in a data set.

---

**Note:** Any match or exception rule specified in these tables will override the settings defined in the **Grouping Rules** table.

---

- **Match Rules:** Use to specify the style rule matched to one or more data values in a group of data in a data collection. Use the **Add** icon to add a row to the table for configuring a match rule for a categorical group and use the **Delete** icon to remove any row selected in the table. Each match rule is represented as a `attributeMatchRule` component, and assigned a unique, consecutively numbered Id, `amr1`, `amr2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

```
<dvt:attributeMatchRule id="amr1" group="Mountain Dew">
 <f:attribute name="color" value="#ffff00"/>
</dvt:attributeMatchRule>
```

For each row added to the table, enter the following:

- **Group Value:** Enter the exact value for the **Group by Value** attribute that will trigger the Match Rule to execute.
- **Property:** Use the dropdown list to select the property to use for styling that data value. Markers can be styled using **color**, **pattern**, **opacity**, **scaleX**, **scaleY**, or any combination of these valid values. The property selected here must match one of the property types listed in the **Marker Properties** for the attribute **Grouping Rules**.
- **Property Value:** Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp.

Valid values for **color** are RGB hexadecimal colors.

Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **large-Crosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

Valid values for **opacity** range from **0.0** for transparent to **1.0** for opaque.

Valid values for **scaleX** and **scaleY** are percentages that are then scaled to a float.

- **Exception Rules:** Use to specify one or more exceptions to the style rules for categorical groups in the data set. Use the **Add** icon to add a row to the table for configuring an exception rule and use the **Delete** icon to remove any row selected in the table. Each exception rule is represented as an `attributeExceptionRule` component, and assigned a unique, consecutively numbered `id`, `aer1`, `aer2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

```
<dvt:attributeExceptionRule id="aer1" condition="{row.name=='TX'}"
 label="Texas">
 <f:attribute name="color" value="#ff00ff"/>
</dvt:attributeExceptionRule>
```

For each row added to the table, enter the following:

- **Condition:** Enter an EL expression, or use the dropdown list to open an Expression Builder dialog to create an EL expression that replaces the style property value with another when certain conditions are met. For example:

```
{row.Sales gt 100000}
```

- **Property:** Use the dropdown list to select the property to use for styling that data value. Markers can be styled using **color**, **pattern**, **opacity**, **scaleX**, or **scaleY**. The property selected here must match one of the property types listed in the **Marker Properties** for the attribute **Grouping Rules**.
- **Property Value:** Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp

Valid values for **color** are RGB hexadecimal colors.

Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **large-Crosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

Valid values for **opacity** range from **0.0** for transparent to **1.0** for opaque.

Valid values for **scaleX** and **scaleY** are percentages ranging from **100** to **500**. The percentages are then scaled to a float, ranging from **1.0** to **5.0**.

- **Legend Label:** Enter a text resource to use for the legend label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press **F1** or click **Help**.

---

**Note:** the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

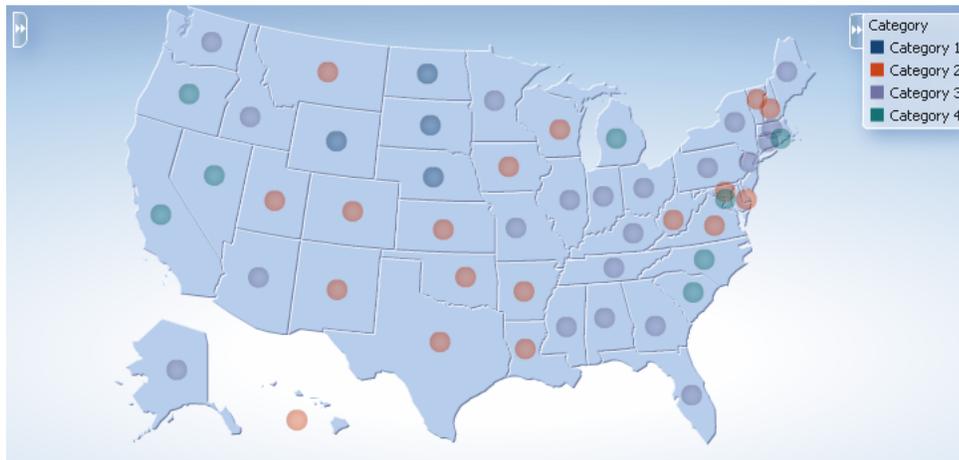

```
#{viewController.ResourceBundle[row.label]}
```

---

- **Messages:** Review and clear as necessary any alerts related to the configuration of the marker.

For example, you can use markers in an area data layer to display categorical groups of data using colors as illustrated in [Figure 33-57](#).

**Figure 33-57 Marker Attribute Groups by Color**

[Example 33-28](#) shows the sample code for marker attribute groups by color.

**Example 33-28 Sample Code for Marker Attribute Groups by Color**

```
<dvt:thematicMap basemap="usa" id="tm1"
 <dvt:areaLayer layer="states" id="a11" labelDisplay="off">
 <dvt:areaDataLayer id="dl1" var="row" value="#{stateData.colorModel}">
 <dvt:areaLocation id="a12" name="#{row.name}">
 <dvt:marker id="m1"
 scaleX="3.0"
 scaleY="3.0"
 shape="circle">
```

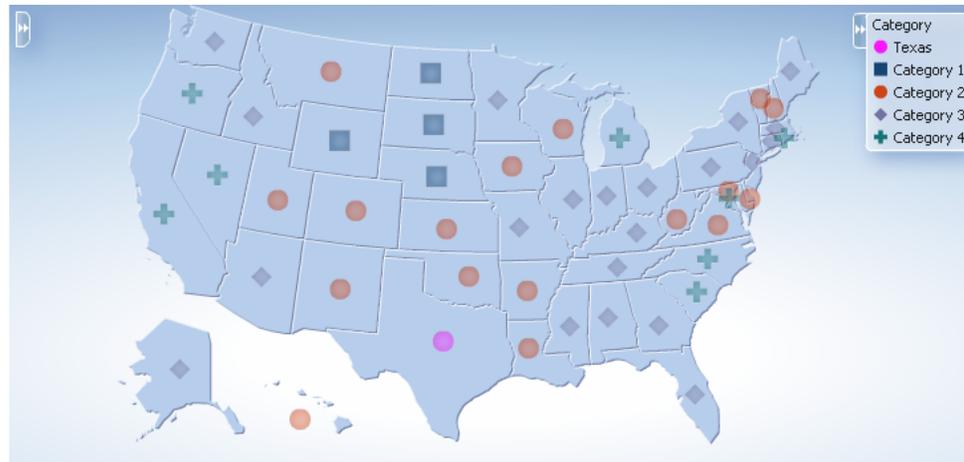

```

 <dvt:attributeGroups id="ag1" type="color" value="{row.category}"
 label="{row.category}"/>
 </dvt:marker>
</dvt:areaLocation>
</dvt:areaDataLayer>
</dvt:areaLayer>
<dvt:legend id="l1">
 <f:facet name="separator"/>
 <dvt:legendSection id="ls1" label="Category" source="ag1"/>
</dvt:legend>
</dvt:thematicMap>

```

You can also use markers to display categorical groups of data using multiple attributes such as color and shape, and display an exception to the grouping rules when certain conditions are met. [Figure 33–58](#) shows a thematic map with categorical groups using color and shape with an exception for the state of Texas.

**Figure 33–58 Multiple Marker Attribute Groups with Exception Rule**

[Example 33–29](#) shows sample code for multiple marker attribute groups with exception rule.

**Example 33–29 Sample Code for Multiple Marker Attribute Groups with Exception Rule**

```

<dvt:thematicMap basemap="usa" id="tm2"
 <dvt:areaLayer layer="states" id="al1" labelDisplay="off">
 <dvt:areaDataLayer id="dl1" var="row" value="{stateData.colorModel}">
 <dvt:areaLocation id="al2" name="{row.name}">
 <dvt:marker id="m1"
 scaleX="3.0"
 scaleY="3.0"
 shape="circle">
 <dvt:attributeGroups id="ag1" type="shape color" value="{row.category}"
 label="{row.category}">
 <dvt:attributeExceptionRule id="aer1" condition="{row.name=='TX'}"
 label="Texas">
 <f:attribute name="color" value="#ff00ff"/>
 </dvt:exceptionRule>
 </dvt:attributeGroups>
 </dvt:marker>
 </dvt:areaLocation>
 </dvt:areaDataLayer>
 </dvt:areaLayer>

```

```

<dvt:legend id="l1">
 <f:facet name="separator"/>
 <dvt:legendSection id="ls1" label="Category" source="ag1"/>
</dvt:legend>
</dvt:thematicMap>

```

### 33.6.7.3 What You May Need to Know About Styling Markers

Thematic maps support a predefined set of seven shapes (`circle`, `square`, and so on) that can be specified using the `shape` attribute in the `marker` component. For custom markers, the `shapePath` attribute can be used to specify the path of an SVG file that will get displayed in place of a predefined shape.

Marker shapes can be also specified through CSS style properties in an ADF skin. Using thematic map style properties, predefined marker shapes can be overwritten, and the paths to SVG files for custom markers can be defined without using the `shapePath` attribute. When using style properties, the `shape` attribute in the `marker` component is used for defining both predefined and custom shapes.

A predefined shape will be overwritten if a global or component-specific style property for that shape is specified in the ADF skin. For example, you can overwrite the predefined `circle` shape by specifying the `newCircle.svg` file in the thematic map component style property as follows:

```

af|dvt-thematicMap::shape-circle{
 -tr-path: url(/resources/path/newCircle.svg);
}

```

In the JSF page, the `marker` component `shape` attribute is set as follows:

```
<dvt:marker id="m1" shape="circle"/>
```

To specify a custom shape in the `marker` component `shape` attribute, you must use a prefix of `custom` in the shape style property name. For example, if the custom shape is named `customName`, then the ADF skin file should define either a global `.AFDVTShapeCustomName:alias` style property, or the thematic map specific `af|dvt-thematicMap::shape-customName` with the `-tr-path` property pointing to the SVG file as follows:

```

af|dvt-thematicMap::shape-customName{
 -tr-path: url(/resource/path/newCShape.svg);
}

```

In the JSF page, the `marker` component `shape` attribute is set as follows:

```
<dvt:marker id="m1" shape="customName"/>
```

For information about using ADF skins and style properties, see the "Customizing the Appearance Using Styles and Skins" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 33.6.7.4 What You May Need to Know About Default Style Values for Attribute Groups

The `attributeGroups` component is used to generate stylistic property values such as colors or shapes based on categorical grouping of the data in a data collection. Based on the attribute representing the column in the data model to group by, the `attributeGroups` component can generate style values for each unique value, or group, in the data.

The type of stylistic properties to generate values for is specified by the `type` attribute of the `attributeGroups` component. Supported types for area components are `color`, `pattern`, and `opacity`. Supported types for marker components are `color`, `shape`, `pattern`, `opacity`, `scaleX`, and `scaleY`. These types can be combined in a space-delimited list to generate multiple stylistic properties for each unique data value.

The default style values that are generated are defined using CSS style properties in the ADF skin. Each `attributeGroups` type has a default ramp defined in the ADF skin that can be customized by setting the index-based selectors to the desired values. [Example 33–30](#) show sample code for using CSS style properties to specify attribute groups using CSS style properties.

**Example 33–30 Attribute Groups CSS Style Properties**

```
af|dvt-attributeGroups::shape1{
 -tr-shape: square;
}
af|dvt-attributeGroups::shape2{
 -tr-shape: square;
}
...
af|dvt-attributeGroups::color1{
 -tr-fill-color: #003366;
}
```

The default ramps for each attribute groups type are displayed in [Table 33–6](#).

**Table 33–6 Default Ramps for Thematic Map Attribute Groups**

Type	Default Ramps
color	j#003366 (blue), #CC3300 (red), #666699 (lavender), #00066666 (emerald), #FF9900 (orange yellow), #993366 (purple), #99CC33 (lime green), #624390 (violet), #669933 (green), #FFCC33 (yellow), #006699 (turquoise blue), and #EBEA79 (pale yellow).
shape	square, circle, diamond, plus, triangleDown, triangleUp, and human
pattern	smallDiagonalLeft, smallDiagonalRight, smallTriangle, smallChecker, smallChecker, smallCrosshatch, smallDiamond, largeDiagonalLeft, largeDiagonalRight, largeTriangle, largeChecker, largeCrosshatch, largeDiamond
opacity	0.25, 0.50, 0.75, 1.0
scaleX and scaleY	1.0, 2.0, 3.0, 4.0, 5.0

For information about using ADF skins and style properties, see the "Customizing the Appearance Using Styles and Skins" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

**33.6.7.5 How to Style Images to Display Data**

You can use images to style data displayed in a thematic map. Using stamping, each row of data in the data model can be identified by an image. Images can be associated with either an area or point data layer.

For example, in an area data layer you can use a house image to identify prime locations on the states map layer of a US base map as illustrated in [Figure 33–59](#).

**Figure 33–59 Thematic Map Styling Data with Images**

**Before you begin:**

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see [Section 33.6.1, "How to Create a Thematic Map Using ADF Data Controls."](#)

**To use an image to display data:**

1. In the Layer Browser, select the area or point data layer where you are configuring an image to display data.
2. In the Structure window, right-click the area or point data layer child `areaLocation` or `pointLocation` component and select **insert inside `dvt:areaLocation` or insert inside `dvt:pointLocation` > Image** to open the Insert Image dialog.
3. In the Insert Image dialog, enter the following:
  - **Source:** Enter the URI specifying the location of the image source. You can use the dropdown menu to choose **Edit** and open an Edit Property: Source dialog or the Expression Builder to specify the location of the image source.
  - **ShortDesc:** Enter the short description of the image used as the `alt` text for screen reader users.

[Example 33–31](#) shows a code sample for using images to display data.

**Example 33–31 Code Sample for Image Configuration**

```
<dvt:thematicMap id="thematicMap" imageFormat="flash" basemap="usa"
 summary="Thematic map showing the important real estate markets">
 <dvt:legend label="Legend">
 <dvt:legendSection source="areaLayer:dataLayer:img1" />
 </dvt:legend>
</dvt:thematicMap>
```

```

</dvt:legend>
<dvt:areaLayer id="areaLayer" layer="states">
 <dvt:areaDataLayer id="dataLayer" contentDelivery="immediate"
 value="#{tmapBean.colorModel}"
 var="row"varStatus="rowStatus">
 <dvt:areaLocation id="dataLoc" name="#{row.name}">
 <af:image id="img1" source="/resources/images/geoMap/mansion.gif"
 rendered="#{row.category == 'category1'}"
 shortDesc="House image">
 <f:attribute name="legendLabel" value="Prime location"/>
 </af:image>
 </dvt:areaLocation>
 </dvt:areaDataLayer>
</dvt:areaLayer>
</dvt:thematicMap>

```

### 33.6.7.6 What You May Need to Know About SVG Files

Scalable Vector Graphics (SVG) is the supported file format for creating custom shapes for thematic map markers.

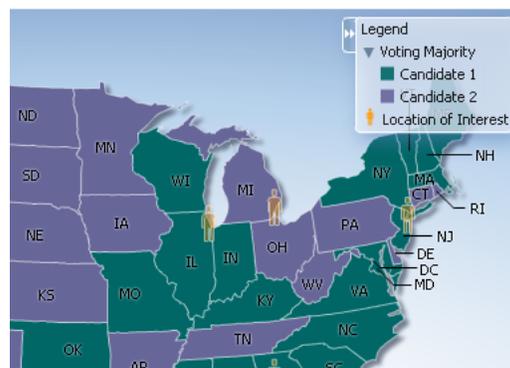

SVG features that are not supported by custom shapes include:

- Image tags within the SVG file. Everything must be declared using SVG's vector shapes.
- Pattern fills
- Gradients on strokes

## 33.6.8 Creating Databound Legends

Legends provide an explanatory table of the thematic map's styled data in symbol and label pairs. Thematic map legend components (`legend`) support symbols for color, shape, custom shape, fill pattern, opacity, images and size. One or more child legend item components (`legendSection`) are sourced from thematic map `area`, `marker`, `attributeGroups`, or `af:image` components stamped to style the data displayed in the map. The legend section structure supports control over content ordering and appearance. You can wrap legend items into a disclosable section using a `showLegendSection` component. [Figure 33–60](#) shows a legend with a disclosable section for map areas and a marker.

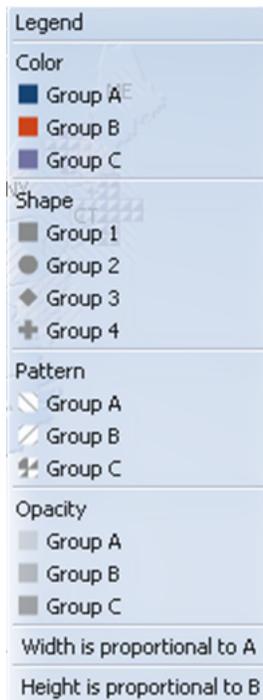

**Figure 33–60** Legend with Disclosable Section and Marker

Legend items sourced from the `attributeGroups` component automatically split area or marker attribute types into different sections. You can specify a separator facet

to draw separators between legend sections. [Figure 33–61](#) shows a legend with attribute groups for color, shape, fill pattern, opacity, and size with separators between each section.

**Figure 33–61 Legend with Attribute Groups**

Legends can be displayed in both Flash (default) and PNG image formats and both formats support bi-directional locales. When rendered in a PNG format, for example when printing the thematic map, disclosable sections in the legend are not supported, and legend items display as disclosed.

When you create a thematic map using the Data Controls panel and the thematic map binding dialogs, the legend data bindings are created for you. If you configure an area or marker as a default stamp across all areas in the thematic map, you can assign a static text resource to a fixed area or marker for the legend.

For default stamps displaying row-varying data, you can use an EL expression to assign the legend text and optionally, a managed bean to retrieve a row-varying key to look up the text resource in a resource bundle. [Example 33–32](#) shows a code sample to generate legend entries for area and marker stamps. The code illustrates a disclosable section for a row-varying area and a fixed marker with an assigned text resource.

**Example 33–32 Code Sample for Legend Area and Marker Stamps**

```
<dvt:thematicMap id="tm1" basemap="usa" ...>
 <dvt:legend label="Legend">
 <dvt:showLegendGroupLabel label="Voting Majority">
 <dvt:legendSection id="ls1" source="all:adl1:areaStamp"/>
 </dvt:showLegendGroupLabel>
 <dvt:legendSection id="ls2" source="all:adl1:fixedMarker">
 </dvt:legend>
 <dvt:areaLayer id="all" layer="states">
 <dvt:areaDataLayer id="adl1" ...>
 <dvt:areaLocation id="aloc1" , , ,>
 <dvt:area id="areaStamp">
```

```

 fillColor="#{row.value > 50 ? tmapLegendBean,color1 :
 tmapLegendBean.color2}"
 <f:attribute name="legendLabel" value="#{row.value > 50 ?
 'Candidate 2' : 'Candidate 1'}" />
 <dvt:marker id="fixedMarker" shape="human" fillColor="#FF9900"
 scaleX="3" scaleY="3">
 <f:attribute name="legendLabel"
 value="#{Bundle.Office_Locations}" />
 </dvt:marker>
</dvt:areaLocation>
</dvt:areaDataLayer>
</dvt:area>
</dvt:thematicMap>

```

If you configure an area or marker to use an attributes group to specify the styling of categorical groups of data in a data collection, you can use an EL expression to assign the legend text and optionally, a managed bean to retrieve a row-varying key to look up the text resource in a resource bundle.

If you specify a match rule for the attributes group, the legend text is specified in the group attribute. If you specify an exception rule, you can specify a text resource from the application resource bundle. [Example 33–33](#) shows sample code for a legend with attribute groups, including both a match rule and an exception rule, and specifying a separator between legend sections.

### **Example 33–33 Sample Code for Legend with Attribute Groups**

```

<dvt:thematicMap id="tm1" basemap="usa" ...>
 <dvt:legend id="l1" label="Legend">
 <f:facet name="separator"
 <af:separator/>
 <dvt:legendSection id="ls1" source="all:adl1:attributeGroupColor" />
 <dvt:legendSection id="ls2" source="all:adl1:attributeGroupShape" />
 <dvt:legendSection id="ls3" source="all:adl1:attributeGroupPattern" />
 <dvt:legendSection id="ls4" source="all:adl1:attributeGroupOpacity" />>
 </dvt:legend>
 <dvt:areaLayer id="all" layer="states">
 <dvt:areaDataLayer id="adl1" value=" " var=" " ...>
 <dvt:areaLocation id="dataLoc" name="#{row.name}">
 <dvt:marker id="m1"... >
 <dvt:attributeGroups id="attributeGroupColor" type="color"
 label="#{row.category1}" value="#{row.category1}" />
 <dvt:attributeMatchRule id="amr1" group="Mountain Dew">
 <f:attribute name="color" value="#ffff00" />
 </dvt:attributeMatchRule>
 <dvt:attributeGroups id="attributeGroupShape" type="shape"
 label="#{row.category2}" value="#{row.category2}" />
 <dvt:attributeExceptionRule id="aer1" condition="#{row.name=='TX'}"
 label="#{viewcontroller.Texas}">
 <f:attribute name="shape" value="human" />
 </dvt:attributeExceptionRule>
 <dvt:attributeGroups id="attributeGroupShape" type="pattern"
 label="#{row.category3}" ... />
 <dvt:attributeGroups id="attributeGroupShape" type="opacity"
 label="#{row.category4}" ... />
 </dvt:marker>
 </dvt:areaLocation>
 </dvt:areaDataLayer>
 </dvt:areaLayer>
</dvt:thematicMap>

```

You configure thematic map legend areas or markers in a custom region in the same way as any other map layer. shows sample code for a custom map layer legend.

**Example 33–34 Sample Code for Legend for Custom Map Layer**

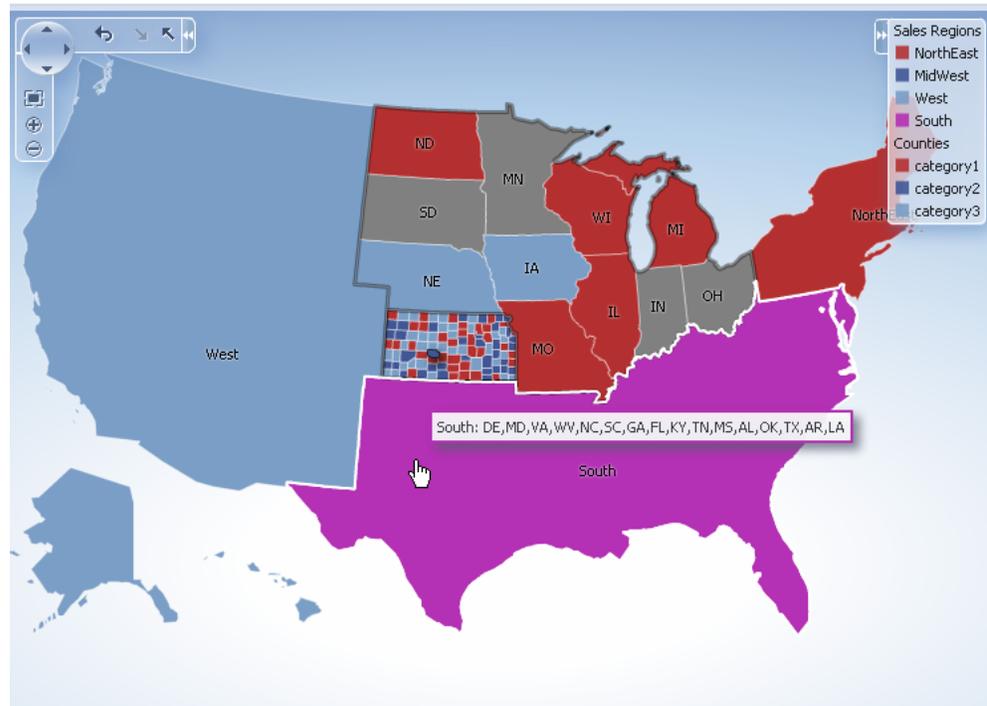

```
<dvt:thematicMap>
 <dvt:legend>
 <dvt:legendSection label="Sales Regions" source="customAreaStamp"/>
 </dvt:legend>
 ...
 <dvt:customAreaLayer id="crl1">
 ...
 </dvt:customAreaLayer>
 <dvt:areaLayer layer="crl1">
 <dvt:areaDataLayer var="row">
 <dvt:areaLocation name="{row.name}" id="all">
 <dvt:area id="customAreaStamp" fillColor="{row.color}">
 <f:attribute name="legendLabel" value="{row.name}"/>
 </dvt:area>
 </dvt:areaLocation>
 </dvt:areaDataLayer>
 </dvt:areaLayer>
</dvt:thematicMap>
```

You can customize the appearance of thematic map legends using ADF skins. For more information, see the "Customizing the Appearance Using Styles and Skins" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*

### 33.6.9 How to Define a Custom Map Layer

You can define a custom map layer from your own regional data and insert it into the natural geographical hierarchy of a thematic map. The custom layer is created by extending a predefined map layer and aggregating the lower level regions to form the new regions in the custom layer. After defining a custom map layer, it is used in the same way as any other map layer.

For example, you could define geographical regions for the NorthEast, Midwest, West and South in the United States in a US Regions custom map layer as illustrated in [Figure 33–62](#). In the figure, the US Regions custom layer is extended from the states layer in the US base map. The new areas in the layer are aggregated from the states in the states layer. The label for the South US Region lists the states in that region. The MidWest US Region is drilled down to display the sales categories in the lower level counties region. For more information about drilling, see [Section 33.6.5, "How to Configure Drilling in Thematic Maps."](#)

**Figure 33–62 US Regions Custom Map Layer**

The `customAreaLayer` component uses a model to access the data in the underlying list. The specific model class is `oracle.adf.view.rich.model.CollectionModel`. You can also use other model instances, for example, `java.util.List`, `java.util.Array`, and `javax.faces.model.DataModel`. The `customAreaLayer` will automatically convert the instance into a `CollectionModel`.

#### Before you begin:

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

You should already have an ADF data control or ADF managed bean that defines the aggregated areas in the predefined base map you are extending.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see [Section 33.6.1, "How to Create a Thematic Map Using ADF Data Controls."](#)

#### How to add and configure a custom map layer:

1. Select the thematic map in the Visual Editor.
2. In the Layer Browser, from the **Add** icon dropdown list, choose **Add Custom Layer** to open the Create Custom Layer dialog. If the Layer Browser is not open in the Visual Editor, right-click in the map and choose **Open Layer Browser**.
3. In the Create Custom Layer dialog, enter the following:
  - **Bind Data Now:** Select and click **Browse** to open the Picker dialog > Data Controls Definitions page. Select the data collection in the ADF data controls you are using to data bind your custom layer and areas.

---

---

**Note:** Alternatively, you can use the Expression Builder page to select an ADF managed bean you are using to databind your custom layer and areas. You can also use the Expression Builder dialog in each remaining field.

---

---

- **Layer Id:** Enter a unique identifier for the `customAreaLayer` component. For example, if you divide the US into aggregate regions (Northeast, Midwest, West, and South), then you might define them with corresponding Ids (NE, MW, W, and S).
- **Extends:** Use the search icon to display the built-in map layers that can be used to aggregate areas for the custom layer. Select the map layer that the custom layer will extend.
- **Area List:** Use the dropdown list to select the data collection attribute representing the list of lower level map regions that are used to aggregate the areas in the custom map layer. The comma separated list of values aggregate the regions in the may layer defined in the in the **Extends** attribute.
- **Area Id:** Use the dropdown list to select the data collection attribute representing the unique identifier of lower level map regions that are used to aggregate the areas in the custom map layer. By default, a unique identifier, `ca1`, `ca2`, and so on, is used in the for the `customArea` component.
- **Area Label:** Use the dropdown list to select the data collection attribute representing the names of lower level map regions that are used to aggregate the areas in the custom map layer. At runtime the label will display the comma separated list of the aggregated regions.

Figure 33–63 shows the completed Create Custom Layer dialog.

**Figure 33–63 Create Custom Layer Dialog**

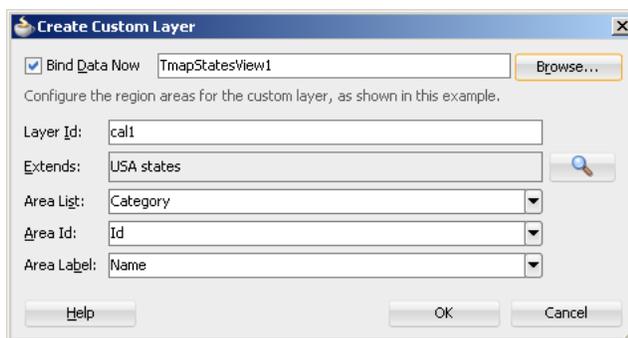

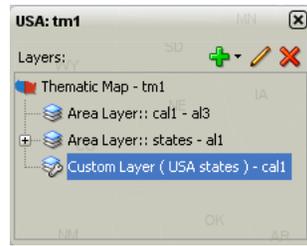

Figure 33–64 shows the Layer Browser after defining a custom layer. In the layer structure, the custom layer `ca11` is referenced in the map layer `a11`, where you add area or point data layers to display data. For more information, see [Section 33.6.4, "How to Add Data Layers to Thematic Maps."](#)

**Figure 33–64 Custom Map Layer in Layer Browser**

Example 33–35 shows the code inserted in the JSF page

**Example 33–35 Custom Map Layer Code**

```
<dvt:thematicMap>
...
<dvt:areaLayer layer="states" id="al1"/>
<dvt:areaLayer layer="cal1" id="al3"/>
<dvt:customAreaLayer id="cal1"
 value="#{bindings.TmapStatesView.collectionModel}"
 var="row"
 extendsLayer="states">
 <dvt:customArea areaId="#{row.RowID}" areaList="#{row.RowID}"
 label="#{row.RowID}" id="cal1"/>
</dvt:customAreaLayer>
...
</dvt:thematicMap>
```

After configuring and adding a custom layer to the map layer hierarchy, you can then use the map layer in the same way as any other map layer. For example, to create the thematic map illustrated in Figure 33–62, you will need to do the following:

- Configure the thematic map to support drilling. For more information, see [Section 33.6.5, "How to Configure Drilling in Thematic Maps."](#)

---

**Note:** If drilling is enabled for the thematic map, drilling between a custom layer and the map layer used to aggregate the custom layer is available without configuring data display for either layer.

---

- Add and configure an area data layer for the county data view. For more information, see [Section 33.6.4, "How to Add Data Layers to Thematic Maps."](#)
- Add and style area components to display the related data for each map layer. For more information, see [Section 33.6.7, "Styling Areas, Markers, and Images to Display Data."](#)
- Configure the thematic map legend. For more information, see [Section 33.6.8, "Creating Databound Legends."](#)

Example 33–36 shows sample code for using a custom layer in a thematic map.

**Example 33–36 Sample Code for Thematic Map with Custom Layer**

```
<dvt:thematicMap id="thematicMap" imageFormat="flash" basemap="usa" drilling="on"
 maintainDrill="true"
 controlPanelBehavior="initExpanded" summary="US Custom Regions">
 <dvt:customAreaLayer id="cr11" value="#{tmapRegions.collectionModel}" var="row"
 varStatus="rowStatus">
```

```

 extendsLayer="states">
 <dvt:customArea areaId="{row.name}" label="{row.name}"
 areaList="{row.regions}" id="ca1"/>
 </dvt:customAreaLayer>
 <dvt:areaLayer id="custom" layer="crl1">
 <dvt:areaDataLayer contentDelivery="immediate"
 value="{tmapRegions.collectionModel}"
 selectionMode="single"
 var="row" varStatus="rowStatus" id="adl1">
 <dvt:areaLocation name="{row.name}" id="al1">
 <dvt:area fillColor="{row.color}" shortDesc="{row.regions}"
 id="a1" value="{row.name}"/>
 </dvt:areaLocation>
 </dvt:areaDataLayer>
 </dvt:areaLayer>
 <dvt:areaLayer id="areaLayerS" layer="states">
 <dvt:areaDataLayer id="dataLayerS" selectionMode="multiple"
 contentDelivery="immediate"
 value="{tmapStates.collectionModel}" var="row"
 varStatus="rowStatus">
 <dvt:areaLocation id="areaLocS" name="{row.name}">
 <dvt:area id="area1S" fillColor="{row.color}"></dvt:area>
 </dvt:areaLocation>
 </dvt:areaDataLayer>
 </dvt:areaLayer>
 <dvt:areaLayer id="areaLayer" layer="counties">
 <dvt:areaDataLayer id="dataLayer" selectionMode="single"
 contentDelivery="immediate"
 value="{tmapCounty.collectionModel}" var="row"
 varStatus="rowStatus">
 <dvt:areaLocation id="areaLoc" name="{row.name}">
 <dvt:area id="area1" fillColor="{row.color}"
 value="{row.category}"></dvt:area>
 </dvt:areaLocation>
 </dvt:areaDataLayer>
 </dvt:areaLayer>
 <dvt:legend label="Sales Regions" id="l1">
 <dvt:legendSection source="custom:adl1:a1" id="ls1"/>
 <dvt:legendSection label="Counties" source="areaLayer:dataLayer:areaLoc"
 id="ls3"/>
 </dvt:legend>
</dvt:thematicMap>

```

## 33.7 Creating Databound Gantt Charts

A Gantt chart is a type of bar graph (with time on the horizontal axis). It is used in planning and tracking projects to show tasks or resources in a time frame with a distinct beginning and end.

When you create a Gantt chart, you can choose from the following types:

- Project
  - A project Gantt chart lists tasks vertically and shows the duration of each task as a bar on a horizontal time line.
- Resource Utilization

A resource utilization Gantt chart shows graphically whether resources are over or under allocated. It shows resources vertically while showing their allocation and, optionally, capacity on the horizontal time axis.

- Scheduling

A scheduling Gantt chart is based on manual scheduling boards and shows resources vertically with corresponding activities on the horizontal time axis. Examples of resources include people, machines, or rooms.

For information about customizing Gantt chart charts after data-binding is completed, see the "Using ADF Gantt Chart Components" chapter in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

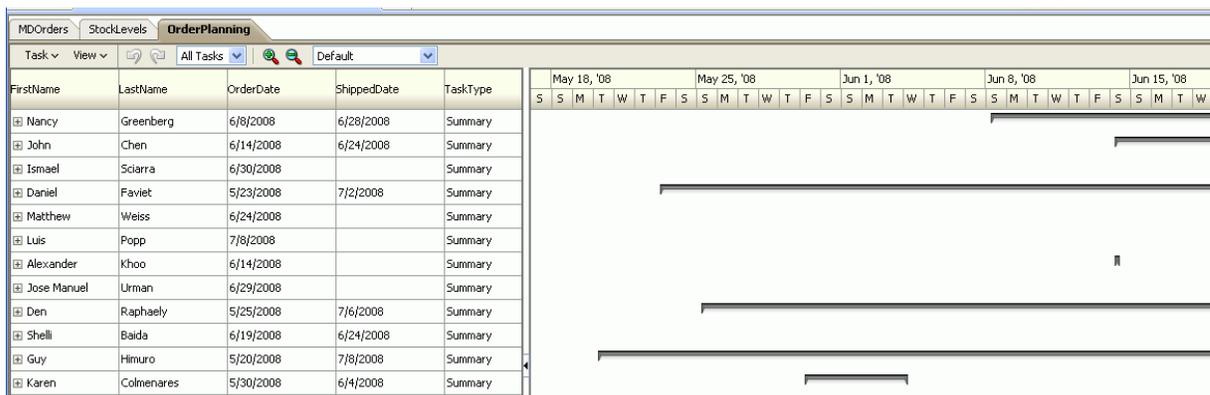

### 33.7.1 How to Create a Databound Project Gantt Chart

For a project Gantt chart, you must specify values for tasks. Optionally, you can specify values for split tasks, subtasks, recurring tasks, and dependencies between tasks, if your data collection has accessors for this additional information.

The project Gantt chart is displayed with default values for overall start time and end time and for the major and minor time axis values. In a project Gantt chart, the setting for the major time axis defaults to weeks and the setting for the minor time axis defaults to days.

Figure 33–65 shows a project Gantt chart in which each task is an order to be filled. The list region on the left side of the splitter shows columns with the name of the person who is responsible for the order and columns for the order date and shipped date. In the chart region on the right side of the splitter, the Gantt chart displays a horizontal bar from the order date to the ship date for each order.

**Figure 33–65 The Order Shipping Project Gantt Chart**

To create a project Gantt chart using a data control, you bind the project Gantt chart component to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

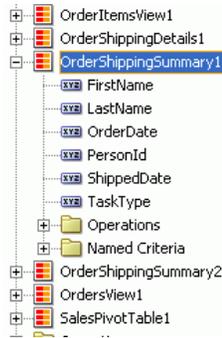

**Tip:** You can also create a project Gantt chart by dragging a project Gantt chart component from the Component Palette and completing the Create Project Gantt dialog. This approach allows you to design the Gantt chart user interface before binding the component to data.

**To create a databound project Gantt chart:**

1. From the Data Controls panel, select a data collection. For a Gantt chart, you can select a row set collection (which produces a flat list of tasks) or a basic tree collection (which produces a hierarchical list of tasks).

Figure 33–66 shows an example where you could select the `OrderShippingSummary1` collection in the Data Controls panel to create a project Gantt chart that displays the progress of order shipping.

**Figure 33–66 Data Collection for Shipping Orders**

2. Drag the collection onto a JSF page and, from the context menu, choose **Gantt > Project**.
3. In the ensuing Create Project Gantt dialog, you do the following to connect task-related controls in the pages at the top of the dialog with corresponding columns in the data collection:
  - a. In the Tasks page at the top of the dialog, you select the columns in the data collection that correspond to each of the following controls: **Task Id**, **Start Time**, and **End Time**. By clicking **Show More** in the dialog, you can select additional columns in the data collection that correspond to the following controls: **Actual Start**, **Actual End**, **% Complete**, **Completed Through**, **Critical**, and **Is Container**.

Optionally, you can select a column in the data collection to map to the task type. If you do not bind **Task Type** to a column in your data collection, then all tasks default to **Normal**. The task type controls the appearance of the task bar when it is rendered in the Gantt chart.

A project Gantt chart component supports the following task types that you configure the data collection to return: Summary, Normal, and Milestone.

- b. If the data collection has an accessor for subtasks, you have the option of using the Subtasks page in the dialog to select the subtasks accessor and to select the columns in the data collection that correspond to each of the following controls: **SubTask Id**, **Start Time**, and **End Time**. Optionally, you can select a column in the data collection to map to the subtask type. If you do not bind **SubTask Type** to data, then all subtasks default to **Normal**.

A project Gantt chart component supports the following task types that you configure the data collection to return: Summary, Normal, and Milestone.

If you do not bind subtasks, then the Gantt chart cannot render a hierarchy view of tasks. If you bind subtasks, then you can drill from tasks to subtasks in the hierarchy view of the Gantt chart.

- c. If the data collection has an accessor for dependent tasks, you have the option of using the **Dependent Tasks** page in the dialog to select the dependent task accessor and to select the columns in the data collection that correspond to the following controls: **Dependency Type**, **From Task Id**, and **To Task Id**.  
 Dependent tasks are linked by their dependency between their finish and start times.  
 A project Gantt chart component supports the following dependency types that you configure the data collection to return: *fs* (for finish to start), *ss* (for start to start), *ff* (for finish to finish), and *sf* (for start to finish).
  - d. If the data collection has an accessor for split tasks, you have the option of using the **Split Tasks** page in the dialog to select **Split Tasks** accessor and to select the columns in that data collection that correspond to each of the following controls: **SplitTask Id**, **Start Time**, and **End Time**.
  - e. If the data collection has an accessor for recurring tasks, you have the option of using the **Recurring Tasks** page in the dialog to select the recurring tasks accessor and to select the columns in that data collection that correspond to each of the following controls: **Recurring Task Id**, **Type**, **Start Time**, and **End Time**.
  - f. You can use the **Appearance** page in the dialog to specify the attributes that correspond to the **Label** of the task bar, and up to three icons to associate with the task bar.
4. In the **Table Columns** section, you specify the columns to appear in the list region of the Gantt chart. Specify one row of information for each column that is to appear. Use the **New** icon to add new rows. Use the arrow icons to arrange the rows in the exact sequence that you want the columns to appear in the Gantt chart list.

---

**Note:** The first row that you specify in the **Table Columns** section designates the nodestamp column for the list region. The nodestamp column is the one that you can expand or collapse when you have a subtask collection.

---

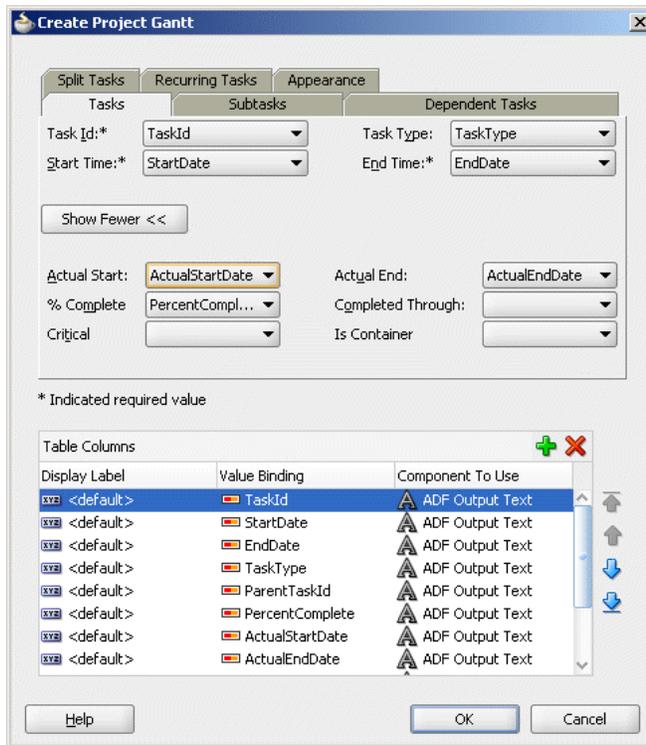

For each row, you provide the following specifications:

- **Display Label:** Select the values for the headers of the columns in the Gantt chart list. If you select **<default>**, then the text for the header is automatically retrieved from the data binding.
  - **Value Binding:** Select the columns in the data collection to use for the columns in the Gantt chart list. The available values are the same as those for the tasks group.
  - **Component to Use:** Select the type of component to display in the cell of the Gantt chart list. The default is the ADF Output Text component.
5. Click **OK**.
  6. If you want to include a legend in the Gantt chart, right-click the project Gantt chart node in the Structure window and choose **Insert inside dvt:projectGantt > Legend**.

The legend shows information about each symbol and color coded bar that is used to represent different task types. It also shows detailed information about the task that is selected in the Gantt chart.

Figure 33–67 shows the dialog used to create the project Gantt dialog from the data collection for shipping orders.

**Figure 33–67 Create Project Gantt Dialog for Orders Shipped**

After completing the data binding dialog, you can use the Property Inspector to specify values for additional attributes for the project Gantt chart.

### 33.7.2 What Happens When You Create a Project Gantt Chart from a Data Control

Dropping a project Gantt chart from the Data Controls panel has the following effect:

- Creates the bindings for the Gantt chart and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

Example 33–37 displays the row set bindings that were generated for the project Gantt chart that displays orders shipped. This code example shows that there are nodes defined for tasks and subtasks, along with attributes. There are also nodes defined for dependent tasks, split tasks, and recurring tasks but no attributes.

**Example 33–37 Bindings for a Project Gantt Chart**

```
<bindings>
 <gant IterBinding="OrderShippingSummary2Iterator" id="GanttProjectView1"
 xmlns="http://xmlns.oracle.com/adfm/dvt">
 <gantDataMap>
 <nodeDefinition DefName="oracle.fod.model.OrderShippingSummary"
 type="Tasks">
 <AttrNames>
 <Item Value="TaskId" type="taskId"/>
 <Item Value="StartDate" type="startTime"/>
 <Item Value="EndDate" type="endTime"/>
 </AttrNames>
 </nodeDefinition>
 </gantDataMap>
 </gant>
</bindings>
```

```

 <Item Value="TaskType" type="taskType"/>
 </AttrNames>
</nodeDefinition>
<nodeDefinition type="subTasks">
 <AttrNames/>
</nodeDefinition>
<nodeDefinition type="Dependents">
 <AttrNames/>
</nodeDefinition>
<nodeDefinition type="SplitTasks">
 <AttrNames/>
</nodeDefinition>
<nodeDefinition type="RecurringTasks">
 <AttrNames/>
</nodeDefinition>
</ganttDataMap>
</gantt>
</bindings>

```

**Example 33–38** shows the code generated on the JSF page for the ADF project Gantt chart. This tag code contains settings for the overall start and end time for the project Gantt chart. It also shows the default time axis settings for the major axis (in weeks) and the minor axis (in days). Finally, it lists the specifications for each column that appears in the list region of the Gantt chart. For brevity, the code in the `af:column` elements for `OrderStatusCode` and `ShippedDate` has been omitted.

**Example 33–38 Code on the JSF Page for a Project Gantt Chart**

```

<dvt:projectGantt id="projectGantt1"
 value="#{bindings.OrderShippingSummary2.projectGanttModel}"
 var="row"
 startTime="2011-04-15" endTime="2011-07-14">
 <f:facet name="major">
 <dvt:timeAxis scale="weeks" id="ta1"/>
 </f:facet>
 <f:facet name="minor">
 <dvt:timeAxis scale="days" id="ta2"/>
 </f:facet>
 <f:facet name="nodeStamp">
 <af:column
 sortProperty="#{bindings.OrderShippingSummary2.hints.FirstName.name}"
 sortable="false"
 headerText="#{bindings.OrderShippingSummary2.hints.FirstName.label}"
 id="c1">
 <af:outputText value="#{row.FirstName}" id="ot1"/>
 </af:column>
 </f:facet>
 <af:column sortProperty="LastName" sortable="false"
 headerText="#{bindings.OrderShippingSummary2.hints.LastName.label}">
 <af:outputText value="#{row.LastName}"/>
 </af:column>
 <af:column sortProperty="OrderDate" sortable="false"
 headerText="#{bindings.OrderShippingSummary2.hints.OrderDate.label}">
 <af:outputText value="#{row.OrderDate}">
 <af:convertDateTime
 pattern="#{bindings.OrderShippingSummary2.hints.OrderDate.format}"/>
 </af:outputText>
 </af:column>
 <af:column sortProperty="ShippedDate" sortable="false"
 headerText="#{bindings.OrderShippingSummary2.hints.ShippedDate.label}">

```

```

 <af:outputText value="#{row.ShippedDate}">
 <af:convertDateTime
 pattern="#{bindings.OrderShippingSummary2.hints.ShippedDate.format}"/>
 </af:outputText>
 </af:column>
 <af:column sortProperty="TaskType" sortable="false"
 headerText="#{bindings.OrderShippingSummary2.hints.TaskType.label}">
 <af:outputText value="#{row.TaskType}"/>
 </af:column>
</projectGantt>

```

### 33.7.3 What You May Need to Know About Summary Tasks in a Project Gantt Chart

A summary task shows start time and end time for a group of tasks (which are usually subtasks). A summary task cannot be moved or extended. However, your application should recalculate the summary task times when the dates of any subtask changes.

To detect a change in task duration, register an event handler by specifying a method binding expression on the `DataChangeListener` attribute of the Gantt chart component. When an action occurs that potentially changes data in the Gantt chart, the event fired is of type `oracle.adf.view.faces.bi.event.DataChangeEvent`. This event contains information about the data changes and is fired to the registered event listener. The listener is responsible for validating the new values and updating the underlying data model.

When the update is completed, the Gantt chart is refreshed with either the old data (if the update failed) or with the new data. The Gantt chart uses partial page rendering so that only the Gantt chart and not the entire page is refreshed.

### 33.7.4 What You May Need to Know About Percent Complete in a Project Gantt Chart

Percent complete can be represented as an inner bar that indicates what percentage of a task is complete. The length of the inner bar is calculated based on percent complete returned by the data object.

The data binding dialog for the project Gantt chart does not provide a control in which you can enter the percentage complete value, but this value is required to render a percent complete. However, the Gantt chart data object does contain a `percentComplete` attribute.

To provide the percent complete integer, you must add a new attribute mapping in the `nodeDefinition` for type `Tasks`. For example, if your data collection has a column named `PercentDone`, then the attribute mapping would appear as follows: `<Item Value="PercentDone" type="percentComplete"/>`.

[Example 33–39](#) shows the percent complete attribute mapping added to the data binding code for the `nodeDefinition` of type `Tasks` in the project Gantt chart binding displayed in [Example 33–37](#).

#### **Example 33–39 Bindings for Project Gantt Chart with Percent Complete**

```

<bindings>
 <nodeDefinition DefName="oracle.fod.model.OrderShippingSummary"
 type="Tasks">
 <AttrNames>
 <Item Value="PersonId" type="taskId"/>
 <Item Value="OrderDate" type="startTime"/>
 <Item Value="TaskType" type="taskType"/>
 <Item Value="ShippedDate" type="endTime"/>
 </AttrNames>
 </nodeDefinition>
</bindings>

```

```

 <Item Value="PercentDone" type="percentComplete"/>
 </AttrNames>
</nodeDefinition>
</bindings>

```

Another attribute (`completedThrough`) exists that allows you to specify a date rather than a percentage. The Gantt chart data object calculates the percentage complete based on the date that the `completedThrough` attribute references. For example, if your data collection has a column named `PercentDone`, then the attribute mapping would appear as follows: `<Item Value="PercentDone" type="completedThrough"/>`.

### 33.7.5 What You May Need to Know About Variance in a Project Gantt Chart

Variance can be rendered within two horizontal bars. One bar represents the base (or original) start and end time for the task. The second bar represents the actual start and end time for the task. You enter the binding information for the base start time and end time in the data binding dialog for a project Gantt chart.

The data binding dialog for Gantt chart does not provide controls in which you can enter the actual start time and actual end time for the Gantt chart, but these values are required to render variance. However, the Gantt chart data object does contain the following attributes: `actualStart` and `actualEnd`.

To provide the actual start and actual end time, you must add two new attribute mappings in the `nodeDefinition` for type `Tasks`. For example, if your data collection has columns named `ActualStartDate` and `ActualEndDate`, then the attribute mappings would appear as shown in [Example 33–40](#).

#### **Example 33–40 Attribute Mappings for Actual Start and Actual End**

```

<Item Value="ActualStartDate" type="actualStart"/>
<Item Value="ActualEndDate" type="actualEnd"/>

```

[Example 33–41](#) shows the actual start and actual end attribute mappings added to the data binding code for the `nodeDefinition` of type `Tasks` for a project Gantt chart.

#### **Example 33–41 Bindings for Project Gantt Chart with Actual Start and Actual End**

```

<nodeDefinition DefName="oracle.fod.model.OrderShippingSummary"
 type="Tasks">
 <AttrNames>
 <Item Value="PersonId" type="taskId"/>
 <Item Value="OrderDate" type="startTime"/>
 <Item Value="TaskType" type="taskType"/>
 <Item Value="ShippedDate" type="endTime"/>
 <Item Value="ActualStartDate" type="actualStart"/>
 <Item Value="ActualEndDate" type="actualEnd"/>
 </AttrNames>
</nodeDefinition>

```

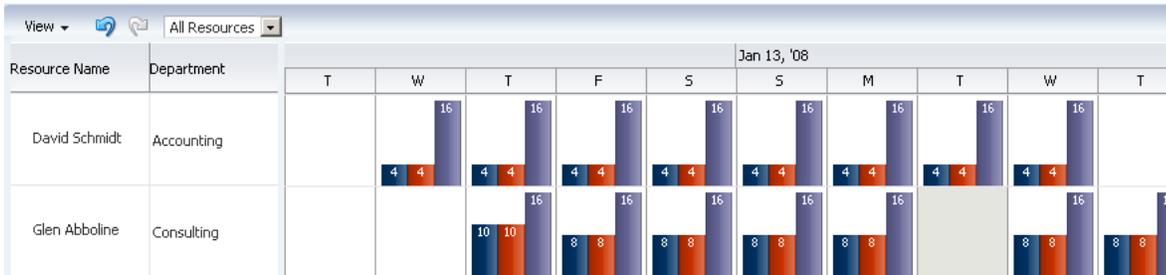

### 33.7.6 How to Create a Databound Resource Utilization Gantt Chart

For a resource utilization Gantt chart, you must supply identification for resources, identification for time, and start and end times for resource usage. Optionally, you can provide data values for subresources.

The resource utilization Gantt chart is displayed with default values for the major and minor time axis values. In a resource utilization Gantt chart, the setting for the major time axis defaults to weeks and the setting for the minor time axis defaults to days.

Figure 33–68 shows a resource utilization Gantt chart that lists each resource and an associated calendar that can display when the resource is in use.

**Figure 33–68 Resource Utilization Gantt Chart**

To create a resource utilization Gantt chart using a data control, you bind the resource utilization component to a data collection. JDeveloper allows you to do this declaratively by dragging a collection from the Data Controls panel and dropping it on a JSF page.

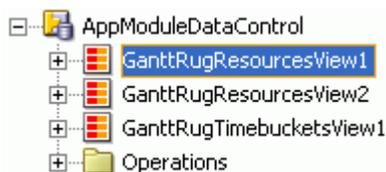

**Tip:** You can also create a resource utilization Gantt chart by dragging a resource utilization Gantt chart component from the Component Palette and completing the Create Resource Utilization Gantt dialog. This approach gives you the option of designing the Gantt chart user interface before binding the component to data.

**To create a resource utilization Gantt chart:**

1. From the Data Controls panel, select a data collection. For a Gantt chart, you can select a row set collection or a basic tree collection.

Figure 33–69 shows an example where you could select the GanttRugResourcesView1 collection in the Data Controls panel to create a resource utilization Gantt chart to display the usage of a resource.

**Figure 33–69 Data Collection for Resource Utilization**

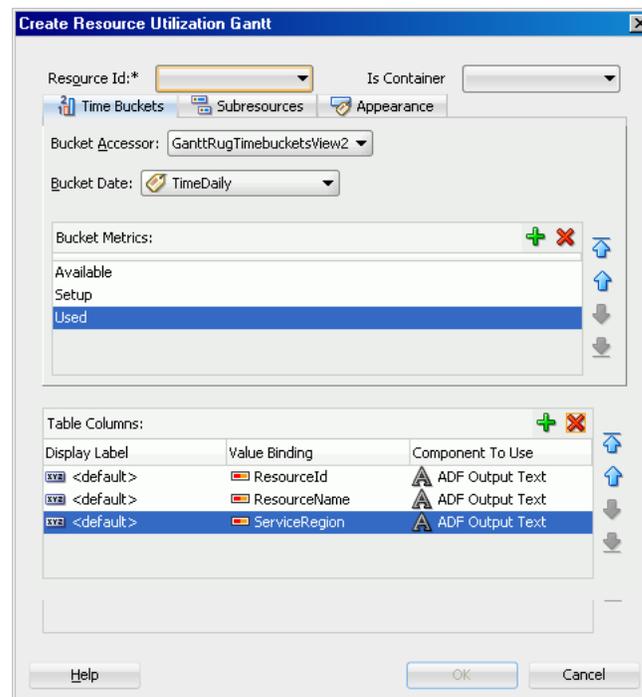

2. Drag the collection onto a JSF page and, from the context menu, choose **Gantt > Resource Utilization**.
3. In the Create Resource Utilization Gantt dialog, connect resource- and time-related controls with corresponding columns in the data collection.
  - a. For **Resource Id**, select the column in the data collection that corresponds to the unique identifier of the resource.

- b. In the **Time Buckets** page, select a value from the **Bucket Accessor** dropdown list that contains the time buckets assigned to the resource and select a value from the **Bucket Date** dropdown list that corresponds to a unit of time.
  - c. In the **Bucket Metrics** list, you can optionally specify attributes that appear as bars within the time bucket. Each attribute that you specify in the **Bucket Metrics** list must be of type Number as the value of the attribute is used to calculate the height of the bar.
  - d. In the **Table Columns** list, specify the column(s) to appear in the list region of the Gantt chart resource utilization on the left side of the splitter. Specify one row of information for each column that is to appear. Use the New icon to add new rows. Use the arrow icon to arrange the rows in the exact sequence that you want the columns to appear in the resource utilization list. For each row, provide values for **Display Label**, **Value Binding**, and **Component to Use**.
  - e. If the data collection has an accessor for subresources, you can use the **Subresources** page to select a subresources accessor and a resource ID.
4. Click OK.

Figure 33–70 shows the dialog used to create a resource utilization Gantt chart from the data collection for resources available for a project.

**Figure 33–70 Create Resource Utilization Gantt Chart**

### 33.7.7 What Happens When You Create a Resource Utilization Gantt Chart

Dropping a resource utilization Gantt chart from the Data Controls panel onto a JSF page has the following effects:

- Creates bindings for the resource utilization Gantt chart and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

[Example 33–42](#) shows the row set bindings that were generated for the resource utilization Gantt chart illustrated in [Figure 33–70](#).

**Example 33–42 Binding XML for a Resource Utilization Gantt Chart**

```
<gantt IterBinding="GanttRugResourcesView2Iterator"
 id="GanttRugResourcesView2"
 xmlns="http://xmlns.oracle.com/adfm/dvt">
 <ganttDataMap>
 <nodeDefinition DefName="model.GanttRugResourcesView" type="Resources">
 <AttrNames>
 <Item Value="ResourceId" type="resourceId" />
 </AttrNames>
 <Accessors>
 <Item Value="GanttRugTimebucketsView2" type="timeBuckets" />
 </Accessors>
 </nodeDefinition>
 <nodeDefinition type="TimeBuckets"
 DefName="model.GanttRugTimebucketsView">
 <AttrNames>
 <Item Value="TimeDaily" type="time" />
 <Item type="metric" Value="Available" />
 <Item type="metric" Value="Setup" />
 <Item type="metric" Value="Used" />
 </AttrNames>
 </nodeDefinition>
 <nodeDefinition type="Subresources">
 <AttrNames />
 </nodeDefinition>
</ganttDataMap>
</gantt>
```

[Example 33–43](#) shows the code generated on the JSF page for the resource utilization Gantt chart. This tag code contains settings for the overall start and end time for the resource utilization Gantt chart. These settings have to be edited manually. The code also shows the time axis settings for the major time axis (in weeks) and the minor time axis (in days). Finally, it lists the specifications for each column to appear in the list region of the resource utilization Gantt chart.

**Example 33–43 Code on the JSF Page for a Resource Utilization Gantt Chart**

```
<dvt:resourceUtilizationGantt id="resourceUtilizationGantt1"
 value="#{bindings.GanttRugResourcesView2.
 resourceUtilizationGanttModel}"
 var="row"
 metrics="#{bindings.GanttRugResourcesView2.metrics}"
 taskbarFormatManager="#{bindings.
 GanttRugResourcesView2.
 resourceUtilizationGanttTaskbarFormatManager}"
 startTime="2011-02-03"
 endTime="2011-02-29">
 <f:facet name="major">
 <dvt:timeAxis scale="weeks" />
 </f:facet>
 <f:facet name="minor">
 <dvt:timeAxis scale="days" />
 </f:facet>
 <f:facet name="nodeStamp">
 <af:column sortProperty="ResourceId" sortable="false">
```

```

 headerText="#{bindings.GanttRugResourcesView2.hints.ResourceId.label}">
 <af:outputText value="#{row.ResourceId}" />
 </af:column>
</f:facet>
<af:column sortProperty="ResourceName" sortable="false"
 headerText="#{bindings.GanttRugResourcesView2.hints.ResourceName.label}">
 <af:outputText value="#{row.ResourceName}" />
</af:column>
<af:column sortProperty="ServiceRegion" sortable="false"
 headerText="#{bindings.GanttRugResourcesView2.hints.ServiceRegion.label}">
 <af:outputText value="#{row.ServiceRegion}" />
</af:column>
</dvt:resourceUtilizationGantt>

```

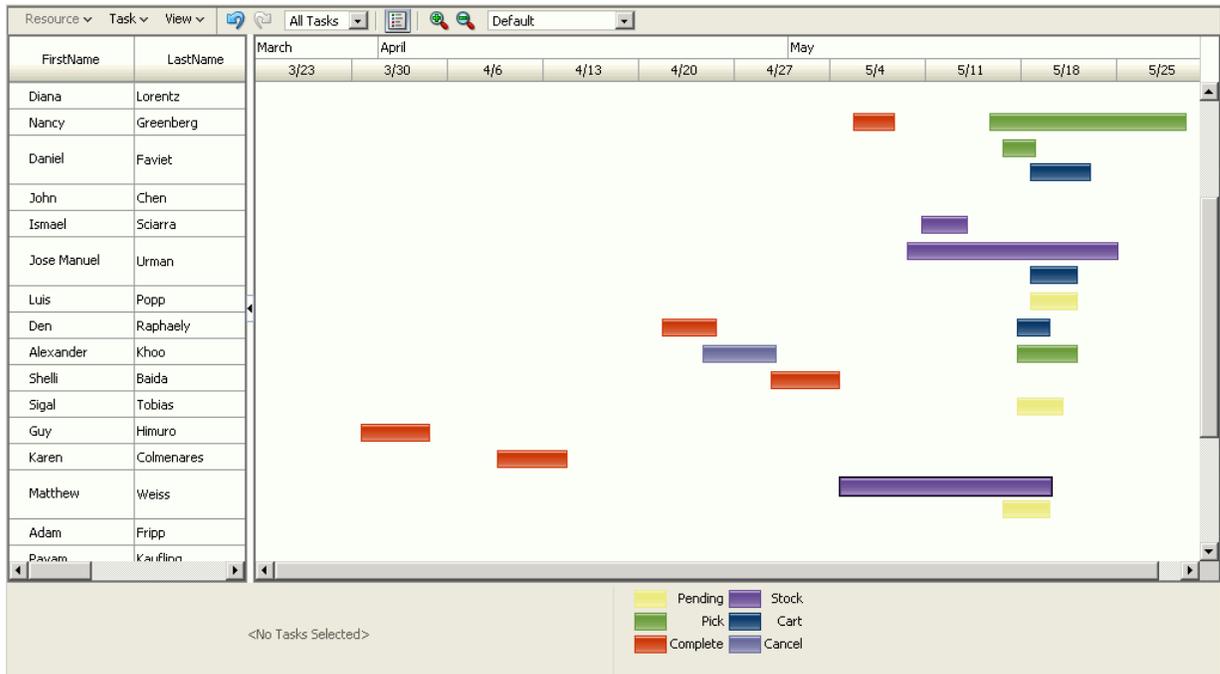

### 33.7.8 How to Create a Databound Scheduling Gantt Chart

For a scheduling Gantt chart, you must supply identification for resources, identification for tasks, and start and end times for tasks. Optionally, you can provide data values for subresources, recurring tasks, split tasks, and dependencies between tasks.

The scheduling Gantt chart is displayed with default values for overall start and end time and for the major and minor time axis values. In a scheduling Gantt chart, the setting for the major time axis defaults to weeks and the setting for the minor time axis defaults to days.

Figure 33–71 shows a scheduling Gantt chart that lists each resource and all the orders for which that resource is responsible. In contrast to a project Gantt chart, the scheduling Gantt chart shows all the tasks for a given resource on the same line, while the project Gantt chart lists each task on a separate line.

**Figure 33–71** The Scheduling Gantt Chart for Order Shipping

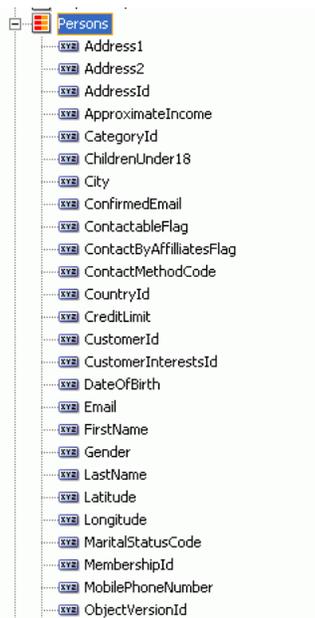

To create a scheduling Gantt chart using a data control, you bind the `schedulingGantt` tag to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

**To create a databound scheduling Gantt chart:**

1. From the Data Controls panel, select a data collection. For a Gantt chart, you can select a row set collection or a basic tree collection.

Figure 33–72 shows an example where you could select the `Persons` data collection to create a scheduling Gantt chart that displays the orders that each resource is responsible for.

**Figure 33–72 Data Collection for Resources**

2. Drag the collection onto a JSF page and, from the context menu, choose **Gantt**, then **Scheduling**.
3. In the ensuing Create Scheduling Gantt dialog, you do the following to connect resource- and task-related controls at the top of the dialog with corresponding columns in the data collection:
  - a. For **Resource Id**, select the column in the data collection that corresponds to the unique identifier of the resource.
  - b. In the Tasks page select a value from the **Task Accessor** dropdown list that contains the tasks assigned to the resource. Select the columns in the data collection that correspond to each of the following controls: **Task Id**, **Start Time**, and **End Time**. You can optionally specify a data column to map to task type. If you do not bind task type to data, then all task types default to **Normal**.
  - c. If the data collection has an accessor that holds dependent tasks, you have the option of using the Dependent Tasks page in the dialog to select the dependent tasks accessor and to select the columns in that data collection that correspond to each of the following controls: **Dependency Type**, **From Task Id**, and **To Task Id**.

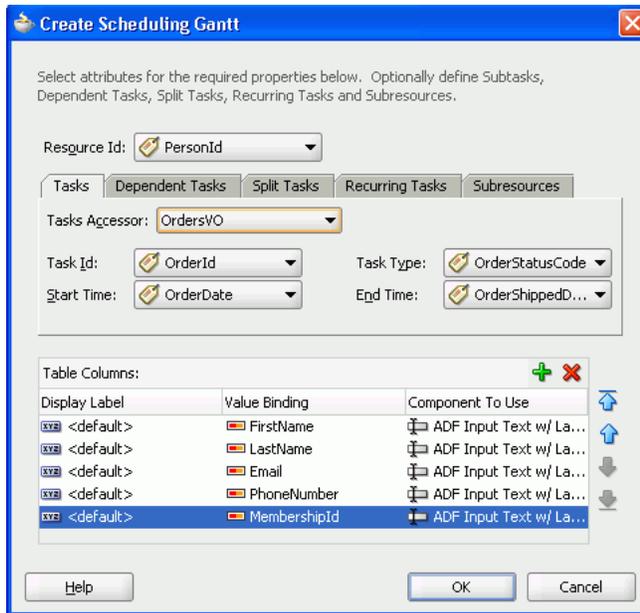

- d. If the data collection has an accessor for split tasks, you have the option of using the Split Tasks page in the dialog to select the split tasks accessor and to select the columns in that data collection that correspond to each of the following controls: **Split Task Id**, **Start Time**, and **End Time**.
  - e. If the data collection has an accessor for recurring tasks, you have the option of using the Recurring Tasks page in the dialog to select the Recurring Tasks accessor and to select the columns in that data collection that correspond to each of the following controls: **Recurring Task Id**, **Type**, **Start Time**, and **End Time**.
  - f. If the data collection has an accessor for subresources (lower-level resources), you have the option of using the Subresources page to specify the appropriate accessor and to select the data column that contains the unique identifier of the subresource.
 

For example, a manager might be a resource and his direct reports might be subresources. If data contains subresources, then you can drill in a resource to locate subresources.
4. In the **Table Columns** section, you specify the columns that will appear in the list region of the Gantt chart on the left side of the splitter. Specify one row of information for each column that is to appear. Use the **New** icon to add new rows. Use the arrow icon to arrange the rows in the exact sequence that you want the columns to appear in the Gantt chart list. For each row, you provide the following specifications:
    - **Display Label:** Select the values for the headers of the columns in the Gantt chart list. If you select `<default>`, then the text for the header is automatically retrieved from the data binding.
    - **Value Binding:** Select the columns in the data collection to use for the column in the Gantt chart list. The available values are the same as those for the tasks group.
    - **Component to Use:** Select the type of component to display in the cell of the Gantt chart list. The default is the **ADF Output Text** component.
  5. Click **OK** to dismiss the Create Scheduling Gantt dialog.
  6. Select the `dvt:schedulingGantt` element in the Structure window of the JSF page and set dates for the following attributes of the `dvt:schedulingGantt` element in the Property Inspector:
    - `StartTime`
    - `EndTime`

The dates that you specify determine the initial view that appears in the scheduling Gantt chart at runtime.

[Figure 33–73](#) shows the dialog used to create the scheduling Gantt chart from the data collection for resources responsible for shipping orders.

**Figure 33–73 Create Scheduling Gantt Dialog**

### 33.7.9 What Happens When You Create a Scheduling Gantt Chart

Dropping a scheduling Gantt chart from the Data Controls panel has the following effect:

- Creates the bindings for the Gantt chart and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

[Example 33–44](#) shows the row set bindings that were generated for the scheduling Gantt chart that displays resources and orders shipped.

**Example 33–44 Binding XML for a Scheduling Gantt Chart**

```
<gantt IterBinding="PersonsIterator" id="Persons"
 xmlns="http://xmlns.oracle.com/adfm/dvt">
 <ganttDataMap>
 <nodeDefinition DefName="oracle.fodemo.storefront.store.queries.PersonsVO"
 type="Resources">
 <AttrNames>
 <Item Value="PersonId" type="resourceId"/>
 </AttrNames>
 <Accessors>
 <Item Value="OrdersVO" type="tasks"/>
 </Accessors>
 </nodeDefinition>
 <nodeDefinition type="Tasks"
 DefName="oracle.fodemo.storefront.store.queries.OrdersVO">
 <AttrNames>
 <Item Value="OrderId" type="taskId"/>
 <Item Value="OrderDate" type="startTime"/>
 <Item Value="OrderStatusCode" type="taskType"/>
 <Item Value="OrderShippedDate" type="endTime"/>
 </AttrNames>
 </nodeDefinition>
 <nodeDefinition type="Dependents">
```

```

 <AttrNames/>
 </nodeDefinition>
 <nodeDefinition type="SplitTasks">
 <AttrNames/>
 </nodeDefinition>
 <nodeDefinition type="RecurringTasks">
 <AttrNames/>
 </nodeDefinition>
 <nodeDefinition type="Subresources">
 <AttrNames/>
 </nodeDefinition>
</ganttDataMap>
</gantt>

```

**Example 33–45** shows the code generated on the JSF page for the scheduling Gantt chart. This tag code contains settings for the overall start and end time for the scheduling Gantt chart. It also shows the time axis settings for the major time axis (in months) and the minor time axis (in weeks). Finally, it lists the specifications for each column that appears in the list region of the Gantt chart. For brevity, the code in the `af:column` elements for `MembershipId`, `Email`, and `PhoneNumber` has been omitted.

**Example 33–45 Code on the JSF Page for a Scheduling Gantt Chart**

```

<dvt:schedulingGantt id="schedulingGantt1"
 value="#{bindings.Persons.schedulingGanttModel}"
 var="row" startTime="2011-03-29"
 endTime="2011-05-30"
 taskbarFormatManager="#{GanttBean.taskbarFormatManager}">
 <f:facet name="major">
 <dvt:timeAxis scale="months"/>
 </f:facet>
 <f:facet name="minor">
 <dvt:timeAxis scale="weeks"/>
 </f:facet>
 <f:facet name="nodeStamp">
 <af:column sortProperty="FirstName" sortable="false"
 headerText="#{bindings.Persons.hints.FirstName.label}">
 <af:outputText value="#{row.FirstName}"/>
 </af:column>
 </f:facet>
 <af:column sortProperty="LastName" sortable="false"
 headerText="#{bindings.Persons.hints.LastName.label}">
 <af:outputText value="#{row.LastName}"/>
 </af:column>
 ...
 <dvt:ganttLegend/>
</dvt:schedulingGantt>

```

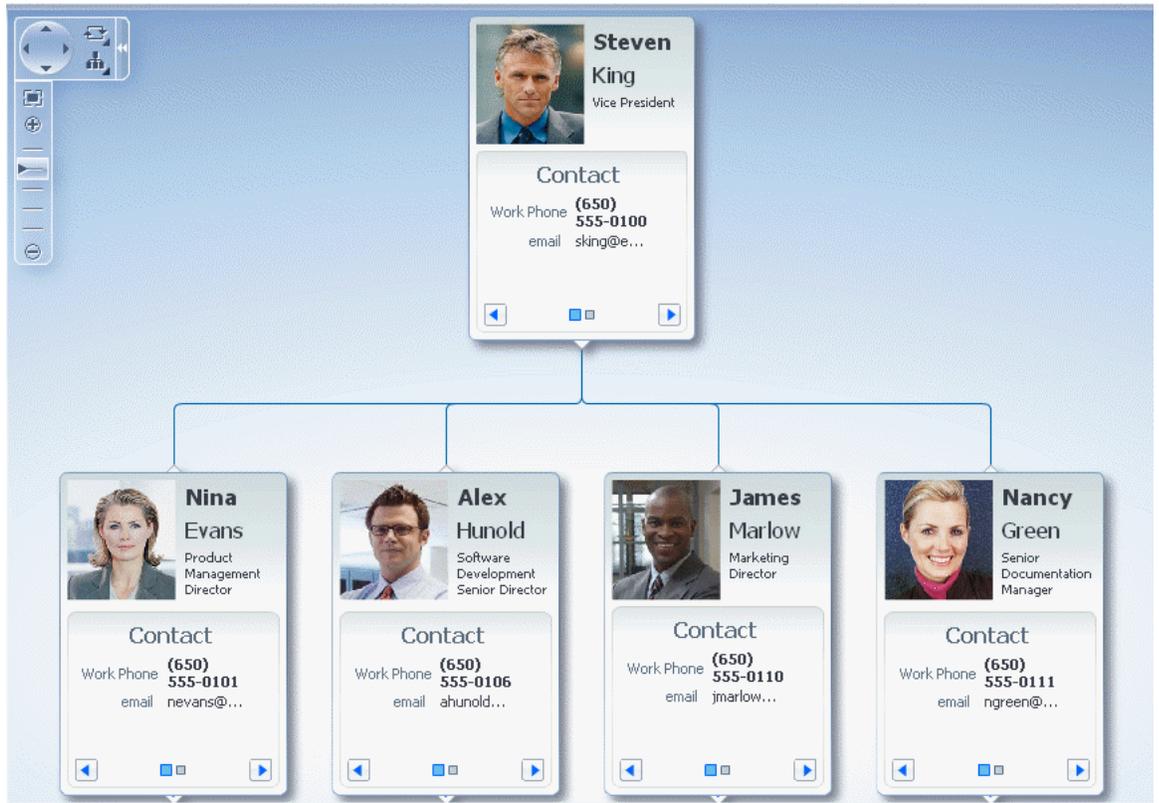

## 33.8 Creating Databound Hierarchy Viewers

A hierarchy viewer is an ADF Data Visualization component that visually displays data where parent-child relationships exist within the data. This component is useful where you want to display organization charts, network diagrams, social networks, or similar visual displays.

Hierarchy viewers use a shape called a *node* to reference the data in a hierarchy. The shape and content of the nodes is configurable, as well as the visual layout of the nodes. Nodes can display multiple views in a panel card.

Figure 33–74 shows a runtime view of a hierarchy viewer component that renders an organization chart.

**Figure 33–74 Hierarchy Viewer Component Rendering an Organization Chart**

Each hierarchy viewer component (`dvt:hierarchyViewer`) that you create can include:

- One or more node elements (`dvt:node`)
- One or more link elements (`dvt:link`)

The optional panel card element (`dvt:panelCard`) can be used in conjunction with the hierarchy viewer component. The panel card provides a method to dynamically switch between multiple sets of content referenced by a node element using animation by, for example, horizontally sliding the content or flipping a node over.

For detailed information about hierarchy viewer end user and presentation features, use cases, tag structure, and adding special features to hierarchy viewers, see the "Using ADF Hierarchy Viewer Components" chapter in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 33.8.1 How to Create a Hierarchy Viewer Using ADF Data Controls

Hierarchy viewers are based on data collections where a master-detail relationship exists between one or more detail collections and a master data collection. Using data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop a

data collection from the Data Controls panel that generates one or more root nodes onto a JSF page.

**Before you begin:**

It may be helpful to have an understanding of how hierarchy viewer attributes and hierarchy viewer child tags can affect functionality. For more information, see the "Configuring Hierarchy Viewers" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

You should already have an ADF data control or ADF managed bean that represents the data you wish to display in the hierarchy viewer.

**To create a hierarchy viewer using the Data Controls panel:**

1. From the Data Controls panel, select a collection.

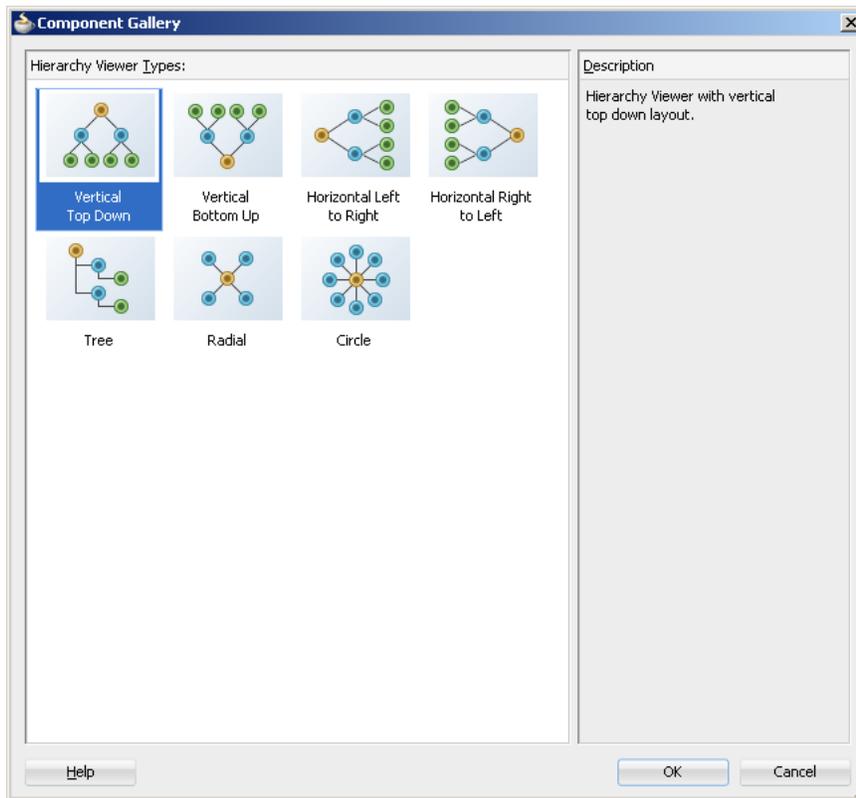

Figure 33–75 shows an example where you could select the `HvtestView1` collection in the Data Controls panel to create a hierarchy viewer representing the personnel data in an organizational chart.

**Figure 33–75 Data Collection for Personnel Organizational Chart**

2. Drag the collection onto a JSF page and, from the context menu, choose **Hierarchy Viewer**.
3. From the Component Gallery, select the layout of the hierarchy viewer you want to create. Figure 33–76 shows the Component Gallery with the vertical top down layout selected.

**Figure 33–76 Hierarchy Viewer Component Gallery**

4. In the Create Hierarchy Viewer dialog, enter the following:
  - **Hierarchy:** Select the collections you want to include as nodes in the runtime diagram. By default, the root collection is selected.
  - **Node:** For each collection that you select in the Hierarchy list, configure the attributes in the Title Area, and the title and attributes in each panel card, using one or more of the zoom levels available to you. By default, the node for the 100% zoom level follows an algorithm that:
    - Assigns the first three attributes in the data collection to the **Title Area**.
    - Assigns the next two attributes to the first panel card.
    - Assigns the following two attributes to the second panel card, and so on until all attributes are assigned to a panel card.

Click the **New** icon to add a new panel card, attribute, or image to the node, relative to your selection in the node. After selecting an existing element, use the arrow icons (**Up**, **Down**, **Top**, **Bottom**) to reorder the element, or use the **Delete** icon to delete the selected element.

Select a panel card, attribute, or image to configure one or more of the following for that element:

- **Text:** Available for panel card elements. Not available for the **Title Area** element. Enter text for the panel card title in the hierarchy, or choose **Select Text Resource** from the dropdown list to open a dialog to select or add a text resource to use for the title. The text resource is a translatable string from an application resource bundle. If you need help, press **F1** or click **Help**.

- **Attribute:** Available for attribute and image elements. From the dropdown list, select the attribute in the data collection that represents the value you wish to display in the hierarchy viewer node.
- **Label:** Available for attributes. Not available for default attributes assigned to the Title Area. From the dropdown list, select the attribute in the data collection that represents the label you wish to display for that element in the hierarchy viewer node. You can use the default **Use Attribute Name** to render the value as a string using the label from the UIHints for that attribute in the underlying `ViewObject`, select **No Label** to render no label for the attribute, or choose **Select Text Resource** to open a Select Text Resource dialog to select or add a text resource to use for the label. The text resource is a translatable string from an application resource bundle.
- **Component:** Available for attributes. Select the type of component to use to display the data in the node. Valid values are: **ADF Output Text/w label**, **ADF Output Text**, **ADF Output Formatted Text w/ Label**, and **ADF Output Formatted Text**. For more information about using these components, see the "Using Output Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

Use the 75%, 50%, and 25% pages to specify the expanded display of the hierarchy at each page level. Select **Add Zoom Level** to enable the page level. By default, the algorithms to assign node attributes and panel cards in the node are similar to the 100% zoom level.

---

**Note:** The hierarchy viewer component defines four zoom levels. You cannot modify these zoom levels or create new zoom levels. The default zoom level is 100%.

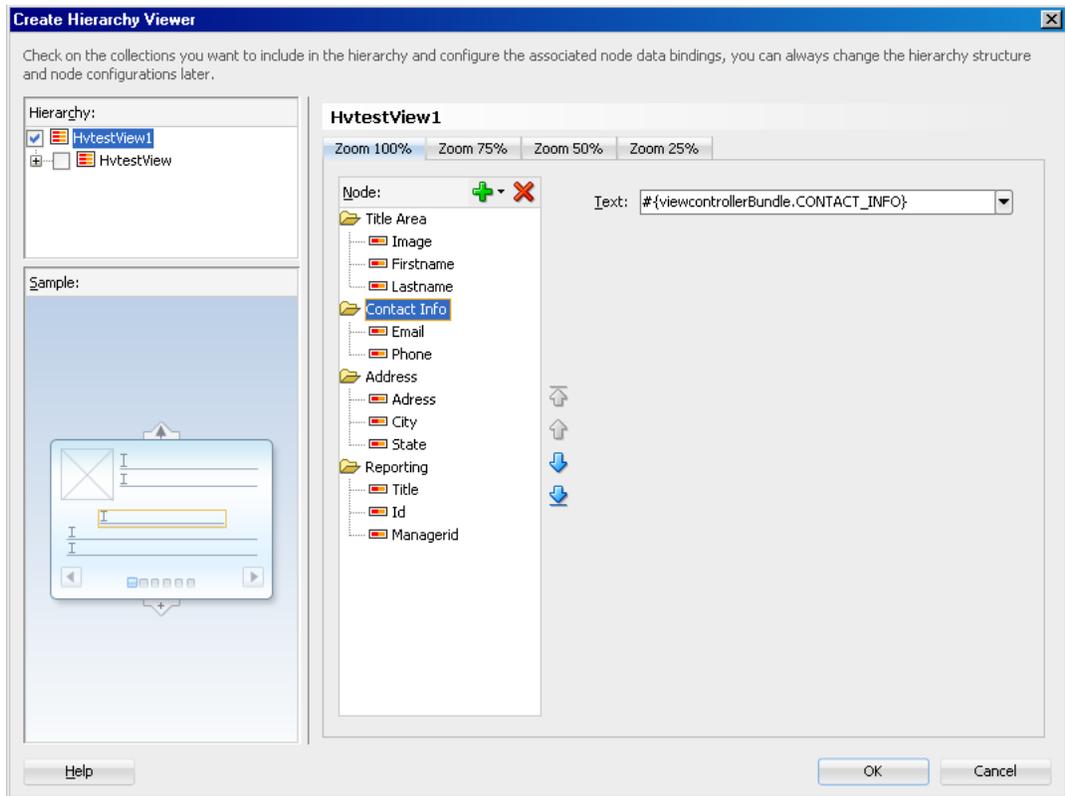

---

- **Sample:** A non-configurable display of the sample outline of the hierarchy viewer node. Areas such as Title Area and attributes are highlighted in the sample when selected in the node area.

5. Click **OK**.

Figure 33-77 shows the Create Hierarchy Viewer dialog that appears if you create a hierarchy viewer using data from a data collection named `HvtestView1`.

**Figure 33–77 Create Hierarchy Viewer Dialog**

After completing the Create Hierarchy Viewer dialog, you can use the Property Inspector to specify settings for the hierarchy viewer attributes and you can also use the child tags associated with the hierarchy viewer tag to customize the hierarchy viewer further.

When editing the hierarchy viewer in the visual editor, the display approximates the runtime display and functionality. You can move between panel cards, and work with stamped elements within the panel cards and title area to rearrange attributes or bind new attributes imported from the Data Controls panel.

### 33.8.2 What Happens When You Create a Databound Hierarchy Viewer

Creating a hierarchy viewer from Data Controls panel has the following effect:

- Creates the bindings for the hierarchy viewer in the page definition file of the JSF page
- Adds the necessary tags to the JSF page for the hierarchy viewer component

[Example 33–46](#) displays bindings that JDeveloper generated for a hierarchy viewer component. The rules for populating the nodes of the master-detail tree are defined as a node definition. The example shows that two node definitions were generated. Each of these node definitions references a view object and associated attributes. The code example also references an accessor `HvtestView`.

**Example 33–46 Bindings for a Hierarchy Viewer**

```
<tree IterBinding="HvtestView1Iterator" id="HvtestView1">
 <nodeDefinition DefName="model.HvtestView"> Name="HvtestView10">
 <AttrNames>
```

```

 <Item Value="Adress"/>
 <Item Value="Email"/>
 <Item Value="Lastname"/>
 <Item Value="Thumburl"/>
 <Item Value="Firstname"/>
 <Item Value="Title"/>
 <Item Value="Managerid"/>
 <Item Value="Id"/>
 <Item Value="Phone"/>
 <Item Value="City"/>
 <Item Value="State"/>
 </AttrNames>
 <Accessors>
 <Item Value="HvtestView"/>
 </Accessors>
</nodeDefinition>
<nodeDefinition DefName="model.HvtestView">
 <AttrNames>
 <Item Value="Adress"/>
 <Item Value="Email"/>
 <Item Value="Lastname"/>
 <Item Value="Thumburl"/>
 <Item Value="Firstname"/>
 <Item Value="Title"/>
 <Item Value="Managerid"/>
 <Item Value="Id"/>
 <Item Value="Phone"/>
 <Item Value="City"/>
 <Item Value="State"/>
 </AttrNames>
 <Accessors>
 <Item Value="ManageridHvtestView"/>
 </Accessors>
</nodeDefinition>
</tree>

```

**Example 33–47** shows the code generated on the JSF page that is associated with the page definition file in **Example 33–46**. For brevity, the code in the facet elements named `zoom75`, `zoom50`, and `zoom25` has been omitted. Some code from elements such as `<af:panelGroupLayout>`, `<af:spacer/>`, and `<af:separator/>` has also been omitted.

The example shows a hierarchy viewer component that references the `HvtestView1` tree binding. It includes a node (`dvt:node`) component that in turn includes a panel card component (`dvt:panelCard`). The panel card component defines `slide_horz` as the effect to use when changing the display of content referenced by the node.

Once you create your hierarchy viewer, you can modify the layout of the component or add additional components, such as a panel card, using the Create Hierarchy dialog illustrated in **Figure 33–77**. To open the dialog, use the **Edit** icon in the Property Inspector for the `hierarchyViewer` component. You can also customize the layout of a hierarchy viewer component directly in the code, in the visual editor, or by setting values in the Property Inspector. You can add additional components, such as panel card, using the Component Palette.

**Example 33–47 Code on the JSF Page for a Hierarchy Viewer**

```

<dvt:hierarchyViewer inlineStyle="width:100%;height:600px;" id="hv1" var="node"
 value="#{bindings.HvtestView1.treeModel}"
 selectionListener="#{bindings.HvtestView1.

```

```

 treeModel.makeCurrent}"
 featuresOff="nodeDetail" layout="hier_vert_top"
 levelFetchSize="#{bindings.HvtestView1.rangeSize}"
 summary="Employee Organizational Chart"/>
<dvt:link linkType="orthogonalRounded" id="l1"/>
<dvt:node type="model.HvtestView" width="233" height="233" id="n1">
 <f:facet name="zoom100">
 <af:image source="#{node.Image}" inlineStyle="width:85px;height:120px;"
 inlineStyle="font-weight:bold;font-size:14px"
 id="ot1"/>
 <af:outputText value="#{node.Firstname}"
 inlineStyle="font-size:14px"
 id="ot2"/>
 <af:outputText value="#{node.Lastname}"
 inlineStyle="font-style:italic;font-size:14px"
 id="ot3"/>
 <dvt:panelCard effect="slide_horz" id="pc1">
 <af:showDetailItem text="#{viewControllerBundle.CONTACT_INFO}"
 id="sdi1">
 <af:panelFormLayout inlineStyle="padding:5px;" id="pf11">
 <af:goLink text="#{viewControllerBundle.EMAIL}"
 destination="mailto:#{node.bindings.Email.inputValue}"/>
 <af:panelLabelAndMessage label="#{viewControllerBundle.PHONE_NUMBER}"
 labelStyle="font-size:14px;color:#5A6A7A"
 id="plam3">
 <af:outputText value="#{node.Phone}"
 inlineStyle="font-size:14px;color:#383A47" id="ot5"/>
 </af:panelLabelAndMessage>
 </af:panelFormLayout>
 </af:showDetailItem>
 <af:showDetailItem text="#{viewControllerBundle.REPORTING}" id="sdi2">
 <af:panelFormLayout inlineStyle="padding:5px;" id="pf12">
 <af:outputText value="#{node.Title}"
 inlineStyle="font-size:14px"
 id="ot6"/>
 <af:panelLabelAndMessage label="#{viewControllerBundle.MANAGER}"
 labelStyle="font-size:14px"
 id="plam4">
 <af:outputText value="#{node.Managerid}"
 inlineStyle="font-size:14px;color:#383A47" id="ot7">
 <af:convertNumber groupingUsed="false"
 pattern="#{bindings.HvtestView1.hints.Managerid.format}"/>
 </af:outputText>
 </af:panelLabelAndMessage>
 <af:panelLabelAndMessage label="#{viewControllerBundle.EMPLOYEE_ID}"
 labelStyle="font-size:14px" id="plam5">
 <af:outputText value="#{node.Id}"
 inlineStyle="font-size:14px" id="ot8">
 <af:convertNumber groupingUsed="false"
 pattern="#{bindings.HvtestView1.hints.Id.format}"/>
 </af:outputText>
 </af:panelLabelAndMessage>
 </af:panelFormLayout>
 </af:showDetailItem>
 <af:showDetailItem text="#{viewControllerBundle.ADDRESS}" id="sdi3">
 <af:panelFormLayout inlineStyle="padding:5px;" id="pf13">
 <af:panelLabelAndMessage label="#{viewControllerBundle.ADDRESS}"
 labelStyle="font-size:14px" id="plam6">
 <af:outputText value="#{node.Address}"
 inlineStyle="font-size:14px" id="ot9"/>
 </af:panelLabelAndMessage>
 </af:panelFormLayout>
 </af:showDetailItem>
 </f:facet>
 </dvt:node>

```

```

<af:panelLabelAndMessage>
<af:panelLabelAndMessage label="{viewcontrollerBundle.STATE}"
 labelStyle="font-size:14px" id="palm7">
 <af:outputText value="{node.State}"
 inlineStyle="font-size:14px" id="ot10"/>
</af:panelLabelAndMessage>
<af:panelLabelAndMessage label="{viewcontrollerBundle.CITY}"
 labelStyle="font-size:14px" id="plam8">
 <af:outputText value="{node.City}"
 inlineStyle="font-size:14px" id="ot11"/>
</af:panelLabelAndMessage>
</af:panelFormLayout>
</af:showDetailItem>
</dvt:panelCard>
</f:facet>
</dvt:node>
</dvt:hierarchyViewer>

```

### 33.8.3 How to Create a Databound Search in a Hierarchy Viewer

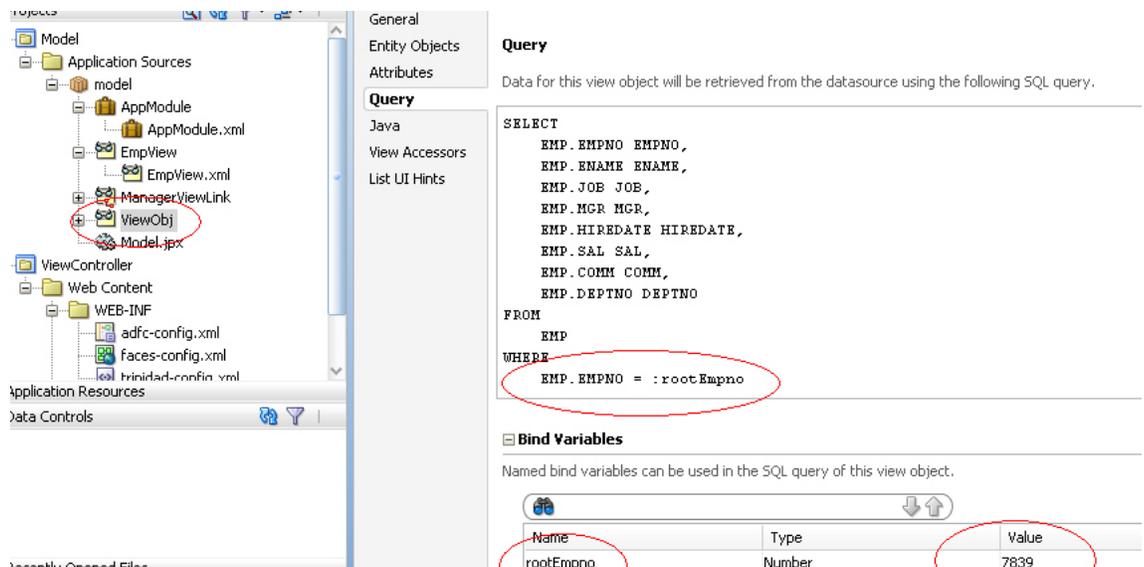

The search function in a hierarchy viewer is based on the searchable attributes or columns of the data collection that is the basis of the hierarchy viewer data model. Using a query results collection defined in data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop an **ExecuteWithParams** operation into an existing hierarchy viewer component on the page.

**Before you begin:**

1. You must have a databound hierarchy viewer component present on your page.
2. Verify the query that retrieves the root node in the hierarchy viewer.

For example, [Figure 33–78](#) shows retrieving the root node by EMPNO column.

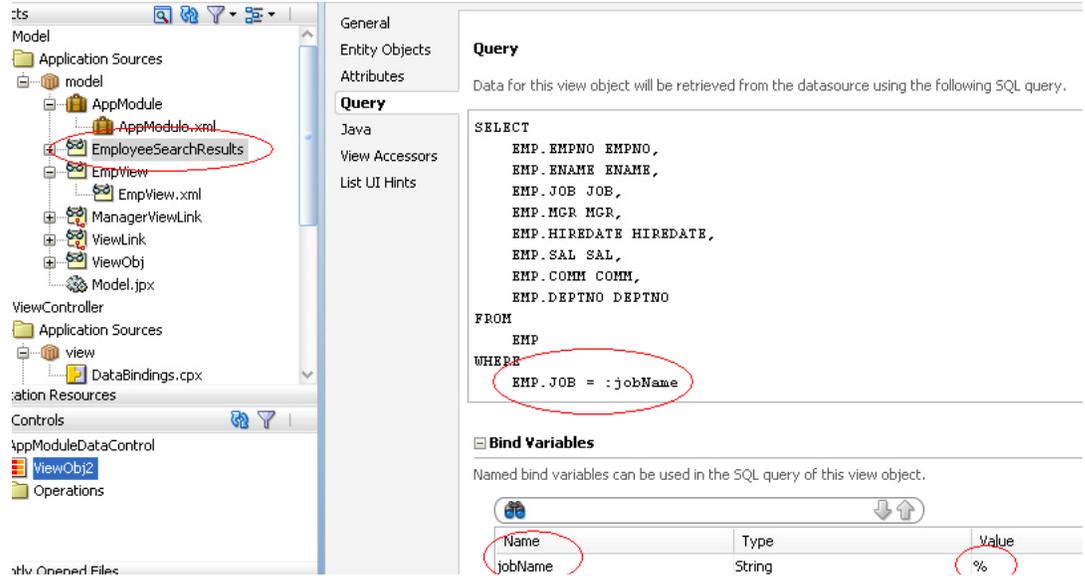

**Figure 33–78 Root Node Query**

3. Create a view object that performs the search.

For example, [Figure 33–79](#) shows the `EmployeeSearchResults` view object that performs the search based on the `Job` column in the data collection with a default value of `%` for matching any value, and a comparison value of `=` specifying an exact match against the column.

**Figure 33–79** *EmployeeSearchResults View Object*

For information about creating a view object, see [Section 5.2.1, "How to Create an Entity-Based View Object."](#)

#### To create a databound search with a hierarchy viewer:

1. From the Data Controls panel, select the collection that corresponds to the query results and expand the **Operations** node to display the **ExecuteWithParams** operation.
2. Drag the **ExecuteWithParams** operation and drop it onto the hierarchy viewer in the visual editor or onto the component in the Structure window. Alternatively, you can drag the parameter onto the hierarchy viewer.
3. In the Create Hierarchy Viewer Search dialog that displays, use the **Add** icon to specify the list of results to display in the Search Results panel, and specify the following for each result:
  - a. **Display Label:** Select the values for the headers of the nodes in the hierarchy. If you select `<default>`, then the text for the header is automatically retrieved from the data binding.
  - b. **Value Binding:** Select the columns in the data collection to use for nodes in the tree for the hierarchy viewer.
  - c. **Component to Use:** Select the type of component to display in the node. The default is the ADF Output Text component.

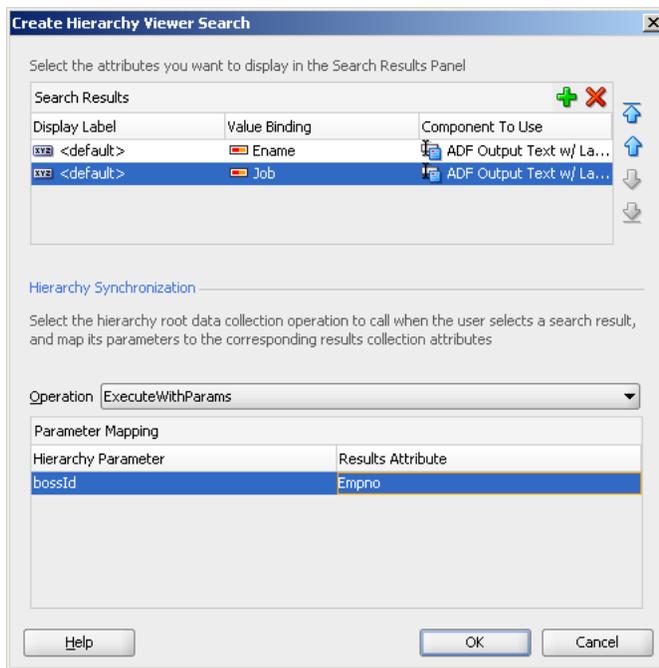

After selecting an existing field, use the arrow icons (**Up**, **Down**, **Top**, **Bottom**) to reorder the results or use the **Delete** icon to delete that result.

4. In the **Operation** dropdown list select the hierarchy root data collection to use when a search result is selected. Valid values include:

- `removeRowWithKey`: Uses the row key as a `String` converted from the value specified by the input field to remove the data object in the bound data collection.
  - `setCurrentRowWithKey`: Sets the row key as a `String` converted from the value specified by the input field. The row key is used to set the currency of the data object in the bound data collection.
  - `setCurrentRowWithKeyValue`: Sets the current object on the iterator, given a key's value.
  - `ExecuteWithParams`: Sets the values to the named bind variables passed as parameters.
5. In the **Parameter Mapping** table, use the dropdown list in the **Results Attribute** column to select the results collection attribute to map to the parameter displayed in the **Hierarchy Parameter** column.

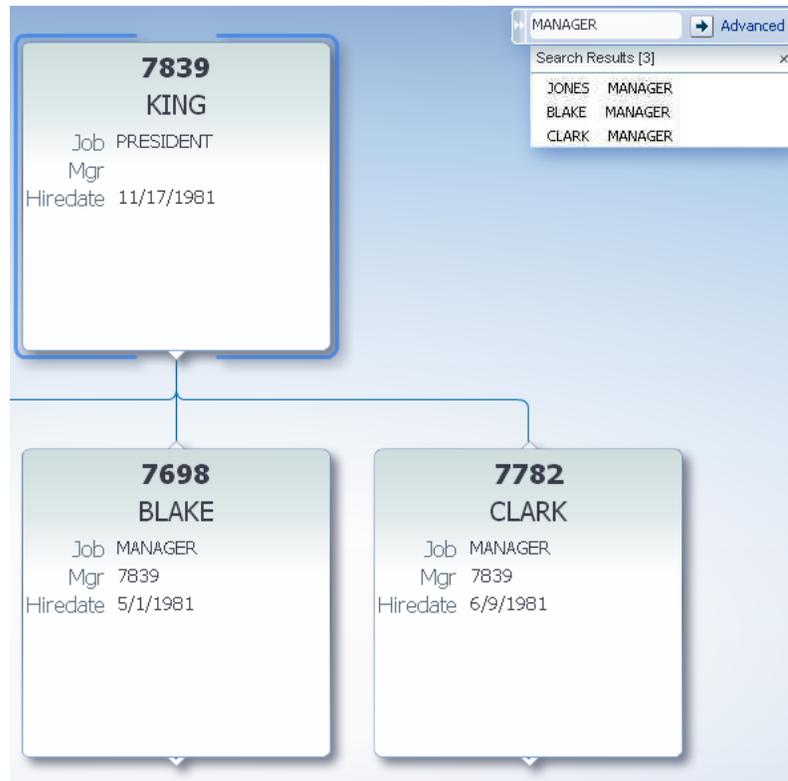

Figure 33–80 shows the Create Hierarchy Viewer Search dialog that appears if you create a hierarchy viewer using data from a data collection named `EmployeesSearchResults1`.

**Figure 33–80 Create Hierarchy Viewer Search Dialog**

At runtime, the search results are displayed in a table by `Ename` and `Job`. Figure 33–81 shows the resulting search results panel when the user enters "MANAGER" in the search box.

**Figure 33–81 Hierarchy Viewer Search Results**

---

---

## Using Contextual Events

This chapter describes how to create, publish, and subscribe to contextual events to facilitate communications between regions.

This chapter includes the following sections:

- [Section 34.1, "About Creating Contextual Events"](#)
- [Section 34.2, "Creating Contextual Events Declaratively"](#)
- [Section 34.3, "Creating Contextual Events Manually"](#)
- [Section 34.4, "Creating Contextual Events Using Managed Beans"](#)
- [Section 34.5, "Creating Contextual Events Using JavaScript"](#)
- [Section 34.6, "Creating the Event Map Manually"](#)
- [Section 34.7, "Registering a Custom Dispatcher"](#)

### 34.1 About Creating Contextual Events

Often a page or a region within a page needs information from somewhere else on the page or from a different region. While you can pass parameters to obtain that information, doing so makes sense only when the parameters are well known and the inputs are EL-accessible to the page. Parameters are also useful when a task flow may need to be restarted if the parameter value changes.

However, suppose you have a task flow with multiple page fragments that contain various interesting values that could be used as input on one of the pages in the flow. If you were to use parameters to pass the value, the task flow would need to surface output parameters for the union of each of the interesting values on each and every fragment. Instead, for each fragment that contains the needed information, you can define a contextual event that will be raised when the page is submitted. The page or fragment that requires the information can then subscribe to the various events and receive the information through the event.

In the StoreFront module, contextual events are used in the customer registration page to display the appropriate informational topic. The user registration page `register.jspx` contains two regions. One region contains the customer registration task flow `customer-registration-task-flow`, and the other contains the informational topic task flow `help-task-flow`. A contextual event is passed from the customer registration region to the informational topic region so that the informational topic task flow can display the information topic. At design time, the event name, producer region, consumer region, consumer handler, and other information is stored in the event map section of the page definition file, as shown in [Example 34-1](#).

**Example 34–1 Event Map in the registerPageDef.xml File**

```

<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
 <event name="queueHelpTopic">
 <producer region="*">
 <consumer region="helptaskflow1"
 handler="helpPageDef.findHelpTextById">
 <parameters>
 <parameter name="helpTopicId" value="{payload}" />
 </parameters>
 </consumer>
 </producer>
 </event>
</eventMap>

```

At runtime, when users enter the customer registration task flow, they progress through a series of view activities from **Basic Information** to **Address** and then to **Payment Options** by entering data and clicking the **Next** button. When the user clicks **Next**, a contextual event with a `payload` parameter is broadcasted by the customer registration task flow. This event is then consumed by the information task flow and its handler, the `helpPageDef.findHelpTextById()` method. The consuming method uses the `payload` parameter to determine which information topic text to display. In the event map, you can specify EL expressions to bind the input parameters to variables and parameters of the page.

Events are configured in the page definition file for the page or region that will raise the event (the producer). In order to associate the producer with the consumer that will do something based on the event, you create an event map also in the page definition (when using events between regions, the page definition file which holds both the regions contains the event map). If the consuming page is in a dynamic region, the event map should be in the page definition file of the consuming page and the producer's attribute `region` set to `"*"`. The attribute `region` is set to `"*"` because at design time, the framework cannot determine the relative path to the producer.

You can raise a contextual event for an action binding, a method action binding, a value attribute binding, or a range binding (table, tree, or list binding). You also can conditionally fire an event and conditionally handle an event using EL expressions.

For action and method action bindings, the event is raised when the action or method is executed. The `payload` contains the method return value. You can also raise a contextual event from an ADF Faces event such as clicking a button or selecting from a menu. An `eventBinding` is created in the page definition to define the event.

For a value attribute binding, the event is triggered by the binding container and raised after the attribute is set successfully. The `payload` is an instance of `DCBindingContainerValueChangeEvent`, which provides access to the new and old value, the producer iterator, the binding container, and the source. If the `payload` property is changed to point to a custom data object, then the `payload` reference will return the object instead. [Example 34–2](#) shows a value change event inside an attribute value binding associated with an input component. The event, `valueChangeEvent`, will be dispatched when the user changes the value of `LAST_NAME` in the page.

**Example 34–2 Value Attribute Event in the Page Definition File**

```

<attributeValues IterBinding="DeptView1Iterator" id="Dname"
 xmlns="http://xmlns.oracle.com/adfm/jcuimodel">
 <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
 <event name="valueChangeEvent" />
 </events>
</attributeValues>

```

```

</events>
<AttrNames xmlns="http://xmlns.oracle.com/adfm/uimodel">
 <Item Value="LAST_NAME"/>
</AttrNames>
</attributeValues>
</bindings>
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
 <event name="valueChangeEvent">
 <producer region="LAST_NAME">
 <consumer region="" handler="consumeEvent"/>
 </producer>
 </event>
</eventMap>

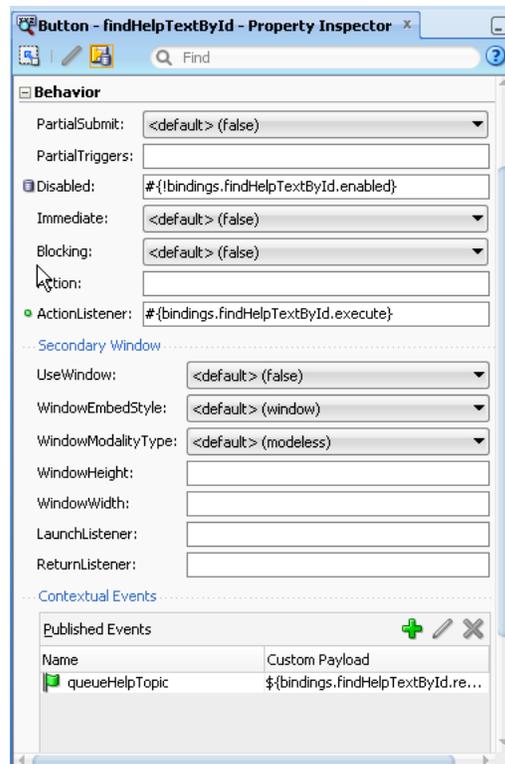

```

For a range binding (tree, table, list), the event is raised after the currency change has succeeded. The `payload` is an instance of `DCBindingContainerValueChangeEvent`, which provides access to the new and old value, the producer iterator, the binding container, and the source.

Value attribute binding and range binding contextual events may also be triggered by navigational changes. For example, if you create an event inside a tree table binding, the event will be dispatched when the user selects a different node of the tree in the page.

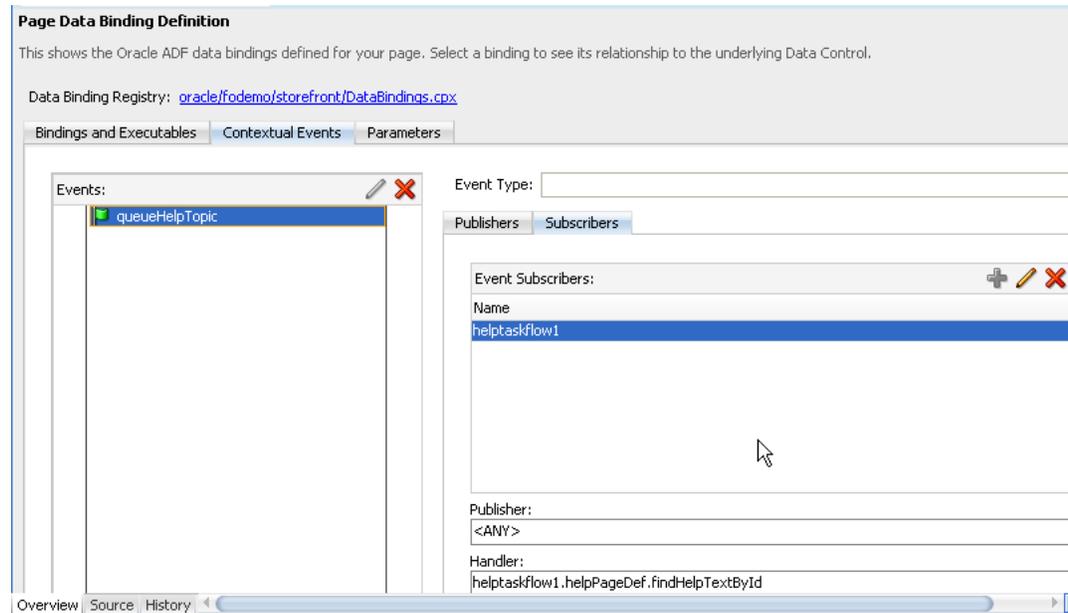

You use the Contextual Events section under the **Behavior** section in the Property Inspector to create, publish, and subscribe to contextual events. The Contextual Events panel will only appear when you select eligible components or regions in the page, as shown in [Figure 34-1](#).

**Figure 34-1** Contextual Events Panel in the Property Inspector

You can also subscribe to contextual events using the overview editor for page definition file's **Contextual Events** tab **Subscriber** section, as shown [Figure 34–2](#)

**Figure 34–2 Page Definition Contextual Events Tab**

Contextual events are not the same as the business events that can be raised by ADF Business Components or the events raised by UI components. For a description of these types of events, see the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. Contextual events can be used, however, in association with UI events. In this case, an action listener that is invoked due to a UI event can, in turn, invoke a method action binding that then raises the event.

The contextual events framework provides the communications between regions within a page. The framework provides the page with the ability to map events that are produced and consumed by the various regions on the page. You can use JDeveloper to declaratively publish events using the page definition file. Similarly, you can declaratively subscribe to those events from the page definition file. You can pass parameters with the event and implement handlers to respond to an event. Other ways to create contextual events include using managed beans and using JavaScript. Note that contextual events do not require regions to be refreshed for the region to uptake parameters.

### 34.1.1 Contextual Events Use Cases and Examples

There are three kinds of communication patterns between a region and the parent page: parent to region, region to parent, and region to region. The contextual events framework is the most powerful communication implementation that works for all three of these scenarios. Also note that contextual events do not require a region to be refreshed in order to consume input parameters.

You should use contextual events to communicate between ADF regions. While it is possible to use ADF task flow parameters to communicate between regions, doing so may create direct dependencies between the regions. ADF task flow parameters may be fine for static regions, but using contextual events will allow you to implement independent communications between regions.

For example, a page may contain a region with a form for entering employee information. When the user updates the employee Id and presses the submit button, a value change contextual event is raised and the employee Id value is also passed as payload. On the same page, another region subscribes to and consumes the event and displays departmental information about the selected employee based on the payload information passed with the contextual event.

### 34.1.2 Additional Functionality for Contextual Events

You may find it helpful to understand other ADF features before you work with contextual events. Following are links to other functionality that may be of interest.

- You can also use ADF task flow parameters to communicate between ADF regions. For more information about using task flows and regions, see [Chapter 21, "Using Task Flows as Regions."](#)

## 34.2 Creating Contextual Events Declaratively

You create contextual events by first creating and publishing the event on the producer based on a method action, action, value attribute, or list binding. On the consumer, you subscribe to the event and create a handler to process the event.

Typically, you create a parent page with regions that contain task flows and view activities. You create contextual events in one region to be published for consumer event handlers in the other region. For more information about using task flows and regions, see [Chapter 21, "Using Task Flows as Regions."](#)

---

---

**Note:** You can also publish an action contextual event from code (for example, from within a managed bean). You can use `getBindingContainer().getEventDispatcher` which returns an instance of `EventDispatcher`. `EventDispatcher` has public APIs which you can use to programmatically raise contextual events.

---

---

### 34.2.1 How to Publish Contextual Events

You use the Property Inspector to create contextual events in the producer's page.

#### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 34.2, "Creating Contextual Events Declaratively."](#)

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see [Section 34.1.2, "Additional Functionality for Contextual Events."](#)

You will need to complete this task:

Decide on the type of component you want to use to raise the contextual event. If you plan to use a method action binding, you must have already created the method to be dropped onto the page

#### To create a contextual event:

1. In the producer page, drag and drop a component from the Data Controls panel to the page that will trigger the event.

The component must have a method action, action, value attribute, or list binding. In the StoreFront module, the `setHelpId()` method from the Data Controls panel was added to the page.

2. In the Property Inspector expand the **Behavior** section.
3. In the **Publish Events** section, click the **Add** icon.
4. In the Publish Contextual Events dialog:
  - a. Select **Create New Event**.
  - b. Enter the name of the event.
  - c. If you are using a table, tree, or tree table, a **Node** field appears for you to enter the node that will publish the event.
  - d. Select **Pass Custom Value From** if you want to pass payload data to the consumer.
  - e. If you are passing payload data, select the type of data from the dropdown list.

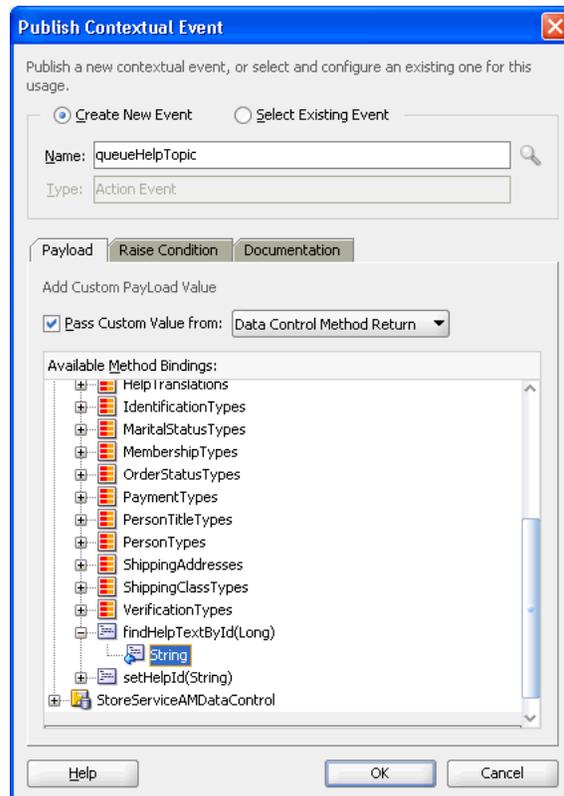

For example, if you want to pass an attribute value from the producer page to the consumer page, you can select **Page Data** and select the attribute from the tree structure.

- f. You can conditionally raise the event by entering an EL expression in the **Raise Condition** tab.

For instance, entering an expression such as `${bindings.LAST_NAME.inputValue == 'KING'}` will cause the event to be raised only if the customer's last name is KING.

- g. Click **OK**.

The event is created on the page, but it is not ready for publishing until it is associated with the component binding.

**Figure 34–3 Publish a Contextual Event**

## 34.2.2 How to Subscribe to and Consume Contextual Events

You use the overview editor for page definition files on the parent page to subscribe to contextual events.

### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 34.2, "Creating Contextual Events Declaratively."](#)

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see [Section 34.1.2, "Additional Functionality for Contextual Events."](#)

You will need to complete this task:

Create a contextual event in the page definition file, as described in [Section 34.2.1, "How to Publish Contextual Events."](#)

### To subscribe and consume the event:

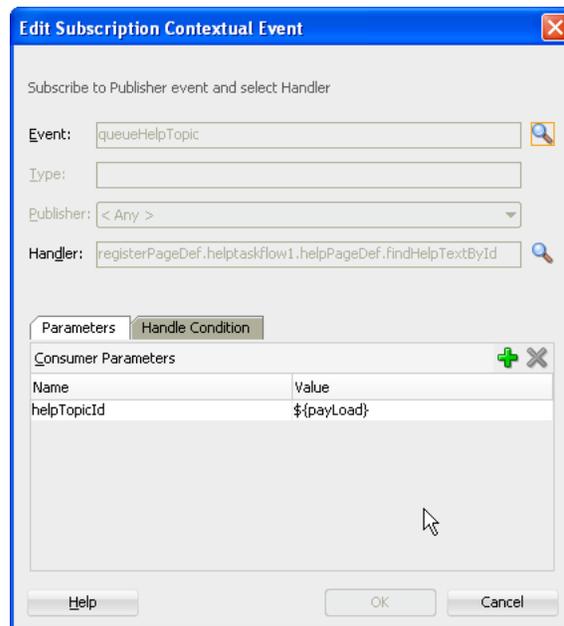

1. In the consuming page, add the components that may respond to the event.

In the StoreFront module, the `findHelpTextById` method handler return value, **String**, is dropped onto the page as an `outputText` component to display the help information.

2. Create a handler to process the event and its payload data.

In the StoreFrontModule example, the `findHelpTextById` handler method was created in the `LookupServiceAMDataControl` module.

3. In the overview editor for the consumer page definition's **Bindings and Executables** tab **Bindings** section, click the **Add** icon.
4. In the Insert Item dialog, select **methodAction** and click **OK**.
5. In the Create Action Binding dialog:
  - a. Select the data collection where you have created your handler.
  - b. From the **Operation** dropdown list, select the handler.
  - c. Click **OK**.
6. In the overview editor for the consumer page definition's **Bindings and Executables** tab **Bindings** section, click the **Add** icon.
7. In the Insert Item dialog, select **attributeValue** and click **OK**.
8. In the Create Attribute Binding dialog:
  - a. From the **Data Source** dropdown list, select **Variable**.
  - b. Select the return value of the handler as the **Attribute**.
  - c. Click **OK**.
9. In the overview editor **Contextual Events** tab, click **Subscribers** and click the **Add** icon in the **Event Subscribers** section.
10. In the Subscribe to Contextual Event dialog, click the **Search** icon.
11. In the Select Contextual Events dialog, select the event you want to subscribe to from the tree and click **OK**.
12. In the Subscribe to Contextual Event dialog:
  - a. Select the producer or **<Any>** from the **Publisher** dropdown list. A contextual event can have more than one producer.  
 Selecting **<Any>** will allow the consumer to subscribe to any producer producing the selected event. In the page definition file, the `producer` attribute will be set to the wildcard `"*"`. If your producer is in a dynamic region, you should set this field to **<Any>** so that the subscriber can consume from any producer.
  - b. Click the **Search** icon next to the **Handler** field.
  - c. In the Select Handler dialog, select the event handler from the tree and click **OK**.
  - d. If the handler requires parameters, select the **Parameters** tab, click **Add**, and enter name-value pair as parameters.
  - e. If you want to conditionally handle the event, select the **Handle** tab, and enter an EL Expression that determines the conditions under which the handler will process the event.
  - f. Click **OK**.

**Figure 34–4** *Subscribe to a Contextual Event*

---

**Note:** You can edit the event map by right-clicking the page definition in the Structure window and choosing **Edit Event Map**. You can also edit event attributes in the page definition file or in the Property Inspector.

---

### 34.2.3 What Happens When You Create Contextual Events

When you create an event for the producer, JDeveloper adds an `events` element to the page definition file. Each event name is added as a child. [Example 34–3](#) shows the event on the `setHelpId` method action binding in the `account_basicinformationPageDef` page definition file of the StoreFront module. This is the page definition for the Basic Information view of the customer registration task flow.

#### **Example 34–3** *Event Definition for the Producer*

```
<methodAction id="setHelpId"
 InstanceName="LookupServiceAMDataControl.dataProvider"
 DataControl="LookupServiceAMDataControl"
 RequiresUpdateModel="true" Action="invokeMethod"
 MethodName="setHelpId" IsViewObjectMethod="false"
 ReturnName="LookupServiceAMDataControl.
 methodResults.setHelpId_
 LookupServiceAMDataControl_dataProvider_
 setHelpId_result">
 <NamedData NDName="usage" NDValue="CREATE_PROFILE"
 NDType="java.lang.String"/>
 <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
 <event name="queueHelpTopic"/>
 </events>
</methodAction>
```

When the method action binding is invoked, the event is broadcasted to its consumers.

When you configure an event map, JDeveloper creates an event map entry in the corresponding page definition file. [Example 34–4](#) shows the event map on the `registerPageDef` page definition file that maps the `queueHelpTopic` event from the `customerregistrationtaskflow1` region to the `helptaskflow1` region. It also maps the `helpPageDef.findHelpTextById` handler method bindings that is defined in the `helpPageDef` page definition file. The consumer invokes a method that determine the information text to display based on the parameters that are passed into it. The mapping is in the `registerPageDef` page definition, as that is the parent container for both the `customerregistrationtaskflow1` and the `helptaskflow1` regions.

**Example 34–4 Event Map in the Parent Page Definition File**

```
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
 <event name="queueHelpTopic">
 <producer region="*">
 <consumer region="helptaskflow1"
 handler="helpPageDef.findHelpTextById">
 <parameters>
 <parameter name="helpTopicId" value="{payload}" />
 </parameters>
 </consumer>
 </producer>
 </event>
</eventMap>
```

## 34.2.4 How to Control Contextual Events Dispatch

You can control the dispatch of contextual events to child regions at the application level or at the page level.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 34.2, "Creating Contextual Events Declaratively."](#)

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see [Section 34.1.2, "Additional Functionality for Contextual Events."](#)

**To disable event dispatch:**

1. To disable event dispatch at the application level, set the `dynamicEventSubscriptions` property to `false` in the `adf-config.xml` file, as shown in [Example 34–5](#).

You can disable the event dispatch to regions that have an event map with producers as wildcards.

**Example 34–5 Disabling Contextual Event Dispatch at the Application Level Using `adf-config.xml`**

```
<?xml version="1.0" encoding="windows-1252" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
 xmlns:cef="http://xmlns.oracle.com/adfm/contextualEvent">
 <cef:DynamicRegionEventsConfig dynamicEventSubscriptions="false">
 </cef:DynamicRegionEventsConfig>
</adf-config>
```

- To disable event dispatch at the individual page level, set the `dynamicEventSubscriptions` property to `false` in the associated page definition file, as shown in [Example 34–6](#).

Contextual events will not be passed to the page and any of its children.

**Example 34–6 Disabling Contextual Event Dispatch for a Page Using the Page Definition File**

```
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
 version="11.1.1.52.8" id="viewBPageDef" Package="view.pageDefs"
 DynamicEventSubscriptions="false">
```

## 34.2.5 What Happens at Runtime: Contextual Events

If both the event producer and the consumer are defined in the same page definition file, then after the corresponding page is invoked and the binding container is created, the event is raised when:

- The corresponding method or action binding is executed
- A value binding is set successfully
- A range binding currency is set successfully

For a method binding, the result of the method execution forms the payload of the event, and the event is queued. In the Invoke Application phase of the JSF lifecycle, all the queued events will be dispatched. The event dispatcher associated with the binding container checks the event map (also in the binding container, as it is part of the same page definition file) for a consumer interested in that event and delivers the event to the consumer.

When the producer and consumer are in different regions, the event is first dispatched to any consumer in the same container, and then the event propagation is delegated to the parent binding container. This process continues until the parent or the topmost binding container is reached. After the topmost binding container is reached, the event is again dispatched to child-binding containers that have regions with pages that have producer set to wildcard "\*" .

## 34.3 Creating Contextual Events Manually

You create contextual events by first creating the event on the producer. You then determine the consumer of the event, and map the producer to the consumer.

### 34.3.1 How to Create Contextual Events Manually

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 34.3, "Creating Contextual Events Manually."](#)

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see [Section 34.1.2, "Additional Functionality for Contextual Events."](#)

You will need to complete this task:

Create a contextual event that has a method binding, action binding, value attribute binding, or list binding on the producer page.

**To create a contextual event:**

1. In the Application Navigator, open the page definition file that contains the binding for the producer of the event.  
  
A producer must have an associated binding that will be used to raise the event. For example, if a method or operation will be the producer, the associated action binding or method action binding will contain the event.
2. In the Structure window, right-click the binding for the producer and choose **Insert inside *binding name* > events** or **Insert inside *binding name* > Contextual Events > events**.
3. In the Structure window, right-click the **events** element just created, and choose **Insert inside events > event**.
4. In the Insert event dialog, enter a name for the event in the **name** field, and click **Finish**.

The event is now created. By default, any return of the associated method or operation will be taken as the payload for the event and stored in the EL-accessible variable `#{payload}`. You now need to map the event to the consumer, and to configure any payload that needs to be passed to the consumer.

5. Open the page definition that contains the binding for the consumer.  
  
The binding container represented by this page provides access to the events from the current scope, including all contained binding containers (such as task flow regions). If regions or other nested containers need to be aware of the event, the event map should be in the page definition of the page in the consuming region.
6. In the Structure window, right-click the topmost node that represents the page definition, and choose **Edit Event Map**.

---

---

**Note:** If the producer event comes from a page in an embedded dynamic region, you may not be able to edit the event map using the Event Map Editor. You can manually create the event map by editing the page definition file or use **insert inside** steps, as described in [Section 34.3, "Creating Contextual Events Manually."](#)

---

---

7. In the Event Map Editor, click the Add icon to add an event entry.
8. In the Add New EventMap Entry dialog, do the following:
  - a. Use the **Producer** dropdown menu to choose the producer.
  - b. Use the **Event Name** dropdown menu to choose the event.
  - c. Use the **Consumer** dropdown menu to choose the consumer. This should be the actual method that will consume the event.
  - d. If the consuming method or operation requires parameters, click the **Add** icon.  
  
In the **Param Name** field, enter the name of the parameter expected by the method. In the **Param Value** field, enter the value. If this is to be the payload from the event, you can access this value using the `#{payload}` expression. If the payload contains many parameters and you don't need them all, use the ellipses button to open the Expression Builder dialog. You can use this dialog to select specific parameters under the **payload** node.

You can also click the **Parameters** ellipses button to launch the selection dialog.

e. Click **OK**.

9. In the Event Map Editor, click **OK**.

## 34.4 Creating Contextual Events Using Managed Beans

You can publish an action contextual event from code such as from within a managed bean. You bind the producer component to the method in the managed bean, as shown in [Example 34-7](#).

In this example, the producer is a command button that invokes an action binding and the consumer is an `outputText` component that displays a string. They are both on the same page.

### **Example 34-7 Event Producer and Event Consumer on the JSF**

```
<af:form id="f1">
 <af:commandButton value="eventProducerButton1" id="cb1"
 action="#{MyBean.myActionPerformed}"
 />
 <af:panelLabelAndMessage label="#{bindings.return.hints.label}" id="plam1">
 <af:outputText value="#{bindings.return.inputValue}" id="ot1"/>
 </af:panelLabelAndMessage>
</af:form>
```

The page definition file contains the method action bindings for the producer, the consumer, and the event map, as shown in [Example 34-8](#).

### **Example 34-8 Page Definition with Event Producer, Event Consumer, and Event Map**

```
<executables>
 <variableIterator id="variables">
 <variable Type="java.lang.String" Name="eventConsumer_return"
 IsQueryable="false" IsUpdateable="0"
 DefaultValue="#{bindings.eventConsumer.result}"/>
 </variableIterator>
</executables>
<bindings>
 <methodAction id="eventProducer"
 InstanceName="AppModuleDataControl.dataProvider"
 DataControl="AppModuleDataControl" RequiresUpdateModel="true"
 Action="invokeMethod" MethodName="eventProducer"
 IsViewObjectMethod="false"
 ReturnName="AppModuleDataControl.methodResults.eventProducer_
 AppModuleDataControl_dataProvider_eventProducer_result">
 <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
 <event name="myEvent"/>
 </events>
 </methodAction>
 <methodAction id="eventConsumer" RequiresUpdateModel="true"
 Action="invokeMethod" MethodName="eventConsumer"
 IsViewObjectMethod="false" DataControl="AppModuleDataControl"
 InstanceName="AppModuleDataControl.dataProvider"
 ReturnName="AppModuleDataControl.methodResults.eventConsumer_
 AppModuleDataControl_dataProvider_eventConsumer_result">
 <NamedData NDName="str" NDValue="test" NDType="java.lang.String"/>
 </methodAction>
```

```
<attributeValues IterBinding="variables" id="return">
 <AttrNames>
 <Item Value="eventConsumer_return" />
 </AttrNames>
</attributeValues>
</bindings>
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
 <event name="myEvent">
 <producer region="eventProducer">
 <consumer region="" handler="eventConsumer">
 <parameters>
 <parameter name="test" value="{payload}" />
 </parameters>
 </consumer>
 </producer>
 </event>
</eventMap>
```

When the button is pressed, the `myActionPerformed` method is invoked and calls the following methods to generate the contextual event with "myString" as the payload:

```
BindingContainer bc =
 (BindingContainer)fc.getApplication().evaluateExpressionGet(fc, "#{bindings}",
 BindingContainer.class);
JUCtrlActionBinding actionBnd =
 (JUCtrlActionBinding)bc.getControlBinding("eventProducer");
...
((DCBindingContainer)bc).getEventDispatcher().queueEvent(actionBnd.
 getEventProducer(), "myString");
((DCBindingContainer)bc).getEventDispatcher().processContextualEvents();
return null;
```

## 34.5 Creating Contextual Events Using JavaScript

Every action and method binding that is accessible from a managed bean can be invoked from JavaScript. ADF Faces provides an `af:serverListener` operation component that can be used to call a managed bean method from client-side JavaScript. To invoke this component using the referenced managed bean method, use the `BindingContext` object to look up the current `BindingContainer` and to access the `OperationBinding` or a `JUEventBinding` binding. The `af:serverListener` component can also be used to send a message payload from the browser client to the managed bean method.

## 34.6 Creating the Event Map Manually

Under most circumstances, you can create the event map using the Event Map Editor as described in [Section 34.3, "Creating Contextual Events Manually."](#) However, in situations such as when the producer event is from a page in an embedded dynamic region, the Event Map Editor at design time cannot obtain the necessary information to create an event map.

### 34.6.1 How to Create the Event Map Manually

#### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 34.6, "Creating the Event Map Manually."](#)

You may also find it useful to understand functionality that can be used with contextual events. For more information, see [Section 34.1.2, "Additional Functionality for Contextual Events."](#)

#### To create the event map manually:

1. In the Application Navigator, open the page definition that contains the binding for the consumer.
2. In the Structure window, right-click the topmost node that represents the page definition, and choose **Insert inside *pagedef name* > eventMap**.
3. In the Structure window, select the **eventMap** node, right-click and choose **Insert inside eventMap > event**.
4. In the Insert Event dialog, enter the name of the event and click **OK**.  
Repeat steps 3 and 4 to add more events.
5. Select the **event** node, right-click and choose **Insert inside event > producer**.
6. In the Insert Producer dialog, enter the name of the binding that is producing this event and click **OK**.

You can also enter the name of the region which has the event producer, in which case all the consumers specified under this tag can consume the event. You can also enter "\*" to denote that this event is available for all consumers under this tag.

7. Select the **producer** node, right-click, and choose **Insert inside producer > consumer**.
8. In the Insert Consumer dialog, enter the name of the handler that will consume the event and click **OK**.

Repeat steps 7 and 8 to add more consumers.

9. If there are parameters being passed, add the parameter name and value.
  - a. Select the **consumer** node, right-click, and choose **Insert inside consumer > parameters**.
  - b. Select the **parameters** node, right-click, and choose **Insert inside parameters > parameter**.
  - c. In the Insert Parameter dialog, enter the name of the parameter and the value of the parameter and click **OK**. The value can be an EL expression.

Repeat this step to add more parameters.

## 34.7 Registering a Custom Dispatcher

By default, the contextual event framework uses `EventDispatcherImpl` to dispatch events that would traverse through the regions. You can create a custom event dispatcher to override the default event dispatcher to provide custom behaviors. After

you have created the custom event dispatcher, you must register it in the `Databindings.cpx` file to override the default dispatcher.

## 34.7.1 How to Register a Custom Dispatcher

### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 34.7, "Registering a Custom Dispatcher."](#)

You may also find it useful to understand functionality that can be used with contextual events. For more information, see [Section 34.1.2, "Additional Functionality for Contextual Events."](#)

### To register a custom event dispatcher:

1. Create a custom event dispatcher Java class based on the `EventDispatcher` class.
2. Register the custom event dispatcher in the `Databindings.cpx` file with a fully qualified name using the following format:

```
EventDispatcher="package_name.CustomEventDispatcher_name"
```

[Example 34-9](#) shows the code for a custom event dispatcher called `NewCustomEventDispatcher` created in package `NewPackage`.

### **Example 34-9 Adding Custom Event Dispatcher in the Databindings.cpx File**

```
<Application xmlns="http://xmlns.oracle.com/adfm/application"
 version="11.1.1.51.60" id="DataBindings" SeparateXMLFiles="false"
 Package="project3" ClientType="JClient"
 EventDispatcher="NewPackage.NewCustomEventDispatcher">
```

3. Create the event in the producer's page definition. For more information, see [Section 34.2, "Creating Contextual Events Declaratively,"](#) or [Section 34.3, "Creating Contextual Events Manually."](#)
4. Create the event map in the consumer region if the consumer is in a dynamic region. If the consumer is not in a dynamic region, you can also specify the event map in the parent page which holds both the producer and consumer regions. For more information, see [Section 34.6, "Creating the Event Map Manually."](#)

## Completing Your Application

Part V contains the following chapters:

- [Chapter 35, "Enabling ADF Security in a Fusion Web Application"](#)
- [Chapter 36, "Testing and Debugging ADF Components"](#)
- [Chapter 37, "Refactoring a Fusion Web Application"](#)
- [Chapter 38, "Reusing Application Components"](#)
- [Chapter 39, "Customizing Applications with MDS"](#)
- [Chapter 40, "Allowing User Customizations at Runtime"](#)
- [Chapter 41, "Deploying Fusion Web Applications"](#)

---

---

## Enabling ADF Security in a Fusion Web Application

This chapter describes how you can enable ADF Security in the Fusion web application to define security policies for Oracle Application Development Framework (Oracle ADF) resources and to restrict the user's ability to view web pages associated those resources.

This chapter includes the following sections:

- [Section 35.1, "About ADF Security"](#)
- [Section 35.2, "ADF Security Process Overview"](#)
- [Section 35.3, "Enabling ADF Security"](#)
- [Section 35.4, "Creating Application Roles"](#)
- [Section 35.5, "Defining ADF Security Policies"](#)
- [Section 35.6, "Creating Test Users"](#)
- [Section 35.7, "Creating a Login Page"](#)
- [Section 35.8, "Testing Security in JDeveloper"](#)
- [Section 35.9, "Preparing the Secure Application for Deployment"](#)
- [Section 35.10, "Disabling ADF Security"](#)
- [Section 35.11, "Advanced Topics and Best Practices"](#)

### 35.1 About ADF Security

The ADF Security framework is the preferred technology to provide authentication and authorization services to the Fusion web application. ADF Security is built on top of the Oracle Platform Security Services (OPSS) architecture, which itself is well-integrated with Oracle WebLogic Server. While other security-aware models exist that can handle user login and resource protection, ADF Security is ideally suited to provide declarative, permission-based protection for ADF bounded task flows, for top-level web pages that use ADF bindings (pages that are not contained in a bounded task flow), and at the lowest level of granularity, for rows of data defined by ADF entity objects and their attributes. In this document, these specific resources that the ADF Security framework protects are known as *ADF security-aware resources*.

You enable ADF Security for Fusion web applications when you run the Configure ADF Security wizard, as described in [Section 35.3, "Enabling ADF Security."](#) The wizard configures ADF Security for the entire Fusion web application, so that any web page associated with an ADF security-aware resource is protected by default. This

means that after you enable ADF Security, your application is locked down so that the pages are considered secure by default.

After you enable ADF Security you must grant users access rights so that they may view the web pages of the Fusion web application. Access rights that you grant users are known as a *security policy* that you specify for the page's corresponding ADF security-aware resource. Ultimately, it is the security policy on the ADF resource that controls the user's ability to enter a task flow or view a web page.

Because ADF Security is based on Java Authentication and Authorization Service (JAAS), security policies identify the principal (the user or application role), the ADF resource, and the permission (an operation defined by the resource's ADF permission class). For example, the StoreFront module of the Fusion Order Demo application secures the web pages contained by the `checkout-task-flow` task flow to grant access only to logged-in users (also known as *authenticated users*). At runtime, the ADF Security framework performs authorization checking against the task flow's security policy to determine the user's right to complete the view operation. In this case, the security policy must grant the view permission to the user if they are to complete the checkout process.

To simplify the task of defining security policies for users and ADF resources, ADF Security defines a containment hierarchy that lets you define one security policy for the ADF bounded task flow and its contains web pages. In other words, when you define the security policy at the level of the bounded task flow, you protect the flow's entry point and then all pages within that flow are secured by the policy it defines. Additionally, instead of granting access to individual users, you group users into application roles and grant the view permission to the role.

Specifically, you will define security policies in the Fusion web application for the following ADF security-aware resources to make web pages accessible to users:

- ADF bounded task flow protects the entry point to the task flow, which in turn controls the user's access to the pages contained by the flow

For example, a series of web pages may guide new customers through a registration process and the bounded task flow controls page navigation for the process. For a description of bounded task flows, see [Section 18.1.2, "About Bounded Task Flows."](#)

The unbounded task flow is not an ADF security-aware component and thus does not participate in authorization checks. When you need to protect the constituent pages of an unbounded task flow, define grants for the page definition files associated with the pages instead.

- ADF page definition files associated with web pages

For example, a page may display a summary of best selling products with data coordinated by the ADF bindings of the page's associated ADF page definition file. For a description of page definitions and ADF bindings, see [Section 13.7, "Working with Page Definition Files."](#)

- ADF entity objects and attributes of entity objects that reference rows of data and help define collections for display in the user interface

For example, a web page may display an ADF Faces table component that displays columns that ADF bindings map to the attributes of an entity object as its data source. In the case of entity objects, enabling ADF Security does not automatically secure entity objects rows. The data will remain accessible to users until you define a security policy to explicitly protect the entity object or its attributes. For a description of entity objects, see [Section 4.1, "About Entity Objects."](#)

JDeveloper tools support iterative development of security so you can easily create, test, and edit security policies that you create for ADF resources. You can proceed to create test users in JDeveloper and run the application in Integrated WebLogic Server to simulate how end users will access the secured resources. This chapter describes how to configure the repository of user identities and login credentials known as the *identity store*.

---

---

**Note:** References to the identity store in this chapter are always in the context of *test* user identities that you create for the purpose of running in Integrated WebLogic Server. Typically, you would not migrate these users to the staging environment when you deploy to Oracle WebLogic Server, as described in [Section 35.9, "Preparing the Secure Application for Deployment."](#)

---

---

To avoid a situation where you have enabled ADF Security but have not yet defined security policies to grant access to test users, the Configure ADF Security wizard lets you grant temporary view rights to all existing ADF resources (a view permission grant will be added to the security policy for each ADF resource). This wizard option gives you the choice to disable automatic grants and proceed to define security policies for ADF resources as you create each resource or to enable automatic view grants and gradually replace these grants with security policies that you define. To understand iterative security development choices, see [Section 35.2, "ADF Security Process Overview."](#)

**Tip:** Before you enable ADF Security and define security policies for the ADF security-aware resources, you will want to understand the rules that govern ADF authorization checking. Understanding these rules will help you to implement the security you intend. For a discussion of these rules, see [Section 35.1.2, "ADF Security Use Cases and Examples."](#)

### 35.1.1 Integration of ADF Security and Java Security

The ADF Security model for securing Fusion web application resources is not based on the URL mapping of a security constraint as exemplified by the Java EE security model. In actual practice, security constraints are not feasible for securing a JavaServer Faces (JSF) web application where page navigation is not supported by specific page URLs. For example, when the user navigates to the next page in a task flow, the URL remains the same throughout the flow. As each new page is displayed, there is no means to trigger a URL-based security constraint.

Instead, ADF Security implements a Java Authentication and Authorization Service (JAAS) security model. The JAAS model is policy-based since JAAS is built on the existing Java security model and integrates with any JAAS implementation, including the Oracle Platform Security Services (OPSS) implementation of the JAAS service. Whereas applications that utilize URL security constraints are security-unaware because they rely on the Java EE container to manage security, Fusion web applications require an explicit call to the ADF Security framework to authorize access to resources based on user-defined policies. Thus, when you enable ADF Security and define access policies for ADF resources, your application is security-aware.

ADF Security simplifies the implementation of a JAAS authorization model. This implementation minimizes the work needed to create a security-aware application by exposing security policies on ADF resources in a declarative fashion and performing authorization checks on these resources at runtime.

The policy store in JDeveloper is file-based and contains a list of entries known as *grants*, which define the security policy for the ADF resource. The grant entry includes all the permissions granted to the user to perform operations on the protected resource, for instance, accessing a web page associated with an ADF bounded task flow. Permissions are granted in the policy store to an application role principal.

ADF Security expands on the JAAS model by allowing you to define grants using the actions specified by the ADF Security framework permission classes. These classes are specific to the ADF resource and map the actions to an operation supported by the resource. The policy store for the Fusion web application therefore contains grants that specify:

- One or more permissions that associate an action defined by the resource's permission class with an instance of the ADF resource in the application (currently, only the view action is supported for bounded task flows and page definitions resources)
- The grantee, which is an application role defined by your application that you populate with member users or, optionally, enterprise roles for whom you wish to confer the same access rights

In the case of entity objects, the permission class defines read, delete, and update actions.

For a description of the ADF permission classes and supported actions, see [Appendix C, "ADF Security Permission Grants."](#)

### 35.1.2 ADF Security Use Cases and Examples

The use of ADF Security enables web applications to easily adjust to real-world business security requirements, because rather than securing paths to application resources, you secure the view operation on ADF resources with JAAS. JAAS-based ADF Security provides:

- Declarative security support for ADF resources, such as the bounded task flow  
Because Java EE security is URL-based or page-based, it is not possible to have a navigation control without custom code. With ADF Security, you can control whether or not the user can enter a task flow. Thus, a single security policy for a task flow can control access to multiple web pages. Additionally, because declarative security lets you secure the ADF resource, not the access path, you can reuse the ADF resource elsewhere in the application and it will remain secured.
- Simplified permission assignment by using application roles that allow for the inheritance of permissions  
While Java EE security roles that are used by Java EE security constraints are flat, JAAS permissions are granted to application roles, which can be nested and may be mapped to enterprise roles that the Oracle WebLogic Server domain defines.
- Utility methods for use in EL expressions to access ADF resources in the security context

You can use the ADF Security EL expression utility methods to determine whether the user is allowed to perform a known operation. For example, you can determine whether the user is allowed to view a particular task flow.

Additionally, JDeveloper enables you to quickly create test users and passwords to test security in Integrated WebLogic Server. When you are ready to deploy to Oracle WebLogic Server, you can migrate the application-specific authorization policies to the

server and the administrator can configure the application to use an LDAP user repository.

[Table 35–1](#) summarizes the effect that enabling ADF Security has on the application and the various ADF security-aware resources. For further discussion about how you can work most effectively with ADF Security, see [Section 35.11.4, "Best Practices for Working with ADF Security."](#)

**Table 35–1 Summary of ADF Security-Aware Resources**

ADF Resource	How ADF Enforces Security	How to Grant Access
Bounded task flows in all user interface projects	Protected by default. Requires a grant to allow users to enter the bounded task flow.	Define the grant for the task flow.  Do <i>not</i> define grants for individual page definition files associated with the web pages of the bounded task flow.
Page definition files in all user interface projects	Protected by default. Requires a grant to allow users to view the page associated with the page definition.	If the web page is part of a bounded task flow, define the grant for the task flow.  Define the grant for the page definition <i>only</i> when the web page is not contained by an unbounded task flow.  Note that the unbounded task flow is not an ADF security-aware component and allows no grants.
Entity objects in the data model project	Not protected by default. Requires a grant to prevent access by users.	Define a grant on the entity object to protect data only if you need to control access at the level of the entire data collection. The data displayed by <i>all</i> components in the user interface that reference the protected entity object will be protected.  Use entity-level security carefully. Instead, consider defining security at the level of the entity attribute.  Note that grants in the data model project are saved as metadata on the entity object itself and do not appear in the ADF policy store.
Attributes of entity objects in the data model project	Not protected by default. Requires a grant to prevent access by users.	Define a grant on the entity object attribute to protect data when you need to control access at the level of the columns of the data collection. The data displayed by <i>all</i> components in the user interface that reference the protected entity attribute will be protected.  Note that grants in the data model project are saved as metadata on the entity object itself and do not appear in the ADF policy store.

### 35.1.3 Additional Functionality for ADF Security

You may find it helpful to understand other ADF features before you start working with ADF Security. Following are links to other functionality that may be of interest.

- To understand the security features of Oracle Platform Security Services, see the *Oracle Fusion Middleware Security Guide*.

## 35.2 ADF Security Process Overview

You work in JDeveloper when you want to secure the ADF resources of your Fusion web application. ADF Security will protect your application's bounded task flows and any web pages contained in an unbounded task flow. You enable this protection by running the Configure ADF Security wizard and later by defining ADF security policies to define user access rights for each resource.

As you create the user interface for your application, you may run the Configure ADF Security wizard at any time. You may choose to:

- Iterate between creating web pages in the UI project and defining security policies on their associated ADF resources
- Complete all of the web pages in the UI project and then define security policies on their associated ADF resources

---

---

**Note:** Before you proceed to secure the Fusion web application, you should become familiar with the ADF security model, as described in [Section 35.1.2, "ADF Security Use Cases and Examples."](#)

---

---

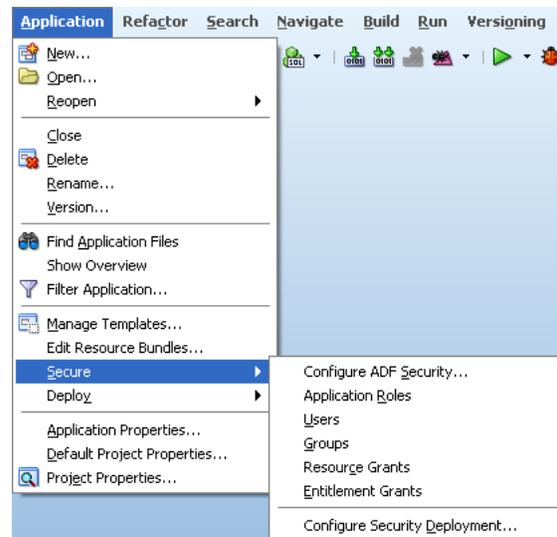

The iterative design and test process is supported by a variety of design time tools.

Each time you create a new bounded task flow or ADF page definition file in your user interface projects, the new ADF resource will be visible in the `jazn-data.xml` file overview editor. You use the overview editor to define security policies for ADF resources associated with web pages for the entire application. You can also use the overview editor to sort ADF resources and easily view those that have no security policy yet defined.

You use another editor to provision a few test users in the ADF identity store. The identity store you create in JDeveloper lets you define user credentials (user ID and password). The editor also displays the relationship between users you create and the application roles that you assign them to for the purpose of conferring the access rights defined by ADF security policies.

At design time, JDeveloper saves all policy store and identity store changes in a single file for the entire application. In the development environment, this is the `jazn-data.xml` file. After you configure the `jazn-data.xml` file using the editors, you can run the application in Integrated WebLogic Server and the contents of the policy store will be added to the domain-level store, the `system-jazn-data.xml` file, while the test users will be migrated to the embedded LDAP server that Integrated WebLogic Server uses for its identity store. The domain-level store allows you to test the security implementation by logging on as test users that you have created.

You access all design time tools for security under the main menu **Application > Secure** menu, as shown in [Figure 35-1](#).

**Figure 35–1 Accessing the ADF Security Design Time Tools**

### Design Phase

To enable ADF Security and set up the policy store in JDeveloper:

1. Enable ADF Security for the application by running the Configure ADF Security wizard.

The wizard configures files that integrate the security framework with OPSS on Oracle WebLogic Server.

2. Create an ADF security-aware resource, such as a bounded task flow with constituent web pages (or regions) or a top-level web page (or region) that is designed using ADF bindings.

**Note:** After you run the Configure ADF Security wizard, any web page associated with an ADF security-aware resource will be protected. This means that you must define security policies to make the web pages accessible *before* you can run the application and test security.

3. Associate the ADF security-aware resource with one or more application roles that you create.

Application roles you create are specific to the application and let you confer the same level of access to a set of users (also known as *member users*). In the test phase you will create some users and add them as members to the application roles you created.

4. Grant view permission to the ADF security-aware resource and each of its associated application roles.

The grant confers access rights to the application role's member users. Without the grant, the user would not be able to access the ADF security-aware resource. In the test phase, you will create some users and add them to your application roles.

### Testing Phase

To provision the identity store and test security using Integrated WebLogic Server:

1. Create some users and, optionally, create their enterprise roles.

You will log in to the application using the user ID and password you define. An *enterprise role* is a logical role that lets you group users and associate these groups

with application roles. The enterprise role is not needed for testing. For more information, see [Section 35.4.3, "What You May Need to Know About Enterprise Roles and Application Roles."](#)

2. Associate the users you created and, optionally, the enterprise roles, with one or more application roles.

A member user may belong to more than one application role when you wish to confer the access right granted to multiple application roles.

3. Optionally, replace the default login page with a custom login page.

The default login page generated by the Configure ADF Security wizard cannot utilize ADF Faces components. It is provided only as a convenience for testing ADF security policies.

4. Run the application in JDeveloper and access any ADF security-aware resource.

The first time you attempt to access an ADF security-aware resource, the security framework will prompt you to log in.

5. Log in and check that you are able to access the page and its resources as you intended.

After you log in, the security framework checks the user's right to access the resource. For example, if you receive an unexpected 401 unauthorized user error, verify that you have created grants as suggested in [Section 35.11.4, "Best Practices for Working with ADF Security."](#)

### Preparation for Staging

To prepare the secure application for deployment to Oracle WebLogic Server in a staging or production environment:

1. Remove any grants to the `test-all` role for all ADF security-aware resources and replace with grants that you define.

Because ADF resources are secure by default, developers testing the application will be granted view access only after security policies are defined. The Configure ADF Security wizard gives you the option to generate grants to the `test-all` role that will make all ADF resources accessible. To avoid compromising enterprise security, you must eventually replace all temporary grants to the `test-all` role with explicit grants that you define.

2. Remove all user identities that you created.

JDeveloper must not be used as an identity store provisioning tool, and you must be careful not to deploy the application with user identities that you create for testing purposes. Deploying user identities with the application introduces the risk that malicious users may gain unintended access. Instead, rely on the system administrator to configure user identities through the tools provided by the domain-level identity management system.

3. Confirm that the application roles shown in the policy store are the ones that you want an administrator to eventually map to domain-level groups.

4. Decide whether or not you want to define a security constraint to protect ADF Faces resource files.

Resource files including images, style sheets, and JavaScript libraries are files that the Fusion web application loads to support the individual pages of the application. These files are not secured by ADF Security, but you can secure their Java EE access paths if you require all users to be authenticated before they can access the application.

5. Migrate the finalized policy store and credentials store to the target server.

Application policies and credentials can be automatically migrated to the domain policy store when the application is deployed to a server in the Oracle WebLogic environment. Support to automatically migrate these stores is controlled by the target server's configuration. If Oracle Enterprise Manager is used to perform the deployment outside of JDeveloper, then the migration configuration settings can be specified in that tool. For information about migrating the `jazn-data.xml` policies and the `cwallet.sso` credentials, see the *Oracle Fusion Middleware Security Guide*.

## 35.3 Enabling ADF Security

To simplify the configuration process which allows ADF Security to integrate with OPSS, JDeveloper provides the Configure ADF Security wizard. The wizard is the starting point for securing the Fusion web application using ADF Security. The wizard is an application-level tool that, once run, will enable ADF Security for all user interface projects that your application contains.

---

**Note:** Because the Configure ADF Security wizard enables ADF Security for all user interface projects in the application, after you run it, users will be required to have authorization rights to view any web page contained by a bounded task flow and all web pages associated with an ADF page definition. Therefore, after you run the wizard, the application is essentially locked down until you define security policies to grant view rights to the user. For an overview of the process, see [Section 35.2, "ADF Security Process Overview."](#)

---

### 35.3.1 How to Enable ADF Security

The Configure ADF Security wizard allows you to choose to enable authentication and authorization separately. You may choose to:

- Enable *only* user authentication.

Although ADF Security leverages Java EE container-managed security for authentication, enabling authentication means that you want to use the ADF authentication servlet to support user login and logout, but that you intend to define container-managed security constraints to secure web pages.

- Enable user authentication and also enable authorization.

Enabling authorization means you intend to control access to the Fusion web application by creating security policies on ADF resources.

The ADF Security framework supports these two choices to give you the option to implement Java EE Security and still be able to support login and logout using the ADF authentication servlet. The benefit of enabling the ADF authentication servlet is that the servlet will automatically prompt the user to log in the first time the application is accessed. The ADF authentication servlet also allows you to redirect the user to a defined start page after successful authentication. You will also be able to manage the page redirect when the user logs out of the application. These redirect features provided by ADF Security are not available using only container-managed security.

**Best Practice:** Because Java EE security constraints cannot interact with the task flow to secure the current page of a task flow, container-managed security is not a useful solution when your application is designed with ADF task flows. When you use ADF task flows, select the **ADF Authentication and Authorization** option in the Configure ADF Security wizard. This option will allow you to define security policies to protect the task flows of your application.

Because ADF Security delegates authentication to the web container, when you run the Configure ADF Security wizard, the wizard prompts you to configure the authentication method that you want the web container to use. The most commonly used types of authentication are HTTP Basic Authentication and Form-Based Authentication. Basic authentication uses the browser login dialog for the user to enter a user name and password. Note that with basic authentication, the browser caches credentials from the user, thus preventing logout. Basic authentication is useful when you want to test the application without requiring a custom login page. Form authentication allows the application developer to specify a custom login UI. If you choose Form-based authentication, you can also use the wizard to generate a simple login page. The default login page is useful for testing your application with Integrated WebLogic Server.

---

---

**Note:** Because the generated login page is a simple JSP or HTML file, you will not be able to modify it with ADF Faces components. For information about replacing the default login page with a custom login page that uses ADF Faces components, see [Section 35.7, "Creating a Login Page."](#)

---

---

#### **Before you begin:**

It may be helpful to have an understanding of the Configure ADF Security wizard. For more information, see [Section 35.3, "Enabling ADF Security."](#)

#### **To enable ADF Security for the application:**

1. In the main menu, choose **Application** and then **Secure > Configure ADF Security**.
2. In the ADF Security page, leave the default **ADF Authentication and Authorization** option selected. Click **Next**.

When you run the wizard with the default option selected, your application will enforce authorization for ADF security-aware resources. Enforcing authorization for ADF resources means that you intend to define security policies for these resources to make the web pages of your application accessible. Until you do so, all pages that rely on the ADF bounded task flows and ADF page definitions will remain protected.

The other two wizard options to configure ADF Security should not be used when you want to enable ADF Security. Those options allow you to temporarily disable ADF Security and run your application without security protection, as described in [Section 35.10, "Disabling ADF Security."](#)

Specifically, the first page of the wizard lets you choose among three options, with the default option set to enable **ADF Authentication and Authorization**, as shown in [Figure 35-2](#):

- **ADF Authentication and Authorization** (default) enables the ADF authentication servlet so that you can redirect to a configured web page when

the user logs in and logs out. This option also enables ADF authorization to enforce authorization checking against security policies that you define for ADF resources. This option assumes that you will define application roles and assign explicit grants to those roles to manage access to ADF security-aware resources.

- **ADF Authentication** enables the ADF authentication servlet to require the user to log in the first time a page in the application is accessed and supports page redirect by mapping the Java EE application root "/" to a Java EE security constraint that will trigger user authentication. Since the wizard disables ADF authorization, authorization checking is not performed, whether or not security policies exist for ADF resources. Once the user is logged in, all web pages containing ADF resources will be available to the user.
- **Remove ADF Security Configuration** disables the ADF authentication servlet and prevents ADF Security from checking policy grants without altering the existing policy store. In this case, you may require users to log in, become authenticated, and test access rights against URL security constraints using standard Java EE security. Note that running the wizard with this option disables fine-grained security against ADF resources.

**Figure 35–2 Using the Configure ADF Security Wizard to Enable Security-Aware Resources**

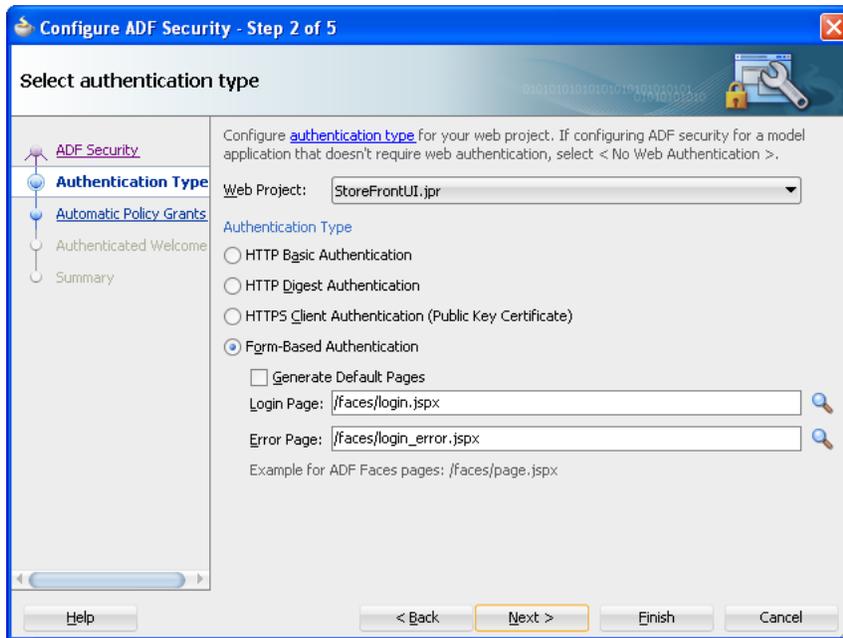

3. In the Authentication Type page, select the authentication type that you want your application to use when the user submits their login information. Click **Next**.

A known issue prevents the ADF authentication servlet from working with Basic type authentication and allows a user to access resources after logout. Use form-based authentication instead of basic authentication. For details about this issue, see [Section 35.7.5, "What You May Need to Know About ADF Servlet Logout and Browser Caching."](#)

If you select **Form-based Authentication**, you can also select **Generate Default Pages** to allow the wizard to generate a default login and error page. By default the wizard generates the login and error pages at the top level of the user interface

project, as shown in [Figure 35-3](#). If you want to change the location, specify the full path relative to the user interface project.

**Figure 35-3 Using the Configure ADF Security Wizard to Generate a Simple Login Page**

4. In the Automatic Policy Grants page, leave the default **No Automatic Grants** option selected. Click **Next**.

When you select **No Automatic Grants**, you must define explicit grants that are specific to your application. The `test-all` application role provides a convenient way to run and test application resources without the restricted access that ADF authorization enforces. However, it increases the risk that your application may leave some resources unprotected.

Alternatively, you can use the wizard to grant to the `test-all` application role. When you enable grants to the `test-all` role, you can postpone defining explicit grants to ADF resources until you are ready to refine the access policies of your application. If you decide to enable automatic grants, do not let application development progress too far and the content of the application become well-established before you replace grants to the `test-all` role with the your application's explicit grants. The explicit grant establishes the necessary privilege (for example, `view` on a page) to allow users to access these resources. For more information about the `test-all` role, see [Section 35.8.3, "How to Use the Built-In test-all Application Role."](#)

5. In the Authenticated Welcome page, select **Redirect Upon Successful Authentication** to direct the user to a specific web page after they log in. Click **Next**.

If you leave the **Redirect Upon Successful Authentication** option unselected, the user will be returned to the page from which the login was initiated. However, when the user presses **Ctrl-N** or **Ctrl-T** to open a new browser window or tab, they will receive a 403 or 404 error unless a welcome page definition appears in the application's `web.xml` file. You can use this option to specify a welcome page so the definition appears in the application's `web.xml` file.

Note that if the web page you specify contains ADF Faces components, you must define the page in the context of `/faces/`. For example, the path for `adffaces_welcome.jspx` would appear in the **Welcome Page** field as `/faces/adffaces_welcome.jspx`.

For details about specifying other redirect options, see [Section 35.7.4, "How to Redirect a User After Authentication."](#)

6. In the Summary page, review your selections and click **Finish**.

### 35.3.2 What Happens When You Enable ADF Security

After you run the Configure ADF Security wizard with the default **ADF Authentication and Authorization** option selected in the ADF Security page, you will have:

- Enabled ADF authentication to prompt the user to log in and to allow page redirects
- Enabled ADF authorization checking so that only authorized users will have access to ADF resources

The wizard updates all security-related configuration files and ensures that ADF resources are secure by default. [Table 35-2](#) shows which files the Configure ADF Security wizard updates.

**Table 35–2 Files Updated for ADF Authentication and Authorization**

File	File Location	Wizard Configuration
web.xml	/public_html/WEB-INF directory relative to the user interface project	<ul style="list-style-type: none"> <li>■ Defines the Oracle <code>JpsFilter</code> filter to set up the OPSS policy provider. The filter defines settings that indicate that your servlet has special privileges. It is important that the <code>JpsFilter</code> be the first filter definition in the <code>web.xml</code> file.</li> <li>■ Adds the Oracle <code>adfAuthentication</code> servlet definition to require the user to log in the first time the application is accessed.</li> <li>■ When you select the <b>ADF Authentication and Authorization</b> option in the wizard, maps the <code>adfAuthentication</code> servlet to a security constraint that will trigger user authentication dynamically.</li> <li>■ When you select the <b>ADF Authentication</b> option in the wizard, maps the Java EE application root <code>"/</code> to the <code>allPages</code> security constraint that will trigger user authentication dynamically.</li> <li>■ Sets the authentication method for the Login configuration to handle user login.</li> <li>■ Defines required security roles, including the role <code>valid-users</code>, which is used to trigger the security constraint that enables dynamic authentication.</li> </ul>
adf-config.xml	/.adf/META-INF directory relative to the web application workspace	<ul style="list-style-type: none"> <li>■ Defines the JAAS security context.</li> <li>■ Enables the use of the ADF authentication servlet (the <code>authenticationRequire</code> parameter in the <code>&lt;JaasSecurityContext&gt;</code> element is set to <code>true</code>). This parameter is used in J2SE applications to trigger displaying a login dialog.</li> <li>■ Enables the use of ADF Security security policies for authorization checking (the <code>authorizationEnforce</code> parameter in the <code>&lt;JaasSecurityContext&gt;</code> element is set to <code>true</code>).</li> </ul>
jps-config.xml	/src/META-INF directory relative to the web application workspace	<ul style="list-style-type: none"> <li>■ Defines the Oracle Platform Security Services context for the credential store.</li> <li>■ Defines the Oracle Platform Security Services context for the identity store and references the <code>jazn-data.xml</code> file as the service provider.</li> <li>■ Defines the Oracle Platform Security Services context for the policy store and references the <code>jazn-data.xml</code> file as the service provider.</li> <li>■ Defines the Oracle Platform Security Services context for the anonymous user, which contains the anonymous service instance and the anonymous login module.</li> </ul>
weblogic.xml	/public_html/WEB-INF directory relative to the web application workspace	<ul style="list-style-type: none"> <li>■ Maps the <code>valid-users</code> security role to the Oracle Platform Security Services principal users.</li> </ul>
jazn-data.xml	./src/META-INF directory relative to the web application workspace	<ul style="list-style-type: none"> <li>■ Sets the default <code>jazn.com</code> realm name for the XML identity store that you configure for use with Integrated WebLogic Server.</li> </ul>

Because authentication is delegated to the web container, the wizard updates the `web.xml` file to enable authentication by the ADF authentication servlet. It defines servlet mapping for the ADF authentication servlet and adds two Java EE security constraints, `allPages` and `adfAuthentication`, to the `web.xml` file, as shown in [Example 35-1](#).

**Example 35-1 ADF Authentication Descriptors in the web.xml File**

```
<servlet>
 <servlet-name>adfAuthentication</servlet-name>
 <servlet-class>
 oracle.adf.share.security.authentication.AuthenticationServlet
 </servlet-class>
 <load-on-startup>1</load-on-startup>
</servlet>
...
<servlet-mapping>
 <servlet-name>adfAuthentication</servlet-name>
 <url-pattern>/adfAuthentication</url-pattern>
</servlet-mapping>
...
<security-constraint>
 <web-resource-collection>
 <web-resource-name>allPages</web-resource-name>
 <url-pattern>/</url-pattern>
 </web-resource-collection>
 <auth-constraint>
 <role-name>valid-users</role-name>
 </auth-constraint>
</security-constraint>
<security-constraint>
 <web-resource-collection>
 <web-resource-name>adfAuthentication</web-resource-name>
 <url-pattern>/adfAuthentication</url-pattern>
 </web-resource-collection>
 <auth-constraint>
 <role-name>valid-users</role-name>
 </auth-constraint>
</security-constraint>
```

Because the `allPages` constraint maps to the `'/'` URL, it protects the Java EE application root. This mapping enables the ADF authentication servlet to trigger user authentication dynamically even before ADF Security is accessed. When the user first accesses the application, it forces the container to challenge the user for the user name and password. Then when the user accesses a page protected by ADF Security, there is no longer a need to authenticate the user and no need to redirect to the ADF authentication servlet.

---

---

**Note:** You can remove the `allPages` constraint from the `web.xml` file if you prefer to provide a login link or button to explicitly trigger login. You could also have a link or button to perform logout. For details about creating a custom component to perform login and logout, see [Section 35.7, "Creating a Login Page."](#) If you keep the constraint to allow dynamic authentication, because it covers everything under the Java EE application root, your login page may not display supporting resources at runtime, as described in [Section 35.7.2.5, "Ensuring That the Login Page's Resources Are Accessible."](#)

---

---

Because every user of the application is required to be able to log in, the security constraint defined against the `adfAuthentication` resource allows all users to access this web resource. As such, the security role associated with the constraint must encompass all users. To simplify this task, the Java EE `valid-users` role is defined. The `weblogic.xml` file maps this role to an implicit `users` group defined by Oracle WebLogic Server. This mapping ensures that every user will have this role because Oracle WebLogic Server configures all properly authenticated users as members of the `users` group, as described in [Section 35.3.7, "What You May Need to Know About the valid-users Role."](#)

---

---

**Note:** The `adfAuthentication` resource constraint provides the definition of a single standard URL pattern against the ADF authentication servlet. Your web pages can provide an explicit login or logout link that references the ADF authentication servlet URL pattern. This explicit login scenario is an alternative to generating a simple login form in the Configure ADF Security wizard and relying on ADF authentication to prompt the user to log in. For details about handling the explicit login scenario, see [Section 35.7, "Creating a Login Page."](#)

---

---

To enable authorization, the wizard updates the `adf-config.xml` file and sets the `authorizationEnforce` parameter in the `<JaasSecurityContext>` element to `true`, as shown in [Example 35-2](#).

**Example 35-2 AuthorizationEnforce Flag Enabled in the `adf-config.xml` File**

```
<JaasSecurityContext
 initialContextFactoryClass="oracle.adf.share.security.JAASInitialContextFactory"
 jaasProviderClass="oracle.adf.share.security.providers.jps.JpsSecurityContext"
 authorizationEnforce="true"
 authenticationRequire="true"/>
```

When authorization is enabled, the ADF security context gets the user principals from the `HttpServletRequest` once the user is authenticated by the container. The user submits a user name and password and that data is compared against the data in the identity store where user information is stored. If a match is found, the originator of the request (the user) is authenticated. The user name is then stored in the ADF security context, where it can be accessed to obtain other security-related information (such as the group the user belongs to) in order to determine authorization rights. For details about accessing the ADF security context, see [Section 35.11.3, "Getting Information from the ADF Security Context."](#)

### 35.3.3 What Happens When You Generate a Default Form-Based Login Page

The wizard-generated login and error pages are simple HTML pages that are added to the top-level folder of your user interface project. The generated login page defines a form with the standard `j_security_check` action. The form takes the user name and password as input to the `j_SecurityCheck` method within the container's security model.

The wizard updates the `web.xml` file to specify Form-based authentication and identify the location of the pages, as shown in [Example 35-3](#).

**Example 35-3 Wizard-Generated Login Page Definition Added to in the `web.xml` File**

```
<login-config>
 <auth-method>FORM</auth-method>
 <form-login-config>
 <form-login-page>/login.html</form-login-page>
 <form-error-page>/error.html</form-error-page>
 </form-login-config>
</login-config>
```

### 35.3.4 What You May Need to Know About the Configure ADF Security Wizard

The first time you run the Configure ADF Security wizard and enable authentication and authorization, you secure ADF resources at the level of the application.

Additionally, you select specific project-level settings for the user interface project, including the authentication type and the authentication welcome. The wizard adds these web application settings to the `web.xml` file in the project you select. When your application contains multiple user interface projects and `web.xml` files, you can return to the wizard and configure these settings in the `web.xml` file for another user interface project that you select.

### 35.3.5 What You May Need to Know About ADF Authentication

Java EE container-managed security defines a standard method for login. There is no standard way to log out and stay within a secured application, so while the login process is delegated to the container, the logout process is handled by the ADF authentication servlet itself.

On the first access to a page that relies on an ADF security-aware resource, if there is no subject defined, OPSS is configured by the `JPSFilter` to create a subject containing the anonymous user principal and the `anonymous-role` role principal. With this role principal, the unauthenticated user will be able to access public web pages that are not associated with any ADF security-aware resources (including ADF bounded task flows or page definitions).

In the case of pages associated with ADF security-aware resources, you must explicitly grant `view` permission to `anonymous-role` to make the page accessible to the anonymous user. For details about granting privileges to the anonymous user, see [Section 35.5.1, "How to Make an ADF Resource Public."](#)

### 35.3.6 What You May Need to Know About the Built-In `test-all` Role

The Configure ADF Security wizard lets you enable automatic grants to the built-in `test-all` application role for the purpose of granting `view` permission to all ADF security-aware resources in your application. Without a permission grant, either an automatic view grant or an explicit grant that you define, ADF Security authorization checking enforcement would prevent you from being able to run the application and

access its resources. You can run the wizard with the `test-all` application role feature enabled and then gradually replace automatic view grants with explicit grants. Be aware that you must not deploy the application with grants to the `test-all` application role in place, since this feature makes all ADF resources public. If you choose to enable the built-in `test-all` application role in the wizard, see [Section 35.9.1, "How to Remove the test-all Role from the Application Policy Store,"](#) before deploying your application.

### 35.3.7 What You May Need to Know About the `valid-users` Role

The `valid-users` role is a Java EE security role defined by ADF Security to ensure that all users will access the `adfAuthentication` servlet web resource defined in the `web.xml` file. The Configure ADF Security wizard updates the `weblogic.xml` file to map this ADF Security role to the `users` principal, as shown in [Example 35-4](#). This mapping ensures that every user will have this role, because Oracle WebLogic Server configures all properly authenticated users as members of the `users` group.

#### **Example 35-4** *valid-users Role Mapping in the `weblogic.xml` File*

```
<security-role-assignment>
 <role-name>valid-users</role-name>
 <principal-name>users</principal-name>
</security-role-assignment>
```

The `users` principal name is a special principal defined by OPSS that serves a purpose similar to an enterprise role. At runtime, the principal is added automatically to a successfully authenticated subject by OPSS. From a security perspective, the `valid-users` role supports ADF authentication only in the case where you need to control access to web resources using security constraints alone. The end result of this mapping relies entirely on Java EE security and does not involve JAAS Permissions.

## 35.4 Creating Application Roles

You create application roles to represent the policy requirements of the application and to define groups of users with the same view permission rights. The application roles that you create in the application policy store are specific to your application. For example, in the context of the work flow, there may be application roles such as `fod-customer`, `fod-productSpecialist`, `fod-supervisor`, and `fod-admin`, where `fod` identifies these roles as specific to the Fusion Order Demo application.

At runtime, the access rights are conferred on the user through the application role for which the user is defined as a member. Thus, before you can define security policies, the policy store must contain the application roles that you intend to issue grants to. This can be an application role that you define (such as `fod-users`) or it can be one of the two built-in application roles defined by OPSS: `authenticated-role` or `anonymous-role`. JDeveloper provides the built-in application roles to let you make ADF resources public, as described in [Section 35.5.1, "How to Make an ADF Resource Public."](#)

After you create the application role, you will:

- Grant permissions to the application roles, as described in [Section 35.5, "Defining ADF Security Policies."](#)
- Associate test users with each application role, as described in [Section 35.6, "Creating Test Users."](#)

**Best Practice:** The ADF Security framework enforces a role-based access control mechanism with permissions granted either to application roles or to individual users. Although you may only need to test security and therefore might not need to create groups of users, you should still create application roles (with at least one user member). Later when you define security policies on the ADF resources, the overview editor for the application policy store will allow you to select an application role for the grant.

### 35.4.1 How to Create Application Roles

JDeveloper lets you add application roles to the policy store of the `jazn-data.xml` file, which appears in the **Descriptors/META-INF** node of the Application Resources panel.

---

**Note:** When you create application roles, be sure to add the new application roles to the policy store, not the identity store. Roles that you add to the identity store define enterprise security roles and provide a way to conveniently group users in the identity store. For more details about enterprise roles, see [Section 35.4.3, "What You May Need to Know About Enterprise Roles and Application Roles."](#)

---

To create application roles in the policy store of the `jazn-data.xml` file, you use the Application Roles page of the overview editor for the `jazn-data.xml` file. This editor lets you view the relationship between identity store members and the application roles you create.

#### Before you begin:

It may be helpful to have an understanding of application roles. For more information, see [Section 35.4, "Creating Application Roles."](#)

#### To create application roles:

1. In the main menu, choose **Application** and then **Secure > Application Roles**.
2. In the Application Roles page of the `jazn-data.xml` overview editor, select the policy store for your application from the **Security Policy** dropdown list.  
The policy store that JDeveloper creates in the `jazn-data.xml` file is automatically based on the name of your application.
3. In the **Roles** list, click the **New** icon.
4. In the **Name** field, enter the name of the role and click any other field to add the application role to the policy store.
5. If you have already setup test users in the identity store, you can map users and roles, as described in [Section 35.6.3, "How to Associate Test Users with Application Roles."](#)

### 35.4.2 What Happens When You Create Application Roles

When you add an application role to the policy store, JDeveloper updates the `jazn-data.xml` file located in the `src/META-INF` directory relative to the application workspace. Application roles are defined in `<app-role>` elements under `<policy-store>`, as shown in [Example 35-5](#). Because the policy store `<application>` element names the application, at runtime all application roles that

you create will be visible to your application only. Other web applications may define a policy store with their own set of application roles.

**Example 35–5 Application Role Definition in the Policy Store**

```
<policy-store>
 <applications>
 <application>
 <name>StoreFrontModule</name>
 <app-roles>
 <app-role>
 <name>fod-users</name>
 <display-name>FOD Users</display-name>
 <class>oracle.security.jps.service.policystore.
 ApplicationRole</class>
 </app-role>
 ...
 </app-roles>
 </application>
 </applications>
</policy-store>
```

### 35.4.3 What You May Need to Know About Enterprise Roles and Application Roles

An *enterprise role* is a role that is maintained in the domain policy store (as opposed to an application policy store). Enterprise roles are available to every application deployed in the domain and defined in the domain identity store, typically represented by an ordered list of authenticators configured in the domain.

An *application role* is a role used by a Fusion web application. It is specific to the application, defined by the application policy, and not necessarily known to the Java EE container. Application roles are scoped in the sense that they can contain only users and roles defined in the application. Application roles must be mapped to enterprise roles.

You use the overview editor for the `jazn-data.xml` file to create enterprise roles to group users that you add to the identity store. You can use this mechanism to assign entire groups of users to application roles that you have defined for the purpose of conferring access rights defined by ADF security policies, as described in [Section 35.6.3, "How to Associate Test Users with Application Roles."](#)

However, Integrated WebLogic Server does not require you to create enterprise roles to run the application within JDeveloper. For the purpose of testing the application, it may be sufficient to create a few test users and assign them directly to application roles. When you run the application in JDeveloper, the users and any enterprise roles you defined will be created in the default security provider (which is embedded LDAP for Integrated WebLogic Server).

Typically, when you deploy the application for staging, you will migrate only the policy store to the target server. You can configure JDeveloper deployment options so that the identity store, including test users and enterprise roles, is not migrated, as described in [Section 35.8.1, "How to Configure, Deploy, and Run a Secure Application in JDeveloper."](#)

After you deploy the secure application, Oracle Fusion Middleware will merge your application's policy store with the policies of the domain-level policy store. To

complete this task, the administrator for the Oracle WebLogic Server will eventually map the application roles of your policy store to the existing domain-level enterprise roles. This application role mapping at the domain level allows enterprise users to access application resources according to the ADF security policies you have defined. The domain-level application role mapping by the administrator also allows you to develop the ADF security policies of your application without requiring any knowledge of the identity store in the production environment.

## 35.5 Defining ADF Security Policies

Authorization relies on a policy store that is accessed at runtime and that contains permissions that grant privileges to execute predefined actions, like `view`, on a specified object. Initially, after you run the Configure ADF Security wizard, the policy store defines no grants. And, because the default wizard option **ADF Authentication and Authorization** enables authorization checking, the web pages of your application that rely on the ADF security-aware resources will be inaccessible to users. You must use JDeveloper to define explicit grants for the resources that you want to permit users to access.

**Best Practice:** When you run the Configure ADF Security wizard with the default option **ADF Authentication and Authorization** selected, you will lock down the web pages of your application. This affords the most protection to the Fusion web application possible since you will define explicit grants to allow users to access only the pages you intend. For a discussion of this guideline and others, see [Section 35.11.4, "Best Practices for Working with ADF Security."](#)

Before you can define security policies, the policy store for your application must contain the application roles that you intend to issue grants to. This can be an application role that you define (such as `fod-users`) or it can be one of the two built-in application roles defined by OPSS: `authenticated-role` or `anonymous-role`. You use application roles to classify users, so that each member of the same role possesses the same access rights. As such, the security policy names the application role as the principal of the grant, rather than specific users. For details about defining application roles, see [Section 35.4, "Creating Application Roles."](#)

For the user interface project, you use the `jazn-data.xml` file overview editor to secure ADF resources, including ADF task flows and ADF page definitions. You open the editor on the `jazn-data.xml` file by double-clicking the `jazn-data.xml` file (located in the Application Resources panel) or by choosing **Secure > Resource Grants** from the **Application** menu in the main menu.

Note that when you open the `jazn-data.xml` file, the overview editor provides additional editor pages that you use to create test users, enterprise roles, and application roles.

For the data model project, you do not secure entity objects or their attributes using the `jazn-data.xml` file overview editor. Instead, you set metadata directly on these objects to manage whether or not the databound UI component displays the data. For details about granting permissions for row-level security, see [Section 35.5.10, "How to Define Policies for Data."](#)

### 35.5.1 How to Make an ADF Resource Public

It is a common requirement that some web pages be available to all users, regardless of their specific access privileges. For example, the home page should be seen by all

visitors to the site, while a corporate site should be available only to those who have identified themselves through authentication.

In both cases, the page may be considered public, because the ability to view the page is not defined by the users' specific permissions. Rather, the difference is whether the user is anonymous or a known identity.

In the ADF security model, you differentiate between the absence of security and public access to content by granting access privileges to the `anonymous-role` principal. The anonymous role encompasses both known and anonymous users, thus permission granted to `anonymous-role` allows access to a resource by unauthenticated users, for example, guest users. To provide access to authenticated users only, the policy must be defined for the `authenticated-role` principal.

---

---

**Note:** For details about creating a public home page which contains links to other pages in the application, see [Section 35.7.3, "How to Create a Public Welcome Page."](#)

---

---

### Before you begin:

It may be helpful to have an understanding of ADF security policies. For more information, see [Section 35.5, "Defining ADF Security Policies."](#)

You will need to complete these tasks:

1. Create bounded task flows as described in [Section 18.2, "Creating a Task Flow."](#)
2. Create web pages with an ADF page definition file as described in [Section 13.7, "Working with Page Definition Files."](#)
3. Run the Configure ADF Security wizard as described in [Section 35.3, "Enabling ADF Security."](#)
4. Create application roles as described in [Section 35.4, "Creating Application Roles."](#)

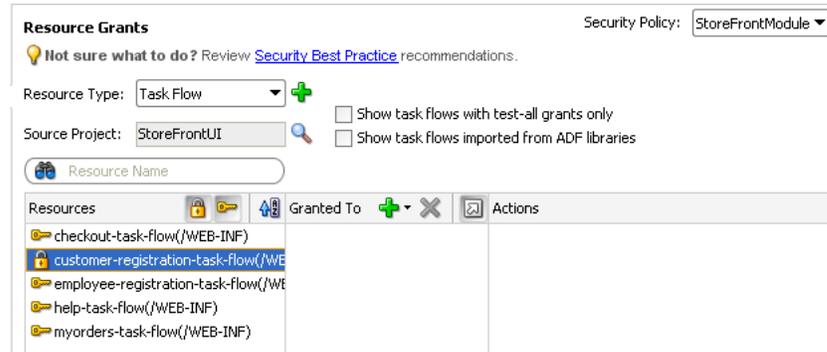

### To grant public access to ADF security-aware resources:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the `jazn-data.xml` file overview editor, select one of the following resources from the **Resource Types** dropdown list:
  - **Task Flow** when you want to make a bounded task flow public. The application displays the web pages under the permission you define for the task flow itself. Thus, all constituent web pages of the bounded task flow will become public.
  - **Web Page** when you want to make individual web pages public. Typically, these pages are defined by an unbounded task flow and are top-level pages in the application, such as a home page.
3. In the **Resources** column, select the ADF resource for which you want to grant access rights.

The resource you select should display the lock icon in the first column next to the resource name. The lock icon indicates that the resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant. For example, in [Figure 35-4](#), the ADF resource `customer-registration-task-flow` (a bounded task flow) shows the lock icon since no grant has been made.

**Tip:** Click the key toggle icon in the header for the overview editor's first column to hide or show resources that already have grants and display only the resources without grants. The key icon indicates that the resource has a grant that will make the resource accessible to users with sufficient access rights.

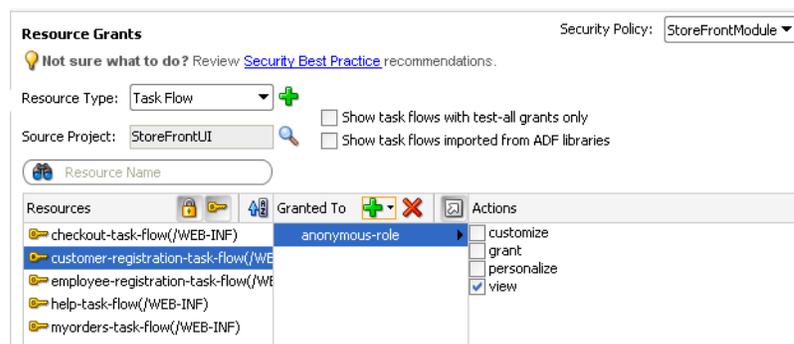

**Figure 35–4** *Selecting an ADF Security-Aware Resource in the Overview Editor*

4. In the **Granted to** column, click the **Add Grantee** icon and choose **Add Application Role**.
5. In the Select Application Roles dialog, select one of these built-in application roles:
  - **anonymous-role** means the resource will be accessible to anyone who visits the site. A grant to this role is necessary if you want to make a web page associated with an ADF security-aware resource accessible before a user logs in. For example, you would grant to `anonymous-role` for a task flow that manages customer registration.
  - **authenticated-role** means the resource will be accessible only to authenticated users (ones who visit the site and log in). For example, you would grant to `authenticated-role` for an employee registration task flow.
6. In the Select Application Roles dialog, click **OK**.
7. In the Resource Grants page of the overview editor, in the **Actions** column, leave the **View** action selected.

By default, the overview editor shows **View** selected, as shown in Figure 35–5. The view action is the only action currently supported for Fusion web applications.

**Figure 35–5** *Granting to anonymous-role in the Overview Editor*

## 35.5.2 What Happens When You Make an ADF Resource Public

When you define a security policy, the `jazn-data.xml` file overview editor updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The overview editor writes the policy information to the `<policy-store>` section of the file. The security policy, or grant, contains both a grantee and one or more permissions. The grantee is the application role that the policy is being defined for—in this case, the anonymous role. Each permission defines the resource being secured and the action that can be performed against that resource.

[Example 35–6](#) shows a security policy in the `jazn-data.xml` file that makes a customer registration task flow public. The grant to `anonymous-role` contains a single view permission for a bounded task flow, `customer-registration-task-flow`. With this grant, all users will be able to enter the customer registration task flow and complete the customer registration process. Additional grants to the anonymous role may be made and will appear in the `<permissions>` section of the anonymous role grant.

### **Example 35–6 Grants to anonymous-role in the Application-Level Policy Store**

```
<policy-store>
 ...
 <jazn-policy>
 <grant>
 <grantee>
 <principals>
 <principal>
 <class>oracle.security.jps.internal.core.
 principals.JpsAnonymousRoleImpl</class>
 <name>anonymous-role</name>
 </principal>
 </principals>
 </grantee>
 <permissions>
 <permission>
 <class>oracle.adf.controller.security.TaskFlowPermission</class>
 <name>/WEB-INF/customer-registration-task-flow.xml#
 customer-registration-task-flow</name>
 <actions>view</actions>
 </permission>
 ...
 </permissions>
 </grant>
 ...
 </jazn-policy>
</policy-store>
```

## 35.5.3 What Happens at Runtime: How the Built-in Roles Are Used

The `anonymous-role` and `authenticated-role` names are special roles defined by Oracle Platform Security Services (OPSS).

When you run the Configure ADF Security wizard, the wizard configures the `JpsFilter` definition in the `web.xml` file to enable support for the anonymous role. The enabled anonymous role allows ADF Security to support browsing of the site by anonymous users—those users who have not yet logged in. In contrast, the

authenticated role is not declared and is always recognized by default. ADF Security supports both of these roles.

When an end user first accesses an ADF security-aware resource, the system creates a subject and populates it with the anonymous role principal. As long as the ADF security-aware resource being accessed has the view grant to anonymous role, the user is permitted access. If the anonymous role is not a grantee of the ADF resource, the user is prompted to log in. After logging in, the authenticated role is added to the subject. The wizard also adds the `JpsFilter` definition to the `web.xml` file, where `remove.anonymous.role` set to `false` ensures that the anonymous role principal is available even after the user logs in. With the authenticated role principal, the user may access resources that have an explicit grant to the authenticated role.

### 35.5.4 How to Define Policies for ADF Bounded Task Flows

You define the access policy for an ADF bounded task flow by creating permission grants in the Resource Grants page of the `jazn-data.xml` file overview editor. The grants you create will appear as metadata in the policy store section of the `jazn-data.xml` file. This metadata defines a permission target (in this case, the bounded task flow definition name) for which you have issued grants to authorize the members of a specific application role.

**Best Practice:** Do not create permission grants for the individual web pages of a bounded task flow. When the user accesses the bounded task flow, security for all pages will be managed by the permissions you grant to the task flow. And, because the contained web pages (with associated page definitions) will be inaccessible by default, ADF Security prevents users from directly accessing the pages of the task flow. This supports a well-defined security model for task flows that enforces a single entry point for all users. For further information about implementing security policies, see [Section 35.11.4, "Best Practices for Working with ADF Security."](#)

You can sort the task flows in the overview editor by clicking the toggle buttons in the **Task Flow** header, as described in [Table 35–3](#).

**Table 35–3** Resource Grant Toggle Buttons for Bounded Task Flows

Button	Toggle Action	Description
	Shows/hides bounded task flows with no grants	Represents a bounded task flow with no permission grants defined. The web pages that the task flow calls will not be accessible to any user.
	Shows/hides bounded task flows with grants	Represents a bounded task flow with one or more permission grants defined. The web pages that the task flow calls will be accessible to users who are members of the application role that received the grant.

The list of available actions displayed by the overview editor is defined by the task flow permission class (`oracle.adf.controller.security.TaskFlowPermission`). The permission class maps these actions to the operations supported by the task flow. [Table 35–4](#) shows the actions displayed by JDeveloper for ADF bounded task flows.

Note that the `view` action is the only action currently supported for Fusion web applications. Do not select `customize`, `grant`, or `personalize` actions—they are reserved for future use in task flow security.

**Table 35–4 Secured Actions of ADF Bounded Task Flows**

Grantable Action	Effect on the User Interface
view	Controls who can read and execute a bounded task flow in a Fusion web application. This is the only operation that the task flow supports.
customize	Reserved for future use. This action is not checked at runtime.
grant	Reserved for future use. This action is not checked at runtime.
personalize	Reserved for future use. This action is not checked at runtime.

To define a grant for the task flow security policy, use the Resource Grants page of the overview editor for the `jazn-data.xml` file.

### Before you begin:

It may be helpful to have an understanding of ADF security policies. For more information, see [Section 35.5, "Defining ADF Security Policies."](#)

You will need to complete these tasks:

1. Create bounded task flows as described in [Section 18.2, "Creating a Task Flow."](#)

**Best Practice:** If you are creating bounded task flows in separate UI projects of the same application, you will want to assign unique task flow definition names. This is necessary because a grant's task flow definition name is scoped in the `jazn-data.xml` policy store by path (for example, `/WEB-INF/mytaskflow-definition.xml#mytaskflow-definition`). Therefore creating bound task flows with unique definition names is the only way to impose project-level scoping of the grants.

2. Run the Configure ADF Security wizard as described in [Section 35.3, "Enabling ADF Security."](#)
3. Create application roles as described in [Section 35.4, "Creating Application Roles."](#)

### To define a permission grant on an ADF bounded task flow:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the `jazn-data.xml` file overview editor, select **Task Flow** from the **Resource Types** dropdown list.

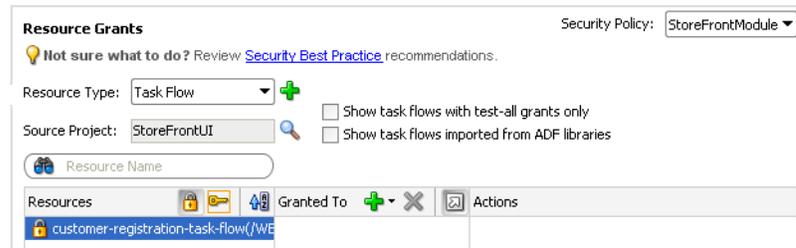

The overview editor displays all the task flows that your application defines. Task flows are defined by task flow definition files (`.xml`) that appear in the Web Content/Page Flows node of the user interface project.

3. In the **Resources** column, select the task flow for which you want to grant access rights.

The first time you make a grant to a bounded task flow, the first column should display the **Resources without any grants** icon (represented by the "lock" icon) next to the task flow name. The overview editor displays the lock icon to indicate that a resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant.

**Tip:** Click the **Resources with grants** icon (represented by the "key" icon) in the header for the **Resources** column to hide all task flows that already have grants. This will display only task flows without grants, as shown in [Figure 35–6](#). Additionally, you can type a partial task flow name in the search field to display only the task flows with character-matching names.

**Figure 35–6 Hiding Task Flows with Grants in the Overview Editor**

4. In the **Granted to** column, click the **Add Grantee** icon and choose **Add Application Role**.
5. In the Select Application Roles dialog, select the application role that you want to make a grantee of the permission.

The Select Application Roles dialog displays application roles from the `jazn-data.xml` file. It also displays the built-in OPSS application roles, **anonymous-role** and **authenticated-role**, as described in [Section 35.5.3, "What Happens at Runtime: How the Built-in Roles Are Used."](#)

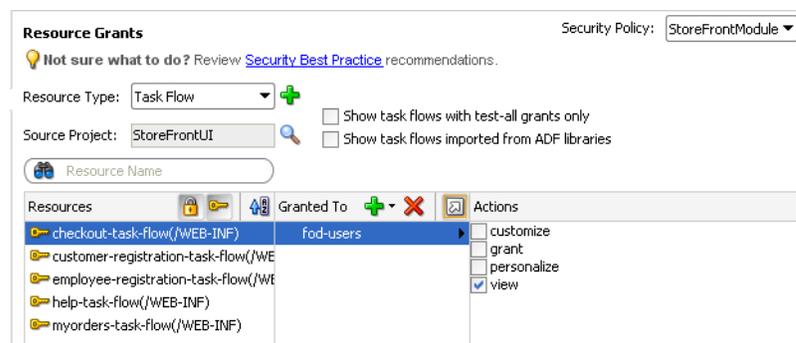

If you do not see application roles that are specific to your application, create the role as described in [Section 35.4, "Creating Application Roles."](#)

6. In the Select Application Roles dialog, click **OK**.
7. In the Resource Grants page of the overview editor, in the **Actions** column, leave the **View** action selected.

By default, the overview editor shows **view** selected, as shown in [Figure 35–7](#). The view action is the only action currently supported for Fusion web applications. Do not select **customize**, **grant**, or **personalize** actions—they are reserved for future use and will not be checked by ADF Security at runtime.

The `TaskFlowPermission` class defines task flow—specific actions that it maps to the task flow's operations, as described in [Table 35–4](#).

**Figure 35–7 Granting to an Application Role for a Bounded Task Flow Definition in the Overview Editor**

8. You can repeat these steps to make additional grants as desired.

The same task flow definition can have multiple grants made for different application roles. The grants appear in the policy store definition of the `jazn-data.xml` file, as described in [Section 35.5.6, "What Happens When You Define the Security Policy."](#)

### 35.5.5 How to Define Policies for Web Pages That Reference a Page Definition

You define the access policy for an ADF page definition by creating permission grants in the Resource Grants page of the `jazn-data.xml` file overview editor. The grants you create will appear as metadata in the policy store section of the `jazn-data.xml` file. This metadata defines a permission target (in this case, the page definition name) for which you have issued grants to authorize the members of a specific application role.

**Best Practice:** Create permission grants for the individual web page only when the page is not a constituent of a bounded task flow. Page-level security is checked for pages that have an associated page definition binding file *only* if the page is directly accessed or if it is accessed in an *unbounded* task flow. For further information about implementing security policies, see [Section 35.11.4, "Best Practices for Working with ADF Security."](#)

You can sort the web page definition resources in the overview editor by clicking the toggle buttons in the **Resources** header, as described in [Table 35–5](#).

**Table 35–5 Resource Grant Toggle Buttons for Web Page Definitions**

Button	Toggle Action	Description
	Shows/hides top-level pages with no grants	Represents a page definition with no permission grants defined for a web page that is contained in an unbounded task flow. The web page will not be accessible to any user.
	Shows/hides top-level pages with grants	Represents a page definition with one or more permission grants defined for a web page that is contained in an unbounded task flow. The web page will be accessible to users who are members of the application role that received the grant.
	Shows/hides pages included in a bounded task flow	Represents a page definition associated with a web page that also is contained in a bounded task flow. Do not grant to these web page definitions. Instead, define a security policy for the bounded task flow.
	Shows/hides unsecurable pages (with no page definition)	Represents a web page with no page definition defined that is contained in an unbounded task flow. (Pages like this that are contained by a bounded task flow are secured by the bounded task flow's permission.) The web page will be accessible to all users since it is not secured by an associated ADF security-aware resource. Optionally, you can secure the page by adding an empty page definition file, as described in <a href="#">Section 35.5.8, "What You May Need to Know About Defining Policies for Pages with No ADF Bindings."</a>

The list of available actions displayed by the overview editor is defined by the region permission class (`oracle.adf.share.security.authorization.RegionPermission`). The permission class maps these actions to the operations supported by the ADF page definition for the web page. [Table 35–6](#) shows the actions displayed by JDeveloper for ADF page definitions.

Note that the `view` action is the only action currently supported for Fusion web applications.

**Table 35–6 Securable Actions of ADF Page Definitions**

Grantable Action	Effect on the User Interface
<code>view</code>	Controls who can view the page. This is the only operation that the page definition supports.

To define a grant for the page definition security policy, use the Resource Grants page of the overview editor for the `jazn-data.xml` file.

#### Before you begin:

It may be helpful to have an understanding of ADF security policies. For more information, see [Section 35.5, "Defining ADF Security Policies."](#)

You will need to complete these tasks:

1. Create the top-level web pages with an ADF page definition file as described in [Section 13.7, "Working with Page Definition Files."](#)

**Best Practice:** If you are creating top-level web pages in separate UI projects of the same application, you will want to assign unique page file names. This is necessary because a grant's page definition name is scoped in the `jazn-data.xml` policy store by package (for example, `view.pageDefs.mytoppagePageDef`). Therefore creating top-level pages with unique file names is the only way to impose project-level scoping of the grants.

2. Run the Configure ADF Security wizard as described in [Section 35.3, "Enabling ADF Security."](#)
3. Create application roles as described in [Section 35.4, "Creating Application Roles."](#)

#### To define a permission grant on an ADF page definition:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the `jazn-data.xml` file overview editor, select **Web Page** from the **Resource Types** dropdown list.

The Resource Grants page of the overview editor displays all web pages, including those that have an associated ADF page definition. This includes any web page that uses ADF data bindings or any web page for which you have created an empty page definition. Page definitions are defined by `PageDef.xml` files that appear in the Application Sources node of the user interface project.

3. In the **Page Definition** column, select the page definition for which you want to grant access rights.

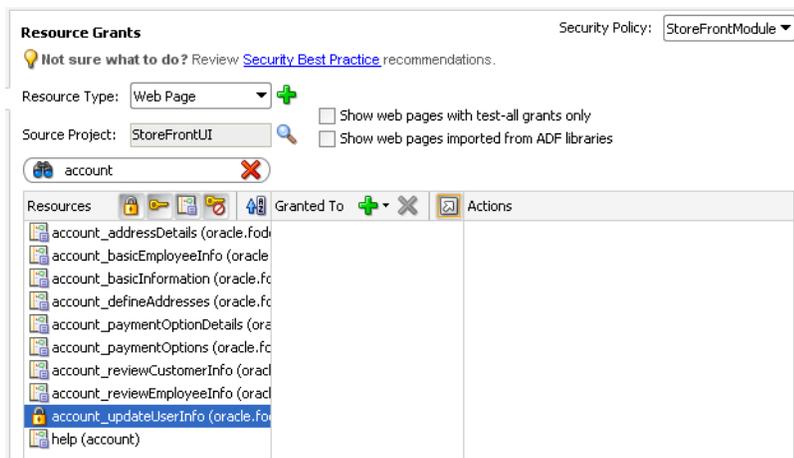

The first time you make a grant to a page definition, the first column should display the **Resource without any grants** icon (represented by the "lock" icon) next to the page definition name. The editor displays the lock icon to indicate that a resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant. For example, the page definition `account_updateUserInfo` shown in [Figure 35–8](#) displays the lock icon since no grant has been made. Other page definitions in [Figure 35–8](#) show the

**Page included in bounded task flow** icon because they are not top-level pages and thus are securable by the containing bounded task flow.

Do not create grants for individual web page definitions that display the **Page included in bounded task flow** icon. Security policies for the associated web pages are secured by their bounded task flow. For example, in [Figure 35–8](#), the page definition associated with the `account_addressDetails.jsff` region will be secured by the containing bounded task flow.

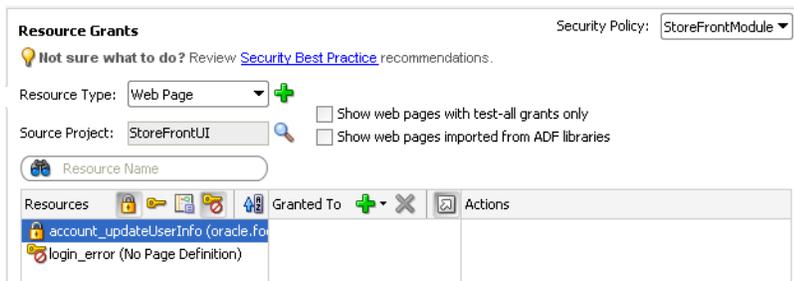

**Tip:** You can type a partial page definition name in the search field to display only the page definitions with character-matching names. For example, a search on the word `account` would display only the page definitions that begin with the word `account`, as shown in [Figure 35–8](#).

**Figure 35–8 Matching Page Definitions by Name in the Overview Editor**

**Tip:** You can click the **Resources with grants** icon (represented by the "key" icon) to hide all page definitions that already have grants. Confirm that the **Show pages included in a bounded task flow** toggle button in the header for the **Resources** column is toggled off to hide all page definitions that are included in a bounded task flow (by default, it is set to hide these pages). This will display top-level pages that have no grants (and unsecurable pages, if any), as shown in [Figure 35–9](#).

**Figure 35–9 Hiding Web Pages with Grants in the Overview Editor**

4. In the **Granted to Roles** column, click the **Add Application Role** icon.

5. In the Select Application Roles dialog, select the application role that you want to make a grantee of the permission.

The Select Application Roles dialog displays application roles from the `jazn-data.xml` file. It also displays the built-in OPSS application roles, **anonymous-role** and **authenticated-role**, as described in [Section 35.5.3, "What Happens at Runtime: How the Built-in Roles Are Used,"](#)

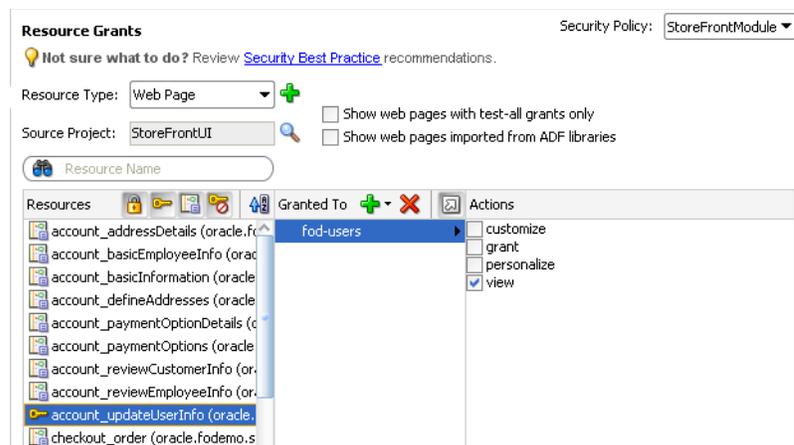

If you do not see application roles that are specific to your application, create the role as described in [Section 35.4, "Creating Application Roles."](#)

6. In the Select Application Roles dialog, click **OK**.
7. In the Resource Grants page of the overview editor, in the **Actions** column, leave the **View** action selected.

By default, the overview editor shows **view** selected, as shown in [Figure 35–10](#). The view action is the only action currently supported for Fusion web applications.

The `RegionPermission` class defines page definition—specific actions that it maps to the page's operations, as described in [Table 35–6](#).

**Figure 35–10** Granting to an Application Role for an ADF Page Definition in the Overview Editor

8. You can repeat these steps to make additional grants as desired.

The same page definition can have multiple grants made for different application roles. The grants appear in the policy store definition of the `jazn-data.xml` file, as described in [Section 35.5.6, "What Happens When You Define the Security Policy."](#)

### 35.5.6 What Happens When You Define the Security Policy

When you define a security policy, the `jazn-data.xml` file overview editor updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The overview editor writes the policy information to the `<policy-store>` section of the file. The security policy, or grant, contains both a grantee and one or more permissions. The grantee is the application role that the policy is being defined for. Each permission defines the resource being secured and the action that can be performed against that resource.

[Example 35–7](#) shows a security policy in the `jazn-data.xml` file that secures a checkout task flow and secures a top-level web page that lets users update account information. The grant to the `fod-users` application role contains a view permission for a bounded task flow, `checkout-task-flow`, and a view permission on the web page with the `account_updateUserInfoPageDef` page definition. With this grant, only users who are authenticated as members of the `fod-users` application role will be able to enter the checkout task flow or view the user information update page.

For the web page, notice that permission has been defined on the `account_updateUserInfoPageDef` page definition created for the user information update page (`updateUserInfo.jspx`). Also, note that this is a top-level web page that is not already secured by a bounded task flow.

### **Example 35–7 Grants in the Application-Level Policy Store**

```
<policy-store>
 ...
 <jazn-policy>
 <grant>
 <grantee>
 <principals>
 <principal>
 <class>oracle.security.jps.service.policystore.ApplicationRole</class>
 <name>fod-users</name>
 </principal>
 </principals>
 </grantee>
 <permissions>
 <permission>
 <class>oracle.adf.controller.security.TaskFlowPermission</class>
 <name>/WEB-INF/checkout-task-flow.xml#checkout-task-flow</name>
 <actions>view</actions>
 </permission>
 <permission>
 <class>oracle.security.jps.service.policystore.ApplicationRole</class>
 <name>oracle.fodemo.storefront.pageDefs.acct_updateUserInfoPageDef</name>
 <actions>view</actions>
 </permission>
 ...
 </permissions>
 </grant>
 ...
 </jazn-policy>
</policy-store>
```

## **35.5.7 What Happens at Runtime: How ADF Security Policies Are Enforced**

Grants that you make for ADF resources are standard JAAS Permissions. When you enable ADF Security in your application, Oracle Platform Security Service (OPSS) running in Oracle WebLogic Server will utilize the grants to allow authorization. In authorization mode, ADF Security uses fine-grained authorization, implemented with JAAS Permissions to perform security checks for access rights to pages. The ADF Security enforcement logic checks to see whether the user, represented by the JAAS subject, has the right permissions to access the resource.

The subject contains the user's principals, which include a user principal that contains their name (could be anonymous, before logging on, or some user name after logging on), and their list of role principals, which would include `authenticated-role` and

some number of other roles that are obtained from the policy and identity stores. The principal is created to represent all of the user's memberships in application roles defined in the policy store. In turn, each application role may have multiple Permissions associated with them. These are the ADF security policies that are created through the overview editor for the `jazn-data.xml` file.

---

**Note:** ADF security policies are scoped by application. This scoping allows two applications to refer to the same permission target, without producing unintentional results. You are not required to name application resources to impose application scoping of the policy store information.

---

Before you run the application using Integrated WebLogic Server, you will need to provision the identity store with test users and add these users to the application roles that you want to configure. The application roles can define members that are specific users or groups of users (also known as *enterprise roles*), as described in [Section 35.6, "Creating Test Users."](#)

Then at runtime, whether the current user has view permission on the page they are trying to access will be determined by the context of the page:

- If the page is an activity of a bounded task flow, the task flow controller determines the permission.
- If the page is a top-level page with an associated page definition file, the ADF model determines the permission.

Oracle Platform Security Services then checks to see whether the subject contains the roles that have the corresponding permissions needed to access the page. If the user is authorized, then the task flow is entered.

In the case of a bounded task flow and top-level pages (defined by an unbounded task flow), if the user is not authorized, ADF Controller throws an exception and passes control to an exception handler that the task flow configuration specifies. For details about specifying an error page, see [Section 35.7.4, "How to Redirect a User After Authentication."](#)

### 35.5.8 What You May Need to Know About Defining Policies for Pages with No ADF Bindings

The default Configure ADF Security wizard option **ADF Authentication and Authorization** enables authorization checking and secures a web page whenever the page is associated with an ADF security-aware resource. Therefore, after you run the wizard, a web page will not be secured if both of these conditions exist:

- The page does not display databound ADF Faces components and therefore no ADF page definition exists for the page.
- The page is not a constituent page of a bounded ADF task flow. (Any page that the user accesses as a process of a bounded task flow is checked under the permission of the task flow.)

JDeveloper will generate an ADF page definition file for you whenever you design a web page using the Data Controls panel to create databound ADF Faces components (for details, see [Section 13.7, "Working with Page Definition Files"](#)). However, if your web page does not use ADF bindings, you can still create an *empty* page definition file by right-clicking the web page in the user interface project and choosing **Go to Page**

**Definition.** The page definition file can remain empty because the page does not need to work with ADF bindings to support databound ADF Faces components.

Once you associate a web page with an ADF page definition file, empty or not, authorization checking will be enforced when the user accesses the associated web page. You can define security policies for the page as you would any other ADF page definition. For details about making grants to an empty ADF page definition, see [Section 35.5.5, "How to Define Policies for Web Pages That Reference a Page Definition."](#)

**To create an empty page definition that you can define security policies for:**

1. In the Application Navigator, locate the web page you want to secure, right-click the node and choose **Go to Page Definition**.
2. In the confirmation dialog, click **Yes** to create a new page definition for the page.

The page definition will be added to the `pageDefs` package.

### 35.5.9 How to Use Regular Expressions to Define Policies on Groups of Resources

When you want to define a grant that applies to multiple resources at once, you can create patterns as defined by the `java.util.regex.Pattern` class to form a regular expression that gets evaluated at runtime. For example, to match a grant to a set of resources, you can enter the expression `.*` (specifies any character zero or more times) on the name of the permission. ADF Security does not support the use of regular expressions on other security objects, such as the principal name.

You might use this feature to group bounded task flows that would have the same permissions into their own subfolders of `WEB-INF` and define the grant for the entire folder, as shown in [Example 35-8](#). In this case, the expression uses the dot character (defined as, any character) followed by the asterisk quantifier (defined as, zero or more times).

**Example 35-8 Task Flow Permission for an Entire Folder Defined in the Application-Level Policy Store**

```
...
<grant>
 <grantee>
 <principals>
 <principal>
 <class>oracle.security.jps.service.policystore.ApplicationRole</class>
 <name>anonymous-role</name>
 </principal>
 </principals>
 </grantee>
 <permissions>
 <permission>
 <class>oracle.adf.controller.security.TaskFlowPermission</class>
 <name>/WEB-INF/.*</name>
 <actions>view</actions>
 </permission>
 </permissions>
</grant>
```

As the overview editor for the `jazn-data.xml` file does not support the use of regular expressions in the user interface, you must edit the file directly. Do not edit the policy store of the `system-jazn-data.xml` file directly. Instead, add grants using

regular expressions to the `jazn-data.xml` file. These grants will then be merged to the policy store when you run or deploy the application.

The use of more complex regular expressions enables you to define business rules in the policy, thus creating a very targeted set of permissions. For example, you can grant the view permission on all page definitions and deny specific page definitions at the same time by defining an exclusion set in your regular expression. [Example 35-9](#) shows how the view permission is granted to `anonymous-role` for all pages except those for which the page definition name starts with `custom`.

**Example 35-9 Using Regular Expressions and Metacharacters to Define a Policy Grant**

```
<grant>
 <grantee>
 <principals>
 <principal>
 <class>oracle.security.jps.service.policystore.ApplicationRole</class>
 <name>anonymous-role</name>
 </principal>
 </principals>
 </grantee>
 <permissions>
 <permission>
 <class>oracle.adf.share.security.authorization.RegionPermission</class>
 <name>[^(custom)].*</name>
 <actions>view</actions>
 </permission>
 </permissions>
</grant>
```

[Table 35-7](#) shows some of the basic regular expression metacharacters that you can use in your policy definitions.

**Table 35-7 Description of Metacharacters**

Metacharacter	Description
[abc]	a, b, or c (included in list)
[^abc]	Any character except a, b, or c (negation)
[a-zA-Z]	a to z or A to Z, inclusive (range)
[a-d[m-p]]	a to d, or m to p $\sim$ [a-dm-p](union)
[a-z&&[def]]	d, e, or f (intersection)
[a-z&&[^bc]]	a through z, without b and c: [a-d-z] (subtraction)
[a-z&&[^m-p]]	a through z, and not m through p
.*	Any number of arbitrary characters (note this expression uses a dot and an asterisk together)

### 35.5.10 How to Define Policies for Data

ADF entity objects in the data model project are security-aware, meaning that predefined resource-specific permissions exist that a developer can grant. Additionally, you can secure just the individual attributes of entity objects.

Entity objects that you secure restrict users from updating data displayed by any web page that renders a UI component bound by an ADF binding to the data accessed by the secured entity object. Additionally, when you secure an entity object, you effectively secure any view object in the data model project that relies on that entity

object. As such, entity objects that you secure define an even broader access policy that applies to all UI components bound to this set of view objects.

**Before you begin:**

It may be helpful to have an understanding of ADF security policies. For more information, see [Section 35.5, "Defining ADF Security Policies."](#)

You may also find it helpful to have an understanding of entity-based view objects. For details about entity-based view objects, see [Section 5.2, "Populating View Object Rows from a Single Database Table."](#)

To secure row data using ADF entity objects:

1. Define a permission map for the specific actions of the entity object or the attributes of the entity object that you want to secure.
2. Grant the permission to an application role that you have added to the policy store.

### 35.5.10.1 Defining Permission Maps on ADF Entity Objects

You can secure operations of the entity objects or their individual attributes.

In the data model project, you use the overview editor for the entity object to define a permission map for the specific actions allowed by the entity object. The metadata consists of a permission class, a permission name, and a set of actions mapped to binding operations.

The list of available operations displayed by the overview editor is defined by the entity object permission class (`oracle.adf.share.security.authorization.EntityPermission`). The permission class maps the operations supported by the entity object to actions. [Table 35–8](#) shows the securable operations of the entity object.

**Table 35–8** *Securable Operations of ADF Business Components*

ADF Component	Securable Operation	Expected Mapped Action	Corresponding Implementation
ADF Business Components entity objects	read	Read	View the rows of a result set that has been restricted by a WHERE clause fragment.
	update	Update	Update any attribute of the bound collection.
	removeCurrentRow	Delete	Delete a row from the bound collection.
ADF Business Components attributes of entity objects	update	Update	Update a specific attribute of the bound collection.

To secure all row-level data that the entity object accesses, use the overview editor for the entity object.

**Before you begin:**

It may be helpful to have an understanding of ADF security for entity objects. For more information, see [Section 35.5.10, "How to Define Policies for Data."](#)

You will need to complete this task:

Create entity objects in the data model project as described in [Chapter 4, "Creating a Business Domain Layer Using Entity Objects."](#)

**To secure an operation on an entity object:**

1. In the data model project displayed in the Application Navigator, double-click the entity object that you want to secure.
2. In the overview editor, click the **General** navigation tab.
3. In the General page, expand the **Security** section and select the operations you want to secure for the entity object.

The **Security** section displays the securable operations that the `EntityPermission` class defines. The class maps the entity object—specific actions to the entity object’s operations, as described in [Table 35-8](#).

For example, to enable **read** permission, select it as shown in [Figure 35-11](#). The permissions appear in the XML definition of the entity object.

**Figure 35-11** *Permission Enabled on read Operation for an ADF Entity Object*

Security: OrderEO	
Operation	Enabled
read	<input checked="" type="checkbox"/>
update	<input type="checkbox"/>
removeCurrentRow	<input type="checkbox"/>

To secure individual columns of data that the entity object accesses, use the **Attributes** page of the overview editor for the entity object.

**To secure an operation on an entity object attribute:**

1. In the data model project displayed in the Application Navigator, double-click the entity object that defines the attribute you want to secure.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the desired attribute, and then expand the **Security** section and select the operation you want to secure for the entity object attribute.

The **Security** section displays the securable operations that the `EntityAttributePermission` class defines. The class maps the entity object-specific actions to the entity object’s operations, as described in [Table 35-8](#).

For example, to enable **update** permission, select it as shown in [Figure 35-12](#). The permission map appears in the XML definition of the entity object.

**Figure 35-12** *Permission Enabled on update Operation for an ADF Entity Object Attribute*

Security: CouponId	
Operation	Enabled
update	<input checked="" type="checkbox"/>

### 35.5.10.2 Granting Permissions on ADF Entity Objects

Once a permission target is configured, any data that derives from entity objects or their attributes remains unsecured until you explicitly define policy grants for the entity object’s permission target.

To define the access policy for an existing entity object permission target, use the Edit Authorization dialog.

**Before you begin:**

It may be helpful to have an understanding of ADF security for entity objects. For more information, see [Section 35.5.10, "How to Define Policies for Data."](#)

You will need to complete these tasks:

1. Run the Configure ADF Security wizard as described in [Section 35.3, "Enabling ADF Security."](#)
2. Create application roles as described in [Section 35.4, "Creating Application Roles."](#)
3. Define the permission target for the entity object or the attributes of the entity object as described in [Section 35.5.10.1, "Defining Permission Maps on ADF Entity Objects."](#)

**To define the access policy for an entity object:**

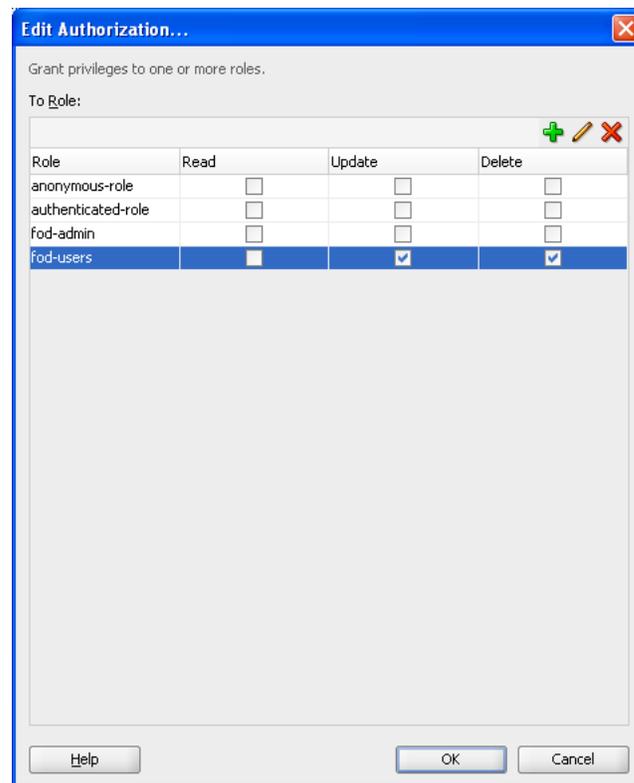

1. In the data model project displayed in the Application Navigator, locate the entity object and select it.
2. In the Structure window, locate the selected entity object or entity object attribute, then right-click the node and choose **Edit Authorization**.

The Edit Authorization dialog displays the available actions of the entity object (or attribute), as described in [Table 35–8](#). The dialog also displays the application roles from the `jazn-data.xml` policy store. The built-in application roles **anonymous-role** and **authenticated-role** will appear with application roles that the application developer created.

3. In the dialog, select the action that you want to grant to a specific application role.

For example, to grant **Update** and **Delete** privileges to the **fod-users** application role, select those actions, as shown in [Figure 35–13](#).

The grant to the application role appears in the `jazn-data.xml` file.

**Figure 35–13 Defining the Access Policy for an Entity Object**

### 35.5.11 How to Aggregate Resource Grants as Entitlement Grants

You define end user access for individual securable Oracle ADF artifacts by creating resource grants. However, for ease of administration and maintenance, resource grants can also be defined as entitlement grants, in which case multiple securable application artifacts are aggregated into a named security group that can be granted to application roles using a single statement. For example, when you want to authorize access to the data exposed in the application by ADF Business Components entity objects, multiple entity object may require the same security policy. Instead of individually granting access privileges to each entity object, you can group them in an entitlement and grant them all at once.

You create entitlement grants in the Entitlements Grants page of the `jazn-data.xml` file overview editor. The grants you create will appear as metadata in the policy store section of the `jazn-data.xml` file. This metadata defines an entitlement (identified in the XML definition as `<permission-set>`) comprised of resource instance /action pairs that you select. This entitlement is a grantable entity that you then grant to an application role.

The list of resource types appears in the security policy overview editor and the resource type you select filters the resource instances defined within the projects of your application's workspace. The resource type selection also determines the list of available actions displayed by the overview editor. For example, when you select the **Task Flow Permission** resource type, the overview editor will display all of the task flows in the user interface projects that you select. The **Task Flow Permission** resource type also defines the **view** action that you can associate with any ADF bounded task flow resource that your application defines.

Table 35–9 lists the resource types displayed in JDeveloper and identifies the associated resource and supported actions for each type.

**Table 35–9 Resource Types of Securable Oracle ADF Artifacts**

Resource Type	Supports These Resources and Actions
Task Flow	Defines view actions on ADF bounded task flows in a user interface project that you select.
Web Page	Defines view actions on regions and web pages backed by ADF page definition files in a user interface project that you select.
ADF Entity Object	Defines read, update, and delete actions on entity objects in a data model project that you select.
ADF Entity Object Attribute	Defines update actions on entity object attributes of a specific entity object in a data model project that you select.

To define an entitlement grant for a securable Oracle ADF artifact, use the Entitlement Grants page of the overview editor for the `jazn-data.xml` file. This editor is also called the security policy overview editor.

#### Before you begin:

You will need to complete this task:

- Create application roles as described in [Section 35.4, "Creating Application Roles."](#)

#### To define an entitlement grant for an Oracle ADF artifact:

1. In the main menu, choose **Application** and then **Secure > Entitlement Grants**.
2. In the Entitlement Grants page of security policy overview editor, click the **Add Entitlements** icon in the **Entitlements** list.

The overview editor displays all the resources that your application defines.

3. In the Resources section, click the **Add Member Resource** icon to add a member resource to the entitlement.
4. In the Select Resources dialog, select the resource from the **Resource Type** dropdown and then select the desired project in the **Source Projects** list.

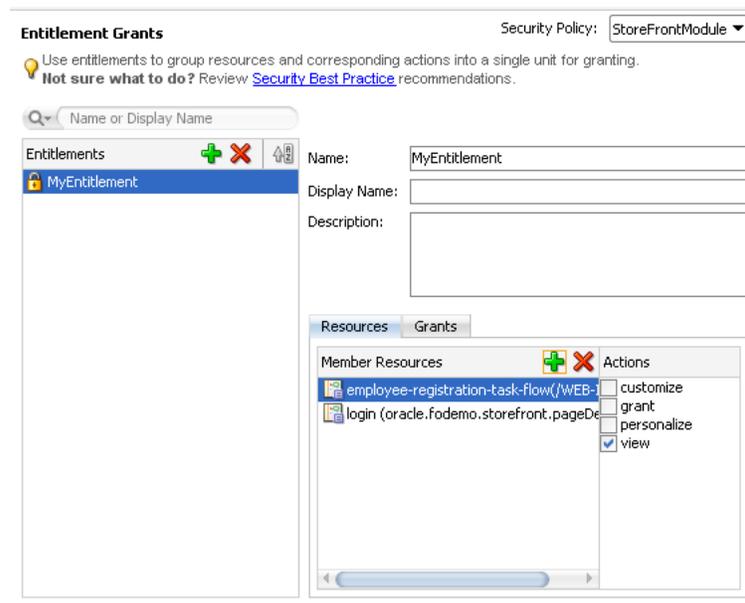

The dialog displays all the projects in your application workspace.

5. In the **Available Resources** list, select the resource from and click the **Add** icon.

The dialog displays all the resources define by your selected project.

6. In the **Actions** lists, select the desired action for the selected resource.

[Figure 35–14](#) shows the overview editor with the **View** action selected for the task flow and added to **MyEntitlement**.

**Figure 35–14 Adding a Bounded Task Flow as a Resource in an Entitlement Grant**

7. Add other desired resources to the list.
8. In the Grants section of the security policy overview editor, click the **Add Role Grants** icon to grant the entitlement to an application role.
9. In the Select Application Roles dialog, select one or more custom application roles.
 

The dialog displays all the application roles from the `jazn-data.xml` file. You must not add a grant to a predefined application role (also called *duty roles* in the terminology of Oracle Fusion Applications). Only select custom application roles that either you created in JDeveloper or that were created by an IT security manager for this purpose.
10. Click **OK**.
11. You can repeat these steps to add other resources and make grants on those resources to the same entitlement for the same custom application role.

### 35.5.12 What Happens After You Create an Entitlement Grant

When you use the security policy editor in JDeveloper to create an entitlement grant, JDeveloper modifies the source for the application policy store in the `jazn-data.xml` file. The policy store section of the file contains a `<resource-type>` definition (that identifies the actions supported for resources of the selected type), a `<resource>` definition (to identify the resource instance that you selected from your application and mapped to a resource type), a `<permission-set>` definition (to define the resources and actions to be granted as an entitlement), and a `<grant>` definition with one or more entitlements (defined in the XML as a permission set) granted to the desired application roles (the grantee).

As [Example 35–10](#) shows, entitlement-based security policies in the Oracle Fusion application are defined in the `<jazn-policies>` element and consist of one or more entitlements granted to a single application role.

#### **Example 35–10 Entitlement-Based Policy Definition in the `jazn-data.xml` File**

```
<?xml version="1.0" ?>
```

```

<jazn-data>
 <policy-store>
 <applications>
 <application>
 <name>MyApp</name>

 <app-roles>
 <app-role>
 <name>AppRole</name>

```

## 35.6 Creating Test Users

JDeveloper provides editors to help you create both the identity and the policy stores. You create both repositories in an application-specific `jazn-data.xml` file. The editor for the identity store section of the file lets you enter the list of valid user IDs and their assigned passwords. The same editor lets you create application roles and assign the test users or enterprise roles as members of the application roles. Once defined, this information appears in the policy store section of the `jazn-data.xml` file.

### 35.6.1 How to Create Test Users in JDeveloper

You seed the identity store of your application with a temporary set of users to simulate the actual users' experience in your production environment. When you run the application in Integrated WebLogic Server, you can log in as any test user and be conferred access rights to view the secure ADF resources of your application.

You can use the identity store to organize users into enterprise roles. Because you typically will configure JDeveloper's deployment options to prevent migrating the identity store to a staging environment, enterprise roles that you create in the `jazn-data.xml` file are for convenience only. For more details about the use of enterprise roles, see [Section 35.4.3, "What You May Need to Know About Enterprise Roles and Application Roles."](#)

---

---

**Caution:** If you choose to deploy the identity store to your standalone server, you must not create users and enterprise roles in your local identity store that are already configured for Oracle WebLogic Server. For example, if you were to deploy the identity store with the user `weblogic` and enterprise role `Administrators`, you would overwrite the default administration configuration on the target server. For a complete list of global roles that Oracle WebLogic Server installs by default, see the *Oracle Fusion Middleware Securing Resources Using Roles and Policies for Oracle WebLogic Server*.

---

---

To enable the user to view resources, you make grants against application roles rather than against the users who are the members of those roles. Therefore, after you seed the identity store with test users, you must associate each user or enterprise role group with an application role. This association confers the access rights defined by ADF security policies to users. For details about conferring access rights to users, see [Section 35.6.3, "How to Associate Test Users with Application Roles."](#)

**Before you begin:**

It may be helpful to have an understanding of the identity store. For more information, see [Section 35.6, "Creating Test Users."](#)

**To create test users and groups:**

1. In the main menu, choose **Application** and then **Secure > Users**.
2. In the Users page of the `jazn-data.xml` file overview editor, select the realm for your application from the **Realm** dropdown list and perform the following steps.

JDeveloper automatically creates the default realm `jazn.com`.

- a. In the **Users** list, click the **New User** icon.
- b. In the **Name** field, enter the user name.

You should avoid choosing a user name already configured for Oracle WebLogic Server (for example, do not enter `webcenter`). For the list of user names installed by Oracle WebLogic Server, see the *Oracle Fusion Middleware Securing Resources Using Roles and Policies for Oracle WebLogic Server*.

- c. In the **Password** field, enter the password for the user and click any other field to add the password to the identity store.

The password must contain at least eight characters and at least one of the characters must be a special character (such as `!`, `%`, `^`, `&`, `$` and so on).

3. Optionally, in the `jazn-data.xml` file overview editor, click the **Enterprise Roles** navigation tab, and select the realm for your application from the **Realm** dropdown list and perform the following steps.

You create enterprise roles only when you want to organize users into groups that you will add to an application role. For the purpose of creating test users to run the application using Integrated WebLogic Server, you do not need to create enterprise role groups.

- a. In the **Enterprise Roles** list, click the **New Role** icon.
- b. In the **Name** field, enter the name of the enterprise role and click any other field to add the role to the identity store.

If you create enterprise role groups, you should avoid choosing a role name that is already configured for Oracle WebLogic Server (for example, do not enter `Administrators`). For a complete list of the default group names installed by Oracle WebLogic Server, see the *Oracle Fusion Middleware Securing Resources Using Roles and Policies for Oracle WebLogic Server*.

## 35.6.2 What Happens When You Create Test Users

When you provision the identity store with user identities and enterprise role groups, JDeveloper updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The dialog writes the user information to the `<jazn-realm>` section of the file corresponding to the identity store. Each user identity has a user name and a user login password. Each enterprise role contains one or more member users.

[Example 35–11](#) shows the identity store in the `jazn-data.xml` file with two users and two enterprise roles. The users `ahunold` and `sking` are both members of the `fod-users` enterprise role, while only `sking` is a member of the `fod-admin` enterprise role.

### **Example 35–11 Users and Enterprise Roles in the Application-Level Identity Store**

```
<jazn-data>
 <jazn-realm default="jazn.com">
 <realm>
 <name>jazn.com</name>
 <users>
 <user>
 <name>sking</name>
 <guid>09FC5C61F68111DCAF1DB790A6B3BAC5</guid>
 <credentials>{903}A0VQ5ozADte7EKIJzcTi6xMZ7YDpRXY5</credentials>
 </user>
 <user>
 <name>ahunold</name>
 <guid>09FEA650F68111DCAF1DB790A6B3BAC5</guid>
 <credentials>{903}/SQSrKZYCLW068VJpHaodILd48mJI47w</credentials>
 </user>
 ...
 </users>
 <roles>
 <role>
 <name>fod-users</name>
 <guid>0A084340F68111DCAF1DB790A6B3BAC5</guid>
 <members>
 <member>
 <type>user</type>
 <name>sking</name>
 </member>
 <member>
 <type>user</type>

 </member>
 ...
 </members>
 </role>
 <role>
 <name>fod-admin</name>
 <guid>0A0CFE30F68111DCAF1DB790A6B3BAC5</guid>
 <members>
```

```

 <member>
 <type>user</type>
 <name>sking</name>
 </member>
 ...
 </members>
</role>
...
</roles>
</realm>
...
</jazzn-realm>
</jazzn-data>

```

### 35.6.3 How to Associate Test Users with Application Roles

Because the ADF Security framework enforces a role-based access control mechanism with permissions granted to application roles, you define a set of roles in the policy store that are specific to your application. For example, in the context of the work flow, there may be roles such as customer, product specialist, supervisor, and administrator.

After you create an application role, you can proceed to associate users that you created in the identity store with one or more roles. At runtime, users who are members of an application role will be conferred the access rights of their application roles. You can assign a user to more than one application role when you want to confer the right of multiple resource grants to a particular user.

For example, one authenticated user might belong to the supervisor role and an employee role, while another user might belong only to the employee role. The security policy for a bounded task flow that permits customer records to be browsed and edited may confer view permission to the supervisor role and limit view permission to the browse page for the employee role. Thus, grants to application roles support multiple levels of access. If the authenticated user is not a member of an application role with a view permission grant for the target ADF resource, the security framework will return an unauthorized user message.

#### Before you begin:

It may be helpful to have an understanding of the identity store. For more information, see [Section 35.6, "Creating Test Users."](#)

You will need to complete these tasks:

1. Run the Configure ADF Security wizard as described in [Section 35.3, "Enabling ADF Security."](#)
2. Create application roles as described in [Section 35.4, "Creating Application Roles."](#)
3. Define security policies for ADF security-aware resources as described in [Section 35.5, "Defining ADF Security Policies."](#)
4. Create test users, and, optionally, create enterprise role groups as described in [Section 35.6.1, "How to Create Test Users in JDeveloper."](#)

#### To associate users with application roles:

1. In the main menu, choose **Application** and then **Secure > Application Roles**.
2. In the Application Roles page of the `jazzn-data.xml` file overview editor, select the policy store for your application from the **Security Policy** dropdown list.

The policy store that JDeveloper creates in the `jazn-data.xml` file are automatically based on the name of your application.

3. In the **Roles** list, select an existing application role and complete these tasks as appropriate:
  - a. In the **Mappings** section, click the **Add User or Role** icon dropdown menu and choose **Add User**, then in the Select Users dialog select the previously created user from the list and click **OK**.
  - b. Optionally, if you have defined enterprise roles in the identity store, in the **Mappings** section, click the **Add User or Role** icon dropdown menu and choose **Add Enterprise Role**, then in the Select Enterprise Roles dialog select the previously created enterprise role from the list and click **OK**.

### 35.6.4 What Happens When You Configure Application Roles

When you associate users with application roles, JDeveloper updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The dialog writes the user information to the `<policy-store>` section of the file. Each application role contains one or more member users or enterprise roles.

[Example 35-12](#) shows the policy store in the `jazn-data.xml` file with the `fod-users` application role, which contains two members, `sking` and `ahunold`.

#### **Example 35-12** *Users Associated with Application Roles in the Application-Level Policy Store*

```
<policy-store>
 <applications>
 <application>
 <name>StoreFrontModule</name>
 <app-roles>
 <app-role>
 <name>fod-users</name>
 <display-name>FOD Users</display-name>
 <class>oracle.security.jps.service.policystore.ApplicationRole</class>
 <members>
 <member>
 <class>oracle.security.jps.internal.core.principals.JpsXmlUserImpl</class>
 <name>sking</name>
 </member>
 <member>
 <class>oracle.security.jps.internal.core.principals.JpsXmlUserImpl</class>
 <name>ahunold</name>
 </member>
 ...
 </members>
 </app-role>
 ...
 </app-roles>
 <jazn-policy>
 ...
 </jazn-policy>
 </application>
 </applications>
</policy-store>
```

## 35.7 Creating a Login Page

ADF Security allows for implicit and explicit authentication:

- In an *implicit authentication* scenario, if a user who is not yet authenticated tries to access a web page associated with ADF security-aware resources that are not granted to `anonymous-role`, then authentication is triggered dynamically. After the user successfully logs in, another check will be done to verify whether the authenticated user has view access granted on the requested page's ADF security-aware resource.
- In an *explicit authentication* scenario, your application has a public page that displays a login link, which, when clicked, triggers an authentication challenge to log in the user. The login link may optionally specify some other target page that should be displayed (assuming the authenticated user has access) after the successful authentication.

The implicit authentication scenario is handled for you by default when you run the Configure ADF Security wizard, as described in [Section 35.3.5, "What You May Need to Know About ADF Authentication."](#)

To handle the explicit authentication scenario you need to replace the `allPages` security constraint added to the `web.xml` file by the Configure ADF Security wizard and trigger an authentication challenge using the security constraint defined for the ADF authentication servlet.

---

---

**Note:** This procedure for creating the user interface for a JSF-based login page relies on APIs that are specific to Oracle WebLogic Server and the login process that it supports. Only use this procedure when you will deploy the Fusion web application to Oracle WebLogic Server.

---

---

To explicitly handle user authentication:

1. Create a login link component and add it to the public home web page for your application.
2. Create a managed bean using API specific to Oracle WebLogic Server to handle the login attempts by the user.
3. Create a JSF login page using ADF Faces components.
4. Configure the container-managed deployment descriptor (`web.xml` file) to use the ADF Faces login page.

### 35.7.1 How to Create a Login Link Component and Add it to a Public Web Page

You can create a standard login link component that can be added to any page in your application to enable users to authenticate or subsequently log off. This component keeps track of the authenticated state of the user and returns the appropriate login or logout URLs and icons. The login link component will redirect users back to a specific page once they are authenticated. Hence, using this login link component provides you with a single, consistent object.

To the unauthenticated user, the login link component will look similar to [Figure 35–15](#).

**Figure 35–15 Component Before User Logs In**

Then when the user clicks the login link and logs in as a user with the appropriate credentials, the component will look similar to [Figure 35–16](#).

**Figure 35–16 Component After User Logs In****Before you begin:**

It may be helpful to have an understanding of ADF authentication. For more information, see [Section 35.7, "Creating a Login Page."](#)

You will need to complete this task:

Copy your login and logout image files (GIF, JPG, or PNG files) to the `public_html` directory of your project.

---

---

**Note:** The images used should reference the appropriate skin image if your application uses skins. For more information about skins, see the "Customizing the Appearance Using Styles and Skins" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

---

---

**To create the login link component and add it to a page:**

1. In the Application Navigator, double-click the web page that will display the component.
2. In the ADF Faces page of the Component Palette, select **Go Image Link** and drag it onto the page.
3. In the Structure window, right-click `af:goImageLink` and choose **Go to Properties**.
4. In the Property Inspector, set the **Text** field for the Go Image Link component to render the link text specified by a conditional Expression Language (EL) expression.

For example, you can enter an EL expression similar to this:

```
{securityContext.authenticated ? '"Click to log out"' :
 '"Click to log in"};
```

The `authenticated` property of the `securityContext` bean will evaluate to `true` and render the log out option if the current user is authenticated. Otherwise, the link is rendered with the login option.

5. In the Property Inspector, set the **Destination** field for the Go Image Link component to forward the user to the URL specified by a conditional EL expression.

For example, you can enter an EL expression similar to this:

```
#{securityContext.authenticated ? '"/adfAuthentication?logout=true&end_url=/faces/welcome.jspx" : '"/adfAuthentication?success_url=/faces/welcome.jspx"}
```

When the user clicks the link, the URL parameters `end_url` and `success_url` forward the destination to the ADF authentication servlet. The `authenticated` property of the `securityContext` bean will evaluate to true and forward to the welcome page if the current user is authenticated. When the user is not authenticated, there is no need to forward to the login page because the ADF authentication servlet triggers log in, which is handled by the container-managed security configuration. Note that log out is handled by the ADF authentication servlet which invalidates the session. Although log out is handled by ADF Security, the browser cache must be cleared to complete the process. For a description of a known issue with Basic type authentication and browser caching, see [Section 35.7.5, "What You May Need to Know About ADF Servlet Logout and Browser Caching."](#)

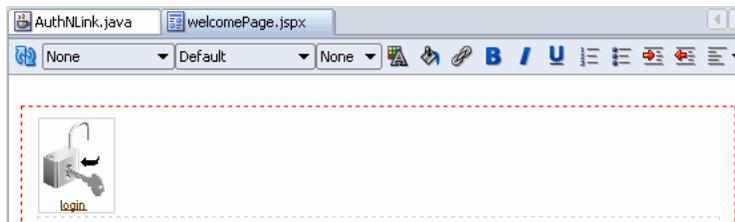

6. In the Property Inspector, set the **Icon** field for the Go Image Link component to render the link component image specified by a conditional EL expression.

For example, this expression renders the link component image as the lock GIF if the user is not authenticated; otherwise, renders the image with the key GIF:

```
#{securityContext.authenticated ? "/images/lock.gif" : "/images/key.gif"}
```

[Figure 35–17](#) shows how the login link component appears when added to the global menu facet of the page.

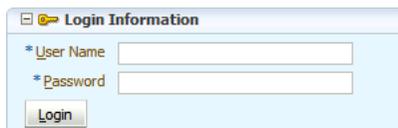

**Figure 35–17 Login Link Component on the Page**

## 35.7.2 How to Create a Login Page

The default login form that is generated for you when you run the Configure ADF Security wizard is provided as a convenience for testing your application within JDeveloper. The default form does not allow you to customize the page using ADF Faces components to match the user interface of the application. You can replace the default form with an ADF Faces-based login page that enables you to include customizable components, as shown in [Figure 35–18](#).

**Figure 35–18 Login Page**

However, if designing a login page with ADF Faces components is not a requirement, then a simple JSP or HTML login page can be also used. For details about generating a

simple login page when running the Configure ADF Security wizard, see [Section 35.3.1, "How to Enable ADF Security."](#)

Web applications typically have a notion of public pages and allow for explicit as well as implicit authentication. This means that users can log in to the application by clicking the login link before they navigate to secured content, or they can navigate to a secured page, which will redirect them to the login page for the application. For more information about implicit and explicit authentication, see [Section 35.8.4, "What Happens at Runtime: How ADF Security Handles Authentication."](#)

### 35.7.2.1 Creating Login Code for the Backing Bean

Before you create the login page as an ADF Faces page, you need to create a managed bean to handle login attempts. Container-based authentication relies on the `javax.security.SecurityCheck` method within the container's security model. The login method that your bean defines use this method to enforce authentication. You will add this bean to the `adfc-config.xml` file and register it with `request` scope.

---

**Note:** Note that the backing bean you will create in this procedure relies on APIs that are specific to Oracle WebLogic Server and the login process that it supports. Only use this procedure when you will deploy the Fusion web application to Oracle WebLogic Server.

---

#### Before you begin:

It may be helpful to have an understanding of the login page. For more information, see [Section 35.7.2, "How to Create a Login Page."](#)

You will need to complete this task:

- Create a new library that contains the following classpath entries and add it to the user interface project where you create the backing bean for login:
  - `modules/com.bea.core.weblogic.security.auth_1.1.0.0.jar`
  - `oracle.wlserver_10.3/server/lib/wls-api.jar`

This library will allow the user interface project to compile and resolve the following import statements from the backing bean code sample.

```
import weblogic.security.SimpleCallbackHandler;
import weblogic.security.services.Authentication;
import weblogic.servlet.security.ServletAuthentication;
```

For details about creating a library and adding it to a project, see the "Working with Applications and Projects" chapter in the *Oracle Fusion Middleware User Guide for Oracle JDeveloper*.

#### To create and register a backing bean for login:

1. In the Application Navigator, right-click the user interface project node and choose **New**.
2. In the New Gallery, expand **General**, select **Java** and then **Java Class**, and click **OK**.
3. In the Create Java Class dialog, enter the name for the login page backing bean class file and disable the default options to generate **Constructors from Superclass** and **Implement Abstract Methods**, and click **OK**.

For convenience, you might name the backing bean based on the name of your login page, for example, *LoginPageName.java*.

4. In the Applications Navigator, expand the **Application Sources** node and double-click the new *LoginPageName.java* backing bean.
5. In the source editor, create two private fields by adding the following in the declaration section of the *LoginPageName.java* file:

```
private String _username;
private String _password;
```

6. Generate or create public accessors for both field.

You can right-click in the source editor and choose **Generate Accessors** to add the following public accessors to the file:

```
public void setUsername(String _username) {
 this._username = _username;
}

public String getUsername() {
 return _username;
}

public void setPassword(String _password) {
 this._password = _password;
}

public String getPassword() {
 return _password;
}
```

7. Add a `doLogin()` method to this Java class to handle user attempts to log in:

```
1 public String doLogin() {
2 String un = _username;
3 byte[] pw = _password.getBytes();
4 FacesContext ctx = FacesContext.getCurrentInstance();
5 HttpServletRequest request =
6 (HttpServletRequest)ctx.getExternalContext().getRequest();
7 CallbackHandler handler = new SimpleCallbackHandler(un, pw);
8 try {
9 Subject mySubject = Authentication.login(handler);
10 ServletAuthentication.runAs(mySubject, request);
11 ServletAuthentication.generateNewSessionID(request);
12 String loginUrl = "/adfAuthentication?success_url=/faces" +
13 ctx.getViewRoot().getViewId();
14 HttpServletResponse response =
15 (HttpServletResponse)ctx.getExternalContext().getResponse();
16 sendForward(request, response, loginUrl);
17 } catch (FailedLoginException fle) {
18 FacesMessage msg = new FacesMessage(FacesMessage.SEVERITY_ERROR,
19 "Incorrect Username or Password",
20 "An incorrect Username or Password" +
21 " was specified");
22 ctx.addMessage(null, msg);
23 } catch (LoginException le) {
24 reportUnexpectedLoginError("LoginException", le);
25 }
26 return null;
27 }
```

The `doLogin()` method performs the following tasks:

**Lines 5-6** get an object encapsulating the HTTP request from the `FacesContext`.

**Line 7** creates a `CallbackHandler`, which is an object that retrieves information for security operations. A `SimpleCallbackHandler` allows security operations to retrieve the username and password that were passed to its constructor; other `CallbackHandler` implementations can obtain the username and password from another source.

**Line 9** creates a `Subject`, which is an object that encapsulates credentials, from the information provided by the `CallbackHandler`.

**Line 10** attempts to log the user issuing the request in using the credentials encapsulated by the `Subject`.

**Line 11** ensures that the session ID for the session is changed after the user is successfully authenticated. This is necessary to prevent leaving the application open to a session fixation attack, which would be a security vulnerability.

**Lines 12-13** construct a URL to which to forward the user. The `getViewId()` call returns the path, from the context root, to the currently rendered page. So, if line executes when the user is on the `home.jspx` page, `forwardURL` will be set to `/adfAuthentication?success_url=/faces/home.jspx`.

**Lines 14-15** retrieve an object which encapsulates the HTTP response from the `FacesContext`.

**Line 16** calls a method, `sendForward()`, which you will implement later in this section to forward the user to the URL specified in Lines 12-13.

**Lines 17-22** handle a `FailedLoginException`, which is the exception thrown when the credentials supplied are incorrect. The lines handle the exception by adding a new message to the `FacesContext`.

**Lines 23-24** handle a `LoginException`, which can be thrown by many different problems with a login. For example, exceptions can result from incorrect credentials or attempts to log into a locked account or uses of an expired password. `FailedLoginException` is a subclass of `LoginException`, but since a `FailedLoginException` will be caught by Line 17, these lines will only be executed when there are login problems other than incorrect credentials. `reportUnexpectedLoginError()` is a method which you will implement to deal with miscellaneous problems with the login process.

**Line 26** returns null so that the ADF Controller will not attempt to follow a control flow case.

#### 8. Import the following classes:

```
javax.faces.application.FacesMessage
javax.faces.context.FacesContext
javax.security.auth.Subject
javax.security.auth.callback.CallbackHandler
javax.security.auth.login.FailedLoginException
javax.security.auth.login.LoginException
javax.servlet.http.HttpServletRequest
javax.servlet.http.HttpServletResponse
weblogic.security.SimpleCallbackHandler
weblogic.security.services.Authentication
weblogic.servlet.security.ServletAuthentication
```

9. Create stubs for the methods `sendForward()` and `reportUnexpectedLoginError()`.

10. Add a `sendForward()` method with its actions:

```
1 private void sendForward(HttpServletRequest request,
2 HttpServletResponse response,
3 String forwardUrl){
4 FacesContext ctx = FacesContext.getCurrentInstance();
5 RequestDispatcher dispatcher = request.getRequestDispatcher(forwardUrl);
6 try {
7 dispatcher.forward(request, response);
8 } catch (ServletException se) {
9 reportUnexpectedLoginError("ServletException", se);
10 } catch (IOException ie) {
11 reportUnexpectedLoginError("IOException", ie);
12 }
13 ctx.responseComplete();
14 }
```

The `sendForward()` method performs the following tasks:

**Lines 5** creates a `RequestDispatcher`, which forwards a response to a particular URI.

**Line 7** uses the `RequestDispatcher` to forward the current HTTP response to the URL.

**Line 8-9** handle a `ServletException`, which is thrown when the resource at the `RequestDispatcher`'s target URI throws an exception.

**Line 10-11** handle an `IOException`, which is thrown when the request cannot be read or the response cannot be written to.

**Lines 13** marks the HTTP response as complete so that the browser can finish rendering it.

11. Import the following classes:

```
javax.servlet.RequestDispatcher
javax.servlet.ServletException
java.io.IOException
```

12. Implement a `reportUnexpectedLoginError()` method:

```
private void reportUnexpectedLoginError(String errType, Exception e){
 FacesMessage msg =
 new FacesMessage(FacesMessage.SEVERITY_ERROR, "Unexpected error
 during login",
 "Unexpected error during login (" + errType + "),
 please consult logs for detail");
 FacesContext.getCurrentInstance().addMessage(null, msg);
 e.printStackTrace();
}
```

This `reportUnexpectedLoginError()` method adds a summary error message to the `FacesContext`, and then prints the full stack trace of the exception to the console.

13. Save the Java file.

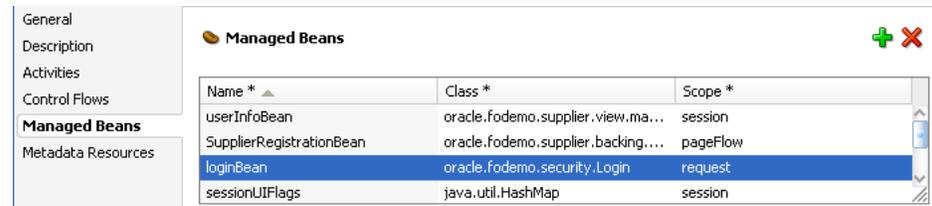

14. In the Application Navigator, double-click the **adfc-config.xml** node in the **WEB-INF** node.

15. In the editor window for the `adfc-config.xml` file, click the **Overview** tab.
16. In the overview editor for task flows, click the **Managed Beans** navigation tab.
17. In the Managed Beans page, in the **Managed Beans** section click the **Add** icon and enter a name for the bean, enter the fully qualified class name, and select `request` scope.

For example, the class name might look like

`oracle.foddemo.security.Login`, as shown in [Figure 35–19](#).

**Figure 35–19 Login Bean Registered in `adfc-config.xml` File**

18. Save all.

### 35.7.2.2 Creating an ADF Faces-Based Login Page

A simple login page that utilizes ADF Faces layout components and ADF Faces user interface components includes two input fields and a button. You must bind the properties of these UI components to the login handler methods that you defined in the managed bean for the login page.

#### Before you begin:

It may be helpful to have an understanding of the login page. For more information, see [Section 35.7.2, "How to Create a Login Page."](#)

You will need to complete this task:

Create the managed bean to handle the user's login attempts as described in [Section 35.7.2.1, "Creating Login Code for the Backing Bean."](#)

#### To create the ADF Faces-based login page:

1. In the Application Navigator, right-click the user interface project node and choose **New**.
2. In the New Gallery, expand **Web Tier**, select **JSF** and then **JSF Page**, and click **OK**.
3. In the Create JSF Page dialog, select **Create as XML Document (\*.jspx)**.
4. In the **File Name** field, specify a name for your login page. For example, enter `LoginPage.jsxpx`.

Select no other options and do not select the option to expose UI components in a managed bean. You will manually bind the components to the managed bean you created for the login page.

5. Click **OK**.
6. Save the page.
7. In the ADF Faces page of the Component Palette, from the Layout panel, drag and drop a **Panel Box** onto the Structure window below the **af:form** node.
8. In the Property Inspector, set the **Text**, **Horizontal**, **Width**, and **Height** fields.

For example, to recreate the login page shown in the Master Price List module of the Fusion Order Demo application, you would enter:

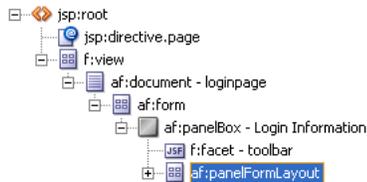

**Text** set to Login Information

**Icon** set to /images/key\_ena.png

**Width/Height** set to 300/200 pixels

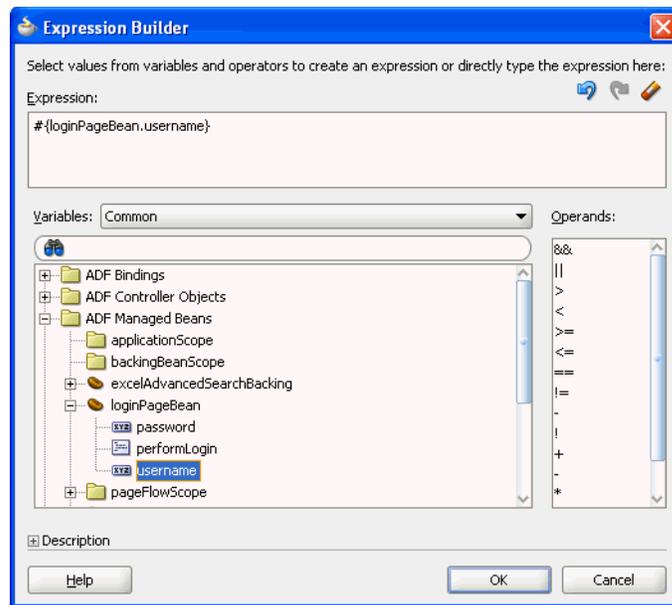

9. From the Component Palette, drag and drop a **Panel Form Layout** below the **af:panelBox** node in the Structure window, as shown in [Figure 35–20](#).

**Figure 35–20 Login Page Structure with Panel Form Layout**

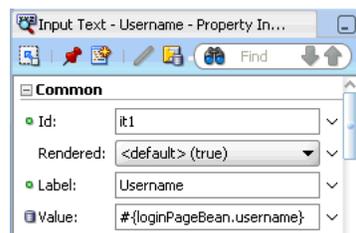

10. From the Component Palette, in the ADF Faces page, drag and drop a **Input Text** onto the **Panel Form Layout** node for the username field and another **Input Text** for the password field.
11. In the Property Inspector for the input fields, set the **Label** fields to Username and Password and set both fields' **Behavior - Required** field to **true**.
12. In the Property Inspector, set the password field's **Appearance - Secret** field to **true**.
13. To handle processing of the values for the two input fields, perform these steps for each field:
  - a. In the Structure window, select one of the input fields (for example, select the **af:inputText - Username** node), then in the Property Inspector click the **Property Menu** dropdown menu to the right of the **Value** field and choose **Expression Builder**.
  - b. In the Expression Builder, expand **ADF Managed Beans** and expand your login bean, then select the expression value corresponding to your bean's handler method.

For example, if you selected the **username** input field in the Structure window, then you would select **username** from the Expression Builder dialog, as shown in [Figure 35–21](#).

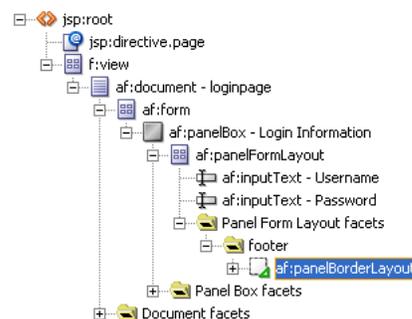

**Figure 35–21** *username Selection in Expression Builder Dialog*

- c. Click **OK**.

The expression shown in the Property Inspector binds the field to the managed bean you created for the login page. For example, for the username input field, the expression is similar to `{loginPageBean.username}` as shown in [Figure 35–22](#).

**Figure 35–22** *username Value in Property Inspector*

14. From the Component Palette, drag and drop a **Panel Border Layout** inside the **footer** node of the **af:panelBox** node, as shown in [Figure 35–23](#).

**Figure 35–23** *Login Page Structure with Panel Border Layout*

15. In the JSP/HTML visual editor, delete the panel border layout facets labeled **End**, **Top**, and **Bottom**. Leave only the **Start** facet.
16. In the Structure window, expand **Panel Border Layout facets** and select the **start** node, and then from the Component Palette drag and drop a **Button**.
17. In the Property Inspector, set the button component's **Text** field to `Login`.
18. To handle processing of the login button action, perform these steps.
  - a. In the Structure window, select **af:commandButton** under the **start** node, then in the Property Inspector click the **Property Menu** dropdown menu to the right of the **Action** field and choose **Expression Builder**.
  - b. In the Expression Builder, expand **ADF Managed Beans** and expand your login bean, then select the expression value corresponding to your login method.  
  
For example, if you created a method in the login bean named `doLogin()`, then you would select **doLogin** in the Expression Builder dialog.
  - c. Click **OK**.

The expression shown in the Property Inspector binds the button to the managed bean you created for the login page. For example, for the login button, the expression is similar to `#{loginPageBean.doLogin}` as shown in [Figure 35–24](#).

**Figure 35–24** *login Action in Property Inspector*

19. Save the page.

### 35.7.2.3 Configuring the web.xml File for an ADF Faces-Based Login Page

Because the login page is called directly from the container, it is not part of the ADF Faces navigation process. As such, you must force a call to the ADF Faces servlet when calling the login page.

You can accomplish this in the Authentication Type page of the Configure ADF Security wizard when you configure ADF Security, or in the `web.xml` file directly. If you have already run the Configure ADF Security wizard, you can use the following procedure to confirm that the `web.xml` file has been updated as described.

#### Before you begin:

It may be helpful to have an understanding of the login page. For more information, see [Section 35.7.2, "How to Create a Login Page."](#)

**To reference a login page as part of the ADF Faces lifecycle:**

1. In the Application Navigator, expand the **WEB-INF** node and double-click **web.xml**.
2. In the overview editor, click the **Security** navigation tab.
3. In the Security page, expand the **Login Authentication** section, and set the login page to include a reference to the ADF Faces servlet such that the login page can be part of the ADF Faces lifecycle `/faces/ADFlogin.jspx` page.

When you add a page using the file browser, the path entered in the `web.xml` file will not specify `/faces`. Modify the entry so that the path references the servlet mapping path for the ADF Faces servlet. For example, if the URL pattern specified by the mapping is `/faces/*`, then your path should look like `/faces/yourpage.jspx`, as shown in [Figure 35–25](#).

**Figure 35–25 Adding a Reference to the Faces Servlet in the Login Configuration**

### 35.7.2.4 Ensuring That the Login Page Is Public

Because the application is secured by ADF Security, all web pages defined within bounded task flows and any web page defined by an ADF page definition will be inaccessible by default. Since all users must be allowed to log on, the login page should remain publicly accessible, and thus you should add no databound components to the page. As long as the login page uses no databound components, then it will be accessible by default.

No further steps are required to ensure that the container will always redirect to the defined authentication point before allowing access to the page (which in this case is the authentication page).

### 35.7.2.5 Ensuring That the Login Page's Resources Are Accessible

When you run the ADF Security wizard and choose the **ADF Authentication** option (because you do not want to enable ADF authorization) if your application uses a custom login page or a custom error page, you may need to edit the default Java EE security constraint added to the `web.xml` file by ADF Security. As shown in [Figure 35–12](#), the default URL pattern (`/*`) defined in the `allPages` security constraint covers everything under the Java EE application root, meaning that the resource files (such as images, style sheets, or JavaScript library) used by the login page are also included.

**Example 35–13 Java EE Security Constraint for ADF Authentication Only**

```
<security-constraint>
 <web-resource-collection>
 <web-resource-name>allPages</web-resource-name>
 <url-pattern>/*</url-pattern>
 </web-resource-collection>
 <auth-constraint>
 <role-name>valid-users</role-name>
 </auth-constraint>
</security-constraint>
```

If the pages you create use resources, such as images, CSS files, or JavaScript libraries, the default `allPages` security constraint in the `web.xml` file will prevent those resources from loading at runtime. To allow your application to display those resources, you should save the resources in a folder of their own and then edit the `allPages` security constraint so that the resources folder is not contained in the URL pattern.

Note that this resource issue does not apply when you run the ADF Security wizard and choose the **ADF Authentication and Authorization** option (the default). Specifically, in that case, the default generated constraint is on the ADF Authentication servlet and the constraint (`/adfAuthentication`) excludes any resource files.

### 35.7.3 How to Create a Public Welcome Page

Because web applications are generally secured, there is always a need for a starting point or home page for unauthenticated users. To create this public welcome page, you create an ADF Faces page to act as the entry point for the application, which contains links to other pages within the application. However, only links to public pages should be rendered to unauthenticated users and, conversely, links to secured pages should be rendered only after the user has logged in and has the appropriate privileges to view the target page.

**Best Practice:** When the user presses **Ctrl-N** or **Ctrl-T** to open a new browser window or tab and no welcome page is defined in the application's `web.xml` file, the browser will display a 403 or 404 error. To prevent this error, you must specify a welcome page definition in the application's `web.xml` file. You can create this definition when you run the Configure ADF Security wizard. For details about running the wizard, see [Section 35.3.1, "How to Enable ADF Security."](#)

#### 35.7.3.1 Ensuring That the Welcome Page Is Public

After you have created a regular ADF Faces page, the page will, by default, be public and accessible by unauthenticated users. If, however, you have associated the welcome page with an ADF resource, for example, by dropping databound ADF Faces components into the welcome page using the Data Controls panel, then ADF Security will secure the page by default. You can make any ADF resource publicly accessible using the `jazn-data.xml` file overview editor to grant a view privilege on the resource to the provided `anonymous-role`. For details about the `anonymous-role` see, [Section 35.5.2, "What Happens When You Make an ADF Resource Public."](#)

#### 35.7.3.2 Adding Login and Logout Links

You can add login and logout links to your public welcome page so that users can explicitly log in and out while they are in the application. While Java EE container-managed security supports the concept of authentication when accessing a secured resource, there is no standard way to log out and stay within a secured application. However, it is a common practice in web applications to allow the user to stay on the same page if that page is public or to return the user to the welcome page if that page is secured. While adding the login and logout links to each page would let the user end their login session anywhere within the application (and return to the welcome page), having these links on the welcome page enables users to explicitly authenticate on entering the application.

For example, you can create an ADF Faces panel group with three components, including an output text area, an image, and a go link. To render the appropriate login or logout link, you can use an EL expression that evaluates the user's authentication

status. Specifically, you can use `securityContext.authenticated` to access the ADF security context, as shown in [Example 35–14](#). The expression evaluates to `true` or `false` and, in this example, the result determines which login/logout image and link to display.

**Example 35–14 ADF Faces Components and EL Expressions to Render Login/Logout Link**

```
<af:panelGroupLayout inlineStyle="width:100%; height:15px;" id="ptpg13">
 <af:spacer width="7" height="10" id="pts2"/>
 <af:outputText value="Welcome #{securityContext.userName}!"
 inlineStyle="font-weight:bold; width:100px" id="ptot2"
 rendered="#{securityContext.authenticated}"/>
 <af:image source="#{securityContext.authenticated ? "/images/lock.gif" : "/images/key.gif}"'
 id="pti2" inlineStyle="width:16px; height:16px;"
 shortDesc="switchable icon"/>
 <af:goLink text="#{securityContext.authenticated ? '"Logout"' : '"Login"}'"
 destination="#{securityContext.authenticated ?
 "/adfAuthentication?logout=true&end_url=/faces/welcome.jspx" :
 "/adfAuthentication?success_url=/faces/welcome.jspx"}"
 inlineStyle="color:White; font-size:14px; font-weight:bold;"/>
 <f:facet name="separator">
 <af:spacer width="5" height="10" id="pts1"/>
 </f:facet>
</af:panelGroupLayout>
```

As an alternative to rendering the link directly within a page, you can create a login link component with the login and logout links that you can add to a page template, as described in [Section 35.7.1, "How to Create a Login Link Component and Add it to a Public Web Page."](#)

### 35.7.3.3 Hiding Links to Secured Pages

Since an anonymous user should not have access to any secured pages, any navigation component on the welcome page that points to a secured page should be hidden from view based on the following two criteria:

- Is the user authenticated with a known user identity?
- Does the specified user identity have permission to view the target?

If either of these criteria has not been met, the `rendered` attribute of any navigation component on a public page that points to a secured resource must have its `rendered` attribute set to `false`, thus hiding it from the anonymous user. To enforce these rules within your welcome page, see [Section 35.11.1, "Using Expression Language \(EL\) with ADF Security."](#)

## 35.7.4 How to Redirect a User After Authentication

After the user accesses a secured web page and logs in, the ADF authentication servlet will redirect back to the original page that initiated the login request. With ADF Security authentication enabled, the ADF authentication servlet automatically passes the original page as the ADF authentication `success_url` parameter on the URL. Typically, this is the desired behavior; however, you can also specify the desired authentication redirect page when you want to display an explicit login link in your page, as shown in [Example 35–15](#).

**Example 35–15 Explicit Login Link with `success_url` in a Web Page**

```
<af:goLink text="Login" destination="/adfAuthentication?success_url=/faces/pagename.jspx"/>
```

Additionally, you can specify the `success_url` parameter as an `<init-param>` within the `web.xml` file to handle any cases where it is not possible to redirect to the original page. Thus, when the user accesses the secured web page and gets redirected to log in, the framework automatically passes the original page as the `success_url` parameter on the URL, which supersedes any `web.xml` setting. Therefore, in practice the only scenario in which an `<init-param>` setting in `web.xml` takes effect is when the user explicitly types the `adfAuthentication` URL into the browser.

In cases where the user is authenticated but not authorized to view a web page, you can redirect the ADF authentication servlet to an error page in your application. Error handling in Fusion web applications is under the control of the ADF Controller exception handler unless you have created an application that does not use a task flow in its design. For example, in an unbounded task flow, where you have defined an unbounded task flow with a top-level welcome page and a browse page (secured through its ADF page definition), you would see an error page from the application, named `authorizationErrorPage.jspx`, specified in the `adfc-config.xml` file, as shown in [Example 35-16](#).

**Example 35-16 Error Page Redirect for Applications That Use Task Flows**

```
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
 <exception-handler>authorizationErrorPage</exception-handler>
 <view id="welcomePage">
 <page>/welcomePage.jspx</page>
 </view>
 <view id="browse">
 <page>/browse.jspx</page>
 </view>
 <view id="authorizationErrorPage">
 <page>/authorizationErrorPage.jspx</page>
 </view>
 <control-flow-rule>
 <from-activity-id>welcomePage</from-activity-id>
 <control-flow-case>
 <from-outcome>goToSecuredPage</from-outcome>
 <to-activity-id>browse</to-activity-id>
 </control-flow-case>
 </control-flow-rule>
</adfc-config>
```

For details about how to specify an error page as a view activity for the ADF Controller exception handler, see [Section 22.4, "Handling Exceptions in Task Flows."](#)

In cases where the user is not authenticated and an authorization failure occurs, the framework redirects to the ADF authentication servlet, which in turn triggers a Java EE constraint that prompts for login. In this case, container-managed security relies on the login page and error page that you specify in the `<login-config>` element of the `web.xml` file.

If you create a Fusion web application without utilizing task flows, then you can specify an `<init-param>` setting in `web.xml` for the ADF binding filter, as shown in [Example 35-17](#). In this case, when no task flow is present in the application, page authorization checking is handled by the ADF binding filter, and the `unauthorizedErrorPage` parameter will be passed to the ADF binding request handler.

---

**Note:** The `unauthorizedErrorPage` parameter feature is provided for compatibility with previous releases where ADF Controller was not available. In Fusion web applications, when you need to redirect users to an error page, you use the task flow exception handler to specify the error page, as shown in [Example 35-16](#).

---

**Example 35-17 Error Page Redirect for Applications That Don't Use Task Flows**

```
<filter>
 <filter-name>adfBindings</filter-name>
 <filter-class>oracle.adf.model.servlet.ADFBindingFilter</filter-class>
 <init-param>
 <param-name>unauthorizedErrorPage</param-name>
 <param-value>faces/authorizationErrorPage.jsp</param-value>
 </init-param>
</filter>
```

## 35.7.5 What You May Need to Know About ADF Servlet Logout and Browser Caching

When basic type authentication is in effect as specified in the application's `web.xml` file, the browser caches authentication credentials. This is a known issue with basic authentication that prevents the ADF authentication servlet from completing log out and allows users to access resources after logout. In this scenario, in order to complete the logout session, it is necessary to close the browser and restart a new browser session.

To ensure the ADF authentication servlet completes logout and prevents a user from being able to access resources after logout, use form-based authentication instead of basic authentication. You can select form-based authentication when you run the Configure ADF Security wizard, as described in [Section 35.3.1, "How to Enable ADF Security."](#)

## 35.8 Testing Security in JDeveloper

Integrated WebLogic Server enables you to run the application directly within JDeveloper and determine whether or not to migrate security objects, including the application policies, users, and credentials that your application defines. By default, all security objects are migrated to Integrated WebLogic Server each time you run the application.

### 35.8.1 How to Configure, Deploy, and Run a Secure Application in JDeveloper

JDeveloper is configured by default to deploy the security objects from your application repositories to Integrated WebLogic Server each time you run the application. You can change this behavior by selecting security deployment options in the Application Properties dialog to:

- Decide whether to overwrite the domain-level policies with those from the application `jazn-data.xml` file
- Decide whether to overwrite the system credentials from the application's `cwallet.sso` file
- Decide whether to migrate the identity store portion of the `jazn-data.xml` file to the domain-level identity store

If you make no changes to the deployment settings, each time you run the application, JDeveloper will overwrite the domain-level security policies and system credentials. Additionally, JDeveloper will migrate new user identities you create for test purposes and update existing user passwords in the embedded LDAP server that Integrated WebLogic Server uses for its identity store. However, if you prefer to run the application without updating the existing security objects in Integrated WebLogic Server, you have this option.

**Before you begin:**

It may be helpful to have an understanding of using Integrated WebLogic Server. For more information, see [Section 35.8, "Testing Security in JDeveloper."](#)

**To configure security deployment and run the application in JDeveloper:**

1. In the main menu, choose **Application** and then **Secure > Configure Security Deployment**.
2. In the Application Properties dialog, in the Deployment page, in the **Security Deployment Options** section, select the security objects that you want to deploy to Integrated WebLogic Server.

By default, each time you run the application, JDeveloper will overwrite the application policies and system credentials at the domain level with those from the application. If you prefer not to overwrite either of these repositories, deselect **Application Policies** or **Credentials**. When deselected, JDeveloper will merge only new polices or credentials into the domain-level stores.

By default, each time you run the application, JDeveloper will migrate new user identities you create for test purposes and update existing user passwords in the embedded LDAP server that Integrated WebLogic Server uses for its identity store. You can disable migration of the application identity store by deselecting **Users and Groups**.

3. Click **OK**.
4. In the Application Navigator, right-click the user interface project that contains the secured web pages and choose **Run**.

When you choose **Run** on the user interface project, JDeveloper will run the application using the default run target you configured for the project. For example, you can configure a task flow activity as the run target to start your application. To configure the default run target, see [Section 18.5, "Testing Task Flows."](#)

The Configure Default Domain dialog displays the first time you run the application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

## 35.8.2 What Happens When You Configure Security Deployment Options

When you run the application using Integrated WebLogic Server, JDeveloper migrates the security policies and credentials to the domain level based on security deployment configuration settings specified in the Application Properties dialog. During the deployment process, JDeveloper updates the `weblogic-application.xml` file that it adds to the deployment archive file with the Application Properties settings, as shown in [Example 35-18](#). Note that these settings are not added to the `weblogic-application.xml` file in the application source directory and thus are not visible.

**Example 35–18 Default Security Deployment Settings in the Archive `weblogic-application.xml` File**

```

<application-param>
 <param-name>jps.credstore.migration</param-name>
 <param-value>OVERWRITE</param-value>
</application-param>
<application-param>
 <param-name>jps.policystore.migration</param-name>
 <param-value>OVERWRITE</param-value>
</application-param>

```

The `OVERWRITE` value allows you to modify the security policies and credentials in your application and redeploy either to Oracle WebLogic Server running in development mode or to Integrated WebLogic Server (set up to run in development mode by default).

---

**Note:** When you eventually deploy to a production environment, the migration settings in the `weblogic-application.xml` file are ignored; it would be considered a security vulnerability to allow existing policies and credentials to be overwritten. For information about deploying to a production environment, see [Section 35.9, "Preparing the Secure Application for Deployment."](#)

---

JDeveloper also updates the `weblogic-application.xml` file with OPSS lifecycle listeners, as shown in [Example 35–19](#). To initiate the migration process before the application runs, the lifecycle listeners observe the migration settings for policies and credentials and overwrite the security objects at the domain level.

**Example 35–19 Security Migration Listeners in the Archive `weblogic-application.xml` File**

```

<listener>
 <listener-class>
 oracle.security.jps.wls.listeners.JpsApplicationLifecycleListener
 </listener-class>
</listener>
<listener>
 <listener-class>
 oracle.security.jps.wls.listeners.JpsAppVersionLifecycleListener
 </listener-class>
</listener>

```

During the migration process, JDeveloper maps the Oracle Platform Security Services (OPSS) application role member classes to the Integrated WebLogic Server member classes and migrates the users to WebLogic Server identity store users and migrates the roles to Integrated WebLogic Server identity store groups. In Oracle WebLogic Server, users is an implicit group equivalent to OPSS `authenticated-role`.

**Example 35–20 Application Role Fragment in the `system-jazn-data.xml` File**

```

<app-roles>
 <app-role>
 <name>fod-users</name>
 <guid>FFFF394F696E786F4134485764511002</guid>
 <display-name/>
 <description/>
 <class>oracle.security.jps.service.policystore.ApplicationRole</class>
 <members>

```

```

 <member>
 <name>fod-users</name>
 <class>weblogic.security.principal.WLSGroupImpl</class>
 </member>
 </members>
</app-role>
</app-roles>

```

Identity store migration is not controlled by the application lifecycle listener settings in the `weblogic-application.xml` file. Instead, an Oracle WebLogic Mbean handles migrating the identities when running in Integrated WebLogic Server or when deploying from JDeveloper. If the user already exists, the Mbean will not migrate the entire user definition. Only the user password will be updated.

### 35.8.3 How to Use the Built-In test-all Application Role

When you run the Configure ADF Security wizard, you can enable the option to add the `test-all` application role to the policy store in the `jazn-data.xml` file. When you enable this option, you also specify the scope of grants to the application role for your application:

- Select **Grant to Existing Objects Only** when you want JDeveloper to grant view rights to the `test-all` application role and you want this policy to apply to all the ADF task flows and web pages that appear in your user interface project at the time you run the wizard.
- Select **Grant to All Objects** when you want JDeveloper to grant view rights to the `test-all` application role and you want this policy to apply to all existing and future ADF task flows and web pages that developers will create in the user interface project. Note that the wizard displays the option **Grant to New Objects** after you run the wizard the first time with the **Grant to All Objects** option selected.

After you run the wizard, the `test-all` role appears in the `jazn-data.xml` file and is visible in the `jazn-data.xml` file overview editor. You will not need to populate the `test-all` role with test users since the wizard assigns the built-in application role `anonymous-role` to the `test-all` role. In this case, all users will automatically have the `anonymous-role` principal and will be permitted to access the application.

---

**Note:** Before you deploy the application, you must remove all occurrences of the `test-all` role from the policy store, as described in [Section 35.9.1, "How to Remove the test-all Role from the Application Policy Store."](#) This will prevent unauthorized users from accessing the web pages of your application.

---

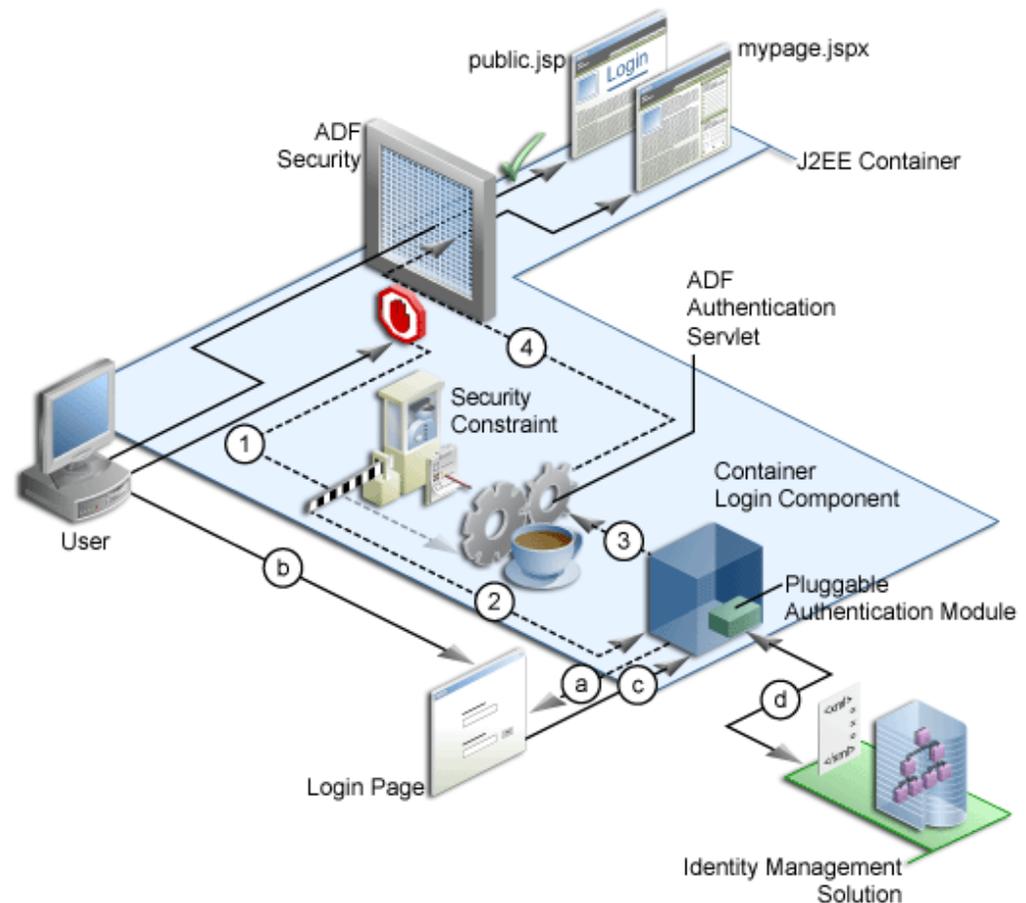

You can rerun the wizard and disable automatic grants at any time. Once disabled, new ADF task flows and web pages that you create will not utilize the `test-all` role and will therefore require that you define explicit grants, as described in [Section 35.5, "Defining ADF Security Policies."](#)

### 35.8.4 What Happens at Runtime: How ADF Security Handles Authentication

When you test the application in JDeveloper using Integrated WebLogic Server, the identity store is migrated to the embedded LDAP server, with information stored in Oracle Internet Directory.

Figure 35–26 illustrates the authentication process when users attempt to access an ADF bounded task flow or any web page containing ADF bindings (such as `mypage.jspx`) without first logging in. Authentication is initiated implicitly because the user does not begin login by clicking a login link on a public page. In the case of the secured page, no grants have been made to the anonymous user.

**Figure 35–26 ADF Security Implicit Authentication**

In Figure 35–26, the implicit authentication process assumes that the resource does not have a grant to `anonymous-role`, that the user is not already authenticated, and that the authentication method is Form-based authentication. In this case, the process is as follows:

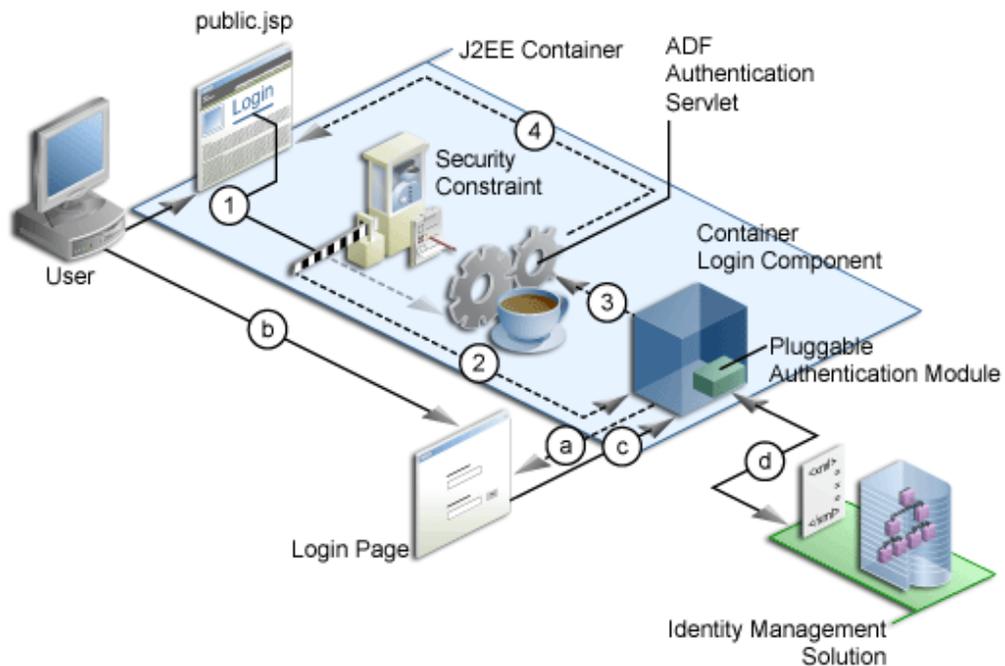

1. When the bounded task flow or web page (with ADF bindings) is requested, the ADF bindings servlet filter redirects the request to the ADF authentication servlet (in the figure, Step 1), storing the logical operation that triggered the login.
2. The ADF authentication servlet has a Java EE security constraint set on it, which results in the Java EE container invoking the configured login mechanism (in the figure, Step 2). Based on the container's login configuration, the user is prompted to authenticate:
  - a. The appropriate login form is displayed for form-based authentication (in the figure, Step 2a).
  - b. The user enters his credentials in the displayed login form (in the figure, Step 2b).

- c. The user posts the form back to the container's `j_security_check()` method (in the figure, Step 2c).
  - d. The Java EE container authenticates the user, using the configured pluggable authentication module (in the figure, Step 2d).
3. Upon successful authentication, the container redirects the user back to the servlet that initiated the authentication challenge, in this case, the ADF authentication servlet (in the figure, Step 3).
  4. On returning to the ADF authentication servlet, the servlet subsequently redirects to the originally requested resource (in the figure, Step 4).

Whether or not the resource is displayed will depend on the user's access rights and on whether authorization for ADF Security is enforced, as explained in [Section 35.8.5, "What Happens at Runtime: How ADF Security Handles Authorization."](#)

Figure 35–27 illustrates the explicit authentication process when the user becomes authenticated starting with the login link on a public page.

**Figure 35–27 ADF Security Explicit Authentication**

In an explicit authentication scenario, an unauthenticated user (with only the anonymous user principal and anonymous-role principal) clicks the **Login** link on a public page (in the figure, Step 1). The login link is a direct request to the ADF authentication servlet, which is secured through a Java EE security constraint in the `web.xml` file.

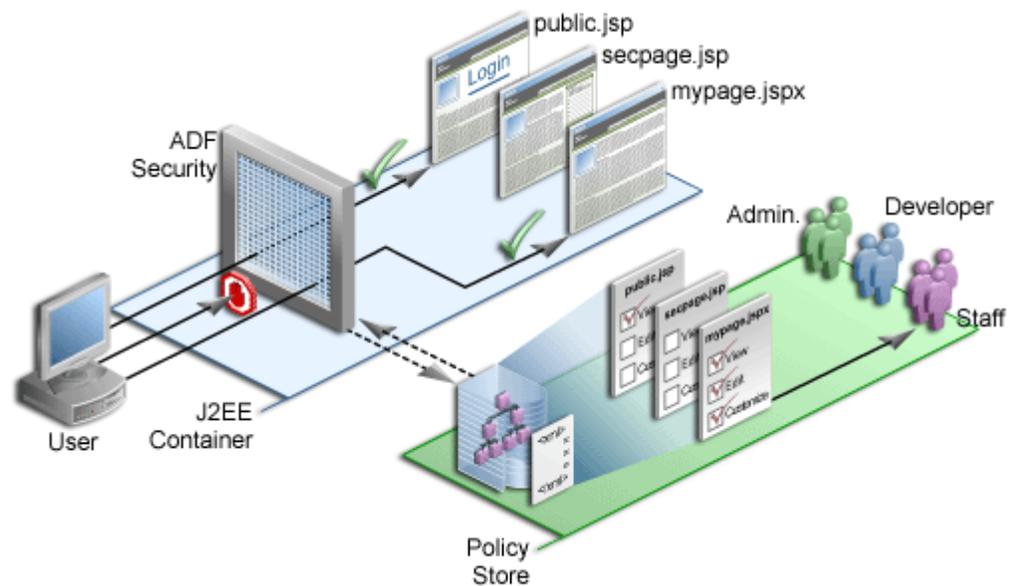

In this scenario, the current page is passed as a parameter to the ADF authentication servlet. As with the implicit case, the security constraint redirects the user to the login page (in the figure, Step 2). After the container authenticates the user, as described in Step a through Step d in the implicit authentication case, the request is returned to the ADF authentication servlet (in the figure, Step 3), which subsequently returns the user to the public page, but now with new user and role principals in place.

### 35.8.5 What Happens at Runtime: How ADF Security Handles Authorization

When ADF authorization is enabled, the ADF bounded task flows and web pages outside of a task flow that have an ADF page definition will be secure by default. When a user attempts to access these web pages, ADF Security checks to determine whether the user has been granted access in the policy store. If the user is not yet authenticated, and the page is not granted to the `anonymous-role`, then the application displays the login page or form. If the user has been authenticated, but does not have permission, a security error is displayed. If you do not configure the policy store with appropriate grants, the pages will remain protected and therefore stay unavailable to the authenticated user.

Figure 35–28 illustrates the authorization process.

**Figure 35–28 ADF Security Authorization**

The user is a member of the application role *staff* defined in the policy store. Because the user has not yet logged in, the security context does not have a subject (a container object that represents the user). Instead, Oracle Platform Security Services provides ADF Security with a subject with the `anonymous` user principal (a unique definition of the user) and the `anonymous-role` principal.

With the `anonymous-role` principal, typically the user would be able to access only pages not defined by ADF resources, such as the `public.jsp` page, whereas all pages that are defined either by an ADF task flow or outside of a task flow using an ADF page definition file are secure by default and unavailable to the user. An exception to this security policy would be if you were to grant `anonymous-role` access to ADF resources in the policy store. In this case, the user would not be allowed immediate access to the page defined by an ADF resource.

When the user tries to access a web page defined by an ADF resource, such as `mypage.jsp` (which is specified by an ADF page definition, for example), the ADF Security enforcement logic intercepts the request and because all ADF resources are secured by default, the user is automatically challenged to authenticate (assuming that the `anonymous-role` is not granted access to the ADF resource).

After successful authentication, the user will have a specific subject. The security enforcement logic now checks the policy store to determine which role is allowed to

view `mypage.jspx` and whether the user is a member of that role. In this example for `mypage.jspx`, the view privilege has been granted to the staff role and because the user is a member of this role, they are allowed to navigate to `mypage.jspx`.

Similarly, when the user tries to access `secpage.jsp`, another page defined by ADF resources, for which the user does not have the necessary view privilege, access is denied.

Users and roles are those already defined in the identity store of the resource provider. Application roles are defined in the policy store of the `jazn-data.xml` file.

## 35.9 Preparing the Secure Application for Deployment

After testing in JDeveloper using Integrated WebLogic Server, you will eventually want to deploy the application to a standalone server. Initially, the server you target will be your staging environment where you can continue development testing using that server's identity store before deploying to the production environment. Thus, you will typically not migrate the test users you created to run with Integrated WebLogic Server. The steps you perform to migrate security policies and system credentials (from the `cwallet.sso` file) to standalone Oracle WebLogic Server will depend on the configured mode of the target server and whether you deploy using JDeveloper or a tool outside of JDeveloper.

---

---

**Note:** For details about deploying from JDeveloper to a development environment, see [Section 41, "Deploying Fusion Web Applications."](#)

---

---

When the target server is configured for *development mode*, you can deploy directly from JDeveloper. In this case, JDeveloper automatically handles the migration of the policy store, system credentials, and identity store (users and groups) as part of the deployment process. Application security deployment properties are configured by default to allow the deployment process to overwrite the domain-level policy store and the system credentials. Additionally, the identity store deployment property is configured by default to migrate the identity store consisting of your test users. You can change this default deployment behavior in the Application Properties dialog, as described in [Section 35.8.1, "How to Configure, Deploy, and Run a Secure Application in JDeveloper."](#)

---

---

**Note:** Note that migration of system credentials to Oracle WebLogic Server running in development mode will be performed only if the target server is configured to permit credential overwrite. For details about configuring Oracle WebLogic Server to support overwriting of system credentials, see the *Oracle Containers for J2EE Security Guide*.

---

---

When the target server is configured for *production mode*, you typically handle the migration task outside of JDeveloper using tools like Oracle Enterprise Manager. For details about using tools outside of JDeveloper to migrate the policy store to the domain-level in a production environment, see the *Oracle Containers for J2EE Security Guide*. Note that Oracle WebLogic Server running in production mode does not support the overwriting of system credentials under any circumstances.

Before you deploy the application, you will want to remove the `test-all` application role if you enabled the automatic grants feature in the Configure ADF Security wizard. Because the `test-all` role makes all ADF resources public, its presence increases the

risk that your application may leave some resources unprotected. You must therefore remove the role before you migrate application-level policy store.

Additionally, when you prepare to deploy the application to Oracle WebLogic Server, you will want to remove the test identities that you created in the `jazn-data.xml` file. This will ensure that users you created to test security policies are not migrated to the domain-level identity store.

**Best Practice:** If you deploy your application to the standalone environment, you must not migrate users and enterprise roles in your local identity store that are already configured for Oracle WebLogic Server. For example, if you were to deploy the identity store with the user `weblogic` and enterprise role `Administrators`, you would overwrite the default administration configuration on the target server. To ensure you avoid all possible conflicts, you can disable migration of the identity store as described in [Section 35.9.2, "How to Remove Test Users from the Application Identity Store."](#)

### 35.9.1 How to Remove the test-all Role from the Application Policy Store

The `jazn-data.xml` file overview editor provides the facility to display all resources with view grants made to ADF Security's built-in `test-all` role. You can use this feature in the overview editor to delete the `test-all` role grant and replace it with a grant to the roles that your application defines.

Alternatively, you could delete the `test-all` role using the overview editor for the `jazn-data.xml` file, by selecting the `test-all` role in the Application Roles page of the editor and clicking the **Delete Application Role** button. However, when you remove the `test-all` role this way, you will still need to create a grant to replace the ones that you delete. Because the overview editor lets you combine both of these tasks, the following procedure describes its usage.

#### Before you begin:

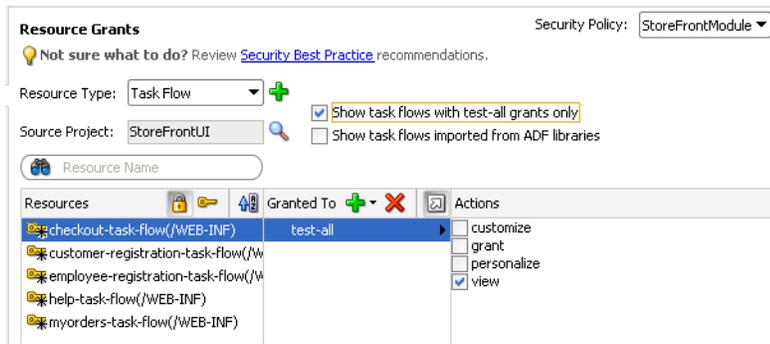

It may be helpful to have an understanding of the Oracle WebLogic Server. For more information, see [Section 35.9, "Preparing the Secure Application for Deployment."](#)

#### To remove the test-all application role and substitute custom application roles:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the `jazn-data.xml` file overview editor, select **Task Flow** from the **Resource Types** dropdown list and then select the **Show task flows with test-all grants only** checkbox to view the list of task flows with grants to this built-in role.

If no grant exists for the `test-all` role, then the **Resources** list in the overview editor will appear empty. The `test-all` role is defined only when enabled in the Configure ADF Security wizard. If it is enabled, you will see those task flows with `test-all` grants listed, as shown in [Figure 35-29](#).

**Figure 35–29 Showing Task Flows with test-all Grants in the Overview Editor**

3. In the **Resources** column, select the first task flow in the list.
4. In the **Granted to** column, select **test-all** and click the **Remove Grantee** icon.
5. In the **Granted to** column, click the **Add Grantee** icon and choose **Add Application Role** and then use the Select Application Roles dialog to add the desired role.
6. Repeat these steps to remove the `test-all` role and substitute your own application role for all remaining task flows.
7. In the Resource Grants page of the overview editor, select **Web Page** from the **Resource Types** dropdown list and repeat these steps to remove the `test-all` role for all web pages and their ADF page definitions.
8. With the **Show task flows/web pages with test-all grants only** checkbox selected, verify that the overview editor displays no resources with `test-all` grants.

### 35.9.2 How to Remove Test Users from the Application Identity Store

The standalone Oracle WebLogic Server that you will deploy to will have its own identity stored already configured. To ensure that you do not migrate test users and enterprise role groups you created in JDeveloper to the domain level, you should remove the test user realm from the `jazn-data.xml` file.

Alternatively, if you are deploying from JDeveloper, you can disable the migration of users and groups by deselecting the **Users and Groups** option in the Application Properties dialog, as described in [Section 35.8.1, "How to Configure, Deploy, and Run a Secure Application in JDeveloper."](#)

#### Before you begin:

It may be helpful to have an understanding of the Oracle WebLogic Server. For more information, see [Section 35.9, "Preparing the Secure Application for Deployment."](#)

#### To remove test users and enterprise role groups from the identity store:

1. In the main menu, choose **Application** menu and then **Secure > Users**.
2. In the editor window for the `jazn-data.xml` file, click the **Source** tab.
3. In the source for the `jazn-data.xml` file, click the **-** icon to the left of the `<jazn-realm>` element so the entire element appears collapsed as shown in [Figure 35–30](#).

**Figure 35–30** Selecting the `<jazn-realm>` Element in the XML Editor

4. With the element selected, press **Delete** and save the file.

### 35.9.3 How to Secure Resource Files Using a URL Constraint

Resource files, including images, style sheets, and JavaScript libraries are files that the Fusion web application loads to support the individual pages of the application. ADF Security does not secure these files. Although securing such files is not a requirement for securing the web pages of the application, in some cases it may be desirable to protect resource files to fully harden your application. Please note that JavaScript files are downloaded to the browser and, as such, can be read at that time.

To serve up resource files, the ADF Faces framework relies on `org.apache.myfaces.trinidad.webapp.ResourceServlet`, which delegates to a resource loader. The Fusion web application's `web.xml` file contains a servlet mapping that maps the resource servlet to URL patterns. By default, JDeveloper uses the patterns `/adf/*` for MyFaces Trinidad Core, and `/afr/*` for ADF Faces.

Because ADF Security does not protect the resource servlet, you can protect the Java EE access paths for the resource servlet with a security constraint. To implement your own security for the resource files in the `web.xml` file, define a security constraint for the `/adflib/*`, `/adf/*` and `/afr/*` paths and assign a specific security role to them. This security constraint will require all users to be authenticated before they can access the first page of the Fusion web application.

[Example 35–21](#) shows the security role `resource_role` and the constraint with the URL patterns mapped to this role. After you define the security role, the administrator for the target server must map this role to an Oracle WebLogic Server enterprise role (user group) or create an enterprise role with the same name (in which case no mapping is required).

#### **Example 35–21** URL Constraint in `web.xml` File for Resource Files

```
<security-role>
 <description>Java EE role to map to an enterprise role. All users who will
 be allowed to run Fusion web app must be members of that role.
 </description>
 <role-name>resource_role</role-name>
</security-role>

<security-constraint>
 <web-resource-collection>
 <web-resource-name>resources</web-resource-name>
 <url-pattern>/adflib/*</url-pattern>
```

```
<url-pattern>/adf/*</url-pattern>
<url-pattern>/afr/*</url-pattern>
</web-resource-collection>
<auth-constraint>
 <role-name>resource_role</role-name>
</auth-constraint>
</security-constraint>
```

## 35.10 Disabling ADF Security

JDeveloper allows you to disable ADF Security when you want to temporarily run the application without enforcing authorization checks against the application policy store. This will allow you to run the application and access all resources without the protection provided by existing security policies.

### 35.10.1 How to Disable ADF Security

To disable ADF Security at the level of your application, run the wizard and choose one of these options:

- **ADF Authentication** disables ADF authorization but leaves the ADF authentication servlet enabled. This option will require the user to log in the first time a page in the application is accessed by mapping the Java EE application root "/" to the a Java EE security constraint that will trigger user authentication. ADF resources will not be security-aware because authorization checking is not enforced. Thus, once the user is logged in, all web pages containing ADF resources will be available to the user.
- **Remove ADF Security Configuration** disables the ADF authentication servlet and disables authorization checking on ADF resources. In this case, you can run the application with no user authentication and no security for ADF resources in place.

You may select either option with the intention of reenabling ADF Security at any time. The wizard specifically does not alter the application policy store that contains the security policies that application developers defined for ADF resources. This means that you can return to the wizard at any time, select the **ADF Authentication and Authorization** option, and reenable ADF Security against your application's existing policy store and identity store.

#### Before you begin:

It may be helpful to have an understanding of disabling ADF Security. For more information, see [Section 35.10, "Disabling ADF Security."](#)

#### To disable ADF authorization checking:

1. In the main menu, choose **Application** and then **Secure > Configure ADF Security**.
2. In the ADF Security page, select either the **ADF Authentication** option or the **Disable ADF Security Configuration** option. Click **Next**.

After you run the wizard with either of these options, the ADF resources of your user interface projects will no longer be security-aware.

3. Click **Finish**.

## 35.10.2 What Happens When You Disable ADF Security

If you run the wizard with the **Remove ADF Security Configuration** option selected, it removes the ADF-specific metadata in the `web.xml` file and `adf-config.xml` file, as described in [Table 35–2](#). Similarly, running the wizard with the **ADF Authentication** option selected sets the `authorizationEnforce` parameter in the `<JaasSecurityContext>` element of the `adf-config.xml` file to `false`, as shown in [Example 35–22](#).

### **Example 35–22 AuthorizationEnforce Flag Disabled in the adf-config.xml File**

```
<JaasSecurityContext
 initialContextFactoryClass="oracle.adf.share.security.JAASInitialContextFactory"
 jaasProviderClass="oracle.adf.share.security.providers.jps.JpsSecurityContext"
 authorizationEnforce="false"
 authenticationRequire="true"/>
```

## 35.11 Advanced Topics and Best Practices

After you have completed the process of enabling ADF Security, you may want to customize your application to work with ADF Security in the user interface. For example, you can use Expression Language (EL) to render UI components in the web page based on evaluation of custom permissions that you define just for a group of UI components. Additionally, you can define methods within a managed bean to expose information, such as the user name and role membership, in your application.

### 35.11.1 Using Expression Language (EL) with ADF Security

You can use Expression Language (EL) to evaluate the policy directly in the UI, while the use of Java enables you to evaluate the policy from within a managed bean. ADF Security implements several convenience methods for use in EL expressions to access ADF resources in the security context. For example, you can use the EL expression convenience methods to determine whether the user is allowed to access a particular task flow. Good security practice dictates that your application should hide resources and capabilities for which the user does not have access. And for this reason, if the user is not allowed access to a particular task flow, you would evaluate the user's permission grant to determine whether or not to render the navigation components that initiate the task flow.

---

**Note:** The ability to evaluate a policy is limited to the current request. For this reason, it is important to understand where the policy evaluation occurs, because evaluating the policy at anything other than the request scope can lead to unexpected results.

---

#### 35.11.1.1 How to Evaluate Policies Using EL

The use of EL within a UI component allows for the component's attribute values to be defined dynamically, resulting in modification of the UI component at runtime. In the case of securing resources, the UI component attribute of interest is the `rendered` attribute, which allows you to show and hide components based on available permissions. By default, the `rendered` attribute is set to `true`. By dynamically changing this value based on the permission, you can set the UI component to be shown or hidden. For example, if the user has the appropriate permission, the `rendered` attribute should be set to `true` so that the UI component is shown. If they do not have permission, the attribute should be set to `false` and the UI component hidden from view.

To evaluate a policy using EL, you must use the ADF Security methods in the `securityContext` EL namespace. These methods let you access information in the ADF security context for a particular user or ADF resource.

[Table 35–10](#) shows the EL expression that is required to determine whether a user has the associated permission. If the user has the appropriate permission, the EL expression evaluates to `true`; otherwise, it returns `false`.

**Table 35–10 EL Expression to Determine View Permissions on ADF Resources**

Expression	Expression action
<pre>#{securityContext.taskflowViewable['MyTaskFlow']}</pre> <p>For example:</p> <pre>#{securityContext.taskflowViewable   ['/WEB-INF/audit-expense-report.xml#audit-expense-report']}</pre>	Where <i>MyTaskFlow</i> is the WEB-INF node-qualified name of the task flow being accessed. Returns <code>true</code> if the user has access rights. Returns <code>false</code> if the user does not have sufficient access rights.
<pre>#{securityContext.regionViewable['MyPagePageDef']}</pre>	Where <i>MyPagePageDef</i> is the qualified name of the page definition file associated with the web page being accessed. Returns <code>true</code> if the user has access rights. Returns <code>false</code> if the user does not have sufficient access rights.

---

**Note:** In the case of page permission, the value of the page definition can be specified dynamically by using late-binding EL within a managed bean, as described in [Section 35.3.7, "What You May Need to Know About the valid-users Role."](#)

---

[Table 35–11](#) shows the EL expression that lets you get general information from the ADF security context not related to a particular ADF resource. For example, you can access the current user name when you want to display the user's name in the user interface. You can also check whether the current user is a member of certain roles or granted certain privileges. Your application may use this result to dynamically hide or show menus.

**Table 35–11 EL Expression to Determine User Information in the ADF Security Context**

Expression	Expression Action
<pre>#{securityContext.userName}</pre>	Returns the user name of the authenticated user.
<pre>#{data.adfContext.enterpriseName}</pre>	Returns the enterprise name of the authenticated user. The enterprise name is an alias that the user knows for themselves and can use to login.
<pre>#{data.adfContext.enterpriseId}</pre>	Returns the enterprise ID of the authenticated user.
<pre>#{securityContext.authenticated}</pre>	Returns <code>true</code> if the user is logged in. Returns <code>false</code> if the user is not logged in. This is useful for rendering a dynamic link for login/logout, or for rendering a "Welcome, <i>username</i> " message when the user has been authenticated. For an example that uses this expression, see <a href="#">Section 35.7.3.2, "Adding Login and Logout Links."</a>

**Table 35–11 (Cont.) EL Expression to Determine User Information in the ADF Security Context**

Expression	Expression Action
<code>#{securityContext.userInRole['roleList']}</code>	Where <i>roleList</i> is a comma-separated list of role names. Returns <code>true</code> if the user is in at least one of the roles. Returns <code>false</code> if the user is in none of the roles, or if the user is not currently authenticated.
<code>#{securityContext.userInAllRoles['roleList']}</code>	Where <i>roleList</i> is a comma-separated list of role names. Returns <code>true</code> if the user is in all of the roles. Returns <code>false</code> if the user is not in all of the roles, or if the user is not currently authenticated.
<code>#{securityContext.userGrantedPermission['permission']}</code>	<p>Where <i>permission</i> is a string containing a semicolon-separated concatenation of <code>permissionClass=&lt;class&gt;;target=&lt;artifact_name&gt;;action=&lt;action&gt;</code>. Returns <code>true</code> if the user has access rights. Returns <code>false</code> if the user does not have sufficient access rights.</p> <p>Note that the convenience methods <code>taskflowViewable</code> and <code>regionViewable</code> shown in <a href="#">Table 35–10</a> provide the same functionality.</p>
<code>#{securityContext.userGrantedResource['resource']}</code>	<p>Where <i>resource</i> is a string containing a semicolon-separated concatenation of <code>resourceName=&lt;name&gt;;resourceType=&lt;type&gt;;action=&lt;action&gt;</code>. Returns <code>true</code> if the user has access rights. Returns <code>false</code> if the user does not have sufficient access rights.</p> <p>You can use this expression to test the permission grant in the <code>rendered</code> attribute of a resource that is not contained in a task flow (like an ADF Faces panel). This provides an alternative to creating a custom permission class that must be packaged with the application.</p> <p>For example, when you want to show or hide a panel in a page based on the permission granted to that resource, the expression might look like:</p> <pre>#{securityContext.userGrantedResource   ['resourceName=myPanel1;    resourceType=myLayoutPanel;    action=myAction']}</pre> <p>In the policy store, a grant to the resource has a <code>&lt;permission&gt;</code> definition like:</p> <pre>&lt;permission&gt;   &lt;class&gt;oracle.security.jps.     ResourcePermission&lt;/class&gt;   &lt;name&gt;resourceType=myLayoutPanel,     resourceName=myPanel1&lt;/name&gt;   &lt;actions&gt;myAction&lt;/actions&gt; &lt;/permission&gt;</pre>

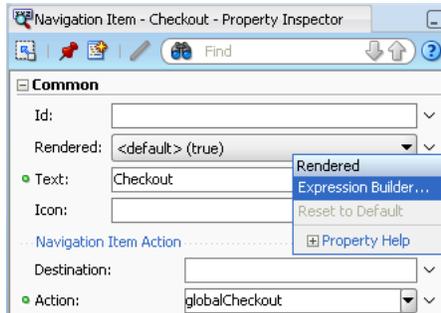

**Before you begin:**

It may be helpful to have an understanding of using EL. For more information, see [Section 35.11.1, "Using Expression Language \(EL\) with ADF Security."](#)

**To associate the rendering of a navigation component with a user's granted permissions on a target task flow or page definition:**

1. In the Application Navigator, double-click the page.
2. Select the component that is used to navigate to the secured page.
3. In the Property Inspector, click the **Property Menu** dropdown menu displayed to the right of the **Rendered** field and choose **Expression Builder**, as shown in [Figure 35–31](#).

**Figure 35–31 Binding the Rendered Property to Data**

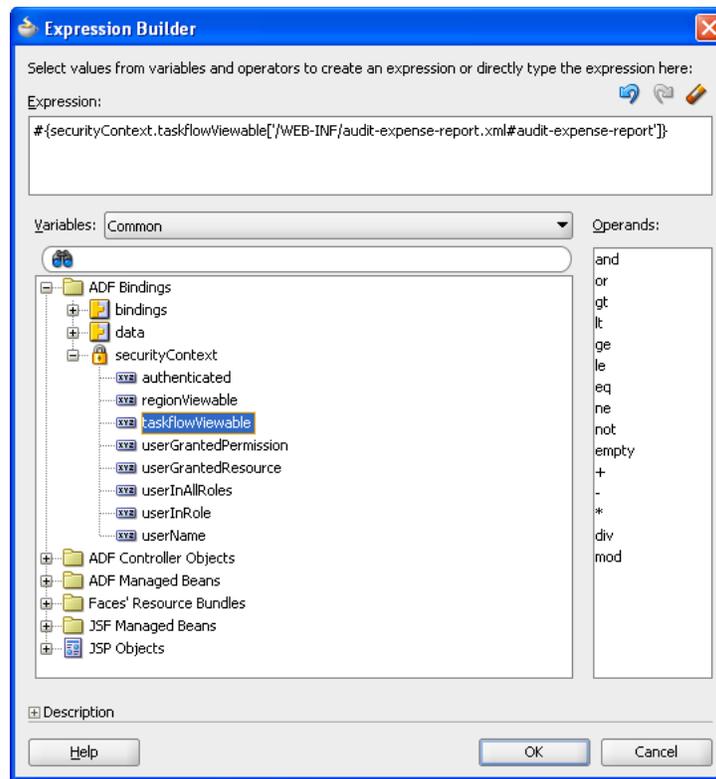

4. In the Expression Builder, expand the **ADF Bindings - securityContext** node and select the appropriate EL value, then in the **Expression** field, enter the qualified name of the ADF resource that the user will attempt to access.

For example, as shown in [Figure 35–32](#), to limit access to a task flow that your application displays, you would create an expression like:

```
#({securityContext.taskflowViewable
 ['/WEB-INF/audit-expense-report.xml#audit-expense-report']})
```

In this example, the expression determines the user's access rights to view the target task flow `audit-expense-report`. If the user has the access rights, then the expression evaluates to `true` and the `rendered` attribute receives the value `true`.

**Figure 35–32 Defining EL in the Expression Builder Dialog**

**Tip:** In the Expression Builder dialog, expand **Description** for additional information about any security EL method you select.

##### 5. Click **OK**.

When you run the application, the component will be rendered or hidden based on the user's ability to view the target page.

### 35.11.1.2 What Happens When You Use the Expression Builder Dialog

When you use the Expression Builder to define an expression for the `rendered` attribute, JDeveloper updates the component definition in the open `.jspx` file. The component's `rendered` attribute appears with an expression that should evaluate to either `true` or `false`, as shown in [Example 35–23](#). In this example, the component is a navigation link with the link text `Checkout` defined by another expression. The page that contains the navigation link renders the component only when the user has sufficient rights to access the checkout task flow.

#### **Example 35–23 EL Expression in Source for .jspx File**

```
<af:commandNavigationItem
 text="#{res['global.nav.checkout']}"
 action="globalCheckout"
 id="cni3"
 rendered="#{securityContext.taskflowViewable
 ['/WEB-INF/checkout-task-flow.xml#checkout-task-flow']}"
/>
```

### 35.11.1.3 What You May Need to Know About Delayed Evaluation of EL

The ability to evaluate a security permission is scoped to the request. If you want to evaluate permissions to access a target page from a managed bean that is scoped to a higher level than request (for example, a global menu that is backed by a managed bean), you must implement delayed EL evaluation (late-binding). By passing in the target page as a managed property of the bean, you ensure that the EL expression is evaluated only after the required binding information is available to the managed bean. Because EL is evaluated immediately when the page is executed, placing the EL expression directly in the properties of a UI component, backed by a managed bean, would result in an out-of-scope error.

[Example 35–24](#) shows a property (`authorized`) of a managed bean that returns `true` or `false` based on a user's ability to view a named target page. In this case, the `_targetPageDef` variable is a managed property containing the name of the target page. Within the UI, the EL expression would reference the `authorized` property.

#### **Example 35–24 Delayed EL Evaluation in a Managed Bean**

```
public boolean isAuthorized()
{
 if (_targetPageDef != null) {
 FacesContext fctx = FacesContext.getCurrentInstance();
 ADFContext adfCtx = ADFContext.getCurrent();
 SecurityContext secCtx = adfCtx.getSecurityContext();
 boolean hasPermission = secCtx.hasPermission(new RegionPermission
 (_targetPageDef, RegionPermission.VIEW_ACTION));
 if (hasPermission) {
 return hasPermission;
 }
 else {
 fctx.addMessage(null, new FacesMessage (
 FacesMessage.SEVERITY_WARN, "Access Permission not defined! " , null));
 return false;
 }
 }
}
```

## 35.11.2 How to Evaluate Policies Using Custom JAAS Permissions and EL

You can use the value `userGrantedPermission` in the ADF Security EL namespace described in [Table 35–10](#) to determine whether to render UI elements in your page. The expression you create can evaluate custom permission grants for the authenticated user. A custom permission is a JAAS Permission class that you create using the Create JAAS Permission dialog. The dialog helps you create a class that extends the `oracle.adf.share.security.authorization.ADFPermission` class to ensure that the permission can be used by ADF Security.

Custom permissions in the Fusion web application give you additional flexibility to define security policies. For example, you might name a custom permission to correspond to the UI element you want to protect. Once you create the permission, you use the `jazn-data.xml` file overview editor to create a security policy for the ADF resource by granting permission to the application roles that your `jazn-data.xml` policy store defines.

**Best Practice:** Custom ADF permission classes let you extend ADF Security to define custom actions for use in grants. This gives you the flexibility to define security policies to manage the user's ability to view UI components without having to overload the built-in actions defined by the ADF resources' permission classes. Be aware that you do not need to create custom permissions to manage access to web pages. This level of access is provided by the default ADF Security view permission that you work with in the `jazn-data.xml` file overview editor.

To evaluate policies using custom JAAS permissions:

1. Create the custom JAAS Permission class.
2. Create the ADF Security policy using the custom permission.
3. Associate the rendering of a UI component with a user's granted custom permission.

### 35.11.2.1 Creating the Custom JAAS Permission Class

You use the Create JAAS Permission dialog to create the custom JAAS Permission class. JDeveloper adds the custom JAAS Permission class to the package you specify. For example, the `oracle.fodemo.storefront.store.view` package of the Fusion Order Demo application defines the custom permission class `AccountPermission.java` shown in [Example 35–25](#).

#### **Example 35–25 Custom JAAS Permission Class**

```
package oracle.fodemo.storefront.store.view;

import oracle.adf.share.security.authorization.ADFPermission;
import oracle.adf.share.security.authorization.PermissionActionDescriptor;
import oracle.adf.share.security.authorization.PermissionTargetDescriptor;

public class AccountPermission extends ADFPermission {
 private static final PermissionActionDescriptor[] actions =
 {new PermissionActionDescriptor("view", "view")};
 private static final PermissionTargetDescriptor[] targets =
 {new PermissionTargetDescriptor("attributeValue", "Attribute")};

 public AccountPermission(String name, String actions) {
 super(name, actions);
 }

 public static PermissionActionDescriptor[] getPermissionActionDescriptors() {
 return actions;
 }

 public static PermissionTargetDescriptor[] getPermissionTargetDescriptors() {
 return targets;
 }
}
```

#### **Before you begin:**

It may be helpful to have an understanding of the ADF Permission class. For more information, see [Section 35.11.2, "How to Evaluate Policies Using Custom JAAS Permissions and EL."](#)

**To create the custom JAAS Permission class:**

1. In the Application Navigator, right-click the project where you want to create the custom JAAS Permission class and choose **New**.
2. In the New Gallery, select **All Items** and then **JAAS Permission**, and click **OK**.
3. In the Create JAAS Permission dialog, enter the name of the permission and the fully qualified package name.

The permission name you choose can be a generic name.

4. In the **Actions** list, enter the name that you want to use for the action grant.

The action name can be a specific name that helps you to identify the permission's purpose. You can add more than one action to the list when you want the permission to apply to the same component, but for different purposes. For example, you might allow a manager and an employee to both view a page menu, but you might want the manager to also be able to choose specific menu items.

5. In the **Targets** list, leave the selection **Attribute** unchanged.

You will specify the actual target name when you create the policy in the policy store using the custom JAAS Permission's action.

6. Click **OK**.

**35.11.2.2 Creating the ADF Security Policy Using a Custom Permission**

You use the overview editor for the `jazn-data.xml` file to create the ADF Security policy based on a custom permission. The finished source should look similar to the custom permission grant defined in the policy store for the Fusion Order Demo application, as shown in [Example 35-26](#).

**Example 35-26 Custom Permission Grant Definition**

```
<grant>
 <grantee>
 <principals>
 <principal>
 <class>oracle.security.jps.service.policystore.ApplicationRole</class>
 <name>fod-admin</name>
 </principal>
 </principals>
 </grantee>
 <permissions>
 <permission>
 <class>oracle.fodemo.storefront.store.view.AccountPermission</class>
 <name>AccountPermission</name>
 <actions>view</actions>
 </permission>
 </permissions>
</grant>
```

The `<permission>` target name can be any name that helps you to identify the permission. For example, a permission that lets users view their account number might be named `AccountPermission`.

The actions that you can enter are those that your custom JAAS Permission class defines. For example, in the Fusion Order Demo application the class `oracle.fodemo.storefront.store.view.AccountPermission` defines the single action `view`.

**Before you begin:**

It may be helpful to have an understanding of the ADF Permission class. For more information, see [Section 35.11.2, "How to Evaluate Policies Using Custom JAAS Permissions and EL."](#)

You will need to complete this task:

Create the custom JAAS permission class, as described in [Section 35.11.2.1, "Creating the Custom JAAS Permission Class."](#)

**To create the ADF security policy using the custom permission:**

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the `jazn-data.xml` file overview editor, select the custom resource from the **Resource Types** dropdown list.

The overview editor displays all custom resources. Initially, the custom resource will not have a resource type associated with it and the editor highlights this, as shown in [Figure 35–33](#).

**Figure 35–33** *Displaying a Custom Resource in the Overview Editor*

3. Next to the **Resource Type** field, click the **New Resource Type** icon.
4. In the Create Resource Type dialog, enter the name and action and click **OK**.
5. In Resource Grants page of the overview editor, in the **Granted to** column, click the **Add Grantee** icon and choose **Add Application Role**.
6. In the Select Application Roles dialog, select the application role and click **OK**.
7. In the Resource Grants page of the overview editor, in the **Actions** column, select desired action.

The overview editor displays the custom permission grant, as shown in [Figure 35–34](#).

**Figure 35–34** *Creating a Custom Permission Grant in the Overview Editor*

**35.11.2.3 Associating the Rendering of a UI Component with a Custom Permission**

You use the Expression Builder dialog that you display for the UI component display property to define an EL expression. For example, in the Fusion Order Demo application, the page `myOrders.jpx` defines the `userGrantedPermission` expression on the `value` attribute of the `af:outputText#ot18` text field, as shown in [Example 35–27](#). In this case, the expression tests whether the user has permission

and then either displays the account number (through `bindings.AccountNumber.inputValue`) or, when the user does not have permission, displays `XXXXXXXXXXXX` in place of the account number. Because the expression is not defined on the text field's rendered attribute, the page always displays the field.

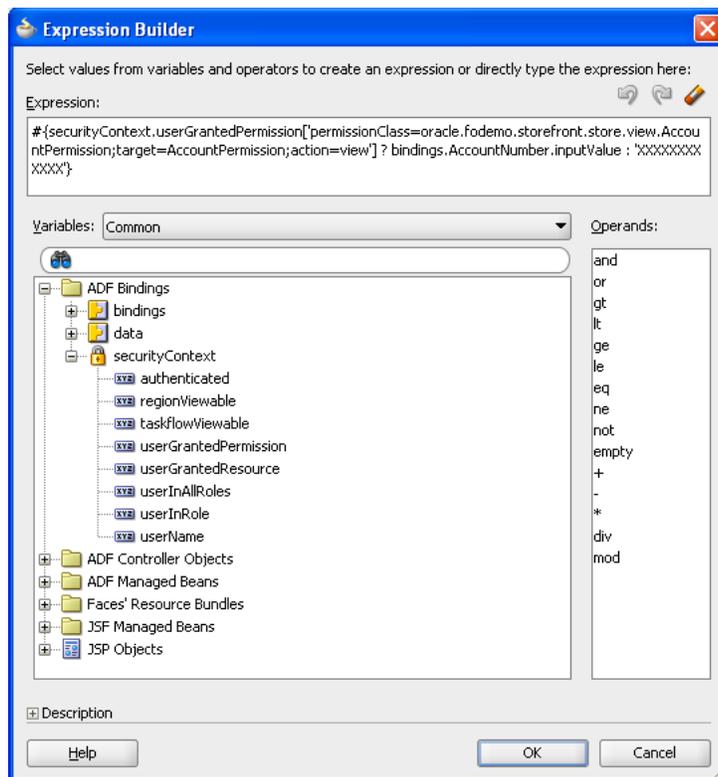

When you run the application, the component will be rendered or hidden based on the user's ability to view the target page.

**Example 35–27 Custom Permission Expression on Value Attribute**

```
#{securityContext.userGrantedPermission
 ['permissionClass=oracle.fodemo.storefront.store.view.AccountPermission;
 target=AccountPermission;action=view']
 ? bindings.AccountNumber.inputValue : 'XXXXXXXXXXXX'}
```

Figure 35–35 shows how the expression appears in the Expression Builder dialog.

**Figure 35–35 Defining EL in the Expression Builder Dialog**

**Before you begin:**

It may be helpful to have an understanding of the ADF Permission class. For more information, see [Section 35.11.2, "How to Evaluate Policies Using Custom JAAS Permissions and EL."](#)

You will need to complete these tasks:

1. Create the custom JAAS permission class, as described in [Section 35.11.2.1, "Creating the Custom JAAS Permission Class."](#)
2. Create the ADF security policy using the custom permission, as described in [Section 35.11.2.2, "Creating the ADF Security Policy Using a Custom Permission."](#)

**To associate the rendering of a UI component with a user's granted custom permission:**

1. In the Application Navigator, double-click the page.
2. Select the component that is used to navigate to the secured page.
3. In the Property Inspector, click the **Property Menu** dropdown menu displayed to the right of the **Rendered** field and choose **Expression Builder**.
4. In the Expression Builder, expand the **ADF Bindings - securityContext** node and select **userGrantedPermission**, and then, in the **Expression** field, enter a concatenated string that defines the permission.

Enter the permission string as a semicolon-separated concatenation of `permissionClass=qualifiedClassName;target=artifactName;action=actionName`. For example, to protect an account number that a text field displays in a page, you would enter an expression similar to the one shown in [Example 35–28](#), where the permission for `userGrantedPermission` is the same name as the custom JAAS permission grant.

**Example 35–28 Custom JAAS Permission Expression**

```
{securityContext.userGrantedPermission
 ['permissionClass=oracle.fodemo.storefront.store.view.AccountPermission;
 target=AccountPermission;action=view']}
```

In [Example 35–28](#), the expression evaluates the permission based on the custom JAAS permission definition named `AccountPermission` that you added to the application policy store.

5. Click OK.

**35.11.3 Getting Information from the ADF Security Context**

The implementation of security in a Fusion web application is by definition an implementation of the security infrastructure of the ADF Security framework. As such, the security context of the framework allows access to information that is required as you define the policies and the overall security for your application.

**35.11.3.1 How to Determine Whether Security Is Enabled**

Because the enforcement of ADF Security can be turned on and off at the container level independent of the application, you should determine whether ADF Security is enabled prior to making authorization checks. You can achieve this by calling the `isAuthorizationEnabled()` method of the ADF security context, as shown in [Example 35–29](#).

**Example 35–29 Using the isAuthorizationEnabled() Method of the ADF Security Context**

```
if (ADFContext.getCurrent().getSecurityContext().isAuthorizationEnabled()){
 //Authorization checks are performed here.
}
```

**35.11.3.2 How to Determine Whether the User Is Authenticated**

As the user principal in a Fusion web application is never `null` (that is, it is either anonymous for unauthenticated users or the actual user name for authenticated users), it is not possible to simply check whether the user principal is `null` to determine if the user has logged on or not. As such, you must use a method to take into account that a user principal of `anonymous` indicates that the user has not

authenticated. You can achieve this by calling the `isAuthenticated()` method of the ADF security context, as shown in [Example 35–30](#).

**Example 35–30 Using the `isAuthenticated()` Method of the ADF Security Context**

```
// ===== User's Authenticated Status =====
private boolean _authenticated;
public boolean isAuthenticated() {
 _authenticated = ADFContext.getCurrent().getSecurityContext().isAuthenticated();
 return _authenticated;
}
```

### 35.11.3.3 How to Determine the Current User Name, Enterprise Name, or Enterprise ID

Fusion web applications support the concept of public pages that, while secured, are available to all users. Furthermore, components on the web pages, such as portlets, require knowledge of the current user identity. As such, the user name in a Fusion web application will never be `null`. If an unauthenticated user accesses the page, the user name `anonymous` will be passed to page components. When the Fusion web application registers an enterprise name for the user, the enterprise name may also be obtained. The enterprise name is an alias that the user knows for themselves and can use to login.

You can determine the current user's name by evaluating the `getUserName()` method of the ADF security context, as shown in [Example 35–31](#). This method returns the string `anonymous` for all unauthenticated users and the actual authenticated user's name for authenticated users.

**Example 35–31 Using the `getUserName()` Method of the ADF Security Context**

```
// ===== Current User's Name/PrincipalName =====
public String getCurrentUser() {
 _currentUser = ADFContext.getCurrent().getSecurityContext().getUserName();
 return _currentUser;
}
```

Because the traditional method for determining a user name in a Faces-based application

(`FacesContext.getCurrentInstance().getExternalContext().getRemoteUser()`) returns `null` for unauthenticated users, you need to use additional logic to handle the public user case if you use that method.

You can determine the current user's enterprise name by evaluating the `getEnterpriseName()` method of the ADF context, as shown in [Example 35–32](#).

**Example 35–32 Using the `getEnterpriseName()` Method of the ADF Context**

```
// ===== Current User's Enterprise Name =====
public String getEnterpriseName() {
 _enterpriseName = ADFContext.getCurrent().getEnterpriseName();
 return _enterpriseName;
}
```

You can determine the current user's enterprise ID by evaluating the `getEnterpriseId()` method of the ADF context, as shown in [Example 35–33](#). This method returns the string `anonymous` for all unauthenticated users and the actual authenticated user's name for authenticated users.

**Example 35–33 Using the `getEnterpriseId()` Method of the ADF Context**

```
// ===== Current User's Enterprise ID =====
public String getEnterpriseId() {
 _enterpriseId = ADFContext.getCurrent().getEnterpriseId();
 return _enterpriseId;
}
```

**35.11.3.4 How to Determine Membership of a Java EE Security Role**

As Fusion web applications are JavaServer Faces-based applications, you can use the `isUserInRole(roleName)` method of the Faces external context, as shown in [Example 35–34](#), to determine whether a user is in a specified role. Because ADF Security is based around JAAS policies, you should not need to use Java EE security roles to secure pages associated with ADF security-aware resources based on role membership. However, you might use the method to check the role for a page that is not associated with an ADF security-aware resource.

In this example, a convenience method (`checkIsUserInRole`) is defined. The use of this method within a managed bean enables you to expose membership of a named role as an attribute, which can then be used in EL.

**Example 35–34 Using the `isUserInRole(roleName)` Method of the Faces Context**

```
public boolean checkIsUserInRole(String roleName){
 return
(FacesContext.getCurrentInstance().getExternalContext().isUserInRole(roleName));
}

public boolean isCustomer() {
 return (checkIsUserInRole("fod-users"));
}
```

**35.11.3.5 How to Determine Permission Using Java**

To evaluate the security policies from within Java, you can use the `hasPermission` method of the ADF security context. This method takes a permission object (defined by the resource and action combination) and returns `true` if the user has the corresponding permission.

In [Example 35–35](#), a convenience function is defined to enable you to pass in the name of the page and the desired action, returning `true` or `false` based on the user's permissions. Because this convenience function is checking page permissions, the `RegionPermission` class is used to define the permission object that is passed to the `hasPermission` method.

**Example 35–35 Using the `hasPermission()` Method to Evaluate Access Policies**

```
private boolean TestPermission (String PageName, String Action) {
 Permission p = new RegionPermission("view.pageDefs." + PageName + "PageDef",
 Action);

 if (p != null) {
 return ADFContext.getCurrent().getSecurityContext().hasPermission(p);
 }
 else {
 return (true);
 }
}
```

As it is possible to determine the user's permission for a target page from within a backing bean, you can use this convenience method to dynamically alter the result of a Faces navigation action. In [Example 35–36](#), you can see that a single command button

can point to different target pages depending on the user's permission. By checking the view permission from the most secured page (the manager page) to the least secured page (the public welcome page), the command button's backing bean will apply the appropriate action to direct the user to the page that corresponds to their permission level. The backing bean that returns the appropriate action is using the convenience method defined in [Example 35-35](#).

**Example 35-36 Altering a Page Navigation Result Based on an Authorization Check**

```
//CommandButton Definition
<af:commandButton text="Goto Your Group Home page"
 binding="#{backing_content.commandButton1}"
 id="commandButton1"

 action="#{backing_content.getSecureNavigationAction}"/>

//Backing Bean Code
public String getSecureNavigationAction() {
 String ActionName;
 if (TestPermission("ManagerPage", "view"))
 ActionName = "goToManagerPage";
 else if (TestPermission("EmployeePage", "view"))
 ActionName = "goToEmployeePage";
 else
 ActionName = "goToWelcomePage";
 return (ActionName);
}
```

## 35.11.4 Best Practices for Working with ADF Security

These best practices summarize the rules that govern enforcement of security by the ADF Security framework. Understanding these best practices will help you to secure the application to allow users to access the web pages you intend.

**Do build your application with ADF Security enabled from the start.**

When you enable security, you essentially lock down the application and you will be required to make explicit permission grants to specific ADF security-aware resources you create. Knowing about these resources and making grants on them as you build the application will enable you to iteratively test security to ensure that you structure your application in a way that achieves the desired result.

**Do define permission grants for bounded task flows.**

Pages that the user accesses within the process of executing a bounded task flow will not be individually permission-checked and will run under the permission grants of the task flow. This means that any page that you add to the task flow should not have its own page definition-level security defined. Upon requesting a flow, the user will be allowed either to view all the pages of the task flow or to view none of the pages, depending on their level of access.

**Do not define permission grants for individual pages of a bounded task flow.**

It is important to realize that task flows do not prevent users from accessing pages directly. Any web page that is located in a directory that is publicly accessible can be reached from a browser using a URL. To ensure that pages referenced by a bounded task flow cannot be accessed directly, remove all permission grants that exist for their associated page definition file. When pages require additional security within the

context of a bounded task flow, wrap those pages in a sub-task flow with additional grants defined on the nested task flow.

**Do use task flows to reduce the number of access points exposed to end users.**

When you use task flows you can reduce the number of access points that you expose to end users. For example, configure an unbounded task flow to display one page that provides navigation to the remaining pages in your application. Use bounded task flows for the remaining pages in the application. By setting the URL Invoke property of these bounded task flows to `url-invoke-disallowed`, your application has one access point (the page on the unbounded task flow). For more information about the URL Invoke property, see [Section 19.6.4, "How to Call a Bounded Task Flow Using a URL."](#)

**Do define permission grants for individual pages outside of a bounded task flow.**

Page-level security is checked for pages that have an associated page definition binding file *only* if the page is directly accessed or if the page is accessed in an *unbounded* task flow. There is a one-to-one relationship between the page definition file and the web page it secures.

If you want to secure a page that uses no ADF bindings, you can create an empty page definition binding file for the page.

**Do define custom permissions to render UI component based on the user's access rights.**

Custom ADF permission classes let you extend ADF Security to define custom actions for use in grants. This gives you the flexibility to define security policies to manage the user's ability to view UI components without having to overload the built-in actions defined by the ADF resources' permission classes.

**Do define entity object attribute permissions to manage the user's access rights to row-level data displayed by UI components.**

Entity objects and entity object attributes both define permission classes that let you define permissions for the read, update, and delete operations that the entity object initiates on its data source. In the case of these data model project components, you must explicitly grant permissions to an application role in order to opt into ADF Security authorization. However, once you enable authorization for an entity object, all rows of data defined by the entity object will be protected by the grant. At this level of granularity, your table component would render in the web page either with all data visible or with no data visible—depending on the user's access rights. As an alternative to securing the entire collection, you can secure individual columns of data. This level of granularity is supported by permissions you set on the individual attributes of entity objects. When entity objects are secured, users may see only portions of the data that the table component displays.

**Do use task flow or page-level permission grants to avoid exposing row-level create/insert operations to users with view-only permission.**

The correct way to control access to a page that should allow only certain users to update new rows in a table is to use task flow or page-level permission grants. However, as an alternative, it is possible to secure table buttons corresponding to particular operations by specifying an EL expression to test the user's access rights to view the button. When the custom permission is defined and the `userGrantedPermission` expression is set on the `Rendered` property of the button, only users with sufficient privileges will see the button. This may be useful in a

case where the user interface displays a page that is not restricted and view-only permission for row-level data is defined for the entity object. In this case, when viewed by the user, the Delete button for the editable table associated with the entity object will appear disabled. However, in the case of an input table, the user interface does not disable the button for the `CreateInsert` operation even though the user may not have update permission.

**Do not use JDeveloper as a user identity provisioning tool.**

JDeveloper must not be used as an identity store provisioning tool, and you must be careful not to deploy the application with user identities that you create for testing purposes. Deploying user identities with the application introduces the risk that malicious users may gain unintended access. Instead, always rely on the system administrator to configure user identities through the tools provided by the domain-level identity management system. You should delete all users and groups that you create in the `jazn-data.xml` file before deploying the application.

**Do not allow users to access a web page by its file name.**

When you deploy the Fusion web application, you should always permit users to access the web page from a view activity defined in the ADF Controller configuration file. Do not allow users to access the JSPX file directly by its physical name (for example, similar to the file name `AllDepartments.jspx`).

Assuming the view activity is named `AllDepartments`, then there are two ways to call the page:

1. `localhost:7101/myapp/faces/AllDepartments`
2. `localhost:7101/myapp/faces/AllDepartments.jspx`

The difference is that the call 1) is in the context of the ADF Controller task flow, which means that navigation on the page will work and any managed beans that are referenced by the page will be properly instantiated. The call in 2) also serves the page, however, the page may not function fully. This may be considered a security breach.

To prevent direct JSPX file access, move the JSPX file under the `/public_html/WEB-INF` directory so that direct file access is no longer possible. To access a document, users will have to call its view activity name.

Note that this suggestion does not protect documents that are unprotected in ADF Security. It only helps to lock down access to the physical file itself.

Thus, the following security guidelines still apply:

1. Apply ADF Security permissions to all JSPX documents associated with view activities defined in the `adfc-config.xml` file.
2. Move all JSPX documents in the user interface project under the `/public_html/WEB-INF` directory to prevent direct file access.
3. Limit the pages in the `adfc-config.xml` to the absolute minimum and place all other pages into bounded task flows.
4. Make bounded task flows inaccessible from direct URL access (which is the default configuration setting for new task flows).
5. Apply ADF Security permissions to bounded task flows.

---

## Testing and Debugging ADF Components

This chapter describes the process of debugging your user interface project. It describes several JDeveloper tools that can be used to help debug an application. It contains debugging procedures with breakpoints using the ADF Declarative Debugger. Finally, it explains how to write and run regression tests for your ADF Business Components-based business services.

This chapter includes the following sections:

- [Section 36.1, "About ADF Debugging"](#)
- [Section 36.2, "Correcting Simple Oracle ADF Compilation Errors"](#)
- [Section 36.3, "Correcting Simple Oracle ADF Runtime Errors"](#)
- [Section 36.4, "Reloading Oracle ADF Metadata in Integrated WebLogic Server"](#)
- [Section 36.5, "Validating ADF Controller Metadata"](#)
- [Section 36.6, "Using the ADF Logger"](#)
- [Section 36.7, "Using the Oracle ADF Model Tester for Testing and Debugging"](#)
- [Section 36.8, "Using the ADF Declarative Debugger"](#)
- [Section 36.9, "Setting ADF Declarative Breakpoints"](#)
- [Section 36.10, "Setting Java Code Breakpoints"](#)
- [Section 36.11, "Regression Testing with JUnit"](#)

### 36.1 About ADF Debugging

Like any debugging task, debugging the web application's interaction with Oracle Application Development Framework (Oracle ADF) is a process of isolating specific contributing factors. However, in the case of web applications, generally this process does not involve compiling Java source code. Your web pages contain no Java source code, as such, to compile. In fact, you may not realize that a problem exists until you run and attempt to use the application. For example, these failures are only visible at runtime:

- A page not found servlet error
- The page is found, but the components display without data
- The page fails to display data after executing a method call or built-in operation (like Next or Previous)
- The page displays, but a method call or built-in operation fails to execute at all
- The page displays, but unexpected validation errors occur

The failure to display data or to execute a method call arises from the interaction between the web page's components and the ADF Model layer. When a runtime failure is observed during ADF lifecycle processing, the sequence of preparing the model, updating the values, invoking the actions, and, finally, rendering the data failed to complete.

Fortunately, most failures in the web application's interaction with Oracle ADF result from simple and easy-to-fix errors in the declarative information that the application defines or in the EL expressions that access the runtime objects of the page's ADF binding container.

In your databound Fusion web application, you should examine the declarative information and EL expressions as likely contributing factors when runtime failures are observed. To understand editing the declarative files, see [Section 36.2, "Correcting Simple Oracle ADF Compilation Errors,"](#) and [Section 36.3, "Correcting Simple Oracle ADF Runtime Errors."](#)

One of the most useful diagnostic tools is the ADF Logger. You use this logging mechanism in JDeveloper to capture runtime traces messages. With ADF logging enabled, JDeveloper displays the application trace in the Message Log window. The trace includes runtime messages that may help you to quickly identify the origin of an application error. Read [Section 36.6, "Using the ADF Logger,"](#) to configure the ADF Logger to display detailed trace messages.

Supported Oracle ADF customers can request Oracle ADF source code from Oracle Worldwide Support. This can make debugging ADF Business Components framework code a lot easier. Read [Section 36.8.1, "Using ADF Source Code with the Debugger,"](#) to understand how to configure JDeveloper to use the Oracle ADF source code.

If the error cannot be easily identified, you can utilize the ADF Declarative Debugger in JDeveloper to set breakpoints. When a breakpoint is reached, the execution of the application is paused and you can examine the data that the ADF binding container has to work with, and compare it to what you expect the data to be. Depending on the types of breakpoints, you may be able to use the step functions to move from one breakpoint to another. For more information about the debugger, read [Section 36.8, "Using the ADF Declarative Debugger."](#)

JDeveloper provides integration with JUnit for your Fusion web application through a wizard that generates regression test cases. Read [Section 36.11, "Regression Testing with JUnit,"](#) to understand how to write test suites for your application.

## 36.2 Correcting Simple Oracle ADF Compilation Errors

When you create web pages and work with the ADF data controls to create the ADF binding definitions in JDeveloper, the Oracle ADF declarative files you edit must conform to the XML schema defined by Oracle ADF. When an XML syntax error occurs, the JDeveloper XML compiler immediately displays the error in the Structure window.

Although there is some syntax checking during design time, the JDeveloper compiler is currently limited by an inability to resolve EL expressions. EL expressions in your web pages interact directly with various runtime objects in the web environment, including the web page's ADF binding container. At present, errors in EL expressions can be observed only at runtime. Thus, the presence of a single typing error in an object-access expression will not be detected by the compiler, but will manifest at runtime as a failure to interact with the binding container and a failure to display data in the page. For information about debugging runtime errors, see [Section 36.3, "Correcting Simple Oracle ADF Runtime Errors."](#)

**Tip:** The Expression Builder is a dialog that helps you build EL expressions by providing lists of objects, managed beans, and properties. It is particularly useful when creating or editing ADF databound EL expressions because it provides a hierarchical list of ADF binding objects and their valid properties from which you can select. You should use the Expression Builder to avoid introducing typing errors. For details, see [Section 13.8, "Creating ADF Data Binding EL Expressions."](#)

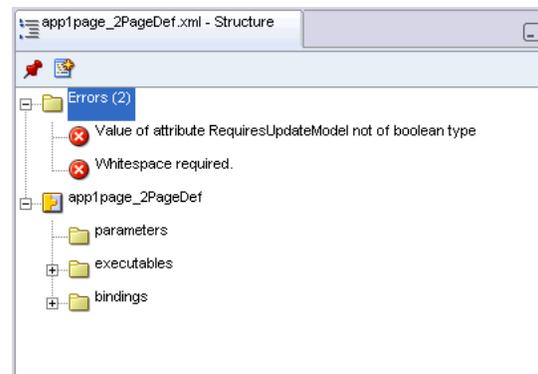

[Example 36–1](#) illustrates two simple compilation errors contained in a page definition file: `tru` instead of `true` and `id="CountryCodesView1Iterator" /` instead of `id="CountryCodesView1Iterator" />` (that is, the ID is missing a closing angle bracket).

#### **Example 36–1 Sample Page Definition File with Two Errors**

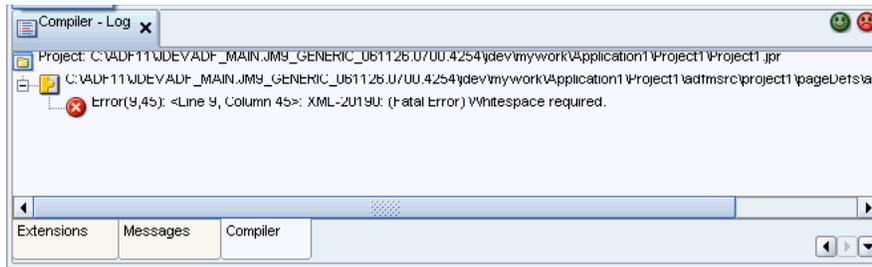

```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
 version="11.1.1.42.54" id="app1page_2PageDef"
 Package="project1.pageDefs">
 <parameters/>
 <executables>
 <iterator Binds="CountryCodesView1" RangeSize="10"
 DataControl="AppModuleDataControl"
 id="CountryCodesView1Iterator" /
 </executables>
 <bindings>
 <action id="Find" RequiresUpdateModel="tru" Action="3"
 IterBinding="CountryCodesView1Iterator" />
 </bindings>
</pageDefinition>
```

During compilation, the Structure window displays the XML errors in the page, as shown in [Figure 36–1](#).

**Figure 36–1 The Structure Window Displays XML Errors**

The Compiler-Log window also displays the compilation errors in the page, as shown in [Figure 36–2](#).

**Figure 36–2 The Compiler Window Displays XML Compile Errors****To view and correct schema validation errors:**

1. From the main menu, choose **View > Structure** to open the Structure window or **View > Log** to open the Log Window.
2. In either window, double-click the error message to open the file in the XML editor.
3. In the XML editor, locate the highlighted lines.  
The highlighted lines will be lines with errors.
4. Correct any errors.  
After an error has been corrected, the corresponding error message will be automatically removed from the Structure window.
5. Optionally, you can recompile the project by choosing **Run > Make** and checking to see whether the compiler still produces the error message.

### 36.3 Correcting Simple Oracle ADF Runtime Errors

Failures of the ADF Model layer cannot be detected by the JDeveloper compiler, in part because the page's data-display and method-execution behavior relies on the declarative ADF page definition files. The ADF Model layer utilizes those declarative files at runtime to create the objects of the ADF binding container.

To go beyond simple schema validation, you will want to routinely run and test your web pages to ensure that none of the following conditions exists:

- The project dependency between the data model project and the user interface project is disabled.

By default, the dependency between projects is enabled whenever you create a web page that accesses a data control in the data model project. However, if the dependency is disabled and remains disabled when you attempt to run the application, an internal servlet error will be generated at runtime:

```
oracle.jbo.NoDefException: JBO-25002: Definition
model.DataControls.dcx of type null not found
```

To correct the error, double-click the user interface project, and select the **Dependencies** node in the dialog. Make sure that the *ModelProjectName.jpr* option appears selected in the panel.

- Page definition files have been renamed, but the `DataBindings.cpx` file still references the original page definition file names.

While JDeveloper does not permit these files to be renamed within the IDE, if a page definition file is renamed outside of JDeveloper and the references in the

DataBindings.cpx file are not also updated, an internal servlet error will be generated at runtime:

```
oracle.jbo.NoDefException: JBO-25002: Definition
oracle.<path>.pageDefs.<pagedefinitionName> of type Form
Binding Definition not found
```

To correct the error, open the DataBindings.cpx file and use the source editor to edit the page definition file names that appear in the <pageMap> and <pageDefinitionUsages> elements.

- The web page file (.jsp or .jspx) has been renamed, but the DataBindings.cpx file still references the original file name of the same web page.

The page controller uses the page's URL to determine the correct page definition to use to create the ADF binding container for the web page. If the page's name from the URL does not match the <pageMap> element of the DataBindings.cpx file, an internal servlet error will be generated at runtime:

```
javax.faces.el.PropertyNotFoundException: Error testing
property <propertyname>
```

To correct the error, open the DataBindings.cpx file and use the source editor to edit the web page file names that appear in the <pageMap> element.

- Bindings have been renamed in the web page EL expressions, but the page definition file still references the original binding object names.

The web page may fail to display information that you expect to see. To correct the error, compare the binding names in the page definition file and the EL expression responsible for displaying the missing part of the page. Most likely the mismatch will occur on a value binding, with the consequence that the component will appear but without data. Should the mismatch occur on an iterator binding name, the error may be more subtle and may require deep debugging to isolate the source of the mismatch.

- Bindings in the page definition file have been renamed or deleted, and the EL expressions still reference the original binding object names.

Because the default error-handling mechanism will catch some runtime errors from the ADF binding container, this type of error can be very easy to find. For example, if an iterator binding named `findUsersByNameIter` was renamed in the page definition file, yet the page still refers to the original name, this error will display in the web page:

```
JBO-25005: Object name <iterator> for type Iterator Binding
Definition is invalid
```

To correct the error, right-click the name in the web page and choose **Go to Page Definition** to locate the correct binding name to use in the EL expression.

- EL expressions were written manually instead of using the expression picker dialog and invalid object names or property names were introduced.

This error may not be easy to find. Depending on which EL expression contains the error, you may or may not see a servlet error message. For example, if the error occurs in a binding property with no runtime consequence, such as displaying a label name, the page will function normally but the label will not be displayed. However, if the error occurs in a binding that executes a method, an internal servlet error `javax.faces.el.MethodNotFoundException: methodname` will display. Or, in the case of an incorrectly typed property name on the method

expression, the servlet error

```
javax.faces.el.PropertyNotFoundException: propertyname will display.
```

If this list of typical errors does not help you to find and fix a runtime error, you can initiate debugging within JDeveloper to find the contributing factor. For an ADF application, start setting ADF declarative breakpoints to find the problem. Using the ADF Declarative Debugger to set ADF declarative breakpoints is described in [Section 36.8, "Using the ADF Declarative Debugger,"](#) and [Section 36.9, "Setting ADF Declarative Breakpoints."](#) This process involves pausing the execution of the application as it proceeds through the application and examining data. You can also use the ADF Declarative Debugger to set Java code breakpoints, as described in [Section 36.10, "Setting Java Code Breakpoints."](#)

## 36.4 Reloading Oracle ADF Metadata in Integrated WebLogic Server

JDeveloper support for hot reloading of Oracle ADF metadata is an alternative to quitting the running application, editing your project's XML definition files, redeploying, and rerunning the application in Integrated WebLogic Server to view the latest changes.

Changes that you make to the Fusion web application projects will not be picked up automatically by an application that you have deployed to Integrated WebLogic Server. You can, however, reload metadata from the data model project and user interface project any time you want to synchronize the running application with changes you have made to your application's XML definition files.

To reload metadata so your changes are reflected in the deployed Fusion web application, you must recompile the project and refresh the web browser.

Metadata that JDeveloper will hot reload in Integrated WebLogic Server, include:

- In the data model project, changes to the definition files of business components.
- In the user interface project, changes to the binding definitions in the page definition files and changes to task flows in the task flow definition files.

This support makes it possible to make incremental changes and test them.

## 36.5 Validating ADF Controller Metadata

Basic validation is performed when ADF Controller retrieves metadata. The most serious errors, for example, a task flow that is missing a default activity, result in parsing exceptions.

The `enable-grammar-validation` setting in `adf-config.xml` allows you to validate the grammar in ADF Controller metadata before deploying an application. When `enable-grammar-validation` is set to `true`, ADF Controller metadata is validated against ADF Controller XSDs. For example, invalid characters in ADF Controller metadata, such as a slash (/) in a view activity ID, are flagged as exceptions.

By default, `enable-grammar-validation` is set to `false`. For performance reasons, it should be set to `true` only during application development or when troubleshooting an application.

## 36.6 Using the ADF Logger

If you are not able to easily find the error in either your web page or its corresponding page definition file, you can use the JDeveloper debugging tools to investigate where your application failure occurs.

You configure the logging session by editing the `logging.xml` configuration file using the editor for Oracle Diagnostic Logging Configuration. Logging configuration can be set at any time, even while the application is running in JDeveloper.

Unlike many files in JDeveloper, you cannot directly open the `logging.xml` file. Instead you use menu commands at these locations to open the Oracle Diagnostic Logging Configuration editor:

- Right-click an active server instance in the Application Server Navigator window.
- Click the Actions dropdown menu displayed in the Log window's debugger process panel, after you have started the application in debug mode.

You use the Oracle Diagnostic Logging Configuration editor to set the desired logging level to control the level and number of messages that are displayed. You can set the logging level for both persistent and transient loggers and declare handlers for each logger.

JDeveloper creates diagnostic log files in the Oracle Diagnostic Logging (ODL) format, used by Oracle Fusion Middleware components. Log file naming and the format of the contents of log files conform to an Oracle standard. By default, the diagnostic messages are in text format. For more information about the ODL format, see the *Oracle Application Server Administrator's Guide*.

In the editor, as an alternative to the default ODL format, you can configure the Java Logger to display Java diagnostic messages.

After you have created a log, you can view and filter the log messages with Oracle Diagnostic Log Analyzer. This tool allows you to set filters for different log levels, define message time frames, and search on message text.

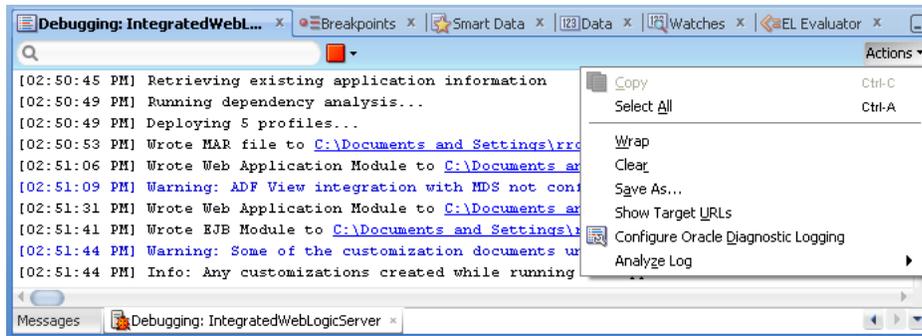

You can then use the ADF Declarative Debugger to set breakpoints and examine the the application. For more information, see [Section 36.9, "Setting ADF Declarative Breakpoints,"](#) and [Section 36.10, "Setting Java Code Breakpoints."](#)

### 36.6.1 How to Set ADF Logging Levels

You can use the Oracle Diagnostic Logging Configuration editor to configure the logging levels specified in the `logging.xml` configuration file. The file can be configured before and while the application is running in Integrated WebLogic Server. The changes will apply without the need to restart the server.

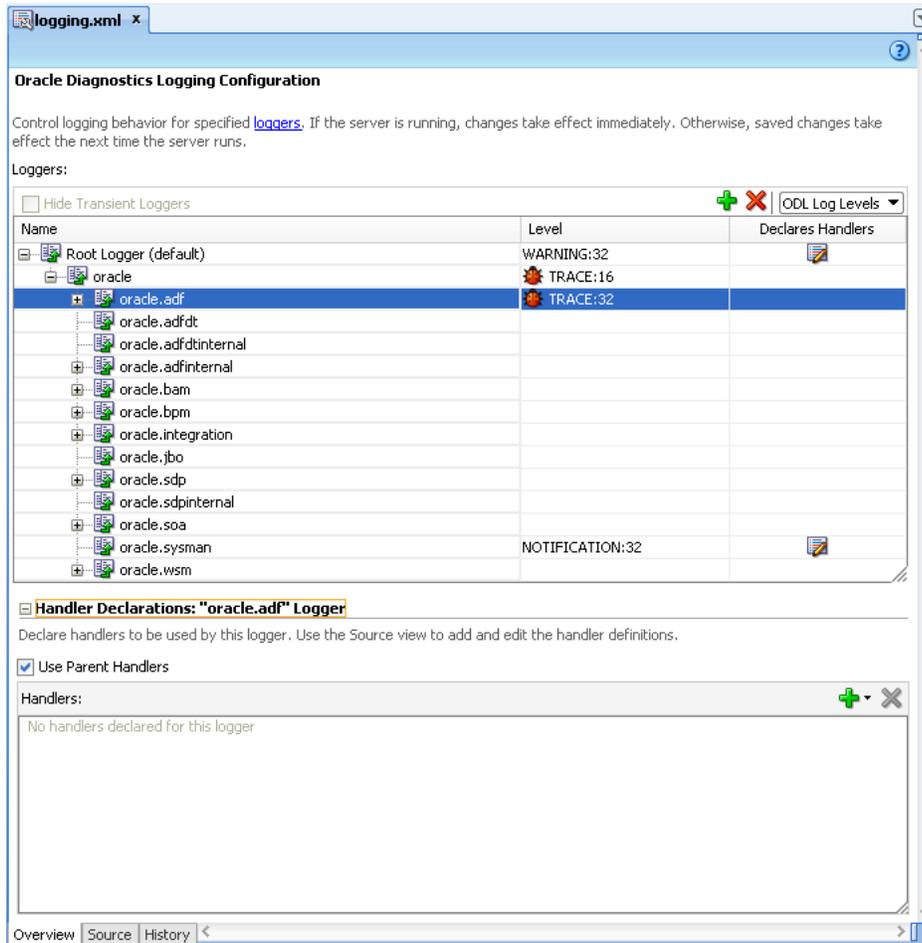

When Integrated WebLogic Server is running, you can define both persistent and transient loggers. When Integrated WebLogic Server is not running, you can only define persistent loggers. The transient loggers will last only for the session and will not be entered in the `logging.xml` configuration file. If the server is not running, you must explicitly save the configuration changes to the `logging.xml` file for the updates to take effect in the next server run.

You can access the Oracle Diagnostic Logging Configuration editor from the Application Server Navigator or from the Log window, which is shown in [Figure 36-3](#).

**Figure 36–3 Log Window with Toolbar**

However, while the server is running, when you access the editor via the Log window menu, then the editor has the ability to add transient loggers.

Figure 36–4 shows the Oracle Diagnostic Logging Configuration while the server is running.

**Figure 36–4 Editor for Oracle Diagnostic Logging Configuration**

You can only use JDeveloper menu commands to open the `logging.xml` configuration file and launch the editor for Oracle Diagnostic Logging Configuration. However, you may find the following information about the location of the configuration file useful.

---

---

**Note:** You can declare and add log handler definitions by clicking the **Source** tab and entering them in the XML editor.

---

---

If you are using Integrated WebLogic Server in JDeveloper on the Windows platform, you can find the `logging.xml` configuration file in a location similar to:

```
C:\Documents and
Settings\username\ApplicationData\JDeveloper\latest_system_
folder\DefaultDomain\config\fmwconfig\servers\DefaultServer
```

The log files for Integrated WebLogic Server are in a location similar to:

```
C:\Documents and
Settings\username\ApplicationData\JDeveloper\latest_system_
folder\DefaultDomain\servers\DefaultServer\logs
```

The log files for a standalone WebLogic Server instance are in a location similar to:

```
$domain_home/servers/your_servername/logs
```

You can configure logging levels before a test run from the Application Server Navigator or during a debug session from the Log window toolbar.

#### To configure the log levels:

1. In the Application Server Navigator, right-click **IntegratedWebLogicServer** and choose **Configure Oracle Diagnostic Logging for server name**.

Or, from the Log window's debug process panel, choose **Actions - Configure Oracle Diagnostic Logging**. The debug process panel is only visible in the Log window after you have started the application in debug mode.

2. In the editor for Oracle Diagnostics Logging Configuration, select **ODL Log Levels** or **Java Log Levels** for the logger type you want to view.
3. If you want to see persistent loggers only, select **Hide Transient Loggers**.
4. To add a logger:
  - a. If the server is running, click the **Add** icon dropdown menu and choose **Add Persistent Logger** or **Add Transient Logger**. If the server is not running, click **Add** to add a persistent logger. You cannot add a transient logger.
  - b. In the Add Logger dialog, enter a logger name.
  - c. Select the logging level.
  - d. Click **OK**.
5. For any logger, including a newly created logger, you can specify its handlers by selecting from a list of available handlers by clicking the **Add** icon in the **Handler Declarations** section.

Or, you can select **Use Parent Handlers** to assign its parent's handler to the logger. By default, a logger uses its parent's handler.

---

---

**Note:** You can declare and add log handler definitions by clicking the **Source** tab and entering them in the XML editor.

---

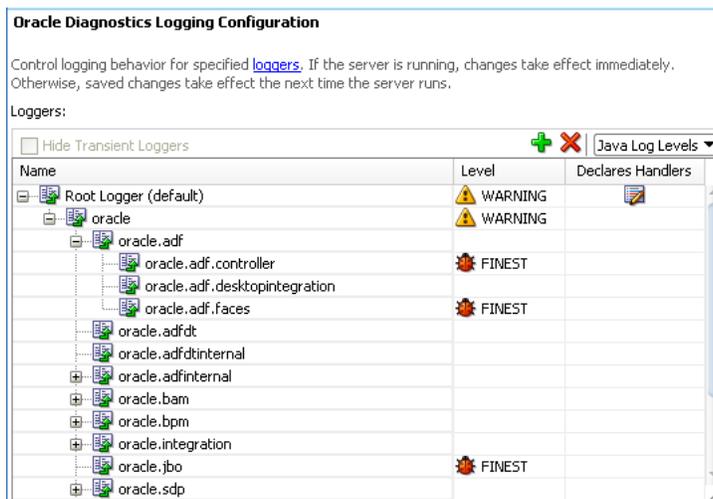

---

## 36.6.2 How to Turn On Diagnostic Logging

Even before you use the actual debugger, running the application with loggers set to Java log level FINE, FINER, or FINEST will enable framework diagnostics logging. The debug diagnostic messages can be helpful to see what happens when the problem occurs. To enable debug diagnostic messages, use the Oracle Diagnostics Logging Configuration Editor to configure the desired loggers with a Java log level set to FINEST.

If you have configured diagnostic logging for the supported loggers, JDeveloper will direct debug diagnostics messages to the JDeveloper Log window. [Figure 36–5](#) shows specific loggers configured to enable the most detailed Oracle ADF debug diagnostics.

**Figure 36–5** Configuring a Logger for Oracle ADF Debugging

For backward compatibility, the Java system property `jbo.debugoutput` set to the value `console` or `ADFLogger` (to route diagnostics through the standard Logger implementation, which can be controlled in a standard way through the `logging.xml` file) is supported. The easiest way to set this system property while running your application inside JDeveloper is to edit your project properties and in the Run/Debug page, select a run configuration and click **Edit**. Then add the string `-Djbo.debugoutput=console` to the **Java Options** field.

## 36.6.3 How to Create an Oracle ADF Debugging Configuration

Oracle ADF leverages the Java Logging API (`java.util.logging.Logger`) to provide logging functionality when you run a debugging session. Java Logging is a standard API that is available in the Java platform at <http://download.oracle.com/javase/1.4.2/docs/guide/util/logging/overview.html>.

**To create an ADF Model debugging configuration:**

1. In the editor for Oracle Diagnostics Logging Configuration, select **ODL Log Levels** or **Java Log Levels** for the logger type you want to view.
2. Expand the **oracle.adf** logger node and select the Java log level **FINEST** for the desired Oracle ADF loggers.
3. Optionally, to enable ADF Business Components diagnostics, for the **oracle.jbo** logger, select the Java log level **FINEST**.

**To create an ADF view Javascript logging configuration:**

1. In the Application Navigator, double-click the application or project **web.xml** file.
2. In the source editor, add the following elements to the file:

```
<context-param>
 <param-name>
 oracle.adf.view.rich.LOGGER_LEVEL
 </param-name>
 <param-value>
 FINE
 </param-value>
</context-param>
```

**To create a core JSF Reference Implementation logging configuration:**

1. Double-click the *logging.properties* file.
2. In the source editor, set the following line to FINE:

```
<java.util.logging.ConsoleHandler.level=FINE>
```

3. Add the following line:

```
com.sun.faces.level=FINE
```

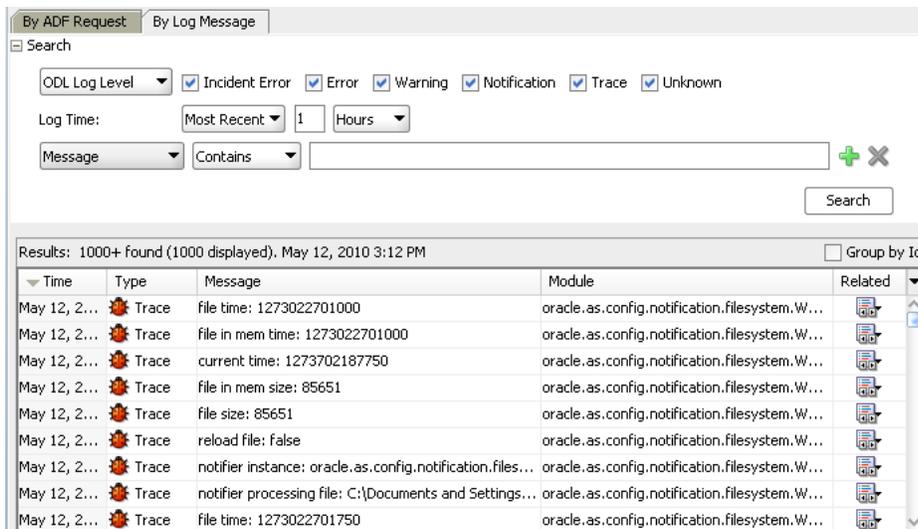

The log now includes JSF Reference Implementation messages such as:

```
FINEST: End execute(phaseId=RESTORE_VIEW 1)
com.sun.faces.lifecycle.LifecycleImpl
hasPostDataOrQueryParams
FINEST: Request Method: POST/PUT
com.sun.faces.lifecycle.LifecycleImpl execute
```

### 36.6.4 How to Use the Log Analyzer to View Log Messages

You can use Oracle Diagnostic Log Analyzer to view the log entries of a log file. The log analyzer allows you to filter the entries by log level, entry type, log time, and entry content (using a query panel). You can also order the messages and show and hide columns for better viewing.

[Figure 36–6](#) shows Oracle Diagnostic Log Analyzer set to view ODL Log levels.

**Figure 36–6 Oracle Diagnostic Log Analyzer Displays ODL Log Messages**

You can also use the log analyzer on log files created in other test runs. For instance, you can analyze the log sent to you by another developer for another application.

### 36.6.4.1 Viewing Diagnostic Messages in the Log Analyzer

You can configure logging levels before a test run from the Application Server Navigator or during a debug session from the Log window toolbar. The level you specify will determine the type and quantity of log messages.

In the case of ADF events, all messages are generated for the ODL log at the level `Notification` or for the Java log at the level `Info`. Fewer ADF messages will be generated at the `Incident Error/Severe` and `Error/Warning` levels.

After you select the log level for the messages you wish to view, you can use the Search panel of the `By Log Message` page to filter the messages to display from the log file.

---

**Note:** For further details about search criteria that you can specify to search on ADF-specific messages, see [Section 36.6.4.3, "Sorting Diagnostic Messages By ADF Events."](#)

---

You can start the log analyzer before a test run from the **Tools** menu or during a debug session from the log window toolbar.

#### Before you begin:

It may be helpful to have an understanding of logging. For more information, see [Section 36.6, "Using the ADF Logger."](#)

You will need to complete these tasks:

1. Enable logging, as described in [Section 36.6.2, "How to Turn On Diagnostic Logging."](#)
2. Set logging levels, as described in [Section 36.6.1, "How to Set ADF Logging Levels."](#)
3. Create a log file, either from your test run or from another source.

**To start the log analyzer:**

1. From the main menu, choose **Tools > Oracle Diagnostic Log Analyzer**.

Or, from the Log window **Action** menu, choose **Analyze Log** and then either **Current in Console** or **Open Selected** (to browse log files in the server log directory).

2. In the editor for Oracle Diagnostic Log Analyzer, click the **By Log Message** tab.
3. In the By Log Message page, navigate to the log file or enter the path and name of the log file.

**Tip:** The Choose Log File dialog helps you to navigate to the directory that contains the log files generated by JDeveloper. Click the **Browse Log Files** icon next to the **Log** text field, and then click the **Server Logs** icon from the scroll list.

4. From the dropdown list, select either **ODL Log Level** or **Java Log Level**.
5. Select the corresponding checkbox for each type of log entry you want to view. You must select at least one type.

The available ODL log level types are:

- Incident Error
- Error
- Warning
- Notification - corresponds to ADF event messages
- Trace
- Unknown.

The available Java log level types are:

- Severe
- Warning
- Info - corresponds to ADF event messages
- Config
- Fine
- Finer
- Finest
- Unknown

6. Specify a time period for the entries you want to view. You can select the most recent *period* or a range.
7. To filter the results, use the Search panel to query the log for a text pattern. For additional Search panels, click **Add**. The supported search criteria include:
  - **Detail:** Filters text in statements from the stack where the method was invoked.
  - **Message:** Filters text in the logged messages.
  - **ADF Context Data:** Filters the log for data related to ADF lifecycle phase names, view object names, view object query statements, data control names,

binding container names, and iterator binding names logged during the execution of ADF events.

- **Source Method:** Filters the log by the method where the message is logged. For example, you can filter on the method `execute` to view all messages logged for view object query execution or ADF lifecycle phase execution.
  - **Application:** Filters the log by the application name where the message is logged. This is useful when the application is running in a composite application and you want to view messages for a specific application.
  - **Source Class:** Filters the log by the fully qualified class name of the method where the message is logged. To see more messages, enter a partial package name. For example, you can enter the partial package name `oracle.adf` or the full package name `oracle.jbo` to filter for all classes related to Oracle ADF.
  - **Module:** Filters the log by the fully qualified package name of the class where the message is logged. This is same package as the source class.
  - **Message Id:** Filters the log by the ID of the logged messages. Many messages share the same ID. For example, message ID `ADFC-52008` might have four `INFO` messages and one `Warning` message. You can select **Group by Id** in the log analyzer Results panel to group messages by their common ID.
8. To initiate the filters and display the log messages, click **Search**.
  9. To order the results by the message ID, select the **Group by Id** checkbox.
  10. To group the messages by time period or by request, in the **Related** column, select either **Related by Time** or **Related by Request**.
  11. To show or hide columns in the **Results** section, click the dropdown list to the right of the column headers and select among the list of displayed columns to change the visibility of a column.

#### 36.6.4.2 Using the Log Analyzer to Analyze the ADF Request

Because Oracle instrumented the Oracle ADF source code to generate log messages during the execution of the ADF lifecycle phases, you can use the log analyzer to investigate the details of the active (or previous) page request in your running application. Specifically, the By ADF Request page of the log analyzer lets you view ADF event messages in a hierarchical list, organized by the sequence of their execution. It also provides a graphical representation of the duration of each event. When you run your application and start the log analyzer with ADF logging configured, you can use this page to quickly identify whether a component of your application is contributing to a performance bottleneck due to unusually long execution times.

---

**Note:** In contrast to the By Log Message page, the By ADF Request page of the log analyzer displays a hierarchical view of ADF event messages. The difference between these two pages is that the By ADF Request page focuses only on ADF page requests made when a page or region is submitted, and it provides the option to examine logged messages from multiple ADF requests. For details about the ADF page lifecycle, see [Chapter 25, "Understanding the Fusion Page Lifecycle."](#)

---

You can use the Search panel of the By ADF Request page to display one or more specific requests from the log file. The Search panel lets you combine any of the following search criteria:

- The number of requests to display
- The timestamp for the request recorded in the log
- The logged-in user name, application name in a composite application, or page name as displayed in the request header

If you search on any of these criteria before the page request is complete, the ADF Web Request panel in the log analyzer displays a yellow triangle symbol to indicate that the phase has not yet completed. [Figure 36–7](#) shows the icon for the JSF lifecycle Render Response phase and the root node for the overall request. To update the ADF Web Request panel with the latest information from the log, you can click on the refresh icon in the panel header.

**Figure 36–7 Oracle Diagnostic Log Analyzer Displays ADF Web Request in Progress**

ADF Message	ADF Data	Time (ms)	Percentages of Request Time
⚠ ADF web request	URL=http://127.0.0.1...		
⊕ JSF lifecycle restore view phase		78	
⊖ JSF lifecycle apply request values phase		235	
⊖ JSF lifecycle process validations phase		0	
⊖ JSF lifecycle update model values phase		31	
⊕ JSF lifecycle invoke application phase		1109	
⚠ JSF lifecycle render response phase			

After the request is completed, the log analyzer displays duration bar graphs for each phase to show the percentages of request time that each event contributed to the overall page request. [Figure 36–8](#) shows the ADF Web Request panel with the JSF lifecycle Render Response phase displaying 34015 milliseconds (34 seconds) for the duration of this portion of the overall page request. This example depicts an usually long duration for the render phase to illustrate how the bar graph can help you to identify a performance bottleneck that may occur during the execution of a page request. The bar graph for the root node of the request event hierarchy (**ADF web request**) displays the total execution time.

---

**Note:** The two colors present in the **Percentage Request Time** bar graph (green and orange) indicate which portion of the request’s execution time resulted from ADF source code that was instrumented to generate ADF event messages and which portion resulted from ADF source code that is uninstrumented (and therefore cannot generate ADF event messages). Additionally, note that the individual phases of the request do not sum to equal the total request time. This is due to the fact that only those phases of the lifecycle that are useful are represented in the log analyzer.

---

**Figure 36–8 Oracle Diagnostic Log Analyzer Displays Completed ADF Web Request**

ADF Message	ADF Data	Time (ms)	Percentages of Request Time
ADF web request	URL=http://127.0.0.1:7101...	35578	
JSF lifecycle restore view pl		875	
JSF lifecycle render respon:		34015	

To examine the request in more detail, you can expand the tree for any ADF lifecycle node to further investigate where in the application the performance bottleneck occurred. Drilling down and then selecting the ADF event node in the ADF Web Request panel gives you details about the component associated with each ADF event. For instance, expanding the **JSF lifecycle render response phase** node displays all ADF events generated during that phase. [Figure 36–9](#) shows the **JSF lifecycle render response phase** node expanded with a long request duration bar graph for the **Execute iterator binding** node and the **Execute query** node. The **Execute query** node has been selected to reveal detailed ADF data in the bottom portion of the panel, including the view object's name and query statement. By drilling down and selecting the ADF event with the long execution time as indicated by the bar graph, you can obtain, for example, the name of the view object in the data model project that should be tuned for improved performance.

**Figure 36–9 Oracle Diagnostic Log Analyzer Displays ADF Event Messages with ADF Data**

ADF Message	ADF Data	Time (ms)	Percentages of Request Time
Refreshing binding corBinding container name=fu...		78	
Attaching an iterator fIterator binding name=Slo...		0	
Estimated row count Iterator binding name=Slo...		312	
Executing iterator bincIterator binding name=Slo...		31453

Estimated row count Iterator binding name=Slo...		0	
Executing iterator bincIterator binding name=Slo...		0	
Converting rows into fIterator binding name=Slo...		15	
Estimated row count Iterator binding name=Slo...		0	
Estimated row count Iterator binding name=Slo...		0	
Estimated row count Iterator binding name=Slo...		0	
Estimated row count Iterator binding name=Slo...		0	

**ADF Data**

Query: SELECT SlowEmp.EMPNO, SlowEmp.ENAME, SlowEmp.JOB, SlowEmp.MGR, SlowEr

Query parameters: none

**Before you begin:**

It may be helpful to have an understanding of logging. For more information, see [Section 36.6, "Using the ADF Logger."](#)

You will need to complete these tasks:

1. Enable logging, as described in [Section 36.6.2, "How to Turn On Diagnostic Logging."](#)
2. Set logging levels, as described in [Section 36.6.1, "How to Set ADF Logging Levels."](#)

To log ADF event messages, do not configure an ODL log level that is more restrictive than `Notification` or a Java log level that is more restrictive than `Info` for the following packages:

- `oracle.adf` will log events generated by source code for the ADF Model data binding layer and ADF Controller source code.
- `oracle.jbo` will log events generated by source code executed for ADF Business Components.
- `oracle.adfinternal` will log events generated by source code executed from Oracle ADF internal classes.

**Tip:** The default log level for the Root Logger displayed by the editor for Oracle Diagnostics Logging Configuration ensures that ADF event messages are logged.

3. Create a log file, either from your test run or from another source.

### To display ADF request messages in the log analyzer:

1. From the main menu, choose **Tools > Oracle Diagnostic Log Analyzer**.

Or, from the Log window **Action** menu, choose **Analyze Log** and then either **Current in Console** or **Open Selected** (to browse log files in the server log directory).

2. In the editor for Oracle Diagnostic Log Analyzer, click the **By ADF Request** tab.
3. In the By ADF Request page, specify how many of the most recent request you want to display.

The default displays only the most recent request.

4. Specify a time period for the entries you want to view. You can select the most recent *period* or a range.
5. To filter the request to display, use the Search panel to query the log for a text pattern. For additional Search panels, click **Add**. The supported search criteria include:
  - The logged-in user name. This can be a specific user or `anonymous` for unauthenticated users.
  - The application name. This is useful when the application is running in a composite application and you want to view messages for a specific application.
  - A JSF page name without the file name extension. The log records the page name in the request header. If the submitted page is `orderSummary.jspx`, the logger records `orderSummary` in the request header. The request header also appears in the collapsible ADF Web Request panel header of the By ADF Request page.
6. To initiate the filters and display the ADF event messages for the ADF request, click **Search**.
7. In the ADF Web Request panel, expand the completed ADF request and look for ADF events that display long execution times as indicated by the Request Time bar graphs.

If the page request has not completed, the yellow triangle symbols are displayed in the ADF Web Request panel. Wait a moment and then click the **Refresh** icon in the ADF Web Request panel.

8. Select the desired ADF event and examine the ADF Data panel for details about the ADF component associated with the ADF event.
9. Examine the component in your application and determine whether optimization is possible.

### 36.6.4.3 Sorting Diagnostic Messages By ADF Events

Oracle instrumented the Oracle ADF source code to generate log messages during the execution of the ADF lifecycle phases and during operations executed in the ADF Model data binding layer, ADF Controller source, and ADF Business Components source. Combined, the log analyzer refers to these messages as ADF events. You can use the log analyzer to investigate ADF events in your running application. The By Log Message page of the log analyzer lets you view ADF event messages in a flat list, organized by time of execution, with the option to switch to the By ADF Request page to view the ADF events in a hierarchical list, organized by the sequence of their execution.

ADF event messages contain useful information that helps you identify which ADF components in your application generated the event. For example, you can search the log for ADF event messages to identify the components related to displaying data in the page, executing queries, or initiating actions:

- Executing iterator binding: Displays the names of the iterators executed to manage displaying data in the page. This can be useful for diagnosing slow query updates.
- Execute query: Displays the name of the view object associated with the executed query. This can be useful when you want to view the query statement, bind parameters, and name of the view object.
- Executing method binding: Displays the names of the Java methods executed on the bound data source. This can be useful for diagnosing slow method execution.

After you display an ADF event message in the log analyzer, you can organize the event in the context of other logged messages. You can select options from the **Related** column to display:

- All messages leading up to the ADF event (related by time)
- All messages in the same web request as the ADF event (related by request)
- Only ADF event messages in the same web request (related by ADF request)

**Tip:** The **Related by ADF Request** option displays detailed ADF data for the ADF event messages. This is the view to use, for example, when you want to display the query statement associated with the `Execute query` message.

Figure 36–10 shows the log analyzer search result for the ADF event message `Create Application Module`. The Results panel displays all messages that match the search criteria and the bottom panel displays detailed information about the component.

**Figure 36–10 Oracle Diagnostic Log Analyzer Displays ADF Event Messages**

The screenshot shows the Oracle Diagnostic Log Analyzer interface. At the top, there are two tabs: "By ADF Request" (selected) and "By Log Message". Below the tabs is a search section with a "Search" button. The search filters include:
 

- Java Log Level: A dropdown menu.
- Severity checkboxes: Severe, Warning, Info, Config, Fine, Finer, Finest, and Unknown, all of which are checked.
- Log Time: A dropdown menu set to "Most Recent", a numeric input field with "1", and a unit dropdown set to "Hours".
- Message: A dropdown menu set to "Message", a "Contains" dropdown, and a text input field containing "Create Application Module".

 A "Search" button is located to the right of the search filters. Below the search section, the results are displayed in a table. The table has columns: Time, Message, Module, Related, Message Id, Type, and Application. Two rows are visible, both with the message "Create Application Module" and type "INFO". Below the table, there is a detailed view of the selected log entry, showing fields like User, Thread Id, Source Class, Source Method, Module, Message, and Detail. Under "Supplemental Attributes", there are entries for ADF\_MESSAGE\_ACTION\_NAME and ADF\_MESSAGE\_STATUS.

When you select **Related by ADF Request** in the **Related** column of the Results panel, the log analyzer switches to display the By ADF Request page with the ADF event messages arranged hierarchically to show their execution dependencies. The By ADF Request page of the log analyzer is the preferred way to diagnose performance issues. For details about the By ADF Request page, see [Section 36.6.4.2, "Using the Log Analyzer to Analyze the ADF Request."](#) In the By Log Message page, the elapsed time is information that you can leave visible or hide from the Results panel.

#### Before you begin:

It may be helpful to have an understanding of logging. For more information, see [Section 36.6, "Using the ADF Logger."](#)

You will need to complete these tasks:

1. Enable logging, as described in [Section 36.6.2, "How to Turn On Diagnostic Logging."](#)
2. Set logging levels, as described in [Section 36.6.1, "How to Set ADF Logging Levels."](#)

To log ADF event messages, do not configure an ODL log level that is more restrictive than `Notification` or a Java log level that is more restrictive than `Info` for the following packages:

- `oracle.adf` will log events generated by source code for ADF Model data binding layer and ADF Controller source code.
- `oracle.jbo` will log events generated by source code executed for ADF Business Components.
- `oracle.adfinternal` will log events generated by source code executed from Oracle ADF internal classes.

**Tip:** The default log level for the Root Logger displayed by the editor for Oracle Diagnostics Logging Configuration ensures ADF event messages are logged.

3. Create a log file, either from your test run or from another source.

**To display messages related by ADF events:**

1. From the main menu, choose **Tools > Oracle Diagnostic Log Analyzer**.  
Or, from the Log window **Action** menu, choose **Analyze Log** and then either **Current in Console** or **Open Selected** (to browse log files in the server log directory).
2. In the editor for Oracle Diagnostic Log Analyzer, click the **By Log Message** tab.
3. In the By Log Message page, select the desired logger type, log levels, and log time.

To search the log for ADF event messages, you must minimally select log level **Notification** (for ODL log level) or **Info** (for Java log level).

4. Choose the search criteria **Message** and **Contains**, and then enter any of the following ADF event messages and click **Search**.

You can also filter the log on these additional ADF event messages:

- Executing iterator binding - this can be useful for diagnosing slow query updates.
- Executing method binding - this can be useful for diagnosing slow method execution.
- Execute query - this can be useful when you want to view the query statement, bind parameters, and name of the view object.
- Refreshing binding container
- Attaching an iterator binding to a datasource
- Converting rows into hierarchical nodes
- Estimated row count
- Get LOV list
- Filter LOV list
- Validate Entity
- Lock Entity's Parent
- Lock Entity
- Before posting the entity's changes
- Posting the entity's changes
- Posting in batches
- Before committing the entity's changes
- After committing the entity's changes
- Before rolling back the entity's changes
- After rolling back the entity's changes
- Entity notifying an event

- Entity notification name
- Removing Entity
- Updating audit columns
- Applying Effective Date change
- Entity DML
- Entity read all attributes
- Create Application Module
- Create nested Application Module
- Passivating Application Module
- Activating Application Module
- Establish database connection
- Commit transaction
- Rollback transaction
- Validate transaction
- Validate value

Examine the bottom portion of the Results panel for the ADF event information.

5. To view a hierarchical sequence of ADF events, with the desired ADF event message selected in the Results panel, choose **Related - Related By ADF Request**.

The editor for Oracle Diagnostic Log Analyzer displays the By ADF Request page for the selected ADF event. Examine the bottom portion of the Results panel for additional ADF data for the ADF event. For example, you can see the query statement associated with the `Execute query` message in the ADF Data area of the Results panel.

### 36.6.5 What You May Need to Know About the Logging.xml File

By default, the level is set to `INFO` for all packages of Oracle ADF. Set `level="FINE"` for detailed logging diagnostics.

For the ADF view layer packages `oracle.adf.view.faces` and `oracle.adfinternal.view.faces`, edit these elements:

```
<logger name="oracle.adf" level="FINE"/>
<logger name="oracle.adfinternal" level="FINE"/>
```

For the ADF Model layer packages, edit these elements:

```
<logger name="oracle.adf" level="FINE"/>
<logger name="oracle.jbo" level="FINE"/>
```

For the ADF Controller layer packages, edit these elements:

```
<logger name="oracle.adf.controller" level="FINE"/>
<logger name="oracle.adfinternal.controller" level="FINE"/>
```

Alternatively, you can create a debug configuration in JDeveloper that you can choose when you start a debugging session.

[Example 36-2](#) shows the portion of the `logging.xml` file where you can change the granularity of the log messages. Note in the example that the log for `oracle.adf.faces` has been changed to `FINE` to display more messages.

**Example 36–2 Sample Section of the logging.xml Configuration File**

```

</logging_configuration>
...
<loggers>
 <logger name="oracle.adf" level="INFO"/>
 <logger name="oracle.adf.faces" level="FINE"/>
 <logger name="oracle.adf.controller" level="INFO"/>
 <logger name="oracle.bc4j" level="INFO"/>
 <logger name="oracle.adf.portal" level="INFO"/>
 <logger name="oracle.vcr" level="INFO"/>
 <logger name="oracle.portlet" level="INFO"/>
 <logger name="oracle.adfinternal" level="INFO"/>
 <logger name="oracle.adfdt" level="INFO"/>
 <logger name="oracle.adfdtinternal" level="INFO"/>
</loggers>
</logging_configuration>

```

For the latest information about the different levels of the Java Logging system, go to <http://www.oracle.com/technetwork/java/index.html>. Normally, the Java logging system supports the following levels:

- SEVERE
- WARNING
- INFO
- CONFIG
- FINE
- FINER
- FINEST

### 36.6.6 What You May Need to Know About ADF Logging and Oracle WebLogic Server

After you have deployed the Fusion web application to Oracle WebLogic Server, the operations performed by the application are logged directly to the Managed Server where the application is running:

```
DOMAIN_HOME/servers/server_name/logs/server_name-diagnostic.log
```

The log files for the different Managed Servers are also available from the Oracle WebLogic Server Administration Console. To verify the logs, access the Oracle WebLogic Server Administration Console `http://<admin_server_host>:<port>/console` and click **Diagnostics-Log Files**.

This log's granularity and logging properties can be changed using Oracle Enterprise Manager Fusion Middleware Control (Fusion Middleware Control). Fusion Middleware Control is a web browser-based, graphical user interface that you can use to monitor and administer a farm.

When the Fusion web application is deployed to a high availability environment, you can receive warning diagnostic messages specific to high availability by setting the level to FINE.

For details about using Fusion Middleware Control to change the log settings of Managed Servers and Oracle ADF, see the *Oracle Application Server Administrator's Guide*.

## 36.7 Using the Oracle ADF Model Tester for Testing and Debugging

The Oracle ADF Model Tester (also referred to as the tester) is a Java application that you launch from JDeveloper when you want to interact with the business objects of the ADF Business Components data model project. The Oracle ADF Model Tester runs outside of JDeveloper and provides a full UI for testing and examining the data model project. You can run the tester to examine the view instances of the ADF application module, navigate the hierarchical relationship of view links, and execute custom methods from the application module's client interface, view object interface, and view row interface. The tester also interacts with the ADF Declarative Debugger to allow you to set breakpoints on the custom methods of these interfaces.

Additionally, the tester simulates many features that the user interface might expose by allowing you to view, insert, and update the contents of business objects in the database specified by the application module's configuration file (`bc4j.xcf`). Specifically, you can use the tester to verify many aspects of the data model design, including master-detail relationships between view instance, view instances and their attributes, view instance query result sets, search forms using view criteria, validation rules defined for attribute values, and dropdown lists on LOV-defined attributes (list of values). For more information about ways to interact with the tester to test your business objects, see [Section 6.3, "Testing View Object Instances Using the Oracle ADF Model Tester."](#) Additional information about testing with the Oracle ADF Model Tester also appears in sections specific to each business object throughout the chapters in the "Building Your Business Services" part of this book.

### 36.7.1 How to Run in Debug Mode and Test with the Oracle ADF Model Tester

Often you will find it useful to analyze and debug custom code in the service methods of your client interface implementation classes. When you use the Oracle ADF Model Tester, you can do this without needing to run the application with the user interface. You can use the Oracle ADF Model Tester as a testing tool to complement your debugging process.

#### **Before you begin:**

Set breakpoints in the custom methods of your client interface, as described in [Section 36.9, "Setting ADF Declarative Breakpoints."](#)

#### **To launch the Oracle ADF Model Tester and go into debug mode:**

1. In the Application Navigator, right-click the desired application module and choose **Debug**.
2. In the Oracle ADF Model Tester, open the method testing panel for the desired client interface, as described in [Section 9.9.4, "How to Test Custom Service Methods Using the Oracle ADF Model Tester."](#)
3. In the method panel, select the desired method from the dropdown list, enter values to pass as method parameters, and click **Execute**.

Return to JDeveloper to step through your code using the ADF Declarative Debugger. When you complete method execution, the method panel displays the return value (if any) and test result. The result displayed in the Oracle ADF Model Tester will indicate whether or not the method executed successfully.

### 36.7.2 How to Run the Oracle ADF Model Tester and Test with a Specific Configuration

When you right-click the application module in the Application Navigator and choose **Run** or **Debug**, JDeveloper will run the Oracle ADF Model Tester using the default

configuration defined for the application module. If you want to test your business components with a different application module configuration (which can specify a different data source and its own set of runtime parameters), you can do so from the **Configurations** page in the overview editor for the application module.

**To run the Oracle ADF Model Tester with a specific configuration:**

1. In the Application Navigator, double-click the application module that you want to test.
2. In the overview editor, click the **Configurations** navigation tab, and select the configuration from the list.

Although the metadata changes that you make are not involved in compiling the project, the compile step is necessary to copy the metadata to the class path and to allow the Oracle ADF Model Tester to reload it.

3. Right-click the selected configuration and choose **Run** or **Debug** to launch the Oracle ADF Model Tester.

### 36.7.3 What Happens When You Run the Oracle ADF Model Tester in Debug Mode

JDeveloper lets you run the Oracle ADF Model Tester in two modes: either in debug mode or non-debug mode. When run in debug mode, the tester interacts with the ADF Declarative Debugger so that you execute custom methods using breakpoints you insert in custom code of the client interfaces. For instance, if you set a breakpoint on a method in the client interface and execute that method in the tester, then in debug mode, you can step through the code before the tester returns a success/fail result. In non-debug mode, the tester will immediately return a result to indicate whether the method executed successfully. Additionally, in either debug or non-debug mode, the tester can display runtime artifacts from the system catalog created at runtime for the application module.

### 36.7.4 How to Verify Runtime Artifacts in the Oracle ADF Model Tester

When you want to run the Oracle ADF Model Tester, but do not require the use of the ADF Declarative Debugger you can display information about the runtime artifacts from the application module's system catalog. The system catalog displays business object metadata and other information that you may find useful when you need to compare business objects.

**To launch the Oracle ADF Model Tester without debugging:**

1. In the Application Navigator, right-click the desired application module and choose **Run**.
2. In the Oracle ADF Model Tester, choose **Create - Create SysCat AM**.
3. In the data model tree, expand the **SysCatAMDefs**, right-click **ViewDefs**, and choose **Show Table**.
4. In the data viewer, scroll vertically to locate the desired view instance in the **SCName** (system catalog name) field.

Exposing the system catalog in the tester allows access to metadata and other information specific to the runtime objects without running the debugger. For example, you can check whether a view instance has a custom Java implementation class or not.

### 36.7.5 How to Refresh the Oracle ADF Model Tester with Application Changes

The Oracle ADF Model Tester is a highly interactive tool. When you run the tester and determine a change is needed in the data model project, you can return to JDeveloper to edit the desired application module instances and refresh the Oracle ADF Model Tester data model to display the changes. This way you can verify your changes without needing to rerun the tester.

#### To reload application metadata in the Oracle ADF Model Tester:

1. In the data model project, edit your business objects and save the changes in the JDeveloper.
2. In the Application Navigator, recompile the data model project. For example, you can right-click the data model project in the Application Navigator and choose **Make** to complete the recompile step.

Although the metadata changes that you make are not involved in compiling the project, the compile step is necessary to copy the metadata to the class path and to allow the Oracle ADF Model Tester to reload it.

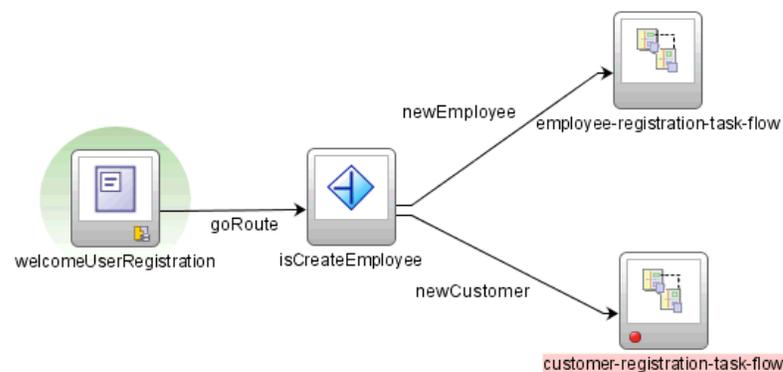

3. In the Oracle ADF Model Tester, in the toolbar, click **Reload application metadata**.

Alternatively, you can choose **Reload Application** from the **File** menu of the Oracle ADF Model Tester.

## 36.8 Using the ADF Declarative Debugger

The ADF Declarative Debugger provides declarative breakpoints that you can set at the ADF object level (such as task flows, page definition executables, method and action bindings, ADF lifecycle phases), as well as standard Java breakpoints. ADF declarative breakpoints provide a high-level object view for debugging ADF applications. For example, you can break before a task flow activity to see what parameters would be passed to the task flow, as shown in [Figure 36–11](#). To perform the same function using only Java breakpoints would require you to know which class or method to place the breakpoint in. ADF declarative breakpoints should be the first choice for ADF applications.

**Figure 36–11 ADF Declarative Breakpoint on a Task Flow Activity**

The ADF Declarative Debugger also supports standard Java code breakpoints. You can set Java code breakpoints in any ADF application. You may be able to use Java code

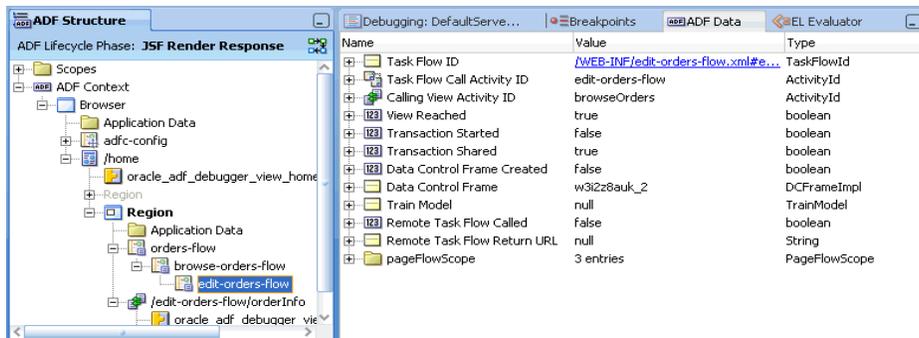

breakpoints when an ADF declarative breakpoint does not break in the place you want.

The ADF Declarative Debugger is built on top of the Java debugger, so it has the features and behaviors of the Java debugger. But instead of needing to know the Java class or method, you can set ADF declarative breakpoints in visual editors.

The ADF Declarative Debugger provides standard debugging features such as the ability to examine variable and stack data. When an application pauses at any breakpoint (ADF Declarative or Java code breakpoint), you can examine the application status using a variety of windows. You can check where the break occurs in the Breakpoints window. You can check the call stack for the current thread using the Stack window. When you select a line in the Stack window, information in the Data window, Watches window, and all Inspector windows is updated to show relevant data. You can use the Data window to display information about arguments, local variables, and static fields in your application.

The ADF Structure window displays the runtime structure of the project. The ADF Data window automatically changes its display information based on the selection in the ADF Structure window. For example, if a task flow node is selected, the ADF Data window displays the relevant debugging information for task flows, as shown in [Figure 36–12](#).

**Figure 36–12 ADF Structure Window and ADF Data Window for a Task Flow Selection**

You can mix ADF declarative breakpoints with Java code breakpoints as needed in your debugging session. Although you can use step functions to advance the application from Java code breakpoint to Java code breakpoint, the step functions for ADF declarative breakpoints have more constraints and limitations. For more information about using step functions on ADF declarative breakpoints, see [Table 36–3](#).

For information on how to use ADF declarative breakpoints, see [Section 36.9, "Setting ADF Declarative Breakpoints."](#)

For information on how to use Java breakpoints on classes and methods, see [Section 36.10, "Setting Java Code Breakpoints."](#)

In a JSF application (including Fusion web applications), when a breakpoint breaks, you can use the EL Evaluator to examine the value of an EL expression. The EL Evaluator has the browse function that helps you select the correct expression to evaluate. For more information, see [Section 36.8.4, "How to Use the EL Expression Evaluator."](#)

Whether you plan to use ADF declarative breakpoints or Java breakpoints, you can use the ADF Declarative Debugger with Oracle ADF source code. You can obtain

Oracle ADF source code with Debug libraries. For more information about loading source code, see [Section 36.8.1, "Using ADF Source Code with the Debugger."](#)

### 36.8.1 Using ADF Source Code with the Debugger

If you have valid Oracle ADF support, you can obtain complete source code for Oracle ADF by opening a service request with Oracle Worldwide Support. You can request a specific version of the Oracle ADF source code. You may be given download and password information to decrypt the source code ZIP file. Contact Oracle Worldwide Support for more information.

Adding Oracle ADF source code access to your application debugging session will:

- Provide access to the JDeveloper Quick Javadoc feature in the source editor. Without the source code, you will have only standard Javadoc.
- Enhance the use of Java code breakpoints by displaying the Oracle source code that's being executed when the breakpoint is encountered. You can also set breakpoints easier by clicking on the margin in the source code line you want to break on. Without the source code, you will have to know the class, method, or line number in order to set a breakpoint within Oracle code.
- For Java code breakpoints set within the source code, you will be able to see the values of all local variables and member fields in the debugger.

The ADF source code ZIP file may be delivered within an encrypted "outer" ZIP file to protect its contents during delivery. The "outer" ZIP name is sometimes a variant of the service request number.

After you have received or downloaded the "outer" ZIP, unzip it with the provided password to access the actual source code ZIP file. The ADF source code ZIP name should be a variant of the ADF version number and build number. For example, the ADF source ZIP may have a format similar to `adf_vvvv_nnnn_source.zip`, where `vvvv` is the version number and `nnnn` is the build number.

After you have access to the source code ZIP, extract its contents to a working directory.

### 36.8.2 How to Set Up the ADF Source User Library

You create a name for the source user library and then associate that name with the source zip file.

#### To add the ADF source zip file to the user library

1. From the main menu, choose **Tools > Manage Libraries**.
2. In the Manage Libraries dialog, with the **Libraries** tab selected, click **New**.
3. In the Create Library window, enter a library name for the source that identifies the type of library.
4. Select the **Source Path** node in the tree structure. Click **Add Entry**.

---

---

**Note:** Do not enter a value for the class path. You need to provide a value only for the source path.

---

---

5. In the Select Path Entry window, browse to the directory where the file was extracted and select the source zip file. Click **Select**.

6. In the Create Library window, verify that the source path entry has the correct path to the source zip file, and deselect **Deployed by Default**. Click **OK**.
7. Click **OK**.

### 36.8.3 How to Add the ADF Source Library to a Project

After the source library has been added to the list of available user libraries, add it to the project you want to debug.

#### To add the ADF source zip file to the project:

1. In the Application Navigator, double-click the project or right-click the project and select **Project Properties**.
2. In the Project Properties dialog, select **Libraries and Classpaths**.
3. Click **Add Library**.
4. In the Add Library dialog, under the **Users** node, select the source library you want to add and click **OK**.

The source library should appear in the **Classpath Entries** section in the Project Properties dialog.

5. Click **OK**.

### 36.8.4 How to Use the EL Expression Evaluator

When the application is paused at a breakpoint, you can use the EL expression evaluator to enter an EL expression for evaluation. You can enter arbitrary EL expressions for evaluation within the current context. If the EL expression no longer applies within the current context, the value will be evaluated to `null`.

The EL Evaluator is different from the Watches window in that EL evaluation occurs only when stopped at a breakpoint, not when stopped at subsequent debugging steps.

The EL Evaluator is available for debugging any JSF application.

---

---

**Caution:** Be wary when you are evaluating EL expressions that you do not indirectly change application data and therefore the behavior of the application. For example, if you evaluate `{foo.bar}`, the corresponding `getBar()` method modifies application data.

---

---

#### To use the EL Evaluator:

1. Set a breakpoint in the application.

The application must be a JSF application. It does not need to be an ADF application.

2. Start the debugging process.

You can:

- From the main menu, choose **Run > Debug**.
- From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
- From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.

- When the breakpoint is reached, the EL Evaluator should appear as a tab in the debugger window area. Click the **EL Evaluator** tab to bring it forward. If it does not appear, choose **View > Debugger > EL Evaluator** from the main menu.

---

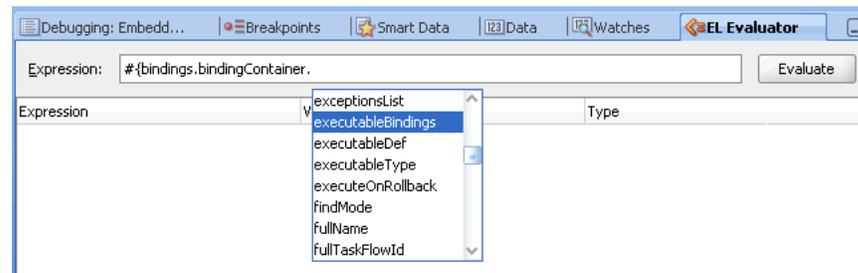

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

- Enter an EL expression in the input field.

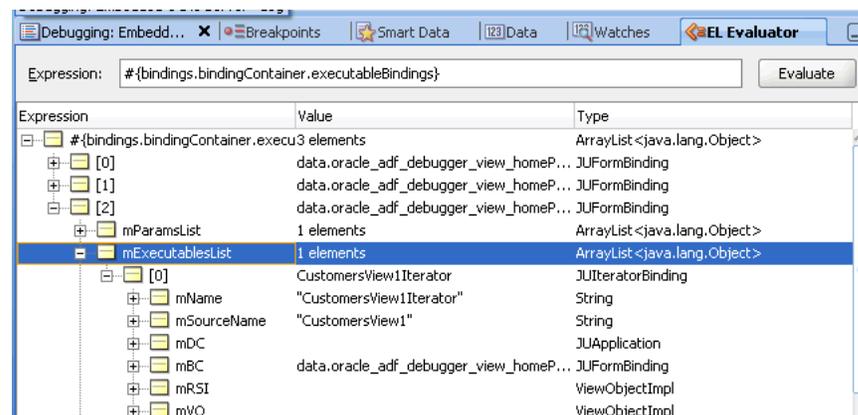

When you click in the field after entering `# {` or after a period, a discovery function provides a selectable list of expression items, as shown in [Figure 36–13](#). Auto-completion will be provided for easy entry. You can evaluate several EL expressions at the same time by separating them with semicolons.

**Figure 36–13 Using the Discovery Function of the EL Evaluator**

- When you finish entering the EL expression, click **Evaluate** and the expression is evaluated, as shown in [Figure 36–14](#).

**Figure 36–14 EL Expression Evaluated**

### 36.8.5 How to View and Export Stack Trace Information

If you are unable to determine what the problem is and to resolve it yourself, typically your next step is to ask someone else for assistance. Whether you post a question in the OTN JDeveloper Discussion Forum or open a service request on Metalink, including the stack trace information in your posting is extremely useful to anyone

who will need to assist you further to understand exactly where the problem is occurring.

JDeveloper's Stack window makes communicating this information easy. Whenever the debugger is paused, you can view the Stack window to see the program flow as a stack of method calls that got you to the current line. Right-click the Stack window background and choose **Preferences**. You can set the Stack window preference to include the line number information, as well as the class and method name that will be there by default. Finally, the context menu option **Export** lets you save the current stack information to an external text file whose contents you can then post or send to whomever might need to help you diagnose the problem.

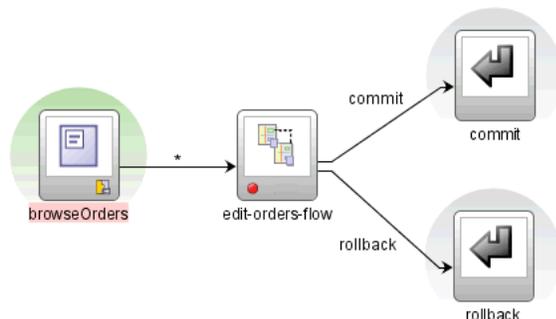

## 36.9 Setting ADF Declarative Breakpoints

You use the ADF Declarative Debugger features in JDeveloper to declaratively set breakpoints on ADF task flow activities, page definition executables, method, action, and value bindings, ADF Lifecycle phases, and contextual events. Instead of needing to know all the internal constructs of the ADF code, such as method names and class names, you can set breakpoints at the highest level of object abstraction.

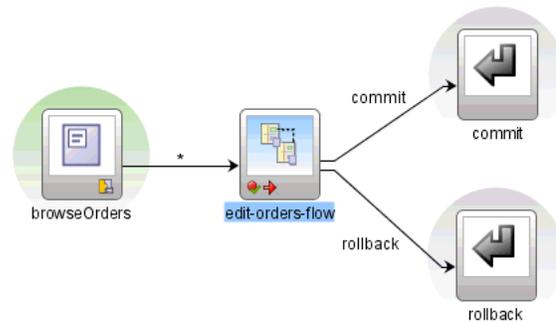

You can add breakpoints to task flow activities in the task flow diagrammer or you can launch the Create ADF Task Flow Activity Breakpoint dialog from the Breakpoints window. In the task flow diagrammer, you can select a task flow activity and use the context menu to toggle or disable breakpoints on that activity, or press the F5 button. After the application pauses at the breakpoint, you can view the runtime structure of the objects in the ADF Structure window as a tree structure. The ADF Data window displays a list of data for a given object selected in the ADF Structure window.

For example, when you set a breakpoint on a task flow call activity in the Browse Orders task flow, a red dot icon appears in the call activity, as shown in [Figure 36–15](#).

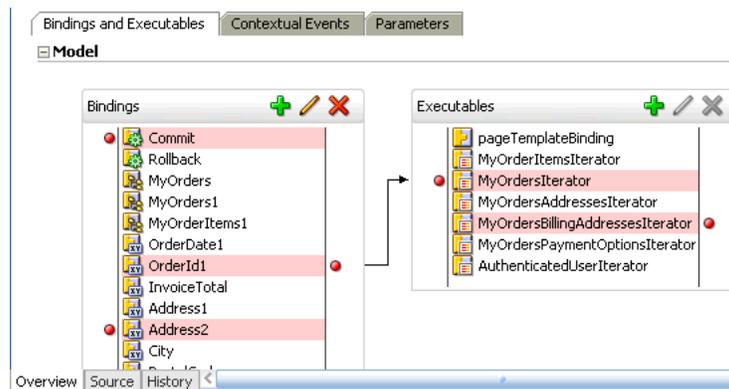

**Figure 36–15 ADF Declarative Breakpoint on a Task Flow Activity**

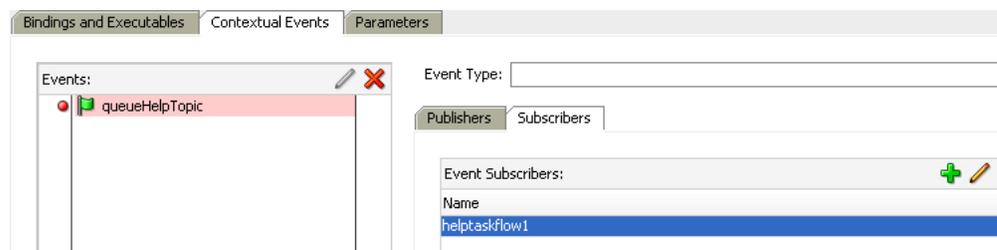

When the breakpoint is reached, the application is paused and the icon changes, as shown in [Figure 36–16](#).

**Figure 36–16 Application Paused at an ADF Declarative Breakpoint**

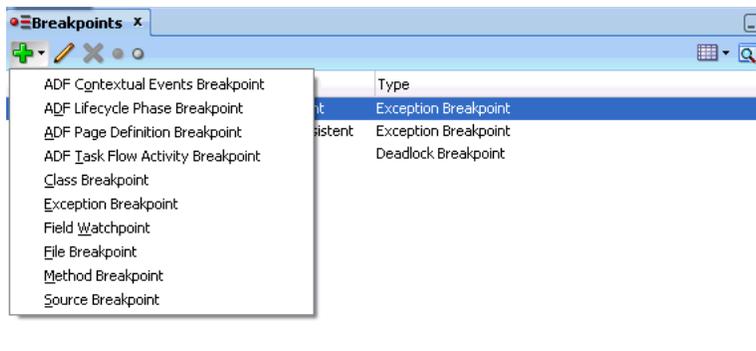

Similarly, you can set Before and After breakpoints in the page definition file. You set breakpoints for supported value bindings (see [Table 36–1](#) for the list of supported value binding) and for executables by clicking on the left or right margin next to the item or by selecting from the context menu. Clicking on the left margin adds a **Before page definition** breakpoint, and clicking on the right margin adds an **After page definition** breakpoint. Again, a red dot icon that indicates the breakpoint is set, as shown in [Figure 36–17](#).

**Figure 36–17 ADF Declarative Breakpoints on ADF Bindings in the Page Definition File**

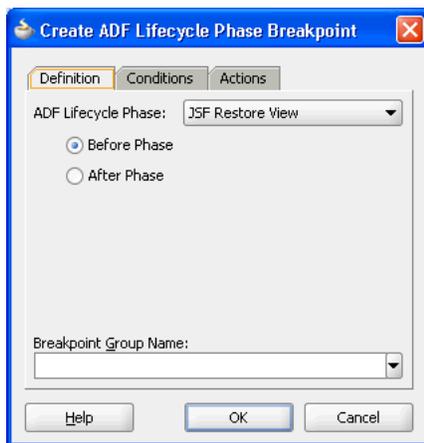

The page definition file also lets you set breakpoints on contextual events that your page or region within a page raises at runtime, as shown in [Figure 36–18](#).

**Figure 36–18 ADF Declarative Breakpoint on a Contextual Event in the Page Definition File**

You can also set Before and After breakpoints on all the ADF lifecycle phases. You can launch the Create ADF Lifecycle Phase Breakpoint dialog from the Breakpoints window, as shown in [Figure 36–19](#).

**Figure 36–19 Breakpoints Window Add Breakpoint Icon Dropdown Menu**

The Create ADF Lifecycle Phase Breakpoint dialog allows you to select different lifecycle breakpoint options, as shown in [Figure 36–20](#).

**Figure 36–20 Create ADF Lifecycle Phase Breakpoint Dialog**

Alternatively, you can use the ADF Lifecycle Breakpoints dialog from the ADF Structure window or the task flow diagrammer to set ADF lifecycle phase breakpoints. For more information about ADF lifecycle phases, see [Chapter 25, "Understanding the Fusion Page Lifecycle."](#)

You can define both ADF declarative breakpoints and standard Java code breakpoints when using the ADF Declarative Debugger. Depending on your debugging scenario, you may only need to use the declarative breakpoints to debug the application. Or you may find it necessary to add additional breakpoints in Java code that are not available declaratively. For information on Java code breakpoints, see [Section 36.10.1, "How to Set Java Breakpoints on Classes and Methods."](#) [Table 36–1](#) lists the available ADF Declarative Debugger breakpoint locations.

**Table 36–1 ADF Declarative Debugger Breakpoints**

<b>ADF Area</b>	<b>Declarative Breakpoint</b>	<b>JDeveloper Editor</b>	<b>JDeveloper Location</b>	<b>JDeveloper Context Menu Command</b>	<b>Description</b>
ADF lifecycle phase	Before ADF lifecycle phase	ADF Structure window	ADF Structure window		A Before breakpoint pauses debugging before the ADF lifecycle phase.
	After ADF lifecycle phase	Task flow diagrammer Breakpoints window	ADF Structure window <b>ADF Lifecycle Breakpoints</b> toolbar button Task flow diagrammer Breakpoints window <b>Add</b> button		<p>An After breakpoint pauses debugging after the ADF lifecycle phase.</p> <p>The ADF lifecycle JSF Render Response and Prepare Render phase Before and After breakpoints are executed in the following order:</p> <ul style="list-style-type: none"> <li>■ Before jsfRenderResponse.</li> <li>■ Before prepareRender. (prepareRender phase executes).</li> <li>■ After prepareRender. (jsfRenderResponse phase executes).</li> <li>■ After jsfRenderResponse.</li> </ul>

Table 36–1 (Cont.) ADF Declarative Debugger Breakpoints

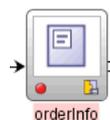

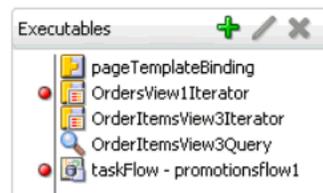

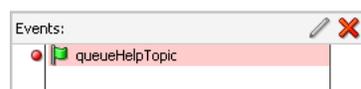

ADF Area	Declarative Breakpoint	JDeveloper Editor	JDeveloper Location	JDeveloper Context Menu Command	Description	
ADF page definition - bindings and executables	Before/After executable:	Overview editor for page definition files	Page Definition <b>Bindings and Executables</b> tab, Executables section Breakpoints window <b>Add</b> button	Toggle Breakpoint or F5	Pauses debugging before or after executable is refreshed. For task flow bindings, this represents two times per lifecycle: first, during <code>prepareModel</code> (initial region creation), and then again during <code>prepareRender</code> (where dynamic regions swap their corresponding task flow ID).	
	<ul style="list-style-type: none"> <li>▪ Iterator</li> <li>▪ <code>invokeAction</code></li> <li>▪ Region instantiation</li> </ul>			Disable Breakpoint		
	Before/After action binding:			Toggle Breakpoint or F5		Pauses debugging before or after binding is executed.
	<ul style="list-style-type: none"> <li>▪ <code>methodAction</code></li> <li>▪ Built-in operations</li> </ul>			Disable Breakpoint		
	Before/After attribute value binding			Page Definition <b>Bindings and Executables</b> tab, Bindings section Breakpoints window <b>Add</b> button		Toggle Breakpoint or F5
Before/After table binding	Page Definition <b>Bindings and Executables</b> tab, Bindings section Breakpoints window <b>Add</b> button	Toggle Breakpoint or F5	Pauses debugging before or after the ADF hierarchical binding's <code>updateValuesFromRows()</code> source code method is executed. New values will be the parameters to <code>updateValuesFromRows()</code> .			
Before/After tree binding	Page Definition <b>Bindings and Executables</b> tab, Bindings section Breakpoints window <b>Add</b> button	Toggle Breakpoint or F5	Pauses in either of these two cases:			
		Disable Breakpoint	<ol style="list-style-type: none"> <li>1. When making a node selection in the tree, pauses debugging before or after the ADF hierarchical binding's <code>updateValuesFromRows()</code> source code method is executed. New values will be the parameters to <code>updateValuesFromRows()</code>.</li> <li>2. When expanding the tree, pauses debugging before or after the ADF tree collection model's <code>modifyExpanded()</code> source code method is executed.</li> </ol>			

**Table 36–1 (Cont.) ADF Declarative Debugger Breakpoints**

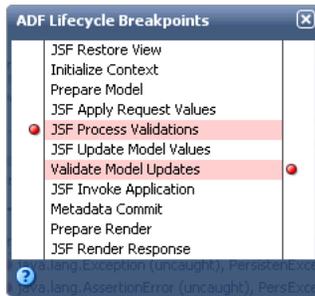

ADF Area	Declarative Breakpoint	JDeveloper Editor	JDeveloper Location	JDeveloper Context Menu Command	Description
ADF page definition - contextual events	Before/After contextual events	Page definition overview editor	Page Definition <b>Contextual Events</b> tab, Events section Breakpoints window <b>Add</b> button	Toggle Breakpoint or F5 Disable Breakpoint	Pauses debugging either before the event is dispatched or after the event, just before the event is consumed by a subscriber to the event.
ADF task flow	Before activity	Task flow diagrammer	Task flow diagrammer Breakpoints window <b>Add</b> button	Toggle Breakpoint or F5 Disable Breakpoint	Pauses debugging before the activity executes within the JSF Invoke Application phase. The activity where the declarative breakpoint is defined has not yet been executed. An exception are view activities; they pause within the JSF Render Response phase after the view activity is executed, but before the new page is rendered. By pausing at that point, the view activity values can be inspected using the ADF Structure and ADF Data windows.

The ADF Declarative Debugger uses the standard debugger icons and notations for setting, toggling, and indicating the status of ADF declarative breakpoints.

When an ADF declarative breakpoint is set, it appears as a red dot icon in the task flow activity, in the page definition breakpoint margins, or in the ADF Lifecycle Breakpoints window, as shown in [Figure 36–21](#), [Figure 36–22](#), [Figure 36–23](#), and [Figure 36–24](#).

**Figure 36–21 ADF Declarative Breakpoint Enabled on a Task Flow Activity****Figure 36–22 ADF Declarative Breakpoints Enabled in the Page Definition Executables****Figure 36–23 ADF Declarative Breakpoint Enabled on a Contextual Event in the Page Definition File**

**Figure 36–24 ADF Lifecycle Phase Breakpoints Enabled in the ADF Lifecycle Breakpoints Window**

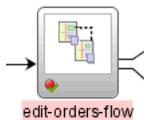

When an ADF task flow or page definition declarative breakpoint is disabled, the red icon becomes a gray icon, as shown in [Figure 36–25](#).

**Figure 36–25 ADF Declarative Breakpoint Disabled**

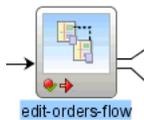

When an ADF task flow declarative breakpoint is active, the red dot icon has a green checkmark, as shown in [Figure 36–26](#).

**Figure 36–26 ADF Declarative Breakpoint Active**

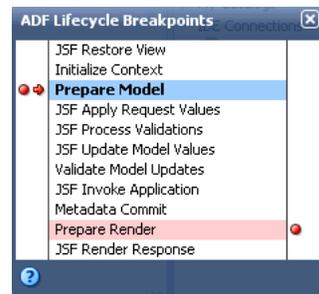

When the application is paused at an ADF declarative breakpoint, an **Execution Point** icon appears, as shown in [Figure 36–27](#).

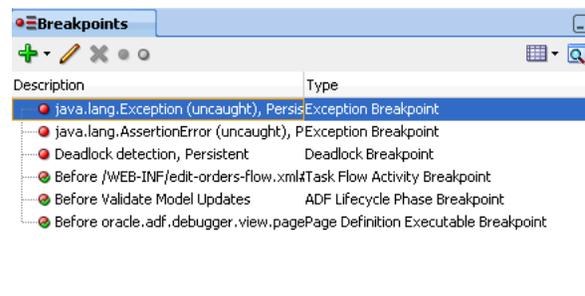

**Figure 36–27 Application Paused at an Execution Point on a Task Flow**

When the application is paused at an ADF lifecycle declarative breakpoint, an **Execution Point** icon appears next to the lifecycle phase in the ADF Lifecycle Breakpoints window, as shown in [Figure 36–28](#). The name of the current ADF lifecycle phase is also displayed in the ADF Structure window.

**Figure 36–28 Application Paused at an Execution Point on an ADF Lifecycle Phase**

The Breakpoints window list all breakpoints, including ADF declarative breakpoints, as shown in [Figure 36–29](#).

**Figure 36–29 Breakpoints Window Showing ADF Declarative and Java Code Breakpoints**

The Breakpoints window has a toolbar that includes buttons to add, edit, delete, enable, and disable breakpoints, as shown in [Figure 36–29](#). The **Add Breakpoint** icon dropdown menu includes functions to create and manage ADF contextual events breakpoints, ADF lifecycle phase breakpoints, ADF page definition breakpoints (for ADF bindings and executables), ADF task flow activity breakpoints, and standard Java code breakpoints.

You can use the Breakpoints window to view the location of the ADF declarative breakpoint in its corresponding source file:

- Double-click a contextual event breakpoint to open the overview editor for the corresponding page definition file. You can then click the Contextual Events tab to view the location of the breakpoint.
- Double-click an ADF lifecycle phase breakpoint to open the ADF Lifecycle Breakpoints window which displays all ADF lifecycle execution points.
- Double-click a task flow activity breakpoint to open the task flow diagrammer for the corresponding task flow.
- Double-click an ADF binding breakpoint to open the overview editor for the corresponding page definition file.

To manage how the debugger handles a breakpoint, you can open the Edit ADF Breakpoint dialog for individual breakpoints that appear in the Breakpoints window. Or, you can select multiple ADF declarative breakpoints and customize the behavior of their common fields.

[Table 36–2](#) lists how an ADF declarative breakpoint will appear in the Breakpoints window under the Description and Type columns.

**Table 36–2 Breakpoints Window Display of ADF Declarative Breakpoints**

Declarative Breakpoint Type	Description Column	Type Column
Before/After contextual event	Before <i>page definition@event name</i> After <i>page definition@event name</i>	Contextual events breakpoint
Before ADF lifecycle phase	Before <i>adf lifecycle phase</i>	ADF lifecycle phase breakpoint
After ADF lifecycle phase	After <i>adf lifecycle phase</i>	ADF lifecycle phase breakpoint
Before/After page definition executable:	Before <i>page definition@executable id</i> After <i>page definition@executable id</i>	Page definition executable breakpoint
<ul style="list-style-type: none"> <li>■ Iterator</li> <li>■ <code>invokeAction</code></li> </ul>		
Before/After page definition action binding:	Before <i>page definition@binding id</i> After <i>page definition@binding id</i>	Page definition binding breakpoint
<ul style="list-style-type: none"> <li>■ <code>methodAction</code></li> <li>■ Built-in Operations</li> </ul>		
Before/After page definition attribute value binding	Before <i>page definition@binding id</i> After <i>page definition@binding id</i>	Page definition binding breakpoint
Before/After page definition table binding	Before <i>page definition@binding id</i> After <i>page definition@binding id</i>	Page definition binding breakpoint
Before/After page definition tree binding	Before <i>page definition@binding id</i> After <i>page definition@binding id</i>	Page definition binding breakpoint
Before ADF task flow activity	Before <i>task flow document#task flow id@activity id</i>	Task flow activity breakpoint

Table 36–3 lists the step commands that can be used with ADF declarative breakpoints.

**Table 36–3 ADF Declarative Debugger Step Commands**

ADF Debugger Step Commands	Description
Find Execution Point	Supported for declarative breakpoints to display the current execution point open and active within the corresponding editor.
Step Over (F8)	<p>Supported for task flow activity declarative breakpoints to step from activity to activity within a task flow. If user interaction is required (for example, page displayed), once it is received (for example, button selected), processing will resume and then will pause before the next task flow activity.</p> <p>supported for page definition executable breakpoints. The application will step to the next page definition executable breakpoint.</p> <p>Supported for ADF lifecycle phase declarative breakpoints to step to the next Before or After ADF lifecycle phase location.</p>
Step Into (F7)	Supported only for task flow activity declarative breakpoints defined on task flow call activities. Task flow activity declarative breakpoints pause the application just before the activity is executed. The Step Into function provides the ability to pause debugging just prior to executing the called task flow default activity. This action would be the same as placing a task flow activity declarative breakpoint on the called task flow default activity.

**Table 36–3 (Cont.) ADF Declarative Debugger Step Commands**

ADF Debugger Step Commands	Description
Step Out (Shift F7)	Supported for task flow activity declarative breakpoints to step out of the current called task flow and back into the caller (if any). If user interaction is required (for example, page displayed) once user interaction received (for example, button selected), processing will resume and will pause before the next user interaction or activity within the calling task flow.
Continue Step (Shift F8)	Not supported for declarative breakpoints.
Step to End of Method	Not supported for declarative breakpoints.
Run to Cursor	Not supported for declarative breakpoints.
Pop Frame	Not supported for declarative breakpoints, as it is for Java code, to return to a previous point of execution.

### 36.9.1 How to Set and Use Task Flow Activity Breakpoints

After you have created a task flow diagram, you can set ADF declarative breakpoints on task flow activities.

#### To set a breakpoint on a task flow activity:

1. Open the task flow in the task flow diagrammer, or from the Breakpoints window, click the **Add** icon and select **ADF Task Flow Activity Breakpoint**.
2. Set the task flow activity breakpoint.
  - If you use the task flow diagrammer, right-click and choose **Toggle Breakpoint** from the context menu, or press F5.  
A breakpoint icon appears on the task flow activity.
  - If you launched the Create ADF Task Flow Activity Breakpoint dialog from the Breakpoints window, click **Browse** to select a task flow definition, select the task flow from the **Task Flow** dropdown list, select the task flow activity from the **Activity** dropdown list, and click **OK**.
3. Optionally, configure a breakpoint's settings to manage the debugger:
  - a. Choose **View > Breakpoints** to open the Breakpoints window.
  - b. Select the task flow activity breakpoint you want to configure and click the **Edit** icon.
  - c. In the Edit ADF Task Flow Activity Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
  - d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.  
  
For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.
4. Start the debugging process.

You can:

- From the main menu, choose **Run > Debug**.

- From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
  - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon appears next to the breakpoint icon on the task flow activity. You can examine the application using different debugger windows.

---

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

---

The application is paused before the task flow activity executes (except for view activities).

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See [Section 36.9.7, "How to Use the ADF Structure Window,"](#) and [Section 36.9.8, "How to Use the ADF Data Window."](#)
7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window. Task flow activity declarative breakpoints pause the application just before the task flow activity is executed. You can use the Step Into (F7) function to pause the application just prior to executing the called task flow default activity.
8. Continue debugging the application as required, using the step functions as described in [Table 36-3](#). The key step function is Step Into (F7).

When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

## 36.9.2 How to Set and Use Page Definition Executable Breakpoints

If your page definition has executables, you can set breakpoints to pause the application before or after these executables. For example, you can set breakpoints to pause the application when iterators are refreshed or when `invokeAction` methods are performed.

---

**Note:** If you are setting an After iterator breakpoint to pause the application after a view object query has been executed, be aware that the application may pause at this breakpoint multiple times. Also be aware that it may pause at this breakpoint even when the query has not been executed. If you need to know whether the query has been executed, select the relevant ADF Business Components in the ADF Structure window and view their corresponding data in the ADF Data window. For more information on how to use these windows, see [Section 36.9.7, "How to Use the ADF Structure Window,"](#) and [Section 36.9.8, "How to Use the ADF Data Window."](#)

For more information about using Java code breakpoints on view object query execution, see [Section 36.10.8, "How to Use Common Oracle ADF Breakpoints."](#)

---

### To set a breakpoint on an executable in the page definition file:

1. In the Application Navigator, double-click the page definition file that contains the executable in which you want to set a breakpoint.
2. In the overview editor, click the **Bindings and Executables** tab, select an executable from the **Executables** list, and click in the breakpoint margin to the left of the item.

A breakpoint icon appears in the margin next to the item.

3. Optionally, configure a breakpoint's settings to manage the debugger:
  - a. Choose **View > Breakpoints** to open the Breakpoints window.
  - b. Select the executable breakpoint you want to configure and click the **Edit** icon.
  - c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
  - d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process.

You can:

- From the main menu, choose **Run > Debug**.
  - From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
  - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon appears in the margin next to the breakpoint icon of the executable item. You can examine the application using several debugger windows.

The application pauses when the executable binding is refreshed. If this is a taskFlow executable, the pause occurs in the `prepareModel` and the `prepareRender` lifecycles.

---

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Executable Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

---

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See [Section 36.9.7, "How to Use the ADF Structure Window,"](#) and [Section 36.9.8, "How to Use the ADF Data Window."](#)
7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
8. When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 36.9.3 How to Set and Use Page Definition Action Binding Breakpoints

You can set breakpoints in the page definition file on action bindings and `methodAction` bindings. The application pauses when the binding is executed.

#### To set a breakpoint on an action binding in the page definition file:

1. In the Application Navigator, double-click the page definition file that contains the binding in which you want to set a breakpoint.
2. In the overview editor, click the **Bindings and Executables** tab, select a `methodAction` binding or built-in operation item from the **Bindings** list, and click in the breakpoint margin to the left of the item.

A breakpoint icon appears next to the item.

3. Optionally, configure a breakpoint's settings to manage the debugger:
  - a. Choose **View > Breakpoints** to open the Breakpoints window.
  - b. Select the action binding breakpoint you want to configure and click the **Edit** icon.
  - c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
  - d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process.

You can:

- From the main menu, choose **Run > Debug**.
- From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.

- From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon appears next to the breakpoint icon on the action binding item. You can examine the application using several debugger windows.

The application is paused when the binding is executed.

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See [Section 36.9.7, "How to Use the ADF Structure Window,"](#) and [Section 36.9.8, "How to Use the ADF Data Window."](#)
7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
8. When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 36.9.4 How to Set and Use Page Definition Value Binding Breakpoints

If the page definition has one of these values bindings, you can set breakpoints to pause the application:

- Attribute value binding
- Tree value binding
- Table value binding

#### To set a breakpoint on a value binding in the page definition file:

1. In the Application Navigator, double-click the page definition file that contains the binding in which you want to set a breakpoint.
2. In the overview editor, click the **Bindings and Executables** tab, select an attribute, tree, or table binding from the **Bindings** list, and click on the breakpoint margin to the left of the item. A breakpoint icon appears next to the value binding.
3. Optionally, configure a breakpoint's settings to manage the debugger:
  - a. Choose **View > Breakpoints** to open the Breakpoints window.
  - b. Select the binding breakpoint you want to configure and click the **Edit** icon.
  - c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
  - d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process.

You can:

- From the main menu, choose **Run > Debug**.
  - From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
  - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon appears next to the breakpoint icon on the attribute value binding. You can examine the application using several debugger windows.

The application pauses before an appropriate method of the ADF source code, as described in [Table 36-1](#). New values will be the parameters that go into the method.

---

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

---

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See [Section 36.9.7, "How to Use the ADF Structure Window,"](#) and [Section 36.9.8, "How to Use the ADF Data Window."](#)
7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
8. Continue debugging the application as required, using the step functions as described in [Table 36-3](#). The key step function is Step Over (F8).

When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 36.9.5 How to Set and Use Page Definition Contextual Event Breakpoints

If the page definition defines contextual events, you can set breakpoints on the contextual events to pause the application.

**To set a breakpoint on a contextual event in the page definition file:**

1. In the Application Navigator, double-click the page definition file that contains the binding in which you want to set a breakpoint.
2. In the overview editor, click the **Contextual Events** tab, select a contextual event from the **Events** list, and click on the breakpoint margin to the left of the item. A breakpoint icon appears next to the contextual event.
3. Optionally, configure a breakpoint's settings to manage the debugger:

- a. Choose **View > Breakpoints** to open the Breakpoints window.
- b. Select the contextual event breakpoint you want to configure and click the **Edit** icon.
- c. In the Edit ADF Contextual Events Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
- d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process.

You can:

- From the main menu, choose **Run > Debug**.
  - From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
  - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon appears next to the breakpoint icon on the contextual event. You can examine the application using several debugger windows.

The application pauses before the contextual event is raised.

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See [Section 36.9.7, "How to Use the ADF Structure Window,"](#) and [Section 36.9.8, "How to Use the ADF Data Window."](#)
7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
8. Continue debugging the application as required, using the step functions as described in [Table 36-3](#). The key step function is Step Over (F8).

When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 36.9.6 How to Set and Use ADF Lifecycle Phase Breakpoints

You can set both Before and After ADF lifecycle phase breakpoints on any of the ADF lifecycle phases. For each phase, you can set Before only, After only, or both. You can set breakpoints on as many phases as you want.

You can create the breakpoint and customize the options using the Create ADF Lifecycle Phase Breakpoint dialog from the Breakpoints window menu. Or You can create breakpoints with the default options using the ADF Lifecycle Breakpoints window. After a lifecycle breakpoint has been set, you can edit the options using the Edit ADF Lifecycle Phase Breakpoint dialog, which is also launched from the Breakpoints window.

You can set ADF lifecycle breakpoints on any of the ADF lifecycle phases:

- JSF Restore View
- Initialize Content
- Prepare Model
- JSF Apply Request Values
- JSF Process Validations
- JSF Update Model Values
- Validate Model Updates
- JSF Invoke Application
- Metadata Commit
- Prepare Render
- JSF Render Response

**To set or manage an ADF lifecycle phase breakpoint from the Breakpoints window:**

1. Choose **View > Breakpoints** to open the Breakpoints window.
2. Click the **Add** icon and choose **ADF Lifecycle Phase Breakpoint**.
3. In the Create ADF Lifecycle Phase Breakpoint dialog **Definition** tab:
  - Select the ADF lifecycle phase where you want to set a breakpoint
  - Select **Before Phase** or **After Phase** breakpoint
4. In the **Conditions** tab, select the options you want and click **OK**.
5. In the **Actions** tab, select the options you want and click **OK**.

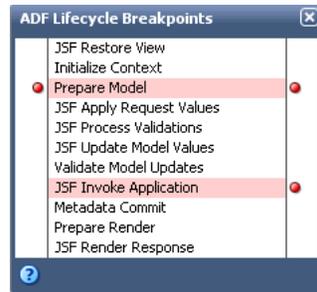

**To set an ADF Lifecycle Phase Breakpoint using the breakpoint icon:**

1. In the task flow diagrammer or in the ADF Structure window, click the **ADF Lifecycle Breakpoints** icon, as shown in [Figure 36–30](#).

**Figure 36–30 ADF Lifecycle Breakpoints Icon**

2. In the ADF Lifecycle Breakpoints window, click on the left margin next to the ADF lifecycle phase to set a Before breakpoint, and on the right margin to set an After breakpoint. A red dot icon appears to indicate the breakpoint is set, as shown in [Figure 36–31](#). The breakpoint will be set with the default breakpoint options. To remove the breakpoint, click the red dot icon.

**Figure 36–31** Setting Breakpoints in the ADF Lifecycle Breakpoints Window

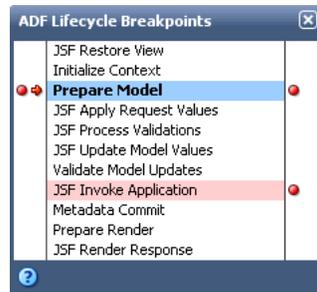

3. If you want to edit breakpoint options, select the breakpoint in the Breakpoints window and choose the **Edit** icon.

### To debug an application using ADF Lifecycle Phase Breakpoints:

1. Start the debugging process.

You can:

- From the main menu, choose **Run > Debug**.
  - From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
  - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
2. When the application is paused at an ADF lifecycle phase breakpoint, an **Execution Point** icon appears next to the breakpoint icon and the ADF lifecycle phase is in bold in the ADF Lifecycle Breakpoints window, as shown in [Figure 36–32](#). You can examine the application using several debugger windows.

**Figure 36–32** Execution Point Displayed in the ADF Lifecycle Breakpoints Window

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window for an breakpoint encounter or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

3. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. The current ADF lifecycle phase is displayed at the top of the ADF Structure window.

For more information, see [Section 36.9.7, "How to Use the ADF Structure Window,"](#) and [Section 36.9.8, "How to Use the ADF Data Window."](#)

4. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
5. Continue debugging the application as required, using the step functions as described in [Table 36–3](#). The key step function is Step Over (F8).

When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 36.9.7 How to Use the ADF Structure Window

When the application is paused at a breakpoint, the ADF Structure window displays a tree structure of the ADF runtime objects and their relationships within the application. In particular, it shows the hierarchy of view ports, which represent either the main browser window or contained regions and portlets. When you select different items in the ADF Structure window, the data display in the accompanying ADF Data window changes. For more information about the ADF Data window, see [Section 36.9.8, "How to Use the ADF Data Window."](#)

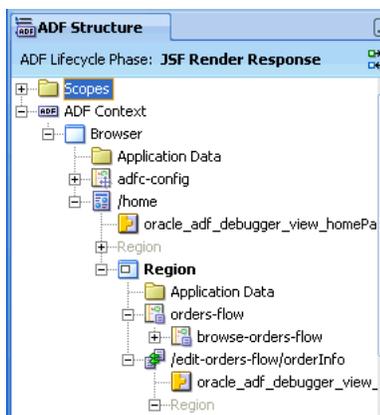

The ADF Structure window and the ADF Data window are shown by default during a debugging session when either of the following is true:

- The project being debugged contains a `WEB-INF/adfc-config.xml` file.
- The project being debugged contains any ADF Faces tag libraries.

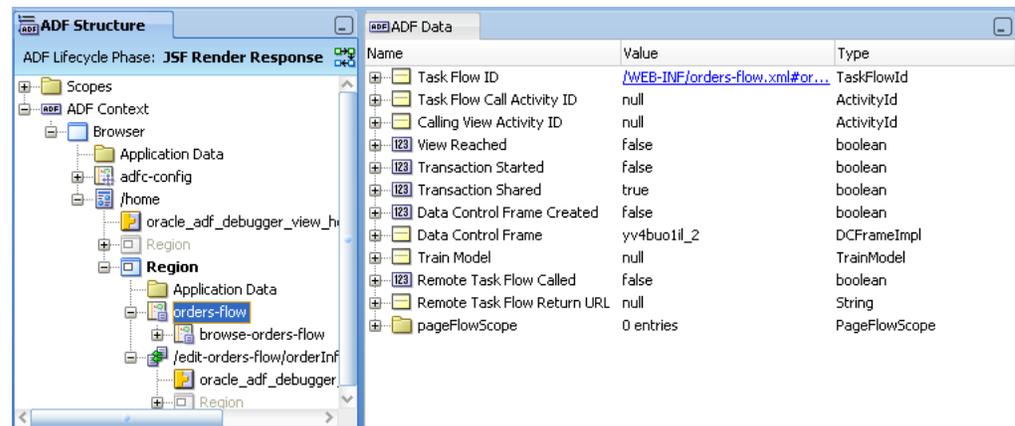

You can launch the ADF Structure window by choosing **View > Debugger > ADF Structure** from the main menu. From the ADF Structure window, you can launch the ADF Lifecycle Breakpoints window using the **ADF Lifecycle Breakpoints** icon.

When a breakpoint is encountered, the ADF Structure window displays the ADF lifecycle phase and a tree structure of the runtime objects, as shown in [Figure 36–33](#).

**Figure 36–33 ADF Structure Window Showing the Runtime Objects**

When you select an item in the ADF Structure window, the data and values associated with that item are displayed in the ADF Data window. [Figure 36–34](#) shows a task flow selected in the ADF Structure window, with its corresponding information displayed in the ADF Data window.

**Figure 36–34 ADF Structure Window Selection and ADF Data Window Data**

The roots of the hierarchy are the sibling nodes **Scopes** and **ADF Context**. The current view port where processing has stopped appears in bold. Default selections within the tree will be retained from the previous breakpoint, so you can monitor any changes between breakpoints. The ADF object where the ADF declarative breakpoint was defined will be opened in the corresponding JDeveloper editor, either the task flow diagrammer or the overview editor for page definition files.

The ADF Structure tree will be rebuilt each time the application breaks and at subsequent steps to reflect the changed state of the objects. Although the entire tree hierarchy will be displayed, only items within the current view port and its parent view port(s) will be available for selection and further inspection. All other items in the tree hierarchy not in the current context will be dimmed and disabled. You can still use the hierarchy to identify runtime object relationships within the application, but it will be limited to the current context (and its parent view ports).

Table 36–4 lists the different types of items that can be displayed in the ADF Structure window hierarchy tree.

**Table 36–4 ADF Structure Window Items**

ADF Structure Tree Item	Description
Scopes	Displayed at the top of the ADF Structure hierarchy above its sibling <b>ADF Context</b> node. There is only one <b>Scopes</b> node in the ADF Structure hierarchy. You can expand the <b>Scopes</b> node to show a list of child scope nodes (such as <b>viewScope</b> and <b>pageFlowScope</b> ). If you select a child scope node, the ADF Data window displays the variables and values for that scope.
ADF context	Displayed as the root node of the ADF Structure hierarchy below its sibling <b>Scopes</b> node. There will only be one <b>ADF Context</b> within the ADF Structure hierarchy.
View port	View ports are an ADF Controller concept. For this reason, view ports appear within the ADF Structure hierarchy only when the application being debugged utilizes ADF Controller. View ports can represent one of the following: <ul style="list-style-type: none"> <li>■ Browser: Main browser view ports, also known as root view ports, appear as children of the root <b>ADF Context</b>. If multiple browser windows are open during the debugging runtime session, multiple browser view ports are presented within the hierarchy. The label of each browser view port displays the text "Browser". The view port also provides a tooltip for the view port ID similar to the following example: "Root View Port: 999999".</li> <li>■ Region: Region view ports appear as the children of page or page fragments. They are also known as child view ports. The label of each region view port displays the text "Region". The region also provides a tooltip for the view port ID similar to the following example: "Child View Port: 999999".</li> </ul>
ADF task flows	The page flow stack corresponding to each view port appears as a hierarchy of ADF task flows. The initial ADF task flow called for the stack is a direct child of its corresponding view port. The label of each ADF task flow reflects the corresponding ADF task flow display name (if any) or its task flow ID. Region view ports will not display the item in their page flow stack hierarchy for their implied unbounded task flow. The task flow also provides a tooltip displaying the ADF task flow path, and a context menu item to open to the corresponding ADF task flow within the editor workspace.  If ADF Controller is not utilized in the application (or if the page is run outside the context of an ADF task flow), ADF task flows will not appear within the hierarchy.
Page	Represents the page (view) currently displayed within a browser view port. Presented along with its associated binding container (if any) as a child. If the application being debugged utilizes ADF Controller, pages will be children of each browser view port. The label of each page reflects its corresponding runtime view ID. The page also provides a tooltip displaying the page path, and a context menu item to open to the corresponding page within the editor workspace. If a visual user interface is not implemented for the application, the page will not appear within the hierarchy.
Page fragment	Represents the page fragment currently displayed within a region view port. Presented along with its associated binding container (if any) as a child. If the application being debugged utilizes ADF Controller, page fragments will be children of each region view port. The label of each page fragment node reflects its corresponding runtime view ID. The page fragment also provides a tooltip displaying the source file page definition path, and a context menu item to open to the corresponding page fragment within the editor workspace.
Binding container	Represents the binding container for the corresponding page or page fragment. The label of each binding container reflects its corresponding file name (page definition file) without the extension. The binding container node will also provide a tooltip displaying the page fragment path. The binding container also appears under current task flows when used to represent task flow activity bindings (for example, method call activity bindings).  If ADF Model is not utilized for the application, binding containers will not appear.
Application data	Represents the application data objects (for example, ADF Business Components objects or ADF Business Components business service objects) instantiated within the data control frame for the corresponding view port (or binding container if ADF Controller is not used). Application data objects don't need to be currently instantiated for the Application Data node to appear.

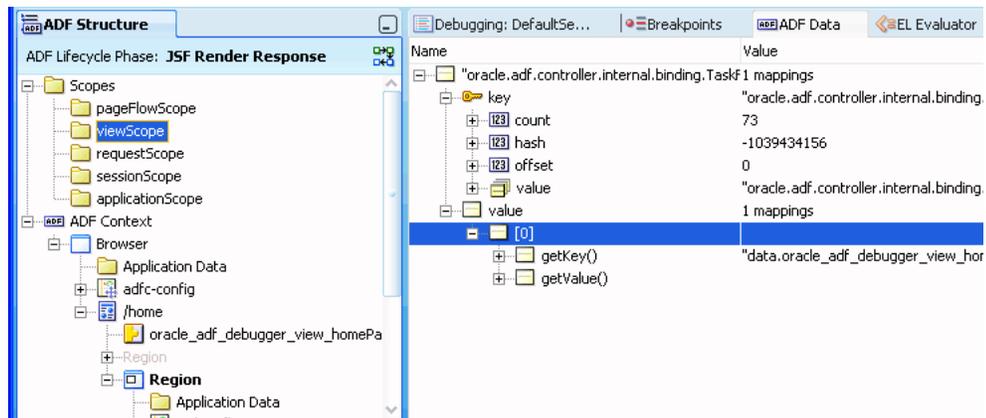

### 36.9.8 How to Use the ADF Data Window

When an application is paused at an ADF declarative breakpoint, the ADF Data window displays relevant data based on the selection in the ADF Structure window. You can launch the ADF Data window by choosing **View > Debugger > ADF Data** from the main menu. The content of the ADF Data window based on the selection in the ADF Structure window is summarized in [Table 36–5](#).

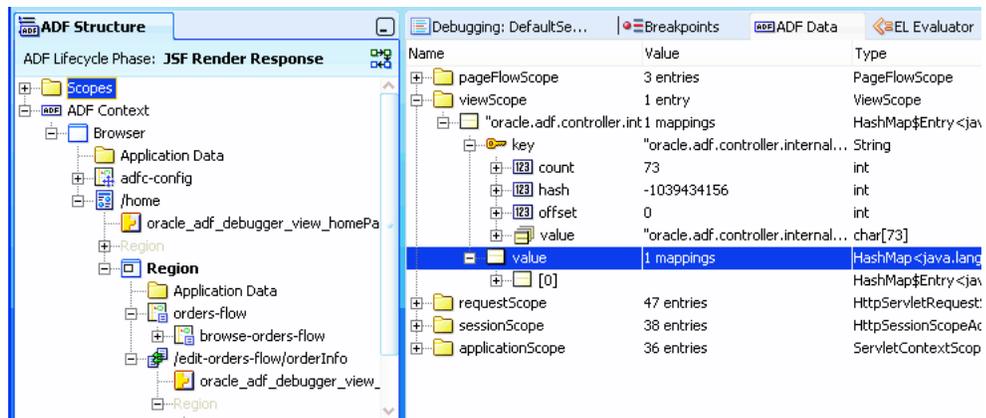

**Table 36–5 ADF Data Window Content for an ADF Structure Window Selection**

ADF Structure Window	ADF Data Content
Scopes	Displays memory scope values based on the current context. <code>pageFlowScope</code> will also appear within ADF task flow content for the <code>pageFlowScope</code> values specific to a selected ADF task flow (not necessarily the current context). <code>viewScope</code> will also appear within the view port content for the <code>viewScope</code> values specific to a selected view port (not necessarily the current context).
ADF context	Displays the ADF context variables and values hierarchy. ADF context variables and values can be inspected by evaluating the <code>#{data.adfContext}</code> EL expression in the EL Evaluator.
View port	Displays view port details, including the <code>viewScope</code> contents.
Page flow stack entry	Displays information for the selected page flow stack entry, including current transaction status and ADF Model save point status.
Page/page fragment	Displays the page or page fragment UI component tree hierarchy for the selected page or page fragment if the page or page fragment has been rendered.
Binding container	Displays the binding container runtime values, including parameters, bindings, and executables.
Application data	Displays application data objects (for example, ADF Business Components objects) instantiated within the current binding context. If the business service layer is implemented with a technology other than ADF Business Components objects (for example, EJB) the application data objects will be displayed in a more generic form.

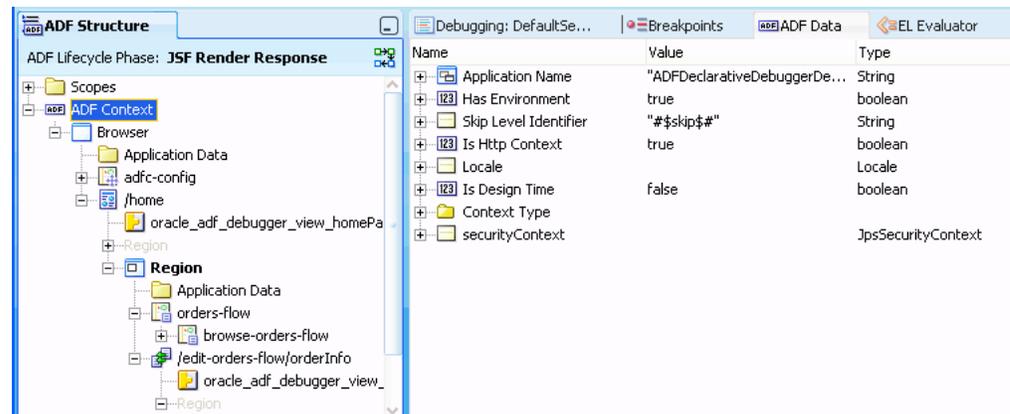

The **Scopes** node in the ADF Structure window can be expanded to show a list of child scope nodes. When a child scope node is selected in the ADF Structure window, the ADF Data window displays the current context values for the selected memory scope, as shown in [Figure 36–35](#).

**Figure 36–35 Child Scope Selected in the ADF Structure Window**

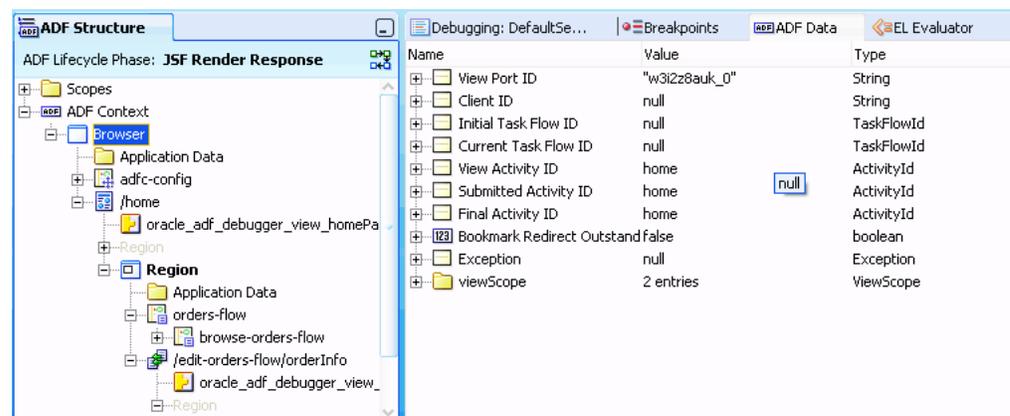

If the **Scopes** node itself is selected, then the full list of memory scopes appears also in the ADF Data windows, which can also be expanded for inspection. [Figure 36–36](#) shows the **Scopes** node selected in the ADF Structure window, and the **viewScope** child node being selected with its values displayed in the ADF Data window. You can inspect the values of `requestScope`, `viewScope`, `pageFlowScope`, `applicationScope`, and `sessionScope` by expanding each corresponding node. `pageFlowScope` will also appear within the ADF Task Flow content to reflect the values of the specific ADF task flow currently selected in the ADF Structure window. `viewScope` will also appear within the view port content to reflect the values of the specific view port currently selected in the ADF Structure window.

**Figure 36–36 Scopes Node Selected in the ADF Structure Window**

When the ADF context is selected in the ADF Structure window, as shown in [Figure 36–37](#), the current value of the ADF context variables will be displayed in the ADF Data window. You can also inspect ADF context variables and values by evaluating the `#(data.adfContext)` EL expression in the EL Evaluator. For more information, see [Section 36.8.4, "How to Use the EL Expression Evaluator."](#)

**Figure 36–37 ADF Context Selected for the ADF Data Window**

Selecting a view port within the ADF Structure hierarchy will display the view port's current view port details in the ADF Data window, as shown in Figure 36–38. Values displayed for each view port are summarized in Table 36–6.

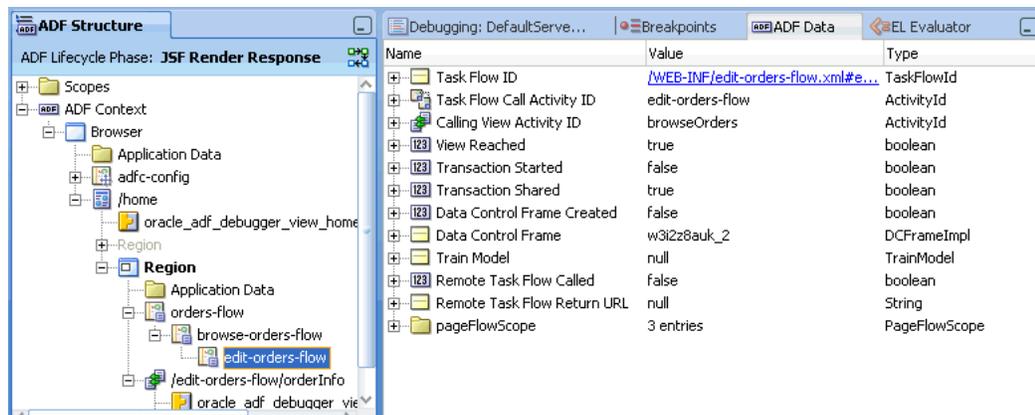

**Figure 36–38 View Port Selected for the ADF Data Window****Table 36–6 ADF Data Window Content for View Port**

View Port	Description
View port ID	It is displayed
Client ID	It is displayed
Initial task flow ID	Initial ADF task flow on the view ports page flow stack. Not displayed for unbounded task flows. Appears as a link to open the corresponding task flow definition in the editor workspace.
Current task flow ID	Displayed for bounded task flows and not displayed for unbounded task flows. Current ADF task flow on the view port's page flow stack. Appears as a link to open the corresponding task flow definition in the editor workspace.
View activity ID	Current ADF task flow view activity ID. Applicable only if the current ADF task flow activity is a view activity.
Submitted activity ID	ADF task flow activity submitting the current request.
Final activity ID	ADF task flow activity receiving the current request.
Bookmark redirect outstanding	(Boolean)

**Table 36–6 (Cont.) ADF Data Window Content for View Port**

View Port	Description
Exception	(If any)
View memory scope	View memory scope variables and values for the selected view port.

In the ADF Structure window, each individual ADF task flow within a page flow stack hierarchy is selectable. An ADF task flow selected in the ADF Structure window will display the current task flow information in the ADF Data window, as shown in [Figure 36–39](#). Task flow templates utilized by the selected ADF task flow will be determined by manually navigating to the ADF task flow source file. This is the same way similar functionalities are handled for Java source files. Current information for a selected ADF task flow is summarized in [Table 36–7](#).

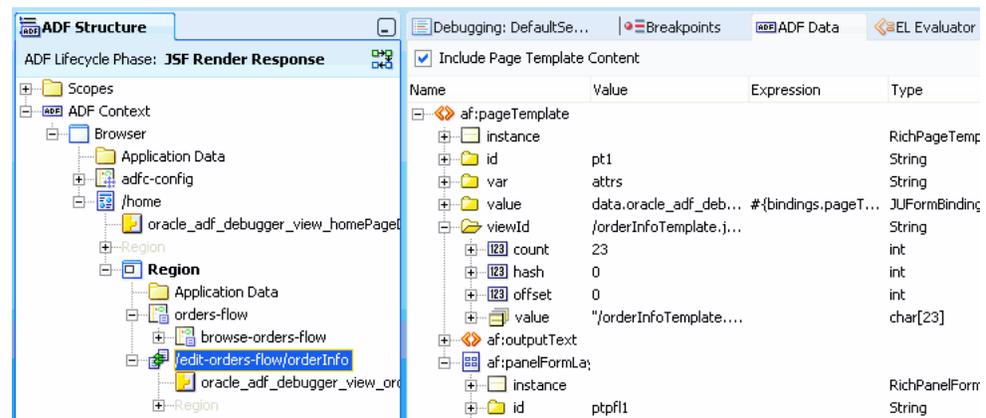

**Figure 36–39 Task Flow Selected for the ADF Data Window****Table 36–7 ADF Data Window Content for Task Flow**

Task Flow	Description
ADF task flow reference	ADF task flow reference
Task flow call activity ID	Task flow activity ID for the calling task flow. Will be null for the first ADF task flow within each view port task flow call hierarchy.
Calling view activity ID	The calling view activity of the current view activity displayed by the ADF task flow, if any.
View reached	(Boolean)
Train model	Only applicable if the ADF task flow is created as a train.
Transaction started	(Boolean) Identifies the current status of the ADF task flow transactional state. For example, did the ADF task flow begin a new transaction?
Transaction shared	(Boolean) Identifies the current status of the ADF task flow transactional state. For example, did the ADF task flow join an existing transaction?
Save point	Identifies the current status of the ADF task flow's ADF Model save point creation state. For example, was a model save point created upon ADF task flow entry?.
Remote task flow called	(Boolean)

**Table 36–7 (Cont.) ADF Data Window Content for Task Flow**

Task Flow	Description
Remote task flow return URL	Applies only when calling an ADF task flow remotely. Identifies the URL for return once the task flow called remotely completes.
Data control frame created	(Boolean)
Data control frame	Name of data control frame associated with the ADF task flow.
Page flow memory scopes	Appears as an expandable node to allow inspection of the values of the page flow memory scopes for the task flow selected in the ADF Structure window.  The page flow memory scopes will also be displayed within the ADF Structure window's <b>Scopes</b> node. However, the page flow memory scope for the <b>Scopes</b> node will always be based on the application's current context, not the selected task flow.

When you select a page or page fragment node in the ADF Structure hierarchy, the corresponding UI component tree is displayed within the ADF Data window, as shown in [Figure 36–40](#). If a page or page fragment is based on a page template, you can include the content coming from the page template outside any facet reference elements by selecting the **Include Page Template Content** checkbox at the top of the ADF Data window. If the page template content is not included, the page or page fragment UI component tree will appear structurally similar to its source file.

**Figure 36–40 Page Selected for the ADF Data Window**

When you select a binding container in the ADF Structure hierarchy, it displays within the ADF Data window the node selection listed in [Table 36–8](#).

**Table 36–8 ADF Data Window Content for Binding Container**

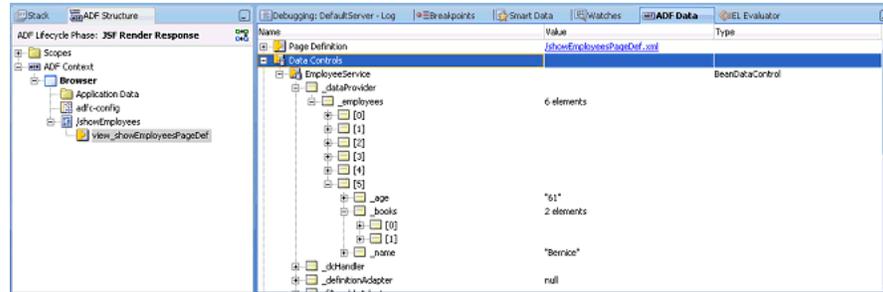

Binding Container	Description
Page definition link	Navigates to the corresponding page definition source file and opens it within the editor workspace.

**Table 36–8 (Cont.) ADF Data Window Content for Binding Container**

Binding Container	Description
Data Controls	<p data-bbox="683 260 1170 287">Displays the binding container's data controls.</p> <p data-bbox="683 302 1341 590">Data controls implemented by ADF Business Components objects and non-ADF Business Components objects will be presented slightly different. ADF Business Components-based data controls will appear similar to the actual business service implementation using row collections. Non-ADF Business Components-based data controls will typically appear as raw member variables similar to what is displayed in the ADF Declarative Debugger Data window. The ADF Data window shows only cached information such as member variables and arrays. Standard debugger functionality can also be used to customize each element.</p> <p data-bbox="683 604 1341 659">Each ADF Business Components data control will display the following information:</p> <ul data-bbox="683 674 1325 989" style="list-style-type: none"> <li>■ Row collections</li> <li>■ Query string for each row collection</li> <li>■ Query string with variable substitution for each row collection</li> <li>■ Application data rows</li> <li>■ Current row indicator</li> <li>■ Change indicator</li> <li>■ Current and original values (if changed within the same request)</li> </ul>
Parameters	Current values of all binding container parameters.
Executables	<p data-bbox="683 1052 1365 1136">Displays executables showing current row indicators, and current and original values (if changed within the same request). This includes the following types of executables:</p> <ul data-bbox="683 1150 1365 1440" style="list-style-type: none"> <li>■ Iterator - presents corresponding attribute bindings along with their <code>Refresh</code> and <code>RefreshCondition</code> properties.</li> <li>■ task flow - current value of the task flow ID assigned to the task flow binding and all of its associated parameter values. Task flow IDs will appear as links navigating to open the corresponding task flow definition source file within the editor workspace. Link text consists of <code>&lt;task flow source document&gt;#&lt;task flow id&gt;</code>.</li> <li>■ Search region - presented similar to iterators, but also displays criteria and criteria with substitution information.</li> </ul>
Bindings	<p data-bbox="683 1461 1349 1516">Displays value, table, tree, and method bindings. Each binding will display the following information:</p> <ul data-bbox="683 1530 1325 1656" style="list-style-type: none"> <li>■ Associated executables</li> <li>■ Change indicator</li> <li>■ Current and original values (if changed within the same request)</li> </ul>
Binding container of page template	If the corresponding page or page fragment utilized a page template, the binding container of the page template will appear as a child of page or page fragment binding container content.

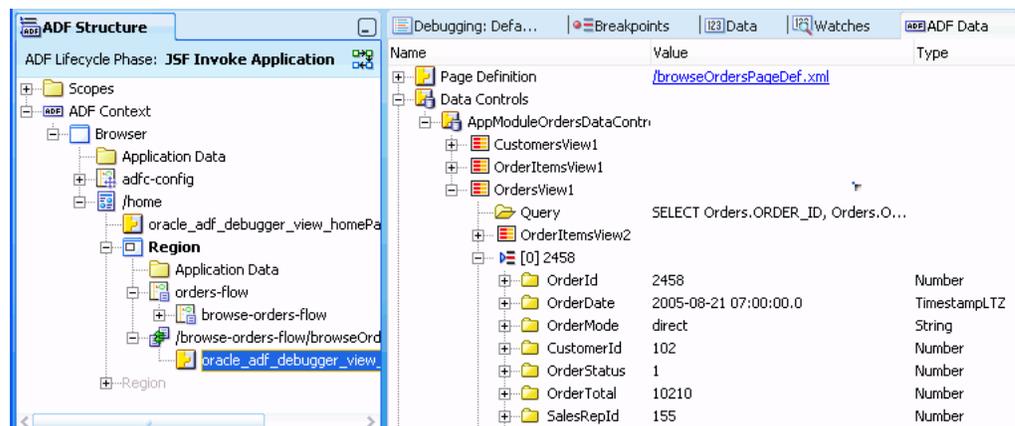

When you select a binding container for an application based on non-ADF Business Components objects, the ADF Data window displays the binding container content, as shown in Figure 36–1.

**Figure 36–41 Binding Container (Non-Business Components) Selected for the ADF Data Window**

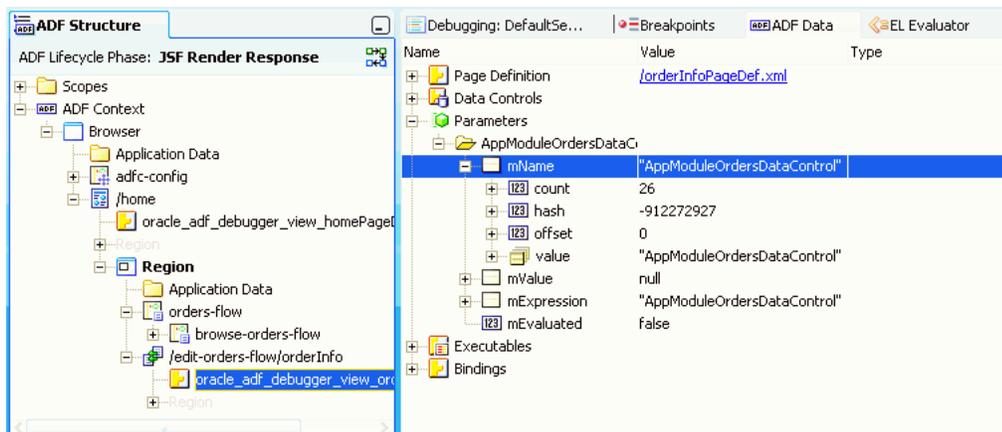

When you select a binding container for an application based on ADF Business Components objects, the ADF Data window displays standard row collection icons, as shown in Figure 36–2.

**Figure 36–42 Binding Container (Business Components) Selected for the ADF Data Window**

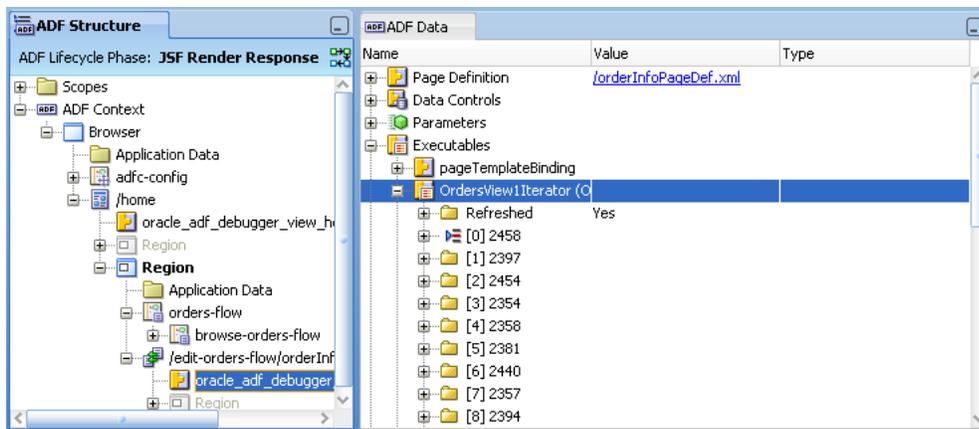

Expanding the Parameters node in the ADF Data window displays information similar to that shown in Figure 36–43.

**Figure 36-43 Parameters Selected for the ADF Data Window**

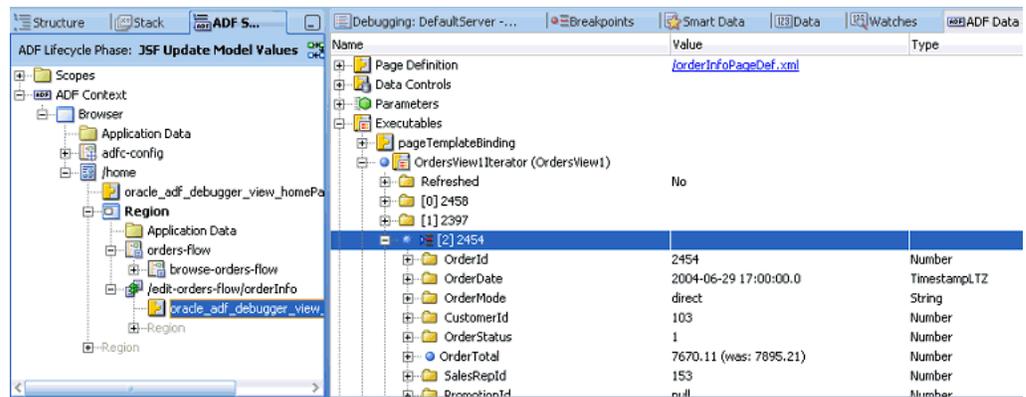

Expanding the Executables node in the ADF Data window displays information similar to that shown in Figure 36-44.

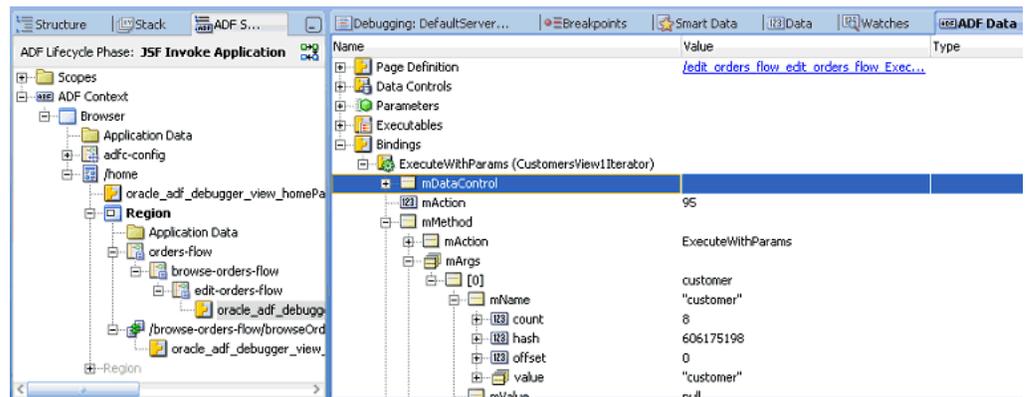

**Figure 36-44 Executables Selected for the ADF Data Window**

If a value has changed, the changed item will be marked with a blue dot to its left and the previous value is displayed in parenthesis. For instance, suppose the OrderTotal value has changed from 7895.81 to 7670.11. The ADF Data window places a blue dot next to OrderTotal and its parent OrdersView1Iterator and displays the current and previous values in the Value column, as shown in Figure 36-45.

**Figure 36–45 A Value Change Is Indicated by a Blue Dot in the ADF Data Window**

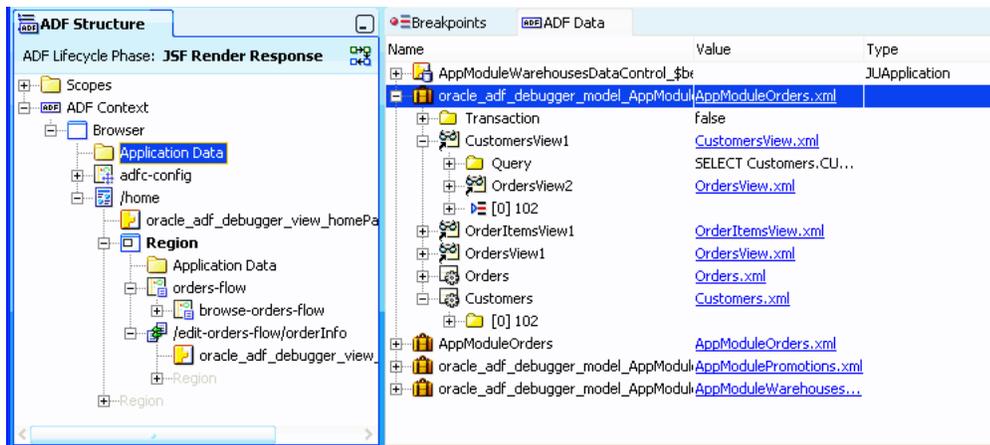

Method binding information is displayed in the ADF Data window similar to what is shown in [Figure 36–46](#).

**Figure 36–46 Method Bindings Selected for the ADF Data Window**

When you select an Application Data node from the ADF Structure window, the ADF Data window displays the application objects, such as ADF Business Components objects, instantiated within the current data control frame for the corresponding view port (or binding context if ADF Controller is not used).

Business services implemented by ADF Business Components objects display the application data content, as shown in [Figure 36–47](#) and described in [Table 36–9](#).

**Figure 36–47 Application Data for ADF Business Components Business Services**

**Table 36–9 ADF Data Window Content for Application Data**

Binding Container	Description
Application module	<p>The application module(s) of the corresponding view port data control frame will appear within the application data hierarchy as the root node(s). An application module design time icon will be used to identify the node(s). The application module node(s) will provide the following information:</p> <ul style="list-style-type: none"> <li>Application module link - link to open the corresponding application module source file within the editor workspace.</li> <li>Transaction - the application module current transaction status, if applicable.</li> <li>View objects</li> <li>Entity objects</li> </ul>

**Table 36–9 (Cont.) ADF Data Window Content for Application Data**

Binding Container	Description
View object	<p>View objects instantiated within the corresponding view port data control frame will appear underneath the corresponding application module root node as subordinate nodes. Design time icons will be used to identify them. Child view objects will appear subordinate to their parent view objects within the hierarchy. Named row sets will appear similar to view objects. Named iterators for a view object will appear similar to child view objects. Each view object node will provide the following information:</p> <ul style="list-style-type: none"> <li>■ View object link - link to open the corresponding view object source file within the editor workspace.</li> <li>■ Query - last executed view object SQL statement. Displays bind variables without value substitution.</li> <li>■ Query with substitution - last executed view object SQL statement. Displays bind variables with value substitution.</li> <li>■ Bind variables - last executed view object SQL statement bind variables and their values.</li> <li>■ View object rows - each row displayed will be identified by its concatenated key values. The current row will be identified with a special icon.</li> <li>■ Attributes - attributes contained on each row will display their current values along with their originating entity object. Transient attributes will also be displayed.</li> <li>■ Modifications - changes made within the same request will be identified by a blue dot to left of attribute, row, and view objects node labels. Both the old and new value of the modification will be displayed.</li> </ul>
Entity object	<p>Entity objects instantiated within the corresponding view port data control frame will appear underneath the application module root node as subordinate nodes. Design time icons will be used to identify them. Each entity object node will provide the following information:</p> <ul style="list-style-type: none"> <li>■ Entity object link - link to open the corresponding entity object source file within the editor workspace.</li> <li>■ Entity object rows - each row displayed will be identified by its concatenated key values. The current entity-state and post-state of the row (e.g., <code>STATUS_MODIFIED</code>) will also be presented.</li> <li>■ Attributes - attributes contained on each row will display their current values.</li> <li>■ Modifications - changes made within the same request will be identified by a blue dot to left of attribute, row, and entity objects node labels. Both the old and new value of the modification will be displayed.</li> </ul>

Business services implemented by non-ADF Business Components objects display application data content using raw member variables. The format is similar to the display of non-ADF Business Components content for the binding container, as shown in [Figure 36–41](#).

### 36.9.9 What Happens When You Set an ADF Declarative Breakpoint

When you set an ADF declarative breakpoint, JDeveloper adds the breakpoint to the appropriate class, method, or other construct in the ADF source Java code that

corresponds to the breakpoint. Once the breakpoint is set in the code, the standard Java debugger mechanism pauses application execution when the breakpoint is reached. When the breakpoint is reached, it will be identified by a red dot icon in the Breakpoints window. Depending on the type of declarative breakpoint that was reached, it will also appear as a red dot icon in the task flow activity, in the page definition breakpoint margins, or in the ADF Lifecycle Breakpoints window.

For task flow activity breakpoints, the debugger pauses the application within the JSF Invoke Application phase before the activity where the breakpoint is set. In other words, the activity where the breakpoint is set is not executed.

For task flow view activities, however, the application is paused within the JSF Render Response phase after the view activity is executed, but before the new page is rendered.

For a page definition Before executable breakpoint, the debugger pauses the application when the executable is refreshed. For a page definition Before action binding breakpoint, the debugger pauses the application when the binding is executed. For a page definition Before attribute value binding breakpoint, the debugger pauses the application before the attribute's `setInputValue()` method in the ADF source code is executed.

For a Before lifecycle breakpoint, the debugger pauses the application before it enters the next lifecycle phase. For an After lifecycle breakpoint, the debugger pauses the application after the lifecycle phase and before the next phase.

## 36.10 Setting Java Code Breakpoints

You can use the ADF Declarative Debugger to set breakpoints on Java classes and methods, as in any standard Java code debugger. You can use Java code breakpoints in combination with ADF declarative breakpoints or by themselves. For most ADF applications, ADF declarative breakpoints will provide enough debugging information to troubleshoot the application. For information about using ADF declarative breakpoints, see [Section 36.9, "Setting ADF Declarative Breakpoints."](#) However, you may need to set breakpoints on specific classes or methods for further inspection. Or, you may be debugging a non-ADF application, in which case, you can use Java code breakpoints.

JDeveloper provides a class locator feature that assists you in finding the class you want to break on. If you can obtain Oracle ADF source code, you can enhance your debugging by having access to various ADF classes and methods. For more information about getting ADF source code, see [Section 36.8.1, "Using ADF Source Code with the Debugger."](#) If you obtained the ADF source, you can further enhance the debugging experience by using the debug library version of the ADF source, as described in [Section 36.10.4, "How to Use Debug Libraries for Symbolic Debugging."](#)

### 36.10.1 How to Set Java Breakpoints on Classes and Methods

You can set Java breakpoints on your classes and methods. If you have ADF source code, you can set Java breakpoints in the source as well. If you are debugging an ADF application, you should check to see whether ADF declarative breakpoints can be used instead of Java code breakpoints. For more information, see [Section 36.9, "Setting ADF Declarative Breakpoints."](#)

Before you attempt to use breakpoints, you should try to run the application and look for missing or incomplete data, actions and methods that are ignored or incorrectly executed, or other unexpected results. If you did not find the problem, create a debugging configuration that will enable the ADF Log and send Oracle ADF messages

to the Log window. For more information, see [Section 36.6.3, "How to Create an Oracle ADF Debugging Configuration."](#)

**To set Java breakpoints to debug an application:**

1. From the main menu, choose **Navigate > Go to Java Type** (or press Ctrl+Minus) and use the dialog to locate the Oracle ADF class that represents the entry point for the processing failure.

---

---

**Note:** JDeveloper will locate the class from the user interface project with current focus in the Application Navigator. If your workspace contains more than one user interface project, be sure that the one with the current focus is the one you want to debug.

---

---

2. Open the class file in the source editor and find the Oracle ADF method call that will enable you to step into the statements of the method.
3. Set a breakpoint on the desired method and run the debugger.
4. When the application stops on the breakpoint, use the Data window to examine the local variables and arguments of the current context.

**Tip:** If you are using the **Go to source** context menu command in the Data, Watches, or Smart Data window, you can go back to the execution point by using the back button. You can also access the back button through the **Navigate** menu.

Once you have set breakpoints to pause the application at key points, you can proceed to view data in the Data window. To effectively debug your web page's interaction with the ADF Model layer, you need to understand:

- The ADF page lifecycle and the method calls that get invoked
- The local variables and arguments that the ADF Model layer should contain during the course of application processing

Awareness of Oracle ADF processing will give you the means to selectively set breakpoints, examine the data loaded by the application, and isolate the contributing factors.

---

---

**Note:** JSF web pages may also use backing beans to manage the interaction between the page's components and the data. Debug backing beans by setting breakpoints for them as you would with any other Java class file.

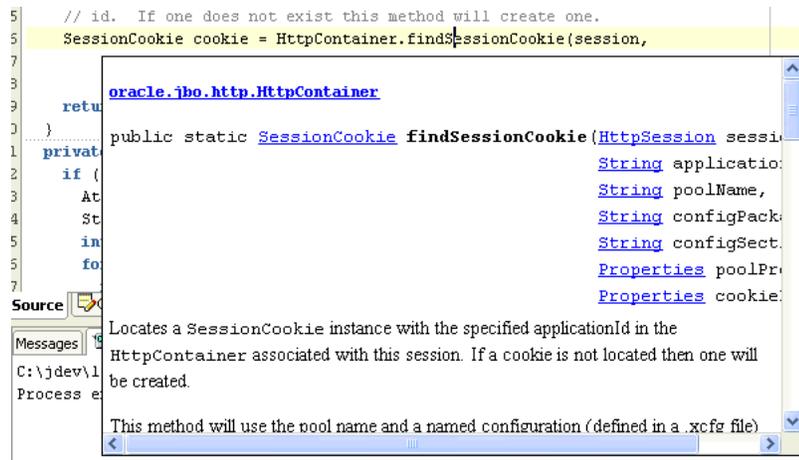

---

---

## 36.10.2 How to Optimize Use of the Source Editor

Once you have added the ADF source library to your project, you have access to the helpful Quick Javadoc feature (Ctrl+D) that the source editor makes available. [Figure 36-48](#) shows Quick Javadoc for a method like `findSessionCookie()`.

**Figure 36–48 Using Quick Javadoc on ADF API in the Source Editor**

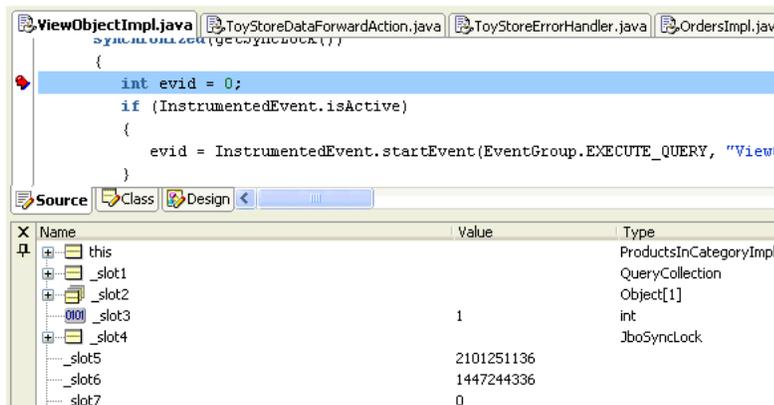

### 36.10.3 How to Set Breakpoints and Debug Using ADF Source Code

After loading the ADF source code, you can debug any Oracle ADF code for the current project the same way that you do your own Java code. This means that you can press **Ctrl+Minus** to type in any class name in Oracle ADF, and JDeveloper will open its source file automatically so that you can set breakpoints as desired.

### 36.10.4 How to Use Debug Libraries for Symbolic Debugging

When debugging Oracle ADF source code, by default you will not see symbol information for parameters or member variables of the currently executing method.

For example, in a debugging session without ADF source code debug libraries, you may see unrecognizable names such as `"_slot"`, as shown in [Figure 36–49](#).

**Figure 36–49 Local Symbols Are Hard to Understand Without Debug Libraries**

These names are hard to decipher and make debugging more difficult. You can make debugging easier by using the debug versions of the ADF JAR files supplied along with the source while debugging in your development environment.

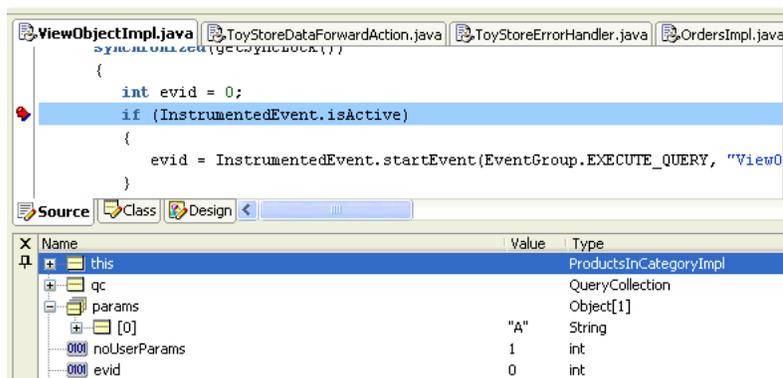

---

**Note:** The supplied debug libraries should not be used in a test or production environment, since they typically have slightly slower runtime performance than the optimized JAR files shipped with JDeveloper.

---

The debug library JARs are versions of Oracle ADF JARs that have been compiled with additional debug information. When you use these debug JAR files instead of the default optimized JARs, you will see all of the information in the debugger. For example, the variable `evid` is now identified by its name in the debugger, as shown in Figure 36–50.

**Figure 36–50** Symbol Information Displayed in the Debugger

Before you replace the standard library JAR, make sure that JDeveloper is not running. If it's currently running, exit from the product before proceeding.

### To replace the standard library JARs with the debug library JARs:

1. With JDeveloper closed, make a backup subdirectory of all existing optimized JAR files in the `./BC4J/lib` directory of your JDeveloper installation. For example, assuming `jdev11` is the JDeveloper home directory:
 

```

C:\jdev11\BC4J\lib> mkdir backup
C:\jdev11\BC4J\lib> copy *.jar backup

```
2. For each ADF library that you want debug symbols for while debugging, copy the `_g.jar` version of the matching library over the existing, corresponding library in the `C:\jdev11\BC4J\lib` directory.

This is safe to do since you made a backup of the optimized JAR files in the backup directory in Step 2.

Since debug libraries typically run a little slower than libraries compiled without debug information, this diagnostic message is to remind you not to use debug libraries for performance timing:

```

*** WARNING: Oracle BC4J debug build executing - do not use for timing ***

```

3. To change back to the optimized libraries, simply copy the JAR file(s) in question from the `./BC4J/lib/backup` directory back to the `./BC4J/lib` directory.

### 36.10.5 How to Use Different Kinds of Java Code Breakpoints

You first need to understand the different kinds of Java code breakpoints and where to create them.

To see the debugger Breakpoints window, choose **View > Breakpoints** from the main menu or press **Ctrl+Shift+R**.

You can create a new Java code breakpoint by choosing **Create Breakpoint** from the context menu in the Breakpoints window. The **Breakpoint Type** dropdown list controls what kind of breakpoint you will create, as shown in [Table 36–10](#).

---

**Note:** You can also use the Create Breakpoint dialog to create an ADF lifecycle phase declarative breakpoint. For information about creating ADF declarative breakpoints, see [Section 36.9.6, "How to Set and Use ADF Lifecycle Phase Breakpoints."](#)

---

**Table 36–10** *Different Types of Java Breakpoints*

Breakpoint Type	The Breakpoint Occurs Whenever	Usage
Exception	An exception of this class (or a subclass) is thrown.	An Exception breakpoint is useful when you don't know where the exception occurs, but you know what kind of exception it is (for example, <code>java.lang.NullPointerException</code> , <code>java.lang.ArrayIndexOutOfBoundsException</code> , <code>oracle.jbo.JboException</code> ). The checkbox options allow you to control whether to break on caught or uncaught exceptions of this class. The <b>Browse</b> button helps you find the fully qualified class name of the exception. The Exception Class combobox remembers the most recently used exception breakpoint classes. Note that this is the default breakpoint type when you create a breakpoint in the breakpoints window.
Source	A particular source line in a particular class in a particular package is run.	You rarely create a source breakpoint in the Create Breakpoint dialog, because it's much easier to create it by first using the <b>Navigate &gt; Go to Java Type</b> menu (accelerator <b>Ctrl+Minus</b> ), then scrolling to the line number you want — or using <b>Navigate &gt; Go to Line</b> (accelerator <b>Ctrl+G</b> ) — and finally clicking in the breakpoint margin at the left of the line you want to break on. This is equivalent to creating a new source breakpoint, but it means you don't have to type in the package, class, and line number by hand.
Method	A method in a given class is invoked.	The Method breakpoint is useful for setting breakpoints on a particular method you might have seen in the call stack while debugging a problem. If you have the source, you can set a source breakpoint wherever you want in that class, but this kind of breakpoint lets you stop in the debugger even when you don't have source for a class.

**Table 36–10 (Cont.) Different Types of Java Breakpoints**

Breakpoint Type	The Breakpoint Occurs Whenever	Usage
Class	Any method in a given class is invoked.	The Class breakpoint can be used when you might know the class involved in the problem, but not the exact method you want to stop on. This kind of breakpoint does not require source. The <b>Browse</b> button helps you quickly find the fully qualified class name you want to break on.
Watchpoint	A given field is accessed or modified.	The Watchpoint breakpoint can be used to find a problem if the code inside a class modifies a member field directly from several different places (instead of going through setter or getter methods each time). You can pause the debugger when any field is modified. You can create a breakpoint of this type by using the <b>Toggle Watchpoint</b> menu item on the context menu when pointing at a member field in your class's source.

### 36.10.6 How to Edit Breakpoints for Improved Control

After creating a Java code breakpoint you can edit the breakpoint in the Breakpoints window by right-clicking it and choosing **Edit** in the context menu.

---

**Note:** You can use the Edit Breakpoint dialog to edit an ADF declarative breakpoint. However, you cannot edit some of the other information such as the information in the **Definition** tab. You can launch the Edit Breakpoint dialog by choosing **Edit** from the context menu in the Breakpoints window. For information about creating ADF declarative breakpoints, see [Section 36.9, "Setting ADF Declarative Breakpoints."](#)

---

Some of the features you can use by editing your breakpoint are:

- Associate a logical "breakpoint group" name to group this breakpoint with others of the same group name. Breakpoint groups make it easy to enable/disable an entire set of breakpoints in one operation.
- Associate a debugger action to a breakpoint when the breakpoint is hit. The default action is to stop the debugger so that you can inspect the application states, but you can add a sound alert, write information to a log file, and enable or disable group of breakpoints.
- Associate a conditional expression with the breakpoint so that the debugger stops only when that condition is met. The expressions can be virtually any boolean expression, including:
  - `expr ==value`
  - `expr.equals("value")`
  - `expr instanceof.fully.qualified.ClassName`

---

**Note:** Use the debugger Watches window to evaluate the expression first to make sure it's valid.

---

### 36.10.7 How to Filter Your View of Class Members

You can use the debugger to filter the members that are displayed in the debugger window for any class. In the debugger's Data window, selecting any item and choosing **Preferences** from the context menu brings up a dialog that lets you customize which members appear in the debugger and (more importantly sometimes) which members *don't* appear. You can filter by class type to simplify the amount of scrolling you need to do in the debugger Data window. This is especially useful when you might be interested only in a handful of a class's members.

### 36.10.8 How to Use Common Oracle ADF Breakpoints

If you loaded Oracle ADF source code, you can use the breakpoints listed in [Table 36–11](#) to debug your application.

By looking at the Stack window when you hit these breakpoints, and stepping through the source, you can get a better idea of what's going on.

**Table 36–11 Commonly Used ADF Breakpoints**

Breakpoint	Breakpoint Type	Usage
<code>oracle.jbo.JboException</code>	Exception	This breakpoint useful for setting a breakpoint on the base class of all ADF Business Components runtime exceptions.
<code>oracle.jbo.DMLEException</code>	Exception	This is the base class for exceptions originating from the database, like a failed DML operation due to an exception raised by a trigger or by a constraint violation.
<code>doIt()</code>	Method	<p>You can also perform the same debugging function by setting an ADF declarative breakpoint on the page definition action binding. See <a href="#">Section 36.9.3, "How to Set and Use Page Definition Action Binding Breakpoints."</a></p> <p>If you prefer to use this Java breakpoint, you can find it in the <code>JUCtrlActionBinding</code> class (<code>oracle.jbo.uicli.binding</code> package).</p> <p>This is the method that will execute when any ADF action binding is invoked, and you can step into the logic and look at parameters if relevant.</p>
<code>oracle.jbo.server.ViewObjectImpl.executeQueryForCollection</code>	Method	This is the method that will be called when a view object executes its SQL query.
<code>oracle.jbo.server.ViewRowImpl.setAttributeInternal</code>	Method	This is the method that will be called when any view row attribute is set.
<code>oracle.jbo.server.EntityImpl.setAttributeInternal</code>	Method	<p>You can also perform the same debugging function by setting an ADF declarative breakpoint on the page definition attribute value binding. See <a href="#">Section 36.9.4, "How to Set and Use Page Definition Value Binding Breakpoints."</a></p> <p>This is the method that will be called when any entity object attribute is set.</p>

## 36.11 Regression Testing with JUnit

Testing your business services is an important part of your application development process. By creating a set of JUnit regression tests that exercise the functionality provided by your application module, you can ensure that new features, bug fixes, or refactorings do not destabilize your application. JDeveloper's integrated support for creating JUnit regression tests makes it easy to test your application. Its integrated support for running JUnit tests means that any developer on the team can run the test suite with a single mouse click, greatly increasing the chances that every team member can run the tests to verify their own changes to the system. Furthermore, by using JDeveloper's integrated support for creating and running Apache Ant build scripts, you can easily incorporate running the tests into your automated build process as well. You can create a JUnit test for your application module, run it, and integrate the tests into an Ant build script.

JDeveloper provides the ability to generate JUnit test cases, test fixtures, and test suites. You can create test cases to test individual Java files containing single or multiple Java classes. You can create JUnit test fixtures that can be reused by JUnit test cases. You can group all these test cases into a JUnit test suite, which you can run together as a unit.

You can also use the JUnit BC4J Test Suite wizard to generate a test suite when there is an application module in the project. The wizard generates a test suite, test fixture, and a test case for each view object in the application module.

You can create a separate project to contain your regression tests or to integrate the test files into an existing project. If you are creating an ADF Business Components test, you should create a separate project for testing.

Creating separate projects for testing has the following advantages:

- The ability to compile the base project without having a dependency on JUnit
- The ability to package the base project for deployment without having to exclude the test classes.

If you are creating separate projects for JUnit testing, you should create directory structures that mirror the structure of the packages being tested. You may want to name the test classes using a naming convention that can easily identify the package being tested. For example, if you are testing `myClass.java`, you can name the test class `myClassTest.java`.

Although having separate projects has many advantages, in certain cases it may be easier to include the tests within the project. For example, the Fusion Order Demo application has a JUnit regression test suite in the `FODCustomization` workspace `Customization Extension` project.

You can use the Create Test wizards in the context of the project to create a JUnit test case, test fixture, or test suite. However, if you do not want to include these tests as part of the deployment, you may want to separate the tests out in their own project.

**Tip:** If you don't see the Create Test wizards, use JDeveloper's **Help > Check for Updates** feature to install the JUnit Integration extension before continuing.

Each test case class contains a `setUp()` and `tearDown()` method that JUnit invokes to allow initializing resources required by the test case and to later clean them up. These test case methods invoke the corresponding `setUp()` and `tearDown()` methods to prepare and clean up the test fixture for each test case execution. Any time a test in the test case needs access to the application module, it uses the test fixture's

`getApplicationModule()` method. The method returns the same application module instance, saved in a member field of the test fixture class, between the initial call to `setUp()` and the final call to `tearDown()` at the end of the test case.

JDeveloper supports JUnit 4, which allows annotations to be used instead of explicitly having to name the methods `setUp()` and `tearDown()`. These annotations — `@Before`, `@After` — allow you to have multiple setup and teardown methods, including inherited ones if required.

The generated `ExampleModuleConnectFixture` is a JUnit test fixture that encapsulates the details of acquiring and releasing an application. It contains a `setUp()` method that uses the `createRootApplicationModule()` method of the `Configuration` class to create an instance of an application module. Its `tearDown()` method calls the matching `releaseRootApplicationModule()` method to release the application module instance.

Your own testing methods can use any of the programmatic APIs available in the `oracle.jbo` package to work with the application module and view object instances in its data model. You can also cast the `ApplicationModule` interface to a custom interface to have your tests invoke your custom service methods as part of their job. During each test, you will call one or more `assertXxx()` methods provided by the JUnit framework to assert what the expected outcome of a particular expression should be. When you run the test suite, if any of the tests in any of the test cases contains assertions that fail, the JUnit Test Runner window displays the failing tests with a red failure icon.

The JUnit test generation wizard generates skeleton test case classes for each view object instance in the data model, each of which contains a single test method named `testAccess()`. This method contains a call to the `assertNotNull()` method to test that the view object instance exists.

```
// In ViewInstanceNameTest.java test case class
public void testSomeMeaningfulName() {
 // test assertions here
}
```

Each generated test case can contain one or more test methods that the JUnit framework will execute as part of executing that test case. You can add a test to the test case simply by creating a public void method in the class whose name begins with the prefix `test` or use the annotation `@Test`.

### 36.11.1 How to Obtain the JUnit Extension

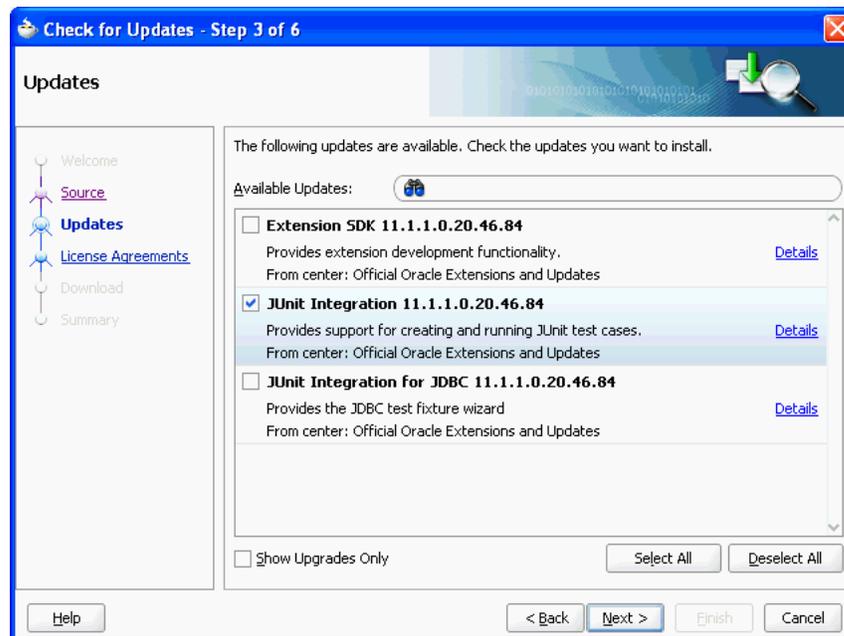

JUnit must be loaded as an extension to JDeveloper before it becomes available and appears in the menu system.

#### To load the JUnit extension:

1. From the main menu, choose **Help > Check for Updates**.
2. In the Source page of the Check for Updates dialog, select **Search Update Centers** and **Official Oracle Extensions and Updates** and click **Next**.

If you have the JUnit zip file or if the JUnit selection does not appear in the **Available Updates** list, select **Install From Local File** to load the JUnit zip file.

3. In the Updates page, select **JUnit Integration** and click **Next**, as shown in [Figure 36–51](#).

**Figure 36–51 Check for Updates Wizard for Adding JUnit Extension**

4. On the License Agreements page, click **I Accept** and click **Finish**.

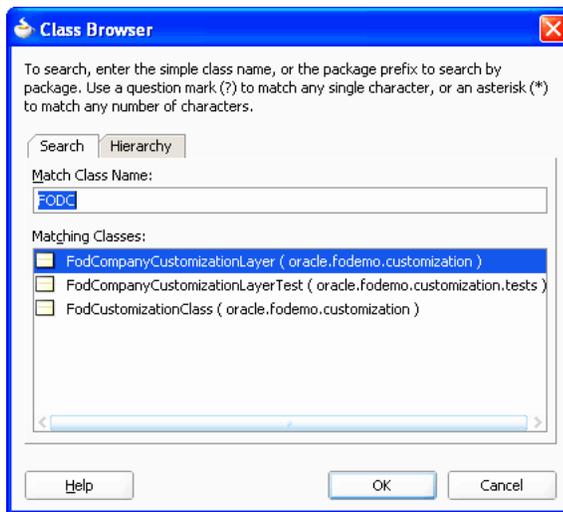

### 36.11.2 How to Create a JUnit Test Case

Before you create a JUnit test case, you must have created a project that is to be tested.

#### To generate a JUnit test case:

1. In the Application Navigator, select the project you want to generate a test case for, right-click and choose **New**.
2. In the New Gallery, expand **General**, select **Unit Tests(JUnit)** and then **Test Case**, and click **OK**.
3. In the Select the Class to Test page of the Create Test Case dialog, enter the class under test or click **Browse**.
4. In the Class Browser dialog, locate the class you want to test or enter the beginning letters in the **Match Class Name** field. The **Match Class** list will be filtered for easier identification.

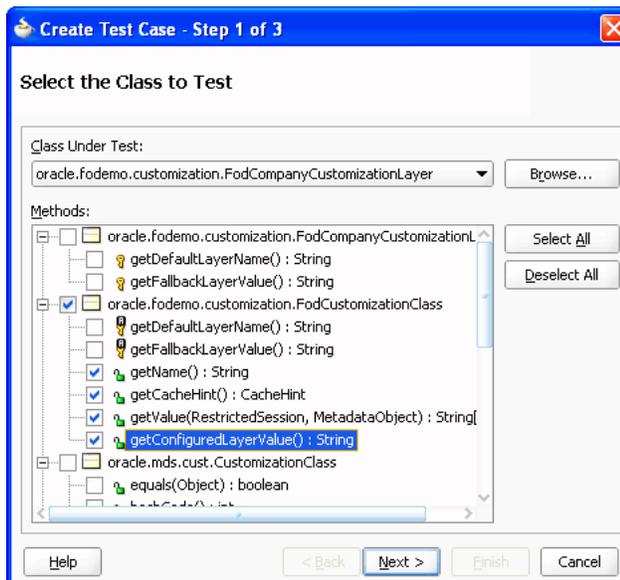

For example, entering FOD filters the list down to three items, as shown in [Figure 36–52](#).

**Figure 36–52 Class Browser for Selecting Class Files to Test**

Select the class and click **OK** to close the dialog. Click **Next**.

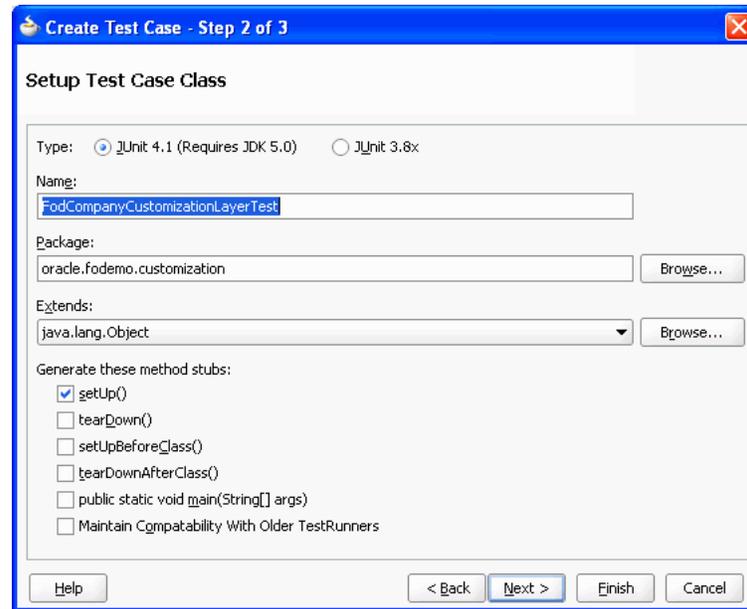

5. Select the individual methods you want to test, and click **Next**.

For example, in [Figure 36–53](#), the four methods that are checked are to be tested.

**Figure 36–53 Create Test Case Dialog for Selecting Methods to Test**

6. In the Setup Test Case Class page, enter the name of the test case, the package, and the class it extends and select the list of built-in functions JUnit will create stubs for. Click **Next**.

For example, in [Figure 36–54](#), JUnit will create a stub for the `setUp()` method for the `FodCompanyCustomizationLayerTest` test case in the `oracle.fodemo.customization` package.

**Figure 36–54 Create Test Case Dialog for Setting Up Classes to Test**

7. In the Select Test Fixtures page, select any test fixtures you want to add to the test case or click **Browse**.
8. Make sure that all the test fixtures you want to add to the test case are selected in the list and click **Finish**.

### 36.11.3 How to Create a JUnit Test Fixture

You should create a JUnit test fixture if you require more than one test for a class or method. A JUnit text fixture allows you to avoid duplicating test code that is needed to initialize testing.

#### To generate a JUnit test fixture:

1. In the Application Navigator, select the project you want to generate a test fixture for, right-click and choose **New**.
2. In the New Gallery, expand **General**, select **Unit Tests(JUnit)** and then **Test Fixture**, and click **OK**.
3. In the Create Test Fixture dialog, enter the name of the test fixture, the package, and any class it extends.
4. Click **OK**.

### 36.11.4 How to Create a JUnit Test Suite

Before you create a JUnit test suite, you should have already created JUnit test cases that can be added to the test suite.

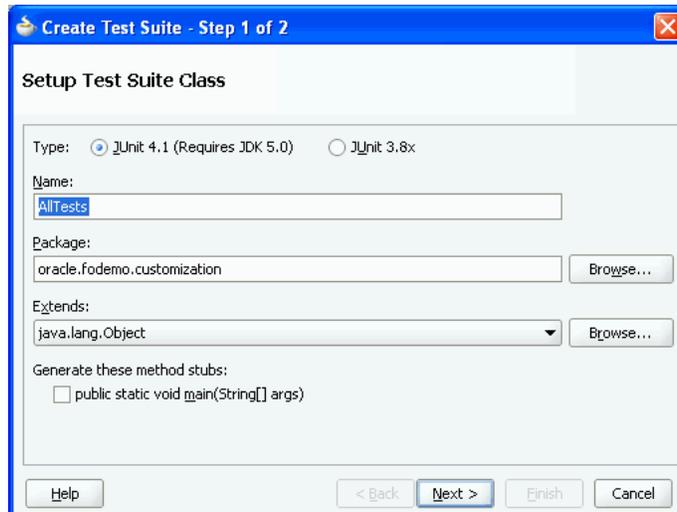

#### To generate a JUnit test suite:

1. In the Application Navigator, select the project you want to generate a test fixture for, right-click and select **New**.
2. In the New Gallery, expand **General**, select **General** and then **Test Suite**, and click **OK**.

- In the Setup Test Suite Class page of the Create Test Suite dialog, enter the name of the test suite, the package, and the class it extends. Click **Next**.

For example, in [Figure 36–55](#), an `AllTests` test suite is created that extends the `java.lang.Object` class.

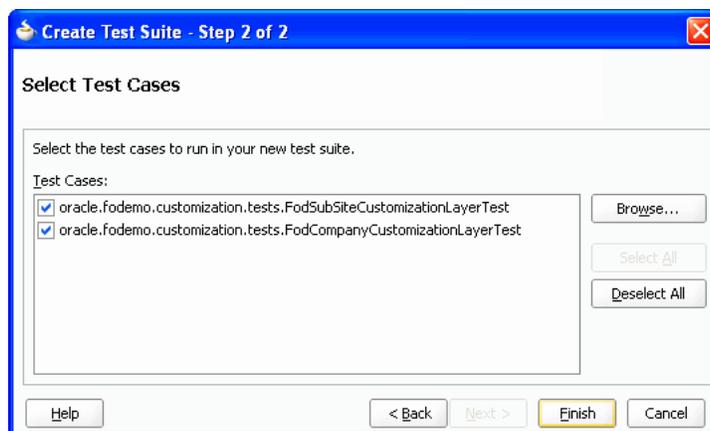

**Figure 36–55** *Create Test Suite Wizard*

- In the Select Test Cases page of the Create Test Suite dialog, check that all the test cases you want included in the test suite have been selected. The test cases you have created will populate the list. Deselect any test cases that you do not want included. Click **Finish**.

For example, in [Figure 36–56](#), both test cases are selected to be in the test suite.

**Figure 36–56** *Selecting Test Cases for a Test Suite*

### 36.11.5 How to Create a Business Components Test Suite

The test fixture that is created is a singleton class to reduce the number of connections. If you want to connect or disconnect for each test case, customize the test case using the JUnit 4 annotations `@Before` and `@After`.

The JUnit BC4J Test Suite wizard will generate tests for each view object in the application module. If the application module does not have exported methods, the

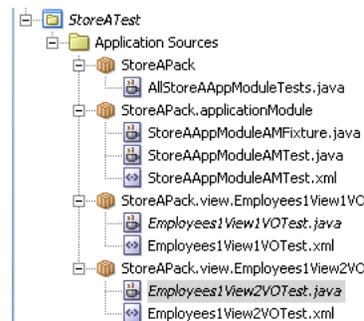

wizard will also generate a test for the application module itself. A generated view object class has the format `view_objectVOTest.java` and is placed into a package with the format `package.view.viewobjectVO`, where `package` is the application module package. A generated application module test has the format `application_moduleAMTest.java` and is placed into a package with the format `package.applicationModule`. A generated test fixture class has the format `applicationmoduleAMFixture.java` and is placed in the same package as the application module test.

The generated all test suite class has the format `AllapplicationmoduleTest.java` and is placed into the package with the same name as the application module package name.

A test case XML file is also generated for each application module or view object test. The XML file contains test methods defined in the application module or view object test cases. It does not include the test methods from the base classes (if any) because there may be too many duplicates.

For instance, after you created a test suite for an application module named `StoreAAppModule` with view objects `Employees1View1` and `Employees1View2` in the package `StoreAPack`, the Application Navigator displays the test hierarchy as shown in [Figure 36–19](#).

**Figure 36–57 Business Components Test Suite in the Application Navigator**

### Before you begin:

Create application modules in the project.

### To create a business components test suite:

1. In the Application Navigator, click **New**.  
You will create a separate project for the business components tests.
2. In the New Gallery, expand **General**, select **Projects** and then **Java Projects**, and click **OK**.
3. In the Project Name page of the Create Java Project wizard, enter a name and the directory path for the test project, and click **Next**.
4. In the Project Java Settings page, enter the package name, the directory of the Java source code in your project, and output directory where output class files will be placed, and click **Finish**.
5. In the Application Navigator, double-click the application module you want to test.
6. In the overview editor, click the **Java** navigation tab.

7. In the Java page, click the **Edit** icon for the **Java Class** section.
8. In the Select Java Options dialog, select **Generate Application Module Class** and click **OK**.
9. In the overview editor **Java** tab, click the **Edit** icon in the **Class Interface** section.
10. In the Edit Client Interface dialog, shuttle the methods you want to test to the **Selected** pane, and click **OK**.
11. In the Application Navigator, right-click the test project you have created and choose **New**.
12. In the New Gallery, expand **General**, select **Unit Tests** and then **Business Components Test Suite**, and click **OK**.
13. In the Configure Tests page of the JUnit BC4J Test Suite wizard, select values for the following and click **Next**:
  - **Business Component Project**: Select the project that has the application module you want to test.
  - **Application Module**: Select the application module you want to test.
  - **Configuration**: Choose a local or shared application module.
  - **Test Base Class-Application Module Extends**: You can specify different base cases. The generated test case classes will extend from that base class where all public abstract methods in the base class will have simple and default implementation method bodies.
  - **Test Base Class-View Object Extends**: You can specify which class the view object extends. The generated test case classes will extend from that base class where all public abstract methods in the base class will have simple and default implementation method bodies.
14. In the Summary page, verify the selections and click **Finish**.

### 36.11.6 How to a Create Business Components Test Fixture

When you create a business components test suite, a business components test fixture is created with it. You can also create Business Components test fixtures independently.

A generated test fixture class has the format `applicationmoduleAMFixture.java` and put into a package with the format `package.applicationModule`, where `package` is the application module package.

#### **Before you begin:**

Create application modules in the project.

#### **To create a business components test fixture:**

1. In the Application Navigator, click **New**.

You will create a separate project for the business components tests.
2. In the New Gallery, expand **General**, select **Projects** and then **Java Projects**, and click **OK**.
3. In the Project Name page of the Create Java Project dialog, enter a name and the directory path for the test project, and click **Next**.

4. In the Project Java Settings page, enter the package name and the source and output directories, and click **Finish**.
5. In the Application Navigator, double-click the application module you want to test.
6. In the overview editor, click the **Java** navigation tab and click the **Edit** icon of the **Java Class** section.
7. In the Select Java Options dialog, select **Generate Application Module Class**, and click **OK**.
8. In the overview editor, click the **Edit** icon of the **Class Interface** section.
9. In the Edit Client Interface dialog, shuttle the methods you want to test to the **Selected** pane, and click **OK**.
10. In the Application Navigator, right-click the test project you have created and choose **New**.
11. In the New Gallery, expand **General**, select **Unit Tests** and then **Business Components Test Fixture**, and click **OK**.
12. In the Configure Tests page of the JUnit BC4J Test Fixture wizard, select values for the following and click **Next**:
  - **Business Component Project**: Select the project that has the application module you want to test.
  - **Application Module**: Select the application module you want to test.
  - **Configuration**: Choose a local or shared application module.
13. In the Summary page, verify the test fixture class and click **Finish**.

### 36.11.7 How to Run a JUnit Test Suite as Part of an Ant Build Script

Apache Ant is a popular, cross-platform build utility for which JDeveloper offers design time support. You can incorporate the automatic execution of JUnit tests and test output report generation by using Ant's built-in `junit` and `junitreport` tasks. [Example 36-3](#) shows a task called `tests` from the `FODCustomizations Ant build.xml` file in the `CustomizationExtension` project. It depends on the `build` and `buildTests` targets that Ant ensures have been executed before running the `tests` target.

#### **Example 36-3 Ant Build Target Runs JUnit Test Suite**

```
<target name="testCustomizations" depends="compileExtensionClasses">
 <junit printsummary="yes" haltonfailure="yes">
 <classpath refid="customization.classpath">
 <pathelement location="{customization.build.dir}"/>
 </classpath>
 <formatter type="plain"/>
 <test name="oracle.fodemo.customization.tests.AllTests"/>
 </junit>
</target>
```

The `junit` tag contains a nested `test` tag that identifies the test suite class to execute and specifies a directory in which to report the results. The `junitreport` tag allows you to format the test results into a collection of HTML pages that resemble the format of Javadoc.

To try running the JUnit test from Ant, select the `build.xml` file in the Application Navigator, and choose **Run Ant Target > *tests*** from the context menu.

---

## Refactoring a Fusion Web Application

This chapter describes considerations for renaming, moving, and deleting files, configuration files, objects, attributes, and elements. In most cases, JDeveloper automatically performs refactoring. However, you may need to complete some manual steps to refactor.

This chapter includes the following sections:

- [Section 37.1, "About Refactoring a Fusion Web Application"](#)
- [Section 37.2, "Renaming Files"](#)
- [Section 37.3, "Moving JSF Pages"](#)
- [Section 37.4, "Refactoring pagedef.xml Bindings Objects"](#)
- [Section 37.5, "Refactoring ADF Business Components"](#)
- [Section 37.6, "Refactoring ADF Business Component Object Attributes"](#)
- [Section 37.7, "Refactoring Named Elements"](#)
- [Section 37.8, "Refactoring ADF Task Flows"](#)
- [Section 37.9, "Refactoring the DataBindings.cpx File"](#)
- [Section 37.10, "Refactoring Limitations"](#)
- [Section 37.11, "Moving the ADF Business Components Project Configuration File \(.jspx\)"](#)

### 37.1 About Refactoring a Fusion Web Application

JDeveloper provides refactoring options to rename, move, and delete attributes, named elements, and ADF Business Components objects that your application uses. These refactoring options synchronize your changes with other parts of the application that are dependent on the changes. For example, renaming an ADF Business Components object such as a view object using the **Rename** option renames any references to it in other XML source files.

#### 37.1.1 Refactoring Use Cases and Examples

During the course of development, you will create objects such as entity objects, as needed, to satisfy the needs of the application. Then you might find that you need to subsequently need to delete an object that is no longer used, rename an object to fit a naming convention, or move a set of objects into a different package to consolidate their location. Using JDeveloper, you can refactor these objects so that they are

updated and the references to these objects in other objects are also updated to maintain the integrity of the whole application.

## 37.2 Renaming Files

You can rename files such as configuration files using the following methods:

- In the Application Navigator, select the file and choose **File > Rename** from the main menu.
- In the Application Navigator, right-click the file and choose **Refactor > Rename**.
- In the source editor, select a class name, right-click it, and choose **Rename**.

## 37.3 Moving JSF Pages

In addition to the other refactoring operations, you can change the package of a JSF page. In the Application Navigator, right-click a JSF page and choose **Refactor > Move to Package** to move the page to another package.

Moving the JSF page to another package updates:

- `faces-config.xml` files that reference the page and its package
- ADF task flows containing views associated with the page
- `DataBindings.cpx` mappings to the page

## 37.4 Refactoring pagedef.xml Bindings Objects

The `pagedef.xml` binding objects that you can refactor include bindings and executables. For more information, see [Section 13.7, "Working with Page Definition Files."](#)

### Before you begin:

It may be helpful to have an understanding of the options you have for refactoring. For more information, see [Section 37.1, "About Refactoring a Fusion Web Application."](#)

In JDeveloper, open the application that contains the objects you want to refactor.

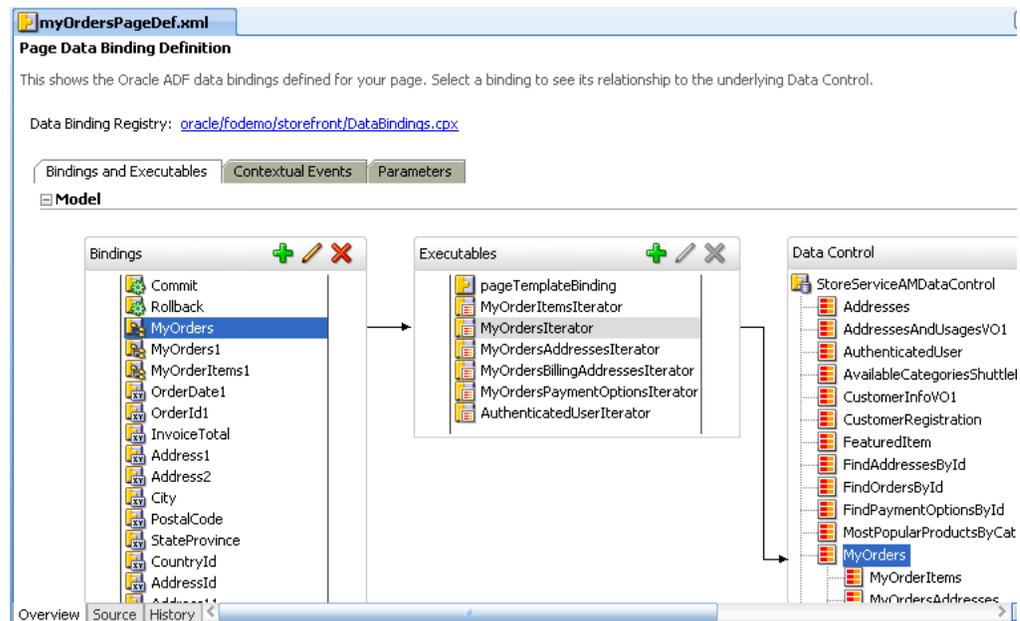

### To refactor pagedef.xml binding objects:

1. In the Application Navigator, select the page node on which you have added a bound object such as an ADF Form or selection list.
2. Right-click the page node and choose **Go to Page Definition**.

If the page does not already have a page definition, the Create Page Definition dialog displays. Click **OK** to create a page definition for the page.

3. In the overview editor, expand the **Model** section.

Data bindings such as list bindings and iterator bindings defined for the page display under **Bindings** and **Executables**, as shown in [Figure 37–1](#).

**Figure 37–1 Page Data Binding Definition Overview Tab**

4. Right-click a data binding or executable, choose **Refactor** and a refactoring option such as **Rename** or **Delete**.
5. To display the usages between bindings, executables, and data controls, right-click a binding or executable and choose **Find Usages**.

## 37.5 Refactoring ADF Business Components

ADF Business Components includes objects such as view objects and entity objects. [Table 37–1](#) shows support for refactoring ADF Business Components.

**Table 37–1 Refactoring ADF Business Components**

Action	Result
Move	Moves the object to a different package or directory and updates all references.
Delete	JDeveloper shows all dependencies on the object and permits a forced delete. The application may not work at this point. You may need to resolve broken references.
Rename	<p>ADF Business Components objects are defined by an XML file. The XML file has a file name identical to the object name. For example, the name of the XML file for a view object named <code>Persons1View</code> is <code>Persons1View.xml</code>. Renaming results in changing the <code>Name</code> attribute, renaming the XML file, and updating all references.</p> <p>For example, the name of an entity (<code>Customer</code>) is stored as an attribute in the XML file (<code>name=Customer</code>). The XML file has the same name the entity name (<code>Customer.xml</code>).</p>
Find Usages	JDeveloper shows all dependencies on the object.

---

---

**Note:** Refactoring does not cross abstraction layers. For example, when a view object is created based on the `Dept` entity object, it is named `DeptView` by default. Renaming the `Dept` entity object updates the entity usage in `DeptView`, but does not change the name of the view object.

---

---

**Before you begin:**

It may be helpful to have an understanding of the options you have for refactoring. For more information, see [Section 37.1, "About Refactoring a Fusion Web Application."](#)

In JDeveloper, open the application that contains the objects you want to refactor.

**To refactor ADF Business Components objects:**

1. In the Application Navigator, expand the **Projects** node containing the object you want to refactor.
2. Within the project, expand the **Application Sources** node and then the package containing the object you want to refactor.
3. Right-click the object and choose **Refactor > Rename** or **Refactor > Move**.
4. To delete the object, choose **Delete**.

If the object is used elsewhere in the application, a dialog displays with the following options:

- **Ignore:** Unresolved usages will remain in the code as undefined references.
- **View Usages:** Display a preview of the usages of the element in the Compiler log. You can use the log to inspect and resolve the remaining usages.

## 37.6 Refactoring ADF Business Component Object Attributes

[Table 37-1](#) shows support for refactoring attributes of ADF Business Component entity objects and view objects.

**Table 37-2 Refactoring Attributes**

Action	Result
Move	Not supported.
Delete	JDeveloper shows all dependencies on the attribute and permits a forced delete. The application may not work at this point. You may need to resolve broken references.
Rename	Attributes share data elements represented in entity and view objects (see <a href="#">Section 4.1, "About Entity Objects"</a> for more information). References to the attribute are updated when you rename the attribute. Renaming results in changing the <code>Name</code> attribute, renaming the XML file, and updating all references.  Renaming an attribute does not change the data it represents, nor does it rename the underlying table column.
Find Usages	JDeveloper shows all dependencies on the attribute.

**Before you begin:**

It may be helpful to have an understanding of the options you have for refactoring. For more information, see [Section 37.1, "About Refactoring a Fusion Web Application."](#)

In JDeveloper, open the application that contains the attributes you want to refactor.

**To refactor attributes:**

1. In the Application Navigator, expand the **Projects** node containing the object you want to refactor.
2. Within the project, expand the **Application Sources** node and then the package containing the object you want to refactor.
3. Double-click the object.
4. In the overview editor, select **Attributes**.
5. In the **Name** column, select an attribute.
6. Right-click and choose **Rename** or **Delete**.
7. To delete the attribute, choose **Delete**.

If the attribute is used elsewhere in the application, a dialog displays with the following options:

- **Ignore:** Unresolved usages will remain in the code as undefined references.
- **View Usages:** Display a preview of the usages of the attribute in the Compiler log. You can use the log to inspect and resolve the remaining usages.

## 37.7 Refactoring Named Elements

Table 37–3 shows support for refactoring named elements in an XML schema. Named elements are any elements in the XML schema that can be referenced by a Name attribute. A named element is not an object or an attribute.

**Table 37–3 Refactoring Named Elements**

Action	Result
Move	Not supported.
Delete	Not supported.
Rename	One exception to the definition of named elements is the design time element <code>Attr</code> , which does have a <code>Name</code> attribute. <code>Attr</code> is a name-value pair, is not accessible from the code editor, and should not be renamed.
Find Usages	JDeveloper shows all dependencies on the named element.

**Before you begin:**

It may be helpful to have an understanding of the options you have for refactoring. For more information, see [Section 37.1, "About Refactoring a Fusion Web Application."](#)

In JDeveloper, open the application that contains the objects you want to refactor.

**To refactor named elements:**

1. In the Application Navigator, expand the **Projects** node containing the object you want to refactor.
2. Within the project, expand the **Application Sources** node and then the package containing the object you want to refactor.
3. Double-click the object.
4. In the overview editor, click the **Source** tab.

5. Scroll down to a named element.

Named elements are indicated by `Name="<element>"` in the source code, for example:

```
<Key Name="PersonsAffContactChk">
```

A named element is not an object or attribute.

6. To rename the element, right-click the element and choose **Rename**.
7. To delete the element, choose **Delete**.

If the element is used elsewhere in the application, a dialog displays with the following options:

- **Ignore:** Unresolved usages will remain in the code as undefined references.
- **View Usages:** Display a preview of the usages of the element in the Compiler log. You can use the log to inspect and resolve the remaining usages.

## 37.8 Refactoring ADF Task Flows

For more information, see [Section 18.6, "Refactoring to Create New Task Flows and Task Flow Templates."](#)

## 37.9 Refactoring the DataBindings.cpx File

The `DataBindings.cpx` file defines the Oracle ADF binding context for the entire application and provides the metadata from which the Oracle ADF binding objects are created at runtime (see [Section A.7.1, "DataBindings.cpx Syntax"](#) for more information). This file is a registry used to quickly find all `.cpx`, `.dcx`, `.jpx`, and `.xcfg` files, which are themselves registries of metadata.

If you rename the `DataBindings.cpx` file to a new name, such as `DataBindingsNew.cpx`, the change is added to the `adfm.xml` file.

[Example 37-1](#) shows the contents of the `adfm.xml` file after `DataBindings.cpx` is refactored to `DataBindingsNew.cpx`.

### **Example 37-1 Renamed DataBindings.cpx file in adfm.xml**

```
<?xml version="1.0" encoding="UTF-8" ?>
<MetadataDirectory xmlns="http://xmlns.oracle.com/adfm/metainf"
version="11.1.1.0.0">
<DataBindingRegistry path="adf/sample/view/DataBindingsNew.cpx"/>
</MetadataDirectory>
```

After this change, the application won't run because the data control cannot be found.

[Example 37-2](#) shows the old ID in the `DataBindingsNew.cpx` file. To enable the application to access the correct bindings file, update the ID value in the `DataBindingsNew.cpx` file to the new file.

### **Example 37-2 DataBindingsNew.cpx ID**

```
<Application xmlns="http://xmlns.oracle.com/adfm/application"
version="11.1.1.49.28" id="DataBinding" SeparateXMLFiles="false"
Package="adf.sample.view" ClientType="Generic">
```

This should be changed to an ID similar to the one shown in [Example 37-3](#).

**Example 37-3 Updated DatabindingNew.cpx ID**

```
<Application xmlns="http://xmlns.oracle.com/adfm/application"
version="11.1.1.49.28" id="DataBindingNew" SeparateXMLFiles="false"
Package="adf.sample.view" ClientType="Generic">
```

## 37.10 Refactoring Limitations

Table 37-4 summarizes the limitations of JDeveloper's refactoring support.

**Table 37-4 Refactoring Limitations**

Area	Limitation
Database	When a database artifact used in an ADF Business Components object is renamed, the object needs to be updated. This type of refactoring is currently not supported.
Service interface	<p>A service interface defines a contract between two separate pieces of software. For example, the ADF Business Components service interface is responsible for exposing business components to the view and model layers. Changing the name of a service interface can cause a conflict. While developing the application, consider removing the service interface, refactoring the object, and regenerating the service interface. Additionally, if your service interface defines a find operation based on a view criteria that specifies bind variables, changing the number or order of the bind variables in the underlying view criteria will require that you regenerate the service interface.</p> <p>For more information, see <a href="#">Chapter 11, "Integrating Service-Enabled Application Modules."</a></p>
Java literal references	<p>The Java code generated by ADF Business Components has literal references to the XML metadata. These literal references are updated during refactoring operations. Generated (type safe) methods are also updated. Also, the refactor delete operation is available for local Java variables.</p> <p>However, if the application code directly refers to the metadata, these references are not updated.</p>
Domain	<p>If a domain needs to be renamed or moved, you must create the new domain, then change the type of existing domain usages.</p> <p>For example, you might rename a domain called <code>EmployeeID</code> to <code>EmployeeNumber</code>. In addition, the entity <code>Emp</code> has an attribute called <code>Empno</code> that is of type <code>EmployeeID</code>.</p> <p>After creating the new domain <code>EmployeeNumber</code>, go to the attributes page for the entity, right-click <b>Empno</b> and choose <b>Change Type</b>. This switches <code>Empno</code> from <code>EmployeeID</code> to <code>EmployeeNumber</code>.</p>
Security	Security policies in the policy store may reference the name of an entity object, attribute, page, or task flow. These policy definitions are not updated in response to the refactoring of the object itself.

**Table 37–4 (Cont.) Refactoring Limitations**

Area	Limitation
Resource Bundles	Entity object definitions can reference a resource in one or more arbitrary resource bundle (.properties) files that you create. You can use this file to define labels for the attributes of entity objects. However, if you rename the .properties file you created, JDeveloper will not update the entity object definitions to reflect the new file name. As an alternative to resource bundle files that you create, you can specify a project setting to generate a single, default resource bundle file for the data model project. In this case, JDeveloper will not allow you to rename this generated file. However, if you attempt to change the project-level default resource bundle file, JDeveloper will warn you about the change. The data model project will honor the new ADF Business Components project-level setting for any objects that have not yet been linked to the default resource bundle file; all existing Business Components that have already been linked to the original default file will continue to use it instead.
.jspx project configuration file	<p>Renaming the ADF Business Components project configuration file (.jspx) is not supported.</p> <p>In previous versions of JDeveloper, ADF Business Components project configuration .jspx files were created only in the root package of the src directory of a project and were named with the same base name as the project. The ADF Business Components objects (entities, views, and application modules) were all created in the model package (for example, /model/AppModule.xml), but the /Model.jsx is not.</p> <p>This may cause a reusability problem when attempting to package them in ADF JAR files for use on the class path. There may be name conflicts because several projects are named Model.</p>

## 37.11 Moving the ADF Business Components Project Configuration File (.jspx)

Although refactoring the ADF Business Components project configuration file (.jspx) is not supported, you may need to change its name or location to avoid conflicts when sharing your project contents as an ADF library. The .jspx file contains configuration information that JDeveloper uses in the design time to allow you to create the data model project with ADF Business Components. If you need to refactor this file, you must do so manually.

### Before you begin:

It may be helpful to have an understanding of the options you have for refactoring. For more information, see [Section 37.1, "About Refactoring a Fusion Web Application."](#)

### To manually move the ADF Business Components project configuration file (.jspx):

1. Move the .jspx file to the new source tree location.  
For example, you can move the Model.jsx file from src/Model.jsx to src/newpackage/name/here/Model.jsx.
2. Change the .jspx file contents. The PackageName attribute of the root element JboProject needs to have the correct value.  
For example, you can specify PackageName="newpackage.name.here".
3. Change the jbo.project attributes in all common/bc4j.xcfg files that contain elements referred to in the .jspx file to include the new package name.

For example:

```
<AppModuleConfig name="ScottDeptAMLocal "
ApplicationName="newpackage.name.here.ScottDeptAM"
DeployPlatform="LOCAL" JDBCName="scottdb"
jbo.project="newpackage.name.here.Model ">
```

4. Change the JDeveloper project file (the .jpr file) contents:

- Set the new .jspx package location. If you later change the default package in the project properties, you will again raise a `NotFound` error for the .jspx file.

For example:

```
<value n="defaultPackage" v="newpackage.name.here" />
```

- Fix any `ownerURL` elements in the `ownerMap` that contain references to the old location of the .jspx file.

For example:

```
<url n="ownerURL"
path="src/newpackage/name/here/Model.jsx" />
```

---

## Reusing Application Components

This chapter describes how to package certain ADF components into the ADF Library for reuse in applications. Reusable ADF components are application modules, business components (entity objects, view objects, associations), data controls, task flows, page templates, and declarative components.

This chapter includes the following sections:

- [Section 38.1, "About Reusable Components"](#)
- [Section 38.2, "Common Functionality of Reusable ADF Components"](#)
- [Section 38.3, "Packaging a Reusable ADF Component into an ADF Library"](#)
- [Section 38.4, "Adding ADF Library Components into Projects"](#)
- [Section 38.5, "Removing an ADF Library JAR from a Project"](#)

### 38.1 About Reusable Components

In the course of application development, certain components will often be used more than once. Whether the reuse happens within the same application, or across different applications, it is often advantageous to package these reusable components into a library that can be shared between different developers, across different teams, and even across departments within an organization.

In the world of Java object-oriented programming, reusing classes and objects is just standard procedure. With the introduction of the model-view-controller (MVC) architecture, applications can be further modularized into separate model, view, and controller layers. By separating the data (model and business services layers) from the presentation (view and controller layers), you ensure that changes to any one layer do not affect the integrity of the other layers. You can change business logic without having to change the UI, or redesign the web pages or front end without having to recode domain logic.

Oracle ADF and JDeveloper support the MVC design pattern. When you create an application in JDeveloper, you can choose many application templates that automatically set up data model and user interface projects. Because the different MVC layers are decoupled from each other, development can proceed on different projects in parallel and with a certain amount of independence.

ADF Library further extends this modularity of design by providing a convenient and practical way to create, deploy, and reuse high-level components. When you first design your application, you design it with component reusability in mind. If you created components that can be reused, you can package them into JAR files and add them to a reusable component repository. If you need a component, you may look into

the repository for those components and then add them into your project or application.

For example, you can create an application module for a domain and package it to be used as the data model project in several different applications. Or, if your application will be consuming components, you may be able to load a page template component from a repository of ADF Library JARs to create common look and feel pages. Then you can put your page flow together by stringing together several task flow components pulled from the library.

An ADF Library JAR contains ADF components and does not, and cannot, contain other JARs. It should not be confused with the JDeveloper library, Java EE library, or Oracle WebLogic shared library.

[Table 38–1](#) lists the reusable components supported by ADF.

**Table 38–1 Oracle ADF Reusable Components**

Reusable Component	Description
Data control	Any data control can be packaged into an ADF Library JAR. Some of the data controls supported by Oracle ADF include application modules, Enterprise JavaBeans, web services, URL services, JavaBeans, and placeholder data controls.
Application module	When you are using ADF Business Components and you generate an application module, an associated application module data control is also generated. When you package an application module data control, you also package up the ADF Business Components associated with that application module. The relevant entity objects, view objects, and associations will be a part of the ADF Library JAR and available for reuse.
Business components	Business components are the entity objects, view objects, and associations used in the ADF Business Components data model project. You can package business components by themselves or together with an application module.
Task flows and taskflow templates	<p>Task flows can be packaged into an ADF Library JAR for reuse.</p> <p>If you drop a bounded task flow that uses page fragments, JDeveloper adds a region to the page and binds it to the dropped task flow.</p> <p>ADF bounded task flows built using pages can be dropped onto pages. The drop will create a link to call the bounded task flow. A task flow call activity and control flow will automatically be added to the task flow, with the view activity referencing the page. If there is more than one existing task flow with a view activity referencing the page, it will prompt you to select the one to automatically add a task flow call activity and control flow.</p> <p>If an ADF task flow template was created in the same project as the task flow, the ADF task flow template will be included in the ADF Library JAR and will be reusable.</p>
Page templates	You can package a page template and its artifacts into an ADF Library JAR. If the template uses image files and they are included in a directory within your project, these files will also be available for the template during reuse.
Declarative components	You can create declarative components and package them for reuse. The tag libraries associated with the component will be included and loaded into the consuming project.

You can also package up projects that have several different reusable components if you expect that more than one component will be consumed. For example, you can create a project that has both an application module and a bounded task flow. When this ADF Library JAR file is consumed, the application will have both the application module and the task flow available for use. You can package multiple components into one JAR file, or you can package a single component into a JAR file. Oracle ADF and

JDeveloper give you the option and flexibility to create reusable components that best suit you and your organization.

You create a reusable component by using JDeveloper to package and deploy the project that contains the components into a ADF Library JAR file. You use the components by adding that JAR to the consuming project. At design time, the JAR is added to the consuming project's class path and so is available for reuse. At runtime, the reused component runs from the JAR file by reference. For the procedure to add the JAR manually, see [Section 38.4.2, "How to Add an ADF Library JAR into a Project Manually."](#) For the procedure to add the JAR using the JDeveloper Resource Catalog, see [Section 38.4.1, "How to Add an ADF Library JAR into a Project using the Resource Palette."](#)

Before you proceed to create reusable components, you should review the guidelines for creating reusable components.

## 38.1.1 Creating Reusable Components

Creating and consuming reusable components should be included in the early design and architectural phases of software projects. You and your development team should consider which components are candidates for reuse, not only in the current applications but also for future applications and including those applications being developed in other departments.

You and your team should decide on the type of repository needed to store the library JARs, where to store them, and how to access them. You should consider how to organize and group the library JARs in a structure that fits your organizational needs. You should also consider creating standardized naming conventions so that both creators and consumers of ADF Library JARs can readily identify the component functionality.

**Tip:** If, in the midst of development, you and your team find a module that would be a good candidate for reuse, you can use the extensive refactoring capabilities of JDeveloper to help eliminate possible naming conflicts and adhere to reusable component naming conventions.

### 38.1.1.1 Naming Conventions

When you create reusable components, you should try to create unique and relevant names for the application, project, application module, task flow, connection, or any other file or component. Do not accept the JDeveloper wizard default names such as Application, Project, ViewController, AppModule, `task-flow-definition.xml`, or Connection. You want to try to have unique names to avoid naming conflicts with other projects, components, or connections in the application. Naming conflicts could arise from components created in the consuming application and those loaded from other JAR files. [Table 38–2](#) lists the objects that you may be required to rename.

**Table 38–2 Example Unique and Relevant Names for Reusable Components**

Type	JDeveloper Default	Example
Application	Application	FusionOrderDemo
Project	Model	OrderBookingService
	ViewController	StoreFrontUI
	Project	

**Table 38–2 (Cont.) Example Unique and Relevant Names for Reusable Components**

Type	JDeveloper Default	Example
Package	Various possibilities. For more information, see <a href="#">Section 38.1.1.1.1</a> .	<code>oracle.foddemo.storefront</code>
Application module	<code>AppModule</code>	<code>StoreServiceAMDataControl</code>
Connection	<code>Connection1</code>	<code>oracle_apps_foddb</code>
Task flow	<code>task-flow-defintion.xml</code>	<code>checkout-task-flow.xml</code>
Page template	<code>templateDef.jspx</code>	<code>StoreFrontTemplate.jspx</code>
Declarative Component	<code>componentDef</code> <code>componentDef.jspx</code>	<code>FODsuperwidgetDef</code> <code>FODsuperwidgetDef.jspx</code>
ADF Library JAR file	<code>adflib&lt;string or 3-digit random number&gt;N</code>  For more information, see <a href="#">Section 38.1.1.2</a> .	<code>adflibStoreFrontService</code>

#### 38.1.1.1.1 Naming Considerations for Packages

Be aware that some components use the default package name of the project without allowing the name to be explicitly set. In this situation, you must take extra care to avoid package name collisions. You can set the package name in the application creation wizard and you should check the names in the Project Properties dialog afterwards. If you don't set the package name, it will default to a variant of the project name, typically with the first letter being lowercase. For example, a project with the name `Project1` will have a default package name of `project1`. You should manually change the package name to a more unique name before you proceed to build the project.

---

**Note:** The basic package naming requirement is that ADF metadata registries (`.dcx`, `.cpx`, and so on) are generated based on the project's package name, and you should avoid metadata naming conflicts between projects that will be combined at runtime.

---

When you are creating a reusable component's web resource files (such as JSPs, HTMLs, and task flows), you should create them in their own relative directories. When the JAR is deployed into another application, there will be less chance for conflict between the reusable component's files and the consuming application's files.

---

**Note:** You can override the staleness period setting of 364 days for all static web application resources in ADF Libraries by adding initialization parameters to the `web.xml` file. For more information, see [Appendix A.13, "web.xml"](#).

---

#### 38.1.1.1.2 Naming Considerations for Connections

Often, several modules in an application will connect to the same data source. You should standardize the connection name to the same data source to avoid confusion because there is only one namespace for connections across the application. This would require coordination with other developers, component producers, and component consumers. For example, if `customers` and `suppliers` both have a connection to the same database, the connection name should be standardized to an agreed upon name, such as `orders_db`.

ADF Library JARs (with connections) may be used in different applications with different connection requirements. ADF Library JAR producers should choose connection names that are at least representative of the connection source, if not the actual standardized connection name. Be aware that consumers of the JAR that was created with connections will be required to satisfy the connection requirements when they add the component to the application.

For example, for a database connection, choosing an endpoint host name is usually not appropriate. The most appropriate name is a complete representative for the schema. Acceptable names for connections are `oracle-appsdb` and `oracle-scottdb`. You should realize that if many reusable components use different names for the same logical connection, then the consumer of the component will have to satisfy each one individually with duplicate information. The consumer will have to supply connection details for several different connection names, when in fact they all refer to the same instance.

#### 38.1.1.1.3 Naming Considerations for Applications with EJB Projects

If an application has both EJB projects and a web application project with data binding, you should check to see that the EJB component names are not in conflict with any other web application project component names. The EJB project components may have global scope because the project is automatically added to the global class path of all web projects in the application. The web application project may mistakenly access a component with the same name in the EJB project rather than within its own project.

For example, if both an EJB project and a web-based project have a `test1.jspx` page, when the web-based project is run, it may try to run the EJB project `test1.jspx` page.

At runtime, JDeveloper detects if there are EJB projects and web application projects with data binding in the same application. If there are both types in the application, when the project is run and the server starts up, a warning message will appear in the Log window.

#### 38.1.1.2 The Naming Process for the ADF Library JAR Deployment Profile

Before you package the project, you must create a deployment profile with the name and path for the JAR file. You should choose a name that follows you and your development team's naming convention and that is descriptive of the function of the component. You should realize that the consuming project may also include other JAR files from other software authors.

For example, if the component is a task flow for self-service paying, you might name it `mycompany.hcm.pay.selfservice.taskflows.jar`. Other examples are `oracle.apps.hcm.pay.model.jar` and `mycompany.hcm.pay.model.overrides.jar`.

When you create the deployment profile, JDeveloper will present a default name with the following format:

```
adflibidentifierN
```

Where *identifier* is random number up to three-digits and *N* is a number that starts with 1 and increments by 1 for each iteration of the profile.

For example, the default name for a profile may be `adf1ib7491` (random number is 749 and suffix is 1). The default name for the another profile may be `adf1ib51` (random number is 5 and suffix is 1).

You can change this default name to a name of your choice.

### 38.1.1.3 Keeping the Relevant Project

When you are creating reusable components, you should eliminate any projects that are not relevant to the reusable component. For example, if you want to create a reusable application module, you would need a data model project, but you would not need a user interface project. In this instance, if you had created an application with both a data model and a view-controller project, you could delete the user interface project. Of course, you should rename the default name `Model` to something more relevant, such as `StoreFrontService`. Similarly, if you are creating a reusable task flow that is not databound, you can delete any data model project from the application.

### 38.1.1.4 Selecting the Relevant Feature

If you know the technology scope of your consuming projects, you can design your component with technologies that will be compatible. For example, if the consuming application uses only standard JSF Faces, then it may not be compatible with a declarative component that is built with ADF Faces.

When you create your application, you can define the features using the Create Application Wizard by selecting from the application template.

After the project has been created, you can define the technology using the Features page of the Project Properties dialog.

### 38.1.1.5 Selecting Paths and Folders

If you are using the file system to store your ADF Library JARs, you should select file system locations that can function as repositories. You may want to put groups of JARs into a common directory folder, for example,

`C:\ADF11\jdev\DevTeamADFRepository`. If your team or organization plans to share ADF Library JARs, you should consider setting up network-accessible repository folders, directories, or services. The Resource Palette has provisions to connect to different repository sources and make multiple connections. For more information about accessing ADF Library JARs using the Resource Palette, see [Section 38.2.2, "Using the Resource Palette."](#)

### 38.1.1.6 Including Connections Within Reusable Components

If the project you are packaging into an ADF Library JAR includes a connection, that information can be included in the JAR and may be available to the consuming project. Oracle ADF uses connection architecture which defines a connection as two parts, the connection name and the connection details (or endpoint definition). JDeveloper will present the producer of the JAR the option to package the connection name only or to include connection details with the connection name.

If a connection is present in the project, the packaged ADF Library JAR will contain a `jar-connections.xml` file and a `jar-adf-config.xml` file. They will be added to the `META-INF` directory. The `jar-connections.xml` file contains the connection name and other relevant connection information. The `jar-adf-config.xml` file stores the information about the credentials used for the connections. If connection

credentials were also specified, then a `jar-credential-jazn-data.xml` will also be included for the credential store. You can select the individual connections or connection types that you want to be packaged with the ADF Library JAR when you create the ADF Library JAR deployment profile. You make connection selections in the Create or Edit ADF Library Deployment Profile Properties dialog Connections page, as described in [Section 38.3.1, "How to Package a Component into an ADF Library JAR."](#)

When an ADF Library JAR is being added to a project, JDeveloper checks for conflicts between the application's connections and the JAR's connections. A dialog will be presented to allow you to decide whether to proceed with adding the JAR to the project. Connections defined in the ADF Library JAR may be added to the consuming project, depending on the following conditions:

- If the connection defined in the JAR is fully configured and there are no connection name conflicts with the consuming project, a new connection will be added.
- If the connection defined in the JAR is partially configured, a new connection will be added to the consuming project but it must be configured before use. Connection dialogs may appear to allow the user to enter connection information. This partially configured connection may be indicated by an incomplete icon.
- If the connection defined in the JAR has the same name as the application's connection, it will not be added to the project. The application's existing connection will be used.
- If the connection defined in the JAR has the same name as the application's connection but is of different type, the JAR's connection will not be added to the project. For example, if a database connection in the JAR and a URL connection in the application have the same name, the database connection will not be added to the application.

For instructions on how to add an ADF Library to a project that includes connections, see [Section 38.4.1, "How to Add an ADF Library JAR into a Project using the Resource Palette."](#)

---

---

**Note:** In the process of adding the ADF Library to a project, you will see one message displayed in the Log window for each connection defined in the JAR. The messages indicate the merge action taking place in the project.

---

---

## 38.1.2 Reusable ADF Components Use Cases and Examples

Packaging projects into ADF Library JARs allows components to be reused multiple times in the same or in different applications. Different development teams can create and consume projects and create libraries of reusable modules. ADF Library JARs support the M-V-C design pattern. You can create ADF Libraries and access them using drag and drop from the Resource Palette.

For instance, you can package up an application module into an ADF Library JAR and place it in a public folder for other team to use. Different implementation teams may access that JAR to create their applications. They may use the application module to create different pages for their use instead on having to create their own application modules. When there is a change in the model, the original developer can repackage the application module and republish the ADF Library JAR. The other implementation teams can update their application using the updated ADF Library.

### 38.1.3 Additional Functionality for Reusable ADF Components

You may find it helpful to understand other ADF features before you work with reusable ADF components. Following are links to other functionality that may be of interest.

- You can package business components for reuse. For more information on application modules, see [Chapter 3, "Getting Started with ADF Business Components."](#)
- You can package application modules for reuse. For more information on application modules, see [Chapter 9, "Implementing Business Services with Application Modules."](#)
- You can package task flows for reuse. For more information on task flows, see [Chapter 18, "Getting Started with ADF Task Flows."](#)
- You can package page templates for reuse. For more information on task flows, see [Chapter 24, "Getting Started with Your Web Interface."](#)
- You can package page templates for reuse. For more information, see the "Using Declarative Components" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

## 38.2 Common Functionality of Reusable ADF Components

When you package or consume an ADF Library JAR, you also include and consume the extension libraries that are associated with the project. When you consume an ADF Library, you can use the Resource Palette.

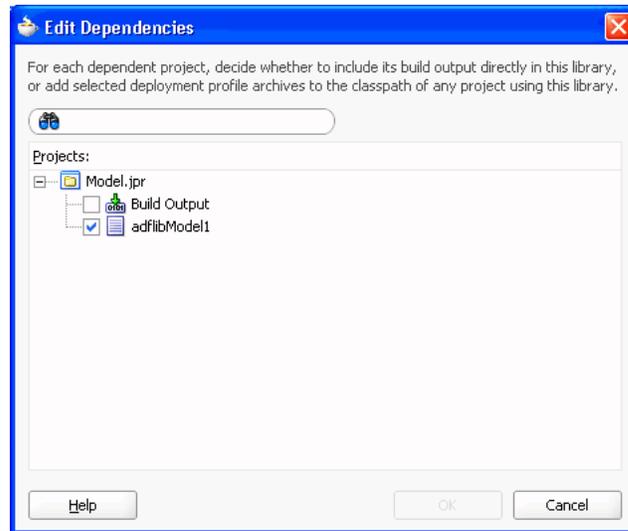

### 38.2.1 Using Extension Libraries

An ADF project usually includes a list of extension libraries that it needs to run. These libraries are loaded in the class path of the project. You can view a project's dependent libraries by selecting the **Libraries and Classpath** node of the Project Properties dialog. Some of the libraries that may appear are JSP Runtime, ADF Page Flow Runtime, Connection Manager, and Oracle JDBC.

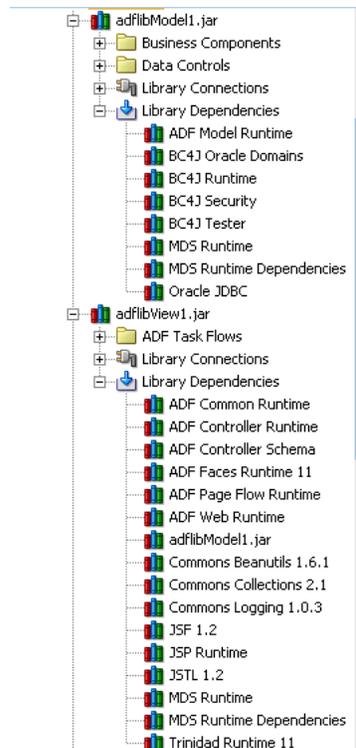

When a project is packaged into an ADF Library JAR, its extension libraries are packaged with it. And when an ADF Library JAR is being consumed by another project, JDeveloper automatically resolves any extension library conflicts between them. During the consuming process, JDeveloper checks to see whether the consuming project already has the extension libraries of the ADF Library JAR in its class path and loads only those libraries that it does not have. For example, if JSP Runtime already exists in the consuming project, it will not be loaded again if the ADF Library JAR also includes it. The consuming project's extension libraries will be a union of its own libraries and the libraries in the ADF Library JAR.

If the project you want to package into an ADF Library has a dependent project, you can include the dependent project's extension libraries directly in the JAR or, if the dependent project has a deployment profile, you can add the dependent project's JAR to the ADF Library. For more information about setting up the deployment process, see [Section 38.3.1, "How to Package a Component into an ADF Library JAR."](#)

For example, suppose that project `view` is being packaged into ADF Library `adfLibView1.jar` and that has a dependency on the `Model` project. For project `view`, the `Model` project is a dependent project with the deployment profile option (`adfLibModel1`) selected, as shown in [Figure 38-1](#).

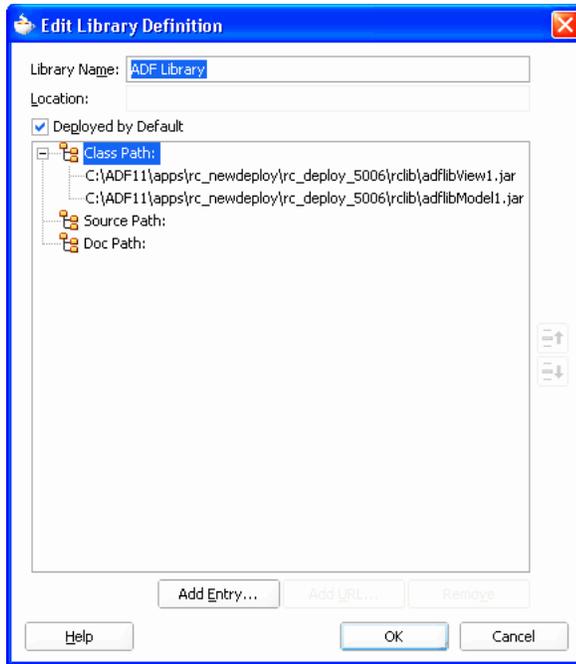

**Figure 38–1 Edit Dependencies Dialog with Deployment Profile Option**

When the deployment profile is selected, the dependent project's JAR file will be added to the ADF Library JAR. As a result, the extension libraries of the dependent project will also be made available to any consuming project. In [Figure 38–2](#), the ADF Library being packaged, `adflibView1.jar`, includes the dependent `adflibModel1.jar` as listed under the Library Dependencies node.

**Figure 38–2 Resource Palette Showing `adflibView1.jar` and `adflibModel1.jar` Extension Libraries**

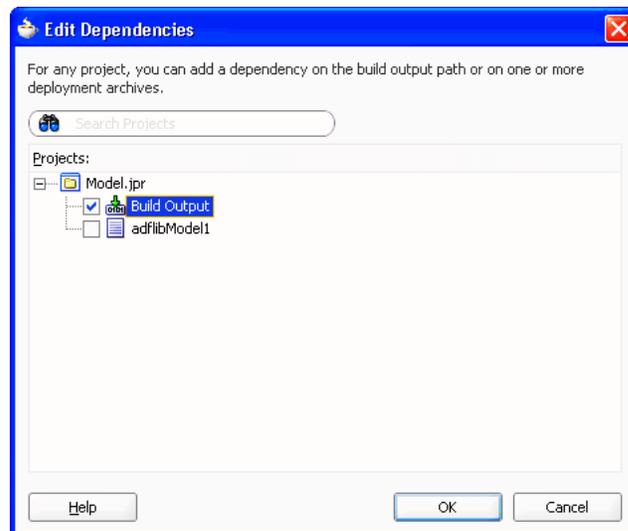

When you select `adfLibView1.jar` in the Resource Palette and choose **Add to Project** from the context menu, both `adfLibView1.jar` and `adfLibModel.jar` will be added to the consuming project's class path.

**Figure 38–3 Class path of Consuming Project Showing ADF Library JAR and Dependent Project Library JAR**

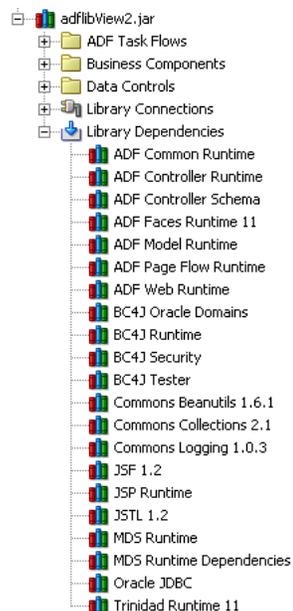

Alternately, you can include the dependent project's artifacts and extension libraries directly into the ADF Library JAR.

For example, project `View` can also be packaged into ADF Library `adfLibView2.jar`. It also has a dependency on the `Model` project. But in this second deployment profile, the `Model` project is a dependent project with the **Build Output** option selected (as opposed to the deployment profile (`adfLibModel1`) being selected), as shown in [Figure 38–4](#).

**Figure 38–4 Edit Dependencies Dialog Used to Built adflibview2.jar**

When **Build Output** is selected, the dependent project's classes and extension libraries will be added directly to the ADF Library JAR. [Figure 38–5](#) shows the ADF Library `adflibView2.jar`, which includes artifacts of the `Model` project and its extension libraries. Note that the extension libraries under the `adflibView2.jar` Library Dependencies node are the same as the combined extension libraries under the `adflibView1.jar` and `adflibModel.jar` shown in [Figure 38–2](#).

**Figure 38–5 Resource Palette Showing adflibView2.jar Extension Libraries**

How you decide to package the dependent project depends on how you intend the ADF Library to be used. Including the dependent project as a JAR may be advantageous when the dependent project is itself a reusable component, or when it is a dependent project for several projects that will be packaged into an ADF Library JAR. In the example, the dependent project `Model` may be a dependent project for several view projects. On the other hand, packaging the dependent project as **Build Output** is straightforward and eliminates the need for multiple JARs.

---

---

**Note:** If you are creating an ADF Library JAR that is included in a JDeveloper extension library, you should include the additional manifest `JDevLibrary: extension_library_name` entry in the JAR. When you use **Add to Project** from the Resource Palette to add a ADF Library JAR that has a `JDevLibrary` manifest entry, the JDeveloper extension library containing this JAR will be added instead of the ADF Library JAR itself.

---

---

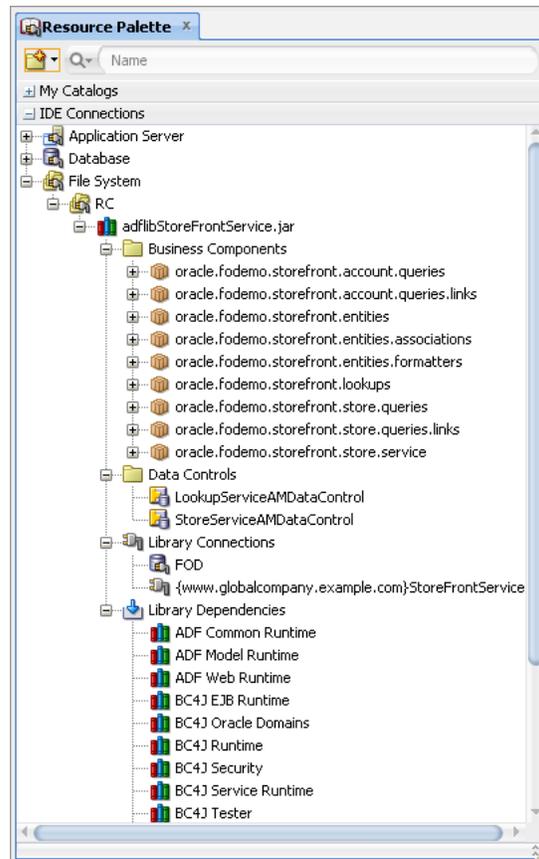

## 38.2.2 Using the Resource Palette

ADF Library JARs can be packaged, deployed, discovered, and consumed like any other Oracle Library component. Creating an ADF Library JAR is the action of packaging all the artifacts (and additional control files) of a project into a JAR. Consuming a reusable component from an ADF Library JAR is the action of loading that ADF Library JAR into the project's set of libraries.

However, the easiest way to manage and use ADF Library JAR components is by using JDeveloper's Resource Palette. With the Resource Palette, developers who want to consume reusable components can easily find and discover available components and add them to their projects. The Resource Palette provides search and browse functions across different data management systems to locate the component. It provides multiple connections to access different sources. It has a structure tree view for displaying different connections and the ADF Library JAR component types. [Figure 38–6](#) shows the Resource Palette window with three file system connections, `RCconnect`, `rcconnect2`, and `StoreFront`. In this example, `StoreFront` contains the ADF Library component, `adflibStorFrontService.jar`.

The Resource Palette tree structure displays each JAR as subcategories. Separate nodes are created for each type of reusable component. For example, application modules are under the Data Controls node, and task flows are under the ADF Task Flows node.

The tree structure for the ADF Library JAR lists any connection information under a Library Connections node and lists all the producing project's extension libraries under the Library Dependencies node.

**Figure 38–6 Resource Palette Showing ADF Library Structure**

### 38.3 Packaging a Reusable ADF Component into an ADF Library

Once you have decided that a certain component or components can be reused, create an application and a project to develop that component. Follow the guidelines in [Section 38.1.1, "Creating Reusable Components"](#) to name your application, project, package, and other objects and files. A project corresponds to one ADF Library JAR. If you create multiple projects and want to reuse components from each of the projects, you may need to create an ADF Library JAR for each project. In other situations, you may be able to involve multiple components under one project to create a single ADF Library JAR. For example, you may be able to create application modules, business components (entity object, view objects, associations), task flows, and page templates all under one project and create one ADF Library JAR.

Creating an ADF Library JAR involves compiling the project and validating the components, creating a resource service file, control files, an `adflibREADME.txt`, and adding the relevant project files into a JAR. For more information about the ADF Library JAR, see [Section 38.3.2, "What Happens When You Package a Project to an ADF Library JAR."](#)

If you are packaging a component that itself uses another ADF Library component, the final consuming project must have both ADF Library JARs added to the project. For example, say you created a reusable task flow that contains tables dropped from a data control in another ADF Library JAR. When you add the task flow from an ADF Library JAR into a consuming project, that project will also require the data control ADF Library JAR.

If you are packaging a component that has dependent JARs, such as third-party JARs, you have two options:

- If the consuming environment has control over the placement of JARs, you can place the ADF Library JAR and its dependent JARs in a JDeveloper Extension Library. The advantage of using a JDeveloper Extension Library is that it does not clutter the consuming project with specific references to the dependent JARs.
- If using JDeveloper Extension Library is not possible, you can place the dependent JARs in the same location as the ADF Library JAR and include a manifest classpath entry for each dependent JAR.

### 38.3.1 How to Package a Component into an ADF Library JAR

To package up a reusable component, you first create a deployment profile that specifies the archive type, the name of the JAR file, and the directory path where the JAR will be created. Then you deploy the project using the deployment profile.

#### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see [Section 38.3, "Packaging a Reusable ADF Component into an ADF Library."](#)

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see [Section 38.1.3, "Additional Functionality for Reusable ADF Components."](#)

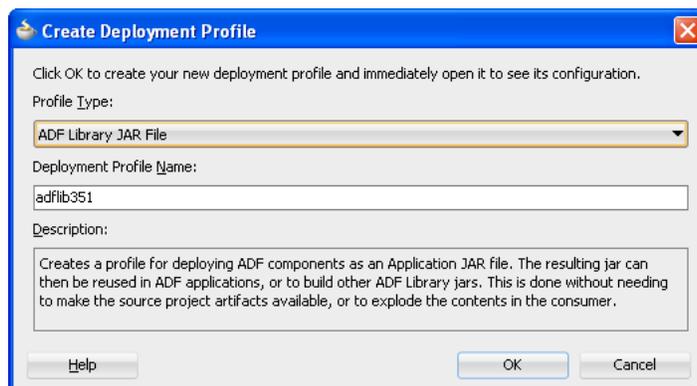

You will need to complete this task:

Create a project and determine whether it has dependent projects and JAR that need to be packaged. For more information, see [Section 38.3, "Packaging a Reusable ADF Component into an ADF Library."](#)

#### To package and deploy a project into the ADF Library JAR:

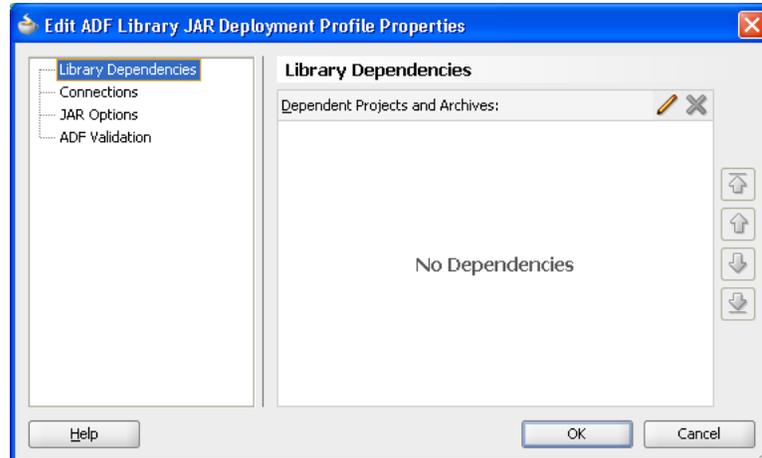

1. In the Application Navigator, double-click the project that contains the component you want to make reusable.
2. In the Project Properties dialog's left pane, select **Deployment** and then click **New**.
3. In the Create Deployment Profile dialog, select **ADF Library JAR file** for **Profile Type**, enter a name or accept the default name for **Deployment Profile Name**, and click **OK**.

**Figure 38–7** Create Deployment Profile Dialog with Default Name

4. In the Project Properties dialog, select the deployment profile and click **Edit**.
5. In the Edit ADF Library JAR Deployment Profile Properties dialog, select the **Library Dependencies** node, as shown in [Figure 38-8](#).

**Figure 38-8 ADF Library JAR Deployment Profile Properties Dialog**

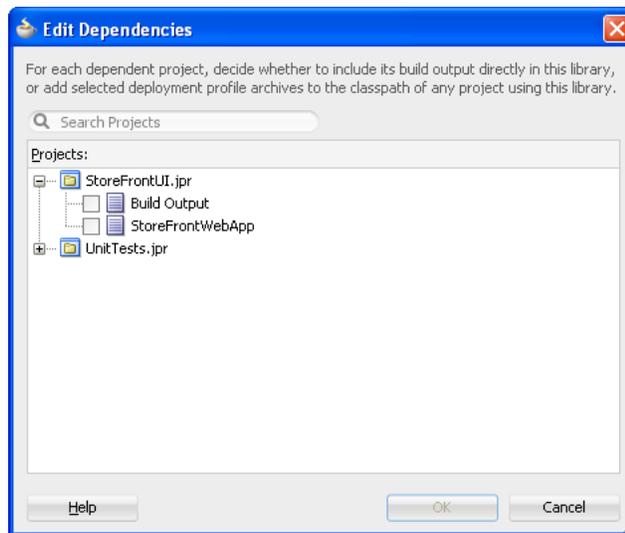

The Library Dependencies pane shows a list of dependent projects for the project being packaged. You can add the dependent project's build output directly into the packaging project's library, or you can add selected deployment profile archives to the class path.

- a. To add dependent projects, click the **Edit** icon to bring up the Edit Dependencies dialog, as shown in [Figure 38-9](#).

If you select **Build Output**, the dependent project's extension libraries will be added directly to the ADF Library JAR. If you select deployment profile, the dependent project's JAR file (which includes its own extension libraries) will be added to the ADF Library JAR. For more information about library dependencies, see [Section 38.2.1, "Using Extension Libraries."](#)

In this example, the `StoreFrontService` project can be set as a dependency only as **Build Output**. However, the `StoreFrontUI` project can be set as a dependency either as **Build Output**, or as a deployment profile (`StoreFrontWebApp`).

**Figure 38–9 ADF Library Deployment Edit Dependencies Dialog**

- b. For each dependent project, select the **Build Output** node for the project or select the dependent profile and click **OK**.
6. In the Edit ADF Library JAR Deployment Profile Properties dialog, select the **Connections** node, as shown in [Figure 38–10](#).

You can select:

- **Connection Details (excluding secure content):** If the project has a connection, select this checkbox if you want to add any available connection details in addition to the connection name. For more information, see [Section 38.1.1.6, "Including Connections Within Reusable Components."](#)
- **Connection Name Only:** Select this checkbox if you want to add the connection name without any connection details such as security.

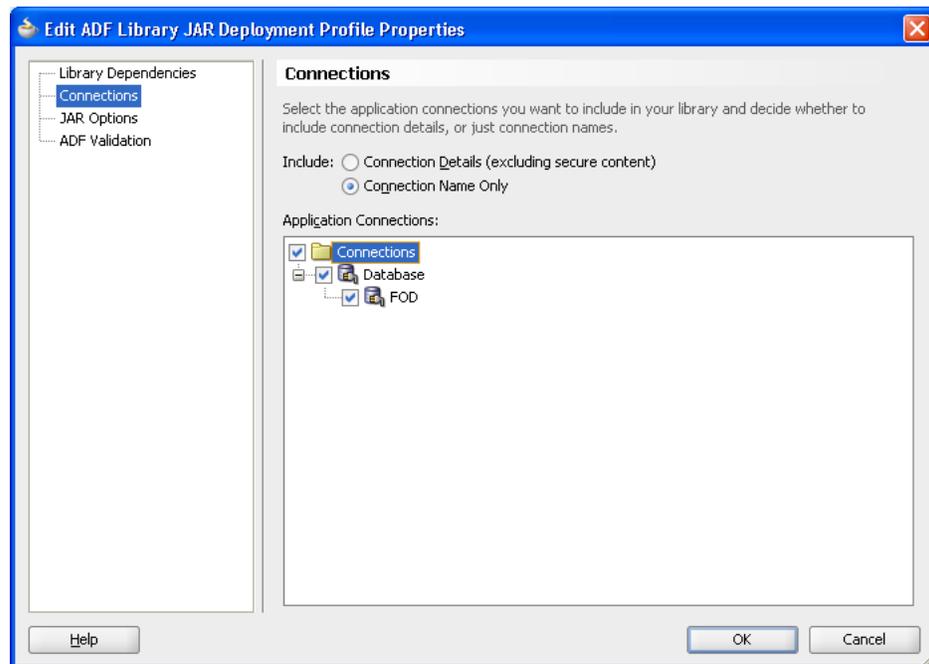

---

**Note:** The connection options available depends on the JDeveloper role. **Connection Details (excluding secure content)** and **Connection Name Only** are the selections available for the Studio Developer role. If your JDeveloper is set to a different role, you may have different options and defaults.

---

In the Applications Connections tree structure, select the checkbox for the level of connection you want to include.

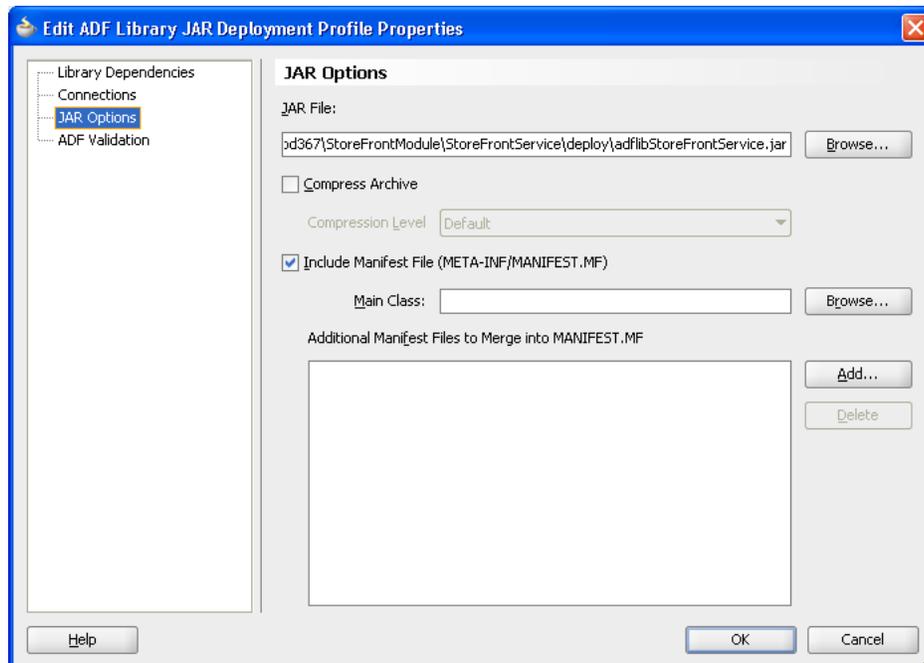

**Figure 38–10** Connections Page of the Edit ADF Library JAR Deployment Profile Properties Dialog

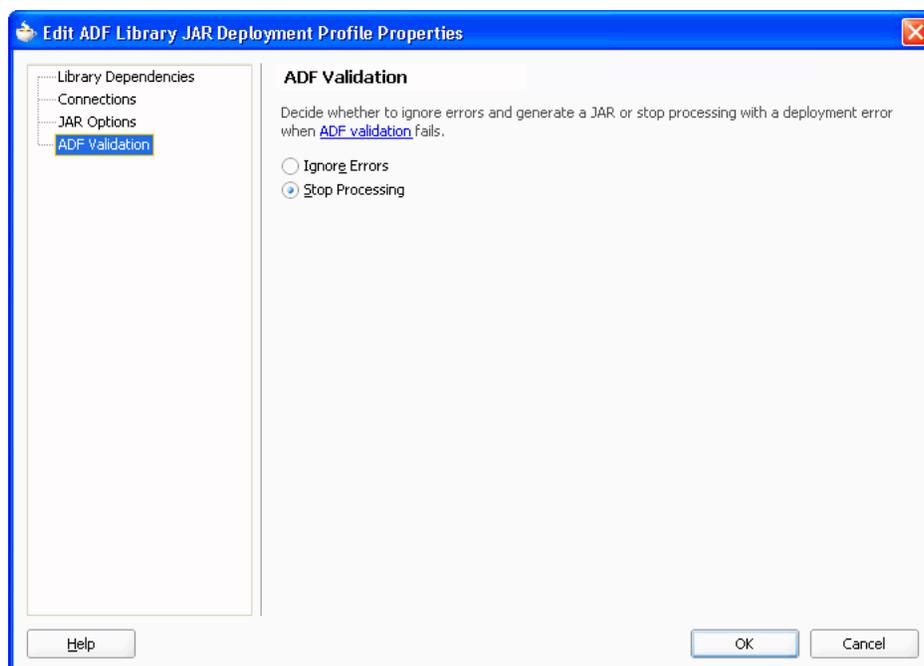

7. In the Edit ADF Library JAR Deployment Profile Properties dialog **JAR Options** node, as shown in [Figure 38–11](#), verify the default directory path or enter a new path to store your ADF Library JAR file.

If the ADF Library JAR is to be included in a JDeveloper extension library, create a text file with a `JDevLibrary: extension_library_name` entry and place the file in the project root directory. Click **Add** to locate and merge that file into the `Manifest.mf` file.

When you create your manifest text file, make sure the `JDevLibrary` entry starts in column 1 with a space after the colon, and that there is a blank line at the end of the file.

**Figure 38–11 ADF Library JAR Deployment Profile Properties Dialog JAR Option**

8. In the Edit ADF Library JAR Deployment Profile Properties dialog **ADF Validation** node, select:
  - **Ignore Errors:** Select this option to create the JAR file even when validation fails. This is the default option.
  - **Stop Processing:** Select this option to stop processing when validation fails.

**Figure 38–12 ADF Library JAR Deployment Profile Properties Dialog ADF Validation**

9. Click **OK** to finish setting up the deployment profile.

10. In the Application Navigator, right-click the project and choose **Deploy > deployment**, where *deployment* is the name of the deployment profile.
11. In the Deploy dialog Deployment Action page, click **Next** and then click **Finish**.  
JDeveloper will create the ADF Library JAR in the directory specified in Step 7. You can check that directory to see whether the JAR was created.

### 38.3.2 What Happens When You Package a Project to an ADF Library JAR

When you deploy the library JAR, JDeveloper packages up all the necessary artifacts, adds the appropriate control files, generates the JAR file, and places it in the directory specified in the deployment profile. During deployment, you will see compilation messages in the Log window.

When you deploy a project into an ADF Library JAR, JDeveloper performs the following actions:

- Package the HTML root directory artifacts into the JAR. When the JAR is added to the consuming project, JDeveloper will make the reusable component's `public_html` resources available by adding it to the class path.
- Add the `adf.xml` file to the JAR. If there are multiple `META-INF/adf.xml` files in the workspace, only the `adf.xml` in the project being deployed is added. JDeveloper modifies this file to include relevant content from any dependent project's `adf.xml` file.
- Add a service resources file, `oracle.adf.common.services.ResourceService.sva`, into the `META-INF` directory of the JAR. The addition of this file differentiates an ADF Library JAR file from standard JAR files. This file defines the service strategies of the JAR and allows the Resource Palette to properly discover and display the contents of the JAR.
- Add a `Manifest.mf` file to the JAR. The `Manifest.mf` file is used to specify dependencies between JAR files, and to determine whether to copy and include the contents of a JAR file or to reference it. JDeveloper will create a default manifest file. For example:  

```
Manifest-Version: 1.0
```
- Adds a `jar-connections.xml` file to the JAR for components that require a connection and that use the connections architecture. Note that in the consuming application, connection information in configuration files that are defined in the class path and accessible at runtime may be merged together. If the same connection is named multiple times in the class path, the connection in the main application will be given priority.

Different types of reusable components have different artifact files and different entries in the service resource file.

#### 38.3.2.1 Application Modules

For application modules, JDeveloper adds these control files to the JAR: `oracle.adf.common.services.ResourceService.sva`, `Manifest.mf`, `adf.xml`, and the business components `.jspx` file. The service resource file for an application module includes entries for the business components associated with the application module, as well as an entry for the application module data control.

The `jar-connections.xml` file may appear for components that use the connection architecture and that contain connection information regarding the data source.

### 38.3.2.2 Data Controls

For data controls such as placeholder data controls, JDeveloper includes three control files in the JAR: `oracle.adf.common.services.ResourceService.sva`, `Manifest.mf`, and `DataControl.dcx` file. Data controls are used when the data source is not based on ADF Business Components, and so business components are not included in the JAR file, as is the case in an application module JAR file. The service resource file for a standard data control has an entry for the data control.

The JAR also includes the `Datacontrol.dcx` file from the project to describe the data control type.

### 38.3.2.3 Task Flows

For task flows, JDeveloper includes three control files in the JAR: `oracle.adf.common.services.ResourceService.sva`, `Manifest.mf`, and `task-flow-registry.xml`. The service resource file for a task flow includes an entry that indicates that one or more task flows are in the JAR.

### 38.3.2.4 Page Templates

For page templates, JDeveloper includes two control files in the JAR: `oracle.adf.common.services.ResourceService.sva` and `Manifest.mf`.

### 38.3.2.5 Declarative Components

For declarative components, JDeveloper includes two control files in the JAR: `oracle.adf.common.services.ResourceService.sva` and `Manifest.mf`.

## 38.3.3 How to Place and Access JDeveloper JAR Files

If you have JAR files that can be reused by other projects, such as third-part JAR files, you can use JDeveloper to place them in an accessible location and create a library file (`.library`) to designate them. The consumer can use JDeveloper to navigate to this location and add the JAR to the project.

An ADF Library JAR contains ADF components and does not and cannot contain other JARs.

#### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see [Section 38.3, "Packaging a Reusable ADF Component into an ADF Library."](#)

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see [Section 38.1.3, "Additional Functionality for Reusable ADF Components."](#)

You will need to complete this task:

Place the JAR files in a accessible location for both the producer and the consumer of these JAR files. For example, the directory may be on a network drive where other shared files are located. For more information, see [Section 38.3, "Packaging a Reusable ADF Component into an ADF Library."](#)

#### To place and access a JDeveloper Library JAR:

1. From the main menu, choose **Tools > Manage Libraries**.
2. In the Manage Libraries dialog, click **Load Dir**.

3. In the Load Directory dialog, select the directory where the secondary JAR files are located.
4. In the Manage Libraries dialog, click **New**.
5. In the Create Library dialog, enter a library name and click **Add Entry**.  
You have created a library file (with a `.library` extension). You should place library files in source control systems.
6. In the Select Path Entry dialog, select the JARs you want to add and click **Select**.
7. In the Create Library dialog, be sure that the **Deployed by Default** option is set correctly for your JAR, click **OK** and then click **OK** again.
8. In the consuming project.
  - a. From the main menu, choose **Tools > Manage Libraries**.
  - b. In the Manage Libraries dialog, click **Load Dir**.
  - c. In the Load Directory dialog, select the directory where the secondary JAR files are located and click **OK**. This should be the same location specified in step 3.
  - d. Right-click the project and select **Project Properties**.
  - e. In the Project Properties window, select **Libraries and Classpath** and click **Add Library**.
  - f. In the Add Library dialog, select the library, click **OK** and then click **OK** again.

## 38.4 Adding ADF Library Components into Projects

After ADF Library JARs are created, they must be distributed to the developers who will use these JARs. Distributing the ADF Library JARs may include putting the JARs into a network file system to be searched, browsed, and discovered. It may include using other forms of data store or services to access and retrieve these JARs. Since ADF Library JARs are simply binary files, they can be distributed like any other file such as ftp and email.

Once you have access to the ADF Library JARs, you can use JDeveloper to access them and add them to your consuming projects. Using the JDeveloper Resource Palette is the easiest and most efficient way. You can also use JDeveloper to manually add the JARs into the project by entering them into the class path.

When a project is packaged into an ADF Library JAR, it captures the list of dependent JARs the project needs for deployment and run time. This list is based on the project's dependent profiles and the information in the project's Libraries and Classpath with **Deployed By Default** selected. When the ADF Library JAR is added to the consuming project, this list of dependent JARs is placed in a library called *ADF Library Dependencies*. This is a locked library in the consuming project and its content will not be shown in the Data Controls panel, Component Palette, or other places in JDeveloper. The library is maintained and updated as different ADF Library JARs are added and deleted from the project. If the dependencies have changed (for example, the producer project was rebuilt), then you can refresh the dependencies in the consuming project using a JDeveloper menu command.

Once reusable components have been added, how they are used depends on the type of component.

### 38.4.1 How to Add an ADF Library JAR into a Project using the Resource Palette

You can use the Resource Palette to search, discover, and add the ADF Library JAR to your project.

#### **Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see [Section 38.4, "Adding ADF Library Components into Projects."](#)

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see [Section 38.1.3, "Additional Functionality for Reusable ADF Components."](#)

You will need to complete this task:

Create an ADF Library JAR in a repository folder. If you do not already have a Resource Palette connection to this repository, you must know the location of this folder. For more information, see [Section 38.4, "Adding ADF Library Components into Projects."](#)

#### **To add a component to the project using the Resource Palette:**

1. From the main menu, choose **View > Resource Palette**.
2. In the Resource Palette, click the **New** icon, and then choose **New Connection > File System**.
3. In the Create File System Connection dialog, enter a name and the path of the folder that contains the JAR.

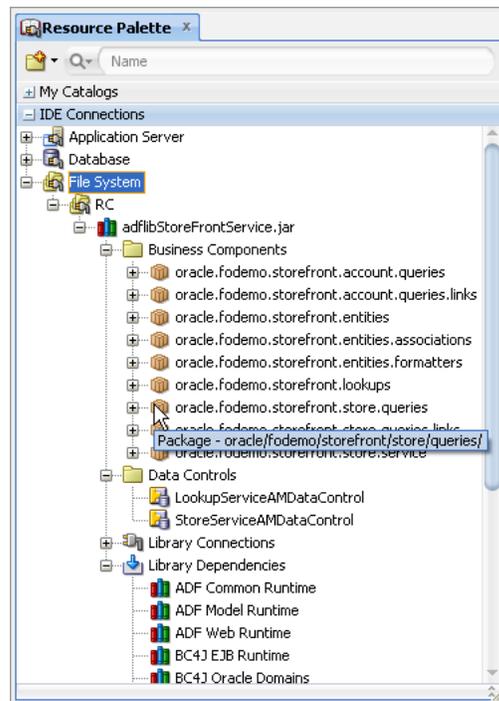

For file path guidelines, see [Section 38.1.1.5, "Selecting Paths and Folders."](#)

4. Click **OK**.

The new ADF Library JAR appears under the connection name in the Resource Palette.

5. To examine each item in the JAR structure tree, use tooltips. The tooltip shows pertinent information such as the source of the selected item.

[Figure 38–13](#) shows a Resource Palette with a tooltip message that shows package information for a business component.

**Figure 38–13** Tooltip Message for a Connection in the Resource Palette

- To add the ADF Library JAR or one of its items to the project, right-click the item and choose **Add to Project**. In the confirmation dialog that appears, click **Add Library**, as shown in [Figure 38–14](#).

**Figure 38–14** Confirm Add ADF Library Dialog

If you had previously added that library JAR, you will get a Confirm Refresh ADF Library dialog asking you whether you want to refresh the library.

- If the ADF Library JAR has changes to its dependencies, you can refresh the project with the new changes. From the Application Navigator, right-click the project and select **Refresh ADF Library Dependencies in project.jpr**.

For application modules and data controls, you have the option to drag and drop the application module or data control from the Resource Palette into the Data Controls panel.

---

**Note:** JDeveloper will load whichever ADF Library JAR extension libraries are not already in the consuming project. Extension libraries from the ADF Library's dependent JARs will also be checked and loaded if not already part of the consuming project. For more information, see [Section 38.2.1, "Using Extension Libraries"](#)

---

## 38.4.2 How to Add an ADF Library JAR into a Project Manually

You can add an ADF Library JAR in the same way as you would other library JARs.

### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see [Section 38.4, "Adding ADF Library Components into Projects."](#)

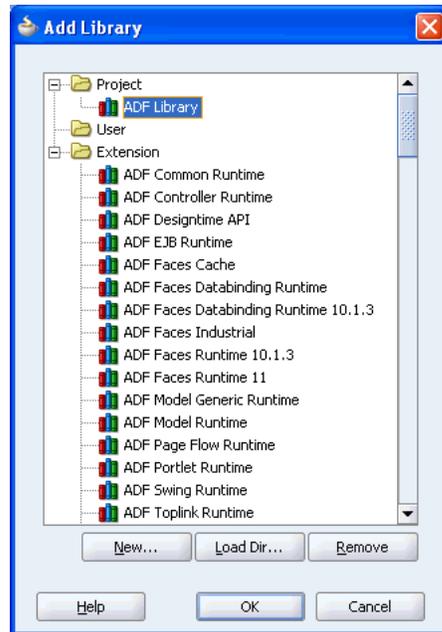

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see [Section 38.1.3, "Additional Functionality for Reusable ADF Components."](#)

You will need to complete this task:

Create an ADF Library JAR. For more information, see [Section 38.4, "Adding ADF Library Components into Projects."](#)

### To add a component to a project manually:

1. In the Application Navigator, double-click the project to which the component is to be added.
2. In the Project Properties dialog, select the **Libraries and Classpath** node and then click **Add Library**.
3. In the Add Library dialog, click **New**.
4. In the Create Library dialog, select **Project** in the **Location** dropdown list and enter a name for the ADF Library. The preferable name is "ADF Library". Select **Deploy by Default**, and click **Add Entry**.
5. In the Select Path Entry dialog, enter or browse to the ADF Library JAR file and click **Select**.
6. The Create Library dialog reappears with the path of the JAR file filled in under the **Class Path** node. Click **OK**.
7. The Add Library dialog reappears with the ADF Library entry filled in under the **Project** node. Click **OK**.

**Figure 38–15 Add Library Dialog**

8. The Project Properties dialog reappears with the JAR file added to the list of libraries. Click **OK**.

### 38.4.3 What Happens When You Add an ADF Library JAR to a Project

When you add an ADF Library JAR to a project, either by using the Resource Palette or by manually adding the JAR, an ADF Library definition is created in the project. The ADF Library JAR file will be added to the class path of the project. The project will access and consume the components in the JAR by reference.

By default, the **ADF Library Deployed by Default** option in the Create Library dialog is set to true. If this option is set, when the application or module is further archived or built into a WAR file, the contents of the ADF Library JAR will be copied to that archive or WAR file. If the Deploy by Default option is not set, then the JARs in the ADF Library must be loaded in some other way, such as by deploying them in a shared library.

Figure 38–16 shows the empty Data Controls panel for a consuming project before the ADF Library was added.

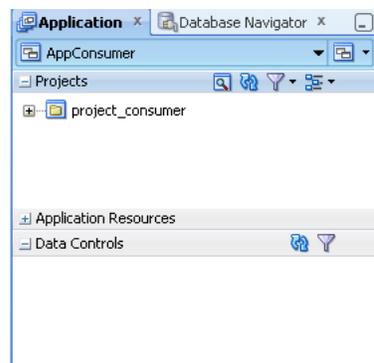

**Figure 38–16 Data Controls Panel of the Consuming Project**

Figure 38–17 shows the `adflibStoreFrontService` ADF Library being added to the consuming project.

**Figure 38–17 Adding the ADF Library JAR to the Project**

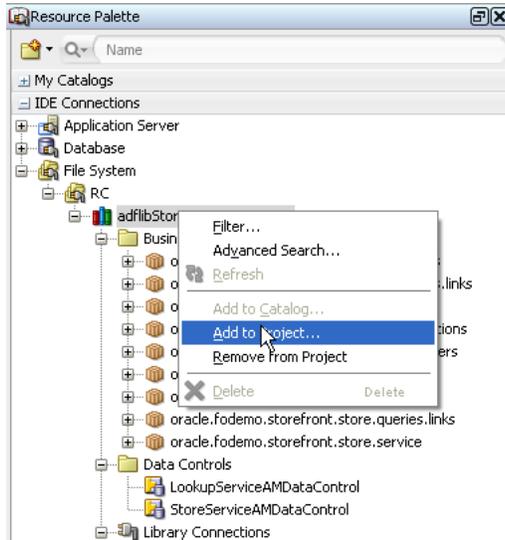

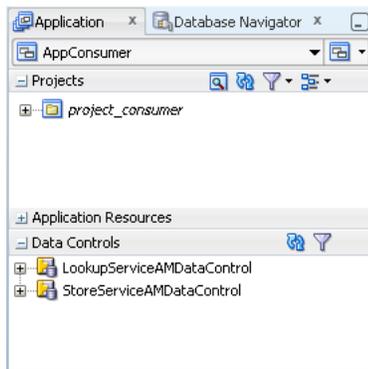

Figure 38–18 shows several data controls from the ADF Library added to the Data Controls panel in the consuming project.

**Figure 38–18 Consuming Project Data Controls Panel with Added Application Modules**

After adding the ADF Library JAR, you may notice some changes to some of the JDeveloper windows. These changes are different depending on the type of components being added. Table 38–3 lists the effects on several JDeveloper windows.

**Table 38–3 JDeveloper Window After Adding an ADF Library**

Added Component	Data Controls Panel	Creation Wizards	Component Palette
Data controls	Data control appears.		
Application module	Application module appears.		

**Table 38–3 (Cont.) JDeveloper Window After Adding an ADF Library**

Added Component	Data Controls Panel	Creation Wizards	Component Palette
Business components		Entity objects available in view object creation wizard. View objects in JAR also available for use.	
Task flows			Task flows appear in Component Palette.
Page template		Page template available during JSF creation wizard.	
Declarative components			Tag library appears in Component Palette. Declarative component appears in the list.

## 38.4.4 What You May Need to Know About Using ADF Library Components

Although the procedure to add an ADF Library JAR to a project is standardized, the component type determines where it appears in JDeveloper and how it can be reused.

### 38.4.4.1 Using Data Controls

When you add a data control to a project, the data control appears in the Data Controls panel. If you are using the Resource Palette, you have the option of dragging and dropping the data control from the Resource Palette onto the Data Controls panel, and then dragging and dropping from the Data Controls panel onto the page.

### 38.4.4.2 Using Application Modules

When you add an application module to a project, the application module appears in the Data Controls panel. If you are using the Resource Palette, you have the option of dragging and dropping the application module item from the Resource Palette onto the Data Controls panel, and then dragging and dropping from the Data Controls panel onto the page.

Application modules are associated with business components. When the reusable application module was packaged, the JAR includes the business components used to create the application module. These components will be available for reuse.

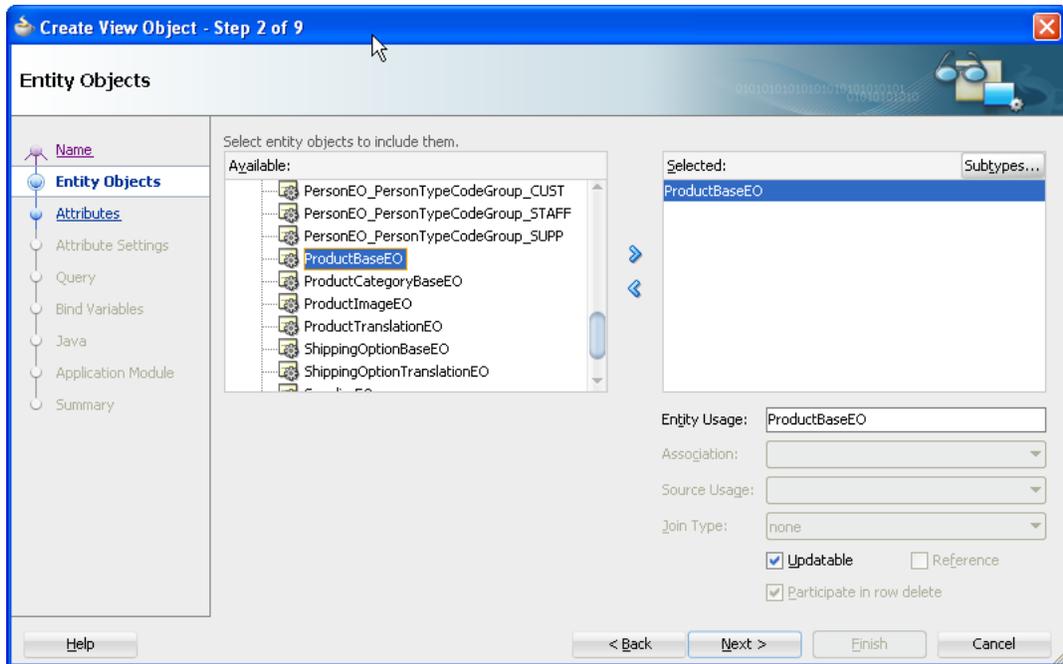

### 38.4.4.3 Using Business Components

Business components can also be packaged and reused. The entity objects, view objects, and associations can be packaged together and added to a consuming project. By default, packaged application modules will include the business components in the

JAR, but business components can be reused by themselves without the accompanying application module.

One way to reuse business components is to create new view objects using the entity objects from an ADF Library JAR. When you add view objects using the wizard, the entity objects will become available within the wizard to support view object generation. For instructions on creating view objects, see [Section 5.2.1, "How to Create an Entity-Based View Object."](#) When the wizard presents a screen for entity objects used to create view objects, the entity objects from the ADF Library will be available in the shuttle window, as shown in [Figure 38–19](#).

**Figure 38–19** *Creating View Object Using Entity Objects from ADF Library*

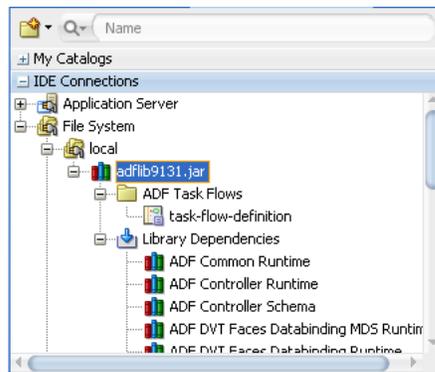

If the consuming project has the **Initialize Project for Business Component** option selected (in the Project Properties dialog Business Components page) before the ADF Library JAR is added, the business components within the JAR will automatically be made available to the project.

If you add the ADF Library JAR first, and then select **Initialize Project for Business Component**, JDeveloper will automatically load the business components.

#### 38.4.4.4 Using Task Flows

Task flows added to a project will appear in the Component Palette when you are adding components to a JSF page. If you are using the Resource Palette, you can also drag and drop the task flow directly from the Resource Palette onto another task flow or page, as shown in [Figure 38–20](#).

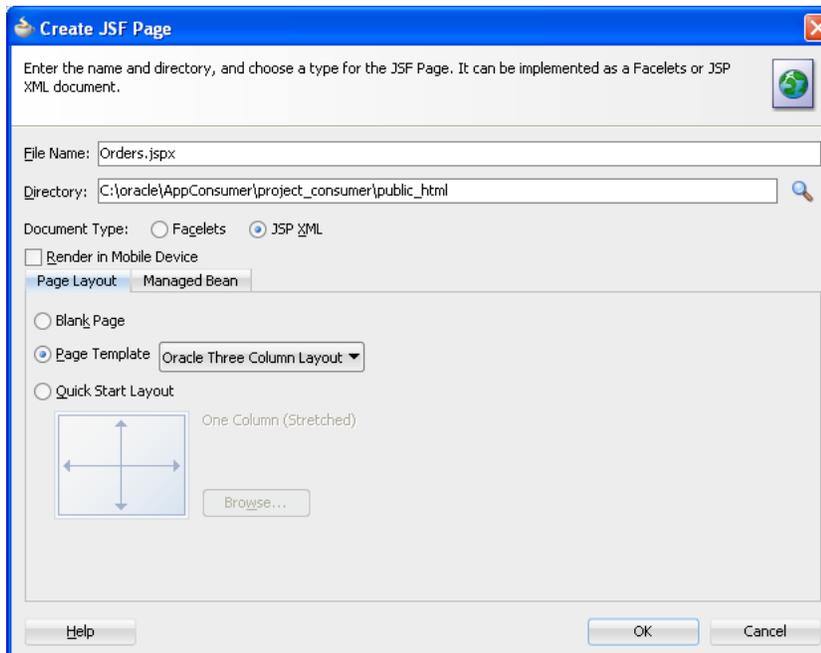

**Figure 38–20 Using the Resource Palette to Drag and Drop Task Flows**

For more information about creating task flows, see [Chapter 18, "Getting Started with ADF Task Flows."](#)

#### 38.4.4.5 Using Page Templates

When you add a page template to a project, the template will not be exposed in the Application Navigator. You will not have direct access to individual supporting files, such as image files. However, the template retains its access to its supporting files inside the JAR and is fully reusable within the project. When you apply the template, it will retain all the images that were loaded with the template.

The page template is exposed and accessible when you create a new JSF page using the wizard. When the wizard presents you with the option to use a page template, the ADF Library template will appear in the dropdown list. For example, if you loaded a page template called `StoreFrontTemplate` from an ADF Library, when you use the wizard to create a JSF page, `StoreFrontTemplate` will appear in the wizard, as shown in [Figure 38–21](#). For information on how to use page templates and create a JSF page, see [Section 24.2, "Using Page Templates"](#) and the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

**Figure 38–21 Using a Page Template from ADF Library**

#### 38.4.4.6 Using Declarative Components

When you add a declarative component to a project, the JSP tag libraries that contain the component will be added to the project. The tag libraries will appear in the Component Palette, and the declarative components will be available for selection. For information about creating and using declarative components, see the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 38.4.5 What You May Need to Know About Differentiating ADF Library Components

If you mix components created during application development with components imported from the ADF Library, you may be able to differentiate between them by using the tooltips feature of JDeveloper.

Move the cursor over an application module or data control and you will see the full path of the source. If you see the ADF Library JAR file in the path, that means the component source is the ADF Library.

---

**Note:** The tooltip for items in the Data Controls panel varies depending on whether or not the node has ever been opened in this session. To ensure that you are seeing the most complete tooltip, you should expand the item.

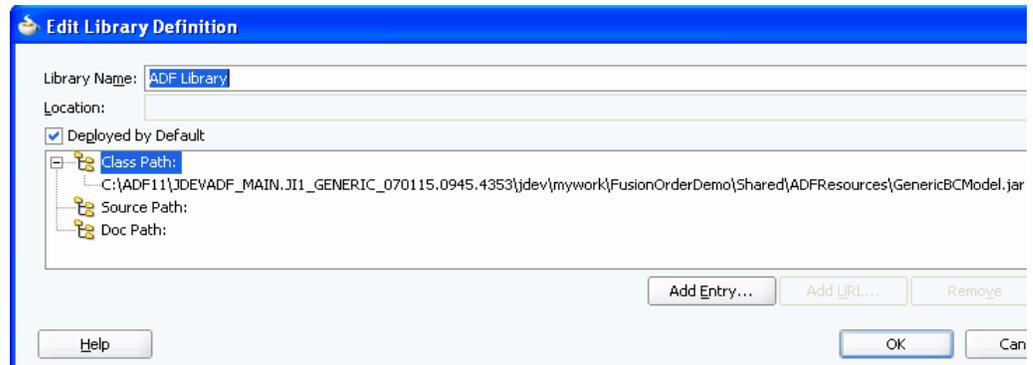

---

### 38.4.6 What Happens at Runtime: Adding ADF Libraries

After an ADF Library JAR has been added to a project and to the class path, it behaves like any other library file. During runtime, any component that uses the component in the ADF Library JAR will reference that object. The process is transparent and there is no need to distinguish between components that were developed for the project and

those that are in ADF Library JARs. [Figure 38–22](#) shows the ADF Library and the path to the JAR as defined for a project.

**Figure 38–22** *Edit Library Definition Dialog Showing the ADF Library in the Class Path*

---

**Note:** Once an ADF Library JAR is created, any Java source used to create the component is not available in the JAR. If you want your consumers to have access to the source, such as for debugging, they must be delivered separately (usually in ZIP files). The consumer can then designate those ZIP files as the related component source for the **Source Path** entry in their ADF Library **Libraries and Classpath** entry in their own projects.

---

## 38.5 Removing an ADF Library JAR from a Project

You can use the Resource Palette to remove an ADF Library JAR from a project, or you can manually remove the JAR using the Project Properties dialog. You can remove an ADF Library JAR only if the components in the project do not have any dependencies on the components in the ADF Library JAR.

When you remove a JAR, it will no longer be in the project class path and its components will no longer be available for use.

### 38.5.1 How to Remove an ADF Library JAR from a Project Using the Resource Palette

The Resource Palette allows you to remove previously added ADF Library JARs from a project using a simple command.

#### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see [Section 38.5, "Removing an ADF Library JAR from a Project."](#)

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see [Section 38.1.3, "Additional Functionality for Reusable ADF Components."](#)

You will need to complete this task:

Add the ADF Library JAR using the Resource Palette. For more information, see [Section 38.4, "Adding ADF Library Components into Projects."](#)

**To remove an ADF Library JAR from the project using the Resource Palette:**

1. From the main menu, choose **View > Resource Palette**.
2. In the Application Navigator, select the project that has the ADF Library JAR you want to remove.
3. In the Resource Palette, locate the ADF Library JAR you want to remove from the current project.
4. Right-click the JAR and choose **Remove from Project**.

### 38.5.2 How to Remove an ADF Library JAR from a Project Manually

When you remove an ADF Library JAR manually, be sure to remove the correct library. Be aware of other libraries that are critical to the operation of the project.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see [Section 38.5, "Removing an ADF Library JAR from a Project."](#)

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see [Section 38.1.3, "Additional Functionality for Reusable ADF Components."](#)

You will need to complete this task:

Add the ADF Library JAR manually. For more information, see [Section 38.4, "Adding ADF Library Components into Projects."](#)

**To remove an ADF Library JAR from the project manually:**

1. In the Application Navigator, double-click the project.
2. In the Project Properties dialog, select the **Libraries and Classpath** node.
3. In the **Classpath Entries** list, select **ADF Library** and click **Edit**.
4. In the Edit Library Definition dialog, select the ADF Library JAR you want to remove under the **Class Path** node, and click **Remove**.
5. Click **OK** to accept the deletion, and click **OK** again to exit the dialog.

---

## Customizing Applications with MDS

The Oracle Metadata Services (MDS) framework allows you to create customizable applications. This chapter describes how to develop applications that can be customized and subsequently deployed by a customer. It also covers how to implement customizations on such applications.

This chapter includes the following sections:

- [Section 39.1, "About Customization and MDS"](#)
- [Section 39.2, "Developing a Customizable Application"](#)
- [Section 39.3, "Customizing an Application"](#)
- [Section 39.4, "Extended Metadata Properties"](#)
- [Section 39.5, "Enabling Runtime Modification of Customization Configuration"](#)

For information on how to deploy customized applications, see [Section 41.4, "Deploying the Application."](#)

### 39.1 About Customization and MDS

Using the customization features provided by MDS, you can create applications that fall into the following customization patterns:

- **Seeded customization**

Seeded customization of an application is the process of taking a generalized application and making modifications to suit the needs of a particular group, such as a specific industry or site. Seeded customizations exist as part of the deployed application, and endure for the life of a given deployment. This chapter describes how to create a customizable application, and then customize the application using JDeveloper.
- **User customization (change persistence)**

User customization allows an end user to change the content of the application at runtime to suit individual preferences (for example, which columns are visible in a table), and have those changes "remembered" the next time the user opens the application. For information about user customization, see [Chapter 40, "Allowing User Customizations at Runtime."](#)
- **Design time at runtime**

Using the features of Oracle WebCenter, you can create applications that are customizable at runtime. This allows business analysts or administrators, using a Web browser interface, to customize the application for their end users. For

information about runtime customization, refer to the *Oracle WebCenter Framework Developer's Guide*.

For more information about the MDS architecture and metadata repositories (database- and file-based) and archives (EAR, MAR), refer to the section about managing the MDS repository in the *Oracle Fusion Middleware Administrator's Guide*.

### 39.1.1 Customization and Layers: Use Cases and Examples

A customized application contains a base application and one or more layers containing customizations. MDS stores the customizations in a metadata repository and retrieves them at runtime to merge the customizations with the base metadata to reveal the customized application. Since the customizations are saved separately from the base, the customizations are upgrade safe; a new patch to base can be applied without breaking customizations. When a customized application is launched, the customization content is applied over the base application.

For example, say you have a generalized payroll application with a validation rule that limits the salary field to 4000. Then you create a customization of that validation rule that limits the salary field to 3300. At runtime, the customization is applied to the base application and the validation rule for the salary field limits it to 3300.

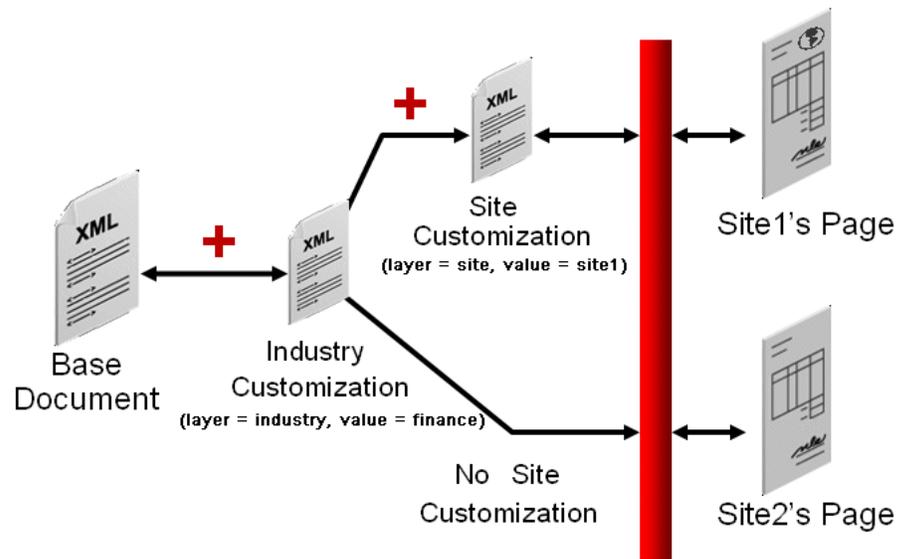

A customizable application can have multiple *customization layers*. Examples of customization layers are `industry` and `site`. Each layer can have multiple *customization layer values*, but typically only one such layer value from each layer is applied at runtime. For example, the `industry` layer for a customizable application can contain values for `healthcare` and `financial` industries; but in the deployed customized application, only one of the values from this layer is used at a time.

Layer values from multiple customization layers can be applied, in a specified order of precedence, on top of the base metadata. For example, a customized application can contain customizations in the `financial` layer value of the `industry` layer and the `Financial Company #1` layer value of the `site` layer. Each customization layer corresponds to a customization document that contains a set of instructions that change the underlying metadata.

The *customization context* of a customized application is defined by the set of customization layer values applied to it.

[Figure 39–1](#) illustrates how layers are applied in a customized application.

Figure 39-1 Example of Layered Customization

To support this, you use JDeveloper to create customization classes, define layers and values, and specify the order of precedence. These processes are described in [Section 39.2, "Developing a Customizable Application."](#)

### 39.1.2 Static and Dynamic Customization Content

Customizations can be categorized as either static or dynamic. Static customizations have only one layer value in effect for all executions of the application, while dynamic customizations can have values that vary based on the execution context of the application. If a customization can vary for different users executing the application, then it is dynamic. If a customization has the same value for all users executing the application then it is static.

When you implement customizations in ADF Business Components objects, the customizations remain the same for entire runtime of the application. This is because these objects are loaded only once for an application and reused for the duration of the application. For example, you can have a customized validation rule in the Healthcare Company #1 value of the site layer that limits salaries for that site to 3300. This is static customization content.

However, you can also implement customizations at the controller or view level that allow the layer value to be determined at runtime, based on user roles (responsibilities) or other application-specific criteria. For example, you can design an application so that users from different organizations see different sets of fields on a given screen. This is dynamic customization content.

The determination of whether a customization is static or dynamic is made in the customization class. In the customization class, if the `getCacheHint()` method returns `ALL_USERS`, then the customization layer is static. For more information about `CacheHint` values, see [Section 39.2.2, "What You May Need to Know About Customization Classes."](#)

All objects could have a static customization layer, depending on how the customization classes are implemented. But for ADF Business Components objects, customizations can only be static.

### 39.1.3 Additional Functionality for Customization

You may find it helpful to understand other features before you start working with customization. Following are links to other functionality that may be of interest.

- For information about the MDS architecture and metadata repositories (database- and file-based) and archives (EAR, MAR), see to the section about managing the MDS repository in the *Oracle Fusion Middleware Administrator's Guide*.
- You can use the ADF Faces change persistence framework to create JSF pages that users can customize at runtime. For information, see [Chapter 40, "Allowing User Customizations at Runtime."](#)
- The features of Oracle WebCenter allow business analysts or administrators, using a Web browser interface, to customize an application for their end users. For information about runtime customization, refer to the *Oracle WebCenter Framework Developer's Guide*.

## 39.2 Developing a Customizable Application

To create a customizable application, create the base application and perform the following procedures:

### To prepare an application for customization:

1. Create the customization classes that will be used, as described in [Section 39.2.1, "How to Create Customization Classes."](#)
2. Enable seeded customization in the application, as described in [Section 39.2.4, "How to Enable Seeded Customizations for View Projects."](#)
3. Specify the customization classes in the `adf-config.xml` file, as described in [Section 39.2.7, "How to Configure the adf-config.xml file."](#)
4. You can optionally restrict runtime customizations on the application, as described in [Section 39.4.1, "How to Edit Extended Metadata Properties."](#)
5. After you have prepared the application for customization, you must prepare JDeveloper so you can use it to implement the customizations, as described in [Section 39.3.4, "How to Configure Customization Layers."](#)

### 39.2.1 How to Create Customization Classes

A customization class is the interface that MDS uses to define which customization applies to the base definition metadata. Each customization class defines a customization layer (for example, `industry` or `site`) and can contain multiple layer values. The customization classes that are used in the application must be available to JDeveloper when customizing the application, and included in the deployed application.

#### 39.2.1.1 Customization Classes

A customization class evaluates the current context and returns a String result. This String result is used to locate the customization layer.

The customization class provides the following information:

- A name, that represents the name of the layer.
- An array of values, that represent the customization layer values. Typically, each layer returns a single value. If multiple values are returned, the customizations

available in the MDS repository for those values are applied in the order in which they appear in the array. For more information, see [Section 39.2.1.2, "Implementing the `getValue\(\)` Method in Your Customization Class."](#)

- An IDPrefix, for objects created in the layer. When new objects are created in a customization layer they need a unique ID. The IDPrefix is added to the autogenerated identifier for the object to create an ID for the newly added object. Each layer needs a unique IDPrefix so that objects created at different customization layers will have unique IDs.
- A cache hint, for the layer defined by the customization class. The cache hint defines whether a layer is static or dynamic. If the `getCacheHint()` method returns `ALL_USERS`, then the customization layer is static. For more information about dynamic customizations, see [Section 39.1.2, "Static and Dynamic Customization Content."](#) For more information about `CacheHint` values, see [Section 39.2.2, "What You May Need to Know About Customization Classes."](#)

Customizations can be used to tailor an application to suit a specific industry domain (verticalization). Each such domain denotes a customization layer and is depicted using a customization class.

To implement seeded customizations using your customization classes:

- The `cust-config` section (under `mds-config`) in the `adf-config.xml` must contain a reference to the customization classes (as shown in [Example 39-6](#)).

The customization configuration (`cust-config`) section provides the customization classes and their precedence for a customized application. See [Section 39.2.7, "How to Configure the `adf-config.xml` file."](#)

- The customization classes must be included in the application to support seeded customizations.

For more information, see [Section 39.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."](#) At runtime, your customization classes must be available in the EAR-level application class loader.

- The layer values must be listed in the `CustomizationLayerValues.xml` file.

This file is located in the `jdev_install\jdev` directory. The names of the layers in this file must be consistent with the customization classes. (For more information, see [Section 39.3.4, "How to Configure Customization Layers."](#)) JDeveloper uses this file to retrieve layer values at design time.

When JDeveloper is launched in the **Customization Developer** role, the Customization Context window displays the available customization layers and layer values. You can select the layer and value to which you want to apply customizations in the Customization Context window. For more information about working in the **Customization Developer** role, see [Section 39.3.1, "Introducing the Customization Developer Role."](#) The layer you choose to customize is called the *tip layer*. For more information, see [Section 39.3.3, "Introducing the Tip Layer."](#)

[Example 39-1](#) shows a sample customization class. Note that all customization classes should have a single, no-argument constructor.

**Example 39-1 Sample IndustryCC customization class in the `mycompany` package**

```
package mycompany;

import java.io.IOException;
import java.io.InputStream;
import java.util.Properties;
```

```
import oracle.mds.core.MetadataObject;
import oracle.mds.core.RestrictedSession;
import oracle.mds.cust.CacheHint;
import oracle.mds.cust.CustomizationClass;

public class IndustryCC extends CustomizationClass {
 private static final String DEFAULT_LAYER_NAME = "industry";
 private String mLayerName = DEFAULT_LAYER_NAME;

 public IndustryCC() {
 }
 public CacheHint getCacheHint() {
 return CacheHint.ALL_USERS;
 }
 public String getName() {
 return mLayerName;
 }

 public String generateIDPrefix(RestrictedSession sess, MetadataObject mo) {
 return new String ("I");
 }

 public String[] getValue(RestrictedSession sess, MetadataObject mo) {
 // This needs to return the appropriate value at runtime.
 return new String[] {"financial"};
 }
}
```

This example shows the four methods that define how the customization class will work: `getCacheHint()`, `getName()`, `generateIDPrefix()`, and `getValue()`.

The return value for `getCacheHint()` indicates to MDS how widely visible a metadata object with this customization is, and therefore its likely duration in memory. It also defines whether or not a layer is static or dynamic. In this example, the `getCacheHint()` method returns `ALL_USERS`, which means the customization layer is static. For more information about `CacheHint` values, see [Section 39.2.2, "What You May Need to Know About Customization Classes."](#)

The `getName()` method returns the name of the customization layer. A `SiteCC` customization class, for example, might return "site." In this example, the `getName()` method returns "industry."

The `generateIDPrefix()` method creates an `IDPrefix`. The `IDPrefix` is a unique, abbreviated string that identifies the name and value of the layer. It is used as the prefix of the ID for objects created in the customization layer. The default implementation (if no `IDPrefix` is specified) returns name of the layer concatenated with customization value. For performance reasons, the `IDPrefix` should be kept short (4 characters or less). Therefore, the default implementation should be overridden. The related `getIDPrefix()` method returns the `IDPrefix` of the customization layer. In this example, the `getIDPrefix()` method would return "I" (for "industry").

The `getValue()` method returns the customization value (or values) for the customization class. In this example, the `getValue()` method returns a single value, "financial," that defines the customization context when combined with the layer name. There are additional techniques for using the `getValue()` method described in [Section 39.2.1.2, "Implementing the getValue\(\) Method in Your Customization Class."](#)

---

---

**Note:** The possible layer values corresponding to a layer name are retrieved by JDeveloper in the **Customization Developer** role from the `CustomizationLayerValues.xml` file. The precedence of layers is defined by the order of the customization classes specified in the `adf-config.xml` file. The names of the layers must be consistent in these files and in the customization classes.

---

---

### 39.2.1.2 Implementing the `getValue()` Method in Your Customization Class

The `getValue()` method is used to retrieve the layer value(s) of the customization class based on the application context and the metadata. For example, calling `getValue()` on a `SiteCC` customization class might return an array with single entry "headquarters." Typically, the `getValue()` method returns an array with a single value, as shown in [Example 39-1](#).

You can also return multiple values from the `getValue()` method, as shown in [Example 39-2](#).

#### **Example 39-2** *The `getValue()` Method Returning Multiple Values*

```
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
 return new String[]{"North America", "US", "CA"}
}
```

When multiple values are returned, customizations applicable to all values are applied. Customizations are applied in the order in which they appear in the array. In this example, `North America` customizations are applied over the base application, then `US` customizations are applied, and finally `CA`.

---

---

**Note:** Returning multiple values for a customization layer is an advanced concept that is typically unnecessary.

---

---

The `getValue()` method can return a layer value based on the current execution context for the current user, pulled either from static or thread local state maintained by the client, or from properties set by the client on the MDS session and based on the metadata object name. [Example 39-3](#) shows this type of implementation.

#### **Example 39-3** *The `getValue()` Method Returning a Layer Value Based on the Current Execution Context*

```
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
 if (mo.getName().equals("/sample/abc.jspx"))
 {
 return new String[]{"Headquarters"};
 }
 else
 {
 return new String[]{"RemoteSite"};
 }
}
```

In this example, the `getValue()` method uses the `getName()` method on the metadata object to determine if the name of the metadata document is `/sample/abc.jspx`. If so, `getValue()` returns `Headquarters` to apply headquarters customizations. If not, it returns `RemoteSite` to apply customizations for remote sites.

---

---

**Note:** Coding the `getValue()` method to return a value based on the metadata object is an advanced concept that is typically unnecessary. Customization context for dynamic layers is typically determined through facets of the application context, such as user name or responsibility.

---

---

An additional technique that can be useful during the development cycle is to use an external properties file to specify layer values. [Example 39-4](#) references a properties file (`customization.properties`) that stores the layer values.

**Example 39-4 The `getValue()` Method Using a Properties File to Specify Layer Values**

```
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
 Properties properties = new Properties();
 String configuredValue = null;
 Class clazz = IndustryCC.class;
 InputStream is = clazz.getResourceAsStream("/customization.properties");
 if (is != null){
 try {
 properties.load(is);
 String propValue = properties.getProperty(mLayerName);
 if (propValue != null){
 configuredValue = propValue;
 }
 } catch (IOException e) {
 e.printStackTrace();
 }
 finally {
 try {
 is.close();
 } catch (IOException e) {
 e.printStackTrace();
 }
 }
 }
 return new String[] {configuredValue};
}
```

When an application using this technique is run in JDeveloper, you can change the layer value in the properties file and refresh the browser to see new customizations being applied. This customization class and properties file combination allows you to maintain the layer value in a separate file so you don't need to modify and recompile Java code to change it for a particular deployment. If you use a `customization.properties` file, it must be packaged with the customization classes so that they are loaded from the same class loader.

[Example 39-5](#) shows a sample `customization.properties` file. When the `IndustryCC` class is loaded with this properties file, the layer value `healthcare` is applied.

**Example 39-5 Sample Contents of a `customization.properties` File**

```
#Configured values for the default layer values
industry=healthcare
site=headquarters
```

### 39.2.1.3 Creating a Customization Class

When creating customization classes, put them in a separate project. This allows you to deploy them to a JAR and to import the JAR into your lowest level project (which is typically the data model project). This approach increases modularity, making it easier to include the customization classes in multiple applications across your company, and easier to patch them centrally. For more information about this approach, see [Section 39.2.3, "How to Consume Customization Classes."](#)

Alternatively, you can put the customization classes in the data model project if you are creating customization classes that will be used in a single application only, or if you have no need to use the **Customization Developer** role and want simply to run the application locally from JDeveloper or to deploy remotely with MDS configuration.

Make sure that there is only one copy of the customization classes in the application and that they are packaged in a JAR file so that they are loaded at the EAR-level application class loader. By default, adding project dependencies will add the customization classes to the WAR profile, which will not work correctly after the application is packaged and deployed. For more information about packaging your application for deployment, see [Section 41.3.2, "How to Create Deployment Profiles."](#)

Use the following procedure to create a customization class.

#### Before you begin:

It may be helpful to have an understanding of the features of customization classes. For more information, see [Section 39.2.1.1, "Customization Classes."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 39.1.3, "Additional Functionality for Customization."](#)

You will need to launch JDeveloper using the **Studio Developer** role, and open (or create) the application that will hold the customization classes.

#### To create a customization class:

1. From the main menu, choose **File > New**.
2. In the New Gallery, expand **General**, select **Projects** and then **Java Project**, and click **OK**.

This opens the Create Java Project dialog. For more information about the options in this dialog, see the online help.

3. Specify the appropriate settings for your project, and click **Finish**.

---

---

**Note:** You should use a single project to hold all of your customization classes.

---

---

4. In the Application Navigator, right-click your project and choose **Project Properties**.
5. In the Project Properties dialog, click **Libraries and Classpath**, and then click **Add Library**.
6. In the Add Library dialog, select **MDS Runtime**, and click **OK**, then click **OK** to close the Project Properties dialog.
7. In the Application Navigator, right-click the project and choose **New**.

8. In the New Gallery, expand **General**, select **Java** and then **Class**, and click **OK**.
9. In the Create Java Class dialog, enter a name for the class and the appropriate package.

---

---

**Note:** Customization classes are typically named for the layer name they return. For example, a customization class that returns the layer name `industry` would be named `IndustryCC`.

---

---

10. In the **Extends** field, enter `oracle.mds.cust.CustomizationClass`.  
For more information about this class, refer to the Javadoc.
11. Make sure that **Implement Abstract Methods** is checked and click **OK**.
12. Replace the code in the generated file with code like that shown in [Example 39-1](#).
13. Save your changes and rebuild the project.

This creates the customization class. The sample code uses the package name `mycompany` and the class name `IndustryCC`. You will need to change these as appropriate for your application.

## 39.2.2 What You May Need to Know About Customization Classes

As described in [Section 39.2.1.1, "Customization Classes,"](#) the customization class defines a `CacheHint` which specifies the visibility of metadata objects in a customization layer, and therefore its likely duration in memory. This information is used by MDS to decide whether or not to cache a customization, and where to cache it. Any customization layers constructed using this customization class have this cache hint.

The following constants are supported values of `CacheHint`:

- `ALL_USERS` — The customization is applied globally (non-conditionally) for a given deployment. This constant is used for static customization layers.
- `MULTI_USER` — The customization is applied to multiple users.
- `REQUEST` — The customization is applied for the duration of the request only.
- `USER` — The customization is applied for a single user to documents which are accessed throughout the user's application session. (In web applications the application session is typically a servlet session.)

---

---

**Note:** Customization classes are likely to be executed frequently, once for each document being accessed to get the layer name and layer value, so take care to ensure their efficiency.

---

---

## 39.2.3 How to Consume Customization Classes

After you have created your customization classes, you can use them at design time in the **Customization Developer** role, and at runtime in the application. To be consumed in an application or in JDeveloper, the classes must be packaged appropriately.

### 39.2.3.1 Making Customization Classes Available to JDeveloper at Design Time

After you create the customization classes, you must make them available to JDeveloper so that you can use them when implementing customizations while working in the **Customization Developer** role.

Because the customization classes are reusable components, you can create a separate project to contain them, and package them into their own JAR file. You can then import the JAR into the consuming application, which makes the customization classes available to JDeveloper. For more information about creating the customization classes in a separate project, see [Section 39.2.1.3, "Creating a Customization Class."](#) For more information about packaging the customization classes into a JAR file, see [Section 41.3.2.6, "Adding Customization Classes into a JAR."](#)

---

---

**Note:** This procedure is not required if you created your customization classes in the data model project of the consuming application.

---

---

Use the following procedure to make the customization classes visible to the application, and then add the customization classes to the `cust-config` section of the `adf-config.xml` file, as described in [Section 39.2.7, "How to Configure the adf-config.xml file."](#)

#### Before you begin:

It may be helpful to have an understanding of the how customization classes are packaged. For more information, see [Section 39.2.1.1, "Customization Classes."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 39.1.3, "Additional Functionality for Customization."](#)

You will also need to complete these tasks:

- Create your customization classes in an external project, as described in [Section 39.2.1.3, "Creating a Customization Class."](#)
- Create a JAR using the procedure described in [Section 41.3.2.6, "Adding Customization Classes into a JAR."](#)
- Launch JDeveloper using the **Studio Developer** role, and open the application that you want to customize.

#### To use customization classes from an external project:

1. In the Application Navigator, right-click the data model project and choose **Project Properties**.
2. In the Project Properties dialog, click **Libraries and Classpath**.
3. Click **Add JAR/Directory**.
4. In the Add Archive or Directory dialog, select the JAR file you created that contains the customization classes, and click **Select**.
5. Click **OK** to close the Project Properties dialog.

Now the customization classes are available to JDeveloper for customization, and for running your project locally in JDeveloper.

### 39.2.3.2 Making Customization Classes Available to the Application at Run Time

When you package and deploy your customized application, the customization classes must be available at the application level on the application's class path.

When you define the deployment profiles for your application, you need to add the customization classes JAR file to the EAR assembly, and to avoid duplication, you need to make sure that the WAR profile does not include the customization classes JAR file. For more information, see [Section 41.3.2.3, "Creating an Application-Level EAR Deployment Profile."](#)

## 39.2.4 How to Enable Seeded Customizations for View Projects

Like all customizable components, the XML elements of a customizable metadata object must be uniquely identifiable by MDS, and therefore must have a unique, non-null identifier. The component's identifier is used to refer to the element in the customization instructions in the customization layer. The ID property is the identifier for each type of component in an ADF Faces `.jspx` or `.jsff` file.

To allow for customizations on your JSF and JSP pages, you must enable seeded customizations in the application's view project, which drives some defaults for your pages. This is not necessary for your model and controller projects.

---

---

**Note:** MDS requires that pages be XML-based to be customized. Therefore, customizations are not allowed on `.jsp` files; use `.jspx` files instead.

Additionally, facelets files must have a `.jsf` extension to be customizable. MDS uses this extension to recognize it as a Facelets file.

---

---

### Before you begin:

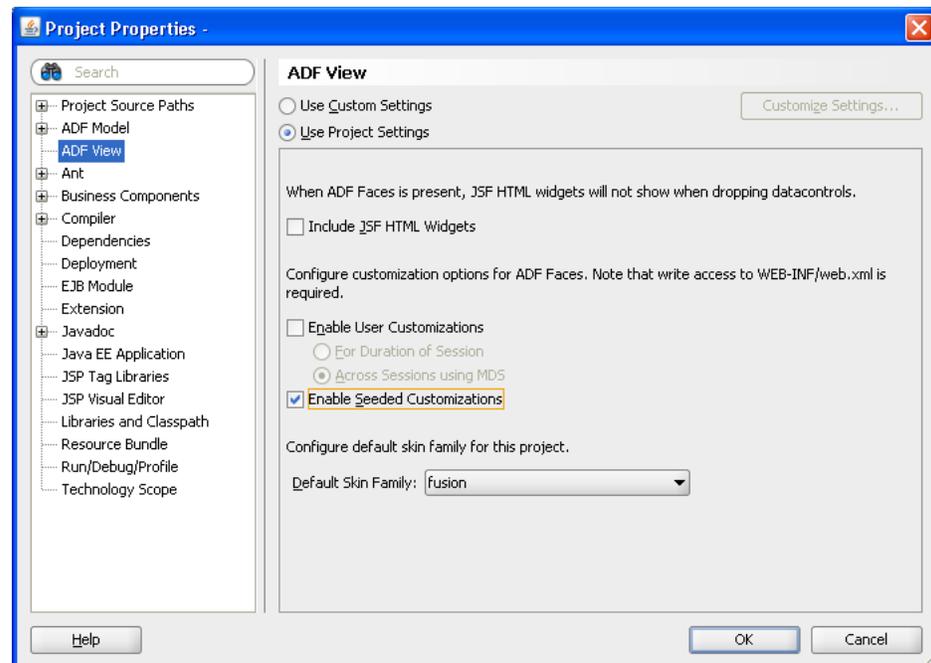

It may be helpful to have an understanding of the how seeded customization works. For more information, see [Section 39.1.1, "Customization and Layers: Use Cases and Examples."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 39.1.3, "Additional Functionality for Customization."](#)

You will also need to launch JDeveloper using the **Studio Developer** role, and open the application that you want to make customizable.

### To enable seeded customizations in your view project:

1. In the Application Navigator, right-click the view project and choose **Project Properties**.
2. In the Project Properties dialog, click **ADF View**.
3. Select the **Enable Seeded Customizations** checkbox, as shown in [Figure 39–2](#).
4. Click **OK**.
5. Save the changes to your project.

**Figure 39–2 Project Properties - Enable Seeded Customizations**

### 39.2.5 How to Enable Seeded Customizations in Existing Pages

If you have pages in your project that were created in an earlier version of JDeveloper, you must make sure that these preexisting pages are also enabled for seeded customizations. This is only necessary if you migrated the application from an earlier version of JDeveloper and did not generate IDs during migration.

#### Before you begin:

It may be helpful to have an understanding of how seeded customization works. For more information, see [Section 39.1.1, "Customization and Layers: Use Cases and Examples."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 39.1.3, "Additional Functionality for Customization."](#)

You will also need to launch JDeveloper using the **Studio Developer** role, and open the application that you want to make customizable.

#### To enable seeded customizations in an existing page:

1. Create an audit profile to implement ID tokens for all XML objects in your page.
  - a. From the **Tools** menu, choose **Preferences**.
  - b. In the Preferences dialog, select **Audit > Profiles**.
  - c. In the **Rules** tab on the Profiles page, deselect all rules.
  - d. Select the rule **ADF Faces > Component ID Rules > Check for ID When ADF Faces is Present**.
  - e. From the **Default Fix** dropdown list, select **Generate a unique ID**.
  - f. Click **Save As**, then enter an identifiable name for the profile (such as **Generate Unique IDs**). and click **Save**.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 39.1.3, "Additional Functionality for Customization."](#)

You will also need to complete these tasks:

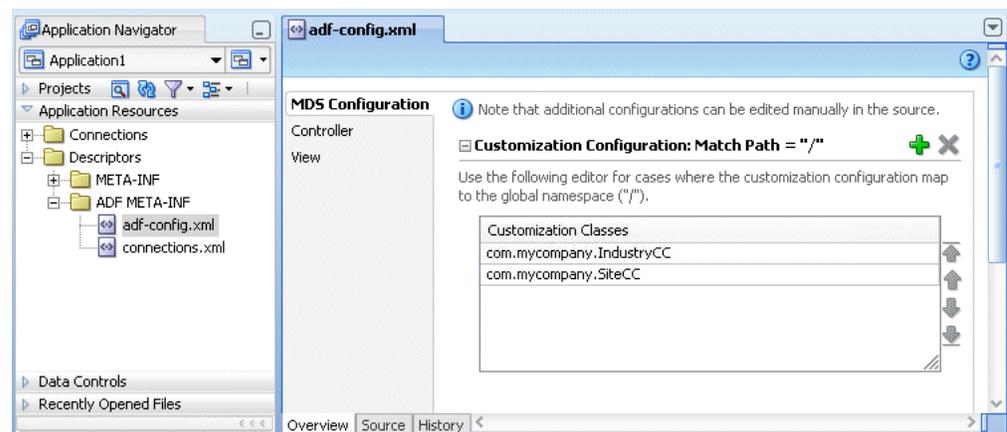

- Create your customization classes, as described in [Section 39.2.1.3, "Creating a Customization Class."](#)
- Make your classes available to JDeveloper, as described in [Section 39.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."](#)
- Create a JAR using the procedure described in [Section 41.3.2.6, "Adding Customization Classes into a JAR."](#)
- Launch JDeveloper using the **Studio Developer** role, and open the application that you want to customize.

#### To identify customization classes in the `adf-config.xml` file:

1. In the Application Navigator, open the Application Resources panel.
2. Expand **Descriptors**, then expand **ADF META-INF**.
3. Right-click `adf-config.xml`, and choose **Open**.
4. In the overview editor, click the **MDS Configuration** navigation tab, and then click the **Add** icon.
5. In the Edit Customization Classes dialog, search for or navigate to the customization classes you have already created.
6. Select the appropriate classes and click **OK**.
7. After you have added all of the customization classes, you can use the arrow icons to put them in the appropriate order.

[Figure 39–3](#) shows the overview editor for the `adf-config.xml` file with two customization classes added.

**Figure 39–3** *adf-config.xml Overview Editor*

The order of the customization-class elements defines the precedence of customization layers. For example, in the code shown in [Example 39–6](#), the `IndustryCC` class is listed before the `SiteCC` class. This means that customizations at the industry layer are applied to the base application, and then customizations at the site layer are applied.

**Example 39–6 Customization Class Order in the adf-config.xml File**

```
<adf-config xmlns="http://xmlns.oracle.com/adf/config">
 <adf-mds-config xmlns="http://xmlns.oracle.com/adf/mds/config">
 <mds-config xmlns="http://xmlns.oracle.com/mds/config" version="11.1.1.000">
 <cust-config>
 <match path="/">
 <customization-class name="com.mycompany.IndustryCC"/>
 <customization-class name="com.mycompany.SiteCC"/>
 </match>
 </cust-config>
 </mds-config>
 </adf-mds-config>
</adf-config>
```

## 39.2.8 What Happens When You Create a Customizable Application

When you create a customizable application, you have a base application that includes the pieces necessary for you or someone else to use as the basis for a customized application.

To perform the customization, you must open the application in JDeveloper using the **Customization Developer** role, as described in [Section 39.3, "Customizing an Application."](#)

## 39.2.9 What You May Need to Know About Customizable Objects and Applications

Oracle ADF components (such as controller, model, and business components objects) must have a unique identifier so that they can be customized. ADF components generated by JDeveloper are created with identifiers by default, with the exception of JSP and JSF pages in your view controller projects. To cause JDeveloper to generate identifiers for components on pages in your view controller projects, you must explicitly specify this at the project level (as explained in [Section 39.2.4, "How to Enable Seeded Customizations for View Projects"](#)).

Before you implement customizations in an application, make sure that all objects that you intend to customize have the necessary identifiers. In many cases, you can run an audit rule to catch and fix any omissions (as explained in [Section 39.2.5, "How to Enable Seeded Customizations in Existing Pages"](#)).

Also, take care to ensure the efficiency of your customization classes, because they can be executed frequently, once for each document being accessed to get the layer name and layer value.

## 39.3 Customizing an Application

Using the **Customization Developer** role, you can create customizations in a customizable application.

### 39.3.1 Introducing the Customization Developer Role

The **Customization Developer** role is used to customize the metadata in a project. Customization features are available only in this role. When you are in the **Customization Developer** role, you can do the following:

- Create and update customizations
- Select and edit the tip layer of a customized application

- Remove existing customizations

When you are in the **Customization Developer** role, the source editor is read-only and the following JDeveloper features are disabled:

- Workspace migration
- Creation, deletion, and modification of application and IDE connections. You must configure connections in Default role before opening an application in Customization Developer role.

When working with an application in the **Customization Developer** role, new objects cannot be created, and noncustomizable objects cannot be modified. However, the following content types are customizable:

- Portal modules
- ADF modules, including ADF Faces, ADF Model, ADF Business Components, and ADF Controller

---

---

**Note:** ADF Business Components objects are customizable only if a static customization class is selected in the Customization Context window. Otherwise, business components objects are read-only.

---

---

When working in the **Customization Developer** role, you cannot edit noncustomizable files, such as Java classes, resource bundles, security policies, deployment descriptors, and configuration files. Noncustomizable files are indicated by a lock icon when you are working in the **Customization Developer** role.

---

---

**Note:** Facelets files must have a `.jsf` extension to be customizable. MDS uses this extension to recognize it as a Facelets file.

---

---

You are also restricted from modifying project settings and customizing certain ADF Business Components features, including service interfaces and business event definitions. Additionally, you cannot refactor, or make changes to customizable files that would, in turn, necessitate changes in noncustomizable files.

### 39.3.2 How to Switch to the Customization Developer Role in JDeveloper

The customization features of JDeveloper are available to you in the **Customization Developer** role. To work in this role, you can either choose it when you start JDeveloper or, if JDeveloper is already running, you can use the **Switch Roles** menu to switch to the **Customization Developer** role.

#### **Before you begin:**

It may be helpful to have an understanding of the features of the **Customization Developer** role. For more information, see [Section 39.3.1, "Introducing the Customization Developer Role."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 39.1.3, "Additional Functionality for Customization."](#)

You will also need to launch JDeveloper.

**To switch to the Customization Developer role in JDeveloper:**

1. From the main menu, choose **Tools > Switch Roles > Customization Developer**.

---

---

**Note:** You can optionally toggle the **Tools > Switch Roles > Always Prompt for Role Selection at Startup** menu item, to specify whether or not you want to choose the role when JDeveloper is launched. If deselected, JDeveloper launches in the role it was in when you last closed it.

---

---

### 39.3.3 Introducing the Tip Layer

When working in the **Customization Developer** role, the layer and layer value combination that is selected in the Customization Context window is called the *tip layer*. The changes you make while in the **Customization Developer** role are applied to this layer.

The metadata displayed in the JDeveloper editors is a combination of the base metadata and the customization layers up to and including the tip layer, according to the precedence set in `adf-config.xml`, with the values specified in the Customization Context window for each layer.

When working in the **Customization Developer** role, you can also see the noncustomized state of the application. When you select **View without Customizations** in the Customization Context window, there is no current tip layer. Therefore, what you see is the noncustomized state. While you are in this view, all customizable files show the lock icon (in the Application Navigator), indicating that these files are read-only.

When you make customizations in a tip layer, these customizations are indicated by an orange icon in the Property Inspector. A green icon indicates non-tip layer customizations. When you see an orange icon beside a property, you have the option of deleting that customization by choosing **Remove Customization** from the dropdown menu for that property.

### 39.3.4 How to Configure Customization Layers

To customize an application, you must specify the customization layers and their values in the `CustomizationLayerValues.xml` file so that they are recognized by JDeveloper.

When you open a customizable application in the **Customization Developer** role, JDeveloper reads the `adf-config.xml` file to determine the customization classes to use and their order of precedence. JDeveloper also reads the `CustomizationLayerValues.xml` file to determine the layer values to make available in the Customization Context window. If there are layer values defined in the `CustomizationLayerValues.xml` file that are not defined in the customization classes listed in the `adf-config.xml` file, they are not displayed in the Customization Context window.

Therefore, you can have a comprehensive list of layer values for all of your customization projects in the `CustomizationLayerValues.xml` file, and only those appropriate for the current application are available in the Customization Context window. Conversely, you could have a comprehensive list of customization classes for an application in the `adf-config.xml` file, and only the subset of layer values that you will work on in your `CustomizationLayerValues.xml` file.

---

---

**Note:** At design time, JDeveloper retrieves customization layer values from the `CustomizationLayerValues.xml` file. But at runtime, the layer values are retrieved from the customization class.

---

---

The names of the layers and layer values that you enter in the `CustomizationLayerValues.xml` file must be consistent with those specified in your customization classes. [Example 39-7](#) shows the contents of a sample `CustomizationLayerValues.xml` file.

**Example 39-7 Layers and Layer Values Defined in `CustomizationLayerValues.xml`**

```
<cust-layers xmlns="http://xmlns.oracle.com/mds/dt">
 <cust-layer name="industry" id-prefix="i">
 <cust-layer-value value="financial" display-name="Financial" id-prefix="f"/>
 <cust-layer-value value="healthcare" display-name="Healthcare" id-prefix="h"/>
 </cust-layer>
 <cust-layer name="site" id-prefix="s">
 <cust-layer-value value="headquarters" display-name="HQ" id-prefix="hq"/>
 <cust-layer-value value="remoteoffices" display-name="Remote" id-prefix="rm"/>
 </cust-layer>
</cust-layers>
```

For each layer and layer value, you can add an `id-prefix` token. This helps to ensure the uniqueness of the `id`, so that customizations are applied accurately. When you add a new element (such as a command button) to a page during customization, JDeveloper adds the `id-prefix` of the layer and layer value (determined by the selected tip layer) to the autogenerated identifier for the element to create an `id` for the newly added element in the customization metadata file. For example, in [Example 39-7](#), the `site` layer has an `id-prefix` of "s" and the `headquarters` layer value has an `id-prefix` of "hq". So, when you select `site/headquarters` as the tip layer and add a command button to a page, the command button will have an `id` of "shqcb1" in the metadata customization file.

For each layer value, you can also add a `display-name` token to provide a human-readable name for the layer value. When you are working in the **Customization Developer** role, the value of the `display-name` token is shown in the Customization Context window for that layer value.

You can define the customization layer values either globally for JDeveloper or in an application-specific file. If you use an application-specific file, it takes precedence over the global file. For more information on configuring layer values globally for JDeveloper, see [Section 39.3.4.1, "Configuring Layer Values Globally."](#) For more information on configuring application-specific layer values, see [Section 39.3.4.2, "Configuring Workspace-Level Layer Values from the Studio Developer Role."](#)

### 39.3.4.1 Configuring Layer Values Globally

The following procedure describes how to configure the `CustomizationLayerValues.xml` file globally for JDeveloper.

**Before you begin:**

It may be helpful to have an understanding of layers and layer values. For more information, see [Section 39.3.4, "How to Configure Customization Layers."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 39.1.3, "Additional Functionality for Customization."](#)

You will also need to complete these tasks:

- Create your customization classes, as described in [Section 39.2.1.3, "Creating a Customization Class."](#)
- Make your classes available to JDeveloper, as described in [Section 39.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."](#)

**To configure design time customization layer values globally for JDeveloper:**

1. Locate and open the `CustomizationLayerValues.xml` file.  
You can find this file in the `jdev` subdirectory of your JDeveloper installation directory (`jdev_install\jdev\CustomizationLayerValues.xml`).
2. For each layer, enter a `cust-layer` element, as shown in [Example 39-7](#).
3. For each layer value, enter a `cust-layer-value` element, as shown in [Example 39-7](#).
4. Save and close the `CustomizationLayerValues.xml` file.
5. After you have made changes to the global `CustomizationLayerValues.xml` file, you must restart JDeveloper.

#### 39.3.4.2 Configuring Workspace-Level Layer Values from the Studio Developer Role

When configuring layer values for an application, you can use either the **Studio Developer** role or the **Customization Developer** role. Note that when you configure an application-specific `CustomizationLayerValues.xml` file, you can create and modify layer values, but you cannot create additional customization layers. It is not necessary to restart JDeveloper to pick up changes made to the application-specific layer values.

When you create an application-specific `CustomizationLayerValues.xml` file, JDeveloper stores it in an application-level directory (for example, `workspace-directory\.mds\dt\customizationLayerValues\CustomizationLayerValues.xml`). You can access this file in the Application Resources panel of the Application Navigator, under the **MDS DT** node.

The following procedure describes how to configure the `CustomizationLayerValues.xml` file for a specific application from the **Studio Developer** role.

**Before you begin:**

It may be helpful to have an understanding of layers and layer values. For more information, see [Section 39.3.4, "How to Configure Customization Layers."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 39.1.3, "Additional Functionality for Customization."](#)

You will also need to complete these tasks:

- Create your customization classes, as described in [Section 39.2.1.3, "Creating a Customization Class."](#)
- Make your classes available to JDeveloper, as described in [Section 39.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."](#)
- Launch JDeveloper using the **Studio Developer** role, and open the application that you want to customize.

**To configure design time customization layer values at the workspace level from the Studio Developer role:**

1. In the Application Navigator, double-click the `adf-config.xml` file.  
The `adf-config.xml` file is in the Application Resources panel of the Application Navigator, under **ADF META-INF** in the **Descriptors** node.
2. In the overview editor, click the **MDS Configuration** navigation tab.
3. On the MDS Configuration page, below the table of customization classes, click the **Configure Design Time Customization Layer Values** link to open the workspace-level `CustomizationLayerValues.xml` file.  
When you click the link, JDeveloper opens the file in the source editor. If the override file doesn't already exist, JDeveloper displays a confirmation dialog. Click **Yes** to create and open a copy of the global file.
4. Specify layer values as necessary, as described in [Section 39.3.4, "How to Configure Customization Layers."](#)
5. Save your changes.

### 39.3.4.3 Configuring Workspace-Level Layer Values from the Customization Developer Role

You can also configure layer values for an application from the **Customization Developer** role. Note that when you configure an application-specific `CustomizationLayerValues.xml` file, you can create and modify layer values, but you cannot create additional customization layers. It is not necessary to restart JDeveloper to pick up changes made to the application-specific layer values.

When you create an application-specific `CustomizationLayerValues.xml` file, JDeveloper stores it in an application-level directory (for example, `workspace-directory\.mds\dt\customizationLayerValues\CustomizationLayerValues.xml`). You can access this file in the Application Resources panel of the Application Navigator, under the **MDS DT** node.

The following procedure describes how to configure the `CustomizationLayerValues.xml` file for a specific application from the **Customization Developer** role.

**Before you begin:**

It may be helpful to have an understanding of layers and layer values. For more information, see [Section 39.3.4, "How to Configure Customization Layers."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 39.1.3, "Additional Functionality for Customization."](#)

You will also need to complete these tasks:

- Create your customization classes, as described in [Section 39.2.1.3, "Creating a Customization Class."](#)
- Make your classes available to JDeveloper, as described in [Section 39.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."](#)
- Launch JDeveloper using the **Customization Developer** role, and open the application that you want to customize.

**To configure design time customization layer values at the workspace level from the Customization Developer role:**

1. In the Customization Context window, click the **Override global layer values** link.

When you click the link, JDeveloper opens the `CustomizationLayerValues.xml` file in the source editor. If the override file doesn't already exist, JDeveloper displays a confirmation dialog. Click **Yes** to create and open a copy of the global file.

2. Specify layer values as necessary, as described in [Section 39.3.4, "How to Configure Customization Layers."](#)
3. Save your changes.

After you make changes to the application-specific `CustomizationLayerValues.xml` file while you are in the **Customization Developer** role, any tip layer you have selected in the Customization Context window is deselected. You can then select the desired tip layer.

### 39.3.5 How to Customize Metadata in JDeveloper

You use the same development procedures and techniques to customize metadata that you use when developing the base application. To implement customizations, however, you must be working in the **Customization Developer** role and specify the customization context by selecting a tip layer and layer value before editing the metadata. For an application to be customizable, customizations must be enabled in your project. For more information, see [Section 39.2, "Developing a Customizable Application."](#)

**Before you begin:**

It may be helpful to have an understanding of the how customization works. For more information, see [Section 39.1.1, "Customization and Layers: Use Cases and Examples,"](#) and [Section 39.3, "Customizing an Application."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 39.1.3, "Additional Functionality for Customization."](#)

You will also need to complete these tasks:

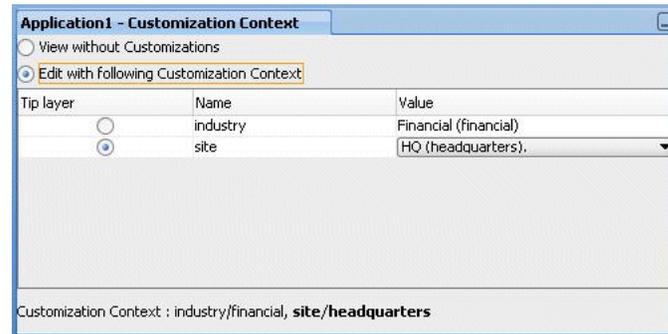

- Create your customization classes, as described in [Section 39.2.1.3, "Creating a Customization Class."](#)
- Make your classes available to JDeveloper, as described in [Section 39.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."](#)
- Create a JAR using the procedure described in [Section 41.3.2.6, "Adding Customization Classes into a JAR."](#)
- Enable seeded customizations in your application, as described in [Section 39.2.4, "How to Enable Seeded Customizations for View Projects,"](#) and [Section 39.2.5, "How to Enable Seeded Customizations in Existing Pages."](#)
- Configure the applications customization layers, as described in [Section 39.3.4, "How to Configure Customization Layers."](#)
- Launch JDeveloper using the **Customization Developer** role, and open the application that you want to customize.

**To customize metadata in JDeveloper:**

1. In the Customization Context window, select the layer and value for which you want to implement customizations.

The **Customization Context** (displayed at the bottom of the Customization Context window) changes to reflect your selection, as shown in [Figure 39–4](#).

**Figure 39–4 Customization Context Window with site/headquarters Selected as the Tip Layer**

---

**Note:** The selection you make in the Customization Context window indicates the context for the customizations that you will implement in JDeveloper. This selection does not directly impact the runtime for the application. At runtime, the customization context is returned from your customization classes. For more information, see [Section 39.2.1, "How to Create Customization Classes."](#)

---

2. Edit the metadata as you typically would during development. For example, right-click an entity object and choose **Open**. Then edit the object using the overview editor.

While you use the same techniques for editing metadata during customization that you would during development, certain restrictions apply. For example, some string properties, such as button labels, cannot be edited directly in the Property Inspector: they must be edited using the Select Text Resource dialog or the Expression Builder. For more information about restrictions to editing during customization, see [Section 39.3.1, "Introducing the Customization Developer Role."](#) For information about using the Expression Builder, see [Section 13.8.1.1, "Opening the Expression Builder from the Property Inspector."](#)

Even though you use the overview editor to implement customizations, you do not make changes to the base metadata file. Your changes are stored separately in a customization metadata file.

---

**Note:** To see the uncustomized base metadata, you can select **View without Customizations** in the Customization Context window.

---

3. You can optionally choose **Remove Customization** from the dropdown menu for a property (in the Property Inspector) to clear the existing customization.

---

---

**Note:** In the Property Inspector, tip layer customizations are indicated by an orange icon, while properties that are not customized in the current tip layer are indicated by a green icon. A customization can only be removed in the context in which it was added. So you can remove only those customizations that have an orange indicator in the Property Inspector.

---

---

4. Choose **Save** from the **File** menu to save your changes.

After you have completed your customizations, you can run and test the customized application.

### 39.3.6 What Happens When You Customize an Application

When you implement customizations in an application, JDeveloper creates a metadata file for the customizations and a subpackage to store them in.

The metadata file contains the customizations for the customized object, which are applied over the base metadata at runtime. The new metadata file is named the same as the base file for the object with an additional `.xml` extension. For example, if you implement customizations for the `browseOrders.jsff` page, the customization metadata file is named `browseOrders.jsff.xml`. Or if you implement customizations on the `OrderItems` entity object, the base metadata file is named `OrderItems.xml` and the customization metadata file is named `OrderItems.xml.xml`.

The customization metadata files are stored in a subpackage hierarchy that is created at the same level as the object you customize. The first-level package is named `mdssys`, and it contains a package named `cust`. The `cust` package contains a package for each customization layer for which you have implemented customizations.

For example, say you have a base application that has a package called `oracle.fod.model` containing your entity objects, and you have a customization layer named `site` with two layer values: `headquarters` and `remoteoffices`. Then you implement customizations for the `OrderItems` entity object at the `headquarters` layer value. When you implement these customizations, JDeveloper creates the subpackage hierarchy `oracle.fod.model.mdssys.cust.site.headquarters` and stores the customization metadata files there.

Similarly, for pages in your view controller project, JDeveloper creates a directory structure to store the customization metadata files. For example, if you customize the `BrowseOrders.jsff` page in the Web Content folder of your view controller project, JDeveloper creates the directory structure `mdssys/cust/site/headquarters` under Web Content and stores the customization metadata file there.

### 39.3.7 How to Customize ADF Library Artifacts in JDeveloper

In the **Customization Developer** role, you can use JDeveloper to customize artifacts in an ADF library. This need can arise when, for example, one development team produces task flows as part of a framework service and makes them available to other teams as an ADF library. Then another development team uses one of the task flows in a consuming application, and needs to fine-tune it to fit the requirements of the application.

You can add an ADF library to your project in the **Customization Developer** role just as you would add it in the **Studio Developer** role. However, in the **Customization Developer** role, content from an ADF library appears as editable to allow you to implement customizations, whereas in the **Studio Developer** role it is read-only. For more information about working with ADF libraries, see [Chapter 38, "Reusing Application Components."](#)

**Before you begin:**

It may be helpful to have an understanding of the how customization works. For more information, see [Section 39.1.1, "Customization and Layers: Use Cases and Examples,"](#) and [Section 39.3, "Customizing an Application."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 39.1.3, "Additional Functionality for Customization."](#)

You will also need to complete these tasks:

- Create your customization classes, as described in [Section 39.2.1.3, "Creating a Customization Class."](#)
- Make your classes available to JDeveloper, as described in [Section 39.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."](#)
- Create a JAR using the procedure described in [Section 41.3.2.6, "Adding Customization Classes into a JAR."](#)
- Enable seeded customizations in your application, as described in [Section 39.2.4, "How to Enable Seeded Customizations for View Projects,"](#) and [Section 39.2.5, "How to Enable Seeded Customizations in Existing Pages."](#)
- Configure the applications customization layers, as described in [Section 39.3.4, "How to Configure Customization Layers."](#)
- Launch JDeveloper using the **Customization Developer** role, and open the application that you want to customize.

**To customize an ADF library artifact:**

1. In the Application Navigator, click the **Navigator Display Options** icon and choose **Show Libraries**.

This displays the libraries in the Application Navigator, so that you can explore them and access their artifacts.

2. Add the desired library to your project if it is not already shown among the libraries in the Application Navigator.

For information about how to do this, see [Section 38.4, "Adding ADF Library Components into Projects."](#)

3. Customize the artifacts just as you would customize other content in your project.

For example, you can drag and drop taskflows from a library to `.jspx` or `.jsff` pages in a consuming project, drag and drop taskflows from a library to a page or fragment in another library, drag and drop library content or taskflows from the Resource catalog, drag and drop data controls from Data Controls panel to `.jspx` or `.jsff` pages in a library, edit business components, and drag and drop a data control from a library to the Data Controls panel and then drop to a page in another palette. All of these actions result in customizations of the library.

### 39.3.7.1 Specifying a Location for ADF Library Customizations

The location where ADF library customizations are stored is `project-dir\libraryCustomizations` by default. If your workspace contains multiple projects, you should change this to a workspace-level location for each project (for example, `workspace-dir\.mds\ADFLibraryCustomizations`).

You can change the location of ADF library customizations on the **Project Source Paths > ADF Library Customizations** page of the Project Properties dialog. If you change this location after you have implemented customizations on an ADF library, you must move the customization metadata files to the new location. To do this, use the file system to move the customization metadata (XML) files from the old directory to the new one.

If you have more than one project in the workspace with existing ADF library customizations that need to be moved to the common location, move the customizations to the new location one project at a time. For each project, change the location of ADF library customizations in the Project Properties dialog, and then move the customization metadata files from the old location to the new location. To mitigate conflicts where an ADF library artifact has customizations in more than one project, you have following options:

- From both projects, open the ADF Library artifact for which there are conflicting customizations, and decide upon which customizations you want. Preserve the customizations you want to keep and delete the others.
- If both customizations are important, open the ADF library artifact from the first project and implement the customizations that were previously done in second project. Then save the customizations in the first project and remove the customizations from the second project.

Do not open ADF library customization metadata files from multiple projects in a text editor and merge their contents. This can corrupt the customization metadata file.

Additionally, the location where ADF library customizations are stored is automatically included when you create a MAR deployment profile. If you change this location after you have created a MAR profile, you must also change the corresponding entry in the contributors list on the User Metadata file group page of the Edit MAR Deployment Profile Properties dialog before packaging. Alternatively, you can re-create the MAR profile to pick up this change. For more information about creating a MAR deployment profile, see [Section 41.3.2, "How to Create Deployment Profiles."](#)

## 39.3.8 How to View ADF Library Runtime Customizations from Exported JARs

When working in the JDeveloper Customization Developer role, you can view runtime customizations implemented on ADF library artifacts contained in an exported JAR.

### Before you begin:

It may be helpful to have an understanding of the how customization works. For more information, see [Section 39.1.1, "Customization and Layers: Use Cases and Examples,"](#) and [Section 39.3, "Customizing an Application."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 39.1.3, "Additional Functionality for Customization."](#)

You will also need to complete these tasks:

- Create your customizable application, as described in [Section 39.2, "Developing a Customizable Application."](#)
- Deploy the application and implement runtime customizations on it, then export the runtime customizations to a JAR file. For more information, see the *Oracle WebCenter Framework Developer's Guide*.
- Launch JDeveloper using the **Customization Developer** role, and open the customizable application.

**To make runtime customizations viewable from JDeveloper:**

1. From the Application Navigator context menu, choose **Application Properties**.
2. In the Application Properties dialog, click **Customization Libraries**.
3. Click **Browse**, and navigate to the location of the exported JAR file.
4. Select the JAR file and click **Select**.
5. Click **OK** to close the Application Properties dialog.

Now the JAR is available so that JDeveloper can look up customizations on ADF library artifacts. When you open an object that contains ADF library artifacts, JDeveloper looks for customizations in this JAR file and displays them if appropriate. JDeveloper decides what to display for a given artifact in a given customization context as follows:

- If the artifact has *neither* runtime customizations *nor* seeded customizations associated with it, the artifact from the ADF library is displayed.
- If the artifact has only *either* runtime customizations *or* seeded customizations associated with it (but not both), the customized artifact is displayed.
- If the artifact has *both* runtime customizations *and* seeded customizations associated with it, the seeded customization takes precedence and is displayed.

Additionally, when you run the application locally from JDeveloper, the runtime customizations are displayed. However, the runtime customizations are not included in any packaging of the application for deployment.

### 39.3.9 What Happens When You Customize ADF Library Artifacts

During the development of enterprise applications, there might be artifacts (such as task flows) that can be reused in multiple applications. To facilitate reuse of these common artifacts they are usually packaged into an ADF library and distributed. This allows you to add the ADF library to the list of libraries on which the consuming application depends on. Then when the application is packaged, the customizations from all such ADF libraries are included in the MAR, which is later deployed to the MDS repository.

---

**Note:** The ADF library provider should take care to ensure that no name conflicts arise due to customizations in the library. In the event that name conflicts arise between customizations packaged in an ADF library and the customizations from the consuming project, the customizations from the ADF library are ignored.

---

When you implement customizations on objects from an ADF library, the customization metadata is stored by default in a subdirectory of the project called `libraryCustomizations`. And although you create ADF library customizations at

the project level, they are merged together during packaging to be available at the application level at runtime. Essentially, ADF libraries are JARs that are added at the project level, which map to library customizations being created at the project level. However, although projects map to web applications at runtime, the MAR (which contains the library customizations) is at the EAR level, so the library customizations are seen from all web applications.

Therefore, you can customize an ADF library artifact in only one place in an application for a given customization context (customization layer and layer value). Customizing the same library content in different projects for the same customization context would result in duplication in MAR packaging. To avoid duplicates that would cause packaging to fail, implement customizations for a given library in only one project in your application.

For example, say the ADF library you are using contains a page fragment `text.jsff`. In the consuming application, customize this library page in only one project. By doing so, customizations are available for all projects in the application that consume this library at runtime.

You are also restricted from customizing an object from an ADF library when your project already contains an object with the same name. In case of duplication, you must fix the projects by deleting one of the duplicate documents or deleting one and manually merging the differences into the other.

Similarly, if the ADF library contains seeded customizations for an artifact within a given customization context (customization layer and layer value), you cannot implement customizations for that artifact within the same customization context. In this situation, the ADF library artifact is read-only. You can, however, implement customizations for the artifact within other customization contexts.

For example, say the ADF library you are using contains seeded customizations for the `Headquarters` layer value in the `Site` layer. When you select this as your tip layer in the Customization Context window, the customized objects in that ADF library are read-only. However, if you select `Site/Remote Site 1` as your tip layer, then the objects are customizable.

---

---

**Note:** When the consuming application implements customizations on content from an ADF library, the customizations are written to the local project directories, but they are not automatically injected with the `web-app-root` during packaging. For more information, see [Section 41.3.2.2, "Creating a MAR Deployment Profile."](#)

---

---

### 39.3.10 How to Package and Deploy Customized Applications

After you customize the application, you will want to deploy it. Before you deploy the customized application, you must follow the configuration procedures for setting up your MDS repository, as described in the *Oracle Fusion Middleware Administrator's Guide*.

An enterprise application can contain model and view-controller projects, and both types of projects can contain customized metadata. The customized metadata is packaged into a MAR for deployment. By default, the customizations from both types of projects are added to a single MAR. For information about how to create a MAR profile, see [Section 41.3.2.2, "Creating a MAR Deployment Profile."](#)

### 39.3.10.1 Implicitly Creating a MAR Profile

When you use JDeveloper to package an ADF application, JDeveloper creates an auto-generated MAR profile that includes default metadata (such as customizations), when *either* of the following conditions are met.

- The **Enable User Customizations > Across Sessions using MDS** checkbox is selected on the ADF View settings page of the Project Properties dialog for the user interface project.
- The MDS configuration section of the `adf-config.xml` file contains a `<metadata-store-usage>` element that is marked as `deploy-target="true"`, as shown in [Example 39-8](#).

#### Example 39-8 `metadata-store-usage` Element in `adf-config.xml`

```
< . . . >
<persistence-config>
 <metadata-namespaces>
 <namespace path="/oracle/apps" metadata-store-usage="repos1"/>
 </metadata-namespaces>
 <metadata-store-usages>
 <metadata-store-usage id="repos1" deploy-target="true">
 . . .
 </metadata-store-usage>
 </metadata-store-usages>
</persistence-config>
< . . . >
```

### 39.3.10.2 Explicitly Creating a MAR Profile

For customizations created in JDeveloper to take effect in the application when it is deployed, these customizations need to be made available to the application at runtime. There are two techniques you can use to accomplish this:

- Package the customizations along with the application using a MAR profile. Create a MAR profile that includes the customization metadata. The MAR profile should be included in the deployed EAR file to ensure that the customizations are available at runtime. Your customization classes must be packaged in the EAR file such that they are in the application-level class loader.

---

---

**Note:** If you have only seeded customizations, you do not need to create a MAR profile to import them into the MDS repository unless you also want to support runtime customizations. If you have seeded customizations and do not have cross-session persistence enabled, the seeded customizations will be packaged in the EAR file by default and loaded from the class path.

---

---

- Import the customizations to the runtime repository used by the application. You typically use this approach if customizations to library metadata need to be applied to an application that is deployed separately. Using this approach, you package the customizations into a JAR file and then use the `importMetadata` WLST command to import them to the MDS runtime repository. For more information about this and other WLST commands, see the *Oracle Fusion Middleware WebLogic Scripting Tool Command Reference*.

If your application has customizations on objects from an ADF library, the customization metadata is implicitly included when you create the MAR profile. If you change the location of ADF library customizations in the Project Properties dialog, you must re-create the MAR profile before packaging.

If you plan to use design time at runtime capabilities to add or edit resource keys in the override bundle at runtime, the override bundle must be packaged as part of the MAR profile. By default, the override bundle is packaged as part of the auto-generated MAR profile if the application contains seeded customizations. However, if the application doesn't contain seeded customizations, you must explicitly create the MAR deployment profile to package the override bundle. When the MAR profile is created explicitly, the override bundle is added and included by default as part of the user metadata.

When you package and deploy the completed customized application, you should do so from the **Studio Developer** role, rather than from the **Customization Developer** role. For information about how to create a MAR profile, see [Section 41.3.2, "How to Create Deployment Profiles."](#)

### 39.3.11 What Happens at Runtime in a Customized Application

At runtime, the application applies the customization metadata files over the base application in the order of precedence defined in the `cust-config` section of the `adf-config.xml` file.

The layer value is retrieved from the customization class at runtime and evaluated in the context the application is running, and the appropriate customizations for that layer value are applied.

### 39.3.12 What You May Need to Know About Customized Applications

When you are customizing an application, you might be using integrated source control or customizing resource strings. When you use these features, there is additional information you need to know.

#### 39.3.12.1 Customization and Integrated Source Control

When working in the **Customization Developer** role, your source control integration complements the process of customization. If JDeveloper is configured to automatically check out and add new files to source control and you attempt to customize a base document that is available from a source control system, JDeveloper behaves in the following way:

- If the corresponding customization file is not already available, then a new customization file is created in source control and the customizations are written to it.
- If the corresponding customization file exists, it is checked out and customizations are written to it.
- If the corresponding customization file exists and it is already checked out or not yet in version control, customizations are written to it without any further version control operation.

Since the base document is not modified in the **Customization Developer** role, the base document is not checked out.

If JDeveloper is not configured to automatically check out or add new files to source control, you must manually make the customization files editable and check in newly

created customization files to source control. For more information about using source control in JDeveloper, see section [Section 1.4.2, "Using a Source Control System."](#)

### 39.3.12.2 Editing Resource Bundles in Customized Applications

During the course of customizing your application, you might want to customize the content to use different resource bundle keys or define and use new resource keys.

You can open a customizable application in the **Customization Developer** role and use the Property Inspector to customize the usages of resource bundle strings. You can change a document to use another already existing resource key in a resource bundle, or create a new resource. For more information about resource bundles, see [Section 4.7, "Working with Resource Bundles."](#)

New resource keys (created in the **Customization Developer** role) are saved to an application-level override bundle (in XLIFF format), and JDeveloper adds an entry to the `adf-config.xml` file like the one shown in [Example 39-9](#) to configure the application-level override bundle.

#### **Example 39-9** *adf-resourcebundle-config* Section in *adf-config.xml*

```
<adf-resourcebundle-config
xmlns="http://xmlns.oracle.com/adf/resourcebundle/config">
 <applicationBundleName>
 path-to-resource-bundle/bundle-name
 </applicationBundleName>
 <bundleList>
 <bundleId>
 package.BundleID
 </bundleId>
 </bundleList>
</adf-resourcebundle-config>
```

---

**Note:** If an application is not configured for customization, you can open it in the **Customization Developer** role and define new resource keys by choosing **Edit Resource Bundles** from the **Application** menu. However, you cannot change a document to use the new resource keys if it is not configured for customization.

---

## 39.4 Extended Metadata Properties

Extended metadata is data that describes the metadata content. The extended metadata file contains additional information about the metadata file. One use of this extended information is to identify which parts of the metadata can be customized at runtime (design time at runtime customizations) and who can customize them. For more information about this use of extended metadata properties, see [Section 39.4.2, "How to Enable Customization for Design Time at Runtime."](#)

You can open a metadata file (such as a `.jspx` file) in JDeveloper and use the Property Inspector to view and edit its extended metadata properties. When you open a metadata file, its extended metadata properties are displayed in the Property Inspector. These properties can be edited to add metadata information at either of the following levels:

- **File-level:** These properties are displayed in the Property Inspector when the root element is selected in the Structure window.

- **Element-level:** These properties are displayed in the Property Inspector when an element is selected in the Structure window. The selected element should have a non-null identifier.

Extended metadata properties are supported for file types that support customizations and can be packaged in a MAR, such as `.jsff` and `.jspx` files.

Extended metadata for a metadata document is stored in an associated resource description framework (RDF) file. RDF is a W3C standard used to define an XML framework for defining metadata. The RDF file associated with the metadata document is created when the first property value is specified using the Property Inspector. Extended metadata properties are editable only when JDeveloper is in the **Studio Developer** role. RDF files are read-only in the **Customization Developer** role.

The RDF file is stored in the `mdssys` directory. For example, if the metadata being described is stored in the file system as `/myapp/data/page1.jsx`, the corresponding extended metadata document would be stored as `/myapp/data/mdssys/mdx/page1.jsx.rdf`. The extended metadata document must then be packaged with the corresponding metadata base file and added to the same deployment profile. For more information about creating a MAR deployment profile, see [Section 41.3.2, "How to Create Deployment Profiles."](#)

---

---

**Note:** Don't edit the extended metadata documents directly. Use the Property Inspector.

---

---

### 39.4.1 How to Edit Extended Metadata Properties

You can use extended metadata properties to provide additional metadata information that is not covered in the metadata file (such as a `.jspx` file). When you open the metadata file in JDeveloper, extended metadata properties are displayed in the Property Inspector, which you can use to edit these properties when you are using JDeveloper in the **Studio Developer** role.

For example, suppose you want to deliver a metadata file in some form to external customers. Along with metadata file, you need to provide additional information about the file, such as the creator, subject, description, format, and rights. You can accomplish this by creating an extended metadata property file for your metadata file.

#### To edit extended metadata properties:

1. Launch JDeveloper using the **Studio Developer** role.
2. In JDeveloper, open the appropriate application and project.
3. In the Application Navigator, select the object for which you want to edit extended metadata properties.
4. In the Structure window, select the appropriate element (typically the root element).
5. In the Property Inspector, expand the appropriate node to edit the properties.  
To display the Property Inspector with the values for the selected component, choose **Property Inspector** from the **View** menu.
6. Edit the value for the desired property and press Enter.
7. Choose **Save** from the **File** menu to save your work.

If you have edited extended metadata properties for a metadata file, you must package your extended metadata (or RDF) files with the metadata files when you deploy the application.

## 39.4.2 How to Enable Customization for Design Time at Runtime

You can also use extended metadata properties to provide information about which parts of the metadata can be customized at runtime and who can customize the metadata content.

By default, all components that you can add to a `.jspx` page are preconfigured to allow runtime customization to support implicit user personalization (such as changing the order of columns in a table). All pages and fragments that you create are also configured to allow customization by default. For more information about user customization, see [Chapter 40, "Allowing User Customizations at Runtime."](#)

Components that are preconfigured to allow customization need no further modification to enable design time at runtime customizations. If you use them in a `.jspx` page, then they are customizable by default.

Depending on the requirements of your application, you will need to modify customization properties in the following situations:

- For components that are configured to allow customization, you can override the default settings to disallow customization.
- For components that are not configured to allow customization and metadata objects (such as `.jspx` pages), you can override the settings to allow customization.
- For components that are configured to allow customization, you can optionally restrict who is allowed to perform customizations at runtime.

If you edit customization properties, you must package your extended metadata (RDF) files with the metadata files when you deploy the application.

Additionally, you can restrict customizations on a entire subtree of components by marking the root of the subtree to disallow customizations. You can then mark individual components of that subtree as customizable to allow customizations for those specific components.

### 39.4.2.1 Editing Customization Properties in the Property Inspector

In the Customization group in the Property Inspector, there are two properties that allow you to specify whether customizations for an object are permitted at runtime and who is permitted to do them. The **CustomizationAllowed** property can be set on any element to specify whether or not it can be customized. The **CustomizationAllowedBy** property controls which users can customize the element. These settings are not enforced when you are implementing seeded customizations using JDeveloper, but are instead enforced when the application is customized at runtime (design time at runtime customizations).

For example, say you have a `.jspx` page with a form that contains two panels, and you need to allow runtime customization for content in Panel1, but not Panel2. You would set **CustomizationAllowed** to `true` for Panel1, and set it to `false` for Panel2. If you need to allow runtime customization on an entire page, you would set **CustomizationAllowed** to `true` for the `.jspx` page root.

#### To edit customization properties:

1. Launch JDeveloper using the **Studio Developer** role.

2. In JDeveloper, open the appropriate application and project.
3. In the Application Navigator, select the object for which you want to edit customization properties.
4. In the Structure window, select the appropriate element.
5. In the Property Inspector, expand the **Customization** node to edit the customization properties.

To display the Property Inspector with the values for the selected component, choose **Property Inspector** from the **View** menu.

6. Edit the property value and press Enter.

For example, to allow runtime customizations on a `.jspx` file, select the file and set the **CustomizationAllowed** property to `true`.

7. Choose **Save** from the **File** menu to save your work.

### 39.4.2.2 Using a Standalone Annotations File to Specify Type-Level Customization Properties

You can optionally use a standalone annotations file to specify whether or not customizations are allowed for a given type of component. This file allows you to set customization properties on element types, rather than on instances. You can override the setting for a given type by explicitly setting `true` or `false` on a specific instance. [Example 39–10](#) shows the contents of a sample standalone annotations file.

#### **Example 39–10** Contents of a Standalone Annotations file

```
<?xml version="1.0" encoding="UTF-8"?>
<grammarMetadata xmlns="http://xmlns.oracle.com/bali/xml/metadata"
 xmlns:md="http://xmlns.oracle.com/bali/xml/metadata"
 xmlns:mmd="http://xmlns.oracle.com/bali/xml/metadata/model"
 xmlns:mds="http://xmlns.oracle.com/mds"
 namespace="http://www.oracle.com/mds/restrictCustomizations">
 <elementMetadata elementName="orderDetail">
 <attributeMetadata attributeName="itemTypeRef">
 <mds:customizationAllowedBy>sales admin</mds:customizationAllowedBy>
 </attributeMetadata>
 <attributeMetadata attributeName="description">
 <mds:customizationAllowed>true</mds:customizationAllowed>
 <mds:customizationAllowedBy>hr</mds:customizationAllowedBy>
 </attributeMetadata>
 <attributeMetadata attributeName="title">
 <mds:customizationAllowed>true</mds:customizationAllowed>
 </attributeMetadata>
 </elementMetadata>

 <elementMetadata elementName="bankTransfer">
 <mds:customizationAllowed>>false</mds:customizationAllowed>
 </elementMetadata>

 <elementMetadata elementName="order">
 <mds:customizationAllowed>true</mds:customizationAllowed>
 <attributeMetadata attributeName="paymentRef">
 <mds:customizationAllowedBy>sales</mds:customizationAllowedBy>
 </attributeMetadata>
 <elementMetadata elementName="itemDetail">
 <attributeMetadata attributeName="itemsRef">
 <mds:customizationAllowedBy>hr</mds:customizationAllowedBy>
 </attributeMetadata>
 </elementMetadata>
 </elementMetadata>
</grammarMetadata>
```

```

 </attributeMetadata>
 </elementMetadata>
</elementMetadata>

</grammarMetadata>

```

If you use a standalone annotations file, you must register it with MDS in the `adf-config.xml` file. Create a `mdsc:standalone-definitions` section in the `mdsc:type-config` section of the `adf-config.xml` file, as shown in [Example 39-11](#).

**Example 39-11** *standalone-definitions Section in adf-config.xml*

```

<?xml version="1.0"?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
 xmlns:mdsc="http://xmlns.oracle.com/mds/config">
 <mdsdata>
 <mdsc:mds-config version="11.1.1.000" >
 <mdsc:type-config>
 <mdsc:type-definitions>
 <mdsc:url>jar:file:/c:/jdev/lib/oafwk.jar!/oracle/apps/schemas/oa.xsd</mdsc:url>
 <mdsc:mds>/oracle/mds/TypeSeven.xml</mdsc:mds>
 <mdsc:mds>/oracle/mds/TypeEight.xml</mdsc:mds>
 <mdsc:file>typefile7.xsd</mdsc:file>
 <mdsc:file>typefile8.xsd</mdsc:file>
 </mdsc:type-definitions>
 <mdsc:standalone-definitions>
 <mdsc:url>jar:file:/c:/jdev/lib/oafwk.jar!/oracle/apps/schemas/oa.xsd</mdsc:url>
 <mdsc:mds>/oracle/mds/standAloneSeven.xml</mdsc:mds>
 <mdsc:mds>/oracle/mds/standAloneEight.xml</mdsc:mds>
 <mdsc:file>standAloneFile7.xsd</mdsc:file>
 <mdsc:file>standAloneFile8.xsd</mdsc:file>
 </mdsc:standalone-definitions>
 </mdsc:type-config>

 </mdsc:mds-config>
 </mdsdata>
</adf-config>

```

## 39.5 Enabling Runtime Modification of Customization Configuration

You can prepare your customized application to accept overrides to the customization configuration (the `cust-config` section of the `adf-config.xml` file) at runtime on a per-session basis, thus allowing the user to change the way customizations are applied for a given session (or web request).

Consider a scenario where an application is configured with a `site` layer and a `user` layer and you want to make design time at runtime customizations to the `site` layer. If you use the application's customization configuration (defined in the `adf-config.xml` file), any customizations that you implement are applied to the `user` layer. So, you need to be able to adjust the customization configuration for a given session to allow your customizations to be applied to the `site` layer.

Or you have a requirement that an administrator wants to see the base metadata document with the `site` layer customizations alone. For cases like this, you need to specify a modified customization configuration, other than what was originally specified in application's `adf-config.xml` file.

For each web request, Oracle ADF creates an MDS session. For any MDS customization configuration modifications that apply to a session (web request), the user could programmatically provide modified MDS session options with a new customization configuration to Oracle ADF that would be applied on top of the original MDS configuration while creating a MDS session.

To implement this functionality, use the following ADF interfaces for `sessionOptionsFactory`:

- `oracle.adf.share.mds.SessionOptionsFactory` is the interface you use to specify modified MDS session options for a web request in an ADF application.

```
SessionOptionsFactory :: oracle.mds.core.SessionOptions
createSessionOptions(oracle.mds.core.SessionOptions defaultOptions)
```

You implement this method to return the modified MDS `sessionOptions` to ADF.

- `oracle.adf.share.config.ConfigUtils` is the public class you can use to register your session options factory with ADF.

```
ConfigUtils :: public static void setSessionOptionsFactory(ADFContext context,
SessionOptionsFactory factory)
```

See your ADF API documentation for further detail on these interfaces.

---

---

**Note:** If you are using Oracle Composer components, you can use the `ComposerSessionOptionsFactory` interface to specify modified MDS session options with Composer.

```
ComposerSessionOptionsFactory :: public SessionOptions
createSessionOptions(SessionOptions defaultOptions, String mode);
```

`oracle.adf.view.page.editor.webapp.WebCenterComposerFilter` loads your `ComposerSessionOptionsFactory` implementation from the current thread context class loader. See the *Oracle WebCenter Framework Developer's Guide* for more information.

---

---

You register your `sessionOptionsFactory` with ADF or Composer in a filter implementation so that ADF can get modified session options from your implementation before the MDS session is created in request lifecycle.

[Example 39-12](#) shows how you can implement `sessionOptionsFactory`. This example sets a modified customization configuration for the session to use the `site` customization layer alone regardless of the customization configuration specified in the `adf-config.xml` file. See the Javadoc for `oracle.mds` for more information.

**Example 39-12 Sample sessionOptionsFactory Class**

```
package mycompany;

import oracle.adf.share.mds.SessionOptionsFactory;
import oracle.mds.config.CustClassListMapping;
import oracle.mds.config.CustConfig;
import oracle.mds.config.MDSConfigurationException;
import oracle.mds.core.SessionOptions;
import oracle.mds.cust.CustClassList;
import oracle.mds.cust.CustomizationClass;
```

```

public class MySessionOptionsFactory implements SessionOptionsFactory {
 public MySessionOptionsFactory() {
 super();
 }
 /**
 * Called to allow the application code to create a new SessionOptions object.
 * The application code should make sure to read the values from the
 * defaultOptions object as part of construction of their new object and make
 * sure they only override the intended values.
 * @param defaultOptions
 * @return modified MDS session options
 */
 public SessionOptions createSessionOptions(SessionOptions defaultOptions) {
 // create new mds Customization configuration
 CustConfig custconfig = null;

 // create customization class array. Just put SiteCC implementation as we
 // wish to apply site customizations alone.
 CustomizationClass[] custclassarray = new CustomizationClass[] {new SiteCC()};

 CustClassList custclasslist = new CustClassList(custclassarray);

 // specify the base metadata package namespace mapping on which site
 // customizations would apply
 CustClassListMapping[] mappings =
 new CustClassListMapping[] {new CustClassListMapping("mycompany/package",
 null, null, custclasslist)};

 // create new customization configuration
 try{
 custconfig = new CustConfig(mappings);
 }
 catch (Exception ex){
 //do nothing
 }

 // now return modified sessionOptions to ADF with new mds customization
 // configuration. Only use newly created customization configuration in here.
 // For rest of option, use whatever available in defaultOptions.
 return new SessionOptions(defaultOptions.getIsolationLevel(),
 defaultOptions.getLocale(),
 custconfig,
 defaultOptions.getVersionContext(),
 defaultOptions.getVersionCreatorName(),
 defaultOptions.getCustomizationPolicy(),
 defaultOptions.getServletContextAsObject());
 }
}

```

---

## Allowing User Customizations at Runtime

This chapter describes how to use the ADF Faces change persistence framework to create JSF pages that users can customize at runtime.

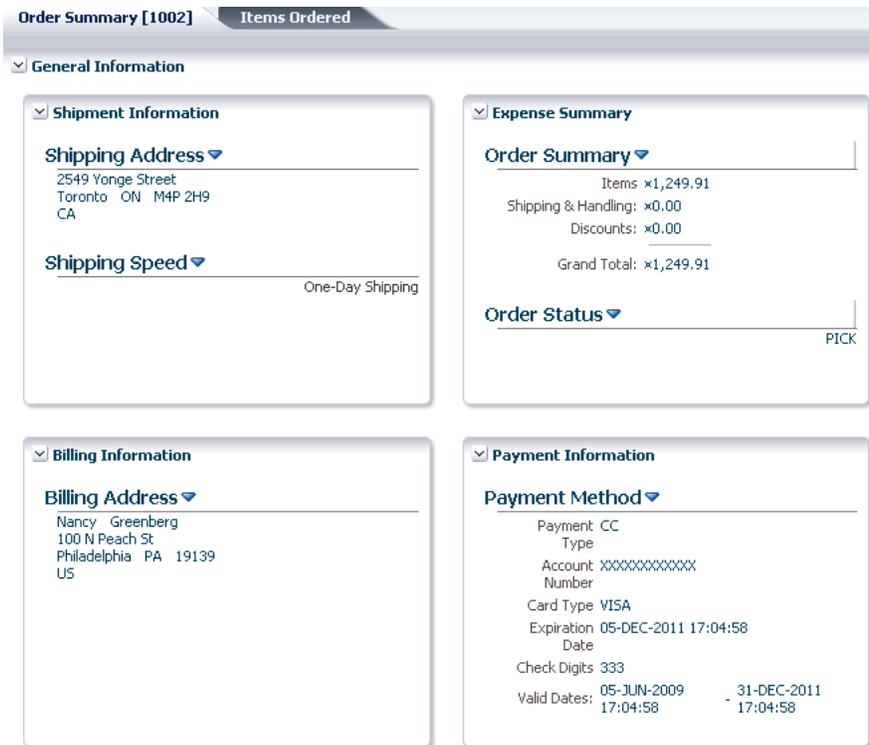

This chapter includes the following sections:

- [Section 40.1, "About User Customizations"](#)
- [Section 40.2, "Enabling Runtime User Customizations for a Fusion Web Application"](#)
- [Section 40.3, "Configuring User Customizations"](#)
- [Section 40.4, "Controlling User Customizations in Individual JSF Pages"](#)
- [Section 40.5, "Implementing Custom User Customizations"](#)
- [Section 40.6, "Creating Implicit Change Persistence in Custom Components"](#)

### 40.1 About User Customizations

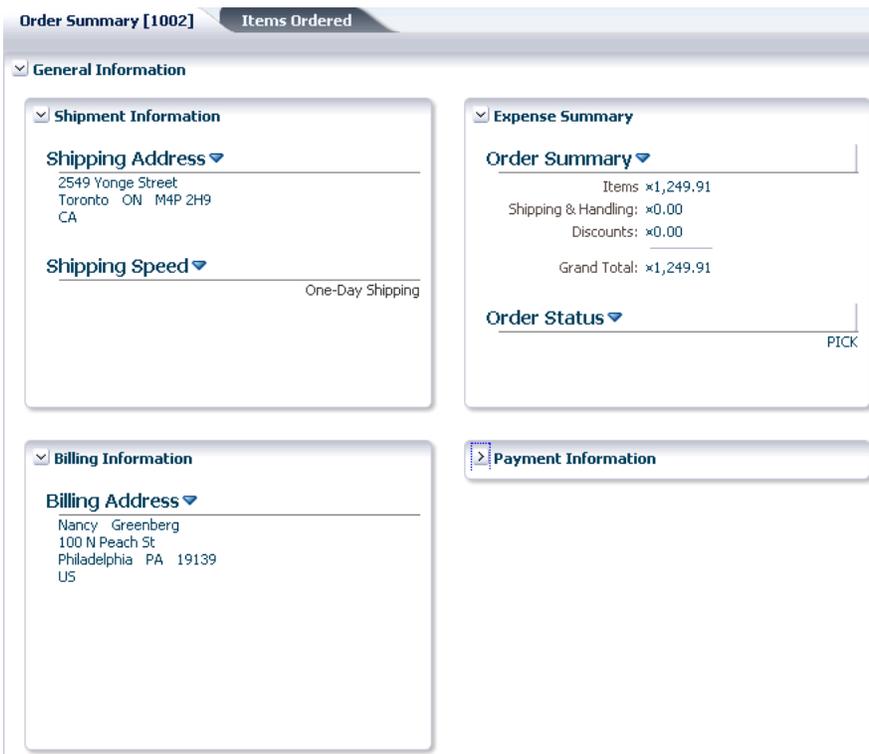

Certain ADF Faces components have attributes that can be saved for a specific user. For example, the value of the `disclosed` attribute on a `panelBox` component can be saved for a specific user during the current session. The `myOrders` page in the `StoreFront` module application contains four `panelBox` components that display order information. By default, they are expanded, as shown in [Figure 40-1](#).

**Figure 40–1 panelBox Components Are Expanded by Default**

However, suppose a user decides to collapse one of the boxes, as shown in Figure 40–2.

**Figure 40–2 panelBox Component Remains Collapsed**

Because this application is configured to allow user customizations, then during the user's session, anytime that user returns to the page, the Payment Information box remains collapsed. You need only to enable user customizations for the project in order for these changes to be persisted to the user's session.

Table 40-1 shows the attribute value changes persisted by an ADF Faces application, after you configure the application to allow user customizations.

**Table 40-1** *Implicitly Persisted Attribute Values*

Component	Attribute	Affect at Runtime
panelBox showDetail showDetailHeader showDetailItem	disclosed	Users can display or hide content using an icon in the header. Detail content will either display or be hidden, based on the last action of the user.
showDetailItem (used in a panelAccordion component)	flex	The heights of multiple showDetailItem components are determined by their relative value of the flex attribute. The showDetailItem components with larger flex values will be taller than those with smaller values. Users can change these proportions, and the new values will be persisted.
showDetailItem (used in a panelAccordion component)	inflexibleHeight	Users can change the size of a panel, and that size will remain.
panelSplitter	collapsed	Users can collapse either side of the splitter. The collapsed state will remain as last configured by the user.
panelSplitter	splitterPosition	The position of the splitter in the panel will remain where last moved by user.
richTextEditor	editMode	The editor will display using the mode (either WYSIWYG or source) last selected by the user.
calendar	activeDay	The day considered active in the current display will remain the active day.
calendar	view	The view (day, week, month, or list) that currently displays activities will be retained.
panelWindow dialog	contentHeight	Users can change the height of a panelWindow or dialog popup component, and that height will remain.
panelWindow dialog	contentWidth	Users can change the width of a panelWindow or dialog popup component, and that width will remain.

**Table 40–1 (Cont.) Implicitly Persisted Attribute Values**

<b>Component</b>	<b>Attribute</b>	<b>Affect at Runtime</b>
activeCommandToolbar Button commandButton commandImageLink commandLink commandMenuItem commandNavigationItem commandToolbarButton	windowHeight	When users change the contentHeight attribute value of a panelWindow or dialog component, any associated windowHeight value on a command component is also changed and will remain.
activeCommandToolbar Button commandButton commandImageLink commandLink commandMenuItem commandNavigationItem commandToolbarButton	windowWidth	When users change the contentWidth attribute value of a panelWindow or dialog component, any associated windowWidth value on a command component is also changed and will remain.
column	displayIndex	ADF Faces columns can be reordered by the user at runtime. The displayIndex attribute determines the order of the columns. (By default, the value is set to -1 for each column, which means the columns will display in the same order as the data source). When a user moves a column, the value on each column is changed to reflect the new order. These new values will be persisted.
column	frozen	ADF Faces columns can be frozen so that they will not scroll. When a column's frozen attribute is set to true, all columns before that column (based on the displayIndex value) will not scroll. When you use the table with a panelCollection component, you can configure the table so that a button appears that allows the user to freeze a column.
column	noWrap	The content of the column will either wrap or not. You need to create code that allows the user to change this attribute value. For example, you might create a context menu that allows a user to toggle the value from true to false.
column	selected	The selected column is based on the column last selected by the user.

**Table 40–1 (Cont.) Implicitly Persisted Attribute Values**

<b>Component</b>	<b>Attribute</b>	<b>Affect at Runtime</b>
column	visible	The column will either be visible or not, based on the last action of the user. You will need to write code that allows the user to change this attribute value. For example, you might create a context menu that allows a user to toggle the value from <code>true</code> to <code>false</code> .
column	width	The width of the column will remain the same size as the user last set it.
table	filterVisible	ADF Faces tables can contain a component that allows users to filter the table rows by an attribute value. For a table that is configured to use a filter, the filter will either be visible or not, based on the last action of the user. You will need to write code that allows the user to change this attribute value. For example, you might create a button that allows a user to toggle the value from <code>true</code> to <code>false</code> .
dvt:areaGraph dvt:barGraph dvt:bubbleGraph dvt:comboGraph dvt:horizontalBarGraph dvt:lineGraph dvt:scatterGraph	timeRangeMode	The time range for the data displayed on a graph time axis can be specified for all data visualization graph components. By default, all data is displayed. The time range can also be set for a relative time range from the last or first data point, or an explicit time range. You will need to write code that allows the user to change this attribute value. For example, you might create a dropdown list to choose the time range for a graph.
dvt:ganttLegend	visible	The legend for data visualization project, resource utilization, and scheduling Gantt chart components will either be visible or not inside the information panel. You will need to write code that allows the user to change this attribute value, for example, a hide and show button to display the legend.
dvt:hierarchyViewer	layout	The data visualization hierarchy viewer component supports nine hierarchy layout options including a top-to-bottom vertical, tree, circle, radial, and so on. Users can change the layout in the map control panel and the last selected layout will be retained.

**Table 40–1 (Cont.) Implicitly Persisted Attribute Values**

<b>Component</b>	<b>Attribute</b>	<b>Affect at Runtime</b>
dvt:map	mapZoom	This data visualization geographic map component attribute specifies the beginning zoom level of the map. The zoom levels are defined in the map cache instance as part of the base map. You will need to write code that allows the user to change this attribute value.
dvt:map	srid	This data visualization geographic map component attribute specifies the srid (spatial reference id) of all the coordinates of the map, which includes the center of the map, defined by startingX and startingY, and all the points in the point theme. You will need to write code that allows the user to change this attribute value.
dvt:map	startingX, startingY	This data visualization geographic map component attribute specifies the X and Y coordinate of the center of the map. The srid for the coordinate is specified in the srid attribute. If the srid attribute is not specified, this attribute assumes that its value is the longitude of the center of the map. You will need to write code that allows the user to change this attribute value.
dvt:projectGantt dvt:resource UtilizationGantt dvt:schedulingGantt	splitterPosition	The position of the splitter in the panel will remain where last moved by user.
dvt:timeAxis	scale	Data visualization components for project, resource utilization, and scheduling Gantt charts use this facet to specify the major and minor time axes in the Gantt chart. The time scale (twoyears, year, halfyears, quarters, twomonths, months, weeks, twoweeks, days, sixhours, threehours, hours, halfhours, quarterhours) can be set by the user using the menu bar <b>View</b> menu and the selection will be retained. Note that a custom time scale can also be named for this component value.
dvt:timeSelector	explicitStart, explicitEnd	Data visualization area, bar, combo, line, scatter, and bubble graph components use this child tag attribute to specify the explicit start and end dates for the time selector. Only value-binding is supported for this attribute. You will need to write code that allows the user to change this attribute value.

## 40.1.1 Runtime User Customization Use Cases and Examples

You can configure an application so that the value of the attributes listed in [Table 40–1](#) can be persisted across sessions using the MDS repository. For example, if the StoreFront module allowed persistence to the MDS repository, then a user could collapse the Payment Information box, as shown in [Figure 40–2](#), and it would be collapsed the next time that user entered the application.

---

---

**Note:** Before you can enable persistence to the repository, you must first follow all MDS configuration procedures as documented in the *Oracle Fusion Middleware Administrator's Guide*.

---

---

Along with the automatic persistence available through ADF Faces, you can create your own custom user customization capabilities for the following types of changes:

- Changing an attribute value
- Adding or removing a facet
- Adding or removing a child component
- Reordering child components
- Moving a child component to a different parent

If you want to create these types of custom user customizations, you need to add code (for example, in an event handler) that will call the APIs to handle the persistence.

Enabling an application to use the change persistence framework requires that you first enable your application to allow user customizations. Part of this process is determining where those changes should be persisted, either to the session or the MDS repository.

If you choose to persist changes to the session, by default all values as shown in [Table 40–1](#) will be saved for the user's session. However if you choose to persist changes to a repository, you must explicitly configure which of these attribute values will be persisted to the repository. Instead of persisting all these attribute values, you can restrict changes so that only certain attribute value changes for a component are persisted, or so that only specific instances of the components persist changes.

---

---

**Note:** You cannot persist changes to a component that is contained inside (anywhere in the subtree) of `af:forEach` or `af:iterator` tags using the `addComponentChange()` method. While such structure results in multiple copies of a component in the view tree, each component has only a single representation in the JSP document. However, the `addDocumentChange()` method does allow persistence for such components. For more information, see the discussion of the `DocumentChange` and `ComponentChange` classes in [Section 40.5.1, "Change Persistence Framework API."](#)

---

---

For any applications that persist changes to an MDS repository, when you deploy your application, you must create a metadata archive (MAR) profile in the application's EAR assembly. For more information, see [Section 41.3.2, "How to Create Deployment Profiles."](#)

## 40.1.2 Additional Functionality for Runtime User Customization

You may find it helpful to understand other features before you start working with user customizations. Following are links to other functionality that may be of interest.

- For information about the MDS architecture and metadata repositories (database- and file-based) and archives (EAR, MAR), see to the section about managing the MDS repository in the *Oracle Fusion Middleware Administrator's Guide*.
- The MDS framework allows you to create customizable applications that can be customized and subsequently deployed by a customer. For information, see [Chapter 39, "Customizing Applications with MDS."](#)
- The features of Oracle WebCenter allow business analysts or administrators, using a Web browser interface, to customize an application for their end users. For information about runtime customization, refer to the *Oracle WebCenter Framework Developer's Guide*.

## 40.2 Enabling Runtime User Customizations for a Fusion Web Application

Enabling an application to allow user customizations (whether for the default changes that some ADF Faces components provide, or for custom capabilities that you create) requires that you configure your application to use the change persistence framework and that you also determine where those changes should be persisted (either the session or the MDS repository).

---

---

**Note:** If you are planning on persisting changes to the MDS repository, before configuring an ADF Faces application to use change persistence, you must first follow all MDS configuration procedures as documented in the *Oracle Fusion Middleware Administrator's Guide*.

---

---

### 40.2.1 How to Enable User Customizations

You enable your application to use the change persistence framework by editing the `web.xml` and `adf-config.xml` files.

#### **Before you begin:**

It may be helpful to have an understanding of the features of runtime user customization. For more information, see [Section 40.2, "Enabling Runtime User Customizations for a Fusion Web Application."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 40.1.2, "Additional Functionality for Runtime User Customization."](#)

You will need to launch JDeveloper using the **Studio Developer** role, and open (or create) the application in which you want to enable runtime user customization.

#### **To enable user customizations:**

1. Double-click the web project in your application.
2. In the Project Properties dialog, select the **ADF View** node.
3. On the ADF View page, select the **Enable User Customizations** checkbox. If you want the changes to be persisted to only the session, select the **For Duration of**

**Session** radio button. If you want the changes to persist to the MDS repository, select **Across Sessions Using MDS**.

4. If you choose to persist to the repository, you now need to declare each component tag and associated attribute values that you want persisted to the repository (if you choose to persist only to the session, all values will be persisted).

For procedures to accomplish this task, see [Section 40.3, "Configuring User Customizations."](#) Once that configuration is complete, you can override those settings on a per component instance basis. For procedures, see [Section 40.4, "Controlling User Customizations in Individual JSF Pages."](#)

---

**Note:** If you have created custom user customization capabilities as documented in [Section 40.5, "Implementing Custom User Customizations,"](#) then you also need to declare those attribute values or operations.

---

## 40.2.2 What Happens When You Enable User Customizations

When you elect to save changes only to the session, JDeveloper adds the `CHANGE_PERSISTENCE` context parameter to the `web.xml` file, and sets the value to `session`. This context parameter registers the `ChangeManager` class that will be used to handle persistence. If you instead elect to save the changes to the MDS repository, the value is set to `oracle.adf.view.rich.change.FilteredPersistenceChangeManager`, as shown in [Example 40-1](#).

### **Example 40-1** Context Parameter in `web.xml` Used For Change Persistence

```
<context-param>
 <param-name>org.apache.myfaces.trinidad.CHANGE_PERSISTENCE</param-name>
 <param-value>
 oracle.adf.view.rich.change.FilteredPersistenceChangeManager
 </param-value>
</context-param>
```

**Tip:** If needed, you can manually set this value to `oracle.adf.view.rich.change.MSDocumentChangeManager` if you do not want any customizations to be restricted based on configurations in the `adf-config.xml` file or on the individual JSF pages, and you always want the changes to be persisted to the MDS repository and not the session.

When you elect to persist to the repository, JDeveloper also does the following:

- Adds the following JARs to the class path if they don't exist:
  - `javatools-nodep.jar`
  - `facesconfigmodel.jar`
  - `taglib.jar`
- Adds another context parameter to `web.xml` to register the `MDSJSPProviderHelper` class to handle merging MDS customization documents with the base JSP document, as shown in [Example 40-2](#)

**Example 40–2 Context Parameter in web.xml Used For Merging Changes**

```
<context-param>
 <param-name>oracle.adf.jsp.provider.0</param-name>
 <param-value>oracle.mds.jsp.MDSJSPPProviderHelper</param-value>
</context-param>
```

- Adds the ADF Faces Change Manager Runtime 11 library to the project.
- In the `adf-config.xml` descriptor file, sets the `persistent-change-manager` element to the `MDSDocumentChangeManager`, which is the class that will be used to persist the changes. [Example 40–3](#) shows the configuration for persisting to the MDS repository.

**Example 40–3 Registered ChangeManager Class for Restricted Change Persistence**

```
<persistent-change-manager>
 <persistent-change-manager-class>
 oracle.adf.view.rich.change.MDSDocumentChangeManager
 </persistent-change-manager-class>
</persistent-change-manager>
```

- Creates JSF JSP pages as XML documents. For more information, see [Section 40.4, "Controlling User Customizations in Individual JSF Pages."](#)

Additionally, when you elect to save the changes to the MDS repository, and you include facelets in your application, JDeveloper adds the `faceletCache` context parameter to the `web.xml` file. The value of this parameter is set to `oracle.adfinternal.view.faces.facelets.rich.MDSFaceletCache`, as shown in [Example 40–4](#).

**Example 40–4 Context Parameter in web.xml Used For Facelet Caching**

```
<context-param>
 <param-name>com.sun.faces.faceletCache</param-name>
 <param-value>oracle.adfinternal.view.faces.facelets.rich.MDSFaceletCache</param-value>
</context-param>
```

The facelets cache enhances the performance of your application and the cache capacity can be configured in MDS on the server. For more information, see the *Oracle Fusion Middleware Administrator's Guide*.

## 40.3 Configuring User Customizations

If you choose to persist changes to an MDS repository, you must decide which of the attribute values that are by default persisted to the session (as shown in [Table 40–1](#)) should also be persisted to the repository. Alternatively, you can configure which changes you do not want persisted.

**Tip:** Often, a system administrator is the one to set the configurations in the `adf-config.xml`. The `persist` and `dontPersist` attributes on a component allow page authors to override that setting as needed.

For example, suppose you decide that you don't want the value for the `width` attribute on columns to be persisted to the repository, but you do want all other default attribute changes for columns to be persisted. You must explicitly set the other default column values that you want to be persisted, and you also must explicitly configure the application to NOT persist the `width` attribute.

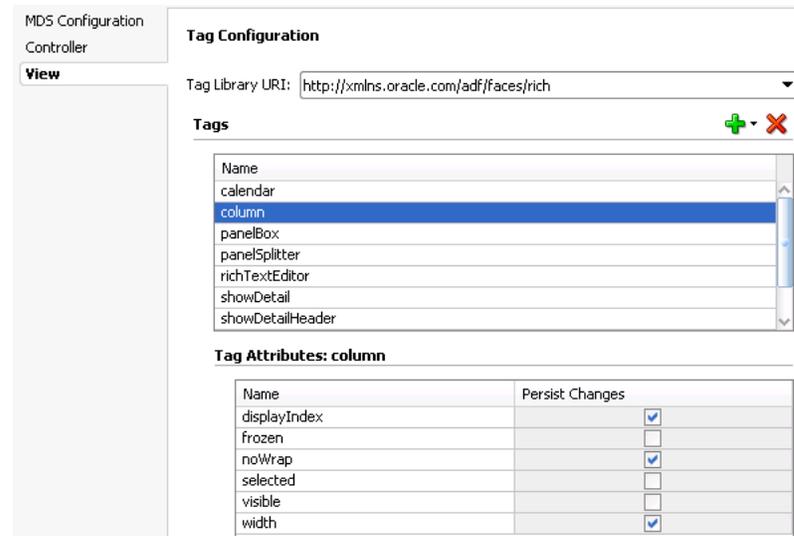

---

**Note:** If you have created custom user customization capabilities as documented in [Section 40.5, "Implementing Custom User Customizations,"](#) then you must explicitly declare those attribute values or operations as well.

---

You set (and unset) these values using the overview editor for the `adf-config.xml` file. [Figure 40–3](#) shows the overview editor where only certain attribute values for the `column` component will be persisted.

**Figure 40–3 Overview Editor for the `adf-config.xml` File**

Once set, you can override persistence for a specific component on a page. For example, suppose you want to disallow change on the `width` attribute on only one table's columns. You want the rest of the tables in the application to persist changes to that attribute. You would configure the columns to globally persist changes to the `width` attribute, but then for that one table, you would override the global configuration directly on the JSF page. For more information, see [Section 40.4, "Controlling User Customizations in Individual JSF Pages."](#)

---

**Note:** If you've enabled just session persistence, then all attribute values shown in [Table 40–1](#) will be persisted to the session. There is no way to override this either globally or on an instance.

---

### 40.3.1 How to Configure Change Persistence

By default, when you configure your application to use any type of change persistence (that is, to either the session or a repository), the values of all attributes shown in [Table 40–1](#) will always be persisted to the user's session. If you configured your changes to be persisted to a repository, then you must declare the attributes whose values should be persisted to that repository. If there are any values that you don't want persisted, then you need to configure those values as well.

#### Before you begin:

It may be helpful to have an understanding of how runtime user customization are persisted. For more information, see [Section 40.3, "Configuring User Customizations."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 40.1.2, "Additional Functionality for Runtime User Customization."](#)

You will need to launch JDeveloper using the **Studio Developer** role, and open (or create) the application in which you want to enable runtime user customization.

**To declare attribute value persistence to a repository:**

1. In the Application Navigator, expand the **Application Resources** pane, expand the **Descriptors** and **ADF META-INF** nodes, and double-click **adf-config.xml**.
2. In the overview editor, click the **View** navigation tab.
3. In the **Tags** table, select the component whose changes you want to persist (or not persist) to the repository.

If the component does not appear in the table, click the **Add** icon to select and add it.

---

**Note:** The filter rules specified in the `adf-config.xml` file are applicable only when you have chosen to persist to the MDS repository (see [Section 40.2.1, "How to Enable User Customizations"](#)). These rules do not apply for persistence within session scope.

If persistence fails for any reason (for example if one of the filter rules fails or there are MDS repository errors), then the values will be stored only within the session scope.

---

4. The **Tag Attributes** table displays all the attributes for the selected component whose values can be persisted. Select **Persist Changes** for all attributes whose values you want persisted. Deselect any if you do not want the values persisted.

---

**Note:** If you are implementing custom user customizations (see [Section 40.5, "Implementing Custom User Customizations"](#)), then you will need to edit the `adf-config.xml` manually to add the configuration. See [Example 40-5](#) for an example on how to configure user customizations.

---

### 40.3.2 What Happens When You Configure Change Persistence

When you select the component tags and attribute values to be persisted in the `adf-config.xml` file, JDeveloper enters tag library information for the components and attributes that are to be persisted. [Example 40-5](#) shows the entry for persisting the value of the `disclosed` attribute on the `panelBox` component.

**Example 40-5 Registration of Attribute Changes in `adf-config.xml`**

```
<taglib-config>
 <taglib uri="http://xmlns.oracle.com/adf/faces/rich">
 <tag name="panelBox">
 <attribute name="disclosed">
 <persist-changes>
 true
 </persist-changes>
 </attribute>
 ...
 </tag>
```

```
</taglib>
</taglib-config>
```

## 40.4 Controlling User Customizations in Individual JSF Pages

Once you have enabled your application to allow user customizations, you can control user customizations for specific components on the page.

By default, the framework persists changes for all component instances, based on the configuration in the `adf-config.xml` file. You can override this default behavior by explicitly setting what should be persisted and what should not be persisted on each component instance using the `persist` and `dontPersist` attributes.

---

---

**Note:** The filter rules specified using the `persist` and `dontPersist` attributes are applicable only when you have chosen to persist to the MDS repository (see [Section 40.2.1, "How to Enable User Customizations"](#)). These rules do not apply for persistence within session scope.

If persistence fails for any reason (for example if one of the filter rules fails or there are MDS repository errors), then the values will be stored only within the session scope.

---

---

The following components support the `persist` and `dontPersist` attributes:

- `panelBox`
- `showDetail`
- `showDetailHeader`
- `showDetailItem`
- `column`
- `tree`
- `treeTable`
- `panelSplitter`
- `calendar`
- `dvt:projectGantt`
- `dvt:resourceUtilizationGantt`
- `dvt:schedulingGantt`
- `dvt:ganttLegend`
- `dvt:hierarchyViewer`
- `dvt:timeAxis`

### 40.4.1 How to Control User Customizations on a JSF Page

You can override any globally set persistence configuration for a component using its `persist` and `dontPersist` attributes.

**Tip:** Often, a system administrator is the one to set the configurations in the `adf-config.xml`. The `persist` and `dontPersist` attributes allow page authors to override that setting as needed.

**Before you begin:**

It may be helpful to have an understanding of how runtime user customizations can be restricted on an individual page. For more information, see [Section 40.4, "Controlling User Customizations in Individual JSF Pages."](#)

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Section 40.1.2, "Additional Functionality for Runtime User Customization."](#)

You will need to launch JDeveloper using the **Studio Developer** role, open the application, and open the page for which you want to modify user customization behavior.

**To implement user customizations on a JSF Page:**

1. Add components to the page, as needed, including components that will be persisting changes.
2. If you want to persist all persistable attributes for a component:
  - a. In the Property Inspector, expand the **Advanced** section.
  - b. Click the drop-down list for the **Persist** field and choose **All Available**.
3. If you do not want to persist any attributes, repeat Step 2 for the **Don'tPersist** field.
4. If more than one attribute can be persisted for the component, and you do not want to persist all of them:
  - a. Click the drop-down menu to the right of the **Persist** field and choose **Edit** to open the Edit Property dialog.
  - b. Shuttle any attributes to be persisted from **Available** to **Selected**.
5. If you do not want to persist an attribute value, repeat Step 4 for the **Don't Persist** field.

---

---

**Note:** The filter rules specified using the `persist` and `dontPersist` attributes take precedence over any `adf-config.xml` configuration set for global component-level restrictions.

Values specified for the `dontPersist` attribute take precedence over values specified for the `persist` attribute. For example, if for a `panelBox` component you set `disclosed` as the value for both the `persist` and `dontPersist` attributes, the value of the `disclosed` attribute will not be persisted.

If you set the value of the `persist` or `dontPersist` attribute to `All Available`, then any values entered as choices using the Edit dialog and the shuttle will be ignored and all available attribute values will be persisted or not persisted.

---

---

## 40.4.2 What Happens at Runtime

When an application is configured to persist changes to the session, any changes made during the session are recorded in a session variable in a data structure that is indexed according to the view ID and the component's ID attribute value. Every time the page is requested, in the subsequent create View or Restore View phase, all changes are applied in the same order as they were added. This means that the changes registered through the session will be applied only during subsequent requests in the same session.

When an application is configured to persist changes to the MDS repository, any changes made during the session are recorded by mutating the Document Object Model that MDS maintains for the JSP document behind the view. A JSF phase listener registered by ADF controller triggers a commit on the MDS session during the appropriate lifecycle phase, resulting in the change document being persisted in the MDS store. Every time the page is requested, Oracle's JSP engine seeks the JSP document from an MDS JSP provider, which provides a flattened document after merging the stored changes to the base document. MDS records the change against the unique value of the component's ID attribute.

**Tip:** If changes are applied in response to a partial submit of the page (for example, a `commandButton` with the `partialSubmit` attribute set to `true`), the component for which changes are applied must be set as the value for the `partialTarget` attribute.

Additionally, be aware that when you run the application from JDeveloper in the Integrated WebLogic Server, MDS creates a local file-based repository to persist metadata customizations. In contrast, when the application is deployed to a test or production environment, customizations are persisted to the configured MDS repository. For more information about MDS repository configuration, see the *Oracle Fusion Middleware Administrator's Guide*. For more information about deploying an application, see [Section 41.4, "Deploying the Application."](#)

## 40.4.3 What You May Need to Know About Using Change Persistence on Templates and Regions

How changes are persisted for components on templates or regions is handled differently, depending on whether the changes are persisted to the session or to the MDS repository. With session persistence, changes are recorded and restored on components against the `viewId` for the given session. As a result, when the change is applied on a component that belongs to a region or page template, that change is applicable only in scope of the page that uses the region or template. It does not span all pages that consume the region or template.

For example, suppose you have `pageOne.jspx` and `pageTwo.jspx`, and they both contain the region defined in `region.jsff`, which in turn contains a `showDetail` component. When `pageOne.jspx` is rendered and the `disclosed` attribute on the `showDetail` component changes, the implicit attribute change is recorded and will be applied only for `pageOne.jspx`. If the user navigates to `pageTwo.jspx`, no attribute change is applied.

When you persist changes to the MDS repository, MDS records and restores customizations for a document identified by a combination of the JSP page path and customization name/value configuration setting as set on the customization class (for more information, see [Section 39.2.1.1, "Customization Classes"](#)). As a result, for a given page that is rendered, when MDS applies a change on a component within a

region or template, it is applicable for all pages that consume the region or template and that have the same customization name and value as the source page.

In the previous example, assume that the `showDetail` component uses the ID of `myShowDetail`. When `pageOne.jspx` is rendered and the `disclosed` attribute on the `showDetail` component changes, the attribute change is recorded for `region.jsff` (and not the page that consumes it). This change is applied when any page that contains the region is rendered, as long as the ID remains the same.

## 40.5 Implementing Custom User Customizations

In addition to the user customization capabilities built in to certain ADF Faces components, you can create your own custom user customization capabilities. The change persistence framework supports the following types of user customizations:

- Changing an attribute value
- Adding or removing a facet
- Adding or removing a child component
- Reordering child components
- Moving a child component to a different parent

To create custom user customizations, you must create a customization class for each type of user customization and then configure your application to use that class. You also need to set up the layers of customization for your application. For more information about both of these procedures, see [Section 39.2, "Developing a Customizable Application."](#)

Once those prerequisites are satisfied, you add logic that calls methods on the ADF Faces classes that handle persisting change either to the session or the MDS repository. To handle the change, you create code that uses the APIs from one of the ADF Faces specialized component change classes. For most cases, you add this code to the event handler method on a managed bean associated with the page the persisting component is on. If you want all instances of a component to persist the same change, you need to add this code for each page on which that component appears.

If you are creating a custom component, you can implement user customizations for the component by adding code directly to the custom component class. In that case, you will need to add the code only to the component class, and not once for each instance of the component. For more information, see [Section 40.6, "Creating Implicit Change Persistence in Custom Components."](#)

### 40.5.1 Change Persistence Framework API

To better understand what you need to do to create custom user customizations, it may help to have a deeper understanding of the change persistence and MDS frameworks. When you elect to persist changes to the MDS repository, the change persistence framework works in conjunction with the MDS framework. Where and how the customizations are saved are determined by how you set up your MDS repository, your customization layers, and your customization classes. Details about the MDS framework and the repository and how to use it are covered in [Chapter 39, "Customizing Applications with MDS."](#)

The change persistence framework uses the underlying change manager classes from Apache MyFaces Trinidad (in the `org.apache.myfaces.trinidad.change` package) along with a few ADF Faces-specific classes (in the `oracle.adf.view.rich.change` package). The instance of the registered

`ChangeManager` class is accessible through the `RequestContext` object. It is responsible for gathering changes as they are created and added during a request, and then persisting them. The `SessionChangeManager` class is an implementation of `ChangeManager` which handles persistence within a session only, while the `MDSDocumentChangeManager` class is an implementation that persists to the MDS repository only. The `FilteredPersistenceChangeManager` class is an implementation of `ChangeManager` that stores the changes that pass the filter rules into the repository using the registered persistence change manager. Any change that does not get persisted to the repository will be persisted to the session when `FilteredPersistenceChangeManager` is used.

Additional classes are used to describe the changes to a component. You use these APIs to handle persisting any changes to components other than the implicit value changes the ADF Faces framework provides (as shown in [Table 40-1](#)). `ComponentChange` is the base class for all classes used to implement specific changes that act on the JSF component hierarchy, such as adding or removing a facet or a child component. These changes are automatically applied during subsequent creation of the view, in the same order in which they were added. Classes that extend the `ComponentChange` class and that also implement the `DocumentChange` interface can directly persist changes to the MDS repository. Classes that do not implement the `DocumentChange` interface can persist changes only to the session.

[Table 40-2](#) describes the specialized classes that handle specific customizations. If "yes" appears in the Repository column, then the class implements the `DocumentChange` interface and it can persist changes to the MDS repository.

**Table 40-2 Classes Used to Handle Change Persistence**

Class Name	Repository	Description
<code>AddChildDocumentChange</code>	Yes	Adds a child or complex child (dvt:) component using document mark up.
<code>AddComplexChildDocumentChange</code>	Yes	While applying this change, the child or complex child component is created and added to the document.
<code>AddComplexChildAttributeChange</code>	Yes	Adds a complex child (dvt:) component attribute.
<code>AttributeComponentChange</code>	No	Changes the value of an attribute.
<code>ComplexAttributeComponentChange</code>	Yes	
<code>AttributeDocumentChange</code>	Yes	Changes the value of a facet attribute.
<code>ComplexAttributeDocumentChange</code>	Yes	
<code>MoveChildComponentChange</code>	Yes	Moves a child from one container to another.
<code>RemoveChildComponentChange</code>	Yes	Removes a child component.
<code>RemoveComplexChildAttributeComponentChange</code>	Yes	Removes a complex child (dvt:) component attribute.
<code>RemoveComplexChildAttributeDocumentChange</code>	Yes	
<code>SetFacetChildComponentChange</code>	No	Adds a child component to the facet using a document markup. While applying this change, the markup will be added to the document.

**Table 40–2 (Cont.) Classes Used to Handle Change Persistence**

Class Name	Repository	Description
SetFacetChildDocumentChange	Yes	Adds a child component to a facet. While applying this change, the DOM element corresponding to the child component is added to the document. If the facet doesn't exist, it will be created. If the facet does exist, all of its content will be removed and the new content added.
RemoveFacetComponentChange	Yes	Removes a facet.
ReorderChildrenComponentChange	Yes	Reorders children of a component.

Aside from a `ChangeManager` class, you may also need to implement and register the `DocumentChangeFactory` interface with the `ChangeManager` class. If the `DocumentChangeFactory` implementation can provide an equivalent `DocumentChange` for a `ComponentChange`, the `ChangeManager` will use it to persist the `DocumentChange` to the repository.

## 40.5.2 How to Create Code for Custom User Customizations

You need to add code to handle any explicit changes you want to create, and to configure the components on the JSF page to handle customization. As with the default user customizations, you also must register the custom changes in the `adf-config.xml` file.

---

**Note:** When the changes are expressible in more than one form, the change must be recorded in the form with highest precedence. For example:

- Attribute change for a component: The attribute can be specified on the component tag or it can be expressed using the `<f:attribute>` tag. In a JSF JSP document, `<f:attribute>` takes lesser precedence over the attribute specified on the component tag. Therefore, the attribute change on the component tag will be recorded for customization.
  - Column header text in a column component: The header text for the column can be specified using either the `headerText` attribute or using `header facet`. In this case, the facet component will have precedence.
- 

### To create custom user customizations:

1. Create a managed bean for the page that contains the component.
2. Add code to the event handler method for the component that will be used to make the change. This code should obtain the component that contains the change. It should then use the component and the appropriate APIs to create, record, and persist the change.

[Example 40–6](#) shows the code on the action event handler for a command button for a change that will be persisted to the MDS repository. When a user clicks the button, that source graphic file changes. The event handler method accesses the component and changes the source attribute for the graphic. It then calls the private `addAttributeChange` method, which first uses the component API to

record the change, and then uses the `AttributeComponentChange` class to set the new source attribute value.

**Example 40–6 Persisting Change to the Repository from an Event Handler on a Managed Bean**

```
public void modifyObjectImage(ActionEvent event) {
 UIComponent uic = event.getComponent().findComponent("oil");
 String source = "/images/mediumAd.gif";
 uic.getAttributes().put("source", source);
 _addAttributeChange(uic, "source", source);
}
.
.
.
private static void _addAttributeChange(UIComponent uic, String attribName,
 Object attribValue) {
 FacesContext fc = FacesContext.getCurrentInstance();
 ChangeManager cm =
 RequestContext.getCurrentInstance().getChangeManager();
 ComponentChange cc =
 new AttributeComponentChange(attribName, attribValue);
 cm.addComponentChange(fc, uic, cc);
}
```

---

**Note:** When you persist changes, in addition to explicitly recording a change on the component (which is done in [Example 40–6](#) using `uic.getAttributes().put("source", source)` method), you must also directly apply the change using the component API, as was done using the private `_addAttributeChange(uic, "source", source)` method. Applying the change in this way allows the user to see the change in response to the same request. If the change is recorded on the component, then the change will not be seen until a subsequent request.

Additionally, if you know that the component will always persist to the repository regardless of any restricted change persistence settings, you can instead call the `AdfFacesContext.getCurrentInstance().getPersistentChangeManager()` method.

---

3. The `ChangeManager` class provides support for automatically converting an `AttributeComponentChange` into an `AttributeDocumentChange`, thereby allowing persistence to a repository. However, if you need to convert another type of change and you use a specialized change manager class that does not implement the `DocumentChange` class, you need to create a custom `DocumentFactory` implementation that converts the component change to a document change.

---

**Note:** Automatic conversion of `AttributeComponentChange` into an `AttributeDocumentChange` assumes that the component attribute is represented as an attribute of the same name on the associated element in the JSPX document.

Only those attribute values that are expressible in the JSPX document can be persisted using `AttributeDocumentChange`. In other words, `CharSequence`, `Number`, `Boolean` and `ValueExpression` are the only supported data types.

Only values that implement `java.io.Serializable` can be persisted using `AttributeComponentChange`.

---

4. If you create a custom `DocumentFactory` implementation, you need to register it with the appropriate change manager class using the following method in your bean:

```
public static void registerDocumentFactory(String targetClassName,
 String converterClassName)
```

Where `targetClassName` is the name of the `ComponentChange` class and `converterClassName` is the name of your `DocumentChangeFactory` extension that is capable of converting the target `ComponentChange` into a `DocumentChange`. The semantics of name for these classes is same as that of `getName()` in the `java.lang.Class` class.

5. If the class you use to create the component change adds a child that has a subtree of components, and you want to persist the changes to the repository, you must create a `DocumentFragment` to represent the change.

[Example 40-7](#) shows how to use the `AddComponentDocumentChange` specialized class to create a `DocumentChange` object and use a `DocumentFragment` to represent the change.

#### **Example 40-7 Converting a ComponentChange Object to a DocumentChange Object**

```
public void appendChildToDocument(ActionEvent event)
{
 UIComponent eventSource = event.getComponent();
 UIComponent uic = eventSource.findComponent("pg1");
 // only allow the image to be added once
 if (_findChildById(uic, "oi3") != null)
 return;
 FacesContext fc = FacesContext.getCurrentInstance();
 DocumentFragment imageFragment = _createDocumentFragment(_IMAGE_MARK_UP);
 DocumentChange change = new AddChildDocumentChange(imageFragment);
 ChangeManager apm = RequestContext.getCurrentInstance().getChangeManager();
 apm.addDocumentChange(fc, uic, change);
}

private static final String _IMAGE_MARK_UP =
"<af:objectImage id='oi3' height='100' width='120' " +
"source='http://www.somewhere.com/someimage.jpg' " +
"xmlns:af='http://xmlns.oracle.com/adf/faces' />";

private static DocumentFragment _createDocumentFragment(
 String markUp)
{
 // prepend XML declaration
 markUp = "<?xml version = '1.0' encoding = 'ISO-8859-1'?>" + markUp;
```

```

DocumentBuilderFactory factory = DocumentBuilderFactory.newInstance();
factory.setNamespaceAware(true);
factory.setValidating(false);
DocumentBuilder builder;
try
{
 builder = factory.newDocumentBuilder();
}
catch (ParserConfigurationException pce)
{
 _LOG.log(Level.WARNING, "Unable to get XML Parser:", pce);
 return null;
}
try
{
 // use a version explicitly with ISO-8859-1 instead
 byte[] markupBytes = markup.getBytes();
 Document newDoc = builder.parse(new ByteArrayInputStream(markupBytes));
 DocumentFragment fragment = newDoc.createDocumentFragment();
 // add the document's root element to the fragment
 fragment.appendChild(newDoc.getDocumentElement());
 return fragment;
}
catch (SAXException se)
{
 _LOG.log(Level.WARNING, "Unable to parse markup:" + markup, se);
 return null;
}
catch (IOException ioe)
{
 _LOG.log(Level.WARNING, "IO Problem with markup:" + markup, ioe);
 return null;
}
}

```

6. Register the user customizations in the `adf-config.xml` file, as documented in [Section 40.3, "Configuring User Customizations."](#) If the custom changes are of any type other than `AttributeDocumentChange`, you will need to manually edit the `adf-config.xml` file and indicate that all changes are allowed for the component, as shown in [Example 40-8](#).

**Example 40-8 Custom Registration in `adf-config.xml`**

```

<tag name="inputText">
 <attribute name="label">
 <persist-changes>true</persist-changes>
 </attribute>
 <persist-operations>ALL</persist-operations>
</tag>

```

## 40.6 Creating Implicit Change Persistence in Custom Components

When you create a custom component, you may decide that you want certain attribute values on that component to be persisted whenever change persistence is enabled in an application. Setting implicit change on a custom component is similar to setting explicit change persistence on existing components. You add code that executes the actual persistence, but instead of you placing that code on a managed bean, that code can be handled directly by the component class. If your component's attribute values

are synchronized with the server using events, then you can use the broadcast method to persist the changes. If the attribute value that you want to persist does not use events, then you need to add code in the renderer and component class.

### 40.6.1 How to Set Implicit Change Persistence For Attribute Values that Use Events

When an attribute value uses events, you need to add code to the component class.

#### To set implicit change persistence for attribute values that use events:

1. Open the custom component class java file.
2. Add code to the broadcast method that will use the specialized class to create a new `ComponentChange` object and then call the `ChangeManager` to add the change.

[Example 40–9](#) shows the code added to the `UIXShowDetail` class that persists a change to the `disclosed` attribute. In this case, the `AttributeComponentChange` class is used.

#### **Example 40–9 Persisting Change from a Component Class**

```
public class UIXShowDetail extends UIXComponentBase
{
 ...
 public void broadcast(FacesEvent event) throws AbortProcessingException
 {
 super.broadcast(event);
 ...
 if (event instanceof DisclosureEvent)
 {
 boolean isDisclosed = ((DisclosureEvent) event).isExpanded();
 setDisclosed(isDisclosed);
 //Record a Change for 'disclosed' attribute
 AttributeComponentChange aa =
 new AttributeComponentChange('disclosed', isDisclosed ? Boolean.TRUE :
Boolean.FALSE);
 AdfFacesContext adfContext = AdfFacesContext.getCurrentInstance();
 adfContext.getChangeManager().addComponentChange(getFacesContext(), this,
aa);
 ...
 }
 }
 ...
}
```

### 40.6.2 How to Set Implicit Change Persistence For Other Attribute Values

When an attribute does not use events, you need to place code in the component's renderer class.

#### To set implicit change persistence for other attribute values:

1. Open the custom component's render class java file.
2. Use the `findTypeConstants` method, which takes a `ClientMetadata` instance and use the `addPersistedProperty` method to mark certain properties as persisted. [Example 40–10](#) shows a code snippet from the renderer class used for the ADF Faces `PanelSplitter` component, which implicitly persists the `splitterPosition` attribute value.

**Example 40–10 Method in Component Renderer Class to Implicitly Persist Changes**

```
// Code snippet from PanelSplitterRendererer.java
protected void findTypeConstants(
 FacesBean.Type type,
 ClientMetadata metadata)
{
 super.findTypeConstants(type, metadata);
 metadata.addRequiredProperty(
 _orientationKey = type.findKey("orientation"));
 metadata.addRequiredProperty(
 _positionedFromEndKey = type.findKey("positionedFromEnd"));
 metadata.addRequiredProperty(
 _disabledKey = type.findKey("disabled"));
 metadata.addRequiredProperty(
 _splitterPositionKey = type.findKey("splitterPosition");
metadata.addPersistedProperty(_splitterPositionKey);
}

```

3. In the JavaScript component peer class, define the attribute value to be persisted, using the `setProperty` function. This function needs to be invoked with the attribute name (as defined in the renderer in the previous step), the value, and "true", meaning the value of the attribute will be set. [Example 40–11](#) shows a code snippet from the `panelSplitter` class that sets the splitter position.

**Example 40–11 Method in Component Class to Implicitly Persist Changes**

```
// Code snippet from AdfDhtmlPanelSplitterPeer.js file where we set the
splitter position

var component = this.getComponent();
component.setProperty("splitterPosition",position, true);
// position is the value to be set

```

---

## Deploying Fusion Web Applications

This chapter describes how to deploy Oracle ADF applications to a target application server. It describes how to create deployment profiles, how to create deployment descriptors, and how to load ADF runtime libraries.

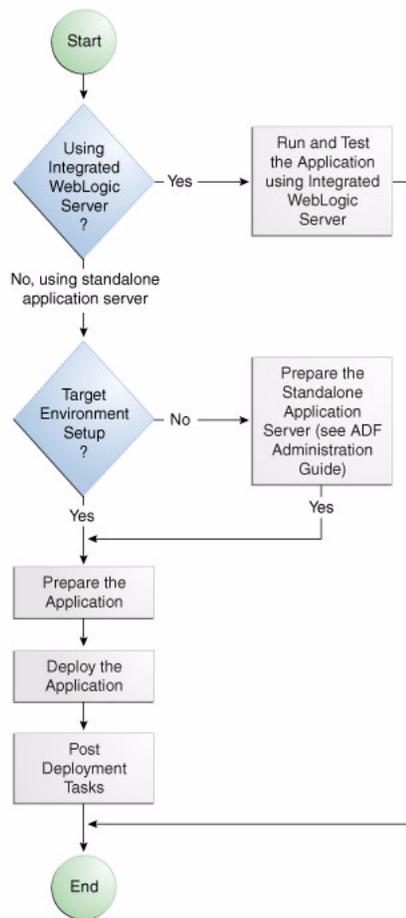

This chapter includes the following sections:

- [Section 41.1, "About Deploying Fusion Web Applications"](#)
- [Section 41.2, "Running an ADF Application in Integrated WebLogic Server"](#)
- [Section 41.3, "Preparing the Application"](#)

### 41.1 About Deploying Fusion Web Applications

Deployment is the process of packaging application files as an archive file and transferring that file to a target application server. You can use JDeveloper to deploy Oracle ADF applications directly to the application server (such as Oracle WebLogic Server or IBM WebSphere), or indirectly to an archive file as the deployment target, and then install this archive file to the target server. For application development, you can also use JDeveloper to run an application in Integrated WebLogic Server. JDeveloper supports deploying to server clusters, but you cannot use JDeveloper to deploy to individual Managed Servers that are members of a cluster.

[Figure 41-1](#) shows the flow diagram that describes the overall deployment process. Note that preparing the target application server for deployment by installing the ADF runtime is described in the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*

**Figure 41–1 Deployment Overview Flow Diagram**

---

**Note:** Normally, you use JDeveloper to deploy applications for development and testing purposes. If you are deploying Oracle ADF applications for production purposes, you can use Enterprise Manager or scripts to deploy to production-level application servers.

For more information about deployment to later-stage testing or production environments, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

---

ADF Java EE applications are based on standardized, modular components and can be deployed to the following application servers:

- Oracle WebLogic Server
 

Oracle WebLogic Server provides a complete set of services for those modules and handles many details of application behavior automatically, without requiring programming. For information about which versions of Oracle WebLogic Server are compatible with JDeveloper, see the certification information website at <http://www.oracle.com/technetwork/developer-tools/jdev/documentation/index.html>.
- IBM WebSphere Application Server

For information about which versions of IBM WebSphere are compatible, see the *Oracle Fusion Middleware Third-Party Application Server Guide*.

Deploying a Fusion web application is slightly different from deploying a standard Java EE application. JSF applications that contain ADF Faces components have a few additional deployment requirements:

- ADF Faces requires Sun's JSF Reference Implementation 1.2 and MyFaces 1.0.8 (or later).

You can use JDeveloper to:

- Run applications in Integrated WebLogic Server

You can run and debug applications using Integrated WebLogic Server and then deploy to standalone WebLogic Server or WebSphere Application Server.

- Deploy directly to the standalone application server

You can deploy applications directly to the standalone application server by creating a connection to the server and choosing the name of that server as the deployment target.

- Deploy to an archive file

You can deploy applications indirectly by choosing an EAR file as the deployment target. The archive file can subsequently be installed on a target application server.

The StoreFront module of the Fusion Order Demo application demonstrates the use of the Fusion web application technology stack to create transaction-based web applications. You can run the StoreFront module of the Fusion Order Demo application in JDeveloper using Integrated WebLogic Server. You cannot run the Fusion Order Demo module in JDeveloper. You must deploy the Fusion Order Demo application to a SOA-enabled Oracle WebLogic Server. For more information about the StoreFront module and the Fusion Order Demo application, see [Section 2.3, "Running the Fusion Order Demo Application StoreFront Module."](#)

### 41.1.1 Developing Applications with Integrated WebLogic Server

If you are developing an application in JDeveloper and you want to run the application in Integrated WebLogic Server, you do not need to perform the tasks required for deploying directly to Oracle WebLogic Server or to an archive file. JDeveloper has a default connection to Integrated WebLogic Server and does not require any deployment profiles or descriptors. Integrated WebLogic Server has a preconfigured domain that includes the ADF libraries, as well as the `-Djps.app.credential.override.allowed=true` setting, that are required to run Oracle ADF applications. You can run an application by choosing **Run** from the JDeveloper main menu.

You debug the application using the features described in [Chapter 36, "Testing and Debugging ADF Components."](#)

### 41.1.2 Developing Applications to Deploy to Standalone Application Server

Typically, for deployment to standalone application servers, you test and develop your application by running it in Integrated WebLogic Server. You can then test the application further by deploying it to standalone Oracle WebLogic Server in development mode or to IBM WebSphere Application Server to more closely simulate the production environment.

In general, you use JDeveloper to prepare the application or project for deployment by:

- Creating a connection to the target application server
- Creating deployment profiles (if necessary)
- Creating deployment descriptors (if necessary, and that are specific to the target application server)
- Updating `application.xml` and `web.xml` to be compatible with the application server (if required)
- Enabling the application for Real User Experience Insight (RUEI) in `web.xml` (if desired)
- Migrating application-level security policy data to a domain-level security policy store
- Configuring the Oracle Single Sign-On (Oracle SSO) service and properties in the domain `jps-config.xml` file when you intend the web application to run using Oracle SSO

You must already have an installed application server. For Oracle WebLogic Server, you can use the Oracle 11g Installer or the Oracle Fusion Middleware 11g Application Developer Installer to install one. For other application servers, follow the instructions in the applications server documentation to obtain and install the server.

You must also prepare the application server for ADF application deployment. For more information, see the "Preparing the Standalone Application Server for Deployment" section of the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

- Installing the ADF runtime into the application server installation:
  - For WebLogic Server
    - If you installed Oracle WebLogic Server together with JDeveloper using the Oracle 11g Installer for JDeveloper, the ADF runtime should already be installed.
    - If the ADF runtime is not installed and you want to use Oracle Enterprise Manager to manage standalone ADF applications (which are applications without Oracle SOA Suite or Oracle WebCenter components), use the Oracle Fusion Middleware 11g Application Developer Installer. This installer will install the necessary Oracle Enterprise Manager components into the Oracle WebLogic installation.
    - If the ADF runtime is not installed and you do not need to install Enterprise Manager, use the Oracle 11g Installer for JDeveloper.
  - For WebSphere Application Server
    - \* Use the Oracle Fusion Middleware 11g Application Developer Installer to install the ADF runtime and the necessary Oracle Enterprise Manager components into the WebSphere installation. For information about installing WebSphere, see the *Oracle Fusion Middleware Third-Party Application Server Guide*.
- Extending Oracle WebLogic Server domains or WebSphere Application Server Cells to be ADF-compatible using the ADF runtime

- For WebLogic, setting the Oracle WebLogic Server credential store overwrite setting as required (`-Djps.app.credential.override.allowed=true` setting).
- Creating a global JDBC data source for applications that require a connection to a data source

After the application and application server have been prepared, you can:

- Use JDeveloper to:
  - Directly deploy to the application server using the deployment profile and the application server connection.
  - Deploy to an EAR file using the deployment profile. For Oracle ADF applications, WAR and MAR files can be deployed only as part of an EAR file.
- Use Enterprise Manager, scripts, or the application server's administration tools to deploy the EAR file created in JDeveloper. For more information, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

## 41.2 Running an ADF Application in Integrated WebLogic Server

JDeveloper is installed with Integrated WebLogic Server which you can use to test and develop your application. For most development purposes, Integrated WebLogic Server will suffice. When your application is ready to be tested, you can select the run target and then choose the **Run** command from the main menu.

---

---

**Note:** The first time you run an application in Integrated WebLogic Server, the Configure Default Domain dialog appears for you to define an administrative password for the new domain.

---

---

When you run the application target, JDeveloper detects the type of Java EE module to deploy based on artifacts in the projects and workspace. JDeveloper then creates an in-memory deployment profile for deploying the application to Integrated WebLogic Server. JDeveloper copies project and application workspace files to an "exploded EAR" directory structure. This file structure closely resembles the EAR file structure that you would have if you were to deploy the application to an EAR file. JDeveloper then follows the standard deployment procedures to register and deploy the "exploded EAR" files into Integrated WebLogic Server. The "exploded EAR" strategy reduces the performance overhead of packaging and unpacking an actual EAR file.

In summary, when you select the run target and run the application in Integrated WebLogic Server, JDeveloper:

- Detects the type of Java EE module to deploy based on the artifacts in the project and application
- Creates a deployment profile in memory
- Copies project and application files into a working directory with a file structure that would simulate the "exploded EAR" file of the application.
- Performs the deployment tasks to register and deploy the simulated EAR into Integrated WebLogic Server
- Automatically migrates identities, credentials, and policies

Later on, if you plan to deploy the application to a standalone WebLogic Server instance, you will need to migrate this security information. For more information, see [Section 41.3.4, "How to Deploy Applications with ADF Security Enabled."](#)

---

**Note:** JDeveloper ignores the deployment profiles that were created for the application when you run the application in Integrated WebLogic Server.

---

The application will run in the base domain in Integrated WebLogic Server. This base domain has the same configuration as a base domain in a standalone WebLogic Server instance. In other words, this base domain will be the same as if you had used the Oracle Fusion Middleware Configuration Wizard to create a base domain with the default options in a standalone WebLogic Server instance.

JDeveloper will extend this base domain with the necessary domain extension templates, based on the JDeveloper technology extensions. For example, if you have installed JDeveloper Studio, JDeveloper will automatically configure the Integrated WebLogic Server environment with the ADF runtime template (JRF Fusion Middleware runtime domain extension template).

You can explicitly create a default domain for Integrated WebLogic Server. You can use the default domains to run and test your applications. Open the Application Server Navigator, right-click **IntegratedWebLogicServer** and choose **Create Default Domain**.

## 41.2.1 How to Run an Application in Integrated WebLogic Server

You can test an application by running it in Integrated WebLogic Server. You can also set breakpoints and then run the application within the ADF Declarative Debugger.

### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.2, "Running an ADF Application in Integrated WebLogic Server."](#)

### To run an application in Integrated WebLogic Server:

1. In the Application Navigator, select the project, unbounded task flow, JSF page, or file as the run target.
2. Right-click the run target and choose **Run** or **Debug**.

The Configure Default Domain dialog displays the first time you run your application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

## 41.2.2 How to Run an Application with Metadata in Integrated WebLogic Server

When an application is running in Integrated WebLogic Server, the MAR (Metadata Archive) profile itself will not be deployed to a repository, but a simulated MDS repository will be configured for the application that reflects the metadata information contained in the MAR. This metadata information is simulated, and the application runs based on this location in source control.

Any customizations or documents created by the application that are not configured to be stored in other MDS repositories are written to this simulated MDS repository

directory. For example, if you customize an object, the customization is written to the simulated MDS repository. If you execute code that creates a new metadata object, then this new metadata object is also written to the same location in the simulated MDS repository. You can keep the default location for this directory (`ORACLE_HOME\jdeveloper\systemXX.XX\o.mds.dt\adrs\Application\AutoGeneratedMar\mds_adrs_writedir`), or you can set it to a different directory. You also have the option to preserve this directory across different application runs, or to delete this directory before each application run.

If your workspace has different working sets, only the metadata from the projects defined in the working set and their dependent projects will be included in the MAR. You can view and change a project's dependencies by right-clicking the project in the Application Navigator, choosing **Project Properties**, and then selecting **Dependencies**. For instance, an application may have several projects but `workingsetA` is defined to be `viewController2` and `viewController5`; and `viewController5` has a dependency on `modelproject1`. When you run or debug `workingsetA`, only the metadata for `viewController2`, `viewController5`, and `modelproject1` will be included in the MAR for deployment.

#### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.2, "Running an ADF Application in Integrated WebLogic Server."](#)

You will need to complete this task:

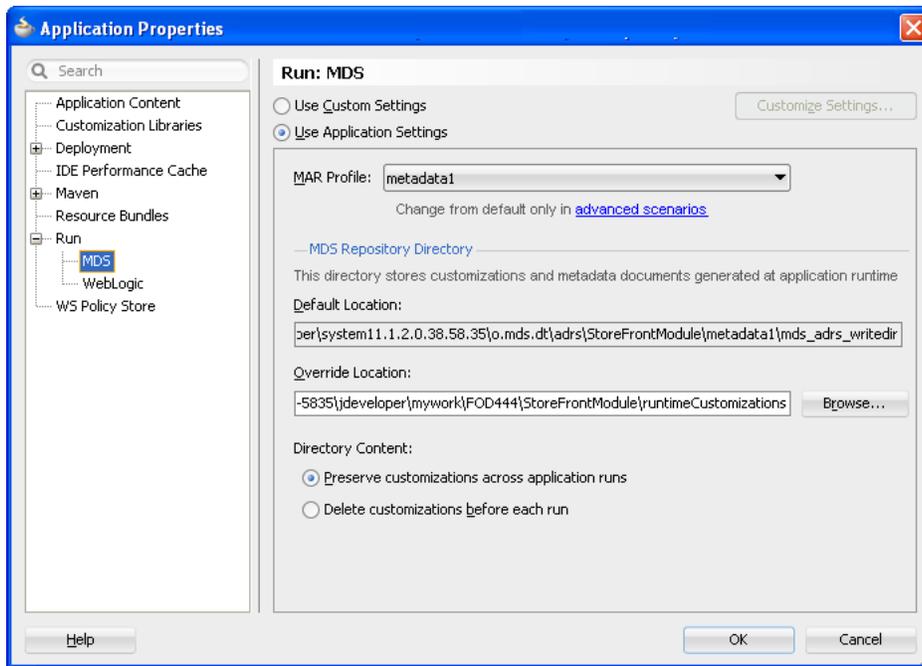

- Created a MAR profile, either manually or automatically by JDeveloper.

#### To deploy the MAR profile to Integrated WebLogic Server:

1. In the Application Navigator, right-click the application and choose **Application Properties**.
2. In the Application Properties dialog, expand **Run** and choose **MDS**.
3. On the Run MDS page:
  - Select the MAR profile from the **MAR Profile** dropdown list
  - Enter a directory path in **Override Location** if you want to customize the location of the simulated MDS repository.
  - Select the **Directory Content** option. You can choose to preserve the customizations across application runs or delete customizations before each run.

Select the MAR profile from the **MAR Profile** dropdown list. [Figure 41–2](#) shows **Demometadata1** selected as the MAR profile.

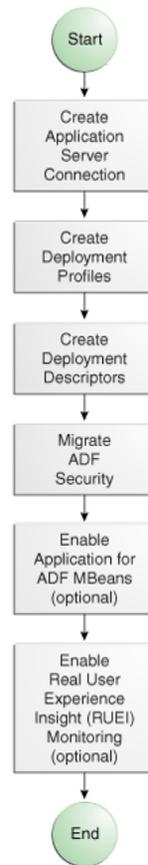

**Figure 41–2 Setting the Run MDS Options**

## 41.3 Preparing the Application

Before you deploy an ADF application to a standalone application server, you must perform prerequisite tasks within JDeveloper to prepare the application for deployment.

Figure 41–3 show the process flow to prepare the application for deployment. After the application has been prepared and the application server has been prepared as described in the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*, you can proceed to deploy the application as described in Section 41.4, "Deploying the Application."

**Figure 41–3 Preparing the Application for Deployment Flow Diagram**

### 41.3.1 How to Create a Connection to the Target Application Server

You can deploy applications to the application server via JDeveloper application server connections.

If your application involves customization using MDS, you should register your MDS repository with the application server:

- WebLogic: register the MDS into the WebLogic Domain

For more information about registering MDS in WebLogic, see the *Oracle Fusion Middleware Administrator's Guide*.

- WebSphere: register the MDS into the WebSphere Cell

For more information about registering MDS in WebSphere, see the *Oracle Fusion Middleware Third-Party Application Server Guide*.

For more information about registering MDS, see the *Oracle Fusion Middleware Administrator's Guide*.

#### **Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.3, "Preparing the Application."](#)

You will need to complete this task:

- Installed an application server.

**Before you begin:**

Install the application server. For more information, see [Section 41.3, "Preparing the Application."](#)

**To create a connection to an application server:**

1. Launch the Application Server Connection wizard.  
You can:
  - In the Application Server Navigator, right-click **Application Servers** and choose **New Application Server Connection**.
  - In the New Gallery, expand **General**, select **Connections** and then **Application Server Connection**, and click **OK**.
  - In the Resource Palette, choose **New > New Connections > Application Server**.
2. In the Create AppServer Connection dialog, on the Usage page, select **Standalone Server**.
3. On the Name and Type page, enter a connection name.
4. In the **Connection Type** dropdown list, choose:
  - **WebLogic 10.3** to create a connection to Oracle WebLogic Server
  - **WebSphere Server 7.x** to create a connection to IBM WebSphere Server
5. Click **Next**.
6. On the Authentication page, enter a user name and password for the administrative user authorized to access the application server.
7. Click **Next**.
8. On the Configuration page, enter the information for your server:
 

For WebLogic:

  - The Oracle WebLogic host name is the name of the WebLogic Server instance containing the TCP/IP DNS where your application (.jar, .war, .ear) will be deployed.
  - In the **Port** field, enter a port number for the WebLogic Server instance on which your application (.jar, .war, .ear) will be deployed.  
If you don't specify a port, the port number defaults to 7001.
  - In the **SSL Port** field, enter an SSL port number for the WebLogic Server instance on which your application (.jar, .war, .ear) will be deployed.  
Specifying an SSL port is optional. It is required only if you want to ensure a secure connection for deployment.  
If you don't specify an SSL port, the port number defaults to 7002.
  - Select **Always Use SSL** to connect to the WebLogic Server instance using the SSL port.
  - Optionally enter a **WebLogic Domain** only if WebLogic Server is configured to distinguish nonadministrative server nodes by name.

For WebSphere:

- In the **Host Name** field, enter the name of the WebSphere server containing the TCP/IP DNS where your Java EE applications (.jar, .war, .ear) are deployed. If no name is entered, the name defaults to localhost.
- In the **SOAP Connector Port** field, enter the port number. The host name and port are used to connect to the server for deployment. The default SOAP connector port is 8879.
- In the **Server Name** field, enter the name assigned to the target application server for this connection.
- In the **Target Node** field, enter the name of the target node for this connection. A node is a grouping of Managed Servers. The default is machineNode01, where machine is the name of the machine the node resides on.
- In the **Target Cell** field, enter the name of the target cell for this connection. A cell is a group of processes that host runtime components. The default is machineNode01Cell, where machine is the name of the machine the node resides on.
- In the **Wsadmin script location** field, enter, or browse to, the location of the wsadmin script file to be used to define the system login configuration for your IBM WebSphere application server connection. Note that you should not use the wsadmin files from the ORACLE\_HOME/oracle\_common/common/bin directory, which are not the correct version. The default location is websphere-home/bin/wsadmin.sh for Unix/Linux and websphere-home/bin/wsadmin.bat for Windows.

9. Click **Next**.

10. If you have chosen WebSphere, the JMX page appears. On the JMX page, enter the JMX information (optional):

---

---

**Note:** JMX configuration is optional and is not required for connecting to the WebSphere Application Server. JMX is only needed for deploying SOA applications.

---

---

- Select **Enable JMX** for this connection to enable JMX.
- In the **RMI Port** field, enter the port number of the WebSphere RMI connector port. The default is 2809.
- In the **WebSphere Runtime Jars Location** field, enter or browse to the location of the WebSphere runtime JARs.
- In the **WebSphere Properties Location (for secure MBEAN access)** field, enter or browse to the location of the file that contains the properties for the security configuration and the mbeans that are enabled. This field is optional.

11. Click **Next**.

12. If the SSL Signer Exchange Prompt dialog appears, click **Y**.

13. On the Test page, click **Test Connection** to test the connection.

JDeveloper performs several types of connections tests. The JSR-88 test must pass for the application to be deployable. If the test fails, return to the previous pages of the wizard to fix the configuration.

14. Click **Finish**.

## 41.3.2 How to Create Deployment Profiles

A *deployment profile* defines the way the application is packaged into the archive that will be deployed to the target environment. The deployment profile:

- Specifies the format and contents of the archive file that will be created
- Lists the source files, deployment descriptors, and other auxiliary files that will be packaged
- Describes the type and name of the archive file to be created
- Highlights dependency information, platform-specific instructions, and other information

You need a WAR deployment profile for each web user interface project that you want to deploy in your application. If you want to package seeded customizations or place base metadata in the MDS repository, you need an application-level metadata archive (MAR) deployment profile as well. For more information about seeded customizations, see [Chapter 39, "Customizing Applications with MDS."](#) If the application has customization classes, you need a JAR file for those classes and you need to add that JAR when you create the EAR file. Finally, you need an application-level EAR deployment profile and you must select the projects (such as WAR and MAR profiles and customization classes JAR files) to include from a list. When the application is deployed, the EAR file will include all the projects that were selected in the deployment profile.

---

---

**Note:** If you create your project or application using the Fusion Web Application (ADF) template, JDeveloper automatically creates default WAR, EAR, MAR, and JAR deployment profiles. Typically, you would not need to edit or create deployment profiles manually.

---

---

For Oracle ADF applications, you can deploy the application only as an EAR file. The WAR and MAR files that are part of the application should be included in the EAR file when you create the deployment profile.

---

---

**Note:** If your ADF application has business services that you want to deploy, you will need to create a Business Component Service Interface deployment profile and deploy it. For more information about business services, see [Section 11.2.20, "How to Deploy Web Services to Oracle WebLogic Server."](#)

---

---

### 41.3.2.1 Creating a WAR Deployment Profile

You will need to create a WAR deployment profile for each web-based project you want to package into the application. Typically, the WAR profile will include the dependent data model projects it requires.

#### **Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.3, "Preparing the Application."](#)

You will need to complete this task:

Create web-based projects. If you used the Fusion Web Application (ADF) template, you should already have a default WAR deployment profile.

**To create WAR deployment profiles for an application:**

1. In the Application Navigator, right-click the web project that you want to deploy and choose **New**.

You will create a WAR profile for each web project.

2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **WAR File**, and click **OK**.

If you don't see **Deployment Profiles** in the **Categories** tree, click the **All Features** tab.

3. In the Create Deployment Profile -- WAR File dialog, enter a name for the project deployment profile and click **OK**.

4. In the Edit WAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.

- If you have customization classes in your application, they must be loaded from the EAR-level application class loader and not from the WAR. You will later add these customization classes to the EAR.

By default, customization classes are added to the data model project's WAR class path. So for each WAR, you must exclude the customization classes.

If you created your customization classes in an extension project of the application, be sure to deselect any customization class archive on the Library Dependencies page of the WAR deployment profile for each user interface project.

If you created your customization classes in the data model project of the application, deselect any customization classes in the Edit WAR Deployment Profiles Properties dialog Filters page for each user interface project. If you are using a `customization.properties` file, it should also be deselected.

- You might also want to change the Java EE web context root setting. To do so, choose **General** in the left pane.

By default, when **Use Project's Java EE Web Context Root** is selected, the associated value is set to the project name, for example, `Application1-Project1-context-root`. You need to change this if you want users to use a different name to access the application.

If you are using custom JAAS LoginModule for authentication with JAZN, the context root name also defines the application name that is used to look up the JAAS LoginModule.

5. Click **OK** to exit the Deployment Profile Properties dialog.
6. Click **OK** again to exit the Project Properties dialog.
7. Repeat Steps 1 through 7 for all web projects that you want to deploy.

**41.3.2.2 Creating a MAR Deployment Profile**

If you have seeded customizations or base metadata that you want to place in the MDS repository, you need to create a MAR deployment profile.

The namespace configuration under `<mds-config>` for MAR content in the `adf-config.xml` file is generated based on your selections in the MAR Deployment Profile Properties dialog.

Although uncommon, an enterprise application (packaged in an EAR) can contain multiple web application projects (packaged in multiple WARs), but the metadata for all these web applications will be packaged into a single metadata archive (MAR). The metadata contributed by each of these individual web applications can be global (available for all the web applications) or local to that particular web application.

To avoid name conflicts for metadata with global scope, make sure that all metadata objects and elements have unique names across all the web application projects that forms part of the enterprise application.

To avoid name conflicts and to ensure that the metadata for a particular web application remains local to that application, you can define a `web-app-root` for that web application project.

The `web-app-root` is an element in the `adf-settings.xml` file for a web application project. The `adf-settings.xml` file should be kept in the `META-INF` directory under the `public_html` directory for the web project. [Example 41-1](#) shows the contents of a sample `adf-settings.xml` file.

**Example 41-1 web-app-root Element in the adf-settings.xml File**

```
<?xml version="1.0" encoding="UTF-8" ?>
<adf-settings xmlns="http://xmlns.oracle.com/adf/settings"
 xmlns:wap="http://xmlns.oracle.com/adf/share/http/config">
 <wap:adf-web-config xmlns="http://xmlns.oracle.com/adf/share/http/config">
 <web-app-root rootName="order"/>
 </wap:adf-web-config>
</adf-settings>
```

In this example, the `adf-settings.xml` file has a `web-app-root` element that defines the `rootName` as `order`.

If your enterprise application has only one web application project then there is no need to define a `web-app-root` element. If your enterprise application has multiple web application projects, then you should supply a `web-app-root` for all the web applications except one, without which the deployment would fail. For example, if you have `web-application1`, `web-application2`, and `web-application3`, two of these web application projects must define a `web-app-root` to preclude any name conflicts.

JDeveloper creates an auto-generated MAR when the **Enable User Customizations** and **Across Sessions using MDS** options are selected in the ADF View page of the Project Properties dialog or when you explicitly specify the deployment target directory in the `adf-config.xml` file.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.3, "Preparing the Application."](#)

You will need to complete this task:

Create an MDS repository for your customization requirements to deploy metadata using the MAR deployment profile. If you used the Fusion Web Application (ADF) template, you should already have a default MAR deployment profile.

**To create a MAR deployment profile:**

1. In the Application Navigator, right-click the application and choose **New**.

You will create a MAR profile if you want to include customizations.

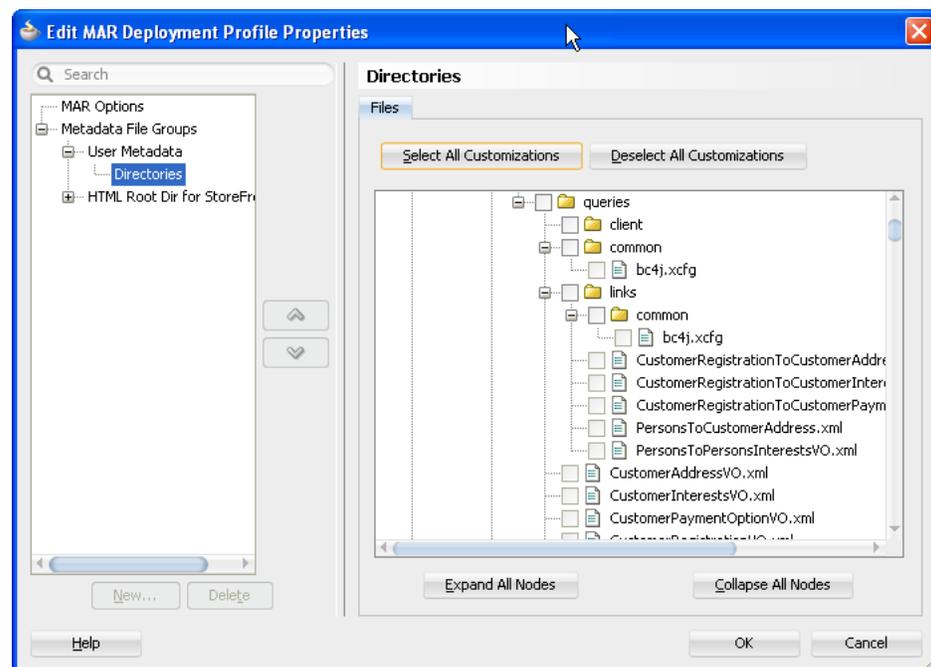

2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **MAR File**, and click **OK**.

If you don't see **Deployment Profiles** in the **Categories** tree, click the **All Features** tab.

3. In the Create Deployment Profile -- MAR File dialog, enter a name for the MAR deployment profile and click **OK**.
4. In the Edit MAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane.

Figure 41–4 shows a sample **User Metadata** directory tree.

**Figure 41–4** Selecting Items for the MAR Deployment Profiles

Note the following important points:

- To include all customizations, you need only create a file group with the desired directories.
- ADF Model and ADF view directories are added by default. No further action is required to package the ADF Model and ADF view customizations into the MAR. ADF view content is added to **HTML Root dir**, while ADF Model and Business Components content is added to **User Metadata**.
- To include the base metadata in the MDS repository, you need to explicitly select these directories in the dialog.

When you select the base document to be included in the MAR, you also select specific packages. When you select one package, all the documents (including subpackages) under that package will be used. When you select a package, you cannot deselect individual items under that package.

- To include files from other than ADF Model and ADF view, users should create a new file group under **User Metadata** with the desired directories and explicitly select the required content in the Directories page.
  - If a dependent ADF library JAR for the project contains seeded customizations, they will automatically be added to the MAR during MAR packaging. They will not appear in the MAR profile.
  - If ADF Library customizations were created in the context of the consuming project, those customizations would appear in the MAR profile dialog by default.
5. Click **OK** to exit the Deployment Profile Properties dialog.
  6. Click **OK** again to exit the Application Properties dialog.

### 41.3.2.3 Creating an Application-Level EAR Deployment Profile

The EAR file contains all the necessary application artifacts for the application to run in the application server. If you used the Fusion Web Application (ADF) template, you should already have a default EAR deployment profile. For more information about the EAR file, see [Section 41.4.5, "What You May Need to Know About EAR Files and Packaging."](#)

#### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.3, "Preparing the Application."](#)

You will need to complete this task:

1. Add classes into a JAR file, as described in [Section 41.3.2.6, "Adding Customization Classes into a JAR."](#)
2. Create the WAR deployment profiles, as described in [Section 41.3.2.1, "Creating a WAR Deployment Profile."](#)

#### To create an EAR deployment profile for an application:

1. In the Application Navigator, right-click the application and choose **New**.  
You will create an EAR profile for the application.
2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **EAR File**, and click **OK**.  
If you don't see **Deployment Profiles** in the Categories tree, click the **All Features** tab.
3. In the Create Deployment Profile -- EAR File dialog, enter a name for the application deployment profile and click **OK**.
4. In the Edit EAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.

Be sure that you:

- Select **Application Assembly** and then in the **Java EE Modules** list, select all the project profiles that you want to include in the deployment, including any **WAR** or **MAR** profiles.

- Select **Platform**, select the application server you are deploying to, and then select the target application connection from the **Target Connection** dropdown list.

---

**Note:** If you are using a custom JAAS LoginModule for authentication with JAZN, the context root name also defines the application name that is used to look up the JAAS LoginModule.

---

5. If you have customization classes in your application, configure these classes so that they load from the EAR-level application class loader.
  - a. In the Edit EAR Deployment Profile Properties dialog, select **Application Assembly**.
  - b. Select the JAR deployment profile that contains the customization classes, and enter `lib` in the **Path in EAR** field at the bottom of the dialog.

---

**Note:** You should have created this JAR as described in [Section 41.3.2.6, "Adding Customization Classes into a JAR."](#)

---

The JAR file containing the customization classes is added to the EAR file's `lib` directory.

---

**Note:** If you have customization classes in your application, you must also make sure they are not loaded from the WAR. By default, customization classes that are added to the data model project's libraries and class path are packaged to the WAR class path.

To make sure customization classes from an extension project are not duplicated in the WAR, be sure to deselect any customization class archive on the Library Dependencies page for the WAR.

If you created your customization classes in the data model project of the consuming application, deselect any customization classes in the Edit WAR Deployment Profile Properties dialog Filters page.

---

6. Click **OK** again to exit the Edit EAR Deployment Profile Properties dialog.
7. Click **OK** again to exit the Application Properties dialog.

---

**Note:** To verify that your customization classes are put correctly in the EAR class path, you can deploy the EAR profile to file system. Then you can examine the EAR to make sure that the customization class JAR is available in the EAR class path (the `EAR/lib` directory) and not available in the WAR class path (the `WEB-INF/lib` and `WEB-INF/classes` directories).

---

#### 41.3.2.4 Delivering Customization Classes as a Shared Library

As an alternative to adding your customization classes to the EAR, as described in [Section 41.3.2.3, "Creating an Application-Level EAR Deployment Profile,"](#) you can also include the customization classes in the consuming application as a shared library.

---

---

**Note:** This procedure describes how to create and use a shared library if you are deploying to Oracle Weblogic Server.

---

---

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.3, "Preparing the Application."](#)

You will need to complete this task:

Add customization classes into a JAR using JDeveloper in Studio Developer role. Follow the procedure described in [Section 41.3.2.6, "Adding Customization Classes into a JAR,"](#) and make sure that you select **Shared Library JAR File** as the type of archive to create.

**To create and use a shared library for your customization classes:**

1. In the Application Navigator, right-click the customization classes project, and choose **Deploy > deployment-profile**.
2. In the Deploy wizard, select **Deploy to a Weblogic Application Server** and click **Next**.
3. Select the appropriate application server, and click **Finish**.  
This makes the shared library available on the application server. You must now add a reference to the shared library from the consuming application.
4. Open the application you want to customize in JDeveloper in the Studio Developer role.
5. In the Application Resources panel of the Application Navigator, double-click the **weblogic-application.xml** file to open it.
6. In the overview editor, click the Libraries tab.
7. In the **Shared Library References** section, click the **Add** icon.
8. In the **Library Name** field of the newly created row in the **Shared Library References** table, enter the name of the customization classes shared library you deployed, and save your changes.

**41.3.2.5 Viewing and Changing Deployment Profile Properties**

After you have created a deployment profile, you can view and change its properties.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.3, "Preparing the Application."](#)

**To view, edit, or delete a project's deployment profile:**

1. In the Application Navigator, right-click the project and choose **Project Properties**.
2. In the Project Properties dialog, click **Deployment**.  
The **Deployment Profiles** list displays all profiles currently defined for the project.
3. In the list, select a deployment profile.
4. To edit or delete a deployment profile, click **Edit** or **Delete**.

### 41.3.2.6 Adding Customization Classes into a JAR

If your application has customization classes, create a JAR that contains only these customization classes. When you create your EAR, you can add the JAR to the EAR assembly. And when you create WAR profiles for your web projects, you must make sure they don't include the customization classes JAR.

#### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.3, "Preparing the Application."](#)

You will need to complete this task:

Make sure that your project has customization classes. You do not need to perform this procedure if the application does not have customization classes. For more information about customization classes, see [Section 39.2.1, "How to Create Customization Classes."](#)

#### To add customization classes into a JAR:

1. In the Application Navigator, right-click the data model project that contains the customization classes you want to create a JAR for, and choose **New**.
2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **JAR File**, and click **OK**.

Alternatively, if you want to create a shared library, select **Shared Library JAR File** from the list of profile types, and click **OK**.

---

**Note:** If you don't see **Deployment Profiles** in the **Categories** tree, click the **All Features** tab.

---

3. In the Create Deployment Profile -- JAR File dialog, enter a name for the project deployment profile (for example, `CCArchive`) and click **OK**.
4. In the Edit JAR Deployment Profile Properties dialog, select **JAR Options**.
5. Enter the location for the JAR file.
6. Expand **Files Groups > Project Output > Filters**.
7. In Filters page Files tab, select the customization classes you want to add to the JAR file.

If you are using a `customization.properties` file, it needs to be in the same class loader as the JAR file. You can select the `customization.properties` file to package it along with the customization classes in the same JAR.

8. Click **OK** to exit the Edit JAR Deployment Profile Properties dialog.
9. Click **OK** again to exit the Project Properties dialog.
10. In the Application Navigator, right-click the project containing the JAR deployment profile, and choose **Deploy > deployment profile > to JAR file**.

---

**Note:** If this is the first time you deploy to a JAR from this deployment profile, you choose **Deploy > deployment profile** and select **Deploy to JAR** in the wizard.

---

### 41.3.3 How to Create and Edit Deployment Descriptors

*Deployment descriptors* are server configuration files that define the configuration of an application for deployment and that are deployed with the Java EE application as needed. The deployment descriptors that a project requires depend on the technologies the project uses and on the type of the target application server. Deployment descriptors are XML files that can be created and edited as source files, but for most descriptor types, JDeveloper provides dialogs or an overview editor that you can use to view and set properties. If you cannot edit these files declaratively, JDeveloper opens the XML file in the source editor for you to edit its contents.

In addition to the standard Java EE deployment descriptors (for example, `application.xml` and `web.xml`), you can also have deployment descriptors that are specific to your target application server. For example, if you are deploying to Oracle WebLogic Server, you can also have `weblogic.xml`, `weblogic-application.xml`, and `weblogic-ejb-jar.xml`.

For WebLogic Server, make sure that the application EAR file includes a `weblogic-application.xml` file that contains a reference to `adf.oracle.domain`, and that it includes an `ADFApplicationLifecycleListener` to clean up application resources between deployment and undeployment actions. [Example 41-2](#) shows a sample `weblogic-application.xml` file.

#### **Example 41-2 Sample `weblogic-application.xml`**

```
<weblogic-application xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
xsi:schemaLocation="http://www.bea.com/ns/weblogic/weblogic-application.xsd"
xmlns="http://www.bea.com/ns/weblogic/weblogic-application">
 <listener>
 <listener-class>oracle.adf.share.weblogic.listeners.
 ADFApplicationLifecycleListener</listener-class>
 </listener>
 <listener>
 <listener-class>oracle.mds.lcm.weblogic.WLlifecycleListener</listener-class>
 </listener>
 <library-ref>
 <library-name>adf.oracle.domain</library-name>
 </library-ref>
</weblogic-application>
```

If you are deploying web services, you may need to modify your `weblogic-application.xml` and `web.xml` files as described in [Section 11.2.20, "How to Deploy Web Services to Oracle WebLogic Server."](#)

If you want to enable the application for Real User Experience Insight (RUEI) monitoring, you must add a parameter to the `web.xml` file, as described in [Section 41.3.3.5, "Enabling the Application for Real User Experience Insight."](#)

During deployment, the application's security properties are written to the `weblogic-application.xml` file to be deployed with the application in the EAR file. For more information, see [Section 35.8.2, "What Happens When You Configure Security Deployment Options."](#)

Because Oracle WebLogic Server runs on Java EE 1.5, you may need to modify the `application.xml` and `web.xml` files to be compatible with the application server.

For IBM WebSphere, the deployment descriptors are created at runtime and cannot be edited. Some of the relevant descriptors are shown in [Table 41-1](#).

**Table 41-1 IBM WebSphere Deployment Descriptors**

WebSphere	Action
ibm-application-bnd.xml	References the security role just mapped in application.xml and maps it to the well-known name AllAuthenticatedUsers. Similar to weblogic.xml for WebLogic Server. Maps the valid-users JEE security role to the well-known name Users.
application.xml	A standard Java EE deployment description. Also used to populate a security mapping for the "valid-users" role (which is defined in web.xml when using ADF Security).
<EAR_ROOT>/META-INF/manifest.mf	References application shared libraries such as adf.oracle.domain
<EAR_ROOT>/META-INF/deployment.xml	References WAR shared libraries such as adf.oracle.domain.webapp

### 41.3.3.1 Creating Deployment Descriptors

JDeveloper automatically creates many of the required deployment descriptors for you. If they are not present, or if you need to create additional descriptors, you can use JDeveloper to create them.

#### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.3, "Preparing the Application."](#)

You will need to complete this task:

Check to see whether JDeveloper has already generated deployment descriptors.

#### To create a deployment descriptor:

1. In the Application Navigator, right-click the project for which you want to create a descriptor and choose **New**.
2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then a descriptor type, and click **OK**.

If you can't find the item you want, make sure that you chose the correct project, and then choose the **All Features** tab or use the **Search** field to find the descriptor. If the item is not enabled, check to make sure that the project does not already have a descriptor of that type. A project is allowed only one instance of a descriptor.

JDeveloper starts the Create Deployment Descriptor wizard and then opens the file in the overview or source editor, depending on the type of deployment descriptor you choose.

---

---

**Note:** For EAR files, do not create more than one deployment descriptor file of the same type per application or workspace. These files can be assigned to projects, but have application workspace scope. If multiple projects in an application have the same deployment descriptor, the one belonging to the launched project will supersede the others. This restriction applies to `application.xml`, `weblogic-jdbc.xml`, `jazn-data.xml`, and `weblogic.xml`.

The best place to create an application-level descriptor is in the **Descriptors** node of the Application Resources panel in the Application Navigator. This ensures that the application is created with the correct descriptors.

Application-level descriptors created in the project will be ignored at runtime. Only the application resources descriptors or descriptors generated at the EAR level will be used by the runtime.

---

---

### 41.3.3.2 Viewing or Modifying Deployment Descriptor Properties

After you have created a deployment descriptor, you can change its properties by using JDeveloper dialogs or by editing the file in the source editor. The deployment descriptor is an XML file (for example, `application.xml`) typically located under the Application Sources node.

#### **Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.3, "Preparing the Application."](#)

#### **To view or change deployment descriptor properties:**

1. In the Application Navigator or in the Application Resources panel, double-click the deployment descriptor.
2. In the overview editor, select either the **Overview tab** or the **Source tab**, and configure the descriptor by setting property values.

If the overview editor is not available, JDeveloper opens the file in the source editor.

### 41.3.3.3 Configuring the `application.xml` File for Application Server Compatibility

You may need to configure your `application.xml` file to be compliant with Java EE 1.5.

---

---

**Note:** Typically, your project has an `application.xml` file that is compatible and you would not need to perform this procedure.

---

---

#### **Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.3, "Preparing the Application."](#)

#### **To configure the `application.xml` file:**

1. In the Application Navigator, right-click the application and choose **New**.

2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then **Java EE Deployment Descriptor Wizard**, and click **OK**.
3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select **application.xml** and click **Next**.
4. On the Select Version page, select **5.0** and click **Next**.
5. On the Summary page, click **Finish**.
6. Edit the `application.xml` file with the appropriate values.

#### 41.3.3.4 Configuring the web.xml File for Application Server Compatibility

You may need to configure your `web.xml` file to be compliant with Java EE 1.5 (which corresponds to servlet 2.5 and JSP 1.2). For more information, see [Section A.13, "web.xml."](#)

---

**Note:** Typically, your project has a `web.xml` file that is compatible and you would not need to perform this procedure. JDeveloper creates a starter `web.xml` file when you create a project.

If the application uses ADF Security and will be deployed to WebSphere, you need to manually edit the `web.xml` file. For more information, see [Section 41.3.4.3.3, "Editing the web.xml File to Protect the Application Root for WebSphere."](#)

---

#### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.3, "Preparing the Application."](#)

#### To configure the web.xml file:

1. In the Application Navigator, right-click the project and choose **New**.
2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then **Java EE Deployment Descriptor**, and click **OK**.
3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select **web.xml** and click **Next**.
4. On the Select Version page, select **2.5** and click **Next**.
5. On the Summary page, click **Finish**.

#### 41.3.3.5 Enabling the Application for Real User Experience Insight

Real User Experience Insight (RUEI) is a web-based utility to report on real-user traffic requested by, and generated from, your network. It measures the response times of pages and transactions at the most critical points in the network infrastructure. Session diagnostics allow you to perform root-cause analysis.

RUEI enables you to view server and network times based on the real-user experience, to monitor your Key Performance Indicators (KPIs) and Service Level Agreements (SLAs), and to trigger alert notifications on incidents that violate their defined targets. You can implement checks on page content, site errors, and the functional requirements of transactions. Using this information, you can verify your business and technical operations. You can also set custom alerts on the availability, throughput, and traffic of all items identified in RUEI.

For more information about RUEI, see the *Oracle Real User Experience Insight User's Guide* at [http://download.oracle.com/docs/cd/E16339\\_01/doc.60/e16359/toc.htm](http://download.oracle.com/docs/cd/E16339_01/doc.60/e16359/toc.htm).

You must enable an application for RUEI by adding the following `context-param` tag to the `web.xml` file, as shown in [Example 41-3](#).

**Example 41-3 Enabling RUEI Monitoring for an Application in web.xml**

```
<context-param>
 <description>This parameter notifies ADF Faces that the
 ExecutionContextProvider service provider is enabled.
 When enabled, this will start monitoring and aggregating
 user activity information for the client initiated
 requests. By default this param is not set or is false.
 </description>
 <param-name>
 oracle.adf.view.faces.context.ENABLE_ADF_EXECUTION_CONTEXT_PROVIDER
 </param-name>
 <param-value>true</param-value>
</context-param>
```

### 41.3.4 How to Deploy Applications with ADF Security Enabled

If you are developing an application in JDeveloper using Integrated WebLogic Server, application security deployment properties are configured by default, which means that the application and security credentials and policies will be overwritten each time you redeploy for development purposes. However, the application security deployment properties are the same for Integrated WebLogic Server and the standalone WebLogic Server.

You can change the default behavior in the Application Properties dialog, as described in [Section 35.8.1, "How to Configure, Deploy, and Run a Secure Application in JDeveloper."](#)

#### 41.3.4.1 Applications That Will Run Using Oracle Single Sign-On (SSO)

Before you can deploy and run the web application with ADF Security enabled on the application server, the administrator of the target server must configure the domain-level `jps-config.xml` file for the Oracle Access Manager (OAM) security provider. To assist with this configuration task, an Oracle WebLogic Scripting Tool (WLST) script has been provided with the JDeveloper install. For details about running this configuration script (with command `addOAMSSOProvider(loginuri, logouturi, autologinuri)`), see the procedure for configuring Oracle WebLogic Server for a web application using ADF Security, OAM SSO, and OPSS SSO in the *Oracle Fusion Middleware Application Security Guide*.

Running the configuration script ensures that the ADF Security framework defers to the OAM service provider to clear the `ObSSOCookie` token. OAM uses this token to save the identity of authenticated users and, unless it is cleared during logout, the user will be unable to log out.

After the system administrator runs the script on the target server, the domain `jps-config.xml` file will contain the following security provider definition that is specific for ADF Security:

```
<propertySet name="props.auth.uri">
 <property name="login.url.FORM" value="/${app.context}/adfAuthentication"/>
 <property name="logout.url" value=""/>
</propertySet>
```

```
</propertySet>
```

Additionally, the authentication type required by SSO is `CLIENT-CERT`. The `web.xml` authentication configuration for the deployed application must specify the `<auth-method>` element as one of the following `CLIENT-CERT` types.

WebLogic supports two types of authentication methods:

- For `FORM`-type authentication method, specify the elements like this:

```
<login-config>
 <auth-method>CLIENT-CERT,FORM</auth-method>
 <realm-name>myrealm</realm-name>
 <form-login-config>
 <form-login-page>/login.html</form-login-page>
 <form-error-page>/error.html</form-error-page>
 </form-login-config>
</login-config>
```

- For `BASIC`-type authentication method, specify the elements like this:

```
<login-config>
 <auth-method>CLIENT-CERT,BASIC</auth-method>
 <realm-name>myrealm</realm-name>
</login-config>
```

WebSphere supports a single authentication method. Specify the elements like this:

```
<login-config>
 <auth-method>CLIENT-CERT</auth-method>
 <realm-name>myrealm</realm-name>
 <form-login-config>
 <form-login-page>/login.html</form-login-page>
 <form-error-page>/error.html</form-error-page>
 </form-login-config>
</login-config>
```

You can configure the `web.xml` file either before or after deploying the web application. For further details about setting up the authentication method for Single Sign-On, see the *Oracle Fusion Middleware Application Security Guide*.

#### 41.3.4.2 Configuring Security for WebLogic Server

In a development environment, JDeveloper will automatically migrate application-level credentials, identities, and policies to the standalone WebLogic Server instance only if the server is set up to be in development mode. Integrated WebLogic Server is set up in development mode by default. You can set up a standalone WebLogic Server to be in development mode during Oracle WebLogic Server domain creation using the Oracle Fusion Middleware Configuration Wizard. For more information about configuring Oracle WebLogic Server domains, see *Oracle Fusion Middleware Creating Domains Using the Configuration Wizard*.

JDeveloper will not migrate application-level security credentials to WebLogic Server setup in production mode. Typically, in a production environment, administrators will use Enterprise Manager or WLST scripts to deploy an application, including its security requirements.

When you deploy an application to WebLogic Server, credentials (in the `cwallet.sso` and `jazn-data.xml` files) will either overwrite or merge with the WebLogic Server's domain-level credential store, depending on whether an option in `weblogic-application.xml` is set to `OVERWRITE` or `MERGE`. In production-mode

WebLogic Server, to avoid security risks, only `MERGE` is allowed. For development-mode WebLogic Server, you can set to `OVERWRITE` to test user names and passwords. You can also set the option by running `setDomainEnv.cmd` or `setDomainEnv.sh` with the following option added to the command (usually located in `ORACLE_HOME/user_projects/domains/MyDomain/bin`).

For `setDomainEnv.cmd`:

```
set EXTRA_JAVA_PROPERTIES=-Djps.app.credential.override.allowed=true
 %EXTRA_JAVA_PROPERTIES%
```

For `setDomainEnv.sh`:

```
EXTRA_JAVA_PROPERTIES="-Djps.app.credential.override.allowed=true
 ${EXTRA_JAVA_PROPERTIES}"
export EXTRA_JAVA_PROPERTIES
```

If the Administration Server is already running, you must restart it for this setting to take effect.

You can check to see whether WebLogic Server is in production mode by using the Oracle WebLogic Server Administration Console or by verifying the following line in WebLogic Server's `config.xml` file:

```
<production-mode-enabled>true</production-mode-enabled>
```

By default, JDeveloper sets the application's credential, identities, and policies to `OVERWRITE` mode. That is, the **Application Policies, Credentials, and Users and Groups** options are selected by default in the Application Properties dialog Deployment page. However, an application's credentials will be migrated only if the target WebLogic Server instance is set to development mode with `-Djps.app.credential.override.allowed=true`

Policy migration only works in development-mode. Identity migration only works when using JDeveloper to directly deploy to WebLogic Server regardless of whether it is in development or production-mode.

When your application is ready for deployment to a production environment, you should remove the identities from the `jazn-data.xml` file or disable the migration of identities by deselecting **Users and Groups** from the Application Properties dialog. Application credentials must be manually migrated outside of JDeveloper.

---

---

**Note:** Before you migrate the `jazn-data.xml` file to a production environment, check that the policy store does not contain duplicate permissions for a grant. If a duplicate permission (one that has the same name and class) appears in the file, the administrator migrating the policy store will receive an error and the migration of the policies will be halted. You should manually edit the `jazn-data.xml` file to remove any duplicate permissions from a grant definition.

---

---

For more information about migrating application credentials and other `jazn-data` user credentials, see the *Oracle Fusion Middleware Application Security Guide*.

#### 41.3.4.2.1 Applications with JDBC URL for WebLogic

If your application has components that use JDBC URL connections, the connection user names and passwords are also stored in the application-level credential and policy stores. For the deployed application to be able to connect to the database using the JDBC URL, these credentials and policies must be migrated. That is, if WebLogic

Server is in production mode, system administrators must migrate this security information. If WebLogic Server is in development mode, it must have domain-level credential and policy stores set to `OVERWRITE` to allow the migration of security information.

#### 41.3.4.2.2 Applications with JDBC Data Source for WebLogic

If your application uses application-level JDBC data sources with password indirection for database connections, you may need to create credential maps in WebLogic Server to enable the database connection. For more information, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

#### 41.3.4.3 Configuring Security for Websphere Application Server

Applications with credentials and policies in the `jazn-data.xml` and `cwallet.sso` files can be migrated to WebSphere. You will need to perform additional tasks in WebSphere. Be aware that the `opss-application.xml` file is not included in the application EAR file if it is intended for WebSphere Application Server.

---

**Note:** Before you migrate the `jazn-data.xml` file to a production environment, check that the policy store does not contain duplicate permissions for a grant. If a duplicate permission (one that has the same name and class) appears in the file, the administrator migrating the policy store will receive an error and the migration of the policies will be halted. You should manually edit the `jazn-data.xml` file to remove any duplicate permissions from a grant definition.

---

For more information about setting up WebSphere to accept credentials and policies, see the *Oracle Fusion Middleware Third-Party Application Server Guide*.

#### 41.3.4.3.1 Applications with JDBC URL for WebSphere

If your application has components that use JDBC URL connections, the connection user names and passwords are also stored in the application-level credential and policy stores. For the deployed application to be able to connect to the database using the JDBC URL, OPSS migration must be enabled.

#### 41.3.4.3.2 Applications with JDBC Data Source for WebSphere

If your application uses application-level JDBC data sources with password indirection for database connections, you will need to create a JDBC data source in WebSphere. For more information, see IBM WebSphere documentation.

#### 41.3.4.3.3 Editing the web.xml File to Protect the Application Root for WebSphere

When you enable ADF Security for your web application, the `web.xml` file includes the Java EE security constraint `allPages` to protect the Java EE application root. By default, to support deploying to Oracle WebLogic Server, JDeveloper specifies the URL pattern for the security constraint as `/` (backslash). If you intend to deploy the application to IBM WebSphere, the correct URL pattern is `/*` (backslash-asterisk). Before you deploy the application to WebSphere, manually edit the `web.xml` file for your application to change the `allPages` security constraint as follows:

```
<security-constraint>
 <web-resource-collection>
 <web-resource-name>allPages</web-resource-name>
```

```

 <url-pattern>/*</url-pattern>
 </web-resource-collection>
 . . .
</security-constraint>

```

### 41.3.5 How to Replicate Memory Scopes in a Clustered Environment

If you are deploying an application that is intended to run in a clustered environment, you need to ensure that all managed beans with a lifespan longer than one request are serializable, and that the ADF framework is aware of changes to managed beans stored in ADF scopes (view scope and page flow scope).

For more information, see [Section 24.4.3, "How to Set Managed Bean Memory Scopes in a Server-Cluster Environment."](#)

### 41.3.6 How to Enable the Application for ADF MBeans

An ADF application uses many XML files for setting configuration information. Three of these configuration files have ADF MBean counterparts that are deployed with the application. After the application has been deployed, you can change configuration properties by accessing the ADF MBeans using the Enterprise Manager Fusion Middleware Control MBean browser.

To enable ADF MBeans, register them in the `web.xml` file. [Example 41-4](#) shows a `web.xml` file with listener entries for connections, configuration, and business components.

#### **Example 41-4 Enabling ADF MBeans in the web.xml File**

```

<listener>
 <listener-class>
 oracle.adf.mbean.share.connection.ADFConnectionLifecycleCallBack
 </listener-class>
</listener>
<listener>
 <listener-class>
 oracle.adf.mbean.share.config.ADFConfigLifecycleCallBack</listener-class>
</listener>
<listener>
 <listener-class>
 oracle.bc4j.mbean.BC4JConfigLifecycleCallBack</listener-class>
</listener>

```

Additionally, ADF connection MBeans require the application to be configured with an MDS repository. ADF Business Components MBeans do not require MDS, but business components configuration is limited to updating the underlying `bc4j.xcfg` file in the exploded EAR location. MDS configuration entries in the `adf-config.xml` file for a file-based MDS are shown in [Example 41-5](#). For more information about configuring MDS, see the *Oracle Fusion Middleware Administrator's Guide*.

#### **Example 41-5 MDS Configuration Entries in the adf-config.xml File**

```

<adf-mds-config xmlns="http://xmlns.oracle.com/adf/mds/config">
 <mds-config xmlns="http://xmlns.oracle.com/mds/config" version="11.1.1.000">
 <persistence-config>
 <metadata-store-usages>
 <metadata-store-usage
 default-cust-store="true" deploy-target="true" id="myStore">
 </metadata-store-usage>
 </metadata-store-usages>
 </persistence-config>
 </mds-config>
</adf-mds-config>

```

```

 </metadata-store-usages>
 </persistence-config>
</mds-config>
</adf-mds-config>

```

In a production environment, an MDS repository that uses a database is required. You can use JDeveloper, Enterprise Manager Fusion Middleware Control or scripts to switch from a file-based repository to a database MDS repository.

Additionally, if several applications are sharing the same MDS configuration, each application can achieve distinct customization layers by defining a `adf:adf-properties-child` property in the `adf-config.xml` file. JDeveloper automatically generates this entry when creating applications. If your `adf-config.xml` file does not have this entry, add it to the file with code similar to that of [Example 41-6](#).

**Example 41-6 Adding MDS Partition Code to the `adf-config.xml` File**

```

<adf:adf-properties-child xmlns="http://xmlns.oracle.com/adf/config/properties">
 <adf-property name="adfAppUID" value="Application3-4434"/>
 <adf-property name="partition_customizations_by_application_id"
 value="true"/>
</adf:adf-properties-child>

```

The `value` attribute is either generated by JDeveloper or you can set it to any unique identifier within the server farm where the application is deployed. This value can be set to the `value` attribute of the `adfAppUID` property.

When `adf-property name` is set to `adfAppUID`, then the corresponding `value` property should be set to the name of the application. By default, JDeveloper generates the `value` property using the application's package name. If the package name is not specified, JDeveloper generates the `value` property by using the workspace name and a four digit random number.

For more information about configuring ADF applications using ADF MBeans, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

### 41.3.7 What You May Need to Know About JDBC Data Source for Oracle WebLogic Server

ADF applications can use either a JDBC data source or a JDBC URL for database connections. You use the Oracle WebLogic Server Administration Console to configure a JDBC data source. For more information about database access, see [Section 9.3, "Configuring Your Application Module Database Connection."](#)

The ADF application module in the data model project can be configured to use a JDBC URL connection type, a JDBC data source connection type, or a combination of both types. By default, ADF application modules use a JDBC URL connection. A component that uses a JDBC URL will attempt to connect directly to the database using the JDBC URL, and it will ignore any JDBC data sources (global or application-level) that are available in WebLogic Server. For more information about migrating JDBC URL security information (user names and passwords) from the application to WebLogic Server, see [Section 41.3.4, "How to Deploy Applications with ADF Security Enabled."](#)

An ADF application can use a JDBC data source to connect to the database. A JDBC data source has three types: global, application level, and application level with password indirection. You generally set up a global JDBC data source in WebLogic

Server. Any application that requires access to that database can use that JDBC data source. An application can also include application-level JDBC data sources. When the application is packaged for deployment, if the **Auto Generate and Synchronize weblogic-jdbc.xml Descriptor During Deployment** option is selected, JDeveloper creates a `connection_name-jdbc.xml` file for each connection that was defined. Each connection's information is written to the corresponding `connection_name-jdbc.xml` file (entries are also changed in `weblogic-application.xml` and `web.xml`). When the application is deployed to WebLogic Server, the server looks for application-level data source information before it looks for the global data source.

If the application is deployed with password indirection set to `true`, WebLogic Server will look for the `connection_name-jdbc.xml` file for user name information and it will then attempt to locate application-level credential maps for these user names to obtain the password. If you are using JDeveloper to directly deploy the application to WebLogic Server, JDeveloper automatically creates the credential map and populates the map to the server using an MBean call.

However, if you are deploying to an EAR file, JDeveloper will not be able to make the MBean call to WebLogic Server. You must set up the credential maps using the Oracle WebLogic Administration Console. Even if you have a global JDBC data source set up, if you do not also have credential mapping set up, WebLogic Server will not be able to map the credentials with passwords and the connection will fail.

Once the data source has been created in Oracle WebLogic Server, it can be used by an application module. For more information, see the "Preparing the Standalone Application Server for Deployment" section of the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

## 41.4 Deploying the Application

You can use JDeveloper to deploy ADF applications directly to the standalone application server or you can create an archive file and use other tools to deploy to the application server.

---

---

**Note:** Before you begin to deploy applications that use Oracle ADF to the standalone application server, you need to prepare the application server environment by performing tasks such as installing the ADF runtime and creating and extending domains or cells. For more information, see the "Preparing the Standalone Application Server for Deployment" section of the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

---

---

Figure 41–5 show the process flow for deploying an application and also for deploying customizations to the target standalone application server.

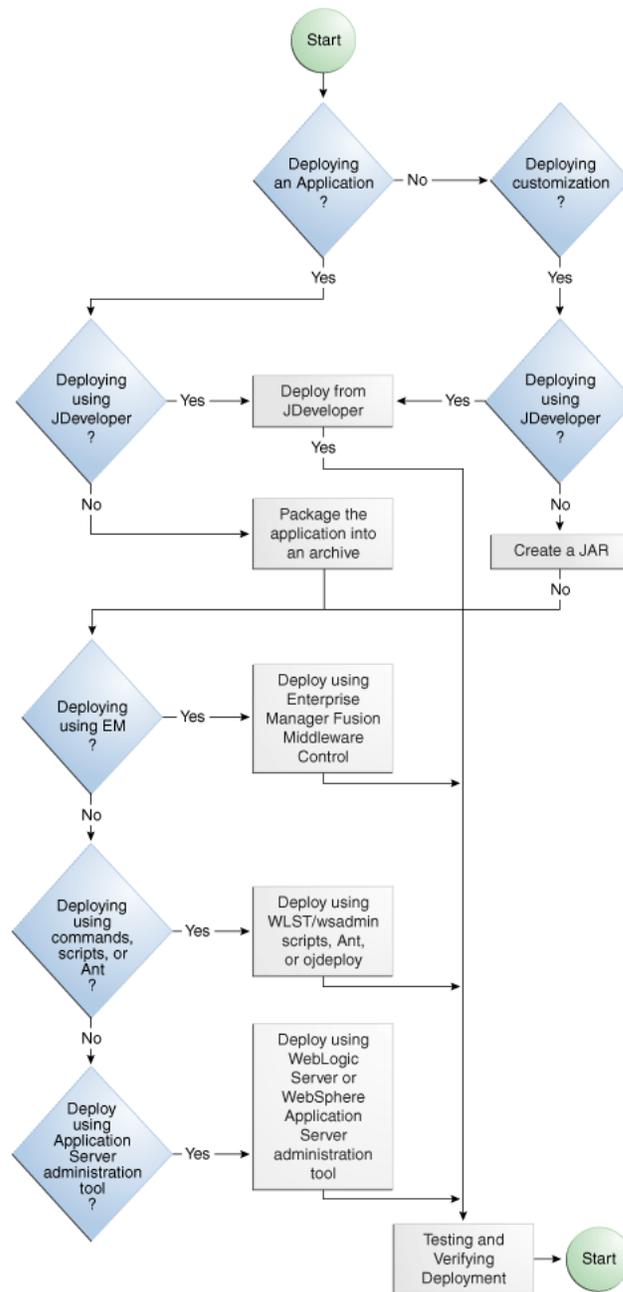

**Figure 41–5 Application Deployment Flow Diagram**

Table 41–2 describes some common deployment techniques that you can use during the application development and deployment cycle. The deployment techniques are listed in order from deploying on development environments to deploying on production environments. It is likely that in the production environment, the system administrators deploy applications by using Enterprise Manager Fusion Middleware Control or scripts.

**Table 41–2 Deployment Techniques for Development or Production Environments**

Deployment Technique	Environment	When to Use
Run directly from JDeveloper	Test or Development	When you are developing your application. You want deployment to be quick because you will be repeating the editing and deploying process many times.  JDeveloper contains Integrated WebLogic Server, on which you can run and test your application.
Use JDeveloper to directly deploy to the target application server	Test or Development	When you are ready to deploy and test your application on an application server in a test environment.  On the test server, you can test features (such as LDAP and Oracle Single Sign-On) that are not available on the development server.  You can also use the test environment to develop your deployment scripts, for example, using Ant.
Use JDeveloper to deploy to an EAR file, then use the target application server's tools for deployment	Test or Development	When you are ready to deploy and test your application on an application server in a test environment. As an alternative to deploying directly from JDeveloper, you can deploy to an EAR file and then use other tools to deploy to the application server.  On the test server, you can test features (such as LDAP and Oracle Single Sign-On) that are not available on the development server.  You can also use the test environment to develop your deployment scripts, for example, using Ant.
Use Enterprise Manager or WLST script to deploy applications	Production	When your application is in a test and production environment. In production environments, system administrators usually use Enterprise Manager or run WLST scripts to deploy applications.

Any necessary MDS repositories must be registered with the application server. If the MDS repository is a database, the repository maps to a data source with MDS-specific requirements.

If you are deploying the application to Oracle WebLogic Server, make sure to target this data source to the WebLogic Administration Server and to all Managed Servers to which you are deploying the application. For more information about registering MDS, see the *Oracle Fusion Middleware Administrator's Guide*.

If you are using the application server's administrative console or scripts to deploy an application packaged as an EAR file that requires MDS repository configuration in `adf-config.xml`, you must run the `getMDSArchiveConfig` command to configure MDS before deploying the EAR file. MDS configuration is required if the EAR file contains a MAR file or if the application is enabled for DT@RT (Design Time At Run Time).

For more information about WLST commands, see the *Oracle Fusion Middleware WebLogic Scripting Tool Command Reference*. For more information about `wsadmin` commands, see the *Oracle Fusion Middleware Third-Party Application Server Guide* and the *Oracle Fusion Middleware Configuration Guide for IBM WebSphere*.

---

---

**Note:** For IBM WebSphere Application Server, after you have deployed the application, you need to perform additional tasks such as starting the server.

For more information about IBM WebSphere Application Server, wsadmin commands, and using the WebSphere Administrative Console, see the *Oracle Fusion Middleware Third-Party Application Server Guide*.

For more information about wsadmin commands specific to Oracle ADF and installing the ADF runtime into the IBM WebSphere Application Server, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

---

---

If you plan to configure ADF connection information, ADF Business Components information, or `adf-config.xml` using ADF MBeans after the application has been deployed, make sure that the application is configured with MDS and have the MBean listeners enabled in the `web.xml` file. For more information, see [Section 41.3.6, "How to Enable the Application for ADF MBeans."](#)

---

---

**Note:** If your ADF application has business services that you want to deploy to WebLogic Server, see [Section 11.2.20, "How to Deploy Web Services to Oracle WebLogic Server."](#)

---

---

### 41.4.1 How to Deploy to the Application Server from JDeveloper

#### **Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.4, "Deploying the Application."](#)

You will need to complete this task:

Create an application-level deployment profile that deploys to an EAR file.

---

---

**Note:** When you are deploying to Oracle WebLogic Server from JDeveloper, ensure that the HTTP Tunneling property is enabled in the Oracle WebLogic Server Administration Console. This property is located under **Servers > ServerName > Protocols**. *ServerName* refers to the name of Oracle WebLogic Server.

---

---

---

---

**Note:** JDeveloper does not support deploying applications to individual Managed Servers that are members of a cluster. You may be able to target one or more Managed Servers within a cluster using the Oracle WebLogic Server Administration Console or other Oracle WebLogic tools; however, the cluster can be negatively affected. For more information about deploying to Oracle WebLogic Server clusters, see the *Oracle Fusion Middleware Administrator's Guide*.

---

---

**To deploy to the target application server from JDeveloper:**

1. In the Application Navigator, right-click the application and choose **Deploy > deployment profile**.
2. In the Deploy wizard, on the Deployment Action page, select **Deploy to Application Server** and click **Next**.
3. On the Select Server page, select the application server connection, and click **Next**.
4. If you are deploying to a WebLogic Server instance, the WebLogic Options page appears. Select a deployment option and click **Next**.

---

---

**Note:** If you are deploying an ADF application, do not use the **Deploy to all instances in the domain** option.

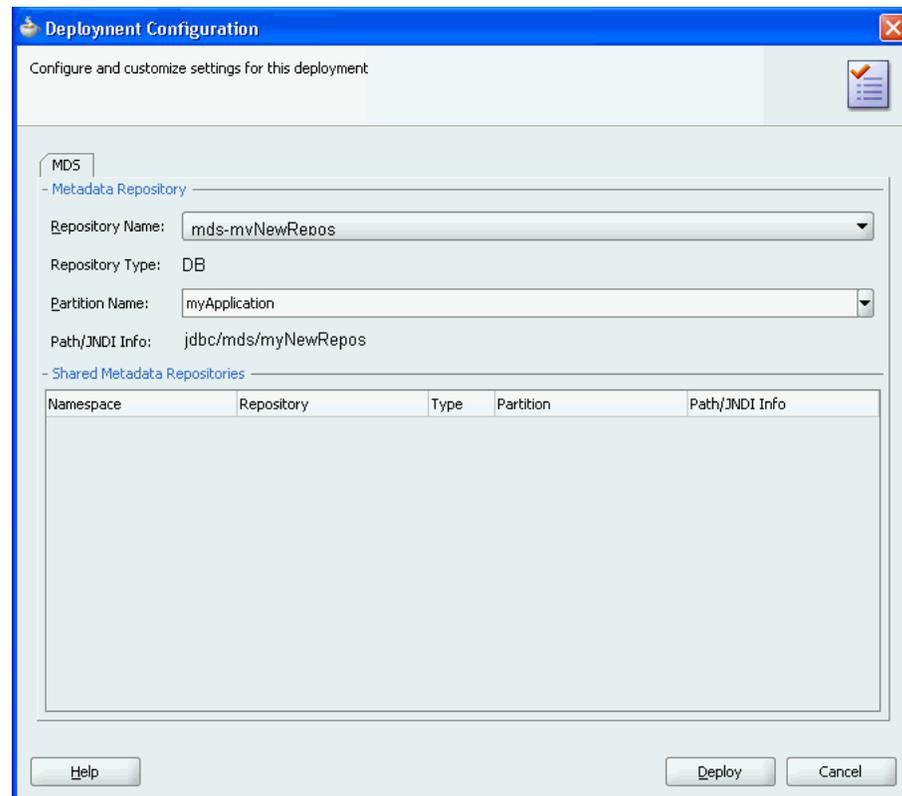

---

---

5. Click **Finish**.

During deployment, you can see the process steps displayed in the deployment Log window. You can inspect the contents of the modules (archives or exploded EAR) being created by clicking on the links that are provided in the log window. The archive or exploded EAR file will open in the appropriate editor or directory window for inspection.

If the `adf-config.xml` file in the EAR file requires MDS repository configuration, the Deployment Configuration dialog appears for you to choose the target metadata repository or shared metadata repositories, as shown in [Figure 41-6](#). The **Repository Name** dropdown list allows you to choose a target metadata repository from a list of metadata repositories registered with the Administration Server. The **Partition Name** dropdown list allows you to choose the metadata repository partition to which the application's metadata will be imported during deployment. You can use WLST/wsadmin commands, the Oracle WebLogic Server Administration Tool, or WebSphere Administrative Tool, respectively, to configure and register MDS. For more information about managing the MDS Repository, see the *Oracle Fusion Middleware Administrator's Guide*.

**Figure 41–6 MDS Configuration and Customization for Deployment**

---

**Note:** If you are deploying a Java EE application, click the application menu next to the Java EE application in the Application Navigator.

---

For more information on creating application server connections, see [Section 41.3.1, "How to Create a Connection to the Target Application Server."](#)

## 41.4.2 How to Create an EAR File for Deployment

You can also use the deployment profile to create an archive file (EAR file). You can then deploy the archive file using Enterprise Manager, WLST/wsadmin scripts, Oracle WebLogic Server Administration Console, or WebSphere Administrative Tool, respectively.

Although an ADF application is encapsulated in an EAR file (which usually includes WAR, MAR, and JAR components), it may have parts that are not deployed with the EAR. For instance, ADF Business Services can be deployed as a JAR. For more information about business services, see [Section 11.2.20, "How to Deploy Web Services to Oracle WebLogic Server."](#)

### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.4, "Deploying the Application."](#)

You will need to complete this task:

Create an application-level deployment profile that deploys to an EAR file.

**To create an EAR archive file:**

- In the Application Navigator, right-click the application containing the deployment profile, and choose **Deploy > deployment profile > to EAR file**.

If an EAR file is deployed at the application level, and it has dependencies on a JAR file in the data model project and dependencies on a WAR file in the user interface project, then the files will be located in the following directories by default:

- *ApplicationDirectory/deploy/EARdeploymentprofile.EAR*
- *ApplicationDirectory/ModelProject/deploy/JARdeploymentprofile.JAR*
- *ApplicationDirectory/ViewControllerProject/deploy/WARdeploymentprofile.WAR*

**Tip:** Choose **View > Log** to see messages generated during creation of the archive file.

### 41.4.3 How to Deploy New Customizations Applied to ADF Library

If you have created new customizations for an ADF Library, you can use the MAR profile to deploy these customizations to any deployed application that consumes that ADF Library. For instance, suppose `applicationA`, which consumes `ADFLibraryB`, is deployed to a standalone application server. Later on, when new customizations are added to `ADFLibraryB`, you only need to deploy the updated customizations into `applicationA`. You do not need to repackage and redeploy the whole application nor do you need to manually patch the MDS repository.

---

---

**Note:** This procedure is for applying ADF Library customizations changes to an application that has already been deployed to a standalone application server. It is not for the initial packaging of customizations into a MAR that will eventually be a part of an EAR. For information about initial packaging of the customization using a MAR, see [Section 41.3.2.2, "Creating a MAR Deployment Profile."](#)

---

---

To deploy ADF Library customizations, create a new MAR profile and only include the customizations to be deployed and then use JDeveloper to:

- Deploy the customizations directly into the MDS repository in the standalone application server.
- Deploy the customizations to a JAR. And then import the JAR into the MDS repository using tools such as the Fusion Middleware Control.

#### 41.4.3.1 Exporting Customization to a Deployed Application

You can export the customizations directly from JDeveloper into the MDS repository for the deployed application on the standalone application server.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.4, "Deploying the Application."](#)

You will need to complete this task:

Create new customizations to the ADF Library.

**To export the customizations directly into the application server:**

1. In the Application Navigator, right-click the application and choose **Deploy > metadata**.
2. In the Deploy metadata dialog on the Deployment Action page, select **Export to a Deployed Application**, and click **Next**.  
If the MAR profile is included in the EAR profile of any application, **Export to a Deployed Application** will be dimmed and disabled.
3. On the Application Server page, select the application server connection and click **Next**.
4. For WebLogic Server, the Server Instance page appears. In this page, select the server instance where the deployed application is located and click **Next**.
5. On the Deployed Application page, select the application you want to apply the customizations to and click **Next**.
6. On the Sandbox Instance page, if you want to deploy to a sandbox, select **Deploy to an associated sandbox**, choose the sandbox instance, and click **Next**.
7. On the Summary page, verify the information and click **Finish**.

**41.4.3.2 Deploying Customizations to a JAR**

When you deploy the ADF Library customizations to a JAR, you are packaging the contents as defined by the MAR profile.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see [Section 41.4, "Deploying the Application."](#)

You will need to complete this task:

Create new customizations to the ADF Library.

**To deploy the customizations as a JAR**

1. In the Application Navigator, right-click the application and choose **Deploy > metadata**.
2. In the Deploy Metadata dialog, on the Deployment Action page, select **Deploy to MAR**.
3. On the Summary page, click **Finish**.
4. Use Enterprise Manager Fusion Middleware Control or the application server's administration tool to import the JAR into the MDS repository.

#### 41.4.4 What You May Need to Know About ADF Libraries

An ADF Library is a JAR file that contains JAR services registered for ADF components such as ADF task flows, pages, or application modules. If you want the ADF components in a project to be reusable, you create an ADF Library deployment profile for the project and then create an ADF Library JAR based on that profile.

An application or project can consume the ADF Library JAR when you add it using the Resource Palette or manually by adding it to the library classpath. When the ADF Library JAR is added to a project, it will be included in the project's WAR file if the **Deployed by Default** option is selected.

For more information, see [Chapter 38, "Reusing Application Components."](#)

#### 41.4.5 What You May Need to Know About EAR Files and Packaging

When you package an ADF application into an EAR file, it can contain the following:

- WAR files: Each web-based view controller project should be packaged into a WAR file.
- MAR file: If the application has customizations that are deployed with the application, it should be packaged into a MAR.
- ADF Library JAR files: If the application consumes ADF Library JARs, these JAR files may be packaged within the EAR.
- Other JAR files: The application may have other dependent JAR files that are required. They can be packaged within the EAR.

#### 41.4.6 How to Deploy the Application Using Scripts and Ant

You can deploy the application using commands and automate the process by putting those commands in scripts. The `ojdeploy` command can be used to deploy an application without JDeveloper. You can also use Ant scripts to deploy the application. JDeveloper has a feature to help you build Ant scripts. Depending on your requirements, you may be able to integrate regular scripts with Ant scripts.

For more information about commands, scripts, and Ant, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

#### 41.4.7 What You May Need to Know About JDeveloper Runtime Libraries

When an application is deployed, it includes some of its required libraries with the application. The application may also require shared libraries that have already been loaded to WebLogic Server as JDeveloper runtime libraries. It may be useful to know which JDeveloper libraries are packaged within which WebLogic Server shared library. For a listing of the contents of the JDeveloper runtime libraries, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

### 41.5 Postdeployment Configuration

After you have deployed your application to WebLogic Server, you can perform configuration tasks.

### 41.5.1 How to Migrate an Application

If you want to migrate an ADF application from one WebLogic Server to another WebLogic Server, you may need to perform some of the same steps you did for a first time deployment.

In general, to migrate an application, you would:

- Load the ADF runtime (if it is not already installed) to the target application server.

For more information, see the "Preparing the Standalone Application Server for Deployment" section of the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

- Configure the target application server with the correct database or URL connection information.
- Migrate security information from the source to the target.

For instructions, see [Section 41.3.4, "How to Deploy Applications with ADF Security Enabled."](#)

- Deploy the application using Enterprise Manager, administration console, or scripts.

For more information, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

### 41.5.2 How to Configure the Application Using ADF MBeans

If ADF MBeans were enabled and packaged with the deployed application, you can configure ADF properties using the Enterprise Manager MBean Browser. For instructions on how to enable an application for MBeans, see [Section 41.3.6, "How to Enable the Application for ADF MBeans."](#)

For information on how to configure ADF applications using ADF MBeans, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

## 41.6 Testing the Application and Verifying Deployment

After you deploy the application, you can test it from the application server. To test-run your ADF application, open a browser window and enter a URL:

- For non-Faces pages: `http://<host>:port/<context root>/<page>`
- For Faces pages: `http://<host>:port/<context root>/faces/<view_id>`

where `<view_id>` is the view ID of the ADF task flow view activity.

**Tip:** The context root for an application is specified in the user interface project settings by default as `ApplicationName/ProjectName/context-root`. You can shorten this name by specifying a name that is unique across the target application server. Right-click the user interface project, and choose **Project Properties**. In the Project Properties dialog, select **Java EE Application** and enter a unique name for the context root.

---

---

**Note:** `/faces` has to be in the URL for Faces pages. This is because JDeveloper configures your `web.xml` file to use the URL pattern of `/faces` in order to be associated with the Faces Servlet. The Faces Servlet does its per-request processing, strips out `/faces` part in the URL, then forwards the URL to the JSP. If you do not include the `/faces` in the URL, then the Faces Servlet is not engaged (since the URL pattern doesn't match). Your JSP is run without the necessary JSF per-request processing.

---

---

# Part VII

---

## Advanced Topics

Part VI contains the following chapters:

- [Chapter 42, "Advanced View Object Techniques"](#)
- [Chapter 43, "Application State Management"](#)
- [Chapter 44, "Tuning Application Module Pools and Connection Pools"](#)
- [Chapter 45, "Using the Active Data Service"](#)

---

---

## Advanced View Object Techniques

This chapter describes advanced techniques you can use while designing and working with your view objects.

This chapter includes the following sections:

- [Section 42.1, "Advanced View Object Concepts and Features"](#)
- [Section 42.2, "Tuning Your View Objects for Best Performance"](#)
- [Section 42.3, "Generating Custom Java Classes for a View Object"](#)
- [Section 42.4, "Working Programmatically with Multiple Named View Criteria"](#)
- [Section 42.5, "Performing In-Memory Sorting and Filtering of Row Sets"](#)
- [Section 42.6, "Using View Objects to Work with Multiple Row Types"](#)
- [Section 42.7, "Reading and Writing XML"](#)
- [Section 42.8, "Using Programmatic View Objects for Alternative Data Sources"](#)
- [Section 42.9, "Creating a View Object with Multiple Updatable Entities"](#)
- [Section 42.10, "Declaratively Preventing Insert, Update, and Delete"](#)

### 42.1 Advanced View Object Concepts and Features

This section describes a number of interesting view object concepts and features that have not been discussed in previous chapters.

---

---

**Note:** To experiment with the examples in this chapter, use the `AdvancedViewObjectsExamples` workspace in the `StandaloneExamples` module of the Fusion Order Demo application, as described in [Section 2.4.5, "Standalone Applications in the AdvancedViewObjectExamples Application Workspace."](#) For information about how to obtain and install the Fusion Order Demo, see [Section 2.2, "Setting Up the Fusion Order Demo Application."](#)

---

---

#### 42.1.1 Limiting the View Object Max Fetch Size to Fetch the First n Rows

The default maximum fetch size of a view object is minus one (-1), which indicates there should be no limit to the number of rows that can be fetched. Keep in mind that by default, rows are fetched as needed, so -1 does not imply a view object will necessarily fetch all the rows. It simply means that if you attempt to iterate through all the rows in the query result, you will get them all.

However, you might want to put an upper bound on the maximum number of rows that a view object will retrieve. You can use the following settings:

- You can configure a global threshold for all view objects queries using the **Row Fetch Limit** property on the Business Components page of the overview editor for the `adf-config.xml` file. You can locate the file in the Application Resources pane by expanding the **Descriptors-ADF META-INF** folder.

**Note:** Since **Row Fetch Limit** specifies a global threshold for all query operations in the application (including iterator binding property **RowCountThreshold** used to determine an estimated row count for the iterator result set), using this property means you can avoid changing settings for individual query operations where that operation's default behavior allows all rows to be fetched. If you do specify a fetch limit for individual view objects, the **Row Fetch Limit** setting will be ignored in those cases.

- You can configure a local threshold for specific view object queries using the **Max Fetch Size** with the **Only up to row number** field selected in the Tuning section of the General page of the overview editor for the view object.

**Tip:** If you want to set the global threshold for query operations using **Row Fetch Limit** and you still need to allow specific view object queries to return all available rows, then you can set the **Max Fetch Size** with the **Only up to row number** field for those view objects to a very large number.

For example, if you write a query containing an `ORDER BY` clause and only want to return the first  $n$  rows to display the "Top-N" entries in a page, you can use the overview editor for the view object to specify a value for the **Only up to row number** field in the Tuning section of the General page. For example, to fetch only the first five rows, you would enter "5" in this field. This is equivalent to calling the `setMaxFetchSize()` method on your view object to set the maximum fetch size to 5. The view object will stop fetching rows when it hits the maximum fetch size. Often you will combine this technique with specifying a **Query Optimizer Hint** of `FIRST_ROWS` also on the Tuning section of the General page of the overview editor. This gives a hint to the database that you want to retrieve the first rows as quickly as possible, rather than trying to optimize the retrieval of all rows.

### 42.1.2 Maintaining New Row Consistency in View Objects Based on the Same Entity

When multiple instances of entity-based view objects in an application module are based on the same underlying entity object, a new row created in one of them can be automatically added (without having to re-query) to the row sets of the others to keep your user interface consistent or simply to consistently reflect new rows in different application pages for a pending transaction. Consider the Fusion Order Demo application's `orderSummary.jspx` page that displays a customer's list of orders. If the customer goes to create a new order, this task is performed through a different view object and handled by a custom application module method. Using this view object new row consistency feature, the newly created order automatically appears in the customer's list of open orders on the `orderSummary.jspx` page without having to re-query the database.

For historical reasons, this capability is known as the *view link consistency* feature because in prior releases of Oracle Application Development Framework (Oracle ADF) the addition of new rows to other relevant row sets only was supported for detail view object instances in a view link based on an association. Now this view link consistency

feature works for any view objects for which it is enabled, regardless of whether they are involved in a view link or not.

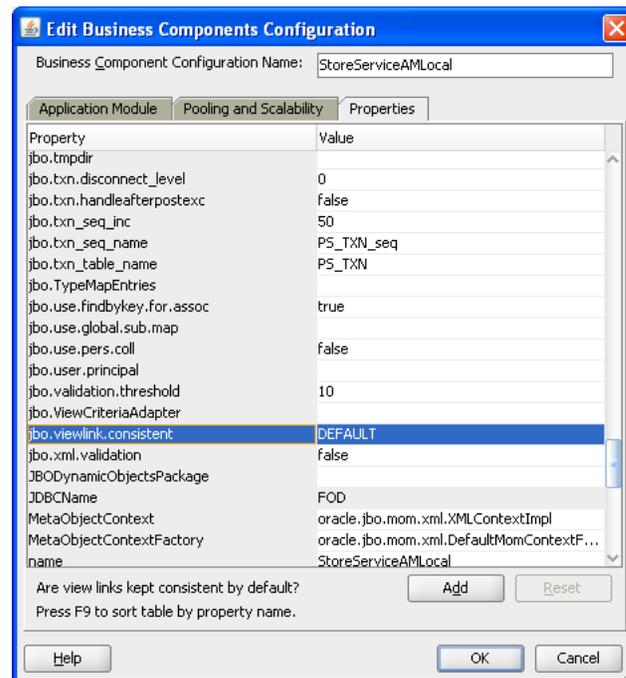

#### 42.1.2.1 What Happens at Runtime When View Link Consistency is Enabled

Consider two entity-based view objects `OrdersViewSummary` and `OrdersView` both based on the same underlying `Orders` entity object. When a new row is created in a row set for one of these view objects (like `OrdersView`) and the row's primary key is set, any of the *other* row sets for view objects based on the same `Orders` entity object (like `OrdersViewSummary`) receive an event indicating a new row has been created. If their view link consistency flag is enabled, then a copy of the new row is inserted into their row set as well.

#### 42.1.2.2 How to Change the Default View Link Consistency Setting

You can use the Edit Business Components Configuration dialog to control the default setting for the view link consistency feature using the `jbo.viewlink.consistent` configuration parameter, as shown in [Figure 42-1](#).

**Figure 42-1** `jbo.viewlink.consistent` Property Setting

To display the configuration editor, right-click the application module in the Application Navigator and choose **Configurations**. Then, in the Manage Configurations dialog, select the configuration and click **Edit**. In the Edit Business Components Configuration dialog, select the Properties tab. The default setting for this parameter is the word "DEFAULT" which has the following meaning. If your view object has:

- A single entity usage, view link consistency is enabled
- Multiple entity usages, and:
  - If all secondary entity usages are marked as contributing reference information, then view link consistency is enabled

- If any secondary entity usage marked as **not** being a reference view link consistency is disabled.

You can globally disable this feature by setting the `jbo.viewlink.consistent` to the value `false` in your configuration. Conversely, you could globally enable this feature by setting `jbo.viewlink.consistent` to the value `true`, but Oracle does **not** recommend doing this. Doing so would force view link consistency to be set on for view objects with secondary entity usages that are not marked as a reference which presently do not support the view link consistency feature well.

To set the feature programmatically, use the `setAssociationConsistent()` API on any `RowSet`. When you call this method on a view object, it affects its default row set.

### 42.1.2.3 How to Use a RowMatch to Qualify Which New, Unposted Rows Get Added to a Row Set

If a view object has view link consistency enabled, any new row created by another view object based on the same entity object is added to its row set. By default the mechanism adds new rows in an unqualified way. If your view object has a design-time `WHERE` clause that queries only a certain subset of rows, you can apply a `RowMatch` object to your view object to perform the same filtering in-memory. The filtering expression of the `RowMatch` object you specify prevents new rows from being added that wouldn't make sense to appear in that view object.

For example, an `OrdersByStatus` view object might include a design time `WHERE` clause like this:

```
WHERE /* ... */ AND STATUS LIKE NVL(:StatusCode, '%')
```

Its custom Java class overrides the `create()` method as shown in [Example 42-1](#) to force view link consistency to be enabled. It also applies a `RowMatch` object whose filtering expression matches rows whose `Status` attribute matches the value of the `:StatusCode` named bind variable (or matches any row if `:StatusCode = '%'`). This `RowMatch` filter is used by the view link consistency mechanism to qualify the row that is a candidate to add to the row set. If the row qualifies by the `RowMatch`, it is added. Otherwise, it is not.

#### **Example 42-1** Providing a Custom RowMatch to Control Which New Rows are Added

```
// In OrdersByStatusImpl.java
protected void create() {
 super.create();
 setAssociationConsistent(true);
 setRowMatch(new RowMatch("Status = :StatusCode or :StatusCode = '%'"));
}
```

See [Section 42.5.4, "Performing In-Memory Filtering with RowMatch"](#) for more information on creating and using a `RowMatch` object. For a list of supported SQL operators see [Table 42-2](#). For a list of supported SQL function, see [Table 42-3](#).

---

**Note:** If the `RowMatch` facility does not provide enough control, you can override the view object's `rowQualifies()` method to implement a custom filtering solution. Your code can determine whether a new row qualifies to be added by the view link consistency mechanism or not.

---

#### 42.1.2.4 What You May Need to Know About the Dynamic WHERE Clause and View Link Consistency

If you call `setWhereClause()` on a view object to set a dynamic WHERE clause, the view link consistency feature is disabled on that view object. If you have provided an appropriate custom `RowMatch` object to qualify new rows for adding to the row set, you can call `setAssociationConsistent(true)` after `setWhereClause()` to reenable view link consistency.

If a row set has view link consistency enabled, then new rows added due to creation by other row sets are added to the bottom of the row set.

If a row set has view link consistency enabled, then when you call the `executeQuery()` method, any qualifying new, unposted rows are added to the top of the row set before the queried rows from the database are added.

### 42.1.3 Understanding View Link Accessors Versus Data Model View Link Instances

View objects support two different styles of master-detail coordination:

- View link *instances* for data model master-detail coordination, as described in [Section 42.1.3.1, "Enabling a Dynamic Detail Row Set with Active Master-Detail Coordination."](#)
- View link *accessor* attributes for programmatically accessing detail row sets on demand, as described in [Section 42.1.3.2, "Accessing a Stable Detail Row Set Using View Link Accessor Attributes."](#)
- You can combine both styles, as described in [Section 42.1.3.3, "Accessor Attributes Create Distinct Row Sets Based on an Internal View Object."](#)

#### 42.1.3.1 Enabling a Dynamic Detail Row Set with Active Master-Detail Coordination

When you add a view link instance to your application module's data model, you connect two specific view object instances. The use of the view link instance indicates that you want active master-detail coordination between the two. At runtime the view link instance in the data model facilitates the eventing that enables this coordination. Whenever the current row is changed on the master view object instance, an event causes the detail view object to be refreshed by automatically invoking `executeQuery()` with a new set of bind parameters for the new current row in the master view object.

A key feature of this data model master-detail is that the master and detail view object instances are stable objects to which client user interfaces can establish bindings. When the current row changes in the master — instead of producing a *new* detail view object instance — the existing detail view object instance updates its default row set to contain the set of rows related to the new current master row. In addition, the user interface binding objects receive events that allow the display to update to show the detail view object's refreshed row set.

Another key feature that is exclusive to data model hierarchy is that a detail view object instance can have multiple master view object instances. For example, an `PaymentOptions` view object instance may be a detail of *both* a `Customers` and a `Orders` view object instance. Whenever the current row in *either* the `Customers` or `Orders` view object instance changes, the default row set of the detail `PaymentOptions` view object instance is refreshed to include the row of payment information for the current customer and the current order. See [Section 42.1.6, "Setting Up a Data Model with Multiple Masters"](#) for details on setting up a detail view object instance with multiple-masters.

### 42.1.3.2 Accessing a Stable Detail Row Set Using View Link Accessor Attributes

When you need to programmatically access the detail row set related to a view object row by virtue of a view link, you can use the view link accessor attribute. You specify the finder name of the view link accessor attribute from the overview editor for the view link. Click the **Edit** icon in the Accessors section of the Relationship page and in the Edit View Link Properties dialog, edit the name of the view link accessor attribute.

[Example 42–2](#) shows the XML for the view link that defines the `_findername` value of the `<Attr>` element.

#### Example 42–2 View Link Accessor Attribute Name

```
<ViewLinkDefEnd
 Name="Orders"
 Cardinality="1"
 Owner="devguide.advanced.multiplemasters.Orders"
 Source="true">
 <AttrArray Name="Attributes">
 <Item Value="devguide.advanced.multiplemasters.Orders.PaymentOptionId"/>
 </AttrArray>
 <DesignTime>
 <Attr Name="_minCardinality" Value="1"/>
 <Attr Name="_isUpdateable" Value="true"/>
 <Attr Name="_finderName" Value="Orders"/>
 </DesignTime>
</ViewLinkDefEnd>
```

Assuming you've named your accessor attribute `AccessorAttrName`, you can access the detail row set using the generic `getAttribute()` API like:

```
RowSet detail = (RowSet)currentRow.getAttribute("AccessorAttrName");
```

If you've generated a custom view row class for the master view object and exposed the getter method for the view link accessor attribute on the client view row interface, you can write strongly-typed code to access the detail row set like this:

```
RowSet detail = (RowSet)currentRow.getAccessorAttrName();
```

Unlike the data model master-detail, programmatic access of view link accessor attributes does not require a detail view object instance in the application module's data model. Each time you invoke the view link accessor attribute, it returns a `RowSet` containing the set of detail rows related to the master row on which you invoke it.

Using the view link accessor attribute, the detail data rows are stable. As long as the attribute value(s) involved in the view link definition in the master row remain unchanged, the detail data rows will not change. Changing of the current row in the master does not affect the detail row set which is "attached" to a given master row. For this reason, in addition to being useful for general programmatic access of detail rows, view link accessor attributes are appropriate for UI objects like the tree control, where data for each master node in a tree needs to retain its distinct set of detail rows.

### 42.1.3.3 Accessor Attributes Create Distinct Row Sets Based on an Internal View Object

When you *combine* the use of data model master-detail with programmatic access of detail row sets using view link accessor, it is even more important to understand that they are distinct mechanisms. For example, imagine that you:

- Define `PersonsVO` and `OrdersVO` view objects

- Define a view link between them, naming the view link accessor `PersonsToOrders`
- Add instances of them to an application module's data model named `master` (of type `PersonsVO`) and `detail` (of type `OrdersVO`) coordinated actively by a view link instance.

If you find a person in the `master` view object instance, the `detail` view object instance updates as expected to show the corresponding orders. At this point, if you invoke a custom method that programmatically accesses the `PersonsToOrders` view link accessor attribute of the current `PersonsVO` row, you get a `RowSet` containing the set of `OrdersVO` rows. You might reasonably expect this programmatically accessed `RowSet` to have come from the `detail` view object instance in the data model, but this is not the case.

The `RowSet` returned by a view link accessor always originates from an *internally created* view object instance, not one you that added to the data model. This internal view object instance is created as needed and added with a system-defined name to the root application module.

The principal reason a distinct, internally-created view object instance is used is to guarantee that it remains unaffected by developer-related changes to their own view objects instances in the data model. For example, if the view row were to use the `detail` view object in the data model for view link accessor `RowSet`, the resulting row set could be inadvertently affected when the developer dynamically:

1. Adds a `WHERE` clause with new named bind parameters

If such a view object instance were used for the view link accessor result, unexpected results or an error could ensue because the dynamically-added `WHERE` clause bind parameter values have not been supplied for the view link accessor's `RowSet`: they were only supplied for the default row set of the `detail` view object instance in the data model.

2. Adds an additional master view object instance for the `detail` view object instance in the data model.

In this scenario, the semantics of the accessor would be changed. Instead of the accessor returning `OrdersVO` rows for the current `PersonsVO` row, it could all of a sudden start returning *only* the `OrdersVO` rows for the current `PersonsVO` that were created by a current logged in customer, for example.

3. Removes the `detail` view object instance or its containing application module instance.

In this scenario, all rows in the programmatically-accessed `detail RowSet` would become invalid.

Furthermore, Oracle ADF needs to distinguish between the data model master-detail and view link accessor row sets for certain operations. For example, when you create a new row in a `detail` view object, the framework automatically populates the attributes involved in the view link with corresponding values of the master. In the data model master-detail case, it gets these values from the current row(s) of the possibly multiple master view object instances in the data model. In the case of creating a new row in a `RowSet` returned by a view link accessor, it populates these values from the master row on which the accessor was called.

#### 42.1.4 Presenting and Scrolling Data a Page at a Time Using the Range

To present and scroll through data a page at a time, you can configure a view object to manage for you an appropriately-sized range of rows. The range facility allows a client

to easily display and update a subset of the rows in a row set, as well as easily scroll to subsequent pages, *n* rows at a time. You call `setRangeSize()` to define how many rows of data should appear on each page. The default range size is one (1) row. A range size of minus one (-1) indicates the range should include all rows in the row set.

---

---

**Note:** When using the ADF Model layer's declarative data binding, the iterator binding in the page definition has a `RangeSize` attribute. At runtime, the iterator binding invokes the `setRangeSize()` method on its corresponding row set iterator, passing the value of this `RangeSize` attribute. The ADF design time by default sets this `RangeSize` attribute to 10 rows for most iterator bindings. An exception is the range size specified for a List binding to supply the set of valid values for a UI component like a dropdown list. In this case, the default range size is minus one (-1) to allow the range to include all rows in the row set.

---

---

When you set a range size greater than one, you control the row set paging behavior using the iterator mode. The two iterator mode flags you can pass to the `setIterMode()` method are:

- `RowIterator.ITER_MODE_LAST_PAGE_PARTIAL`

In this mode, the last page of rows may contain fewer rows than the range size. For example, if you set the range size to 10 and your row set contains 23 rows, the third page of rows will contain only three rows. This is the style that works best for Fusion web applications.

- `RowIterator.ITER_MODE_LAST_PAGE_FULL`

In this mode, the last page of rows is kept full, possibly including rows at the top of the page that had appeared at the bottom of the previous page. For example, if you set the range size to 10 and your row set contains 23 rows, the third page of rows will contain 10 rows, the first seven of which appeared as the last seven rows of page two. This is the style that works best for desktop-fidelity applications using Swing.

### 42.1.5 Efficiently Scrolling Through Large Result Sets Using Range Paging

As a general rule, for highest performance, Oracle recommends building your application in a way that avoids giving the end user the opportunity to scroll through very large query results. To enforce this recommendation, call the `getEstimatedRowCount()` method on a view object to determine how many rows would be returned by the user's query *before* actually executing the query and allowing the user to proceed. If the estimated row count is unreasonably large, your application can demand that the end-user provide additional search criteria.

However, when you *must* work with very large result sets, typically over 100 rows, you can use the view object's access mode called "range paging" to improve performance. The feature allows your applications to page back and forth through data, a range of rows at a time, in a way that is more efficient for large data sets than the default "scrollable" access mode.

The range paging access mode is typically used for paging through read-only row sets, and often is used with read-only view objects. You allow the user to find the row they are looking for by paging through a large row set with range paging access mode, then you use the `Key` of that row to find the selected row in a different view object for editing.

Range paging for view objects supports a standard access mode and a variation of the standard access mode that combines the benefits of range paging and result set scrolling with a minimum number of visits to the database. These modes for the view object range paging feature include:

- `RANGE_PAGING`, standard access mode fetches the number of rows specified by a range size. In this mode, the number of rows that may be scrolled without requerying the database is determined by a range size that you set. The default is to fetch a single row, but it is expected that you will set a range size equal to the number of rows you want to be able to display to the user before they scroll to the next result set. The application requeries the database each time a row outside of the range is accessed by the end user. Thus, scrolling backward and forward through the row set will requery the database. For clarification about this database-centric paging strategy, see [Section 42.1.5.1, "Understanding How to Oracle Supports "TOP-N" Queries."](#)
- `RANGE_PAGING_INCR`, incremental access mode gives the UI designer more flexibility for the number of rows to display at a time while keeping database queries to a minimum. In this mode, the UI incrementally displays the result set from the memory cache and thus supports scrolling within a single database query. The number of rows that the end user can scroll through in a single query is determined by the range size and a range paging cache factor that you set. For example, suppose that you set the range size to 4 and the cache factor to 5. Then, the maximum number of rows to cache in memory will be  $4 \times 5 = 20$ . For further explanation of the caching behavior, see [Section 42.1.5.4, "What Happens When View Rows are Cached When Using Range Paging."](#)

---

**Caution:** Additionally, the view object supports a `RANGE_PAGING_AUTO_POST` access mode to accommodate the inserting and deleting of rows from the row set. This mode behaves like the `RANGE_PAGING` mode, except that it eagerly calls `postChanges()` on the database transaction whenever any changes are made to the row set. However, this mode is typically not appropriate for use in Fusion web applications unless you can guarantee that the transaction will definitely be committed or rolled-back during the same HTTP request. Failure to heed this advice can lead to strange results in an environment where both application modules and database connections can be pooled and shared serially by multiple different clients.

---

### 42.1.5.1 Understanding How to Oracle Supports "TOP-N" Queries

The Oracle database supports a feature called a "Top-N" query to efficiently return the first  $n$  ordered rows in a query. For example, if you have a query like:

```
SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
```

If you want to retrieve the top 5 employees by salary, you can write a query like:

```
SELECT * FROM (
 SELECT X.*, ROWNUM AS RN FROM (
 SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
) X
) WHERE RN <= 5
```

which gives you results like:

```
EMPNO ENAME SAL RN
```

```

7839 KING 5000 1
7788 SCOTT 3000 2
7902 FORD 3000 3
7566 JONES 2975 4
7698 BLAKE 2850 5

```

The feature is not only limited to retrieving the first  $n$  rows in order. By adjusting the criteria in the outermost `WHERE` clause you can efficiently retrieve any range of rows in the query's sorted order. For example, to retrieve rows 6 through 10 you could alter the query this way:

```

SELECT * FROM (
 SELECT X.*,ROWNUM AS RN FROM (
 SELECT EMPNO,ENAME,SAL FROM EMP ORDER BY SAL DESC
) X
) WHERE RN BETWEEN 6 AND 10

```

Generalizing this idea, if you want to see page number  $P$  of the query results, where each page contains  $R$  rows, then you would write a query like:

```

SELECT * FROM (
 SELECT X.*,ROWNUM AS RN FROM (
 SELECT EMPNO,ENAME,SAL FROM EMP ORDER BY SAL DESC
) X
) WHERE RN BETWEEN ((:P - 1) * :R) + 1 AND (:P) * :R

```

As the result set you consider grows larger and larger, it becomes more and more efficient to use this technique to page through the rows. Rather than retrieving hundreds or thousands of rows over the network from the database, only to display ten of them on the page, instead you can produce a clever query to retrieve only the  $R$  rows on page number  $P$  from the database. No more than a handful of rows at a time needs to be returned over the network when you adopt this strategy.

To implement this database-centric paging strategy in your application, you could handcraft the clever query yourself and write code to manage the appropriate values of the `:R` and `:P` bind variables. Alternatively, you can use the view object's range paging access mode, which implements it automatically for you.

#### 42.1.5.2 How to Enable Range Paging for a View Object

You can use the Tuning panel of the overview editor for the view object to set the access mode to either standard range paging or incremental range paging. The **Range Paging Cache Factor** field is only editable when you select **Range Paging Incremental**. [Figure 42–2](#) shows the view object's **Access Mode** set to **Range Paging** (standard mode) with the default range size of 1. To understand the row set caching behavior of both access modes, see [Section 42.1.5.4, "What Happens When View Rows are Cached When Using Range Paging."](#)

Business Components Project: [StoreFrontService](#)

**Tuning**

Enter tuning parameters for this View, to control SQL execution and how data is fetched from the database.

**Retrieve from the Database**

All Rows  Only up to row number

in Batches of:

As Needed  All at Once

At Most One Row

No Rows (i.e. used only for inserting new rows)

Query Optimizer Hint:

e.g FIRST\_ROWS, ALL\_ROWS, etc.

Fill Last Page of Rows when Paging through Rowset

Passivate State (e.g. Current Row, Bind Values, etc.)

Including All Transient Values

Retain View Link Accessor Rowset

Access Mode:

Range Size:

Range Paging Cache Factor:

To programmatically enable standard range paging for your view object, first call `setRangeSize()` to define the number of rows per page, then call the following method with the desired mode:

```
yourViewObject.setAccessMode(RowSet.RANGE_PAGING | RANGE_PAGING_INCR);
```

If you set `RANGE_PAGING_INCR`, then you must also call the following method to set the cache factor for your defined range size:

```
yourViewObject.setRangePagingCacheFactor(int f);
```

### 42.1.5.3 What Happens When You Enable Range Paging

When a view object's access mode is set to `RANGE_PAGING`, the view object takes its default query like:

```
SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
```

and automatically "wraps" it to produce a Top-N query.

For best performance, the statement uses a combination of greater than and less than conditions instead of the `BETWEEN` operator, but the logical outcome is the same as the Top-N wrapping query you saw above. The actual query produced to wrap a base query of:

```
SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
```

looks like this:

```
SELECT * FROM (
 SELECT /*+ FIRST_ROWS */ IQ.*, ROWNUM AS Z_R_N FROM (
 SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
) IQ WHERE ROWNUM < :0)
WHERE Z_R_N > :1
```

The two bind variables are bound as follows:

- :1 index of the first row in the current page
- :0 is bound to the last row in the current page

#### 42.1.5.4 What Happens When View Rows are Cached When Using Range Paging

When a view object operates in `RANGE_PAGING` access mode, it only keeps the current range (or "page") of rows in memory in the view row cache at a time. That is, if you are paging through results ten at a time, then on the first page, you'll have rows 1 through 10 in the view row cache. When you navigate to page two, you'll have rows 11 through 20 in the cache. This also can help make sure for large row sets that you don't end up with tons of rows cached just because you want to preserve the ability to scroll backwards and forwards.

When a view object operates in `RANGE_PAGING_INCR` access mode, the cache factor determines the number of rows to cache in memory for a specific range size. For example, suppose the range size is set to 4 and cache factor to 5. Then, the memory will keep at most  $4 \times 5 = 20$  rows in its collection. In this example, when the range is refreshed for the first time, the memory will have just four rows even though the range paging query is bound to retrieve rows 0 to 19 (for a total of twenty rows). When the range is scrolled past the fourth row, more rows will be read in from the current result set. This will continue until all twenty rows from the query result are read. If the user's action causes the next set of rows to be retrieve, the query will be re-executed with the new row number bind values. The exact row number bind values are determined by the new range-start and the number of rows that can be retained from the cache. For example, suppose all twenty rows have been filled up and the user asks to move the range-start to 18 (0-based). This means that memory can retain row 18 and row 19 and will need two more rows to fill the range. The query is re-executed for rows 20 and 21.

#### 42.1.5.5 How to Scroll to a Given Page Number Using Range Paging

When a view object operates in `RANGE_PAGING` access mode, to scroll to page number *n* call its `scrollToRangePage()` method, passing *n* as the parameter value.

#### 42.1.5.6 Estimating the Number of Pages in the Row Set Using Range Paging

When a view object operates in `RANGE_PAGING` access mode, you can access an estimate of the total number of pages the entire query result would produce using the `getEstimatedRangePageCount()` method.

#### 42.1.5.7 Understanding the Tradeoffs of Using a Range Paging Mode

You might ask yourself, "Why wouldn't I *always* want to use `RANGE_PAGING` or `RANGE_PAGING_INCR` mode?" The answer is that using range paging potentially causes more overall queries to be executed as you are navigating forward and backward through your view object rows. You would want to avoid using `RANGE_PAGING` mode in these situations:

- You plan to read all the rows in the row set immediately (for example, to populate a dropdown list).

In this case your range size would be set to -1 and there really is only a single "page" of all rows, so range paging does not add value.

- You need to page back and forth through a small-sized row set.

If you have 100 rows or fewer, and are paging through them 10 at a time, with `RANGE_PAGING` mode you will execute a query each time you go forward and backward to a new page. Otherwise, in the default scrollable mode, you will cache the view object rows as you read them in, and paging backwards through the previous pages will not re-execute queries to show those already-seen rows. Alternatively, you can use `RANGE_PAGING_INCR` mode to allow scrolling through in-memory results based on a row set cache factor that you determine.

In the case of a very large (or unpredictably large) row set, the trade off of potentially doing a few more queries — each of which only returns up to the `RangeSize` number of rows from the database — is more efficient than trying to cache all of the previously-viewed rows. This is especially true if you allow the user to jump to an arbitrary page in the list of results. Doing so in default, scrollable mode requires fetching and caching all of the rows between the current page and the page the users jumps to. In `RANGE_PAGING` mode, it will ask the database just for the rows on that page. Then, if the user jumps back to a page of rows that they have already visited, in `RANGE_PAGING` mode, those rows get re-queried again since only the current page of rows is held in memory in this mode. The incremental range paging access mode `RANGE_PAGING_INCR` combines aspects of both standard range paging and scrollable access mode since it allows the application to cache more rows in memory and permits the user to jump to any combination of those rows without needing to requery.

### 42.1.6 Setting Up a Data Model with Multiple Masters

When useful, you can set up your data model to have multiple master view object instances for the same detail view object instance. Consider view objects named `Customers`, `Orders`, and `PaymentOptions` with view links defined between:

- `Customers` and `PaymentOptions`
- `Orders` and `PaymentOptions`

---

---

**Note:** The examples in this section are not based on the Fusion Order Demo application. They currently refer to the `MultipleMasters` project in the `AdvancedViewObjectExamples` workspace, available as noted at the beginning of this chapter for download.

---

---

[Figure 42-3](#) shows what the data model panel looks like when you've configured both `Customers` and `Orders` view object instances to be masters of the same `PaymentOptions` view object instance.

**Figure 42–3 Multiple Master View Object Instances for the Same Detail**

To set up the data model as shown in [Figure 42–3](#) open the overview editor for the application module and follow these steps in the Data Model Components section of the Data Model page:

1. Add an instance of the `Customers` view object to the data model.  
Assume you name it `Customers`.
2. Add an instance of the `Orders` view object to the data model  
Assume you name it `Orders`.
3. Select the `Customers` view object instance in the **Data Model** list
4. In the **Available View Objects** list, select the `PaymentOptions` view object indented beneath the `Customers` view object and enter the view object instance name of `PaymentOptions` in the **New Instance Name** field. Click **>** to shuttle it into data model as a detail of the existing `Customers` view object instance.
5. Select the `Orders` view object instance in the **Data Model** list
6. In the **Available View Objects** list, select the `PaymentOptions` view object indented beneath the `Orders` view object and enter the view object instance name of `PaymentOptions` in the **New Instance Name** field. Click **>** to shuttle it into data model as a detail of the existing `Orders` view object instance.  
  
An alert will appear: **An instance of a View Object with the name `PaymentOptions` has already been used in the data model. Would you like to use the same instance?**
7. Click **Yes** to confirm you want the `PaymentOptions` view object instance to *also* be the detail of the `Orders` view object instance.

### 42.1.7 Understanding When You Can Use Partial Keys with `findByKey()`

View objects based on multiple entity usages support the ability to find view rows by specifying a partially populated key. A partial key is a multi-attribute `Key` object with some of its attributes set to `null`. However, there are strict rules about what kinds of partial keys can be used to perform the `findByKey()`.

If a view object is based on  $n$  entity usages, where  $n > 1$ , then the view row key is by default comprised of all of the primary key attributes from *all* of the participating entity usages. Only the ones from the *first* entity object are *required* to participate in the view row key, but by default all of them do.

If you allow the key attributes from some *secondary* entity usages to remain as key attributes at the view row level, then you should leave *all* of the attributes that form

the primary key for that entity object as part of the view row key. Assuming you have left the one or more key attributes in the view row for  $m$  of the  $n$  entity usages, where ( $m \leq n$ ), then you can use `findByKey()` to find rows based on any subset of these  $m$  entity usages. Each entity usage for which you provide values in the `Key` object, requires that you must provide non-null values for *all* of the attributes in that entity's primary key.

You have to follow this rule because when a view object is based on at least one or more entity usages, its `findByKey()` method finds rows by delegating to the `findByPrimaryKey()` method on the entity definition corresponding to the first entity usage whose attributes in the view row key are non-null. The entity definition's `findByPrimaryKey()` method requires all key attributes for any given entity object to be non-null in order to find the entity row in the cache.

As a concrete example, imagine that you have a `OrderInfoVO` view object with a `OrderEO` entity object as its primary entity usage, and an `AddressEO` entity as secondary reference entity usage. Furthermore, assume that you leave the **Key Attribute** property of *both* of the following view row attributes set to `true`:

- `OrderId` — primary key for the `OrderEO` entity
- `AddressId` — primary key for the `AddressEO` entity

The view row key will therefore be the (`OrderId`, `AddressId`) combination. When you do a `findByKey()`, you can provide a `Key` object that provides:

- A completely specified key for the underlying `OrderEO` entity
 

```
Key k = new Key(new Object[]{new Number(200), null});
```
- A completely specified key for the underlying `AddressEO` entity
 

```
Key k = new Key(new Object[]{null, new Number(118)});
```
- A completely specified key for both entities
 

```
Key k = new Key(new Object[]{new Number(200), new Number(118)});
```

When a valid partial key is specified, the `findByKey()` method can return multiple rows as a result, treating the missing entity usage attributes in the `Key` object as a wildcard.

## 42.1.8 Handling View Object Queries with Primary Keys Defined by Transient Attributes

If your programmatic view object query relies on transient attributes for its primary key, it is possible for the user to receive a null pointer exception when they scroll the UI out of the view object's cached rows. In this case, since the view object query is not generated from a database table, your view object implementation must override the `ViewObjectImpl` classes' `retrieveByKey()` method to return the rows (or return an empty array when no rows are found).

Overriding this method will allow ADF Business Components to execute `findByKey()` to first find the requested rows from the cache. When that fails (because the primary key is a transient attribute), ADF Business Components will execute your `retrieveByKey()` override to perform the operations you defined to retrieve the rows that match the key coming in. The default implementation of this method tries to issue a database query to get the row(s) from the database:

```
protected Row[] retrieveByKey(ViewRowSetImpl rs, Key key, int maxNumOfRows,
boolean skipWhere)
```

The method has these arguments:

`maxNumOfRows` is the `maxNumOfRows` you passed into the call to `findByKey()`. It may be `1 .. n` or `-1`. `n` means that it's looking for `n` many rows whose key matches the one that got passed in. `-1` means match all rows. Note that it is possible for the view object to have more than one row that matches the key when the key is a partial key and the view object is based on multiple entity objects.

`skipWhere` controls whether `findByKey()` should apply the same `WHERE` clause as the base view object. If the base view object has a `WHERE` clause `DEPTNO = 10`, if `skipWhere` is `false`, you're supposed to apply the same `WHERE` clause when looking for the row(s) from the backing store. If `skipWhere` is `true`, then don't bother with the `WHERE` clause from the base view object.

### 42.1.9 Creating Dynamic Attributes to Store UI State

You can add one or more dynamic attributes to a view object at runtime using the `addDynamicAttribute()` method. Dynamic attributes can hold any serializable object as their value. Typically, you will consider using dynamic attributes when writing generic framework extension code that requires storing some additional per-row transient state to implement a feature you want to add to the framework in a global, generic way.

### 42.1.10 Working with Multiple Row Sets and Row Set Iterators

While you typically work with a view object's *default* row set, you can call the `createRowSet()` method on the `ViewObject` interface to create secondary, named row sets based on the same view object's query. One situation where this could make sense is when your view object's SQL query contains named bind variables. Since each `RowSet` object stores its own copy of bind variable values, you could use a single view object to produce and process multiple row sets based on different combinations of bind variable values. You can find a named row set you've created using the `findRowSet()` method. When you're done using a secondary row set, call its `closeRowSet()` method.

For any `RowSet`, while you typically work with its *default* row set iterator, you can call the `createRowSetIterator()` method of the `RowSet` interface to create secondary, named row set iterators. You can find a named row set iterator you've created using the `findRowSetIterator()` method. When you're done using a secondary row set iterator, call its `closeRowSetIterator()` method.

**Performance Tip:** When you need to perform programmatic iteration over a result set, create a secondary iterator to avoid disturbing the current row of the *default* row set iterator. For example, through the ADF Model declarative data binding layer, user interface pages in your application work with the default row set iterator of the default row set of view objects in the application module's data model. In this scenario, if you did not create a secondary row set iterator for the business logic you write to iterate over a view object's default row set, you would consequently change the current row of the *default* row set iterator used by the user interface layer.

### 42.1.11 Optimizing View Link Accessor Access By Retaining the Row Set

Each time you retrieve a view link accessor row set, by default the view object creates a new `RowSet` object to allow you to work with the rows. This does *not* imply *re-executing* the query to produce the results each time, only creating a new instance of

a `RowSet` object with its default iterator reset to the "slot" before the first row. To force the row set to refresh its rows from the database, you can call its `executeQuery()` method.

You can enable caching of the view link accessor row set when you do not want the application to incur the small amount of overhead associated with creating new detail row sets. For example, because view accessor row sets remain stable as long as the master row view accessor attribute remains unchanged, it would not be necessary to recreate a new row set for UI components, like the tree control, where data for each master node in a tree needs to retain its distinct set of detail rows. The view link accessor's detail row set can also be accessed programmatically. In this case, if your application makes numerous calls to the same view link accessor attributes, you can consider caching the view link accessor row set. This style of managing master-detail coordination differs from creating view link instances in the data model, as explained in [Section 42.1.3, "Understanding View Link Accessors Versus Data Model View Link Instances."](#)

You can enable retention of the view link accessor row set using the overview editor for the view object that is the source for the view link accessor. Select **Retain View Link Accessor Row Set** in the Tuning section of the General page of the overview editor for the view object.

Alternatively, you can enable a custom Java class for your view object, override the `create()` method, and add a line after `super.create()` that calls the `setViewLinkAccessorRetained()` method passing `true` as the parameter. It affects all view link accessor attributes for that view object.

When this feature is enabled for a view object, since the view link accessor row set is not recreated each time, the current row of its default row set iterator is also retained as a side-effect. This means that your code will need to explicitly call the `reset()` method on the row set you retrieve from the view link accessor to reset the current row in its default row set iterator back to the "slot" before the first row.

Note, however, that with accessor retention enabled, your failure to call `reset()` each time before you iterate through the rows in the accessor row set can result in a subtle, hard-to-detect error in your application. For example, if you iterate over the rows in a view link accessor row set like this, for example to calculate some aggregate total:

```
RowSet rs = (RowSet)row.getAttribute("OrdersShippedToPurchaser");
while (rs.hasNext()) {
 Row r = rs.next();
 // Do something important with attributes in each row
}
```

The first time you work with the accessor row set the code will work. However, since the row set (and its default row set iterator) are retained, the second and subsequent times you access the row set the current row will already be at the end of the row set and the while loop will be skipped since `rs.hasNext()` will be `false`. Instead, with this feature enabled, write your accessor iteration code like this:

```
RowSet rs = (RowSet)row.getAttribute("OrdersShippedToPurchaser");
rs.reset(); // Reset default row set iterator to slot before first row!
while (rs.hasNext()) {
 Row r = rs.next();
 // Do something important with attributes in each row
}
```

Recall that if view link consistency is on, when the accessor is retained the new unposted rows will show up at the end of the row set. This is slightly different from when the accessor is not retained (the default), where new unposted rows will appear at the beginning of the accessor row set.

## 42.2 Tuning Your View Objects for Best Performance

You can use view objects to read rows of data, create and store rows of transient data, as well as automatically coordinate inserts, updates, and deletes made by end users with your underlying business objects. How you design and use your view objects can definitely affect their performance at runtime. This section provides guidance on configuring your view objects to get the best possible performance.

### 42.2.1 Use Bind Variables for Parameterized Queries

Whenever the `WHERE` clause of your query includes values that might change from execution to execution, you should use named bind variables. The Create View Criteria dialog that you display from the Query page of the view object overview editor makes this an easy task. Their use also protects your application against abuse through SQL injection attacks by malicious end-users. For information about defining view criteria with bind variables, see [Section 5.11.1, "How to Create Named View Criteria Declaratively."](#)

#### 42.2.1.1 Use Bind Variables to Avoid Re-parsing of Queries

Bind variables are place holders in the SQL string whose value you can easily change at runtime without altering the text of the SQL string itself. Since the query text doesn't change from execution to execution, the database can efficiently reuse the same parsed statement each time. Avoiding re-parsing of your statement alleviates the database from having to continually re-determine its query optimization plan and eliminates contention by multiple end-users on other costly database resources used during this parsing operation. This savings leads to higher runtime performance of your application. See [Section 5.10.1, "How to Add Bind Variables to a View Object Definition"](#) for details on how to use named bind variables.

#### 42.2.1.2 Use Bind Variables to Prevent SQL-Injection Attacks

Using bind variables for parameterized `WHERE` clause values is especially important if their values will be supplied by *end-users* of your application. Consider the example shown in [Example 42-3](#). It adds a dynamic `WHERE` clause formed by concatenating a user-supplied parameter value into the statement.

#### **Example 42-3 Using String Concatenation Instead of Bind Variables is Vulnerable to SQL-Injection Attacks**

```
// EXAMPLE OF BAD PRACTICE, Do not follow this approach!
String userSuppliedValue = ... ;
yourViewObject.setWhereClause("BANK_ACCOUNT_ID = "+userSuppliedValue);
```

A user with malicious intentions — if able to learn any details about your application's underlying database schema — could supply a carefully-constructed "bank account number" as a field value or URL parameter like:

```
BANK_ACCOUNT_ID
```

When the code in [Example 42-3](#) concatenates this value into the dynamically-applied where clause, what the database sees is a query predicate like this:

```
WHERE (BANK_ACCOUNT_ID = BANK_ACCOUNT_ID)
```

This `WHERE` clause retrieves *all* bank accounts instead of just the current user's, perhaps allowing the hacker to view private information of another person's account. This technique of short-circuiting an application's `WHERE` clause by trying to supply a maliciously-constructed parameter value into a SQL statement is called a SQL injection

attack. Using named bind variables instead for these situations as shown in [Example 42-4](#) prevents the vulnerability.

**Example 42-4 Use Named Bind Variables Instead of String Concatenation**

```
// Best practice using named bind variables
String userSuppliedValue = ... ;
yourViewObject.setWhereClause("BANK_ACCOUNT_ID = :BankAccountId");
yourViewObject.defineNamedWhereClauseParam("BankAccountId", null, null);
yourViewObject.setNamedWhereClauseParam("BankAccountId", userSuppliedValue);
```

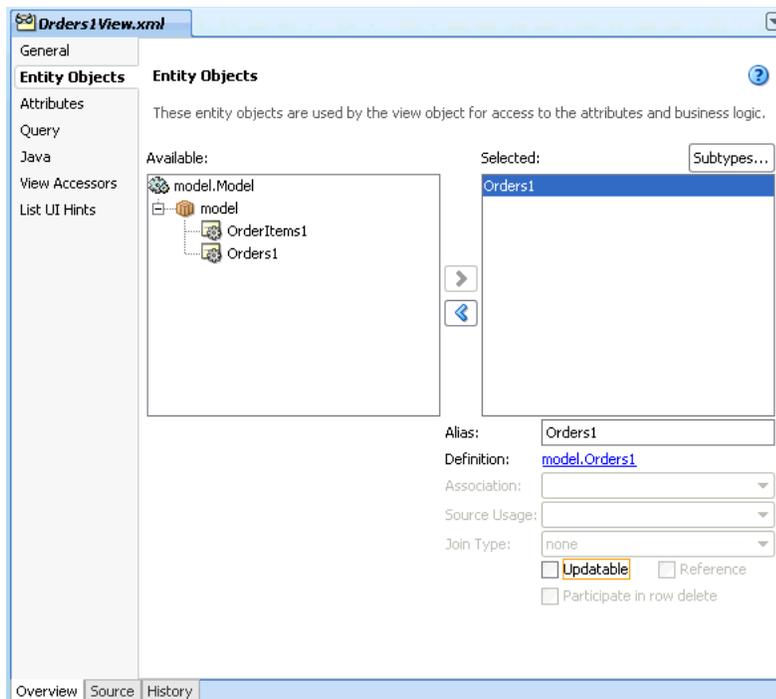

If a malicious user supplies an illegal value in this case, they receive an error your application can handle instead of obtaining data they are not suppose to see.

## 42.2.2 Consider Using Entity-Based View Objects for Read-Only Data

Typically view objects used for SQL-based validation purposes, as well as for displaying the list of valid selections in a dropdown list, can be read-only. You need to decide what kind of functionality your application requires and design the view object accordingly.

**Best Practice:** When you need to create a read-only view object for data lookup, you should use the entity-based view object and deselect the **Updatable** option in the Entity Objects page of the view object overview editor. The approach benefits from the design time editors which aid in generating the SQL query. The alternative of creating an expert-mode view object requires writing a SQL query. Expert mode queries are still useful for cases where Unions and Group By queries cannot be expressed using entity objects.

View objects can either be related to underlying entity objects or not. When a view object is related to one or more underlying entity objects the default behavior supports creating new rows and modifying or removing queried rows. However, the update feature can be disabled by deselecting **Updatable** in the overview editor for the entity-based view object, as shown in [Figure 42-4](#).

**Figure 42–4 Deselecting the Updatable Option for an Entity-based View Object**

The alternative is to create a read-only view object and define the SQL query using **Expert Mode** in the Edit Query dialog. For the Business Components developer not comfortable with constructing a complex SQL statement, it will always be more convenient to create a non-updatable view object based on an entity object since the editor simplifies the task of creating the query. Entity-based view objects that you set to non-updatable compare favorably to read-only, expert mode-based view objects:

- There is the ability to optimize the select list at runtime to include only those attributes that are required by the user interface
- There is no significant performance degradation incurred by using the entity object to create the local cache
- The data in the view object will reflect the state of the local cache rather than need to return to the database for each read operation
- The data in the local cache will stay consistent should another view object you define need to perform an update on the non-updatable view object's base entity object.

So, while there is a small amount of runtime overhead associated with the coordination between view object rows and entity object rows (estimates show less than 5% overhead), weigh this against the ability to keep the view object definition entirely declarative and maintain a customizable view object. Expert mode-based view objects are not customizable but they can be used to perform Unions and Group By queries that cannot be expressed in entity objects. Expert mode-based view objects are also useful in SQL-based validation queries used by the view object-based Key Exists validator.

When data is not read-only, the best (and only) choice is to create entity-based view objects. Entity-based view objects that are updatable (default behavior) are the only way to pickup entity-derived attribute default values, reflect pending changes made to relevant entity object attributes through other view objects in the same transaction,

and reflect updated reference information when foreign key attribute values are changed is to use an entity-based view object.

### 42.2.3 Use SQL Tracing to Identify Ill-Performing Queries

After deciding whether your view object should be mapped to entities or not, your attention should turn to the query itself. On the Query page of the view object overview editor, click the **Edit SQL Query** icon to display the Edit Query dialog. Click the **Explain Plan** button on the Query page of the Edit Query dialog to see the query plan that the database query optimizer will use. If you see that it is doing a full table scan, you should consider adding indexes or providing a value for the **Query Optimizer Hint** field on the Tuning section of the overview editor's General page. This will let you explicitly control which query plan will be used. These facilities provide some useful tools to the developer to evaluate the query plans for individual view object SQL statements. However, their use is not a substitute for tracing the SQL of the entire application to identify poorly performing queries in the presence of a production environment's amount of data and number of end users.

You can use the Oracle database's SQL Tracing facilities to produce a complete log of all SQL statements your application performs. The approach that works in all versions of the Oracle database is to issue the command:

```
ALTER SESSION SET SQL_TRACE TRUE
```

Specifically in version 10g of Oracle, the DBA would need to grant `ALTER SESSION` privilege in order to execute this command.

This command enables tracing of the current database session and logs all SQL statements to a server-side trace file until you either enter `ALTER SESSION SET SQL_TRACE FALSE` or close the connection. To simplify enabling this option to trace your Fusion web applications, override the `afterConnect()` method of your application module (or custom application module framework extension class) to conditionally perform the `ALTER SESSION` command to enable SQL tracing based on the presence of a Java system property as shown in [Example 42-5](#).

#### **Example 42-5** *Conditionally Enabling SQL Tracing in an Application Module*

```
// In YourCustomApplicationModuleImpl.java
protected void afterConnect() {
 super.afterConnect();
 if (System.getProperty("enableTrace") != null) {
 getDBTransaction().executeCommand("ALTER SESSION SET SQL_TRACE TRUE");
 }
}
```

After producing a trace file, you use the `TKPROF` utility supplied with the database to format the information and to better understand information about each query executed like:

- The number of times it was (re)parsed
- The number of times it was executed
- How many round-trips were made between application server and the database
- Various quantitative measurements of query execution time

Using these techniques, you can decide which additional indexes might be required to speed up particular queries your application performs, or which queries could be changed to improve their query optimization plan. For details about working with the

TKPROF utility, see sections "Understanding SQL Trace and TKPROF" and "Using the SQL Trace Facility and TKPROF" in the *Oracle Database Performance Tuning Guide*.

---

**Note:** The Oracle database provides the DBMS\_MONITOR package that further simplifies SQL tracing and integrates it with Oracle Enterprise Manager for visually monitoring the most frequently performed query statements your applications perform.

---

## 42.2.4 Consider the Appropriate Tuning Settings for Every View Object

The Tuning section on the General page of the view object overview editor lets you set various options that can dramatically effect your query's performance. [Figure 42-5](#) shows the default options that the new view object defines.

**Figure 42-5 View Object Default Tuning Options**

**General**

- Entity Objects
- Attributes
- Query
- Java
- View Accessors
- List UI Hints

**View Object**

View objects are for joining, filtering, projecting, and sorting your business data for the specific needs of a given application task.

Name: CustomerAddressVO

Package: oracle.fodemo.storefront.account.queries

Extends: <None>

Property Set: <None>

Business Components Project: [StoreFrontService](#)

**Tuning**

Enter tuning parameters for this View, to control SQL execution and how data is fetched from the database.

**Retrieve from the Database**

All Rows  Only up to row number

in Batches of:

As Needed  All at Once

At Most One Row

No Rows (i.e. used only for inserting new rows)

Query Optimizer Hint:

e.g FIRST\_ROWS, ALL\_ROWS, etc.

Fill Last Page of Rows when Paging through Rowset

Passivate State (e.g. Current Row, Bind Values, etc.)

Including All Transient Values

Retain View Link Accessor Rowset

Access Mode:

Range Size:

Range Paging Cache Factor:

### 42.2.4.1 Set the Database Retrieval Options Appropriately

The **Retrieve from the Database** group box, controls how the view object retrieves rows from the database server. The options for the fetch mode are **All Rows**, **Only Up To Row Number**, **At Most One Row**, and **No Rows**. Most view objects will stick with the default **All Rows** option, which will be retrieved **As Needed** (default) or **All at Once** depending on which option you choose.

---

---

**Note:** The **All at Once** option does not enforce a single database round trip to fetch the rows specified by the view object query. The **As Needed** and **All at Once** options work in conjunction with the value of **in Batches of** (also known as fetch size) to determine the number of round trips. For best database access performance, you should consider changing the fetch size as described in [Section 42.2.4.2, "Consider Whether Fetching One Row at a Time is Appropriate."](#)

---

---

The **As Needed** option ensures that an `executeQuery()` operation on the view object initially retrieves only as many rows as necessary to fill the first page of a display, whose number of rows is set based on the view object's range size. If you use **As Needed**, then you will require only as many database round trips as necessary to deliver the number of rows specified by the initial range size. Whereas, if you use **All at Once**, then the application will perform as many round trips as necessary to deliver all the rows based on the value of **in Batches of** (fetch size) and the number of rows identified by the query.

For view objects whose `WHERE` clause expects to retrieve a *single* row, set the option to **At Most One Row** for best performance. This way, the view object knows you don't expect any more rows and will skip its normal test for that situation. Finally, if you use the view object only for creating new rows, set the option to **No Rows** so no query will ever be performed.

#### 42.2.4.2 Consider Whether Fetching One Row at a Time is Appropriate

The fetch size controls how many rows will be returned in each round trip to the database. By default, the framework will fetch rows in batches of one row at a time. If you are fetching any more than one row, you will gain efficiency by setting this **in Batches of** value.

However the higher the number, the larger the client-side buffer required, so avoid setting this number arbitrarily high. If you are displaying results  $n$  rows at a time in the user interface, it's good to set the fetch size to at least  $n+1$  so that each page of results can be retrieved in a single round trip to the database.

---

---

**Caution:** Unless your query *really* fetches just one row, leaving the *default* fetch size of one (1) in the **in Batches of** field on the Tuning section of the General page of the view object overview editor is a recipe for bad performance due to many unnecessary round trips between the application server and the database. Oracle strongly recommends considering the appropriate value for each view object's fetch size.

---

---

#### 42.2.4.3 Specify a Query Optimizer Hint if Necessary

The **Query Optimizer Hint** field allows you to specify an optional hint to the Oracle query optimizer to influence what execution plan it will use. You can set this hint in the Tuning page of the overview editor for the view object, as shown in [Figure 42-5](#).

At runtime, the hint you provide is added immediately after the `SELECT` keyword in the query, wrapped by the special comment syntax `/*+ YOUR_HINT */`. Two common optimizer hints are:

- `FIRST_ROWS` — to hint that you want the first rows as quickly as possible
- `ALL_ROWS` — to hint that you want all rows as quickly as possible

There are many other optimizer hints that are beyond the scope of this manual to document. Reference the Oracle database reference manuals for more information on available hints.

### 42.2.5 Using Care When Creating View Objects at Runtime

It's important to understand the overhead associated with creating view objects at runtime. Avoid the temptation to do this without a compelling business requirement. For example, if your application issues a query against a table whose name you know at design time and if the list of columns to retrieve is also fixed, then create a view object at design time. When you do this, your SQL statements are neatly encapsulated, can be easily explained and tuned during development, and incur no runtime overhead to discover the structure and data types of the resulting rows.

In contrast, when you use the `createViewObjectFromQueryStmt()` API on the `ApplicationModule` interface at runtime, your query is buried in code, it's more complicated to proactively tune your SQL, and you pay a performance penalty each time the view object is created. Since the SQL query statement for a dynamically-created view object could theoretically be different each time a new instance is created using this API, an extra database round trip is required to discover the "shape" of the query results on-the-fly. Only create queries dynamically if you *cannot* know the name of the table to query until runtime. Most other needs can be addressed using a design-time created view object in combination with runtime API's to set bind variables in a fixed where clause, or to add an additional `WHERE` clause (with optional bind variables) at runtime.

### 42.2.6 Use Forward Only Mode to Avoid Caching View Rows

Often you will write code that programmatically iterates through the results of a view object. A typical situation will be custom validation code that must process multiple rows of query results to determine whether an attribute or an entity is valid or not. In these cases, if you intend to read each row in the row set a single time and never require scrolling backward or re-iterating the row set a subsequent time, then you can use "forward only" mode to avoid caching the retrieved rows. To enable forward only mode, call `setForwardOnly(true)` on the view object.

---

---

**Note:** Using a read-only view object (with no entity usages) in forward-only mode with an appropriately tuned fetch size is the most efficient way to programmatically read data.

---

---

You can also use forward-only mode to avoid caching rows when inserting, updating, or deleting data as long as you never scroll backward through the row set and never call `reset()` to set the iterator back to the first row. Forward only mode only works with a range size of one (1).

## 42.3 Generating Custom Java Classes for a View Object

As you've seen, all of the basic querying functionality of a view object can be achieved without using custom Java code. Clients can retrieve and iterate through the data of any SQL query without resorting to any custom code on the view object developer's part. In short, for many read-only view objects, once you have defined the SQL statement, you're done. However, it's important to understand how to enable custom Java generation for a view object when your needs might require it. For example, reasons you might write code in a custom Java class include:

- To add validation methods (although Groovy Script expressions can provide this support without needing Java)
- To add custom logic
- To augment built-in behavior

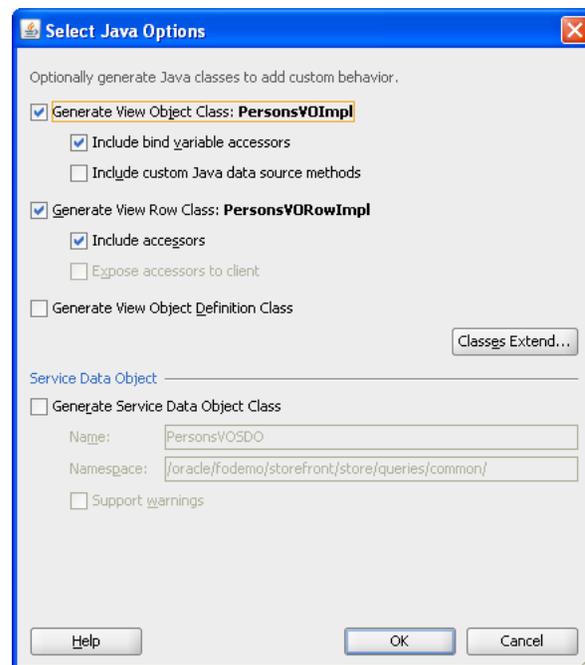

[Appendix D, "Most Commonly Used ADF Business Components Methods"](#) provides a quick reference to the most common code that you will typically write, use, and override in your custom view object and view row classes.

### 42.3.1 How To Generate Custom Classes

To enable the generation of custom Java classes for a view object, use the **Java** page of the view object overview editor. As shown in [Figure 42–6](#), there are three optional Java classes that can be related to a view object. The first two in the list are the most commonly used:

- *View object class*, which represents the component that performs the query
- *View row class*, which represents each row in the query result

**Figure 42–6 View Object Custom Java Generation Options**

#### 42.3.1.1 Generating Bind Variable Accessors

When you enable the generation of a custom view object class, if you also select the **Bind Variable Accessors** checkbox, then JDeveloper generates getter and setter methods in your view object class. Since the `Users` view object had three named bind variables (`TheName`, `LowUserId`, and `HighUserId`), the custom `PersonsImpl.java` view object class would have corresponding methods like this:

```
public String getTheName() {...}
public void setTheName(String value){...}
public Number getHighUserId(){...}
public void setHighUserId(Number value) {...}
public Number getLowUserId() {...}
```

```
public void setLowUserId(Number value) {...}
```

These methods allow you to set a bind variable with compile-time type-checking to ensure you are setting a value of the appropriate type. That is, instead of writing a line like this to set the value of the `LowUserId`:

```
vo.setNamedWhereClauseParam("LowUserId",new Number(150));
```

You can write the code like:

```
vo.setLowUserId(new Number(150));
```

You can see that with the latter approach, the Java compiler would catch a typographical error had you accidentally typed `setLowUserName` instead of `setLowUserId`:

```
// spelling name wrong gives compile error
vo.setLowUserName(new Number(150));
```

Or if you were to incorrectly pass a value of the wrong data type, like "ABC" instead of `Number` value:

```
// passing String where number expected gives compile error
vo.setLowUserId("ABC");
```

*Without* the generated bind variable accessors, an incorrect line of code like the following cannot be caught by the compiler:

```
// Both variable name and value wrong, but compiler cannot catch it
vo.setNamedWhereClauseParam("LowUserName", "ABC");
```

It contains both an incorrectly spelled bind variable name, as well as a bind variable value of the wrong datatype. If you use the generic APIs on the `ViewObject` interface, errors of this sort will raise exceptions at runtime instead of being caught at compile time.

### 42.3.1.2 Generating View Row Attribute Accessors

When you enable the generation of a custom view row class, if you also select the **Accessors** checkbox, then `JDeveloper` generates getter and setter methods for each attribute in the view row. For example, for the `Persons` view object, the corresponding custom `PersonsRowImpl.java` class might have methods like this generated in it:

```
public Number getPersonId() {...}
public void setPersonId(Number value) {...}
public String getEmail() {...}
public void setEmail(String value) {...}
public String getFirstName() {...}
public void setFirstName(String value) {...}
public String getLastName() {...}
public void setLastName(String value) {...}
```

These methods allow you to work with the row data with compile-time checking of the correct datatype usage. That is, instead of writing a line like this one that gets the value of the `PersonId` attribute:

```
Number personId = (Number)row.getAttribute("PersonId");
```

you can write the code like:

```
Number personId = row.getPersonId();
```

You can see that with the latter approach, the Java compiler would catch a typographical error had you accidentally typed `PersonIdentifier` instead of `PersonId`:

```
// spelling name wrong gives compile error
Number personId = row.getPersonIdentifier();
```

*Without* the generated view row accessor methods, an incorrect line of code like the following cannot be caught by the compiler:

```
// Both attribute name and type cast are wrong, but compiler cannot catch it
String personId = (String)row.getAttribute("PersonIdentifier");
```

It contains both an incorrectly spelled attribute name, as well as an incorrectly-typed cast of the `getAttribute()` return value. Using the generic APIs on the `Row` interface, errors of this kind will raise exceptions at runtime instead of being caught at compile time.

### 42.3.1.3 Exposing View Row Accessors to Clients

When enabling the generation of a custom view row class, if you choose to generate the view row attribute accessor, you can also optionally select the **Expose Accessor to the Client** checkbox. This causes an additional custom row interface to be generated which application clients can use to access custom methods on the row without depending directly on the implementation class.

**Best Practice:** When you create client code for business components, you should use business service interfaces rather than concrete classes. Using the interface instead of the implementation class, ensures that client code does not need to change when your server-side implementation does. For more details working with client code, see in [Section 3.5.9, "Custom Interface Support for Client-Accessible Components."](#)

For example, in the case of the `Persons` view object, exposing the accessors to the client will generate a custom row interface named `PersonsRow`. This interface is created in the common subpackage of the package in which the view object resides. Having the row interface allows clients to write code that accesses the attributes of query results in a strongly typed manner. [Example 42-6](#) shows a `TestClient3` sample client program that casts the results of the `next()` method to the `PersonsRow` interface so that it can call accessors like `getPersonId()` and `getEmail()`.

#### **Example 42-6 Simple Example of Using Client Row Interface with Accessors**

```
package devguide.examples.readonlyvo.client;

import devguide.examples.readonlyvo.queries.common.PersonsRow;
import oracle.jbo.*;
import oracle.jbo.client.Configuration;
import oracle.jbo.domain.Number;

public class TestClient3 {
 public static void main(String[] args) {
 String amDef = "devguide.examples.PersonService";
 String config = "PersonServiceLocal";
 ApplicationModule am =
 Configuration.createRootApplicationModule(amDef, config);
 ViewObject vo = am.findViewObject("PersonList");
```

```

vo.executeQuery();
while (vo.hasNext()) {
 // Cast next() to a strongly-typed PersonsRow interface
 PersonsRow curPerson = (PersonsRow)vo.next();
 Number personId = curPerson.getPersonId();
 String email = curPerson.getEmail();
 System.out.println(personId+ " " + email);
}
Configuration.releaseRootApplicationModule(am, true);
}
}

```

#### 42.3.1.4 Configuring Default Java Generation Preferences

You've seen how to generate custom Java classes for your view objects when you need to customize their runtime behavior, or if you simply prefer to have strongly typed access to bind variables or view row attributes.

To change the default settings that control how JDeveloper generates Java classes, choose **Tools | Preferences** and open the **Business Components** page. The settings you choose will apply to all future business components you create.

Oracle recommends that developers getting started with ADF Business Components set their preference to generate no custom Java classes by default. As you run into specific needs, you can enable just the bit of custom Java you need for that one component. Over time, you'll discover which set of defaults works best for you.

### 42.3.2 What Happens When You Generate Custom Classes

When you choose to generate one or more custom Java classes, JDeveloper creates the Java file(s) you've indicated.

For example, in the case of a view object named `devguide.examples.Persons`, the default names for its custom Java files will be `PersonsImpl.java` for the view object class and `PersonsRowImpl.java` for the view row class. Both files get created in the same `./devguide/examples` directory as the component's XML component definition file.

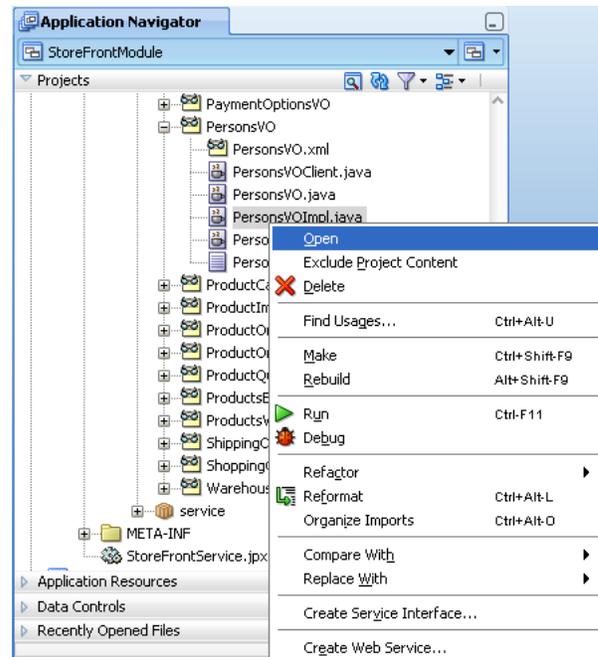

The Java generation options for the view object continue to be reflected on the Java page on subsequent visits to the view object overview editor. Just as with the XML definition file, JDeveloper keeps the generated code in your custom Java classes up to date with any changes you make in the editor. If later you decide you didn't require a custom Java file for any reason, unchecking the relevant options in the Java page causes the custom Java files to be removed.

#### 42.3.2.1 Seeing and Navigating to Custom Java Files

As shown in [Figure 42-7](#), when you've enabled generation of custom Java classes, they also appear under the node for the view object. When you need to see or work with the source code for a custom Java file, there are two ways to open the file in the source editor:

- Choose **Open** in the context menu as shown in [Figure 42-7](#)
- With the Java file node selected in the Application Navigator, double-click a node in the Structure window

Figure 42–7 Seeing and Navigating to Custom Java Classes for a View Object

### 42.3.3 What You May Need to Know About Custom Classes

This section provides additional information to help you use custom Java classes.

#### 42.3.3.1 About the Framework Base Classes for a View Object

When you use an "XML-only" view object, at runtime its functionality is provided by the default ADF Business Components implementation classes. Each custom Java class that gets generated will automatically extend the appropriate ADF Business Components base class so that your code inherits the default behavior and can easily add or customize it. A view object class will extend `ViewObjectImpl`, while the view row class will extend `ViewRowImpl` (both in the `oracle.jbo.server` package).

#### 42.3.3.2 You Can Safely Add Code to the Custom Component File

Based perhaps on previous negative experiences, some developers are hesitant to add their own code to generated Java source files. Each custom Java source code file that JDeveloper creates and maintains for you includes the following comment at the top of the file to clarify that it is safe to add your own custom code to this file:

```
// -----
// --- File generated by Oracle ADF Business Components Design Time.
// --- Custom code may be added to this class.
// --- Warning: Do not modify method signatures of generated methods.
// -----
```

JDeveloper does not blindly regenerate the file when you click the **OK** or **Apply** button in the component dialogs. Instead, it performs a smart update to the methods that it needs to maintain, leaving your own custom code intact.

#### 42.3.3.3 Attribute Indexes and InvokeAccessor Generated Code

The view object is designed to function either in an XML-only mode or using a combination of an XML component definition and a custom Java class. Since attribute

values are not stored in private member fields of a view row class, such a class is not present in the XML-only situation. Instead, attributes are defined as an `AttributesEnum` type, which specifies attribute names (and accessors for each attribute) based on the view object's XML component definition, in sequential order of the `<ViewAttribute>` tag, the association-related `<ViewLinkAccessor>` tag, and the `<ViewAccessor>` tag in that file. At runtime, the attribute values in a view row are stored in a structure that is managed by the base `ViewRowImpl` class, indexed by the attribute's numerical position in the view object's attribute list.

For the most part this private implementation detail is unimportant. However, when you enable a custom Java class for your view row, this implementation detail is related to some of the generated code that JDeveloper automatically maintains in your view row class, and you may want to understand what that code is used for. For example, in the custom Java class for the `Users` view row, [Example 42-7](#) shows that each attribute, view link accessor attribute, or view accessor attribute has a corresponding generated `AttributesEnum` enum. JDeveloper defines enums instead of constants in order to prevent merge conflicts that could result when multiple developers add new attributes to the XML component definition.

**Example 42-7 Attribute Constants Are Automatically Maintained in the Custom View Row Java Class**

```
public class PersonsRowImpl extends ViewRowImpl implements PersonsRow {
 /**
 * AttributesEnum: generated enum for identifying attributes and accessors. Do not
 * modify.
 */
 public enum AttributesEnum {...}
 public static final int PERSONID = AttributesEnum.PersonId.index();
 public static final int EMAIL = AttributesEnum.Email.index();
 public static final int FIRSTNAME = AttributesEnum.FirstName.index();
 public static final int LASTNAME = AttributesEnum.LastName.index();
 public static final int PERSONTYPECODE = AttributesEnum.PersonTypeCode.index();
 public static final int PRIMARYADDRESSID = AttributesEnum.PrimaryAddressId.index
 ();
 // etc.
```

You'll also notice that the automatically maintained, strongly typed getter and setter methods in the view row class use these attribute constants like this:

```
public String getEmail() {
 return (String) getAttributeInternal(EMAIL); // <-- Attribute constant
}
public void setEmail(String value) {
 setAttributeInternal(EMAIL, value); // <-- Attribute constant
}
```

The last two aspects of the automatically maintained code related to view row attribute constants defined by the `AttributesEnum` type are the `getAttrInvokeAccessor()` and `setAttrInvokeAccessor()` methods. These methods optimize the performance of attribute access by numerical index, which is how generic code in the `ViewRowImpl` base class typically accesses attribute values. An example of the `getAttrInvokeAccessor()` method looks like the following from the `PersonsRowImpl.java` class. The companion `setAttrInvokeAccessor()` method looks similar.

```
protected Object getAttrInvokeAccessor(int index, AttributeDefImpl attrDef) throws Exception {
 if ((index >= AttributesEnum.firstIndex()) && (index < AttributesEnum.count())) {
 return AttributesEnum.staticValues()[index - AttributesEnum.firstIndex()].get(this);
 }
}
```

```

return super.getAttrInvokeAccessor(index, attrDef);
}

```

The rules of thumb to remember about this generated attribute-related code are the following.

#### The Do's

- Add custom code if needed inside the strongly typed attribute getter and setter methods
- Use the view object overview editor to change the order or type of view object attributes

JDeveloper will change the Java signature of getter and setter methods, as well as the related XML component definition for you.

#### The Don'ts

- Don't modify the list of enums in the generated `AttributesEnum` enum
- Don't modify the `getAttrInvokeAccessor()` and `setAttrInvokeAccessor()` methods

## 42.4 Working Programmatically with Multiple Named View Criteria

You can define *multiple* named view criteria in the overview editor for a view object and then selectively apply any combination of them to your view object at runtime as needed. For information about working with named view criteria at design time, see [Section 5.11.1, "How to Create Named View Criteria Declaratively."](#)

---

---

**Note:** The example in this section refers to the `MultipleViewCriteria` project in the `AdvancedViewObjectsExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

### 42.4.1 Applying One or More Named View Criteria

To apply one or more named view criteria, use the `setApplyViewCriteriaNames()` method. This method accepts a `String` array of the names of the criteria you want to apply. If you apply more than one named criteria, they are AND-ed together in the WHERE clause produced at runtime. New view criteria that you apply with the `setApplyViewCriteriaNames()` method will not overwrite view criteria that were previously applied.

When you need to apply more than one named view criteria, you can expose custom methods on the client interface of the view object to encapsulate applying combinations of the named view criteria. For example, [Example 42-8](#) shows custom methods `showMaleCustomers()`, `showFemaleStaff()`, and `showFemaleCustomers()`, each of which uses the `setApplyViewCriteriaNames()` method to apply an appropriate combination of named view criteria. Once these methods are exposed on the view object's client interface, at runtime clients can invoke these methods as needed to change the information displayed by the view object.

#### **Example 42-8 Exposing Client Methods to Enable Appropriate Named Criteria**

```
// In PersonsViewImpl.java
```

```

public void showMaleCustomers() {
 ViewCriteriaManager vcm = getViewCriteriaManager();
 ViewCriteria vc_gender = vcm.getViewCriteria("GenderIsNotFCriteria");
 ViewCriteria vc_type = vcm.getViewCriteria("IsCustomerCriteria");
 VariableValueManager vvm_gender = vc_gender.ensureVariableManager();
 VariableValueManager vvm_type = vc_type.ensureVariableManager();
 vvm_gender.setVariableValue("bv_Gender", "F");
 vvm_type.setVariableValue("bv_PersonTypeCode", "CUST");
 setApplyViewCriteriaNames(new String[]{"GenderIsNotFCriteria",
 "IsCustomerCriteria"});
}

public void showFemaleStaff() {
 ViewCriteriaManager vcm = getViewCriteriaManager();
 ViewCriteria vc_gender = vcm.getViewCriteria("GenderIsFCriteria");
 ViewCriteria vc_type = vcm.getViewCriteria("IsStaffSupplierCriteria");
 VariableValueManager vvm_gender = vc_gender.ensureVariableManager();
 VariableValueManager vvm_type = vc_type.ensureVariableManager();
 vvm_gender.setVariableValue("bv_Gender", "F");
 vvm_type.setVariableValue("bv_PersonTypeCode", "CUST");
 setApplyViewCriteriaNames(new String[]{"GenderIsFCriteria",
 "IsStaffSupplierCriteria"});

 executeQuery();
}

public void showFemaleCustomers() {
 ViewCriteriaManager vcm = getViewCriteriaManager();
 ViewCriteria vc_gender = vcm.getViewCriteria("GenderIsFCriteria");
 ViewCriteria vc_type = vcm.getViewCriteria("IsCustomerCriteria");
 VariableValueManager vvm_gender = vc_gender.ensureVariableManager();
 VariableValueManager vvm_type = vc_type.ensureVariableManager();
 vvm_gender.setVariableValue("bv_Gender", "F");
 vvm_type.setVariableValue("bv_PersonTypeCode", "CUST");
 setApplyViewCriteriaNames(new String[]{"GenderIsFCriteria",
 "IsCustomerCriteria"});

 executeQuery();
}

```

## 42.4.2 Removing All Applied Named View Criteria

To remove any currently applied named view criteria, use `setApplyViewCriteriaNames(null)`. For example, you could add the `showAll()` method in [Example 42-9](#) to the `Users` view object and expose it on the client interface. This would allow clients to return to an unfiltered view of the data when needed.

Do not remove any design time view criteria because the row level bind variable values may already be applied on the row set. To help ensure this, named view criteria that get defined for a view accessor in the design time, will be applied as "required" view criteria on the view object instance so that it does not get removed by the view criteria's life cycle methods.

### **Example 42-9 Removing All Applied Named View Criteria**

```

// In UsersImpl.java
public void showAll() {
 setApplyViewCriteriaNames(null);
 executeQuery();
}

```

---

---

**Note:** The `setApplyViewCriteriaas(null)` removes all applied view criteria, but allows you to later reapply any combination of them. In contrast, the `clearViewCriteriaas()` method *deletes* all named view criteria. After calling `clearViewCriteriaas()` you would have to use `putViewCriteriaas()` again to define new named criteria before you could apply them.

---

---

### 42.4.3 Using the Named Criteria at Runtime

At runtime, your application can invoke different client methods on a single view object interface to return different filtered sets of data. [Example 42–10](#) shows the interesting lines of a `TestClient` class that works with the `Persons` view object described above. The `showResults()` method is a helper method that iterates over the rows in the view object to display some attributes.

#### **Example 42–10 Test Client Code Working with Named View Criteria**

```
// In TestClientMultipleViewCriteriaas.java
PersonsView vo = (PersonsView)am.findViewObject("PersonsView");
vo.showMaleCustomers();
showResults(vo,"After applying view criterias for male customers");
vo.applyViewCriteriaas(null);
vo.showFemaleStaff();
showResults(vo,"After applying view criterias for female staff");
vo.showFemaleCustomers();
showResults(vo,"After applying view criterias for female customers");
vo.showAll();
vo.showResults(vo,"After clearing all view criterias");
```

Running the `TestClient` program produces output as follows:

```
---After applying view criterias for male customers ---
Daniel Faviet [CUST, M]
John Chen [CUST, M]
Ismael Sciarra [CUST, M]
Jose Manuel Urman [CUST, M]
Luis Popp [CUST, M]
Den Raphaely [CUST, M]
Alexander Khoo [CUST, M]
Sigal Tobias [CUST, M]
Guy Himuro [CUST, M]
Matthew Weiss [CUST, M]
Adam Fripp [CUST, M]
Payam Kaufling [CUST, M]
Kevin Mourgos [CUST, M]
James Landry [CUST, M]
Steven Markle [CUST, M]
...
---After applying view criterias for female staff ---
Neena Kochhar [STAFF, F]
Valli Pataballa [STAFF, F]
Diana Lorentz [STAFF, F]
Terra Bralick [SUPP, F]
Rachel Berman [SUPP, F]
Claudia Benghiat [SUPP, F]
Sharon Hemant [SUPP, F]
Alison Chen [SUPP, F]
Alex Duckers [SUPP, F]
```

```
Katrina Han [SUPP, F]
---After applying view criterias for female customers ---
Nancy Greenberg [CUST, F]
Shelli Baida [CUST, F]
Karen Colmenares [CUST, F]
Shanta Vollman [CUST, F]
Julia Nayer [CUST, F]
Irene Mikkilineni [CUST, F]
Laura Bissot [CUST, F]
---After clearing all view criterias ---
Steven King [STAFF, M]
Neena Kochhar [STAFF, F]
Lex De Haan [STAFF, M]
Alexander Hunold [STAFF, M]
Bruce Ernst [STAFF, M]
David Austin [STAFF, M]
Valli Pataballa [STAFF, F]
Diana Lorentz [STAFF, F]
Nancy Greenberg [CUST, F]
...
```

## 42.5 Performing In-Memory Sorting and Filtering of Row Sets

By default a view object performs its query against the database to retrieve the rows in its resulting row set. However, you can also use view objects to perform in-memory searches and sorting to avoid unnecessary trips to the database.

---

---

**Note:** The example in this section refers to the InMemoryOperations project in the AdvancedViewObjectsExamples application workspace in the StandaloneExamples module of the Fusion Order Demo application.

---

---

### 42.5.1 Understanding the View Object's SQL Mode

The view object's SQL mode controls the source used to retrieve rows to populate its row set. The `setQueryMode()` allows you to control which mode, or combination of modes, are used:

- `ViewObject.QUERY_MODE_SCAN_DATABASE_TABLES`  
This is the default mode that retrieves results from the database.
- `ViewObject.QUERY_MODE_SCAN_VIEW_ROWS`  
This mode uses rows already in the row set as the source, allowing you to progressively refine the row set's contents through in-memory filtering.
- `ViewObject.QUERY_MODE_SCAN_ENTITY_ROWS`  
This mode, valid only for entity-based view objects, uses the entity rows presently in the entity cache as the source to produce results based on the contents of the cache.

You can use the modes individually, or combine them using Java's logical OR operator ( $X \mid Y$ ). For example, to create a view object that queries the entity cache for unposted new entity rows, as well as the database for existing rows, you could write code like:

```
setQueryMode(ViewObject.QUERY_MODE_SCAN_DATABASE_TABLES |
 ViewObject.QUERY_MODE_SCAN_ENTITY_ROWS)
```

If you combine the SQL modes, the view object automatically handles skipping of duplicate rows. In addition, there is an implied order to the results that are found:

1. Scan view rows (if specified)
2. Scan entity cache (if specified)
3. Scan database tables (if specified) by issuing a SQL query

If you call the `setQueryMode()` method to change the SQL mode, your new setting takes effect the next time you call the `executeQuery()` method.

## 42.5.2 Sorting View Object Rows In Memory

To sort the rows in a view object at runtime, use the `setSortBy()` method. You pass a sort expression that looks like a SQL `ORDER BY` clause. However, instead of referencing the column names of the table, you use the view object's attribute names. For example, for a view object containing attributes named `Customer` and `DaysOpen`, you could sort the view object first by `Customer` descending, then by `DaysOpen` by calling:

```
setSortBy("Customer desc, DaysOpen");
```

Alternatively, you can use the *zero-based* attribute index position in the sorting clause like this:

```
setSortBy("3 desc, 2");
```

After calling the `setSortBy()` method, the rows will be sorted the next time you call the `executeQuery()` method. The view object translates this sorting clause into an appropriate format to use for ordering the rows depending on the SQL mode of the view object. If you use the default SQL mode, the `SortBy` clause is translated into an appropriate `ORDER BY` clause and used as part of the SQL statement sent to the database. If you use either of the in-memory SQL modes, then the `SortBy` clause is translated into one or more `SortCriteria` objects for use in performing the in-memory sort.

---

**Note:** While SQL `ORDER BY` expressions treat column names in a case-insensitive way, the attribute names in a `SortBy` expression are case-sensitive.

---

### 42.5.2.1 Combining `setSortBy` and `setQueryMode` for In-Memory Sorting

You can perform an in-memory sort on the rows produced by a read-only view object using the `setSortBy()` and `setQueryMode()` methods. [Example 42-11](#) shows the interesting lines of code from the `TestClientSetSortBy` class that uses `setSortBy()` and `setQueryMode()` to perform an in-memory sort on the rows produced by a read-only view object `ClosedOrders`.

#### **Example 42-11** Combining `setSortBy` and `setQueryMode` for In-Memory Sorting

```
// In TestClientSetSortBy.java
am.getTransaction().executeCommand("ALTER SESSION SET SQL_TRACE TRUE");
ViewObject vo = am.findViewObject("ClosedOrders");
vo.executeQuery();
showRows(vo, "Initial database results");
```

```

vo.setSortBy("Customer desc");
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_VIEW_ROWS);
vo.executeQuery();
showRows(vo,"After in-memory sorting by Customer desc");
vo.setSortBy("Customer desc, DaysOpen");
vo.executeQuery();
showRows(vo,"After in-memory sorting by Customer desc, DaysOpen");

```

Running the example produces the results:

```

--- Initial database results ---
106,Ice machine not working,1,mhartste
103,Washing machine leaks,4,ngreenbe
105,Air in dryer not hot,4,jmurman
109,Freezer is not cold,4,jwhalen
:
--- After in-memory sorting by Customer desc ---
100,I have noticed that every time I do a...,9,dfaviet
101,Agitator does not work,8,sbaida
103,Washing machine leaks,4,ngreenbe
105,Air in dryer not hot,4,jmurman
:
--- After in-memory sorting by Customer desc, DaysOpen ---
100,I have noticed that every time I do a...,9,dfaviet
101,Agitator does not work,8,sbaida
105,Air in dryer not hot,4,jmurman
109,Freezer is not cold,4,jwhalen
:

```

The first line in [Example 42-11](#) containing the `executeCommand()` call issues the `ALTER SESSION SET SQL TRACE` command to enable SQL tracing for the current database session. This causes the Oracle database to log every SQL statement performed to a server-side trace file. It records information about the text of each SQL statement, including how many times the database parsed the statement and how many round-trips the client made to fetch batches of rows while retrieving the query result.

---

---

**Note:** You might need a DBA to grant permission to the FOD account to perform the `ALTER SESSION` command to do the tracing of SQL output.

---

---

Once you've produced a trace file, you can use the `TKPROF` utility that comes with the database to format the file:

```
tkprof xe_ora_3916.trc trace.prf
```

For details about working with the `TKPROF` utility, see sections "Understanding SQL Trace and `TKPROF`" and "Using the SQL Trace Facility and `TKPROF`" in the *Oracle Database Performance Tuning Guide*.

This will produce a `trace.prf` file containing the interesting information shown in [Example 42-12](#) about the SQL statement performed by the `ClosedOrders` view object. You can see that after initially querying six rows of data in a single execute and fetch from the database, the two subsequent sorts of those results did not cause any further executions. Since the code set the SQL mode to `ViewObject.QUERY_MODE_SCAN_VIEW_ROWS` the `setSortBy()` followed by the `executeQuery()` performed the sort in memory.

**Example 42–12 TKPROF Output of a Trace File Confirming Sort Was Done In Memory**

```

SELECT * FROM (select o.order_id,
 case
 when length(o.giftwrap_message) > 5 then
 rtrim(substr(o.giftwrap_message,1,5))||'...'
 else o.giftwrap_message
 end as giftwrap_message,
 ceil(
 (select trunc(max(creation_date))
 from order_histories
 where order_id = or.order_id)
 - trunc(o.order_date)
) as days_open,
 p.email as customer
from orders o, persons p
where o.customer_id = p.person_id
 and order status code = 'COMPLETE')

call count cpu elapsed disk query current rows

Parse 1 0.00 0.00 0 0 0 0
Execute 1 0.00 0.00 0 0 0 0
Fetch 1 0.00 0.00 0 22 0 6

total 3 0.00 0.00 0 22 0 6

```

**42.5.2.2 Extensibility Points for In-Memory Sorting**

Should you need to customize the way that rows are sorted in memory, you have the following two extensibility points:

1. You can override the method:

```
public void sortRows(Row[] rows)
```

This method performs the actual in-memory sorting of rows. By overriding this method you can plug in an alternative sorting approach if needed.

2. You can override the method:

```
public Comparator getRowComparator()
```

The default implementation of this method returns an `oracle.jbo.RowComparator`. `RowComparator` invokes the `compareTo()` method to compare two data values. These methods/objects can be overridden to provide custom compare routines.

**42.5.3 Performing In-Memory Filtering with View Criteria**

To filter the contents of a row set using `ViewCriteria`, you can call:

- `applyViewCriteria()` or `setApplyViewCriteriaNames()` followed by `executeQuery()` to produce a new, filtered row set.
- `findByViewCriteria()` to retrieve a new row set to process programmatically without changing the contents of the original row set.

Both of these approaches can be used against the database or to perform in-memory filtering, or both, depending on the view criteria mode. You set the criteria mode using

the `setCriteriaMode()` method on the `ViewCriteria` object, to which you can pass either of the following integer flags, or the logical OR of both:

- `ViewCriteria.CRITERIA_MODE_QUERY`
- `ViewCriteria.CRITERIA_MODE_CACHE`

When used for in-memory filtering with view criteria, the operators supported are shown in [Table 42–1](#). You can group subexpressions with parenthesis and use the AND and OR operators between subexpressions.

**Table 42–1 SQL Operators Supported By In-Memory Filtering with View Criteria**

Operator	Operation
<code>=, &gt;, &lt;, &lt;=, &gt;=, &lt;&gt;, LIKE, BETWEEN</code>	Comparison
<code>NOT</code>	Logical negation
<code>AND</code>	Conjunction
<code>OR</code>	Disjunction

[Example 42–13](#) shows the interesting lines from a `TestClientFindByViewCriteria` class that uses the two features described above both against the database and in-memory. It uses a `CustomerList` view object instance and performs the following basic steps:

1. Queries customers from the database with a last name starting with a 'C', producing the output:
 

```
--- Initial database results with applied view criteria ---
John Chen
Emerson Clabe
Karen Colmenares
```
2. Subsets the results from step 1 in memory to only those with a first name starting with 'J'. It does this by adding a second view criteria row to the view criteria and setting the conjunction to use "AND". This produces the output:
 

```
--- After augmenting view criteria and applying in-memory ---
John Chen
```
3. Sets the conjunction back to OR and re-applies the criteria to the database to query customers with last name like 'J%' or first name like 'C%'. This produces the output:
 

```
--- After changing view criteria and applying to database again ---
John Chen
Jose Manuel Urman
Emerson Clabe
Karen Colmenares
Jennifer Whalen
```
4. Defines a new criteria to find customers in-memory with first or last name that contain a letter 'o'
5. Uses `findByViewCriteria()` to produce new row set instead of subsetting, producing the output:
 

```
--- Rows returned from in-memory findByViewCriteria ---
John Chen
Jose Manuel Urman
Emerson Clabe
```

Karen Colmenares

6. Shows that original row set hasn't changed when `findByViewCriteria()` was used, producing the output:

```
--- Note findByViewCriteria didn't change rows in the view ---
John Chen
Jose Manuel Urman
Emerson Clabe
Karen Colmenares
Jennifer Whalen
```

**Example 42–13 Performing Database and In-Memory Filtering with View Criteria**

```
// In TestClientFindByViewCriteria.java
ViewObject vo = am.findViewObject("CustomerList");
// 1. Show customers with a last name starting with a 'M'
ViewCriteria vc = vo.createViewCriteria();
ViewCriteriaRow vcr1 = vc.createViewCriteriaRow();
vcr1.setAttribute("LastName", "LIKE 'M%'");
vo.applyViewCriteria(vc);
vo.executeQuery();
vc.add(vcr1);
vo.executeQuery();
showRows(vo, "Initial database results with applied view criteria");
// 2. Subset results in memory to those with first name starting with 'S'
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_VIEW_ROWS);
ViewCriteriaRow vcr2 = vc.createViewCriteriaRow();
vcr2.setAttribute("FirstName", "LIKE 'S%'");
vcr2.setConjunction(ViewCriteriaRow.VCROW_CONJ_AND);
vc.setCriteriaMode(ViewCriteria.CRITERIA_MODE_CACHE);
vc.add(vcr2);
vo.executeQuery();
showRows(vo, "After augmenting view criteria and applying in-memory");
// 3. Set conjunction back to OR and re-apply to database query to find
// customers with last name like 'H%' or first name like 'S%'
vc.setCriteriaMode(ViewCriteria.CRITERIA_MODE_QUERY);
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_DATABASE_TABLES);
vcr2.setConjunction(ViewCriteriaRow.VCROW_CONJ_OR);
vo.executeQuery();
showRows(vo, "After changing view criteria and applying to database again");
// 4. Define new criteria to find customers with first or last name like '%%'
ViewCriteria nameContainsO = vo.createViewCriteria();
ViewCriteriaRow lastContainsO = nameContainsO.createViewCriteriaRow();
lastContainsO.setAttribute("LastName", "LIKE '%%'");
ViewCriteriaRow firstContainsO = nameContainsO.createViewCriteriaRow();
firstContainsO.setAttribute("FirstName", "LIKE '%%'");
nameContainsO.add(firstContainsO);
nameContainsO.add(lastContainsO);
// 5. Use findByViewCriteria() to produce new rowset instead of subsetting
nameContainsO.setCriteriaMode(ViewCriteria.CRITERIA_MODE_CACHE);
RowSet rs = (RowSet)vo.findByViewCriteria(nameContainsO,
-1, ViewObject.QUERY_MODE_SCAN_VIEW_ROWS);
showRows(rs, "Rows returned from in-memory findByViewCriteria");
// 6. Show that original rowset hasn't changed
showRows(vo, "Note findByViewCriteria didn't change rows in the view");
```

## 42.5.4 Performing In-Memory Filtering with RowMatch

The `RowMatch` object provides an even more convenient way to express in-memory filtering conditions. You create a `RowMatch` object by passing a query predicate expression to the constructor like this:

```
RowMatch rm =
 new RowMatch("LastName = 'Popp' or (FirstName like 'A%' and LastName like 'K%')")
;
```

As you do with the `SortBy` clause, you phrase the `RowMatch` expression in terms of the view object attribute names, using the supported operators shown in [Table 42-2](#). You can group subexpressions with parenthesis and use the `and` and `or` operators between subexpressions.

**Table 42-2 SQL Operators Supported By In-Memory Filtering with RowMatch**

Operator	Operation
=, >, <, <=, >=, <>, LIKE, BETWEEN	Comparison
NOT	Logical negation
AND	Conjunction
OR	Disjunction

You can also use a limited set of SQL functions in the `RowMatch` expression, as shown in [Table 42-3](#).

**Table 42-3 SQL Functions Supported By In-Memory Filtering with RowMatch**

Operator	Operation
UPPER	Converts all letters in a string to uppercase.
TO_CHAR	Converts a number or date to a string.
TO_DATE	Converts a character string to a date format.
TO_TIMESTAMP	Converts a string to timestamp.

---

**Note:** While SQL query predicates treat column names in a case-insensitive way, the attribute names in a `RowMatch` expression are case-sensitive.

---

### 42.5.4.1 Applying a RowMatch to a View Object

To apply a `RowMatch` to your view object, call the `setRowMatch()` method. In contrast to a `ViewCriteria`, the `RowMatch` is only used for *in-memory* filtering, so there is no "match mode" to set. You can use a `RowMatch` on view objects in any supported SQL mode, and you will see the results of applying it the next time you call the `executeQuery()` method.

When you apply a `RowMatch` to a view object, the `RowMatch` expression can reference the view object's named bind variables using the same `:VarName` notation that you would use in a SQL statement. For example, if a view object had a named bind variable named `StatusCode`, you could apply a `RowMatch` to it with an expression like:

```
Status = :StatusCode or :StatusCode = '%'
```

**Example 42–14** shows the interesting lines of a `TestClientRowMatch` class that illustrate the `RowMatch` in action. The `CustomerList` view object used in the example has a transient `Boolean` attribute named `Selected`. The code performs the following basic steps:

1. Queries the full customer list, producing the output:

```
--- Initial database results ---
Neena Kochhar [null]
Lex De Haan [null]
Nancy Greenberg [null]
:
```

2. Marks odd-numbered rows selected by setting the `Selected` attribute of odd rows to `Boolean.TRUE`, producing the output:

```
--- After marking odd rows selected ---
Neena Kochhar [null]
Lex De Haan [true]
Nancy Greenberg [null]
Daniel Faviet [true]
John Chen [null]
Ismael Sciarra [true]
:
```

3. Uses a `RowMatch` to subset the row set to contain only the select rows, that is, those with `Selected = true`. This produces the output:

```
--- After in-memory filtering on only selected rows ---
Lex De Haan [true]
Daniel Faviet [true]
Ismael Sciarra [true]
Luis Popp [true]
:
```

4. Further subsets the row set using a more complicated `RowMatch` expression, producing the output:

```
--- After in-memory filtering with more complex expression ---
Lex De Haan [true]
Luis Popp [true]
```

**Example 42–14 Performing In-Memory Filtering with RowMatch**

```
// In TestClientRowMatch.java
// 1. Query the full customer list
ViewObject vo = am.findViewObject("CustomerList");
vo.executeQuery();
showRows(vo, "Initial database results");
// 2. Mark odd-numbered rows selected by setting Selected = Boolean.TRUE
markOddRowsAsSelected(vo);
showRows(vo, "After marking odd rows selected");
// 3. Use a RowMatch to subset row set to only those with Selected = true
RowMatch rm = new RowMatch("Selected = true");
vo.setRowMatch(rm);
// Note: Only need to set SQL mode when not defined at design time
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_VIEW_ROWS);
vo.executeQuery();
showRows(vo, "After in-memory filtering on only selected rows");
// 5. Further subset rowset using more complicated RowMatch expression
```

```

rm = new RowMatch("LastName = 'Popp' "+
 "or (FirstName like 'A%' and LastName like 'K%')");
vo.setRowMatch(rm);
vo.executeQuery();
showRows(vo,"After in-memory filtering with more complex expression");
// 5. Remove RowMatch, set query mode back to database, requery to see full list
vo.setRowMatch(null);
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_DATABASE_TABLES);
vo.executeQuery();
showRows(vo,"After re-querying to see a full list again");

```

#### 42.5.4.2 Using RowMatch to Test an Individual Row

In addition to using a RowMatch to filter a row set, you can also use its `rowQualifies()` method to test whether any individual row matches the criteria it encapsulates. For example:

```

RowMatch rowMatch = new RowMatch("CountryId = 'US'");
if (rowMatch.rowQualifies(row)) {
 System.out.println("Customer is from the United States ");
}

```

#### 42.5.4.3 How a RowMatch Affects Rows Fetched from the Database

Once you apply a RowMatch, if the view object's SQL mode is set to retrieve rows from the database, when you call `executeQuery()` the RowMatch is applied to rows as they are fetched. If a fetched row does not qualify, it is not added to the rowset.

Unlike a SQL WHERE clause, a RowMatch can evaluate expressions involving transient view object attributes and not-yet-posted attribute values. This can be useful to filter queried rows based on RowMatch expressions involving transient view row attributes whose values are calculated in Java. This interesting aspect should be used with care, however, if your application needs to process a large rowset. Oracle recommends using database-level filtering to retrieve the smallest-possible rowset first, and then using RowMatch as appropriate to subset that list in memory.

## 42.6 Using View Objects to Work with Multiple Row Types

Sometimes you will create a view object to work with entity rows of a single type like `Supplier`, which perhaps includes `Supplier`-specific attributes. At other times you may want to query and update rows based on an entity object inheritance hierarchy in the same row set. For example, you might work, in the same row set, with attributes that are common to the inheritance hierarchy of `Persons`, `Supplier`, and `Staff` entity objects.

---

---

**Note:** To experiment with the example described in this section, use the same `InheritanceAndPolymorphicQueries` project in the `AdvancedEntityExamples` workspace used in [Section 4.19, "Using Inheritance in Your Business Domain Layer."](#)

---

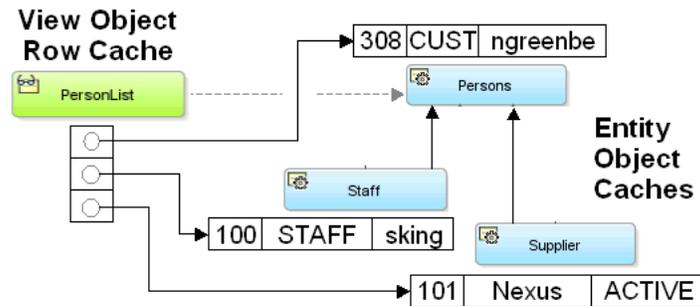

---

### 42.6.1 Working with Polymorphic Entity Usages

A *polymorphic* entity usage is one that references a base entity object in an inheritance hierarchy and is configured to handle *subtypes* of that entity as well. [Figure 42–8](#) shows the results of using a view object with a polymorphic entity usage. The entity-based `PersonList` view object has the `Person` entity object as its primary entity usage. The view object partitions each row retrieved from the database into an entity row part of

the appropriate entity object *subtype* of *Person*. It creates the appropriate entity row subtype based on consulting the value of the discriminator attribute. For example, if the `PersonList` query retrieves one row for person `ngreenbe`, one row for staff `sking`, and one row for supplier `ahunold`, the underlying entity row parts would be as shown in the figure.

**Figure 42–8 View Object with a Polymorphic Entity Usage Handles Entity Subtypes**

## 42.6.2 How to Create a View Object with a Polymorphic Entity Usage

To create a view object with a polymorphic entity usage, follow these steps:

1. Identify the entity object that represents the base type in the entity inheritance hierarchy you want to work with.

For example, the data model project might define a base `Persons` entity object in order to support the creation of view objects with polymorphic entity usages for the `Supplier` and `Staff` entity objects.

2. Create an entity-based view object with that base entity as its entity usage.

For example, you might create the `SupplierList` view object based on the `Persons` entity object.

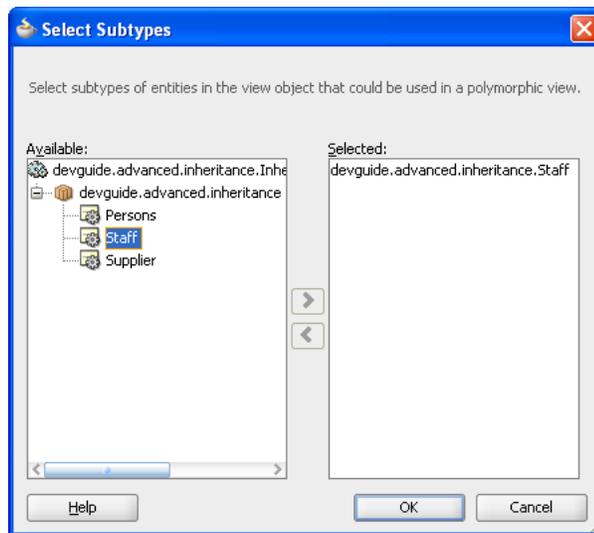

---

**Note:** When an entity-based view object references an entity object with a discriminator attribute, then JDeveloper enforces that the discriminator attribute is included in the query as well (in addition to the primary key attribute).

---

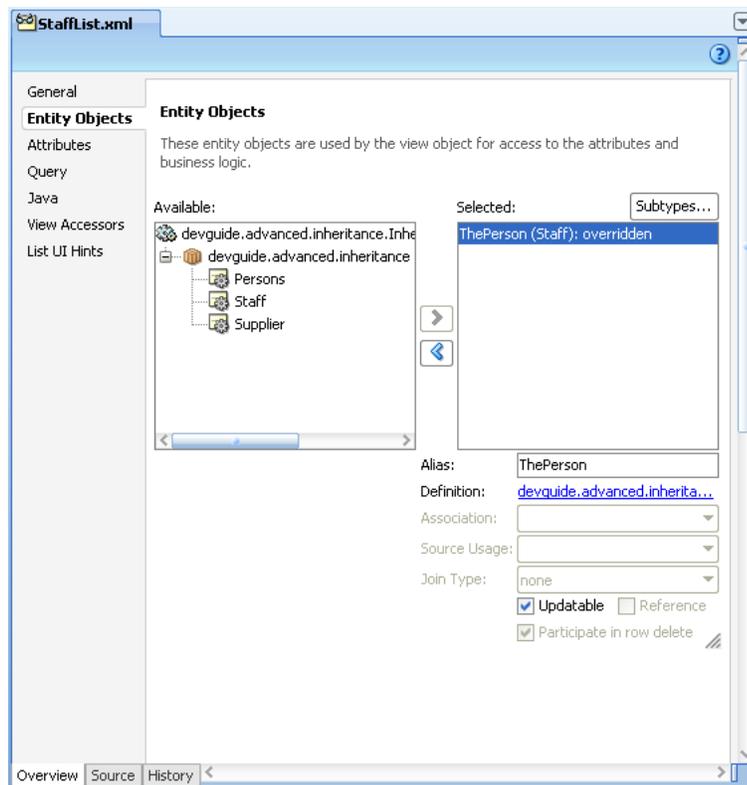

3. On the Entity Objects page of the view object overview editor, select the entity usage in the **Selected** list and click **Subtypes**.
4. In the **Subtypes** dialog, shuttle the desired entity subtypes you want to allow from the **Available** to the **Selected** list, and click **OK**.

For example, for the `StaffList` view object you would select the entity subtype `Staff`, as shown in [Figure 42–9](#).

**Figure 42–9 View Object with a Entity Subtype Selection**

5. Click **OK**.

The Entity Objects page of the overview editor identifies the selected entity object with the entity subtype override. For example, overview editor for the `StaffList` view object identifies the overridden entity object `ThePerson (Staff)`: overridden with the subtype in parenthesis, as shown in [Figure 42–10](#).

**Figure 42–10 View Object Editor Shows Entity Subtype is Overridden**

### 42.6.3 What Happens When You Create a View Object with a Polymorphic Entity Usage

When you create an entity-based view object with a polymorphic entity usage, JDeveloper adds information about the allowed entity subtypes to the view object's XML component definition. For example, when creating the `PersonList` view object above, the names of the allowed subtype entity objects are recorded in an `<AttrArray>` tag like this:

```
<ViewObject Name="PersonList" ... >
 <EntityUsage Name="ThePerson"
 Entity="devguide.advanced.inheritance.Persons" >
 </EntityUsage>
 ...
 <AttrArray Name="EntityImports">
 <Item Value="devguide.advanced.inheritance.Staff" />
 <Item Value="devguide.advanced.inheritance.Supplier" />
 </AttrArray>
 <!-- etc. -->
</ViewObject>
```

### 42.6.4 What You May Need to Know About Entity Usages

This section provides additional information to help you work with polymorphic entity usages.

#### 42.6.4.1 Your Query Must Limit Rows to Expected Entity Subtypes

If your view object expects to work with only a *subset* of the available entity subtypes in a hierarchy, you need to include an appropriate `WHERE` clause that limits the query to only return rows whose discriminator column matches the expected entity types.

#### 42.6.4.2 Exposing Selected Entity Methods in View Rows Using Delegation

By design, clients do not work directly with entity objects. Instead, they work indirectly with entity objects through the view rows of an appropriate view object that presents a relevant set of information related to the task at hand. Just as a view object can expose a particular set of the underlying *attributes* of one or more entity objects related to the task at hand, it can also expose a selected set of *methods* from those entities. You accomplish this by enabling a custom view row Java class and writing a method in the view row class that:

- Accesses the appropriate underlying entity row using the generated entity accessor in the view row, and
- Invokes a method on it

For example, assume that the `Persons` entity object contains a `performPersonFeature()` method in its `PersonsImpl` class. To expose this method to clients on the `PersonsList` view row, you can enable a custom view row Java class and write the method shown in [Example 42–15](#). JDeveloper generates an entity accessor method in the view row class for each participating entity usage based on the entity usage *alias* name. Since the alias for the `Persons` entity in the `PersonsList` view object is "ThePerson", it generates a `getThePerson()` method to return the entity row part related to that entity usage.

#### **Example 42–15 Exposing Selected Entity Object Methods on View Rows Through Delegation**

```
// In PersonListRowImpl.java
public void performPersonFeature() {
```

```

 getThePerson().performPersonFeature();
}

```

The code in the view row's `performPersonFeature()` method uses this `getThePerson()` method to access the underlying `PersonImpl` entity row class and then invokes *its* `performPersonFeature()` method. This style of coding is known as *delegation*, where a view row method delegates the implementation of one of *its* methods to a corresponding method on an underlying entity object. When delegation is used in a view row with a polymorphic entity usage, the delegated method call is handled by appropriate underlying entity row subtype. This means that if the `PersonsImpl`, `StaffImpl`, and `SupplierImpl` classes implement the `performPersonFeature()` method in a different way, the appropriate implementation is used depending on the entity subtype for the current row.

After exposing this method on the client row interface, client programs can use the custom row interface to invoke custom business functionality on a particular view row. [Example 42–16](#) shows the interesting lines of code from a `TestEntityPolymorphism` class. It iterates over all the rows in the `PersonList` view object instance, casts each one to the custom `PersonListRow` interface, and invokes the `performPersonFeature()` method.

**Example 42–16 Invoking a View Row Method That Delegates to an Entity Object**

```

PersonList personlist = (PersonList)am.findViewObject("PersonList");
personlist.executeQuery();
while (personlist.hasNext()) {
 PersonListRow person = (PersonListRow)personlist.next();
 System.out.print(person.getEmail()+"->");
 person.performPersonFeature();
}

```

Running the client code in [Example 42–16](#) produces the following output:

```

austin->## performPersonFeature as Supplier
hbaer->## performPersonFeature as Person
:
sking->## performPersonFeature as Staff
:

```

Rows related to `Persons` entities display a message confirming that the `performPersonFeature()` method in the `PersonsImpl` class was used. Rows related to `Supplier` and `Staff` entities display a different message, highlighting the different implementations that the respective `SupplierImpl` and `StaffImpl` classes have for the inherited `performPersonFeature()` method.

#### 42.6.4.3 Creating New Rows With the Desired Entity Subtype

In a view object with a polymorphic entity usage, when you create a new view row it contains a new entity row part whose type matches the base entity usage. To create a new view row with one of the entity *subtypes* instead, use the `createAndInitRow()` method. [Example 42–17](#) shows two custom methods in the `PersonList` view object's Java class that use `createAndInitRow()` to allow a client to create new rows having entity rows either of `Staff` or `Supplier` subtypes. To use the `createAndInitRow()`, as shown in the example, create an instance of the `NameValuePairs` object and set it to have an appropriate value for the discriminator attribute. Then, pass that `NameValuePairs` to the `createAndInitRow()` method to create a new view row with the appropriate entity row subtype, based on the value of the discriminator attribute you passed in.

**Example 42–17 Exposing Custom Methods to Create New Rows with Entity Subtypes**

```
// In PersonListImpl.java
public PersonListRow createStaffRow() {
 NameValuePairs nvp = new NameValuePairs();
 nvp.setAttribute("PersonTypeCode", "STAFF");
 return (PersonListRow)createAndInitRow(nvp);
}
public PersonListRow createSupplierRow() {
 NameValuePairs nvp = new NameValuePairs();
 nvp.setAttribute("PersonTypeCode", "SUPP");
 return (PersonListRow)createAndInitRow(nvp);
}
```

If you expose methods like this on the view object's custom interface, then at runtime, a client can call them to create new view rows with appropriate entity subtypes.

[Example 42–18](#) shows the interesting lines relevant to this functionality from a `TestEntityPolymorphism` class. First, it uses the `createRow()`, `createStaffRow()`, and `createSupplierRow()` methods to create three new view rows. Then, it invokes the `performPersonFeature()` method from the `PersonListRow` custom interface on each of the new rows.

As expected, each row handles the method in a way that is specific to the subtype of entity row related to it, producing the results:

```
performPersonFeature as Person
performPersonFeature as Staff
performPersonFeature as Supplier
```

**Example 42–18 Creating New View Rows with Different Entity Subtypes**

```
// In TestEntityPolymorphism.java
PersonListRow newPerson = (PersonListRow)Personlist.createRow();
PersonListRow newStaff = Personlist.createStaffRow();
PersonListRow newSupplier = Personlist.createSupplierRow();
newPerson.performPersonFeature();
newStaff.performPersonFeature();
newSupplier.performPersonFeature();
```

## 42.6.5 Working with Polymorphic View Rows

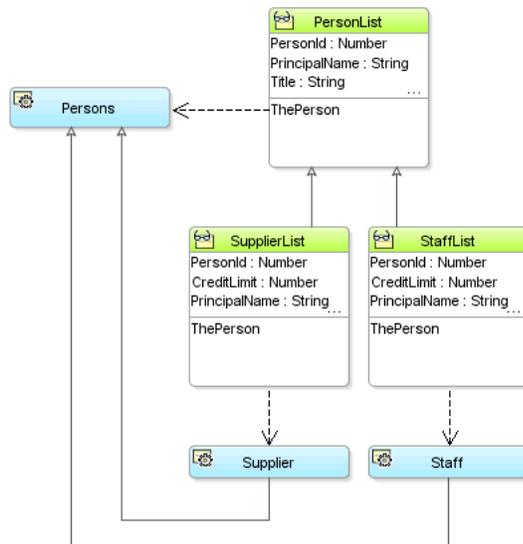

In the example shown in [Section 42.6, "Using View Objects to Work with Multiple Row Types,"](#) the polymorphism occurs "behind the scenes" at the entity object level. Since the client code works with all view rows using the same `PersonListRow` interface, it cannot distinguish between rows based on a `Staff` entity object from those based on a `Persons` entity object. The code works with all view rows using the same set of view row attributes and methods common to all types of underlying entity subtypes.

If you configure a view object to support polymorphic view rows, then the client can work with different types of view rows using a view row interface specific to the type of row it is. By doing this, the client can access view attributes or invoke view row methods that are specific to a given subtype as needed. [Figure 42–11](#) illustrates the hierarchy of view objects that enables this feature for the `PersonList` example considered above. `SupplierList` and `StaffList` are view objects that extend the base `PersonList` view object. Notice that each one includes an additional attribute specific to the subtype of `Person` they have as their entity usage. `SupplierList` includes an additional `ContractExpires` attribute, while `StaffList` includes the additional `DiscountEligible` attribute. When configured for view row polymorphism as described in the next section, a client can work with the results of the `PersonList` view object using:

- `PersonListRow` interface for view rows related to persons
- `SupplierListRow` interface for view rows related to suppliers
- `StaffListRow` interface for view rows related to staff

As you'll see, this allows the client to access the additional attributes and view row methods that are specific to a given subtype of view row.

**Figure 42–11 Hierarchy of View Object Subtypes Enables View Row Polymorphism**

### 42.6.6 How to Create a View Object with Polymorphic View Rows

To create a view object with polymorphic view rows, follow these steps:

1. In the Application Navigator, double-click the view object that you want to be the base.

In the example above, the `PersonList` view object is the base.

2. In the overview editor, click the **Attributes** navigation tab and select a discriminator attribute for the view row, and then click the **Details** tab.
3. In the Details section, give the discriminator attribute a default value and check the **Polymorphic Discriminator** checkbox to mark the attribute as the one that distinguishes which view row interface to use.

You must supply a value for the **Subtype Value** field that matches the attribute value for which you expect the base view object's view row interface to be used. For example, in the `PersonList` view object, you would mark the `PersonTypeCode` attribute as the discriminator attribute and supply a default subtype value of "person".

4. Enable a custom view row class for the base view object, and expose at least one method on the client row interface. This can be one or all of the view row attribute accessor methods, as well as any custom view row methods.
5. Create a new view object that *extends* the base view object
 

In the example above, `SupplierList` extends the base `PersonList` view object.
6. Enable a custom view row class for the extended view object.

If appropriate, add additional custom view row methods or override custom view row methods inherited from the parent view object's row class.

7. Supply a *distinct* value for the discriminator attribute in the extended view object.

The `SupplierList` view object provides the value of "SUPP" for the `PersonTypeCode` discriminator attribute.

8. Repeat steps 4-6 to add additional extended view objects as needed.

For example, the `StaffList` view object is a second one that extends `PersonList`. It supplies the value "STAFF" for the `PersonTypeCode` discriminator attribute.

After setting up the view object hierarchy, you need to define the list of view object subtypes that participate in the view row polymorphism. To accomplish this, do the following:

1. Add an instance of each type of view object in the hierarchy to the data model of an application module.

For example, the `PersonModule` application module in the example has instances of `PersonList`, `SupplierList`, and `StaffList` view objects.

2. In the overview editor for the application module, click the **Data Model** navigation tab and click the **Subtypes** button.

3. In the **Subtypes** dialog that appears, shuttle the desired view object subtypes that you want to participate in view row polymorphism from the **Available** to the **Selected** list, and click **OK**.

## 42.6.7 What You May Need to Know About Polymorphic View Rows

This section provides additional information to help you work with polymorphic view rows.

### 42.6.7.1 Selecting Subtype-Specific Attributes in Extended View Objects

When you create an extended view object, it inherits the entity usage of its parent. If the parent view object's entity usage is based on an entity object with subtypes in your domain layer, you may want your extended view object to work with one of these subtypes instead of the inherited parent entity usage type. Two reasons you might want to do this are:

1. To select attributes that are *specific* to the entity subtype
2. To be able to write view row methods that delegate to methods *specific* to the entity subtype

In order to do this, you need to override the inherited entity usage to refer to the desired entity subtype. To do this, perform these steps in the overview editor for your extended view object:

1. In the Application Navigator, double-click the view object.
2. In the overview editor, click the **Entity Objects** navigation tab and verify that you are working with an extended entity usage.

For example, when creating the `SupplierList` view object that extends the `PersonList` view object, the entity usage with the alias `ThePerson` will initially display in the **Selected** list as: **ThePerson(Person): extended**. The type of the entity usage is in parenthesis, and the "extended" label confirms that the entity usage is currently inherited from its parent.

3. Select the desired entity *subtype* in the **Available** list that you want to override the inherited one. It must be a subtype entity of the existing entity usage's type.

For example, you would select the `Supplier` entity object in the **Available** list to overridden the inherited entity usage based on the `Persons` entity type.

4. Click **>** to shuttle it to the **Selected** list
5. Acknowledge the alert that appears, confirming that you want to override the existing, inherited entity usage.

When you have performed these steps, the **Selected** list updates to reflect the overridden entity usage. For example, for the `SupplierList` view object, after overriding the `Persons`-based entity usage with the `Supplier` entity subtype, it updates to show: **ThePerson (Supplier): overridden.**

After overriding the entity usage to be related to an entity subtype, you can then use the **Attributes** tab of the editor to select additional attributes that are specific to the subtype. For example, the `SupplierList` view object includes the additional attribute named `ContractExpires` that is specific to the `Supplier` entity object.

#### 42.6.7.2 Delegating to Subtype-Specific Methods After Overriding the Entity Usage

After overriding the entity usage in an extended view object to reference a subtype entity, you can write view row methods that delegate to methods specific to the subtype entity class. [Example 42–19](#) shows the code for a `performSupplierFeature()` method in the custom view row class for the `SupplierList` view object. It casts the return value from the `getThePerson()` entity row accessor to the subtype `SupplierImpl`, and then invokes the `performSupplierFeature()` method that is specific to `Supplier` entity objects.

##### **Example 42–19 View Row Method Delegating to Method in Subtype Entity**

```
// In SupplierListRowImpl.java
public void performSupplierFeature() {
 SupplierImpl supplier = (SupplierImpl) getThePerson();
 supplier.performSupplierFeature();
}
```

---

**Note:** You need to perform the explicit cast to the entity subtype here because `JDeveloper` does not yet take advantage of the `JDK` feature called covariant return types that would allow a subclass like `SupplierListRowImpl` to override a method like `getThePerson()` and change its return type.

---

#### 42.6.7.3 Working with Different View Row Interface Types in Client Code

[Example 42–20](#) shows the interesting lines of code from a `TestViewRowPolymorphism` class that performs the following steps:

1. Iterates over the rows in the `PersonList` view object.
 

For each row in the loop, it uses Java's `instanceof` operator to test whether the current row is an instance of the `StaffListRow` or the `SupplierListRow`.
2. If the row is a `StaffListRow`, then cast it to this more specific type and:
  - Call the `performStaffFeature()` method specific to the `StaffListRow` interface, and

- Access the value of the `DiscountEligible` attribute that is specific to the `StaffList` view object.
- 3. If the row is a `SupplierListRow`, then cast it to this more specific type and:
  - Call the `performSupplierFeature()` method specific to the `SupplierListRow` interface, and
  - Access the value of the `ContractExpires` attribute that is specific to the `SupplierList` view object.
- 4. Otherwise, just call a method on the `PersonListRow`

#### **Example 42–20 Using View Row Polymorphism in Client Code**

```
// In TestViewRowPolymorphism.java
ViewObject vo = am.findViewObject("PersonList");
vo.executeQuery();
// 1. Iterate over the rows in the PersonList view object
while (vo.hasNext()) {
 PersonListRow person = (PersonListRow)vo.next();
 System.out.print(Person.getEmail()+"-");
 if (Person instanceof StaffListRow) {
 // 2. If the row is a StaffListRow, cast it
 StaffListRow mgr = (StaffListRow)person;
 mgr.performStaffFeature();
 System.out.println("Discount Status: "+mgr.getDiscountEligible());
 }
 else if (Person instanceof SupplierListRow) {
 // 3. If the row is a SupplierListRow, cast it
 SupplierListRow tech = (SupplierListRow)person;
 tech.performSupplierFeature();
 System.out.println("Contract expires: "+tech.getContractExpires());
 }
 else {
 // 4. Otherwise, just call a method on the PersonListRow
 person.performPersonFeature();
 }
}
}
```

Running the code in [Example 42–20](#) produces the following output:

```
daustin->## performSupplierFeature called
Contract expires: 2006-05-09
hbaer->## performPersonFeature as Person
:
sking->## performStaffFeature called
Discount Status: Y
:
```

This illustrates that by using the view row polymorphism feature the client was able to distinguish between view rows of different types and access methods and attributes specific to each subtype of view row.

#### **42.6.7.4 View Row Polymorphism and Polymorphic Entity Usage are Orthogonal**

While often even more useful when used *together*, the view row polymorphism and the polymorphic entity usage features are distinct and can be used separately. In particular, the view row polymorphism feature can be used for read-only view objects, as well as for entity-based view objects. When you combine both mechanisms, you can have both the entity row part being polymorphic, as well as the view row type.

Note to use view row polymorphism with either view objects or entity objects, you must configure the discriminator attribute property separately for each. This is necessary because read-only view objects contain no related entity usages from which to infer the discriminator information.

In summary, to use view row polymorphism:

1. Configure an attribute to be the discriminator at the view object level in the root view object in an inheritance hierarchy.
2. Have a hierarchy of inherited view objects each of which provides a distinct value for the Subtype Value property of that view object level discriminator attribute (identified as `DefaultValue` for the attribute in the view object definition file).
3. List the subclassed view objects in this hierarchy in the application module's list of Subtypes.

Whereas, to create a view object with a polymorphic entity usage:

1. Configure an attribute to be the discriminator at the entity object level in the root entity object in an inheritance hierarchy.
2. Have a hierarchy of inherited entity objects, each of which overrides and provides a distinct value for the Subtype Value property of that entity object level discriminator attribute.
3. List the subclassed entity objects in a view object's list of Subtypes.

## 42.7 Reading and Writing XML

The Extensible Markup Language (XML) standard from the Worldwide Web Consortium (W3C) defines a language-neutral approach for electronic data exchange. Its rigorous set of rules enables the structure inherent in data to be easily encoded and unambiguously interpreted using human-readable text documents.

View objects support the ability to write these XML documents based on their queried data. View objects also support the ability to read XML documents in order to apply changes to data including inserts, updates, and deletes. When you've introduced view links, this XML capability supports reading and writing multi-level nested information for master-detail hierarchies of any complexity. While the XML produced and consumed by view objects follows a canonical format, you can combine the view object's XML features with XML Stylesheet Language Transformations (XSLT) to easily convert between this canonical XML format and any format you need to work with.

---

---

**Note:** The example in this section refers to the `ReadingAndWritingXML` project in the `AdvancedViewObjectsExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

### 42.7.1 How to Produce XML for Queried Data

To produce XML from a view object, use the `writeXML()` method. It offers two ways to control the XML produced:

1. For precise control over the XML produced, you can specify a view object attribute map indicating which attributes should appear, including which view link accessor attributes should be accessed for nested, detail information:

```
Node writeXML(long options, HashMap voAttrMap)
```

2. To producing XML that includes all attributes, you can simply specify a depth-level that indicates how many levels of view link accessor attributes should be traversed to produce the result:

```
Node writeXML(int depthCount, long options)
```

The `options` parameter is a integer flag field that can be set to one of the following bit flags:

- `XMLInterface.XML_OPT_ALL_ROWS`  
Includes all rows in the view object's row set in the XML.
- `XMLInterface.XML_OPT_LIMIT_RANGE`  
Includes only the rows in the current range in the XML.

Using the logical OR operation, you can combine either of the above flags with the `XMLInterface.XML_OPT_ASSOC_CONSISTENT` flag when you want to include new, unposted rows in the current transaction in the XML output.

Both versions of the `writeXML()` method accept an optional third argument which is an XSLT stylesheet that, if supplied, is used to transform the XML output before returning it.

## 42.7.2 What Happens When You Produce XML

When you produce XML using `writeXML()`, the view object begins by creating a wrapping XML element whose default name matches the name of the view object definition. For example, for a `Persons` view object in the `devguide.advanced.xml.queries` package, the XML produces will be wrapped in an outermost `<Persons>` tag.

Then, it converts the attribute data for the appropriate rows into XML elements. By default, each row's data is wrapped in an row element whose name is the name of the view object with the `Row` suffix. For example, each row of data from a view object named `Persons` is wrapped in an `<PersonsRow>` element. The elements representing the attribute data for each row appear as nested children inside this row element.

If any of the attributes is a view link accessor attribute, and if the parameters passed to `writeXML()` enable it, the view object will include the data for the detail rowset returned by the view link accessor. This nested data is wrapped by an element whose name is determined by the name of the view link accessor attribute. The return value of the `writeXML()` method is an object that implements the standard W3C `Node` interface, representing the root element of the generated XML.

---

**Note:** The `writeXML()` method uses view link accessor attributes to programmatically access detail collections. It does not require adding view link instances in the data model.

---

For example, to produce an XML element for all rows of a `Persons` view object instance, and following view link accessors as many levels deep as exists, [Example 42-21](#) shows the code required.

### **Example 42-21** *Generating XML for All Rows of a View Object to All View Link Levels*

```
ViewObject vo = am.findViewObject("PersonsView");
printXML(vo.writeXML(-1, XMLInterface.XML_OPT_ALL_ROWS));
```

The `Persons` view object is linked to a `Orders` view object showing the orders created by that person. In turn, the `Orders` view object is linked to a `OrderItems` view object providing details on the items ordered by customers. Running the code in [Example 42–21](#) produces the XML shown in [Example 42–22](#), reflecting the nested structure defined by the view links.

**Example 42–22 XML from a Persons View Object with Two Levels of View Linked Details**

```

## 42.7.3 What You May Need to Know About Reading and Writing XML

This section provides additional information to help you work with XML.

### 42.7.3.1 Controlling XML Element Names

You can use the Property Inspector to change the default XML element names used in the view object's canonical XML format by setting several properties. To accomplish this, open the overview editor for the view object, then:

- Select the attribute on the Attributes page and in the Property Inspector, select the Custom Properties navigation tab and set the custom *attribute*-level property named **Xml Element** to a value *SomeOtherName* to change the XML element name used for that attribute to `<SomeOtherName>`

For example, the Email attribute in the Persons view object defines this property to change the XML element you see in [Example 42-22](#) to be `<EmailAddress>` instead of `<Email>`.

- Select the General navigation tab in the Property Inspector and set the custom *view object*-level property named **Xml Row Element** to a value *SomeOtherRowName* to change the XML element name used for that view object to `<SomeOtherRowName>`.

For example, the `Persons` view object defines this property to change the XML element name for the rows you see in [Example 42–22](#) to be `<Person>` instead of `<PersonsRow>`.

- To change the name of the element names that wrapper nested row set data from view link attribute accessors, use the View Link Properties dialog. To open the dialog, in the view link overview editor, click the **Edit accessors** icon on the Accessors section of Relationship page. Enter the desired name of the view link accessor attribute in the **Accessor Name** field.

### 42.7.3.2 Controlling Element Suppression for Null-Valued Attributes

By default, if a view row attribute is `null`, then its corresponding element is omitted from the generated XML. Select the attribute on the Attributes page of the overview editor and in the Property Inspector, select the Custom Properties navigation tab and set the custom *attribute*-level property named **Xml Explicit Null** to any value (e.g. `"true"` or `"yes"`) to cause an element to be included for the attribute if its value is `null`. For example, if an attribute named `AssignedDate` has this property set, then a row containing a `null` assigned date will contain a corresponding `<AssignedDate null="true"/>` element. If you want this behavior for all attributes of a view object, you can define the **Xml Explicit Null** custom property at the view object level as a shortcut for defining it on each attribute.

### 42.7.3.3 Printing or Searching the Generated XML Using XPath

Two of the most common things you might want to do with the `XMLNode` object returned from `writeXML()` are:

1. Printing the node to its serialized text representation — to send across the network or save in a file, for example
2. Searching the generated XML using W3C XPath expressions

Unfortunately, the standard W3C Document Object Model (DOM) API does not include methods for doing *either* of these useful operations. But there is hope. Since ADF Business Components uses the Oracle XML parser's implementation of the DOM, you can cast the `Node` return value from `writeXML()` to the Oracle specific classes `XMLNode` or `XMLElement` (in the `oracle.xml.parser.v2` package) to access additional useful functionality like:

- Printing the XML element to its serialized text format using the `print()` method
- Searching the XML element in memory with XPath expressions using the `selectNodes()` method
- Finding the value of an XPath expression related to the XML element using the `valueOf()` method.

[Example 42–23](#) shows the `printXML()` method in the `TestClientWriteXML`. It casts the `Node` parameter to an `XMLNode` and calls the `print()` method to dump the XML to the console.

#### **Example 42–23 Using the XMLNode's print() Method to Serialize XML**

```
// In TestClientWriteXML.java
private static void printXML(Node n) throws IOException {
 ((XMLNode)n).print(System.out);
}
```

#### 42.7.3.4 Using the Attribute Map For Fine Control Over Generated XML

When you need fine control over which attributes appear in the generated XML, use the version of the `writeXML()` method that accepts a `HashMap`. [Example 42–24](#) shows the interesting lines from a `TestClientWriteXML` class that use this technique. After creating the `HashMap`, you put `String[]`-valued entries into it containing the names of the attributes you want to include in the XML, keyed by the fully-qualified name of the view definition those attributes belong to. The example includes the `PersonId`, `Email`, `PersonTypeCode`, and `OrdersView` attributes from the `Persons` view object, and the `OrderId`, `OrderStatusCode`, and `OrderTotal` attributes from the `OrdersView` view object.

---

**Note:** For upward compatibility reasons with earlier versions of ADF Business Components the `HashMap` expected by the `writeXML()` method is the one in the `com.sun.java.util.collections` package.

---

While processing the view rows for a given view object instance:

- If an entry exists in the attribute map with a key matching the fully-qualified view definition name for that view object, then only the attributes named in the corresponding `String` array are included in the XML.

Furthermore, if the string array includes the name of a view link accessor attribute, then the nested contents of its detail row set are included in the XML. If a view link accessor attribute name does not appear in the string array, then the contents of its detail row set are not included.

- If no such entry exists in the map, then *all* attributes for that row are included in the XML.

#### **Example 42–24 Using a View Definition Attribute Map for Fine Control Over Generated XML**

```
HashMap viewDefMap = new HashMap();
viewDefMap.put("devguide.advanced.xml.queries.PersonsView",
 new String[]{"PersonId", "Email", "PersonTypeCode",
 "OrdersView" /* View link accessor attribute */
 });
viewDefMap.put("devguide.advanced.xml.queries.OrdersView",
 new String[]{"OrderId", "OrderStatusCode", "OrderTotal"});
printXML(vo.writeXML(XMLInterface.XML_OPT_ALL_ROWS, viewDefMap));
```

Running the example produces the XML shown in [Example 42–25](#), including only the exact attributes and view link accessors indicated by the supplied attribute map.

#### **Example 42–25 XML from a Users View Object Produced Using an Attribute Map**

```
<OrdersViewRow>
 <OrderId>1033</OrderId>
 <OrderDate>2009-01-30 13:59:39.0</OrderDate>
 <OrderShippedDate>2009-02-02 13:59:39.0</OrderShippedDate>
 <OrderStatusCode>COMPLETE</OrderStatusCode>
 <OrderTotal>2677.96</OrderTotal>
 <CustomerId>108</CustomerId>
 <ShipToAddressId>20</ShipToAddressId>
 <ShippingOptionId>1</ShippingOptionId>
 <PaymentOptionId>1016</PaymentOptionId>
 <DiscountId>3</DiscountId>
```

```

<FreeShippingFlag>Y</FreeShippingFlag>
<CustomerCollectFlag>Y</CustomerCollectFlag>
<CollectionWarehouseId>101</CollectionWarehouseId>

 <ObjectVersionId>0</ObjectVersionId>
 </OrderItemsViewRow>
</OrderItemsView>
</OrdersViewRow>
...

```

#### 42.7.3.5 Use the Attribute Map Approach with Bi-Directional View Links

If your view objects are related through a view link that you have configured to be bi-directional, then you must use the `writeXML()` approach that uses the attribute map. If you were to use the `writeXML()` approach in the presence of bi-directional view links and were to supply a maximum depth of `-1` to include all levels of view links that exist, the `writeXML()` method will go into an infinite loop as it follows the bi-directional view links back and forth, generating deeply nested XML containing duplicate data until it runs out of memory. Use `writeXML()` with an attribute map instead in this situation. Only by using this approach can you control which view link accessors are included in the XML and which are not to avoid infinite recursion while generating the XML.

#### 42.7.3.6 Transforming Generated XML Using an XSLT Stylesheet

When the canonical XML format produced by `writeXML()` does not meet your needs, you can supply an XSLT stylesheet as an optional argument. It will produce the XML as it would normally, but then transform that result using the supplied stylesheet before returning the final XML to the caller.

Consider the XSLT stylesheet shown in [Example 42–26](#). It is a simple transformation with a single template that matches the root element of the generated XML from [Example 42–25](#) to create a new `<CustomerEmailAddresses>` element in the result. The template uses the `<xsl:for-each>` instruction to process all `<PersonsView>` elements that contain more than one `<OrdersViewRow>` child element inside a nested `<OrdersViews>` element. For each `<PersonsView>` element that qualifies, it creates a `<Customer>` element in the result whose `Contact` attribute is populated from the value of the `<Email>` child element of the `<PersonsView>`.

**Example 42–26 XSLT Stylesheet to Transform Generated XML Into Another Format**

```
<?xml version="1.0" encoding="windows-1252" ?>
<xsl:stylesheet version="1.0" xmlns:xsl="http://www.w3.org/1999/XSL/Transform">
 <xsl:template match="/">
 <CustomerEmailAddresses>
 <xsl:for-each
 select="/PersonsView/PersonsViewRow[count(OrdersView/OrdersViewRow) >
 1]">
 <xsl:sort select="Email"/>
 <Customer Contact="{Email}"/>
 </xsl:for-each>
 </CustomerEmailAddresses>
 </xsl:template>
</xsl:stylesheet>
```

[Example 42–27](#) shows the interesting lines from a `TestClientWriteXML` class that put this XSLT stylesheet into action when calling `writeXML()`.

**Example 42–27 Passing an XSLT Stylesheet to writeXML() to Transform the Resulting XML**

```
// In TestClientWriteXML.java
XSLStylesheet xsl = getXSLStylesheet();
printXML(vo.writeXML(XMLInterface.XML_OPT_ALL_ROWS, viewDefMap, xsl));
```

Running the code in [Example 42–27](#) produces the transformed XML shown here:

```
<CustomerEmailAddresses>
 <Customer Contact="dfaviet"/>
 <Customer Contact="jchen"/>
 <Customer Contact="ngreenbe"/>
</CustomerEmailAddresses>
```

The `getXSLStylesheet()` helper method shown in [Example 42–28](#) is also interesting to study since it illustrates how to read a resource like an XSLT stylesheet from the classpath at runtime. The code expects the `Example.xsl` stylesheet to be in the same directory as the `TestClientWriteXML` class. By referencing the `Class` object for the `TestClientWriteXML` class using the `.class` operator, the code uses the `getResource()` method to get a URL to the resource. Then, it passes the URL to the `newXSLStylesheet()` method of the `XSLProcessor` class to create a new `XSLStylesheet` object to return. That object represents the compiled version of the XSLT stylesheet read in from the `*.xsl` file.

**Example 42–28 Reading an XSLT Stylesheet as a Resource from the Classpath**

```
private static XSLStylesheet getXSLStylesheet()
 throws XMLParseException, SAXException, IOException, XSLException {
 String xslurl = "Example.xsl";
 URL xslURL = TestClientWriteXML.class.getResource(xslurl);
```

```
XSLProcessor xslProc = new XSLProcessor();
return xslProc.newXSLStylesheet(xslURL);
}
```

---

---

**Note:** When working with resources like XSLT stylesheets that you want to be included in the output directory along with your compiled Java classes and XML metadata, you can use the **Compiler** page of the **Project Properties** dialog to update the **Copy File Types to Output Directory** field to include `.xsl` in the semicolon-separated list.

---

---

### 42.7.3.7 Generating XML for a Single Row

In addition to calling `writeXML()` on a view object, you can call the same method with the same parameters and options on any `Row` as well. If the `Row` object on which you call `writeXML()` is a entity row, you can bitwise-OR the additional `XMLInterface.XML_OPT_CHANGES_ONLY` flag if you only want the changed entity attributes to appear in the XML.

## 42.7.4 How to Consume XML Documents to Apply Changes

To have a view object consume an XML document to process inserts, updates, and deletes, use the `readXML()` method:

```
void readXML(Element elem, int depthcount)
```

The canonical format expected by `readXML()` is the same as what would be produced by a call to the `writeXML()` method on the same view object. If the XML document to process does not correspond to this canonical format, you can supply an XSLT stylesheet as an optional third argument to `readXML()` to transform the incoming XML document *into* the canonical format before it is read for processing.

## 42.7.5 What Happens When You Consume XML Documents

When a view object consumes an XML document in canonical format, it processes the document to recognize row elements, their attribute element children, and any nested elements representing view link accessor attributes. It processes the document recursively to a maximum level indicated by the `depthcount` parameter. Passing `-1` for the `depthcount` to request that it process all levels of the XML document.

### 42.7.5.1 How `ViewObject.readXML()` Processes an XML Document

For each row element it recognizes, the `readXML()` method does the following:

- Identifies the related view object to process the row.
- Reads the children attribute elements to get the values of the primary key attributes for the row.
- Performs a `findByKey()` using the primary key attributes to detect whether the row already exists or not.
- If the row exists:
  - If the row element contains the marker attribute `bc4j-action="remove"`, then the existing row is deleted.
  - Otherwise, the row's attributes are updated using the values in any attribute element children of the current row element in the XML

- If the row does not exist, then a new row is created, inserted into the view object's rowset. Its attributes are populated using the values in any attribute element children of the current row element in the XML.

#### 42.7.5.2 Using readXML() to Processes XML for a Single Row

The same `readXML()` method is also supported on any `Row` object. The canonical XML format it expects is the same format produced by a call to `writeXML()` on the same row. You can invoke `readXML()` method on a row to:

- Update its attribute values from XML
- Remove the row, if the `bc4j-action="remove"` marker attribute is present on the corresponding row element.
- Insert, update, or delete any nested rows via view link accessors

Consider the XML document shown in [Example 42–29](#). It is in the canonical format expected by a single row in the `PersonsView` view object. Nested inside the root `<PersonsViewRow>` element, the `<ConfirmedEmail>` attribute represents the customer's email address. The nested `<OrdersView>` element corresponds to the `Orders` view link accessor attribute and contains three `<OrdersViewRow>` elements. Each of these includes `<OrderId>` elements representing the primary key of a `OrdersView` row.

#### **Example 42–29 XML Document in Canonical Format to Insert, Update, and Delete Rows**

```
<PersonsViewRow>
 <!-- This will update Person's ConfirmedEmail attribute -->
 <PersonId>110</PersonId>
 <ConfirmedEmail>NewConfirmed</ConfirmedEmail>
 <OrdersView>
 <!-- This will be an update since it does exist -->
 <OrdersViewRow>
 <OrderId>1011</OrderId>
 <OrderStatusCode>SHIP</OrderStatusCode>
 </OrdersViewRow>
 <!-- This will be an insert since it doesn't exist -->
 <OrdersViewRow>
 <OrderId>1070</OrderId>
 <OrderStatusCode>PENDING</OrderStatusCode>
 </OrdersViewRow>
 <!-- This will be deleted -->
 <OrdersViewRow bc4j-action="remove">
 <OrderId>1026</OrderId>
 </OrdersViewRow>
 </OrdersView>
</PersonsViewRow>
```

[Example 42–30](#) shows the interesting lines of code from a `TestClientReadXML` class that applies this XML datagram to a particular row in the `PersonsView` view object. `TestClientReadXML` class performs the following basic steps:

1. Finds a target row by key (e.g. for customer "jchen").
2. Shows the XML produced for the row before changes are applied.
3. Obtains the parsed XML document with changes to apply using a helper method.
4. Reads the XML document to apply changes to the row.
5. Shows the XML with the pending changes applied.

TestClientReadXML class is using the `XMLInterface.XML_OPT_ASSOC_CONSISTENT` flag described in [Section 42.7.1, "How to Produce XML for Queried Data"](#) to ensure that new, unposted rows are included in the XML.

**Example 42–30 Applying Changes to an Existing Row with readXML()**

```
ViewObject vo = am.findViewObject("CustomersView");
Key k = new Key(new Object[] { 110 });
// 1. Find a target row by key (e.g. for customer "jchen")
Row jchen = vo.findByKey(k, 1)[0];
// 2. Show the XML produced for the row before changes are applied
printXML(jchen.writeXML(-1, XMLInterface.XML_OPT_ALL_ROWS));
// 3. Obtain parsed XML document with changes to apply using helper method
Element xmlToRead = getInsertUpdateDeleteXMLGram();
printXML(xmlToRead);
// 4. Read the XML document to apply changes to the row
jchen.readXML(getInsertUpdateDeleteXMLGram(), -1);
// 5. Show the XML with the pending changes applied
printXML(jchen.writeXML(-1, XMLInterface.XML_OPT_ALL_ROWS |
XMLInterface.XML_OPT_ASSOC_CONSISTENT));
```

Running the code in [Example 42–30](#) initially displays the "before" version of John Chen's information. Notice that:

- The `ConfirmedEmail` attribute has the value "JCHEN"
- The status code for order 1011 has a level of "CANCEL"
- There is an orders row for order 1026, and
- There is no orders row related to order 1070.

```
<PersonsViewRow>
 <PersonId>110</PersonId>
 <PrincipalName>JCHEN</PrincipalName>
 <FirstName>John</FirstName>
 <LastName>Chen</LastName>
 <PersonTypeCode>CUST</PersonTypeCode>
 <ProvisionedFlag>N</ProvisionedFlag>
 <PrimaryAddressId>37</PrimaryAddressId>
 <MembershipId>1</MembershipId>
 <Email>JCHEN</Email>
 <ConfirmedEmail>JCHEN</ConfirmedEmail>
 <PhoneNumber>706.555.0103</PhoneNumber>
 <DateOfBirth>1967-09-28</DateOfBirth>
 <MaritalStatusCode>MARR</MaritalStatusCode>
 <Gender>M</Gender>
 <ContactableFlag>Y</ContactableFlag>
 <ContactByAffiliatesFlag>Y</ContactByAffiliatesFlag>
 <CreatedBy>SEED_DATA</CreatedBy>
 <CreationDate>2009-02-23 13:59:38.0</CreationDate>

 <ObjectVersionId>0</ObjectVersionId>
 </OrderItemsViewRow>
 </OrderItemsView>
 </OrdersViewRow>
 ...

```

After applying the changes from the XML document using `readXML()` to the row and printing its XML again using `writeXML()` you see that:

- The `ConfirmedEmail` is now "NewConfirmed"
- A new orders row for order 1070 got created.
- The status code for order 1011 has a level of "SHIP", and
- The orders row for order 1026 is removed

```

<PersonsViewRow>

...

```

---

**Note:** The example illustrated using `readXML()` to apply changes to a single row. If the XML document contained a wrapping `<PersonsView>` row, including the primary key attribute in each of its one or more nested `<PersonsViewRow>` elements, then that document could be processed using the `readXML()` method on the `PersonsView` view object for handling operations for multiple `PersonsView` rows.

---

## 42.8 Using Programmatic View Objects for Alternative Data Sources

By default view objects read their data from the database and automate the task of working with the Java Database Connectivity (JDBC) layer to process the database result sets. However, by overriding appropriate methods in its custom Java class, you can create a view object that programmatically retrieves data from alternative data sources like a `REF CURSOR`, an in-memory array, or a Java `*.properties` file, to name a few.

## 42.8.1 How to Create a Read-Only Programmatic View Object

To create a read-only programmatic view object, you use the Create View Object wizard.

### To create the read-only programmatic view object:

1. In the Application Navigator, right-click the project in which you want to create the view object and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **View Object**, and click **OK**.
3. In the Create View Object wizard, in the Name page, provide a name and package for the view object. For the data source, select **Rows populated programmatically, not based on a query**.
4. In the Attributes page, click **New** one or more times to define the view object attributes your programmatic view object requires.
5. In the Attribute Settings page, adjust any setting you may need to for the attributes you defined.
6. In the Java page, select **Generate View Object Class** to enable a custom view object class (`ViewObjImpl`) to contain your code.
7. Click **Finish** to create the view object.

In your view object's custom Java class, override the methods described in [Section 42.8.3, "Key Framework Methods to Override for Programmatic View Objects"](#) to implement your custom data retrieval strategy.

## 42.8.2 How to Create an Entity-Based Programmatic View Object

To create an entity-based view object with programmatic data retrieval, create the view object in the normal way, enable a custom Java class for it, and override the methods described in the next section to implement your custom data retrieval strategy.

## 42.8.3 Key Framework Methods to Override for Programmatic View Objects

A programmatic view object typically overrides all of the following methods of the base `ViewObjectImpl` class to implement its custom strategy for retrieving data:

- `create()`

This method is called when the view object instance is created and can be used to initialize any state required by the programmatic view object. At a minimum, this overridden method will contain the following lines to ensure the programmatic view object has no trace of a SQL query related to it:

```
// Wipe out all traces of a query for this VO
getViewDef().setQuery(null);
getViewDef().setSelectClause(null);
setQuery(null);
```

- `executeQueryForCollection()`

This method is called whenever the view object's query needs to be executed (or re-executed).

- `hasNextForCollection()`

This method is called to support the `hasNext()` method on the row set iterator for a row set created from this view object. Your implementation returns `true` if you have not yet exhausted the rows to retrieve from your programmatic data source.

- `createRowFromResultSet()`

This method is called to populate each row of "fetched" data. Your implementation will call `createNewRowForCollection()` to create a new blank row and then `populateAttributeForRow()` to populate each attribute of data for the row.

- `getQueryHitCount()`

This method is called to support the `getEstimatedRowCount()` method. Your implementation returns a count, or estimated count, of the number of rows that will be retrieved by the programmatic view object's query.

- `protected void releaseUserDataForCollection()`

Your code can store and retrieve a user data context object with each row set. This method is called to allow you to release any resources that may be associated with a row set that is being closed.

Since the view object component can be related to several active row sets at runtime, many of the above framework methods receive an `Object` parameter named `qc` in which the framework will pass the collection of rows in question that your code is supposed to be filling, as well as the array of bind variable values that might affect which rows get populated into the specific collection.

You can store a user-data object with each collection of rows so your custom datasource implementation can associate any needed datasource context information. The framework provides the `setUserDataForCollection()` and `getUserDataForCollection()` methods to get and set this per-collection context information. Each time one of the overridden framework methods is called, you can use the `getUserDataForCollection()` method to retrieve the correct `ResultSet` object associated with the collection of rows the framework wants you to populate.

The examples in the following sections each override these methods to implement different kinds of programmatic view objects.

#### 42.8.4 How to Create a View Object on a REF CURSOR

Sometimes your application might need to work with the results of a query that is encapsulated within a stored procedure. PL/SQL allows you to open a cursor to iterate through the results of a query, and then return a reference to this cursor to the client. This so-called `REF CURSOR` is a handle with which the client can then iterate the results of the query. This is possible even though the client never actually issued the original SQL `SELECT` statement.

---

---

**Note:** The example in this section refers to the `ViewObjectOnRefCursor` project in the `AdvancedViewObjectsExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

Declaring a PL/SQL package with a function that returns a `REF CURSOR` is straightforward. For example, your package might look like this:

```
CREATE OR REPLACE PACKAGE RefCursorExample IS
```

```

TYPE ref_cursor IS REF CURSOR;
FUNCTION get_orders_for_customer(p_email VARCHAR2) RETURN ref_cursor;
FUNCTION count_orders_for_customer(p_email VARCHAR2) RETURN NUMBER;
END RefCursorExample;

```

After defining an entity-based `OrdersForCustomer` view object with an entity usage for a `Order` entity object, go to its custom Java class `OrdersForCustomerImpl.java`. At the top of the view object class, define some constant `Strings` to hold the anonymous blocks of PL/SQL that you'll execute using `JDBC CallableStatement` objects to invoke the stored functions:

```

/*
 * Execute this block to retrieve the REF CURSOR
 */
private static final String SQL =
 "begin ? := RefCursorSample.get_orders_for_customer(?);end;";
/*
 * Execute this block to retrieve the count of orders that
 * would be returned if you executed the statement above.
 */
private static final String COUNTSQL =
 "begin ? := RefCursorSample.count_orders_for_customer(?);end;";

```

Then, override the methods of the view object as described in the following sections.

#### 42.8.4.1 The Overridden `create()` Method

The `create()` method removes all traces of a SQL query for this view object.

```

protected void create() {
 getViewDef().setQuery(null);
 getViewDef().setSelectClause(null);
 setQuery(null);
}

```

#### 42.8.4.2 The Overridden `executeQueryForCollection()` Method

The `executeQueryForCollection()` method is executed when the framework needs to issue the database query for the query collection based on this view object. One view object can produce many related result sets, each potentially the result of different bind variable values. If the row set in query is involved in a framework-coordinated master/detail view link, then the `params` array will contain one or more framework-supplied name-value pairs of bind parameters from the source view object. If there are any user-supplied bind parameter values, they will *precede* the framework-supplied bind variable values in the `params` array, and the number of user parameters will be indicated by the value of the `numUserParams` argument.

The method calls a helper method `retrieveRefCursor()` to execute the stored function and return the `REF CURSOR` return value, cast as a `JDBC ResultSet`.

```

protected void executeQueryForCollection(Object qc, Object[] params,
 int numUserParams) {
 storeNewResultSet(qc, retrieveRefCursor(qc, params));
 super.executeQueryForCollection(qc, params, numUserParams);
}

```

Then, it calls the helper method `storeNewResultSet()` that uses the `setUserDataForCollection()` method to store this `ResultSet` with the collection of rows for which the framework is asking to execute the query.

```

private void storeNewResultSet(Object qc, ResultSet rs) {
 ResultSet existingRs = getResultSet(qc);
 // If this query collection is getting reused, close out any previous rowset
 if (existingRs != null) {
 try {existingRs.close();} catch (SQLException s) {}
 }
 setUserDataForCollection(qc,rs);
 hasNextForCollection(qc); // Prime the pump with the first row.
}

```

The `retrieveRefCursor()` method uses the helper method described in [Section 12.6, "Invoking Stored Procedures and Functions"](#) to invoke the stored function and return the REF CURSOR:

```

private ResultSet retrieveRefCursor(Object qc, Object[] params) {
 ResultSet rs = (ResultSet)callStoredFunction(OracleTypes.CURSOR,
 "RefCursorExample.get_requests_for_customer(?)",
 new Object[]{getNamedBindParamValue("CustEmail",params)});
 return rs ;
}

```

#### 42.8.4.3 The Overridden `createRowFromResultSet()` Method

For each row that the framework needs fetched from the data source, it will invoke your overridden `createRowFromResultSet()` method. The implementation retrieves the collection-specific `ResultSet` object from the user-data context. It uses the `getResultSet()` method to retrieve the result set wrapper from the query-collection user data, and the `createNewRowForCollection()` method to create a new blank row in the collection, and then uses the `populateAttributeForRow()` method to populate the attribute values for each attribute defined at design time in the view object overview editor.

```

protected ViewRowImpl createRowFromResultSet(Object qc, ResultSet rs) {
 /*
 * We ignore the JDBC ResultSet passed by the framework (null anyway) and
 * use the resultset that we've stored in the query-collection-private
 * user data storage
 */
 rs = getResultSet(qc);

 /*
 * Create a new row to populate
 */
 ViewRowImpl r = createNewRowForCollection(qc);
 try {
 /*
 * Populate new row by attribute slot number for current row in Result Set
 */
 populateAttributeForRow(r,0, rs.getLong(1));
 populateAttributeForRow(r,1, rs.getString(2));
 populateAttributeForRow(r,2, rs.getString(3));
 }
 catch (SQLException s) {
 throw new JboException(s);
 }
 return r;
}

```

#### 42.8.4.4 The Overridden hasNextForCollectionMethod()

The overridden implementation of the framework method `hasNextForCollection()` has the responsibility to return `true` or `false` based on whether there are more rows to fetch. When you've hit the end, you call the `setFetchCompleteForCollection()` to tell view object that this collection is done being populated.

```
protected boolean hasNextForCollection(Object qc) {
 ResultSet rs = getResultSet(qc);
 boolean nextOne = false;
 try {
 nextOne = rs.next();
 /*
 * When were at the end of the result set, mark the query collection
 * as "FetchComplete".
 */
 if (!nextOne) {
 setFetchCompleteForCollection(qc, true);
 /*
 * Close the result set, we're done with it
 */
 rs.close();
 }
 }
 catch (SQLException s) {
 throw new JboException(s);
 }
 return nextOne;
}
```

#### 42.8.4.5 The Overridden releaseUserDataForCollection() Method

Once the collection is done with its fetch-processing, the overridden `releaseUserDataForCollection()` method gets invoked and closes the `ResultSet` cleanly so no database cursors are left open.

```
protected void releaseUserDataForCollection(Object qc, Object rs) {
 ResultSet userDataRS = getResultSet(qc);
 if (userDataRS != null) {
 try {
 userDataRS.close();
 }
 catch (SQLException s) {
 /* Ignore */
 }
 }
 super.releaseUserDataForCollection(qc, rs);
}
```

#### 42.8.4.6 The Overridden getQueryHitCount() Method

Lastly, in order to properly support the view object's `getEstimatedRowCount()` method, the overridden `getQueryHitCount()` method returns a count of the rows that would be retrieved if all rows were fetched from the row set. Here the code uses a `CallableStatement` to get the job done. Since the query is completely encapsulated behind the stored function API, the code also relies on the PL/SQL package to provide an implementation of the count logic as well to support this functionality.

```
public long getQueryHitCount(ViewRowSetImpl viewRowSet) {
 Object[] params = viewRowSet.getParameters(true);
```

```

BigDecimal id = (BigDecimal)params[0];
CallableStatement st = null;
try {
 st = getDBTransaction().createCallableStatement(COUNTSQL,
 DBTransaction.DEFAULT);

 /*
 * Register the first bind parameter as our return value of type CURSOR
 */
 st.registerOutParameter(1,Types.NUMERIC);
 /*
 * Set the value of the 2nd bind variable to pass id as argument
 */
 if (id == null) st.setNull(2,Types.NUMERIC);
 else st.setBigDecimal(2,id);
 st.execute();
 return st.getLong(1);
}
catch (SQLException s) {
 throw new JboException(s);
}
finally {try {st.close();} catch (SQLException s) {}}
}

```

## 42.9 Creating a View Object with Multiple Updatable Entities

By default, when you create a view object with multiple entity usages, each secondary entity usage that you add to a view object in the overview editor is configured with these settings:

- The **Updatable** checkbox is deselected
- The **Reference** checkbox is selected

You can change the default behavior to enable a secondary entity usage to be updatable by selecting the usage in the **Selected** list of the **Entity Objects** page of the view object overview editor and selecting the **Updatable** checkbox.

Additionally, for each entity usage, you can decide whether to leave **Reference** select to control whether or not to refresh the attributes of the secondary entity when the entity lookup information changes. By default, **Reference** is selected to ensure attributes of each secondary entity objects will be refreshed. For details about this setting when you allow row inserts with multiple entity usages, see [Section 42.9.2, "What Happens at Runtime: View Row Creation."](#)

[Table 42–4](#) summarizes the combinations you can select when you define multiple entity usages for a view object.

**Table 42–4 View Object Properties to Control View Row Creation Behavior**

Updatable	Reference	View Row Behavior
true	true	This combination allows the entity usage's attributes to be updated and keeps its attributes synchronized with the value of the primary key. Since this combination works fine with the view link consistency feature, you can use it to make sure your view object only has one entity object usage that will participate in inserts.

**Table 42–4 (Cont.) View Object Properties to Control View Row Creation Behavior**

Updatable	Reference	View Row Behavior
true	false	<p>This combination allows the entity usage's attributes to be updated but prevents its attributes from being changed by the a primary key lookup. This is a rather rare combination, and works best in situations where you only plan to use the view object to update or delete existing data. With this combination, the user can update attributes related to any of the non-reference, updatable entity usages and the view row will delegate the changes to the appropriate underlying entity rows.</p> <p>Note: The combination of the view link consistency feature with a view object having some of its secondary entity usages set as Updatable=true, Reference=false can end up creating unwanted extra new entities in your application.</p>
false	true	<p>This is the default behavior, described in <a href="#">Section 5.5.1, "How to Create Joins for Entity-Based View Objects."</a> This combination assumes you do not want the entity usage to be updatable.</p>

If you need a view object with multiple updatable entities to support creating new rows (Updatable=true, Reference=false) and the association between the entity objects is not a composition, then you need to write a bit of code, as described in [Section 42.9.1, "How to Programmatically Create New Rows With Multiple Updatable Entity Usages."](#)

### 42.9.1 How to Programmatically Create New Rows With Multiple Updatable Entity Usages

If you need a view object with multiple updatable entities to support creating new rows (Updatable=true, Reference=false) and the association between the entity objects is not a composition, then you need to override the `create()` method of the view object's custom view row class to enable that to work correctly.

---

**Note:** You only need to write code to handle creating new rows when the association between the updatable entities is not a composition. If the association is a composition, then ADF Business Components handles this automatically.

---

When you call `createRow()` on a view object with multiple update entities, it creates new entity row parts for each updatable entity usage. Since the multiple entities in this scenario are related by an association, there are three pieces of code you might need to implement to ensure the new, associated entity rows can be saved without errors:

1. You may need to override the `postChanges()` method on entity objects involved to control the correct posting order.

2. If the primary key of the associated entity is populated by a database sequence using `DBSequence`, and if the multiple entity objects are associated but not composed, then you need to override the `postChanges()` and `refreshFKInNewContainees()` method to handle cascading the refreshed primary key value to the associated rows that were referencing the temporary value.
3. You need to override the `create()` method of the view object's custom view row class to modify the default row creation behavior to pass the context of the parent entity object to the newly-created child entity.

To understand the code for steps 1 and 2, see the example with associated `Suppliers` and `Products` entity objects described in [Section 4.14.7, "How to Control Entity Posting Order to Prevent Constraint Violations."](#) The last thing you need to understand is how to override `create()` method on the view row. Consider a `ProductAndSupplier` view object with a primary entity usage of `Product` and secondary entity usage of `Supplier`. Assume the `Product` entity usage is marked as updatable and non-reference, while the `Supplier` entity usage is a reference entity usage.

[Example 42–31](#) shows the commented code required to correctly sequence the creation of the multiple, updatable entity row parts during a view row create operation.

**Example 42–31 Overriding View Row `create()` Method for Multiple Updatable Entities**

```
/**
 * By default, the framework will automatically create the new
 * underlying entity object instances that are related to this
 * view object row being created.
 *
 * We override this default view object row creation to explicitly
 * pre-populate the new (detail) ProductsImpl instance using
 * the new (master) SuppliersImpl instance. Since all entity objects
 * implement the AttributeList interface, we can directly pass the
 * new SuppliersImpl instance to the ProductsImpl create()
 * method that accepts an AttributeList.
 */
protected void create(AttributeList attributeList) {
 // The view row will already have created "blank" entity instances
 SuppliersImpl newSupplier = getSupplier();
 ProductsImpl newProduct = getProduct();
 try {
 // Let product "blank" entity instance to do programmatic defaulting
 newSupplier.create(attributeList);
 // Let product "blank" entity instance to do programmatic
 // defaulting passing in new SuppliersImpl instance so its attributes
 // are available to the EmployeeImpl's create method.
 newProduct.create(newSupplier);
 }
 catch (JboException ex) {
 newSupplier.revert();
 newProduct.revert();
 throw ex;
 }
 catch (Exception otherEx) {
 newSupplier.revert();
 newProduct.revert();
 throw new RowCreateException(true /* EO Row? */,
 "Product" /* EO Name */,
 otherEx /* Details */);
 }
}
```

```
 }
}
```

In order for this `ProductAndSupplier` view object's view row class (`ProductAndSupplierRowImpl` class) to be able to invoke the protected `create()` method on the `Suppliers` and `Products` entity objects, the entity object classes need to override their `create()` methods:

```
/**
 * Overriding this method in this class allows friendly access
 * to the create() method by other classes in this same package, like the
 * ProductsAndSuppliers view object implementation class, whose overridden
 * create() method needs to call this.
 * @param nameValuePair
 */
protected void create(AttributeList nameValuePair) {
 super.create(nameValuePair);
}
```

When overriding the `create()` method, the declaration of the method will depend on the following conditions:

- If the view object and entity objects are in the same package, the overridden `create()` method can have protected access and the `ProductAndSupplierRowImpl` class will have access to them.
- If either entity object is in a different package, then `SupplierImpl.create()` and `ProductImpl.create()` (whichever is in a different package) have to be declared `public` in order for the `SupplierAndProductViewRowImpl` class to be able to invoke them.

## 42.9.2 What Happens at Runtime: View Row Creation

If you need a view object with multiple updatable entities to support creating new rows, you will want to understand that the **Reference** flag controls behavior related to view row creation, as well as automatic association-driven lookup of information. If you disable the **Reference** flag for a given entity usage, then:

- Each time a new view row is created, a new entity instance will be created for that entity usage.
- The entity row to which the view row points for its storage of view row attributes related to that entity usage is never changed automatically by the framework.

Conversely, if you leave the **Reference** flag enabled (default) for an entity usage then:

- No new entity instance will be created for that entity usage when a new view row is created.
- The entity row to which the view row points for storage of view row attributes related to that entity usage will automatically be kept in sync with changes made to attributes in the view row that participate in an association with said entity.

Consider an `EmployeeView` view object that joins information from the `DEPT` and `EMP` tables to show `Empno`, `Ename`, `EmpDeptno` (a name chosen in the view object editor to identify this as an attribute of `EmployeeView`), `DeptDeptno` (a name chosen in the view object editor to identify this as an attribute of `DepartmentView`) and `Dname` attributes.

Now, consider what happens at runtime for the default case where you setup the secondary entity object marked as both updatable and reference:

- The Employee EO is the primary entity usage.
- The Department EO is a secondary entity usage and is marked as a Reference.

When the user creates a new row in the `EmployeeView`, ADF Business Components only creates a new Employee EO instance (since the Reference flag for the Department EO usage is enabled). If the user changes the employee's `DeptDeptno` attribute to 10, then ADF Business Components will automatically look up the Department entity with primary key 10 in the entity cache (reading it in from the database if not already in the cache) and make this new view row's Department entity usage point to this department 10 entity. That has the result of automatically reflecting the right `Dname` value for department 10.

In the default scenario, the reference lookup occurs both because the entity usage for Department is marked as a reference, as well as the fact that an association exists between the Employee entity and the Department entity. Through the association definition, ADF Business Components knows which attributes are involved on each side of this association. When any of the attributes on the Employee side of the `EmpToDept` association are modified, if the Department entity usage is marked as a Reference, ADF Business Components will perform that automatic reference lookup. If the user sets the `Dname` to `NewDept` in this new view row, after committing the change, the database will have a new employee in department 10 and have updated the name of department 10 to `NewDept`.

Now, consider what happens at runtime where you setup the secondary entity object marked as updatable and reference is disabled:

- The Employee entity object is the primary entity usage.
- The Department entity object is a secondary entity usage, but this usage is not marked as a Reference.

In this scenario, when the user creates a new row in the `EmployeeView`, ADF Business Components will create both a new Employee EO instance and a new Department EO instance (since the Reference flag for the Department EO usage is disabled). If the user changes the employee's `Deptno` attribute to 10, it will have no effect on the value of the `Dname` attribute being displayed in the row. Additionally, if the user sets `DeptDeptno` to 99 and `Dname` to `NewDept` in this new view row, after committing the changes, the database will have both a new employee in department 10 and a new department number 99.

## 42.10 Declaratively Preventing Insert, Update, and Delete

Some 4GL tools like Oracle Forms provide declarative properties that control whether a given data collection allows inserts, updates, or deletes. While the view object does not yet support this as a built-in feature in the current release, it's easy to add this facility using a framework extension class that exploits custom metadata properties as the developer-supplied flags to control insert, update, or delete on a view object.

---

---

**Note:** The example in this section refers to the `DeclarativeBlockOperations` project in the `AdvancedViewObjectsExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

To allow developers to have control over individual view object instances, you could adopt the convention of using application module custom properties by the same

name as the view object instance. For example, if an application module has view object instances named `ProductsInsertOnly`, `ProductsUpdateOnly`, `ProductsNoDelete`, and `Products`, your generic code might look for application module custom properties by these same names. If the property value contains `Insert`, then insert is enabled for that view object instance. If the property value contains `Update`, then update is allowed. And, similarly, if the property value contains `Delete`, then delete is allowed. You could use helper methods like this to test for these application module properties and determine whether insert, update, and delete are allowed for a given view object:

```
private boolean isInsertAllowed() {
 return isStringInAppModulePropertyNamedAfterVOInstance("Insert");
}
private boolean isUpdateAllowed() {
 return isStringInAppModulePropertyNamedAfterVOInstance("Update");
}
private boolean isDeleteAllowed() {
 return isStringInAppModulePropertyNamedAfterVOInstance("Delete");
}
private boolean isStringInAppModulePropertyNamedAfterVOInstance(String s) {
 String voInstName = getViewObject().getName();
 String propVal = (String)getApplicationModule().getProperty(voInstName);
 return propVal != null ? propVal.indexOf(s) >= 0 : true;
}
```

[Example 42–32](#) shows the other code required in a custom framework extension class for view rows to complete the implementation. It overrides the following methods:

- `isAttributeUpdateable()`  
To enable the user interface to disable fields in a new row if insert is not allowed or to disable fields in an existing row if update is not allowed.
- `setAttributeInternal()`  
To prevent setting attribute values in a new row if insert is not allowed or to prevent setting attributes in an existing row if update is not allowed.
- `remove()`  
To prevent remove if delete is not allowed.
- `create()`  
To prevent create if insert is not allowed.

**Example 42–32 Preventing Insert, Update, or Delete Based on Custom Properties**

```
public class CustomViewRowImpl extends ViewRowImpl {
 public boolean isAttributeUpdateable(int index) {
 if (hasEntities() &&
 ((isNewOrInitialized() && !isInsertAllowed()) ||
 (isModifiedOrUnmodified() && !isUpdateAllowed()))) {
 return false;
 }
 return super.isAttributeUpdateable(index);
 }
 protected void setAttributeInternal(int index, Object val) {
 if (hasEntities()) {
 if (isNewOrInitialized() && !isInsertAllowed())
 throw new JboException("No inserts allowed in this view");
 else if (isModifiedOrUnmodified() && !isUpdateAllowed())
 throw new JboException("No updates allowed in this view");
 }
 }
}
```

```
 }
 super.setAttributeInternal(index, val);
}
public void remove() {
 if (!hasEntities() || isDeleteAllowed() || isNewOrInitialized())
 super.remove();
 else
 throw new JboException("Delete not allowed in this view");
}
protected void create(AttributeList nvp) {
 if (isInsertAllowed()) {
 super.create(nvp);
 } else {
 throw new JboException("Insert not allowed in this view");
 }
}
// private helper methods omitted from this example
}
```

---

---

## Application State Management

This chapter describes the Fusion web application state management facilities and how to use them.

This chapter includes the following sections:

- [Section 43.1, "Understanding Why State Management is Necessary"](#)
- [Section 43.2, "Introduction to Fusion Web Application State Management"](#)
- [Section 43.3, "Using Save For Later"](#)
- [Section 43.4, "Setting the Application Module Release Level at Runtime"](#)
- [Section 43.5, "What Model State Is Saved and When It Is Cleaned Up"](#)
- [Section 43.6, "Timing Out the HttpSession"](#)
- [Section 43.7, "Managing Custom User-Specific Information"](#)
- [Section 43.8, "Managing the State of View Objects"](#)
- [Section 43.9, "Using State Management for Middle-Tier Savepoints"](#)
- [Section 43.10, "Testing to Ensure Your Application Module is Activation-Safe"](#)
- [Section 43.11, "Keeping Pending Changes in the Middle Tier"](#)

### 43.1 Understanding Why State Management is Necessary

Most real-world business applications need to support multi-step user tasks. Modern sites tend to use a step-by-step style user interface to guide the end user through a logical sequence of pages to complete these tasks. When the task is done, the user can save or cancel everything as a unit. However, the HTTP protocol is built on the concept of individual, stateless requests, so the responsibility of grouping a sequence of user actions into a logical, stateful unit of work falls to the application developer.

#### 43.1.1 Examples of Multi-Step Tasks

In a typical search-then-edit scenario, the end user searches to find an appropriate row to update, then may open several different pages of related master/detail information to make edits before deciding to save or cancel his work. Consider another scenario where the end user wants to book a vacation online. The process may involve the end user's entering details about:

- One or more flight segments that comprise the journey
- One or more passengers taking the trip
- Seat selections and meal preferences

- One or more hotel rooms in different cities
- Car they will rent

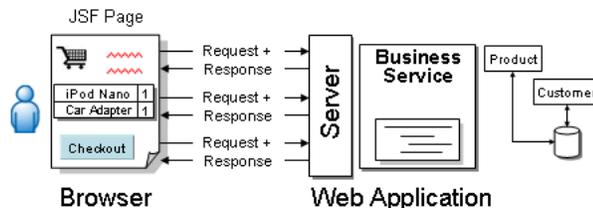

Along the way, the user might decide to complete the transaction, save the reservation for finishing later, or abandon the whole thing.

It's clear these scenarios involve a logical unit of work that spans multiple web pages. You've seen in previous chapters how to use JDeveloper's JSF page navigation diagram to design the page flow for these use cases, but that is only part of the puzzle. The pending changes the end user makes to business domain objects along the way — Trip, Flight, Passenger, Seat, HotelRoom, Auto, etc. — represent the in-progress state of the application for each end user. Along with this, other types of "bookkeeping" information about selections made in previous steps comprise the complete picture of the application state.

### 43.1.2 Stateless HTTP Protocol Complicates Stateful Applications

While it may be easy to imagine these multi-step scenarios, *implementing* them in web applications is complicated by the stateless nature of HTTP, the hypertext transfer protocol. [Figure 43-1](#) illustrates how an end user's visit to a site comprises a series of HTTP request/response pairs. However, HTTP affords a web server no way to distinguish one user's request from another user's, or to differentiate between a single user's first request and any subsequent requests he makes while interacting with the site. The server gets each request from any user always as if it were the first (and only) one they make.

**Figure 43-1 Web Applications Use the Stateless HTTP Protocol**

### 43.1.3 How Cookies Are Used to Track a User Session

As shown in [Figure 43-2](#), the technique used to recognize an ongoing sequence of requests from the same end user over the stateless HTTP protocol involves a unique identifier called a *cookie*. A cookie is a name/value pair that is sent in the header information of each HTTP request the user makes to a site. On the initial request made by a user, the cookie is not part of the request. The server uses the *absence* of the cookie to detect the start of a user's session of interactions with the site, and it returns a unique identifier to the browser that represents this session for this user. In practice, the cookie value is a long string of letters and numbers, but for the simplicity of the illustration, assume that the unique identifier is a letter like "A" or "Z" that corresponds to different users using the site.

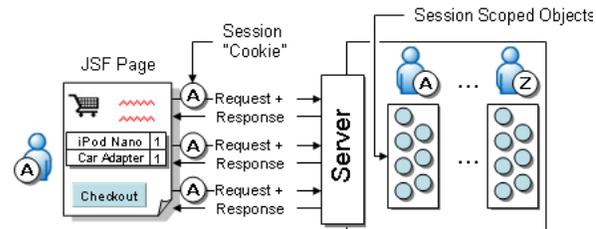

Web browsers support a standard way of recognizing the cookie returned by the server that allows the browser to identify the following:

- the site that sent the cookie
- how long it should remember the cookie value

On each subsequent request made by that user, until the cookie expires, the browser sends the cookie along in the header of the request. The server uses the value of the cookie to distinguish between requests made by different users.

Cookies can be set to live beyond a single browser session so that they might expire in a week, a month, or a year from when they were first created, while a session cookie expires when you close your browser.

**Figure 43–2 Tracking State Using a Session Cookies and Server-Side Session**

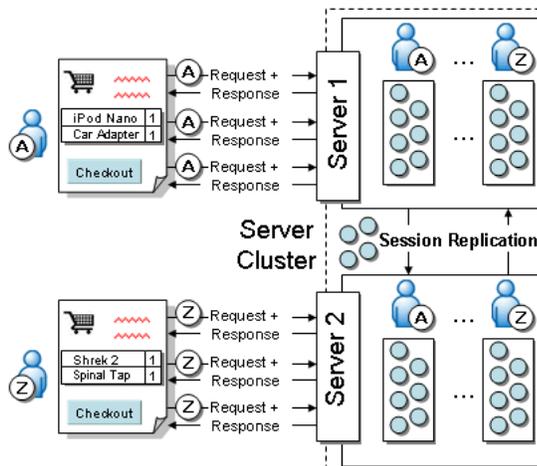

Java EE-compliant web servers provide a standard server-side facility called the `HttpSession` that allows a web application to store Java objects related to a particular user's session as named attribute/value pairs. An object placed in this session Map on one request can be retrieved by the application while handling a subsequent request during the same session.

The session remains active while the user continues to send new requests within the timeframe configured by the `<session-timeout>` element in the `web.xml` file. The default session length is 35 minutes.

#### 43.1.4 Performance and Reliability Impact of Using `HttpSession`

The `HttpSession` facility is an ingredient in most application state management strategies, but it can present performance and reliability problems if not used judiciously. First, because the session-scope Java objects you create are held in the memory of the Java EE web server, the objects in the HTTP session are lost if the server should fail.

As shown in [Figure 43–3](#), one way to improve the reliability is to configure multiple Java EE servers in a cluster. By doing this, the Java EE application server replicates the objects in the HTTP session for each user across multiple servers in the cluster so that if one server goes down, the objects exist in the memory of the other servers in the cluster that can continue to handle the users requests. Since the cluster comprises separate servers, replicating the HTTP session contents among them involves broadcasting the changes made to HTTP session objects over the network.

**Figure 43-3 Session Replication in a Server Cluster**

You can begin to see some of the performance implications of overusing the HTTP session:

- The more active users, the more HTTP sessions will be created on the server.
- The more objects stored in each HTTP session, the more memory you will need. Note that the memory is not reclaimed when the user becomes inactive; this only happens with a session timeout or an explicit session invalidation. Session invalidations don't always happen because users don't always logout.
- In a cluster, the more objects in each HTTP session that *change*, the more network traffic will be generated to replicate the changed objects to other servers in the cluster.

At the outset, it would seem that keeping the number of objects stored in the session to a minimum addresses the problem. However, this implies leveraging an alternative mechanism for temporary storage for each user's pending application state. The most popular alternatives involve saving the application state to the database between requests or to a file of some kind on a shared file system.

Of course, this is easier said than done. A possible approach involves eagerly saving the pending changes to your underlying database tables and committing the transaction at the end of each HTTP request. But this idea has two key drawbacks:

- *Your database constraints might fail.*  
At any given step of the multi-step process, the information may only be partially complete, and this could cause errors at the database level when trying to save the changes.
- *You complicate rolling back the changes.*  
Cancelling the logical of unit of work would involve carefully deleting all of the eagerly-committed rows in possible multiple tables.

These limitations have led developers in the past to invent solutions involving a "shadow" set of database tables with no constraints and with all of the column types defined as character-based. Using such a solution becomes very complex very quickly. Ultimately, you will conclude that you need some kind of generic application state management facility to address these issues in a more generic and workable way. The solution comes in the form of ADF Business Components, which implements this for you out of the box.

## 43.2 Introduction to Fusion Web Application State Management

State management enables you to easily create web applications that support multi-step use cases without falling prey to the memory, reliability, or implementation complexity problems described in [Section 43.1, "Understanding Why State Management is Necessary."](#)

Application state management is provided at two levels, by the Save For Later feature in a task flow, and application module state management in the model layer.

Save For Later is activated at the controller layer and automatically saves a "snapshot" of the current UI and controller states, and delegates to the model layer to *passivate* (save) its state as well.

If you are not using ADF data controls, you can still use application module state management alone, but since this will save only the model state, this is an outside case for most applications.

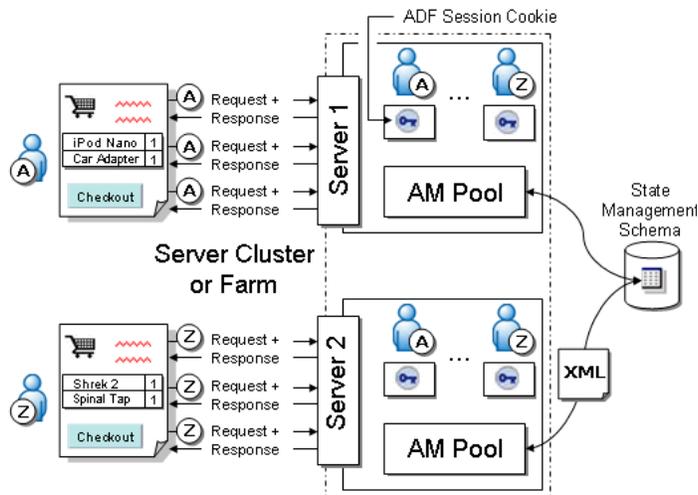

### 43.2.1 Basic Architecture of the Save for Later Facility

Save for Later saves an incomplete transaction without enforcing validation rules or submitting the data. The end user can resume working on the same transaction later with the same data that was originally saved when the application was exited.

### 43.2.2 Basic Architecture of the Application Module State Management Facility

Your ADF Business Components-based application automatically manages the application state of each user session. This provides the simplicity of a stateful programming model that you are accustomed to in previous 4GL tools, yet implemented in a way that delivers scalability nearing that of a purely stateless application. Understanding what happens behind the scenes is essential to make the most efficient use of this important feature.

You can use application module components to implement completely stateless applications or to support a unit of work that spans multiple browser pages. [Figure 43-4](#) illustrates the basic architecture of the state management facility to support these multi-step scenarios. An application module supports *passivating* (storing) its pending transaction state to an XML document, which is stored in the database in a single, generic table, keyed by a unique passivation snapshot ID. It also supports the reverse operation of *activating* pending transaction state from one of these saved XML snapshots. This passivation and activation is performed automatically by the application module pool when needed.

**Figure 43–4 ADF Provides Generic, Database-Backed State Management**

The ADF binding context is the one object that lives in the `HttpSession` for each end user. It holds references to lightweight application module data control objects that manage acquiring an application module instance from the pool during the request (when the data control is accessed) and releasing it to the pool at the end of each request. The data control holds a reference to the ADF session cookie that identifies the user session. In particular, business domain objects created or modified in the pending transaction are *not* saved in the `HttpSession` using this approach. This minimizes both the session memory required per user and eliminates the network traffic related to session replication if the servers are configured in a cluster.

For improved reliability, serialize your session objects. Objects stored in distributed sessions need to implement the `java.io.Serializable` interface. Implementing this interface ensures the data can be transported over-the-wire to each server instance in the cluster. Use a custom method like the `addObjectToSession(String key, Serializable value)` method, instead of the default `HttpSession.setAttribute(String key, Object value)` method when adding session data. The distinction is, if you were to call the `addObjectToSession()` method with a non-serializable object, you would see a compile-time error. If you were to try to replicate a session object that had non-serializable objects placed into session with the `put()` method, you would see a runtime error and potentially, a broken user experience.

Additionally, if you have multiple application servers and you enable the optional ADF Business Components failover support (explained in [Section 43.2.2.2, "How Passivation Changes When Optional Failover Mode is Enabled"](#)), then subsequent end-user requests can be handled by any server in your server farm or cluster. The session cookie can reactivate the pending application state from the database-backed XML snapshot if required, regardless of which server handles the request.

#### 43.2.2.1 Understanding When Passivation and Activation Occurs

To better understand when the automatic passivation and activation of application module state occurs, consider the following simple case:

1. At the beginning of an HTTP request, the application module data control handles the `beginRequest` event by checking out an application module instance from the pool.

The application module pool returns an *unreferenced* instance. An unreferenced application module is one that is not currently managing the pending state for any other user session.

2. At the end of the request, the application module data control handles the `endRequest` event by checking the application module instance back into the pool in "managed state" mode.

That application module instance is now *referenced* by the data control that just used it. And the application module instance is an object that still contains pending transaction state made by the data control (that is, entity object and view object caches; updates made but not committed; and cursor states), stored in memory. As you'll see below, it's not *dedicated* to this data control, just referenced by it.

3. On a subsequent request, the same data control — identified by its `SessionCookie` — checks out an application module instance again.

Due to the "stateless with user affinity" algorithm the pool uses, you might assume that the pool returns the exact same application module instance, with the state still there in memory. (To understand this algorithm, read [Section 44.1, "About Application Module Pooling"](#) and the discussion of Referenced Pool Size in [Section 44.2.7.2, "Pool Sizing Parameters."](#))

Sometimes due to a high number of users simultaneously accessing the site, application module instances must be sequentially reused by different user sessions. In this case, the application pool must *recycle* a currently referenced application module instance for use by another session, as follows:

1. The application module data control for User A's session checks an application module instance into the application pool at the end of a request. Assume this instance is named `AM1`.
2. The application module data control for User Z's new session requests an application module instance from the pool for the first time, but there are no unreferenced instances available. The application module pool then:
  - Passivates the state of instance `AM1` to the database.
  - Resets the state of `AM1` in preparation to be used by another session.
  - Returns the `AM1` instance to User Z's data control.
3. On a subsequent request, the application module data control for User A's session requests an application module instance from the pool. The application module pool then:
  - Obtains an unreferenced instance.
    - This could be instance `AM1`, obtained by following the same steps as in (2) above, or another `AM2` instance if it had become unreferenced in the meantime.
  - Activates the appropriate pending state for User A from the database.
  - Returns the application module instance to User A's data control.

The process of passivation, activation, and recycling allows the state referenced by the data control to be preserved across requests without requiring a dedicated application module instance for each data control. Both browser users in the above scenario are carrying on an application transaction that spans multiple HTTP requests, but the end users are unaware whether the passivation and activation is occurring in the background. They just continue to see the pending changes. In the process, the

pending changes never need to be saved into the underlying application database tables until the end user is ready to commit the logical unit of work.

Note that this keeps the session memory footprint low because the only business component objects that are directly referenced by the session (and are replicable) are the data control and the session cookie.

The application module pool makes a best effort to keep an application module instance "sticky" to the current data control whose pending state it is managing. This is known as maintaining user session affinity. The best performance is achieved if a data control continues to use exactly the same application module instance on each request, since this avoids any overhead involved in reactivating the pending state from a persisted snapshot.

#### 43.2.2.2 How Passivation Changes When Optional Failover Mode is Enabled

The `jbo.dofailover` parameter controls when and how often passivation occurs. You can set this parameter in your application module configuration on the **Pooling and Scalability** tab of the Business Components Configuration dialog. When the failover feature is disabled, which it is by default, then application module pending state will only be passivated on demand when it must be. This occurs just before the pool determines it must hand out a currently-referenced application module instance to a *different* data control.

The passivation activity (and the corresponding wait) occurs only if failover is disabled *and* session replication is disabled. If either failover or session replication is enabled, then the recycling thread will reuse the snapshot that was already acquired to support the failover.

---

---

**Note:** Passivation can also occur when an application module is timed out. For more information about application pool removal algorithms (such as `jbo.ampool.timetolive`), see [Section 44.2.7.3, "Pool Cleanup Parameters."](#)

---

---

In contrast, with the failover feature turned on, the application module's pending state is passivated every time it is checked back into application module pool. This provides the most pessimistic protection against application server failure. The application module instances' state is always saved and may be activated by any application module instance at any time. Of course, this capability comes at expense of the additional overhead of eager passivation on each request.

**Best Practice:** By default, the failover feature is disabled (`jbo.dofailover=false`) as a performance optimization when there is only one web server instance configured, by reducing the need for passivation and activation. This allows for application module affinity to a specific user session.

For high availability, enable the failover feature (`jbo.dofailover=true`) to ensure that more application modules are readily available, thereby increasing scalability. In this mode, passivation occurs at the end of every request.

To understand application module pooling and the "stateless with affinity" algorithm, read [Section 44.1, "About Application Module Pooling"](#) and the discussion of Referenced Pool Size in [Section 44.2.7.2, "Pool Sizing Parameters."](#)

---

---

**Note:** When running or debugging an application that uses failover support within the JDeveloper environment, you are frequently starting and stopping the application server. The ADF failover mechanism has no way of knowing whether you stopped the server to simulate an application server failure, or whether you stopped it because you want to retest something from scratch in a fresh server instance. If you intend to do the latter, exit out of your browser before restarting the application on the server. This eliminates the chance that you will be confused by the correct functioning of the failover mechanism when you didn't intend to be testing that aspect of your application.

---

---

### 43.2.2.3 About State Management Release Levels

When a data control handles the `endRequest` notification indicating the processing for the current HTTP request has completed, it releases the application module instance by checking it back into the application module pool. The application module pool manages instances and performs state management tasks (or not) based on the *release level* you use when returning the instance to the pool.

There are three release levels used for returning an instance of an application module to a pool:

- **Managed** - This is the default level, where the application module pool prefers to keep the same application module instance for the same data control, but may release an instance if necessary.
- **Unmanaged** - No state needs to be preserved beyond the current request.
- **Reserved** - A one-to-one relationship is preserved between an application module instance and a data control.

---

---

**Caution:** In general, it is strongly recommended never to use Reserved release level. You would normally avoid using this mode because the data control to application module correlation becomes one to one, the scalability of the application reduces very sharply, and so does reliability of the application.

---

---

**43.2.2.3.1 About Managed Release Level** This is the default release level and implies that application module's state is relevant and has to be preserved for this data control to span over several HTTP requests. Managed level does not guarantee that for the next request this data control will receive the same physical application module instance, but it does guarantee that an application module with identical state will be provided so it is logically the same application module instance each time. It is important to note that the framework makes the best effort it can to provide the same instance of application module for the same data control if it is available at the moment. This is done for better performance since the same application module does not need to activate the previous state which it still has intact after servicing the same data control during previous request. However, the data control is not guaranteed to receive the same instance for all its requests and if the application module that serviced that data control during previous is busy or unavailable, then a different application module will activate this data control's state. For this reason, it is not valid to cache references to application module objects, view objects, or view rows across HTTP requests in controller-layer code.

This mode was called the "Stateful Release Mode" in previous releases of JDeveloper.

---

---

**Note:** If the `jbo.ampool.doampooling` configuration property is `false` — corresponding to your unchecking the **Enable Application Module Pooling** option in the **Pooling and Scalability** tab of the Business Components Configuration dialog — then there is effectively no pool. In this case, when the application module instance is released at the end of a request it is immediately removed. On subsequent requests made by the same user session, a new application module instance must be created to handle each user request, and pending state must be reactivated from the passivation store. Setting this property to `false` is useful to discover problems in your application logic that might occur when reactivation does occur due to unpredictable load on your system. However, the property `jbo.ampool.doampooling` set to `false` is not a supported configuration for production applications and must be set to `true` before you deploy your application. For further details, see [Section 43.10, "Testing to Ensure Your Application Module is Activation-Safe."](#)

---

---

**43.2.2.3.2 About Unmanaged Release Level** This mode implies that no state associated with this data control has to be preserved to survive beyond the current HTTP request. This level is the most efficient in performance because there is no overhead related to state management. However, you should limit its use to applications that require no state management, or to cases when state no longer needs to be preserved at this point. Usually, you can programmatically release the application module with the unmanaged level when you want to signal that the user has ended a logical unit of work.

**Performance Tip:** .The default release level is Managed, which implies that the application module's state is relevant and has to be preserved to allow the data control to span over several HTTP requests. Set release level to Unmanaged programmatically at runtime for particular pages to eliminate passivation and achieve better performance. A typical example is releasing the application module after servicing the HTTP request from a logout page.

This mode was called the "Stateless Release Mode" in previous releases of JDeveloper.

**43.2.2.3.3 About Reserved Release Level** This level guarantees that each data control will be assigned its own application module during its first request and for all subsequent requests coming from the `HttpSession` associated with this data control. This data control will always receive the same physical instance of application module. This mode exists for legacy compatibility reasons and for very rare special use cases.

An example of using Reserved level occurs when there is a pending database state across a request resulting from the `postChanges()` method or a PL/SQL stored procedure but not issuing a `commit()` or `rollback()` at the end of the request. In this case, if any other release level is used instead of Reserved, when the application module instance is recycled, a rollback is issued on the database connection associated with this application module instance and all uncommitted changes would be lost.

**Performance Tip:** If you must use Reserved level, call `setReleaseLevel()` on the data control to keep its period as short as possible. For details about changing the release level programmatically, see [Section 43.4, "Setting the Application Module Release Level at Runtime."](#)

Consequences of Reserved mode can be adverse. Reliability suffers because if for whatever reason the application module is lost, the data control will not be able to receive any other application module in its place from the pool, and so `HttpSession` gets lost as well, which is not the case for managed level.

The failover option is ignored for an application module released with Reserved release level since its use implies your application absolutely requires working with the same application module instance on each request.

#### 43.2.2.4 State Management and Subclassed Entity Objects

If your application employs subclassed entity objects, the key attribute of new entities must be prepopulated. If the key is not prepopulated, passivation and activation will fail. You can prepopulate the key attribute by overriding the `create()` method or by using the `DBSequence` type that will assign a temporary negative value to the key before the real value is fetched from the database after commit. For more information, see [Section 4.10.10, "How to Get Trigger-Assigned Primary Key Values from a Database Sequence."](#)

## 43.3 Using Save For Later

To enable Save For Later, you must first add Save Points to the application at points where you would like application state and data to be preserved if the end user leaves the application. You can use it to save data and state information about a region, view port, or portlet. Later, you use the Save Point Restore activity to restore application state and data associated with a Save Point.

For more information on how create and restore Save Points, see [Section 22.6, "Using Save Points in Task Flows."](#)

Save For Later can also perform implicit saves. These occur when data is saved automatically without the end user performing an explicit Save action when the user session times out or closes the browser window, for example.

For more information on how to perform an implicit save, see [Section 22.6, "Using Save Points in Task Flows."](#)

## 43.4 Setting the Application Module Release Level at Runtime

If you do not want to use the default "Managed State" release level for application modules, you can set your desired level programmatically.

### 43.4.1 How to Set Unmanaged Level

To set a data control to release its application module using the unmanaged level, call the `resetState()` method on the `DCDataControl` class (in the `oracle.adf.model.binding` package).

You can call this method any time during the request. This will cause application module not to passivate its state at all when it is released to the pool at the end of the request. Note that this method only affects the current application module instance in

the current request. After this, the application module is released in unmanaged level to the pool, it becomes unreferenced and gets reset. The next time the application module is used by a client, it will be used in the managed level again by default.

---

---

**Note:** You can programmatically release the application module with the unmanaged level when you want to signal that the user has ended a logical unit of work. This will happen automatically when the `HTTPSession` times out, as described below.

---

---

### 43.4.2 How to Set Reserved Level

To set a data control to release its application module using the reserved level, call the `setReleaseLevel()` method of the `DCJboDataControl` class (in the `oracle.adf.model.bc4j` package), and pass the integer constant `ApplicationModule.RELEASE_LEVEL_RESERVED`.

When the release level for an application module has been changed to "Reserved" it will stay so for all subsequent requests until explicitly changed.

### 43.4.3 How to Set Managed Level

If you have set an application module to use reserved level, you can later set it back to use managed level by calling the `setReleaseLevel()` method of the `DCJboDataControl` class, and passing the integer constant `ApplicationModule.RELEASE_LEVEL_MANAGED`.

### 43.4.4 How to Set Release Level in a JSF Backing Bean

[Example 43–1](#) shows calling the `resetState()` method on a data control named `UserModuleDataControl` from the action method of a JSF backing bean.

#### **Example 43–1 Calling `resetState()` on Data Control in a JSF Backing Bean Action Method**

```
package devguide.advanced.releasestateless.controller.backing;
import devguide.advanced.releasestateless.controller.JSFUtils;
import oracle.adf.model.BindingContext;
import oracle.adf.model.binding.DCDataControl;
/**
 * JSF Backing bean for the "Example.jspx" page
 */
public class Example {
 /**
 * In an action method, call resetState() on the data control to cause
 * it to release to the pool with the "unmanaged" release level.
 * In other words, as a stateless application module.
 */
 public String commandButton_action() {
 // Add event code here...
 getDataControl("UserModuleDataControl").resetState();
 return null;
 }
 private DCDataControl getDataControl(String name) {
 BindingContext bc =
 (BindingContext)JSFUtils.resolveExpression("#{data}");
 return bc.findDataControl(name);
 }
}
```

### 43.4.5 How to Set Release Level in an ADF PagePhaseListener

[Example 43–2](#) shows calling the `resetState()` method on a data control named `UserModuleDataControl` from the `after-prepareRender` phase of the ADF lifecycle using a custom ADF page phase-listener class. You would associate this custom class to a particular page by setting the `ControllerClass` attribute on the page's page definition to the fully-qualified name of this class.

#### **Example 43–2 Calling `resetState()` on Data Control in a Custom `PagePhaseListener`**

```
package devguide.advanced.releasestateless.controller;
import oracle.adf.controller.v2.lifecycle.Lifecycle;
import oracle.adf.controller.v2.lifecycle.PagePhaseEvent;
import oracle.adf.controller.v2.lifecycle.PagePhaseListener;
import oracle.adf.model.binding.DCDataControl;
public class ReleaseStatelessPagePhaseListener
 implements PagePhaseListener {
 /**
 * In the "after" phase of the final "prepareRender" ADF Lifecycle
 * phase, call resetState() on the data control to cause it to release
 * to the pool with the "unmanaged" release level. In other words,
 * as a stateless application module.
 *
 * @param event ADF page phase event
 */
 public void afterPhase(PagePhaseEvent event) {
 if (event.getPhaseId() == Lifecycle.PREPARE_RENDER_ID) {
 getDataControl("UserModuleDataControl", event).resetState();
 }
 }
 // Required to implement the PagePhaseListener interface
 public void beforePhase(PagePhaseEvent event) {}
 private DCDataControl getDataControl(String name,
 PagePhaseEvent event) {
 return event.getLifecycleContext()
 .getBindingContext()
 .findDataControl(name);
 }
}
```

### 43.4.6 How to Set Release Level in an ADF PageController

[Example 43–3](#) shows calling the `resetState()` method on a data control named `UserModuleDataControl` from an overridden `prepareRender()` method of a custom ADF page controller class. You would associate this custom class to a particular page by setting the `ControllerClass` attribute on the page's page definition to the fully-qualified name of this class.

---

**Note:** You can accomplish basically the same kinds of page-specific lifecycle customization tasks using a custom `PagePhaseListener` or a custom `PageController` class. The key difference is that the `PagePhaseListener` interface can be implemented on any class, while a custom `PageController` must extend the `PageController` class in the `oracle.adf.controller.v2.lifecycle` package.

---

#### **Example 43–3 Calling `resetState()` on Data Control in a Custom ADF `PageController`**

```
package devguide.advanced.releasestateless.controller;
```

```

import oracle.adf.controller.v2.context.LifecycleContext;
import oracle.adf.controller.v2.lifecycle.PageController;
import oracle.adf.controller.v2.lifecycle.PagePhaseEvent;
import oracle.adf.model.binding.DCDataControl;
public class ReleaseStatelessPageController extends PageController {
 /**
 * After calling the super in the final prepareRender() phase
 * of the ADF Lifecycle, call resetState() on the data control
 * to cause it to release to the pool with the "unmanaged"
 * release level. In other words, as a stateless application module.
 *
 * @param lcCtx ADF lifecycle context
 */
 public void prepareRender(LifecycleContext lcCtx) {
 super.prepareRender(lcCtx);
 getDataControl("UserModuleDataControl", lcCtx).resetState();
 }
 private DCDataControl getDataControl(String name,
 LifecycleContext lcCtx) {
 return lcCtx.getBindingContext().findDataControl(name);
 }
}

```

#### 43.4.7 How to Set Release Level in a Custom ADF PageLifecycle

If you wanted to build a Fusion web application where every request was handled in a completely stateless way, use a global custom `PageLifecycle` class as shown in [Example 43-4](#). For details on how to configure your application to use your custom lifecycle see [Section 25.2, "About the JSF and ADF Page Lifecycles."](#)

**Example 43-4 Calling `resetState()` on Data Control in a Custom ADF PageLifecycle**

```

package devguide.advanced.releasestateless.controller;
import oracle.adf.controller.faces.lifecycle.FacesPageLifecycle;
import oracle.adf.controller.v2.context.LifecycleContext;
import oracle.adf.model.binding.DCDataControl;
public class ReleaseStatelessPageLifecycle extends FacesPageLifecycle {
 /**
 * After calling the super in the final prepareRender() phase
 * of the ADF Lifecycle, call resetState() on the data control
 * to cause it to release to the pool with the "unmanaged"
 * release level. In other words, as a stateless application module.
 *
 * @param lcCtx ADF lifecycle context
 */
 public void prepareRender(LifecycleContext lcCtx) {
 super.prepareRender(lcCtx);
 getDataControl("UserModuleDataControl", lcCtx).resetState();
 }
 private DCDataControl getDataControl(String name,
 LifecycleContext lcCtx) {
 return lcCtx.getBindingContext().findDataControl(name);
 }
}

```

### 43.5 What Model State Is Saved and When It Is Cleaned Up

The information saved by application model passivation is divided in two parts: transactional and non-transactional state. Transactional state is the set of updates made

to entity object data – performed either directly on entity objects or on entities through view object rows – that are intended to be saved into the database. Non-transactional state comprises view object runtime settings, such as the current row index, `WHERE` clause, and `ORDER BY` clause.

### 43.5.1 State Information Saved During Passivation

The information saved as part of the application module passivation "snapshot" includes the following.

#### Transactional State

- New, modified, and deleted entities in the entity caches of the root application module for this user session's (including old/new values for modified ones).

#### Non-Transactional State

- For each active view object (both statically and dynamically created):
  - Current row indicator for each row set (typically one)
  - New rows and their positions. (New rows are treated differently than updated ones. Their index in the view object is traced as well.)
  - ViewCriteria and all related parameters such as view criteria row, etc.
  - Flag indicating whether or not a row set has been executed
  - Range start and Range size
  - Access mode
  - Fetch mode and fetch size
  - Any view object-level custom data

---

---

**Note:** Transient view object attributes can be saved if they are selected for passivation at design time. However, use this feature judiciously because this results in a snapshot that will grow in size with the number of rows that have been retrieved.

---

---

- `SELECT`, `FROM`, `WHERE`, and `ORDER BY` clause if created dynamically or changed from the View definition

---

---

**Note:** If you enable ADF Business Components runtime diagnostics, the contents of each XML state snapshot are also saved. See [Section 6.3.8, "How to Enable ADF Business Components Debug Diagnostics"](#) for information on how to enable diagnostics.

---

---

### 43.5.2 Where the Model State Is Saved

By default, passivation snapshots are saved in the database, but you can configure it to use the file system as an alternative.

#### 43.5.2.1 How Database-Backed Passivation Works

The passivated XML snapshot is written to a BLOB column in a table named `PS_TXN`, using a connection specified by the `jbo.server.internal_connection` property. Each time a passivation record is saved, it is assigned a unique passivation snapshot ID based on the sequence number taken from the `PS_TXN_SEQ` sequence. The ADF

session cookie held by the application module data control in the ADF binding context remembers the latest passivation snapshot ID that was created on its behalf and remembers the previous ID that was used.

### 43.5.2.2 Controlling the Schema Where the State Management Table Resides

The ADF runtime recognizes a configuration property named `jbo.server.internal_connection` that controls which database connection and schema should be used for the creation of the `PS_TXN` table and the `PS_TXN_SEQ` sequence. If you don't set the value of this configuration parameter explicitly, then the state management facility creates the temporary tables using the credentials of the current application database connection.

To keep the temporary information separate, the state management facility uses a different connection *instance* from the database connection pool, but the database credentials are the same as the current user. Since the framework creates temporary tables, and possibly a sequence if they don't already exist, the implication of not setting a value for the `jbo.server.internal_connection` is that the current database user must have `CREATE TABLE`, `CREATE INDEX` and `CREATE SEQUENCE` privileges. Since this is often not desirable, Oracle recommends always supplying an appropriate value for the `jbo.server.internal_connection` property, providing the credentials for a state management schema where table and schema be created. Valid values for the `jbo.server.internal_connection` property in your configuration are:

- A fully-qualified JDBC connection URL like:
 

```
jdbc:oracle:thin:username/password@host:port:SID
```
- A JDBC datasource name like:
 

```
java:/comp/env/jdbc/YourJavaEEDataSourceName
```

**Performance Tip:** When creating the `PS_TXN` table, use securefiles to store LOB data (the content column), and create a primary column index on the `PS_TXN` table as global, partitioned reverse key index. The securefile configuration delivers superior performance over the basicfile configuration when working with LOB data. The reverse key index helps by reducing contention that can happen when the rate of inserts is high.

### 43.5.2.3 Configuring the Type of Passivation Store

Passivated information can be stored in several places. You can control it programmatically or by configuring an option in the application module configuration. The choices are database or a file stored on local file system:

- **File**

This choice may be the fastest available, because access to the file is faster than access to the database. This choice is good if the entire middle tier (one or multiple Oracle Application Server installation(s) and all their server instances) is either installed on the same machine or has access to a commonly shared file system, so passivated information is accessible to all. Usually, this choice may be good for a small middle tier where one Oracle Application Server is used. In other words this is a very suitable choice for small middle tier such as one Oracle Application Server with all its components installed on one physical machine. The location and name of the persistent snapshot files are determined by `jbo.tmpdir` property if specified. It follows usual rules of ADF property precedence for a configuration

property. If nothing else is specified, then the location is determined by `user.dir` if specified. This is a default property and the property is OS specific.

- **Database**

This is the *default* choice. While it may be a little slower than passivating to file, it is by far the most reliable choice. With passivation to file, the common problem might be that it is not accessible to Oracle Application Server instances that are remotely installed. In this case, in a cluster environment, if one node goes down the other may not be able to access passivated information and then failover will not work. Another possible problem is that even if file is accessible to the remote node, the access time for the local and remote node may be very different and performance will be inconsistent. With database access, time should be about the same for all nodes.

To set the value of your choice in design time, set the property `jbo.passivationstore` to `database` or `file`. The value `null` will indicate that a connection-type-specific default should be used. This will use database passivation for Oracle or DB2, and file serialization for any others.

To set the storage programmatically use the method `setStoreForPassiveState()` of interface `oracle.jbo.ApplicationModule`. The parameter values that you can pass are:

- `PASSIVATE_TO_DATABASE`
- `PASSIVATE_TO_FILE`

### 43.5.3 Cleaning Up the Model State

Under normal circumstances, the ADF state management facility provides automatic cleanup of the passivation snapshot records.

#### 43.5.3.1 Previous Snapshot Removed When Next One Taken

When a passivation record is saved to the database on behalf of a session cookie, as described above, this passivation record gets a new, unique snapshot ID. The passivation record with the previous snapshot ID used by that same session cookie is deleted as part of the same transaction. In this way, assuming no server failures, there will only ever be a single passivation snapshot record per active end-user session.

#### 43.5.3.2 Passivation Snapshot Removed on Unmanaged Release

The passivation snapshot record related to a session cookie is removed when the application module is checked into the pool with the unmanaged state level. This can occur when:

- Your code specifically calls `resetState()` on the application module data control.
- Your code explicitly invalidates the `HttpSession`, for example, as part of implementing an explicit "Logout" functionality.
- The `HttpSession` times out due to exceeding the session timeout threshold for idle time and failover mode is disabled (which is the default).

In each of these cases, the application module pool also resets the application module referenced by the session cookie to be "unreferenced" again. Since no changes were ever saved into the underlying database tables, once the pending session state snapshots are removed, there remains no trace of the unfinished work the user session had completed up to that point.

### 43.5.3.3 Passivation Snapshot Retained in Failover Mode

When the failover mode is enabled, if the `HttpSession` times out due to session inactivity, then the passivation snapshot is retained so that the end user can resume work upon returning to the browser.

After a break in the action, when the end user returns to his browser and continues to use the application, it continues working as if nothing had changed. The session cookie is used to reactivate any available application module instance with the user's last pending state snapshot before handling the request. So, even though the user's next request will be processed in the context of a new `HttpSession` (perhaps even in a different application server instance), the user is unaware that this has occurred.

---

---

**Note:** If an application module was released with reserved level then the `HttpSession` times out, the user will have to go through authentication process, and all unsaved changes are lost.

---

---

## 43.5.4 Cleaning Up Temporary Storage Tables

JDeveloper supplies the `adfbrc_purge_statesnapshots.sql` script to help with periodically cleaning up the application module state management table. You can find this file in the `oracle_common` subdirectory of your Oracle Middleware installation directory (for example, `ORACLE_HOME\oracle_common\common\sql`).

Persistent snapshot records can accumulate over time if the server has been shutdown in an abnormal way, such as might occur during development or due to a server failure. Running the script in SQL\*Plus will create the `BC4J_CLEANUP` PL/SQL package. The two relevant procedures in this package are:

- `PROCEDURE Session_State(olderThan DATE)`  
This procedure cleans-up application module session state storage for sessions older than a given date.
- `PROCEDURE Session_State(olderThan_minutes INTEGER)`  
This procedure cleans-up application module session state storage for sessions older than a given number of minutes.

You can schedule periodic cleanup of your ADF temporary persistence storage by submitting an invocation of the appropriate procedure in this package as a database job.

You can use an anonymous PL/SQL block like the one shown in [Example 43-5](#) to schedule the execution of `bc4j_cleanup.session_state()` to run starting tomorrow at 2:00 am and each day thereafter to cleanup sessions whose state is over 1 day (1440 minutes) old.

### Example 43-5 Scheduling Periodic Cleanup of the State Management Table

```
SET SERVEROUTPUT ON
DECLARE
 jobId BINARY_INTEGER;
 firstRun DATE;
BEGIN
 -- Start the job tomorrow at 2am
 firstRun := TO_DATE(TO_CHAR(SYSDATE+1, 'DD-MON-YYYY') || ' 02:00',
 'DD-MON-YYYY HH24:MI');
 -- Submit the job, indicating it should repeat once a day
 dbms_job.submit(job => jobId,
```

```

-- Run the ADF Purge Script for Session State
-- to cleanup sessions older than 1 day (1440 minutes)
what => 'bc4j_cleanup.session_state(1440);',
next_date => firstRun,
-- When completed, automatically reschedule
-- for 1 day later
interval => 'SYSDATE + 1'
);
dbms_output.put_line('Successfully submitted job. Job Id is '||jobId);
END;
.
/

```

## 43.6 Timing Out the HttpSession

Since HTTP is a stateless protocol, the server receives no implicit notice that a client has closed his browser or gone away for the weekend. Therefore any Java EE-compliant server provides a standard, configurable session timeout mechanism to allow resources tied to the HTTP session to be freed when the user has stopped performing requests. You can also programmatically force a timeout.

### 43.6.1 How to Configure the Implicit Timeout Due to User Inactivity

You configure the session timeout threshold using the `<session-timeout>` tag in the `web.xml` file. The default value is 35 minutes. When the `HttpSession` times out the `BindingContext` goes out of scope, and along with it, any data controls that might have referenced application modules released to the pool in the managed state level. The application module pool resets any of these referenced application modules and marks the instances unreferenced again.

### 43.6.2 How to Code an Explicit HttpSession Timeout

To end a user's session before the session timeout expires, you can call the `invalidate()` method on the `HttpSession` object from a backing bean in response to the user's click on a Logout button or link. This cleans up the `HttpSession` in the same way as if the session time had expired. Using JSF and ADF, after invalidating the session, you *must* perform a redirect to the next page you want to display, rather than just doing a forward. [Example 43-6](#) shows sample code to perform this task from a Logout button.

#### **Example 43-6** Programatically Terminating a Session

```

public String logoutButton_action() throws IOException{
 ExternalContext ectx = FacesContext.getCurrentInstance().getExternalContext();
 HttpServletResponse response = (HttpServletResponse)ectx.getResponse();
 HttpSession session = (HttpSession)ectx.getSession(false);
 session.invalidate();
 response.sendRedirect("Welcome.jspx");
 return null;
}

```

As with the implicit timeouts, when the HTTP session is cleaned up this way, it ends up causing any referenced application modules to be marked unreferenced.

## 43.7 Managing Custom User-Specific Information

It is fairly common practice to add custom user-defined information in the application module in the form of member variables or some custom information stored in `oracle.jbo.Session` user data hashtable. The ADF state management facility provides a mechanism to save this custom information to the passivation snapshot as well, by overriding the `passivateState()` method and either the `activateState()` method or the `prepareForActivation()` method in the `ApplicationModuleImpl` class.

---

---

**Note:** Similar methods are available on the `ViewObjectImpl` class and the `EntityObjectImpl` class to save custom state for those objects to the passivation snapshot as well.

---

---

### 43.7.1 How to Passivate Custom User-Specific Information

You can override `passivateState()` and `activateState()` to ensure that custom application module state information is included in the passivation/activation cycle. [Example 43-7](#) shows how this is done.

---

---

**Note:** The `activateState()` method is called at the end of the activation process after the view object have been activated. Most of the time this is where you want to place the application module state activation logic. However, if your application module activation logic needs to setup custom state information before the ADF statement management facility activates the view objects (for example, you might need to write custom code to allow the view objects to internally reference custom values at execution time), then the `prepareForActivation()` method in the `ApplicationModuleImpl` class would be the right place since it fires at the beginning of the activation process.

---

---

In the example, `jbo.counter` contains custom values you want to preserve across passivation and activation of the application module state. Each application module has an `oracle.jbo.Session` object associated with it that stores application module-specific session-level state. The session contains a user data hashtable where you can store transient information. For the user-specific data to "survive" across application module passivation and reactivation, you need to write code to save and restore this custom value into the application module state passivation snapshot.

#### **Example 43-7** *Passivating and Activating Custom Information in the State Snapshot XML Document*

```
/**
 * Overridden framework method to passivate custom XML elements
 * into the pending state snapshot document
 */
public void passivateState(Document doc, Element parent) {
 // 1. Retrieve the value of the value to save
 int counterValue = getCounterValue();
 // 2. Create an XML element to contain the value
 Node node = doc.createElement(COUNTER);
 // 3. Create an XML text node to represent the value
 Node cNode = doc.createTextNode(Integer.toString(counterValue));
 // 4. Append the text node as a child of the element
```

```

node.appendChild(cNode);
// 5. Append the element to the parent element passed in
parent.appendChild(node);
}
/**
 * Overridden framework method to activate custom XML elements
 * into the pending state snapshot document
 */
public void activateState(Element elem) {
 super.activateState(elem);
 if (elem != null) {
 // 1. Search the element for any <jbo.counter> elements
 NodeList nl = elem.getElementsByTagName(COUNTER);
 if (nl != null) {
 // 2. If any found, loop over the nodes found
 for (int i=0, length = nl.getLength(); i < length; i++) {
 // 3. Get first child node of the <jbo.counter> element
 Node child = nl.item(i).getFirstChild();
 if (child != null) {
 // 4. Set the counter value to the activated value
 setCounterValue(new Integer(child.getNodeValue()).intValue()+1);
 break;
 }
 }
 }
 }
}
/**
 * Helper Methods
 */
private int getCounterValue() {
 String counterValue = (String)getSession().getUserData().get(COUNTER);
 return counterValue == null ? 0 : Integer.parseInt(counterValue);
}
private void setCounterValue(int i) {
 getSession().getUserData().put(COUNTER, Integer.toString(i));
}
private static final String COUNTER = "jbo.counter";

```

### 43.7.1.1 What Happens When You Passivate Custom Information

In [Example 43-7](#), when `activateState()` is overridden, the following steps are performed:

1. Search the element for any `jbo.counter` elements.
2. If any are found, loop over the nodes found in the node list.
3. Get first child node of the `jbo.counter` element.

It should be a DOM Text node whose value is the string you saved when your `passivateState()` method above got called, representing the value of the `jbo.counter` attribute.

4. Set the counter value to the activated value from the snapshot.

When `passivateState()` is overridden, it performs the reverse job by doing the following:

1. Retrieve the value of the value to save.
2. Create an XML element to contain the value.

3. Create an XML text node to represent the value.
4. Append the text node as a child of the element.
5. Append the element to the parent element passed in.

---

**Note:** The API's used to manipulate nodes in an XML document are provided by the Document Object Model (DOM) interfaces in the `org.w3c.dom` package. These are part of the Java API for XML Processing (JAXP). See the Javadoc for the `Node`, `Element`, `Text`, `Document`, and `NodeList` interfaces in this package for more details.

---

## 43.8 Managing the State of View Objects

By default, all view objects are marked as passivation-enabled, so their state will be saved. However, view objects that have transient attributes do not have those attributes passivated by default. You can change how a view object is passivated, and even which attributes are passivated, using the Tuning page of the view object overview editor.

### 43.8.1 How to Manage the State of View Objects

Each view object can be declaratively configured to be passivation-enabled or not. If a view object is not passivation enabled, then no information about it gets written in the application module passivation snapshot.

**Performance Tip:** There is no need to passivate read-only view objects since they are not intended to be updated and are easily recreated from the XML definition. This eliminates the performance overhead associated with passivation and activation and reduces the CPU usage needed to maintain the application module pool.

**To set the passivation state of a view object:**

1. In the Application Navigator, double-click a view object to open it in the overview editor.
2. On the General page, expand the **Tuning** section.
3. Select **Passivate State** to make sure the view object data is saved.

Optionally, you can select **Including All Transient Attributes** to passivate all transient attributes at this time, but see [Section 43.8.4, "What You May Need to Know About Passivating Transient View Objects"](#) for additional information.

### 43.8.2 What You May Need to Know About Passivating View Objects

The activation mechanism is designed to return your view object to the state it was in when the last passivation occurred. To ensure that, Oracle ADF stores in the state snapshot the values of any bind variables that were used for the last query execution. These bind variables are in addition to those that are set on the row set at the time of passivation. This approach works for an application that does not dynamically reset the WHERE clause and bind variables on each request. In this case, the set of bind variable values used for the last `executeQuery()` and the set of bind variables current on the row set at passivation time are the same. The passivated state also stores the user-supplied WHERE clause on the view object related to the row set at the time of passivation.

However, when your application needs to dynamically change WHERE clauses and corresponding bind variables during the span of a single HTTP request, you need to ensure that the user-defined WHERE clause on the view object at the time of passivation matches the set of bind variable values used the last time the view object was executed before passivation. In this case, this is the correct sequence to follow:

1. (Request begins and AM is acquired.)
2. Call `setWhereClause()` on a view object instance that references  $n$  bind variables.
3. Call `setWhereClauseParam()` to set the  $n$  values for those  $n$  bind variables.
4. Call `executeQuery()`.
5. Call `setWhereClause(null)` to clear WHERE clause.
6. Call `setWhereClauseParams(null)` to clear the WHERE clause bind variables.
7. (AM is released.)

If you do not adhere to this strategy of changing runtime view object settings before using them, your application will fail with an SQL exception during application module pooling state activation:

```
JBO-27122: SQLStmtException: <... SQL Statement ...>
```

Because many of the view object's instance settings are saved in the passivation state snapshot and restored on activation (as described in [Section 43.5.1, "State Information Saved During Passivation"](#)), it is not advisable to change any of these settings just after executing the view object if you won't be re-executing the view object again during the same block of code (and so, during the same HTTP request). Instead, change the view object instance settings the next time you need them to be different before executing the query.

If you are dynamically adding named WHERE clause parameters to your view object instances, you might find it useful to add the following helper method to your `ViewObjectImpl` framework extension class. This method removes named bind variables that have been added to the view instance at runtime, without removing the ones that have been declaratively defined on the view definition at design time.

```
protected void clearWhereState() {
 ViewDefImpl viewDef = getViewDef();
 Variable[] viewInstanceVars = null;
 VariableManager viewInstanceVarMgr = ensureVariableManager();
 if (viewInstanceVarMgr != null) {
 viewInstanceVars = viewInstanceVarMgr.getVariablesOfKind(Variable.VAR_KIND_
WHERE_CLAUSE_PARAM);
 if (viewInstanceVars != null) {
 for (Variable v: viewInstanceVars) {
 // only remove the variable if its not on the view def.
 if (!hasViewDefVariableNamed(v.getName())) {
 removeNamedWhereClauseParam(v.getName());
 }
 }
 }
 }
 getDefaultRowSet().setExecuteParameters(null, null, true);
 setWhereClause(null);
 getDefaultRowSet().setWhereClauseParams(null);
}

private boolean hasViewDefVariableNamed(String name) {
```

```
boolean ret = false;
VariableManager viewDefVarMgr = getViewDef().ensureVariableManager();
if (viewDefVarMgr != null) {
 try {
 ret = viewDefVarMgr.findVariable(name) != null;
 }
 catch (NoDefException ex) {
 // ignore
 }
}
return ret;
}
```

### 43.8.3 How to Manage the State of Transient View Objects and Attributes

Because view objects are marked as passivated by default, a transient view object — one that contains only transient attributes — is marked to be passivation enabled, but only passivates its information related to the current row and other non-transactional state.

**Performance Tip:** Transient view object attributes are not passivated by default. Due to their nature, they are usually intended to be read-only and are easily recreated. So, it often doesn't make sense to passivate their values as part of the XML snapshot. This also avoids the performance overhead associated with passivation and activation and reduces the CPU usage needed to maintain the application module pool.

**To individually set the passivation state for transient view object attributes:**

1. In the Application Navigator, double-click a view object to open it in the overview editor.
2. On the Attributes page, select the transient attribute you want to passivate and then click the **Details** tab.
3. In the Details section, select the **Passivate** checkbox.

### 43.8.4 What You May Need to Know About Passivating Transient View Objects

Passivating transient view object attributes is more costly resource-wise and performance-wise, because transactional functionality is usually managed on the entity object level. Since transient view objects are not based on an entity object, this means that all updates are managed in the view object row cache and not in the entity cache. Therefore, passivating transient view objects or transient view object attributes requires special runtime handling.

Usually passivation only saves the values that have been changed, but with transient view objects passivation has to save entire row. The row will include only the view object attributes marked for passivation.

### 43.8.5 How to Use Transient View Objects to Store Session-level Global Variables

Using passivation, you can use a view object to store one or more global variables, each on a different transient attribute. When you mark a transient attribute as passivated, the ADF Business Components framework will remember the transient values across passivation and activation in high-throughput and failover scenarios. Therefore, it is an easy way to implement a session-level global value that is backed up

by the state management mechanism, instead of the less-efficient HTTP Session replication. This also makes it easy to bind to controls in the UI if necessary.

There are two basic approaches to store values between invocations of different screens, one is controller-centric, and the other is model-centric.

### Implementation of the task in the ADF controller

The controller-centric approach involves storing and referencing values using attributes in the pageFlow scope. This approach might be appropriate if the global values do not need to be referenced internally by any implementations of ADF Business Components.

For more information about pageFlow scope, see [Section 18.2.4, "What You May Need to Know About Memory Scope for Task Flows."](#)

### Implementation of the task in the ADF model

The model-centric approach involves creating a transient view object, which is conceptually equivalent to a non-database block in Oracle Forms.

1. Create a new view object using the View Object Wizard, as described in [Section 5.2.1, "How to Create an Entity-Based View Object."](#)
  - On step 1 of the wizard, select the option for **Rows populated programmatically, not based on a query.**
  - On step 2, click **New** to define the transient attribute names and types the view object should contain. Make sure to set the **Updateable** option to **Always.**
  - Click **Finish** and the newly-created view object appears in the overview editor.
2. Disable any queries from being performed in the view object.
  - On the General page of the overview editor, expand the **Tuning** section, and in the **Retrieve from Database** group box, select the **No Rows** option.
3. Make sure data in the view object is not cleared out during a rollback operation. To implement this, you enable a custom Java class for the view object and override two rollback methods.
  - On the Java page of the overview editor, click the **Edit** icon in the **Java Classes** section to open the Java dialog.
  - In the Java dialog, select **Generate View Object Class** and click **OK.**
  - In the overview editor, click on the hyperlink next to the View Object Class in the **Java Classes** section to open the source editor.
  - From the **Source** menu, choose **Override Methods.**
  - In the Override Methods dialog, select the `beforeRollback()` and `afterRollback()` methods to override, and click then **OK.**
  - In both the `beforeRollback()` and `afterRollback()` methods, comment out the call to `super` in the Java code.
4. Add an instance of the transient view object to your application module's data model, as described in [Section 9.2.3.2, "Adding Master-Detail View Object Instances to an Application Module."](#)
5. Create an empty row in the view object when a new user begins using the application module.
  - Enable a Java class for your application module if you don't have one yet.

- Override the `prepareSession()` method of the application module, as described in [Section 9.11.1, "How to Override a Built-in Framework Method."](#)
- After the call to `super.prepareSession()`, add code to create a new row in the transient view object and insert it into the view object.

Now you can bind read-only and updateable UI elements to the "global" view object attributes just as with any other view object using the Data Controls panel.

## 43.9 Using State Management for Middle-Tier Savepoints

In the database server you are likely familiar with the savepoint feature that allows a developer to rollback to a certain point within a transaction instead of rolling back the entire transaction. An application module offers the same feature but implemented in the middle tier.

---

---

**Best Practice:** Oracle ADF provides a declarative approach to working with savepoints, described in [Section 22.6, "Using Save Points in Task Flows."](#) Use the programmatic approach described in [Section 43.9.1, "How to Use State Management for Savepoints"](#) only if the declarative approach doesn't meet your needs.

---

---

### 43.9.1 How to Use State Management for Savepoints

To use state management for implementing middle-tier savepoints, you override three methods in the `oracle.jbo.ApplicationModule` interface

```
public String passivateStateForUndo(String id,byte[] clientData,int flags)
public byte[] activateStateForUndo(String id,int flags)
public boolean isValidIdForUndo(String id)
```

You can use these methods to create a stack of named snapshots and restore the pending transaction state from them by name. Keep in mind that those snapshots do not survive past duration of transaction (for example, events of commit or rollback). This feature could be used to develop complex capabilities of the application, such as the ability to undo and redo changes. Another ambitious goal that could exploit this functionality would be functionality to make the browser back and forward buttons behave in an application-specific way. Otherwise, simple uses of these methods can come quite in handy.

## 43.10 Testing to Ensure Your Application Module is Activation-Safe

If you have not *explicitly* tested that your application module functions when its pending state gets activated from a passivation snapshot, then you may encounter an unpleasant surprise in your production environment when heavy system load tests this aspect of your system for the first time.

### 43.10.1 Understanding the `jbo.ampool.doampooling` Configuration Parameter

The `jbo.ampool.doampooling` configuration property corresponds to the **Enable Application Module Pooling** option in the **Pooling and Scalability** tab of the Business Components Configuration dialog. By default, this checkbox is checked so that application module pooling is enabled. Whenever you deploy your application in a production environment the default setting of `jbo.ampool.doampooling` to `true` is the way you will run your application. But, as long as you run your application in a test environment, setting the property to `false` can play an important role in your

testing. When this property is false, there is effectively no application pool. When the application module instance is released at the end of a request it is immediately removed. On subsequent requests made by the same user session, a new application module instance must be created to handle it and the pending state of the application module must be reactivated from the passivation store.

### 43.10.2 Disabling Application Module Pooling to Test Activation

As part of your overall testing plan, you should adopt the practice of testing your application modules with the `jbo.ampool.doampooling` configuration parameter set to `false`. This setting completely disables application module pooling and forces the system to activate your application module's pending state from a passivation snapshot on *each* page request. It is an excellent way to detect problems that might occur in your production environment due to assumptions made in your custom application code.

---

**Caution:** It is important to reenable application module pooling after you conclude testing and are ready to deploy the application to a production environment. The configuration property `jbo.ampool.doampooling` set to `false` is not a supported configuration for production applications and must be set to `true` before deploying the application.

---

For example, if you have transient view object attributes you believe *should* be getting passivated, this technique allows you to test that they are working as you expect. In addition, consider situations where you might have introduced:

- Private member fields in application modules, view objects, or entity objects
- Custom user session state in the `Session` user data hashtable

Your custom code likely assumes that this custom state will be maintained across HTTP requests. As long as you test with a single user on the JDeveloper Integrated WebLogic Server, or test with a small number of users, things will appear to work fine. This is due to the "stateless with affinity" optimization of the ADF application module pool. If system load allows, the pool will continue to return the same application module instance to a user on subsequent requests. However, under heavier load, during real-world use, it may not be able to achieve this optimization and will need to resort to grabbing any available application module instance and reactivating its pending state from a passivation snapshot. If you have not correctly overridden `passivateState()` and `activateState()` (as described in [Section 43.7, "Managing Custom User-Specific Information"](#)) to save and reload your custom component state to the passivation snapshot, then your custom state will be missing (i.e. `null` or back to your default values) after this reactivation step. Testing with `jbo.ampool.doampooling` set to `false` allows you to quickly isolate these kinds of situations in your code.

## 43.11 Keeping Pending Changes in the Middle Tier

The ADF state management mechanism relies on passivation and activation to manage the state of an application module instance. Implementing this feature in a robust way is only possible if all pending changes are managed by the application module transaction in the middle tier. The most scalable strategy is to keep pending changes in middle-tier objects and not perform operations that cause pending database state to exist across HTTP requests. This allows the highest leverage of the performance

optimizations offered by the application module pool and the most robust runtime behavior for your application.

When the `jbo.doconnectionpooling` configuration parameter is set to `true` — typically in order to share a common pool of database connections across multiple application module pools — upon releasing your application module to the application module pool, its JDBC connection is released back to the database connection pool and a `ROLLBACK` will be issued on that connection. This implies that all changes which were posted but *not committed* will be lost. On the next request, when the application module is used, it will receive a JDBC connection from the pool, which may be a different JDBC connection instance from the one it used previously. Those changes that were posted to the database but not committed during the previous request are lost.

---

**Caution:** When the `jbo.doconnectionpooling` configuration parameter is set to `true` — typically in order to share a common pool of database connections across multiple application module pools — upon releasing your application module to the application module pool, its JDBC connection is released back to the database connection pool and a `ROLLBACK` will be issued on that connection. This implies that all changes which were posted but *not committed* will be lost. On the next request, when the application module is used, it will receive a JDBC connection from the pool, which may be a different JDBC connection instance from the one it used previously. Those changes that were posted to the database but not committed during the previous request are lost.

The `jbo.doconnectionpooling` configuration parameter is set by checking the **Disconnect Application Module Upon Release** property on the **Pooling and Scalability** tab of the Business Components Configuration dialog.

---

### 43.11.1 How to Confirm That Applications Use Optimistic Locking

Oracle recommends using optimistic locking, the default mode for web applications. Pessimistic locking should not be used for web applications as it creates pending transactional state in the database in the form of row-level locks. If pessimistic locking is set, state management will work, but the locking mode will not perform as expected. Behind the scenes, every time an application module is recycled, a rollback is issued in the JDBC connection. This releases all the locks that pessimistic locking had created.

**Performance Tip:** Always use the default mode optimistic locking for web applications. Only optimistic locking is compatible with the application module unmanaged release level mode, which allows the application module instance to be immediately released when a web page terminates. This provides the best level of performance for web applications that expect many users to access the application simultaneously.

To ensure your configuration uses optimistic locking, open the **Properties** tab of the Business Components Configuration dialog and confirm that the value of the `jbo.locking.mode` property is set to `optimistic` or `optupdate`.

---

---

**Note:** To open the Business Components Configuration dialog, right-click the application module in the Application Navigator, and choose **Configurations** from the context menu. Then, in the Manage Configurations dialog, select the configuration you want to edit and click **Edit**.

---

---

Optimistic locking (`optimistic`) issues a `SELECT FOR UPDATE` statement to lock the row, then detects whether the row has been changed by another user by comparing the change indicator attribute — or, if no change indicator is specified, the values of all the persistent attributes of the current entity as they existed when the entity object was fetched into the cache.

Optimistic update locking (`optupdate`) does not perform any locking. The `UPDATE` statement determines whether the row was updated by another user by including a `WHERE` clause that will match the existing row to update only if the attribute values are unchanged since the current entity object was fetched.

### 43.11.2 How to Avoid Clashes Using the `postChanges()` Method

The transaction-level `postChanges()` method exists to force the transaction to post unvalidated changes without committing them. This method is not recommended for use in web applications unless you can guarantee that the transaction will definitely be committed or rolled-back during the same HTTP request. Failure to heed this advice can lead to strange results in an environment where both application modules and database connections can be pooled and shared serially by multiple different clients.

### 43.11.3 How to Use the Reserved Level For Pending Database States

If for some reason you need to create a transactional state in the database in some request by invoking `postChanges()` method or by calling PL/SQL stored procedure, but you cannot issue a commit or rollback by the end of that same request, then you *must* release the application module instance with the **reserved** level from that request until a subsequent request when you either commit or rollback.

**Performance Tip:** Use as short a period of time as possible between creation of transactional state in the database and performing the concluding commit or rollback. This ensures that reserved level doesn't have to be used for a long time, as it has adverse effects on application's scalability and reliability.

Once an application module has been released with reserved level, it remains at that release level for all subsequent requests until release level is explicitly changed back to managed or unmanaged level. So, it is your responsibility to set release level back to managed level once commit or rollback has been issued.

For more information, see [Section 43.4, "Setting the Application Module Release Level at Runtime."](#)

---

---

## Tuning Application Module Pools and Connection Pools

This chapter describes how ADF Business Components application module pools work and how you can tune both application module pools and database connection pools to optimize application performance.

This chapter includes the following sections:

- [Section 44.1, "About Application Module Pooling"](#)
- [Section 44.2, "Setting Pool Configuration Parameters"](#)
- [Section 44.3, "Initializing Database State and Pooling Considerations"](#)

### 44.1 About Application Module Pooling

An application module pool is a collection application module instances of the same type. For example, the Fusion Order Demo application has one or more instances of the application module in it, based on the number of users that are visiting the site. This pool of application module instances is shared by multiple browser clients whose typical "think time" between submitting web pages allows optimizing the number of application module components to be effectively smaller than the total number of active users working on the system. That is, twenty users visiting the web site from their browser might be able to be serviced by 5 or 10 application module instances instead of having as many application module instances as you have browser users.

Application module components can be used to support Fusion web application scenarios that are completely stateless, or they can be used to support a unit of work that spans multiple browser pages. As a performance optimization, when an instance of an application module is returned to the pool in "managed state" mode, the pool tracks session references to the application module. The application module instance is still in the pool and available for use, but it would *prefer* to be used by the same session that was using it the last time because maintaining this so-called "session affinity" improves performance.

So, at any one moment in time, the instances of application modules in the pool are logically partitioned into three groups, reflecting their state:

- Unconditionally *available* for use
- Available for use, but *referenced* for session affinity reuse by an active user session
- *Unavailable*, inasmuch as it's currently in use (at that very moment) by some thread in the web container.

Section 44.2.5, "What You May Need to Know About Configuration Property Scopes" describes the application module pool configuration parameters and how they affect the behavior of the pool.

## 44.1.1 Types of Pools Created When Running the Fusion Web Application

There are two kinds of pools in use when running a typical Fusion web application, Application Module pools and database connection pools. It's important to understand how many of each kind of pool your application will create.

### 44.1.1.1 Application Module Pools

Application Module components can be used at runtime in two ways:

- As an application module the client accesses directly
- As a reusable component aggregated (or "nested") inside of another application module instance

When a client accesses it directly, an application module is called a *root application module*. Clients access nested application modules *indirectly* as a part of their containing application module instance. It's possible, but not common, to use the same application module at runtime in both ways. The important point is that ADF only creates an application module pool for a *root* application module.

The basic rule is that one application module pool is created for each *root* application module used by a Fusion web application in *each* Java VM where a root application module of that type is used by the ADF controller layer.

### 44.1.1.2 Database Connection Pools

The type of database connection pool the Fusion web application uses depends on the connection type that you configure for your application modules:

- JDBC URL (e.g. `jdbc:oracle:thin:@penguin:1521:ORCL`)
- JNDI name for a data source (e.g. `java:comp/env/jdbc/YourConnectionDS`)

If you supply a JDBC URL connection while configuring your application module — which happens when you select a JDeveloper named connection which encapsulates the JDBC URL and username information — then the ADF database connection pool will be used for managing the connection pool.

If you supply the JNDI name of a JDBC data source then the ADF database connection pool will *not* be used and the configuration parameters described below relating to the ADF database connection pool are not relevant.

---

---

**Note:** To configure the database connection pool for JDBC data sources looked-up by JNDI from your Java EE web and/or EJB container, consult the documentation for your Java EE container to understand the pooling configuration options and how to set them.

---

---

When using ADF database connection pooling, you have the following basic rule: One database connection pool is created for each unique `<JDBCURL, Username>` pair, in *each* Java VM where a `<JDBCURL, Username>` connection is requested by a root application used by the ADF controller layer.

## 44.1.2 Understanding Application Module and Connection Pools

The number of pools and the type of pools that your application will utilize will depend upon how the target platform is configured. For example, will there be more than one Java Virtual Machine (JVM) available to service the web requests coming from your application users and will there be more than one Oracle Application Server instance? To understand how many pools of which kinds are created for an application in both a single-JVM scenario and a multiple-JVM runtime scenario, review the following assumptions:

- Your Fusion web application makes use of two application modules `HRModule` and `PayablesModule`.
- You have a `CommonLOVModule` containing a set of commonly used view objects to support list of values in your application, and that both `HRModule` and `PayablesModule` aggregate a nested instance of `CommonLOVModule` to access the common LOV view objects it contains.
- You have configured both `HRModule` and `PayablesModule` to use the same `JDeveloper` connection definition named `appuser`.
- In both `HRModule` and `PayablesModule` you have configured `jbo.passivationstore=database` (the default) and configured the ADF "internal connection" (`jbo.server.internal_connection`) used for state management persistence to have the value of a fully-qualified JDBC URL that points to a *different* username than the `appuser` connection does.

### 44.1.2.1 Single Oracle Application Server Instance, Single Oracle WebLogic Server Instance, Single JVM

If you deploy this application to a single Oracle Application Server instance, configured with a single Oracle WebLogic Server instance having a single Java VM, there is only a single Java VM available to service the web requests coming from your application users.

Assuming that all the users are making use of web pages that access both the `HRModule` and the `PayablesModule`, this will give:

- One application module pool for the `HRModule` root application module
- One application module pool for the `PayablesModule` root application module
- One DB connection pool for the `appuser` connection
- One DB connection pool for the JDBC URL supplied for the internal connection for state management.

This gives a total of two application module pools and two database pools in this single Java VM.

---

**Note:** There is no separate application module pool for the nested instances of the reusable `CommonLOVModule`. Instances of `CommonLOVModule` are wrapped by instances of `HRModule` and `PayablesModule` in their respective application module pools.

---

### 44.1.2.2 Multiple Oracle Application Server Instances, Single Oracle WebLogic Server Instance, Multiple JVMs

Next consider a deployment environment involving multiple Java VMs. Assume that you have installed Oracle Application Server onto two different physical machines,

with a hardware load-balancer in front of it. On each of these two machines, imagine that the Oracle Application Server instance is configured to have one Oracle WebLogic Server instance with two JVMs. As users of your application access the application, their requests are shared across these two Oracle Application Server instances, and within each Oracle Application Server instance, across the two JVMs that its Oracle WebLogic Server instance has available.

Again assuming that all the users are making use of web pages that access both the `HRModule` and the `PayablesModule`, this will give:

- Four application module pools for `HRModule`, one in each of four JVMs.  
(1 `HRModule` root application module) x (2 Oracle Application Server Instances) x (2 Oracle WebLogic Server JVMs each)
- Four application module pools for `PayablesModule`, one in each of four JVMs.  
(1 `PayablesModule` root application module) x (2 Oracle Application Server Instances) x (2 Oracle WebLogic Server JVMs each)
- Four DB connection pools for `appuser`, one in each of four JVMs.  
(1 `appuser` DB connection pool) x (2 Oracle Application Server Instances) x (2 Oracle WebLogic Server JVMs each)
- Four DB connection pools for the internal connection JDBC URL, one in each of four JVMs.  
(1 internal connection JDBC URL DB connection pool) x (2 Oracle Application Server Instances) x (2 Oracle WebLogic Server JVMs each)

This gives a total of eight application module pools and eight DB connection pools spread across four JVMs.

As you begin to explore the configuration parameters for the application module pools in [Section 44.2.7, "What You May Need to Know About Application Module Pool Parameters,"](#) keep in mind that the parameters apply to a given application module pool for a given application module in a single JVM.

As the load balancing spreads user requests across the multiple JVMs where ADF is running, each individual application module pool in each JVM will have to support one  $n^{\text{th}}$  of the user load — where  $n$  is the number of JVMs available to service those user requests. The appropriate values of the application module and DB connection pools need to be set with the number of Java VMs in mind. The basic approach is to base sizing parameters on load testing and the results of the application module pooling statistics, then divide that total number by the  $n$  number of pools you will have based on your use of multiple application servers and multiple Oracle WebLogic Server instances. For example, if you decide to set the minimum number of application modules in the pool to ten and you end up with five pools due to having five Oracle WebLogic Server instances servicing this application, then you would want to configure the parameter to 2 (ten divided by five), not 10 (which would only serve a given application module in a single JVM).

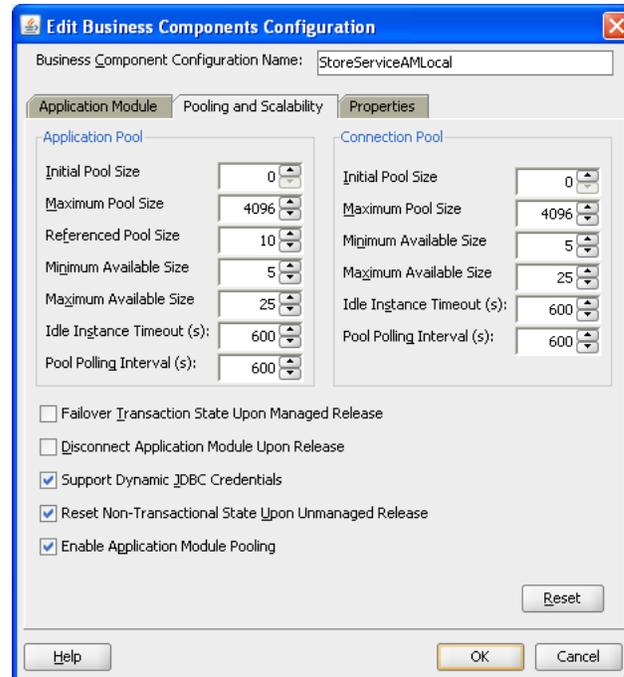

## 44.2 Setting Pool Configuration Parameters

You control the runtime behavior of an application module pool by setting appropriate configuration parameters. You can set these declaratively in an application module configuration, supply them as Java System parameters, or set them programmatically at runtime.

## 44.2.1 How to Set Configuration Properties Declaratively

The **Pooling and Scalability** tab of the Edit Business Components Configuration dialog shown in [Figure 44–1](#) is used for viewing and setting parameters.

**Figure 44–1** *Pooling and Scalability Tab of the Configuration Manager*

### To edit your application module's pooling configuration:

1. In the Application Navigator, double-click the application module.
2. In the overview editor, click the **Configurations** navigation tab.
3. In the Configurations page, double-click the configuration you want to edit.
4. In the Edit Business Components Configuration dialog, click the **Pooling and Scalability** tab and edit the desired runtime properties and click **OK** to save the changes for your configuration.

## 44.2.2 What Happens When You Set Configuration Properties Declaratively

The values that you supply through the Configuration Manager are saved in an XML file named `bc4j.xcfg` in the `./common` subdirectory relative to the application module's XML component definition. All of the configurations for all of the application modules in a single Java package are saved in that same file.

For example, if you look at the `bc4j.xcfg` file in the `./src/oracle/fodemo/storefront/store/service/common` directory of the Fusion Order Demo application's StoreFront project, you will see the three named configurations for its StoreServiceAM application module, as shown in [Example 44–1](#). In this case, The StoreServiceAMLocal and the StoreServiceAMLocalWeb configurations specify JDBC URL connections for use by the Oracle ADF Model Tester. The connection details for the JDBC connections appear in the `connections.xml` file located in the `./adf/META-INF` subdirectory relative to the project directory. The third configuration StoreFrontService specifies a JDBC data source name and is used by the Fusion web application. This

type of configuration is generated by default when you expose a service interface for the application module in the Service Interface page of the overview editor.

#### Example 44–1 Configuration Settings for the StoreService Application Module

```
<BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/configuration">
 <AppModuleConfigBag ApplicationName="oracle.fodemo.storefront.store.service.StoreServiceAM">
 <AppModuleConfig
 DeployPlatform="LOCAL"
 JDBCName="FOD"
 jbo.project="StoreFrontService"
 name="StoreServiceAMLocal"
 ApplicationName="oracle.fodemo.storefront.store.service.StoreServiceAM">
 <Database jbo.locking.mode="optimistic"/>
 <Security AppModuleJndiName="oracle.fodemo.storefront.store.service.StoreServiceAM"/>
 </AppModuleConfig>
 <AppModuleConfig
 DeployPlatform="LOCAL"
 JDBCName="FOD"
 jbo.project="StoreFrontService"
 name="StoreServiceAMLocalWeb"
 ApplicationName="oracle.fodemo.storefront.store.service.StoreServiceAM">
 <AM-Pooling jbo.ampool.initpoolsize="1"/>
 <Database jbo.locking.mode="optimistic"/>
 <Security AppModuleJndiName="oracle.fodemo.storefront.store.service.StoreServiceAM"/>
 <Custom fod.application.isssoaenabled="true"/>
 </AppModuleConfig>
 <AppModuleConfig
 name="StoreFrontService"
 ApplicationName="oracle.fodemo.storefront.store.service.StoreServiceAM"
 jbo.project="StoreFrontService"
 DeployPlatform="SI">
 <AM-Pooling jbo.ampool.resetnontransactionalstate="true"/>
 <Database jbo.SQLBuilder="ORACLE" jbo.locking.mode="optimistic"
 jbo.TypeMapEntries="Java"/>
 <Security AppModuleJndiName="oracle.fodemo.storefront.store.service.StoreServiceAM"/>
 <Custom JDBCDataSource="java:comp/env/jdbc/FODDS"/>
 </AppModuleConfig>
 </AppModuleConfigBag>
</BC4JConfig>
```

Note that attributes of child elements of the `<AppModuleConfig>` tag have names beginning with `jbo` that match the names of their ADF Business Components properties (for example, the `<Database>` tag defines the attribute `jbo.locking.mode` that corresponds to the property `jbo.locking.mode`). It's also important to understand that if a property is currently set to its runtime *default* value in the Edit Business Components Configuration dialog, then JDeveloper does *not* write the entry to the `bc4j.xcfg` file.

### 44.2.3 How to Set Configuration Properties as System Parameters

As an alternative to specifying configuration properties in the `bc4j.xcfg` file, you can also set Java VM system parameters with the same property names. These system parameters will be used *only if* a corresponding property *does not exist* in the relevant `bc4j.xcfg` file for the application module in question. In other words, configuration parameters that appear in the application module configuration take precedence over parameters of the same name supplied as Java system parameters.

You typically set Java system parameters using the `-D` command line flag to the Java VM like this:

```
java -Dproperty=value -jar yourserver.jar
```

Alternatively, your Java EE container probably has a section in its own configuration files where Java system parameters can be specified for use at Java EE container startup time.

If you adopt the technique of specifying site-specific *default* values for Oracle Application Development Framework (Oracle ADF) configuration parameters as Java system parameters, you should make sure that your application's `bc4j.xcfg` files do *not* include references to these parameters unless you want to define an application-module-specific exception to these global default values.

---

---

**Caution:** The values of **Idle Instance Timeout**, **Pool Polling Interval** settings for both the **Application Pool** and the database **Connection Pool** are displayed and edited in this dialog as a number of *seconds*, but are saved to the configuration file in milliseconds. If you provide a value for any of these four parameters as a Java System parameter — or if you hand-edit the `bc4j.xcfg` file — make sure to provide these time interval values in milliseconds!

---

---

#### 44.2.4 How to Programmatically Set Configuration Properties

You can set configuration properties programmatically by creating a Java class that implements the `EnvInfoProvider` interface in the `oracle.jbo.common.ampool` package. In your class, you override the `getInfo()` method and call `put()` to put values into the environment `Hashtable` passed in as shown in [Example 44-2](#).

##### **Example 44-2** Setting Environment Properties with a Custom `EnvInfoProvider`

```
package devguide.advanced.customenv.view;
import java.util.Hashtable;
import oracle.jbo.common.ampool.EnvInfoProvider;
/**
 * Custom EnvInfoProvider implementation to set
 * environment properties programmatically
 */
public class CustomEnvInfoProvider implements EnvInfoProvider {
 /**
 * Overridden framework method to set custom values in the
 * environment hashtable.
 *
 * @param string - ignore
 * @param environment Hashtable of config parameters
 * @return null - not used
 */
 public Object getInfo(String string, Object environment) {
 Hashtable envHashtable = (Hashtable)environment;
 envHashtable.put("some.property.name", "some value");
 return null;
 }
 /** Required to implement EnvInfoProvider */
 public void modifyInitialContext(Object object) {}
 /** Required to implement EnvInfoProvider */
 public int getNumOfRetries() {return 0;}
}
```

```
}
```

When creating an application module for a stateless or command-line-client, with the `createRootApplicationModule()` method of the `Configuration` class, you can pass the custom `EnvInfoProvider` as the optional second argument. In order to use a custom `EnvInfoProvider` in an ADF web-based application, you need to implement a custom session cookie factory class as shown in [Example 44-3](#). To use your custom session cookie factory, set the `jbo.ampool.sessioncookiefactoryclass` configuration property to the fully-qualified name of your custom session cookie factory class.

**Example 44-3 Custom SessionCookieFactory to Install a Custom EnvInfoProvider**

```
package devguide.advanced.customenv.view;
import java.util.Properties;
import oracle.jbo.common.ampool.ApplicationPool;
import oracle.jbo.common.ampool.EnvInfoProvider;
import oracle.jbo.common.ampool.SessionCookie;
import oracle.jbo.http.HttpSessionCookieFactory;
/**
 * Example of custom http session cookie factory
 * to install a custom EnvInfoProvider implementation
 * for an ADF web-based application.
 */
public class CustomHttpSessionCookieFactory
 extends HttpSessionCookieFactory {
 public SessionCookie createSessionCookie(String appId,
 String sessionId,
 ApplicationPool pool,
 Properties props) {
 SessionCookie cookie =
 super.createSessionCookie(appId, sessionId, pool, props);
 EnvInfoProvider envInfoProv = new CustomEnvInfoProvider();
 cookie.setEnvInfoProvider(envInfoProv);
 return cookie;
 }
}
```

## 44.2.5 What You May Need to Know About Configuration Property Scopes

Each runtime configuration property used by ADF Business Components has a scope. The scope of each property indicates at what level the property's value is evaluated and whether its value is effectively shared (i.e. static) in a single Java VM, or not. The ADF Business Components `PropertyManager` class is the registry of all supported properties. It defines the property names, their default values, and their scope. This class contains a `main()` method so that you can run the class from the command line to see a list of all the configuration property information.

Assuming `JDEVHOME` is the JDeveloper installation directory, to see this list of settings for reference, do the following:

```
$ java -cp JDEVHOME/BC4J/lib/bc4jmt.jar oracle.jbo.common.PropertyManager
```

Issuing this command will send all of the ADF Business Components configuration properties to the console. It also lists a handy reference about the different levels at which you can set configuration property values and remind you of the precedence order these levels have:

```

Properties loaded from following sources, in order:
```

1. Client environment [Provided programmatically  
or declaratively in `bc4j.xcfg`]
  2. Applet tags
  3. -D flags (appear in `System.properties`)
  4. `bc4j.properties` file (in current directory)
  5. `/oracle/jbo/BC4J.properties` resource
  6. `/oracle/jbo/commom.jboserver.properties` resource
  7. `/oracle/jbo/common.Diagnostic.properties` resource
  8. System defined default
- 

You'll see each property is listed with one of the following scopes:

- **MetaObjectManager**  
Properties at this scope are initialized once per Java VM when the ADF PropertyManager is first initialized.
- **SessionImpl**  
Properties at this scope are initialized once per invocation of `ApplicationModule.prepareSession()`.
- **Configuration**  
Properties at this scope are initialized when the ApplicationModule pool is first created and the application module's configuration is read the first time.
- **Diagnostic**  
Properties at this scope are specific to the built-in ADF Business Components diagnostic facility.

At each of these scopes, the layered value resolution described above is performed when the properties are initialized. Whenever property values are initialized, if you have specified them in the *Client Environment* (level 1 in the resolution order) the values will take precedence over values specified as System parameters (level 3 in the resolution order).

The Client Environment is a hashtable of name/value pairs that you can either programatically populate, or which will be automatically populated for you by the Configuration object when loaded, with the name/value pairs it contains in its entry in the `bc4j.xcfg` file. The implication of this is that for any properties scoped at MetaObjectManager level, the most reliable way to ensure that all of your application modules use the same default value for those properties is to do both of the following:

1. Make sure the property value does not appear in any of your application module's `bc4j.xcfg` file configuration name/value pair entries.
2. Set the property value using a Java system property in your runtime environment.

If, instead, you leave any MetaObjectManager-scoped properties in your `bc4j.xcfg` files, you will have the undesirable behavior that they will take on the value specified in the configuration of the *first* application module whose pool gets created after the Java VM starts up.

## 44.2.6 What You May Need to Know About How Database and Application Module Pools Cooperate

How ADF application module pools use the database connection pool depends on the setting of the `jbo.doconnectionpooling` application module configuration

parameter. In the Configuration Manager panel shown in [Figure 44-1](#), you set this parameter using the checkbox labelled **Disconnect Application Module Upon Release**.

---

**Note:** The notion of *disconnecting* the application module upon release to the pool better captures what the actual feature is doing than the related configuration parameter name (`jbo.doconnectionpooling`) does. The setting of `jbo.doconnectionpooling=false` does not mean that there is no database connection pooling happening. What it means is that the application module is not disconnected from its JDBC connection upon check in back to the application module pool.

---

If the default setting of `jbo.doconnectionpooling=false` is used, then when an application module instance is created in any pool it acquires a JDBC connection from the appropriate connection pool (based on the JDBC URL in the ADF case, or from the underlying JDBC data source implementation's pool in the case of a JNDI data source name). That application module instance holds onto the JDBC connection object that it acquired from the pool until the application module instance is removed from the application module pool. During its lifetime, that application module instance may service many different users, and ADF worries about issuing rollbacks on the database connection so that different users don't end up getting pending database state confused. By holding onto the JDBC connection, it allows each application module instance to keep its JDBC `PreparedStatement` objects open and usable across subsequent accesses by clients, thereby providing the best performance.

If `jbo.doconnectionpooling=true`, then each time a user session finishes using an application module (typically at the end of each HTTP request), the application module instance disassociates itself with the JDBC connection it was using on that request and it returns it to the JDBC connection pool. The next time that application module instance is used by a user session, it will reacquire a JDBC connection from the JDBC connection pool and use it for the span of time that application module is checked out of the application module pool (again, typically the span of one HTTP request). Since the application module instance "unplugs" itself from the JDBC connection object used to create the `PreparedStatements` it might have used during the servicing of the current HTTP request, those `PreparedStatements` are no longer usable on the next HTTP request because they are only valid in the context of the Connection object in which they were created. So, when using the connection pooling mode turned on like this, the trade-off is slightly more JDBC overhead setup each time, in return for using a smaller number of overall database connections.

The key difference is seen when many application module pools are all using the same underlying database user for their application connection.

- If 50 different application module pools each have even just a single application module instance in them, with `jbo.doconnectionpooling=false` there will be 50 JDBC application connections in use. If the application module pooling parameters are set such that the application module pools are allowed to shrink to 0 instances after an appropriate instance idle timeout by setting `jbo.ampool.minavailablesize=0`, then when the application module is removed from its pool, it will put back the connection its holding onto.
- In contrast, if 50 different application module pools each have a single application module instance and `jbo.doconnectionpooling=true`, then the amount of JDBC connections in use will depend on how many of those application modules are *simultaneously* being used by different clients. If an application module instance

is in the pool and is not currently being used by a user session, then with `jbo.doconnectionpooling=true` it will have released its JDBC connection back to the connection pool and while the application module instance is sitting there waiting for either another user to need it again, or to eventually be cleaned up by the application module pool monitor, it will not be "hanging on" to a JDBC connection.

**Performance Tip:** Leave the `jbo.doconnectionpooling` configuration parameter set to `false` for best performance without sacrificing scalability and reliability. Database connection pooling is still achieved through application module pooling. The only exception is when multiple application module pools (and therefore a large number of application module instances) share the same database, making the total available database connections the highest priority.

Highest performance is achieved by not disconnecting the application module instance from its database connection on each check in to the application module pool. Accordingly, the default setting of the `jbo.doconnectionpooling` configuration parameter is `false`. The pooling of application module instances is already an effective way to optimize resource usage, and the Oracle ADF runtime is more efficient when you do not have to disconnect application module instances from their associated JDBC connection after each release to the pool. Effectively, by pooling the application modules which are related one-to-one with a JDBC connection, you are already achieving a pooling of database connections that is optimal for most Fusion web applications.

However, when minimizing the total overall number of database sessions is a priority, one situation in which it might be appropriate to use database connection pooling is when you have a large number of application module pools all needing to use database connections from the same underlying application user at the database level. In this case, the many application module pools can economize on the total overall database sessions by sharing a single, underlying database connection pool of JDBC connections, albeit at a loss of efficiency of each one. This choice would be favored only if total overall database sessions is of maximum priority. In this scenario, if a user scrolls through some, but not all rows of a view object's row set, then with `jbo.doconnectionpooling=true`, Oracle ADF will automatically passivate the pending application module state (including current row information) so that the next time the application module is used, the queried view object can be put back into the same current row with the same initial rows fetched. This passivation behavior may reduce performance.

## 44.2.7 What You May Need to Know About Application Module Pool Parameters

The application module pool configuration parameters fall into three logical categories relating to pool behavior, pool sizing, and pool cleanup behavior.

### 44.2.7.1 Pool Behavior Parameters

[Table 44–1](#) lists the application module configuration parameters that affect the behavior of the application module pool.

**Table 44–1 Application Module Pool Behavior Configuration Parameters**

Pool Configuration Parameter	Description
Failover Transaction State Upon Managed Release ( <code>jbo.dofailover</code> )	<p>Enables eager passivation of pending transaction state each time an application module is released to the pool in "Managed State" mode. See <a href="#">Section 43.2.2.2, "How Passivation Changes When Optional Failover Mode is Enabled"</a> for more information.</p> <p>Fusion web applications should set <code>enable failover (true)</code> to allow any other application module to activate the state at any time.</p> <p>By default, the failover feature is disabled (<code>jbo.dofailover=false</code>) as a performance optimization when there is only one web server instance configured, by reducing the need for passivation and activation. This allows for application module affinity to a specific user session.</p> <p>For high availability, enable the failover feature (<code>jbo.dofailover=true</code>) to ensure that more application modules are readily available, thereby increasing scalability. In this mode, passivation occurs at the end of every request.</p>
Row-Level Locking Behavior Upon Release ( <code>jbo.locking.mode</code> )	<p>Forces the application module pool not to create a pending transaction state on the database with row-level locks each time the application module is released to the pool. See <a href="#">Section 43.11.1, "How to Confirm That Applications Use Optimistic Locking"</a> for more information.</p> <p>Fusion web applications should leave the locking mode set to the default value <code>optimistic</code> to avoid creating the row-level locks.</p> <p>This feature is disabled when the property is set to <code>pessimistic</code>.</p>
Disconnect Application Module Upon Release ( <code>jbo.doconnectionpooling</code> )	<p>Forces the application module pool to release the JDBC connection used each time the application module is released to the pool. See <a href="#">Section 44.2.6, "What You May Need to Know About How Database and Application Module Pools Cooperate"</a> for more information.</p> <p>This feature is disabled by default (<code>false</code>).</p>

**Table 44–1 (Cont.) Application Module Pool Behavior Configuration Parameters**

Pool Configuration Parameter	Description
Transaction Memory State Upon Release ( <code>jbo.txn.disconnect_level</code> )	<p>By default, after the application module is passivated, the view objects and its row sets are closed and removed, to be recreated and reverted to their original state upon activation. This behavior corresponds to the default <code>jbo.txn.disconnect_level=0</code>.</p> <p>When setting <code>jbo.txn.disconnect_level=1</code> the application module, view objects and row sets all remain in memory and stay valid but their corresponding references to JDBC objects are dropped. Upon activation, the framework reexecutes and synchronizes the cursor positions.</p> <p>Setting <code>jbo.txn.disconnect_level=1</code> can improve performance when enabling application modules to disconnect from their JDBC connection (when used in conjunction with <code>jbo.doconnectionpooling=true</code>) and reduces the memory overhead associated with this situation.</p>
Enable Application Module Pooling ( <code>jbo.ampool.doampooling</code> )	<p>Enables application module pooling by default. Whenever you deploy your application in a production environment the default setting of <code>jbo.ampool.doampooling</code> set to <code>true</code> is the way you will run your application. But, as long as you run your application in a test environment, setting the property to <code>false</code> can play an important role in your testing. When this property is <code>false</code>, there is effectively no application pool. See <a href="#">Section 43.10, "Testing to Ensure Your Application Module is Activation-Safe"</a> for more information.</p> <p>This feature is enabled by default (<code>true</code>).</p>
Support Dynamic JDBC Credentials ( <code>jbo.ampool.dynamicjdbccredentials</code> )	<p>Enables additional pooling lifecycle events to allow developer-written code to change the database credentials (username/password) each time a new user session begins to use the application module.</p> <p>This feature is enabled by default (<code>true</code>), however this setting is a necessary but not sufficient condition to implement the feature. The complete implementation requires additional developer-written code.</p>

**Table 44–1 (Cont.) Application Module Pool Behavior Configuration Parameters**

Pool Configuration Parameter	Description
Reset Non-Transactional State Upon Unmanaged Release ( <code>jbo.ampool.resetnontransactionalstate</code> )	<p>Forces the application module to reset any non-transactional state like view object runtime settings, JDBC prepared statements, bind variable values, etc. when the application module is released to the pool in unmanaged or "stateless" mode.</p> <p>This feature is enabled by default (<code>true</code>). Disabling this feature can improve performance, however since it does not clear bind variable values, your application needs to ensure that it systemically sets bind variable values correctly. Failure to do so with this feature disabled can mean one user might see data with another users bind variable values.)</p>

#### 44.2.7.2 Pool Sizing Parameters

Table 44–2 lists the application module configuration parameters that affect the sizing of the application module pool.

**Table 44–2 Application Module Pool Sizing Configuration Parameters**

Pool Configuration Parameter	Description
Initial Pool Size ( <code>jbo.ampool.initpoolsize</code> )	<p>The number of application module instances to created when the pool is initialized.</p> <p>The default is 0 (zero) instances. A general guideline is to configure this to 10% more than the anticipated number of concurrent application module instances required to service all users.</p> <p>Creating application module instances during initialization takes the CPU processing costs of creating application module instances during the initialization instead of on-demand when additional application module instances are required.</p>
Maximum Pool Size ( <code>jbo.ampool.maxpoolsize</code> )	<p>The maximum number of application module instances that the pool can allocate. The pool will never create more application module instances than this limit imposes.</p> <p>The default is 4096 instances. A general guideline is to configure this to 20% more than the initial pool size to allow for some additional growth. If this is set too low, then some users may see an error accessing the application if no application module instances are available.</p>

**Table 44–2 (Cont.) Application Module Pool Sizing Configuration Parameters**

Pool Configuration Parameter	Description
Referenced Pool Size ( <code>jbo.recyclethreshold</code> )	<p>The maximum number of application module instances in the pool that attempt to preserve session affinity for the next request made by the session which used them last before releasing them to the pool in managed-state mode.</p> <p>The referenced pool size should always be less than or equal to the maximum pool size. The default is to allow 10 available instances to try and remain "loyal" to the affinity they have with the most recent session that released them in managed state mode.</p> <p>Configure this value to maintain the application module instance's affinity to a user's session. A general guideline is to configure this to the expected number of concurrent users that perform multiple operations with short think times. If there are no users expected to use the application with short think times, then this can be configured to 0 zero to eliminate affinity.</p> <p>Maintaining this affinity as much as possible will save the CPU processing cost of needing to switch an application module instance from one user session to another.</p>
Maximum Instance Time to Live ( <code>jbo.ampool.timetolive</code> )	<p>The number of milliseconds after which to consider an application module instance in the pool as a candidate for removal during the next resource cleanup regardless of whether it would bring the number of instances in the pool below <code>minavailablesize</code>.</p> <p>The default is 3600000 milliseconds of total time to live (which is 3600 seconds, or one hour). The default value is sufficient for most applications.</p>

### 44.2.7.3 Pool Cleanup Parameters

A single "application module pool monitor" per Java VM runs in a background thread and wakes up every so often to do resource reclamation. [Table 44–3](#) lists the parameters that affect how resources are reclaimed when the pool monitor does one of its resource cleanup passes.

**Best Practice:** When you specify the length of time between application module pool cleanup passes, set all application modules to use the same **Pool Polling Interval** value. Since there is only a single application monitor pool monitor per Java VM, the value that will effectively be used for the application module pool monitor polling interval will be the value found in the application module configuration read by the *first* application module pool that gets created. Setting all application modules to use the same value ensures that this value is set in a predictable way.

**Table 44–3 Application Module Resource Management Configuration Parameters**

Pool Configuration Parameter	Description
Pool Polling Interval ( <code>jbo.ampool.monitorsleepinterval</code> )	<p>The length of time in milliseconds between pool resource cleanup.</p> <p>While the number of application module instances in the pool will never exceed the maximum pool size, available instances which are candidates for getting removed from the pool do not get "cleaned up" until the next time the application module pool monitor wakes up to do its job.</p> <p>The default is to have the application module pool monitor wake up every 600000 milliseconds (which is 600 seconds, or ten minutes). Configuring a lower interval results in inactive application module instances being removed more frequently to save memory. Configuring a higher interval results in less frequent resource cleanups.</p>
Maximum Available Size ( <code>jbo.ampool.maxavailablesize</code> )	<p>The ideal maximum number of available application module instances in the pool when not under abnormal load.</p> <p>When the pool monitor wakes up to do resource cleanup, it will try to remove available application module instances to bring the total number of available instances down to this ideal maximum. Instances that have been not been used for a period longer than the idle instance time-out will always get cleaned up at this time, then additional available instances will be removed if necessary to bring the number of available instances down to this size.</p> <p>The default maximum available size is 25 instances. Configure this to leave the maximum number of available instances desired after a resource cleanup. A lower value generally results in more application module instances being removed from the pool on a cleanup.</p>
Minimum Available Size ( <code>jbo.ampool.minavailablesize</code> )	<p>The minimum number of available application module instances that the pool monitor should leave in the pool during a resource cleanup operation.</p> <p>Set to 0 (zero) if you want the pool to shrink to contain no instances when all instances have been idle for longer than the idle time-out after a resource cleanup.</p> <p>The default is 5 instances.</p>

**Table 44–3 (Cont.) Application Module Resource Management Configuration Parameters**

Pool Configuration Parameter	Description
Idle Instance Timeout ( <code>jbo.ampool.maxinactiveage</code> )	<p>The number of milliseconds after which to consider an inactive application module instance in the pool as a candidate for removal during the next resource cleanup.</p> <p>The default is 600000 milliseconds of idle time (which is 600 seconds, or ten minutes). A lower value results in more application module instances being marked as a candidate for removal at the next resource cleanup. A higher value results in fewer application module instances being marked as a candidate for removal at the next resource cleanup.</p>
Maximum Instance Time to Live ( <code>jbo.ampool.timetolive</code> )	<p>The number of milliseconds after which to consider an connection instance in the pool as a candidate for removal during the next resource cleanup regardless of whether it would bring the number of instances in the pool below <code>minavailablesize</code>.</p> <p>The default is 3600000 milliseconds of total time to live (which is 3600 seconds, or one hour). A lower value reduces the time an application module instance can exist before it must be removed at the next resource cleanup. The default value is sufficient for most applications. A higher value increases the time an application module instance can exist before it must be removed at the next cleanup.</p>

## 44.2.8 What You May Need to Know About Data Source Configuration

When you specify a JDBC data source as your application module's connection type, any configuration parameters that you have configured for the database connection pool will be ignored. To configure the connection pool for your data source, you must use the means provided by your Java EE container. In the case of Oracle WebLogic Server, you configure the data source using the Oracle WebLogic Server Administration Console.

The main steps for configuring JDBC data sources are:

1. Create a data source for each data base that you want to connect to. When you create the data source, specify the configuration options to match the ones for ADF Business Components database connection pools described in [Table 44–4](#). The configuration settings that you specify will depend on your database and the capacity planning that you need anticipate for your application.

For details about configuring JDBC data sources and connection pool capacity planning, see *Oracle Fusion Middleware Configuring and Managing JDBC for Oracle WebLogic Server*.

2. Optionally, configure transaction options for the data source.
3. Optionally, configure connection testing options for the data source.
4. Optionally, target the data source to additional servers and clusters.

For detailed procedures for each of these steps, see the topic "Configure JDBC data sources" in the Administration Console Online Help.

**Table 44–4 Equivalent Oracle WebLogic Server Data Source Parameters**

ADF Business Components Parameter	\Oracle WebLogic Server Parameter
Initial Pool Size (jbo.initpoolsize)	Initial Capacity
Maximum Pool Size (jbo.maxpoolsize)	Maximum Capacity
Pool Polling Interval (jbo.poolmonitorsleepinterval)	No equivalent for Oracle WebLogic Server.
Maximum Available Size (jbo.poolmaxavailablesize)	Maximum Capacity
Minimum Available Size (jbo.poolminavailablesize)	Maximum Capacity
Idle Instance Timeout (jbo.poolmaxinactiveage)	Shrink Frequency Seconds

### 44.2.9 What You May Need to Know About Database Connection Pool Parameters

If you are using a JDBC URL for your connection information so that the ADF database connection pool is used, then configuration parameters listed in [Table 44–5](#) can be used to tune the behavior of the database connection pool. A single "database connection pool monitor" per Java VM runs in a background thread and wakes up every so often to do resource reclamation. The parameters in [Table 44–3](#) include the ones that affect how resources are reclaimed when the pool monitor does one of its resource cleanup passes.

---

**Note:** The configuration parameters for database connection pooling have MetaObjectManager scope (described in [Section 44.2.5, "What You May Need to Know About Configuration Property Scopes"](#) earlier). This means their settings are global and will be set once when the first application module pool in your application is created. To insure the most predictable behavior, leave the values of these parameters in the **Connection Pool** section of the **Pooling and Scalability** tab at their *default* values — so that no entry for them is written into the `bc4j.xcfg` file — and to instead set the desired values for the database connection pooling tuning parameters as Java System Parameters in your Java EE container.

---

**Table 44–5 Database Connection Pool Parameters**

Pool Configuration Parameter	Description
Initial Pool Size (jbo.initpoolsize)	The number of JDBC connection instances to created when the pool is initialized  The default is an initial size of 0 instances.
Maximum Pool Size (jbo.maxpoolsize)	The maximum number of JDBC connection instances that the pool can allocate.  The pool will never create more JDBC connections than this imposes. The default is 4096 instances.

**Table 44–5 (Cont.) Database Connection Pool Parameters**

Pool Configuration Parameter	Description
Pool Polling Interval ( <code>jbo.poolmonitorsleepinterval</code> )	<p>The length of time in milliseconds between pool resource cleanup.</p> <p>While the number of JDBC connection instances in the pool will never exceed the maximum pool size, available instances which are candidates for getting removed from the pool do not get "cleaned up" until the next time the JDBC connection pool monitor wakes up to do its job.</p> <p>The default is 600000 milliseconds of idle time (which is 600 seconds, or ten minutes). Configuring a lower interval results in inactive connection instances being removed more frequently to save memory. Configuring a higher interval results in less frequent resource cleanups.</p>
Maximum Available Size ( <code>jbo.poolmaxavailablesize</code> )	<p>The ideal maximum number of JDBC connection instances in the pool when not under abnormal load.</p> <p>When the pool monitor wakes up to do resource cleanup, it will try to remove available JDBC connection instances to bring the total number of available instances down to this ideal maximum. Instances that have been not been used for a period longer than the idle instance time-out will always get cleaned up at this time, then additional available instances will be removed if necessary to bring the number of available instances down to this size. The default is an ideal maximum of 25 instances (when not under load).</p>
Minimum Available Size ( <code>jbo.poolminavailablesize</code> )	<p>The minimum number of available JDBC connection instances that the pool monitor should leave in the pool during a resource cleanup operation. Set to zero (0) if you want the pool to shrink to contain no instances when all instances have been idle for longer than the idle time-out.</p> <p>The default is to not let the minimum available size drop below 5 instances.</p>
Idle Instance Timeout ( <code>jbo.poolmaxinactiveage</code> )	<p>The number of seconds after which to consider an inactive JDBC connection instance in the pool as a candidate for removal during the next resource cleanup.</p> <p>The default is 600000 milliseconds of idle time (which is 600 seconds, or ten minutes).</p>

Notice that since the database connection pool does not implement the heuristic of session affinity, there is *no* configuration parameter for the database connection pool which controls the referenced pool size.

## 44.3 Initializing Database State and Pooling Considerations

Sometimes you may need to invoke stored procedures to initialize database state related to the current user's session. The correct place to perform this initialization is in an overridden `prepareSession()` method of your application module.

### 44.3.1 How to Set Database State Per User

The Fusion web application can set database state on a per-user basis. You typically create a database `CONTEXT` namespace, associate a PL/SQL procedure with it, and then use the `SYS_CONTEXT()` SQL function to reference values from the context.

For example, you can use the PL/SQL package to set and get a package-level variable that holds the name of the currently authenticated Fusion web application user as shown in [Example 44-4](#).

#### **Example 44-4** *CONTEXT\_PKG PL/SQL Package*

```
create or replace package context_pkg as
 procedure set_app_user_name(username varchar2);
 function app_user_name return varchar2;
end context_pkg;
```

Then your application can define the `WHERE` clause of a view object to reference the `context_pkg.app_user_name` function and query the per-user state.

To set the database state, the application module framework extension class (`AppModuleImpl.java`) defines a `callStoredProcedure()` helper method similar to the ones in [Section 12.6.2, "How to Invoke Stored Procedure with Only IN Arguments."](#) The custom application module class then extends this framework extension class and defines the `setCurrentUserInPLSQLPackage()` helper method shown in [Example 44-5](#). The helper method uses the `callStoredProcedure()` method to invoke the `context_pkg.set_app_user_name()` stored procedure, passing the value of the currently authenticated user as a parameter value.

#### **Example 44-5** *Method to Call Context\_Pkg.Set\_App\_User\_Name Stored Procedure*

```
// In CustomAppModuleImpl.java
public void setCurrentUserInPLSQLPackage() {
 String user = getUserPrincipalName();
 callStoredProcedure("context_pkg.set_app_user_name(?)", new Object[]{user});
}
```

With this helper method in place, the custom application module class then overrides the `prepareSession()` method as shown in [Example 44-6](#).

#### **Example 44-6** *Overridden afterConnect() and prepareSession() to Set Database State*

```
// In CustomAppModuleImpl.java
protected void prepareSession(Session session) {
 super.prepareSession(session);
 getLoggedInUser().retrieveUserInfoForAuthenticatedUser();
 setUserIdIntoUserDataHashtable();
 setCurrentUserInPLSQLPackage();
}
```

### 44.3.2 What You May Need to Know About Database User State and `jbo.doconnectionpooling = true`

The default setting for `jbo.doconnectionpooling` is `false`. This means the application module instance hangs onto its JDBC connection while it's in the application module pool. This is the most efficient setting because the application module can keep its JDBC prepared statements open across application module checkouts/checkins. The application module instance will trigger its `prepareSession()` method each time a new user session begins using it.

If you set `jbo.doconnectionpooling` to `true`, then on each checkout of an application module from the pool, that application module pool will acquire a JDBC connection from the database connection pool and use it during the span of the current request. At the end of the request when the application module is released back to the application module pool, that application module pool releases the JDBC connection it was using back to the database connection pool.

It follows that with `jbo.doconnectionpooling` set to `true` the application module instance in the pool may have a completely different JDBC connection each time you check it out of the pool. In this situation, the `prepareSession()` method will fire each time the application module is checked out of the pool to give you a chance to reinitialize the database state.

Alternatively, you can set `jbo.txn.disconnect_level=1` (default is 0) to ensure that all application modules, view objects and row sets remain in memory and stay valid after their corresponding references to JDBC connections are dropped. Upon activation, the framework reexecutes and synchronizes the cursor positions. When used in conjunction with `jbo.doconnectionpooling=true`, setting `jbo.txn.disconnect_level=1` reduces the memory overhead associated with this situation.

## Using the Active Data Service

This chapter provides information for using the ADF Model layer and ADF Faces components with an active data service.

This chapter includes the following sections:

- [Section 45.1, "About the Active Data Service"](#)
- [Section 45.2, "Configuring the Active Data Service"](#)
- [Section 45.3, "Configuring Components to Use the Active Data Service"](#)
- [Section 45.4, "Using the Active Data Proxy"](#)
- [Section 45.5, "Using the Active Data with a Scalar Model"](#)

### 45.1 About the Active Data Service

The Fusion technology stack includes Active Data Service (ADS), which is a server-side push framework that allows you to provide real-time data updates for ADF Faces components. You bind ADF Faces components to a data source and ADS pushes the data updates to the browser client without requiring the browser client to explicitly request it. For example, you may have a table bound to attributes of an ADF data control whose values change on the server periodically, and you want the updated values to display in the table. You can configure your application and the component so that whenever the data changes on the server, the ADF Model layer notifies the component and the component rerenders the changed data with the new value highlighted, as shown in [Figure 45-1](#).

**Figure 45-1 Table Displays Updated Data as Highlighted**

Row No	Description	Price	Detail
	Some text to describe the object v458	v455 78,000 USD	Text v464
	Some text to describing the object v463	v468 53,000 USD	Read only text v466
	Some text v460	v460 21,000 USD	Text text v460
	Text describing the object v469	v456 583,000 USD	Text v459
	Description v450	v450 1,000,000 USD	Text only v467
	A very long description that may be truncated v470	v465 1,200 USD	Read only data v465
	Description v462	v461 336,981 USD	Data text v461
	Some text v437	v449 209,000 USD	Data v326

#### 45.1.1 Active Data Service Use Cases and Examples

Using ADS is an alternative to using automatic partial page rendering (PPR) to re-render data that changes on the backend as a result of business logic associated with

the ADF data control bound to the ADF Faces component. Whereas automatic PPR requires sending a request to the server (typically initiated by the user), ADS enables changed data to be pushed from the data store as the data arrives on the server. Also, in contrast to PPR, ADS makes it possible for the component to re-render only the changed data instead of the entire component. This makes ADS ideal for situations where the application needs to react to data that changes periodically.

To use this functionality, you must configure the application to use ADS. If your application services do not support ADS, then you also need to create a proxy of the service so that the components can display the data as it updates in the source.

Any ADF Faces page can use ADS. However, you can configure only the following ADF Faces components to work with active data:

- `activeCommandToolBarButton`
- `activeImage`
- `activeOutputText`
- `table`

---

---

**Note:** Do not use filtering on a table that will be using active data. Once a table is filtered at runtime, active data cannot be displayed. Currently, ADS supports `table` components with the `outputText` component contained within a column; other components are not supported inside the table column

---

---

- `tree`
- `treeTable`
- DVT graph, gauge, and geographical map components

### 45.1.2 Limitations of the Active Data Service Framework

The framework for ADS has the following limitations.

- ADS does not support active data for ADF Faces components added dynamically, using PPR.
- ADS does not support active data for ADF Faces components that appear in a web page or region that gets invoked from a task flow call activity. Do not use task flow call activities with bounded task flows when active data is required.
- ADS does not support active data in web browsers that have popup blockers enabled.

Before users can run the ADF Faces page with ADS configured for the application, they must disable the popup blocker for their web browser.

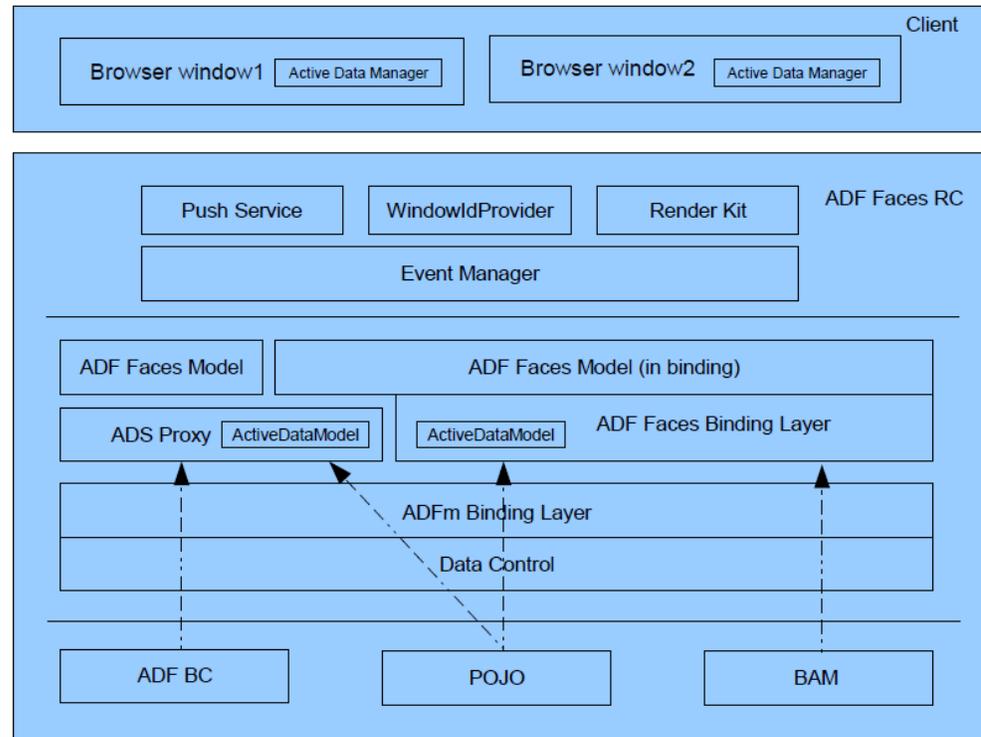

- ADS does not support active data on ADF Faces table components with filtering enabled. Once a table is filtered at runtime, active data cannot be displayed.

### 45.1.3 Active Data Service Framework

The framework for ADS contains a number of components that work together to send the active data from the source to the UI component. When a data event occurs, if the associated ADF Model layer binding is configured for active data, the Active Data model delivers the data to the Event Manager. The Event Manager then retrieves the data and invokes the Push Service, which delivers the data to the correct component,

based on how the service is configured (for more information, see [Section 45.1.4, "Data Transport Modes"](#)). The component then applies the new data pushed from the server. [Figure 45-2](#) shows the ADS framework.

**Figure 45-2 Active Data Service Framework**

In order to use the Active Data Service, you need to have a data store that publishes events when data is changed, and you need to create business services that react to those events. By default, ADF Business Components does not react to data events. The Active Data Proxy framework allows all types of data sources, including ADF Business Components, to work with ADS. It combines the `ActiveDataModel` with the JSF model, so that you need to override functionality only on this proxy rather than on both the `ActiveDataModel` and the JSF model.

The following comprise the ADS framework:

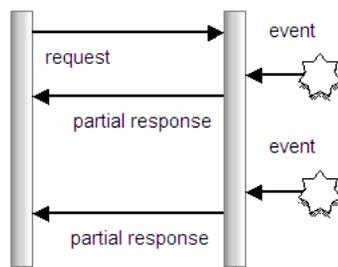

- `ActiveDataModel` interface: Abstraction of the active data model. Its responsibilities include:
  - Starting and stopping active data
  - Keeping track of the current active data event ID
  - Letting the renderer know whether the model needs active data or not.
- `Event Manager`: A server-side component that works with the ADF Model layer. It is responsible for the following:
  - Listening to binding events
  - Retrieving active data
  - Managing active data encoding
  - Invoking the Push service to send the encoded active data

- Push service: A delivery channel that interacts with the Event Manager on the server side and with the Active Data Manager on the client side. It provides the following:
  - Establishing and maintaining the connection between the server and the client
  - Transmitting the active data over this connection from the server to the client
  - Ensuring that active data gets delivered within desired parameters and forcing component update if not
- Active Data Manager: A client-side component that distributes the active data to the correct component. Specifically, it is responsible for the following;
  - Delivering events from the server side that are coming through the channel, using an event delivery service
  - Handling multiple browser windows through a shared channel
  - Dispatching active data events to rich client components, so that the components can render the change accordingly
- Active Data Proxy: A proxy that allows all types of data sources to enable push functionality. Specifically, the proxy is responsible for the following:
  - Implementing and delegating `ActiveDataModel` functionality
  - Delegating to JSF models
  - Listening to data change events from the data source
  - Generating active data events based on the data change events

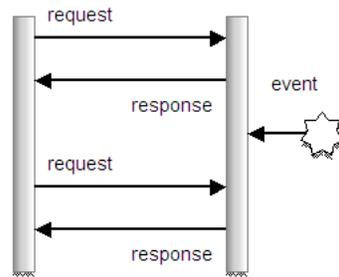

#### 45.1.4 Data Transport Modes

Active data is sent to the client using data streaming (push) or one of two types of data polling. With *data streaming*, there is only one request, which stays open. When a data change event occurs, a partial response is sent (the response is not closed), the client is notified, and the associated component is updated to show the new data, as shown in [Figure 45-3](#).

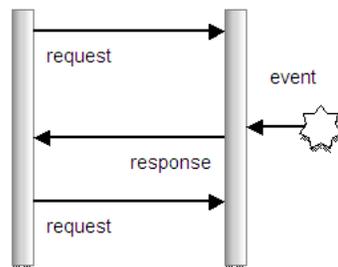

**Figure 45-3 Streaming Mode**

With *data polling*, the application is configured to poll the data source at specified intervals, as shown in [Figure 45-4](#). With each request, a response is sent and closed, whether or not a data change event has occurred. If the data has changed, then the client is notified and the component is updated.

**Figure 45–4 Poll Mode**

*Long polling* is similar to streaming. When the page is rendered, a request is sent to the active channel. However, a response is not returned until there is a data change event. At that point, the connection is closed. As soon as the connection is closed, a new connection is initiated, which results in the connection being active most of the time: there are no specific intervals. Long polling results in the majority of data change events being received when they occur, because the connection is already established and ready to send a response to the client, as shown in [Figure 45–5](#).

**Figure 45–5 Long Polling Mode**

For more information, see [Section 45.2.2, "What You May Need to Know About Transport Modes."](#)

To use ADS, you need to configure your application to determine the method of data transport, as well as other performance options. You also need to configure the bindings for your components so that they can use ADS. If you are using ADF Business Components, you need to modify your model to implement the `ActiveModel` interface to register itself as the listener for active data events using the Active Data Proxy.

**Tip:** Oracle offers Oracle Business Activity Monitoring (BAM), which is a complete solution that provides the ability to create an active data store. For more information, see the *Oracle Fusion Middleware Developer's Guide for Oracle SOA Suite*.

## 45.2 Configuring the Active Data Service

You need to configure ADS to determine the data transport mode, as well as to set other configurations, such as a latency threshold and reconnect information.

**Note:** If you enable ADS but do not configure it, the ADS framework will use the default values shown in [Table 45-1](#).

### 45.2.1 How to Configure the Active Data Service

Configuration for running the Fusion web application with ADS in JDeveloper and Integrated WebLogic Server is done in the `adf-config.xml` file. For more information about the `adf-config.xml` file, including how to create one if you need to, see the "Configuration in `adf-config.xml`" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

**Note:** To support automatic replication and failover for web applications within a clustered environment, Oracle WebLogic Server supports mechanisms for replicating HTTP session state across clusters. You can configure Oracle Application Development Framework (Oracle ADF) to ensure the Fusion web application's state can be restored from any server in the cluster. To support failover for pages configured to display active data, it is necessary to enable failover for the ADF Business Components application module and to enable ADF Controller to track changes to the ADF memory scopes. With these ADF settings configured, when failover occurs, the ADF server will detect the failover and request all pages configured to display active data to refresh themselves, after that ADS restarts and data is pushed to the client. For details about how to enable failover for the Fusion web application in a high availability environment, see the *Oracle Fusion Middleware High Availability Guide*.

**To configure the Active Data Service:**

1. In the Application Resources panel, double-click the `adf-config.xml` file.
2. Click the **Source** tab to open the file in the source editor, and create an entry for each of the elements shown in [Table 45-1](#).

**Table 45-1 ADS Configuration Elements in `adf-config.xml`**

Element	Description	Default Value (in milliseconds)	Minimum Value (in milliseconds)
<code>&lt;transport&gt;</code>	<p>The method by which data will be delivered to the client. Value values are:</p> <ul style="list-style-type: none"> <li>▪ streaming (default)</li> <li>▪ polling</li> <li>▪ long-polling</li> </ul> <p>For more information, see <a href="#">Section 45.2.2, "What You May Need to Know About Transport Modes."</a></p>		
<code>&lt;latency threshold&gt;</code>	Latency threshold in milliseconds. Active data messages with network delays greater than this threshold will be treated as late.	10000	1000

**Table 45–1 (Cont.) ADS Configuration Elements in *adf-config.xml***

Element	Description	Default Value (in milliseconds)	Minimum Value (in milliseconds)
<keep-alive-interval>	Frequency in milliseconds for sending keep-alive messages when no events are generated.	10000	5000
<polling-interval>	When <transport> set to polling, frequency in milliseconds of the poll request.	5000	1000
<max-reconnect-attempt-time>	Maximum period of time in milliseconds a client will attempt to reconnect the push channel to server upon getting disconnected.	1800000 (30 minutes)	0
<reconnect-wait-time>	Time interval in milliseconds to wait between reconnect attempts.	10000	1000

**Performance Tip:** Keep the following in mind when configuring the ADS.

- Set the latency threshold to more than 1000 to avoid frequent component refreshing.
- Set the keep-alive interval and reconnect wait time to be less than the browser's keep-alive timeout.
- Set the max reconnect time to be less than your web server's session timeout.

[Example 45–1](#) shows a sample configuration that has content pushed to the client.

**Example 45–1 Sample Configuration for ADS in *adf-config.xml***

```
<?xml version="1.0" encoding="utf-8" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
 xmlns:ads="http://xmlns.oracle.com/adf/activedata/config">
 <ads:adf-activedata-config xmlns=
 "http://xmlns.oracle.com/adf/activedata/config">
 <transport>streaming</transport>
 <latency-threshold>5000</latency-threshold>
 <keep-alive-interval>10000</keep-alive-interval>
 <max-reconnect-attempt-time>90000</max-reconnect-attempt-time>
 <reconnect-wait-time>8000</reconnect-wait-time>
 </ads:adf-activedata-config>
</adf-config>
```

3. Synchronize the clocks on the data server and on the application server. If these are not synchronized, then events may appear to ADS to have occurred in the future.

## 45.2.2 What You May Need to Know About Transport Modes

ADS can use one of three transport modes to deliver active data to the component: streaming, polling, or long polling.

When you configure ADS to use the streaming mode, data is pushed to the client whenever a change event is raised by the data. On the client side, after the push channel is established, if there is no activity within the time of the value for the `latency-threshold` element plus the `keep-alive-interval`, an `establish-channel-request` will be sent out repeatedly based on the value of the `reconnect-wait-time` element, until the amount of time passed reaches the value of the `max-reconnect-attempt-time` element. After that, the connection will be considered disconnected. For example, given the values in [Example 45-1](#), if there is no activity in 15,000 milliseconds, an establish channel request will be sent out every 8,000 milliseconds for up to 90,000 milliseconds. After that, the connection will be considered disconnected.

On the server side, the server disconnects the push channel and starts a timer to clean up with a `cleanup-delay-time` when there is an empty active data message or when it fails to send out an active data message. The `cleanup-delay-time` is calculated as `max-reconnect-attempt-time + 30 * 1000 ms`. Its default value is 30 minutes.

When you configure ADS to use the polling mode, on the client side the polling request is scheduled to be sent out repeatedly after the value of the `polling-interval` element has been reached. If no response is received after the value of the `max-reconnect-attempt-time` has elapsed, the connection is treated as disconnected and no more requests will be sent. After receiving a polling response, if the time the response has taken is greater than the `polling-interval` element, the service sends the next request out right away. If it is less, the next request will be sent as scheduled.

For the server side, the session ends after the polling response is returned. At that point, a timer with a `cleanup-delay-time` is set up to trigger cleanup. If a new request comes in before the timer fires, the old timer is canceled, and new timer is created.

When you configure ADS to use the long polling mode, requests are made as they are in streaming mode; however, as soon as the connection is treated as disconnected, a new connection is initiated. The result is a significant reduction in latency.

[Table 45-2](#) compares the three different modes.

**Table 45-2 Comparison of Streaming, Polling, and Long-Polling Modes**

	Streaming	Polling	Long-Polling
<b>Latency</b>	Very good. Directly after an event occurs on the server side, a partial response is sent to the client. If there is another event, immediately, it is also sent as a partial response. There is almost no latency with this approach.	Poor, depending on the polling interval. If the polling interval is short (for example, 0.5 seconds), it will slow down the network because the connections are repeatedly opened. It is also expensive on the client- and server-side resources.	Good. However, when there is a new event immediately after a response has been closed, there is some latency until the new data appears on the client side. On average, this is not a problem.

**Table 45–2 (Cont.) Comparison of Streaming, Polling, and Long-Polling Modes**

	<b>Streaming</b>	<b>Polling</b>	<b>Long-Polling</b>
<b>HTTP Proxy</b>	Poor.  For some older servers, because the response is never released, when a proxy is sitting between client and server, it is possible that the proxy will buffer responses.  This is an unfortunate optimization that prevents real-time data from flowing into the browser. Long polling should be used if a proxy is used.	Good.	Good.
<b>Number of live connections</b>	Poor.  Many concurrent connections, as the stream is always live.	Good.  Connections are live only during the actual poll. Note however that if there is a high polling rate then the number of concurrent connections will also be high.	Poor.  Many concurrent connections, as the stream is almost always live.
<b>Communication channel</b>	HTTP GET  This can result in the display of a "busy" cursor or the animation of a browser's "throbber" icon.	XMLHttpRequest (XHR)  HTTP GET	XMLHttpRequest (XHR)  HTTP GET

### 45.3 Configuring Components to Use the Active Data Service

How you configure components to use ADS depends on whether or not you must use the Active Data proxy. If your application uses a data store that publishes events when data is changed, and your business services react to those events (for example, if your application uses BAM), then you do not need to use the Active Data proxy.

If your business services do not react to those events (for example, if your application uses ADF Business Components), then you must use the Active Data proxy and follow different procedures for configuring your components.

---

---

**Note:** If your business service requires the use of the Active Data proxy, then you can only use the following components with active data:

- table
  - tree
  - treeTable
  - DVT graph, gauge, and geographical map components
- 
- 

### 45.3.1 How to Configure Components to Use the Active Data Service Without the Active Data Proxy

To use ADS without the proxy, you need to set a value on the binding element in the corresponding page definition file.

**To configure a component to display active data without the Active Data proxy:**

1. Drop a component onto a JSF page.
2. If you are using an ADF bound tree or tree table, you need to ensure the following:
  - The binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
  - The binding rule contains a single attribute.
  - The table does not use filtering.
  - The tree component's `nodeStamp` facet contains a single `outputText` tag and contains no other tags, as described in [Section 45.3.3, "What You May Need to Know About Displaying Active Data in ADF Trees."](#)
3. Open the page's associated page definition file.
4. In the Structure window for the page definition file, select the node that represents the attribute binding for the component. In the Property Inspector, set the **ChangeEventPolicy** attribute to **Push**.

**Tip:** You can use the `statusIndicator` component to indicate the server state. For more information, see the "Displaying Application Status Using Icons" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 45.3.2 How to Configure Components to Use the Active Data Service with the Active Data Proxy

To use ADS with the proxy, you need bind the value of your component to decorator class that will use the proxy. For more information about this class, see [Section 45.4, "Using the Active Data Proxy."](#) to set a value on the binding element in the corresponding page definition file.

**To configure a component to display active data with the Active Data proxy:**

1. Drop a component onto a JSF page.
2. Change the value attribute to be bound to a decorator class that you will create for use with the proxy. For more information, see [Section 45.4, "Using the Active Data Proxy."](#)

If you are using an ADF bound tree or tree table, you need to ensure the following:

- The binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
- The binding rule contains a single attribute.
- The table does not use filtering.
- The tree component's `nodeStamp` facet contains a single `outputText` tag and contains no other tags, as described in [Section 45.3.3, "What You May Need to Know About Displaying Active Data in ADF Trees."](#)

### 45.3.3 What You May Need to Know About Displaying Active Data in ADF Trees

When you create an ADF Faces tree (or tree table) component, you configure a `nodeStamp` facet, which is a holder for the component used to display the data for each node of the tree. Each node is rendered (stamped) once, repeatedly for all nodes.

Because of this stamping behavior, only certain types of components are supported as children inside an ADF Faces tree component. When the tree component is not bound to an active data source, all components that have no behavior are supported. However, when you configure the tree to use ADS, only the `outputText` component is supported inside of the `nodeStamp` facet, as shown in [Example 45–2](#). The `nodeStamp` facet must not contain any other tags. So, for example, active data will not work if you add `panelGroupLayout` tags to the `nodeStamp` facets of a tree configured to use ADS.

**Example 45–2 Tree Configured to Use ADS Must Contain outputText Component**

```
<f:facet name="nodeStamp">
 <af:outputText value="#{row.str2}"/>
</f:facet>
```

### 45.3.4 What Happens at Runtime: How Components Render When Bound to Active Data

After you configure your application and the component for ADS, whenever the data changes on the server, the component is notified and rerenders with only the changed data. In contrast, a component not configured for either active data or automatic PPR will need to be explicitly refreshed after a data change occurs. The explicit refresh will refetch all data that is visible on the client, including data that has not changed. Consequently, this will force the entire component to rerender. Additionally, when the component is bound to an active data source (with active data policy "Push"), the component rerenders with the new value highlighted.

### 45.3.5 What You May Need to Know About ADS and Google Chrome

When the Fusion web application runs in the Google Chrome web browser and a user presses Ctrl+N (or Ctrl+T) to open a new window (or tab) and then copies the URL from the original window into the new window, active data in the original window will stop streaming. According to the Google Chrome process model, the new browser window will be created in a separate process and both windows will share the same HTTP session. However, because browser windows that are created in two separate processes cannot communicate with each other, ADS will become out of sync between the client and server and will stop streaming. As a workaround, to allow active data in multiple Google Chrome windows, before copying the URL from the original window into the new window users must press Ctrl-Shift-N to open the browser window in

incognito mode (private browsing). Because Ctrl-Shift-N opens the window in a separate process and a separate HTTP session, ADS will not attempt to synchronize between the windows and streaming will be unaffected.

## 45.4 Using the Active Data Proxy

You use the active data proxy when your business services do not react to data events. If you want your components to update based on events passed into ADF Business Components, then you need to use the Active Data Proxy.

**Tip:** If your application uses BAM for the business service, then you do not need to use the Active Data Proxy.

---

---

**Note:** If your business service requires the use of the Active Data Proxy, then you can only use the following components with active data:

- table
  - tree
  - treeTable
  - DVT graph, geographical map, and gauge components
- 
- 

You need to create a Java class that subclasses one of the following decorator classes:

- `ActiveCollectionModelDecorator` class
- `ActiveDataModelDecorator` class (for use with graphs)
- `ActiveGeoMapDataModelDecorator` class
- `ActiveGaugeDataModelDecorator` class

These classes are wrapper classes that delegate the active data functionality to a default implementation of `ActiveDataModel`. The `ActiveDataModel` class listens for data change events and interacts with the Event Manager. Specifically, it does the following:

- Starts and stops the active data and the `ActiveDataModel` object, and registers and unregisters listeners to the data source.
- Wraps the JSF model interface. For example, the `ActiveCollectionModelDecorator` class wraps the `CollectionModel` class.
- Generates active data events based on data change events from the data source.
- Manages listeners from the Event Manager and pushes active data events to the Event Manager.

You need to implement methods on this Java class that registers itself as the listener of the active data source and gets the model to which the data is being sent.

---

**Note:** The Active Data framework does not support complicated business logic or transformations that require the ADF runtime context, such as a user profile or security. For example, the framework cannot convert an ADF context locale-dependent value and return a locale-specific value.

As an example of complicated business logic, say you have logic that allows a user to move an order from `open` status to `pending`. This change results in an `update` event, which should cause the order to be removed from a data object called "Open Orders." The framework cannot handle this event type transformation based on business logic. Instead, you need to have your data source handle this before publishing the data change event.

---

### Before you begin:

Implement the logic to fire the active data events asynchronously from the data source. For example, this logic might be a business process that updates the database, or a JMS client that gets notified from JMS.

### To use the active data service:

1. Create a Java class that extends the decorator class appropriate for your component. [Example 45-3](#) shows a class created for a table.

#### **Example 45-3 Extend the Decorator Class**

```
package view;

import oracle.adf.view.rich.model.ActiveCollectionModelDecorator;
import oracle.adf.view.rich.activedata.ActiveDataEventUtil;
import oracle.adf.view.rich.activedata.JboActiveDataEventUtil;

/**
 * This code wraps the existing collection model in the page and implements the
 * ActiveDataModel interface to enable ADS for the existing page.
 */
public class DeptModel
 extends ActiveCollectionModelDecorator
{
}
```

2. Implement the method that returns the model. [Example 45-4](#) shows an implementation of the `getCollectionModel()` method that relies on expression language (EL) to avoid needing to typecast to an internal class. The method returns the `DepartmentsView1` collection from the binding container.

#### **Example 45-4 Return the Model**

```
public CollectionModel getCollectionModel()
{
 if (_model == null)
 {
 FacesContext fc = FacesContext.getCurrentInstance();
 Application app = fc.getApplication();
 ExpressionFactory elFactory = app.getExpressionFactory();
 ELContext el = fc.getELContext();

 // This is EL to avoid typecasting to an Internal class.
```

```

 ValueExpression ve = elFactory.createValueExpression(el,
 "#{bindings.DepartmentsView1.collectionModel}", Object.class);

 // Now GET the collectionModel
 _model = (CollectionModel)ve.getValue(el);
 }
 return _model;
}

```

3. Create an inner class that is your own implementation of an `ActiveDataModel` class, which the decorator can use to start and stop the active data and connect and disconnect from the data source. This class should also use the `changeCount` API to maintain data read consistency, as shown in [Example 45–5](#). For more information, see [Section 45.4.1, "What You May Need to Know About Read Consistency."](#)

**Example 45–5 Connect to the Data Source**

```

public class MyActiveDataModel extends BaseActiveDataModel
{
 protected void startActiveData(Collection<Object> rowKeys,
 int startChangeCount)
 {
 _listenerCount.incrementAndGet();
 if (_listenerCount.get() == 1)
 {
 System.out.println("start up");

 Runnable dataChanger = new Runnable()
 {
 public void run()
 {
 System.out.println("MyThread starting.");
 try
 {
 Thread.sleep(2000);
 System.out.println("thread running");
 triggerDataChange(MyActiveDataModel.this);
 }
 catch (Exception exc)
 {
 System.out.println("MyThread exceptioned out.");
 }
 System.out.println("MyThread terminating.");
 }
 };
 Thread newThrd = new Thread(dataChanger);
 newThrd.start();
 }
 }

 protected void stopActiveData(Collection<Object> rowKeys)
 {
 _listenerCount.decrementAndGet();
 if (_listenerCount.get() == 0)
 {
 System.out.println("tear down");
 }
 }
}

```

```

public int getCurrentChangeCount()
{
 return _currEventId.get();
}

public void bumpChangeCount()
{
 _currEventId.incrementAndGet();
}

public void dataChanged(ActiveDataUpdateEvent event)
{
 fireActiveDataUpdate(event);
}

private final AtomicInteger _listenerCount = new AtomicInteger(0);
private final AtomicInteger _currEventId = new AtomicInteger();
}

```

4. Implement the method that will return the `ActiveDataModel` class, as shown in [Example 45-6](#).

**Example 45-6 Return the ActiveDataModel**

```

public ActiveDataModel getActiveDataModel()
{
 return _activeDataModel;
}

```

5. Create a method that creates application-specific events that can be used to insert or update data on the active model.

[Example 45-7](#) shows the `triggerDataChange()` method, which uses the active model (an instance of `MyActiveDataModel`) to create `ActiveDataUpdateEvent` objects to insert and update data. You will need to import `oracle.adf.view.rich.activedata.ActiveDataEventUtil` and `oracle.adf.view.rich.activedata.JboActiveDataEventUtil` to implement this method.

**Example 45-7 Create Event Objects to Update Model**

```

public void triggerDataChange(MyActiveDataModel l)
 throws Exception
{

 // do an update on dept 1
 l.bumpChangeCount();
 ActiveDataUpdateEvent event =
 ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.UPDATE,
 l.getCurrentChangeCount(),
 JboActiveDataEventUtil.convertKeyPath(new Key
 (new Object[] { new Long(1), new Integer(0) })),
 null,
 new String[] { "name" },
 new Object[] { "Name Pushed" });

 l.dataChanged(event);
}

```

```
try
{
 Thread.sleep(2000);
}
catch (InterruptedException ie)
{
 ie.printStackTrace();
}
// insert dept 99

l.bumpChangeCount();
event =
 ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.INSERT_AFTER,
 l.getCurrentChangeCount(),
 JboActiveDataEventUtil.convertKeyPath(new Key
 (new Object[]{ new Long(99), new Integer(0) })),
 JboActiveDataEventUtil.convertKeyPath(null),
 new String[]{ "addr1", "name" },
 new Object[]{ "Addr Inserted", "Name Inserted" });

l.dataChanged(event);

try
{
 Thread.sleep(2000);
}
catch (InterruptedException ie)
{
 ie.printStackTrace();
}

// delete dept 10

l.bumpChangeCount();
event =
 ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.REMOVE,
 l.getCurrentChangeCount(),
 JboActiveDataEventUtil.convertKeyPath(new Key
 (new Object[]{ new Long(9), new Integer(0) })),
 null, null, null);

l.dataChanged(event);

try
{
 Thread.sleep(2000);
}
catch (InterruptedException ie)
{
 ie.printStackTrace();
}

// refresh the entire table

l.bumpChangeCount();
event =
 ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.REFRESH,
 l.getCurrentChangeCount(),
```

```

 null, null, null, null);

 l.dataChanged(event);
}

private MyActiveDataModel _activeDataModel = new MyActiveDataModel();

private CollectionModel _model = null;
}

```

### 45.4.1 What You May Need to Know About Read Consistency

Using active data means that your component has two sources of data: the active data feed and the standard data fetch. Because of this, you must make sure your application maintains read consistency.

For example, say your page contains a table and that table has active data enabled. The table has two methods of delivery from which it updates its data: normal table data fetch and active data push. Say the back end data changes from `foo` to `bar` to `fred`. For each of these changes, an active data event is fired. If the table is refreshed *before* those events hit the browser, the table will display `fred` because standard data fetch will always get the latest data. But then, because the active data event might take longer, some time *after* the refresh the data change event would cause `foo` to arrive at the browser, and so the table would update to display `foo` instead of `fred` for a period of time. Therefore, you must implement a way to maintain the read consistency.

To achieve read consistency, the `ActiveDataModel` has the concept of a *change count*, which effectively timestamps the data. Both data fetch and active data push need to maintain this `changeCount` object by monotonically increasing the count, so that if any data returned has a lower `changeCount`, the active data event can throw it away. [Example 45-7](#) shows how you can use your implementation of the `ActiveDataModel` class to maintain read consistency.

## 45.5 Using the Active Data with a Scalar Model

ADF components that display collection-based data can be configured to work with ADS and require no extra setup in the view layer. However, imagine that your JSPX page uses an `activeOutputText` component to display new counts based on a Java timer. In this case, you will replace the model layer with scalar or "flat" data that you display from a Java Bean.

To implement the scalar model, follow these basic steps (as illustrated in the [Example 45-8](#)):

1. Use the `ActiveModelContext` API to register the bean with ADS so the bean (a scalar model) imitates an actual model.
2. Implement a custom mechanism to push the data to the view layer.

### **Example 45-8 Implement the Scalar Model in the Java Bean**

```

package oracle.adfdemo.view.feature.rich;

import java.util.Collection;
import java.util.Timer;
import java.util.TimerTask;

```

```
import java.util.concurrent.atomic.AtomicInteger;

import oracle.adf.view.rich.activedata.ActiveModelContext;
import oracle.adf.view.rich.activedata.BaseActiveDataModel;
import oracle.adf.view.rich.activedata.ActiveDataEventUtil;
import oracle.adf.view.rich.event.ActiveDataEntry;
import oracle.adf.view.rich.event.ActiveDataUpdateEvent;

public class CounterBean extends BaseActiveDataModel
// Example using a Java timer to create new counts
{
 public CounterBean()
 // 1. Use the ActiveModelContext API to register the scalar model key path for
 // the "state" attribute.
 {
 ActiveModelContext context = ActiveModelContext.getActiveModelContext();
 Object[] keyPath = new String[0];
 context.addActiveModelInfo(this, keyPath, "state");

 timer.schedule(new UpdateTask(), 2000, 2000);
 }

 public String getState()
 {
 return String.valueOf(counter);
 }

 // Not needed. We do not need to connect to a (real) active data source.
 protected void startActiveData(Collection<Object> rowKeys, int
 startChangeCount) {}

 // Not needed. We do not need to connect to a (real) active data source.
 protected void stopActiveData(Collection<Object> rowKeys) {}

 public int getCurrentChangeCount()
 {
 return counter.get();
 }

 protected class UpdateTask extends TimerTask
 {
 public void run()
 {
 counter.incrementAndGet();

 // 2. Use ActiveDataEventUtil to create an event object to update the model.
 ActiveDataUpdateEvent event =
 ActiveDataEventUtil.buildActiveDataUpdateEvent(
 ActiveDataEntry.ChangeType.UPDATE,
 counter.get(),
 new String[0],
 null,
 new String[] { "state" },
 new Object[] { counter.get() });
 fireActiveDataUpdate(event);
 }
 }
}
```

```

private static final Timer timer = new Timer();
private final AtomicInteger counter = new AtomicInteger(0);
}

```

After you create the bean, register the bean as a managed bean in the `faces-config.xml` file (as illustrated for `counterBean` in [Example 45-9](#)):

#### **Example 45-9 Register the Managed Bean**

```

...
<managed-bean>
 <managed-bean-name>counterBean</managed-bean-name>
 <managed-bean-class>
 oracle.adfdemo.view.feature.rich.CounterBean
 </managed-bean-class>
 <managed-bean-scope>session</managed-bean-scope>
</managed-bean>

```

Once the bean is registered, you can use ADS to stream the data to the view layer. Your ADF Faces component use expression language to receive the pushed data (as illustrated by the `activeOutputText` component value attribute in [Example 45-10](#)):

#### **Example 45-10 Display the Active Data**

```

...
<f:view>
 <af:document title="Active Data Visual Design Demo"
 binding="#{templateBindings.documentComponent}"
 smallIconSource="#{aboutBean.smallIconSource}"
 largeIconSource="#{aboutBean.largeIconSource}" theme="dark"
 id="d1">
 <af:pageTemplate id="dmoTpl" viewId="#{templates.componentTemplate}">
 <f:attribute name="tagName" value="Active Data Visual Design"/>
 <f:attribute name="demoKind" value="visualDesign"/>
 <f:attribute name="customEditorPresent" value="true"/>
 <f:facet name="center">
 <af:panelGroupLayout layout="scroll">
 <af:activeOutputText
 value="#{counterBean.state}"
 inlineStyle=
 "color:brown;
 font-size:100px;
 font-weight:bold;
 text-align:center;"
 />
 </af:panelGroupLayout>
 </f:facet>
 </af:pageTemplate>
 </af:document>
</f:view>

```

## Oracle ADF XML Files

This appendix provides reference for the Oracle ADF metadata files that you create in your data model and user interface projects. You may use this information when you want to edit the contents of the metadata these files define.

This appendix includes the following sections:

- [Section A.1, "Introduction to the ADF Metadata Files"](#)
- [Section A.2, "ADF File Overview Diagram"](#)
- [Section A.3, "ADF File Syntax Diagram"](#)
- [Section A.4, "adfm.xml"](#)
- [Section A.5, "modelProjectName.jpx"](#)
- [Section A.6, "bc4j.xcfg"](#)
- [Section A.7, "DataBindings.cpx"](#)
- [Section A.8, "pageNamePageDef.xml"](#)
- [Section A.9, "adfc-config.xml"](#)
- [Section A.10, "task-flow-definition.xml"](#)
- [Section A.11, "adf-config.xml"](#)
- [Section A.12, "adf-settings.xml"](#)
- [Section A.13, "web.xml"](#)
- [Section A.14, "logging.xml"](#)

### A.1 Introduction to the ADF Metadata Files

Metadata files in the Oracle Fusion web application are structured XML files used by the application to:

- Specify the parameters, methods, and return values available to your application's Oracle ADF data control usages
- Create objects in the Oracle ADF binding context and define the runtime behavior of those objects
- Define configuration information about the UI components in JSF and Oracle ADF Faces
- Define application configuration information for the Java EE application server

In the case of ADF bindings, you can use the binding-specific editors to customize the runtime properties of the binding objects. You can open a binding editor when you display the Structure window for a page definition file and choose **Properties** from the context menu.

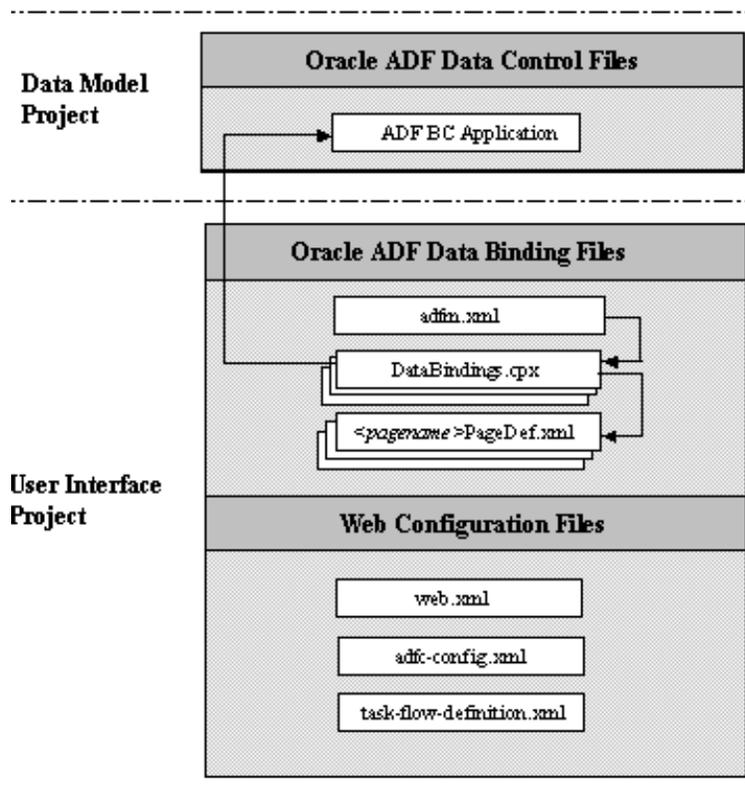

Additionally, you can view and edit the contents of any metadata file in JDeveloper's XML editor. The easiest way to work with these files is through the Structure window and Property Inspector. In the Structure window, you can select an element and in the Property Inspector, you can define attribute values for the element, often by choosing among dropdown menu choices. Use this reference to learn the choices you can select in the case of the Oracle ADF-specific elements.

## A.2 ADF File Overview Diagram

The relationship between the Oracle ADF metadata files defines dependencies between the model data and the user interface projects. The dependencies are defined as file references within XML elements of the files.

Figure A-1 illustrates the hierarchical relationship of the XML metadata files that you might work with in a Fusion web application that uses an ADF Business Components application module as a service interface to JSF web pages.

*Figure A-1 Oracle ADF File Hierarchy Overview for the Fusion Web Application*

### A.2.1 Oracle ADF Data Control Files

In an ADF Business Components application, the data control implementation files are contained within the application. The application module and view object XML component descriptor files provide the references for the data control. These files, in

conjunction with the `bc4j.xcfg` file, provide the necessary information for the data control.

An application that uses ADF Business Components in one project and a non-ADF Business Components data control in another project may have a `DataControls.dcx` file, as well as supporting `<sessionbeaname>.xml` and `<beaname>.xml` files.

## A.2.2 Oracle ADF Data Binding Files

These standard XML configuration files for a Fusion web application appear in your user interface project:

- `adfm.xml`: This file lists the `DataBindings.cpx` file that is available in the current project.

See [Section A.4, "adfm.xml"](#) for more information.

- `DataBindings.cpx`: This file contains the page map, page definitions references, and data control references. The file is created the first time you create a data binding for a UI component (either from the Structure window or from the Data Controls Panel). The `DataBindings.cpx` file defines the Oracle ADF binding context for the entire application. The binding context provides access to the bindings and data controls across the entire application. The `DataBindings.cpx` file also contains references to the `<pagename>PageDef.xml` files that define the metadata for the Oracle ADF bindings in each web page.

For more information, see [Section A.7, "DataBindings.cpx"](#).

- `<pagename>PageDef.xml`: This is the page definition XML file. It associates web page UI components with data, or data controls. JDeveloper creates this file each time you design a new web page using the Data Controls Panel or Structure window. These XML files contain the metadata used to create the bindings that populate the data in the web page's UI components. For every web page that refers to an ADF binding, there must be a corresponding page definition file with binding definitions.

For more information, see [Section A.8, "pageNamePageDef.xml"](#).

## A.2.3 Web Configuration Files

These standard XML configuration files required for a JSF application appear in your user interface project:

- `web.xml`: Part of the application's configuration is determined by the contents of its Java EE application deployment descriptor, `web.xml`. The `web.xml` file defines everything about your application that a server needs to know. The file plays a role in configuring the Oracle ADF data binding by setting up the `ADFBindingFilter`. Additional runtime settings include servlet runtime and initialization parameters, custom tag library location, and security settings.

For more information about ADF data binding and JSF configuration options, see [Section A.13, "web.xml"](#).

An ADF Faces application typically uses its own set of configuration files in addition to `web.xml`. For more information, see the "Configuration in `trinidad-config.xml`" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

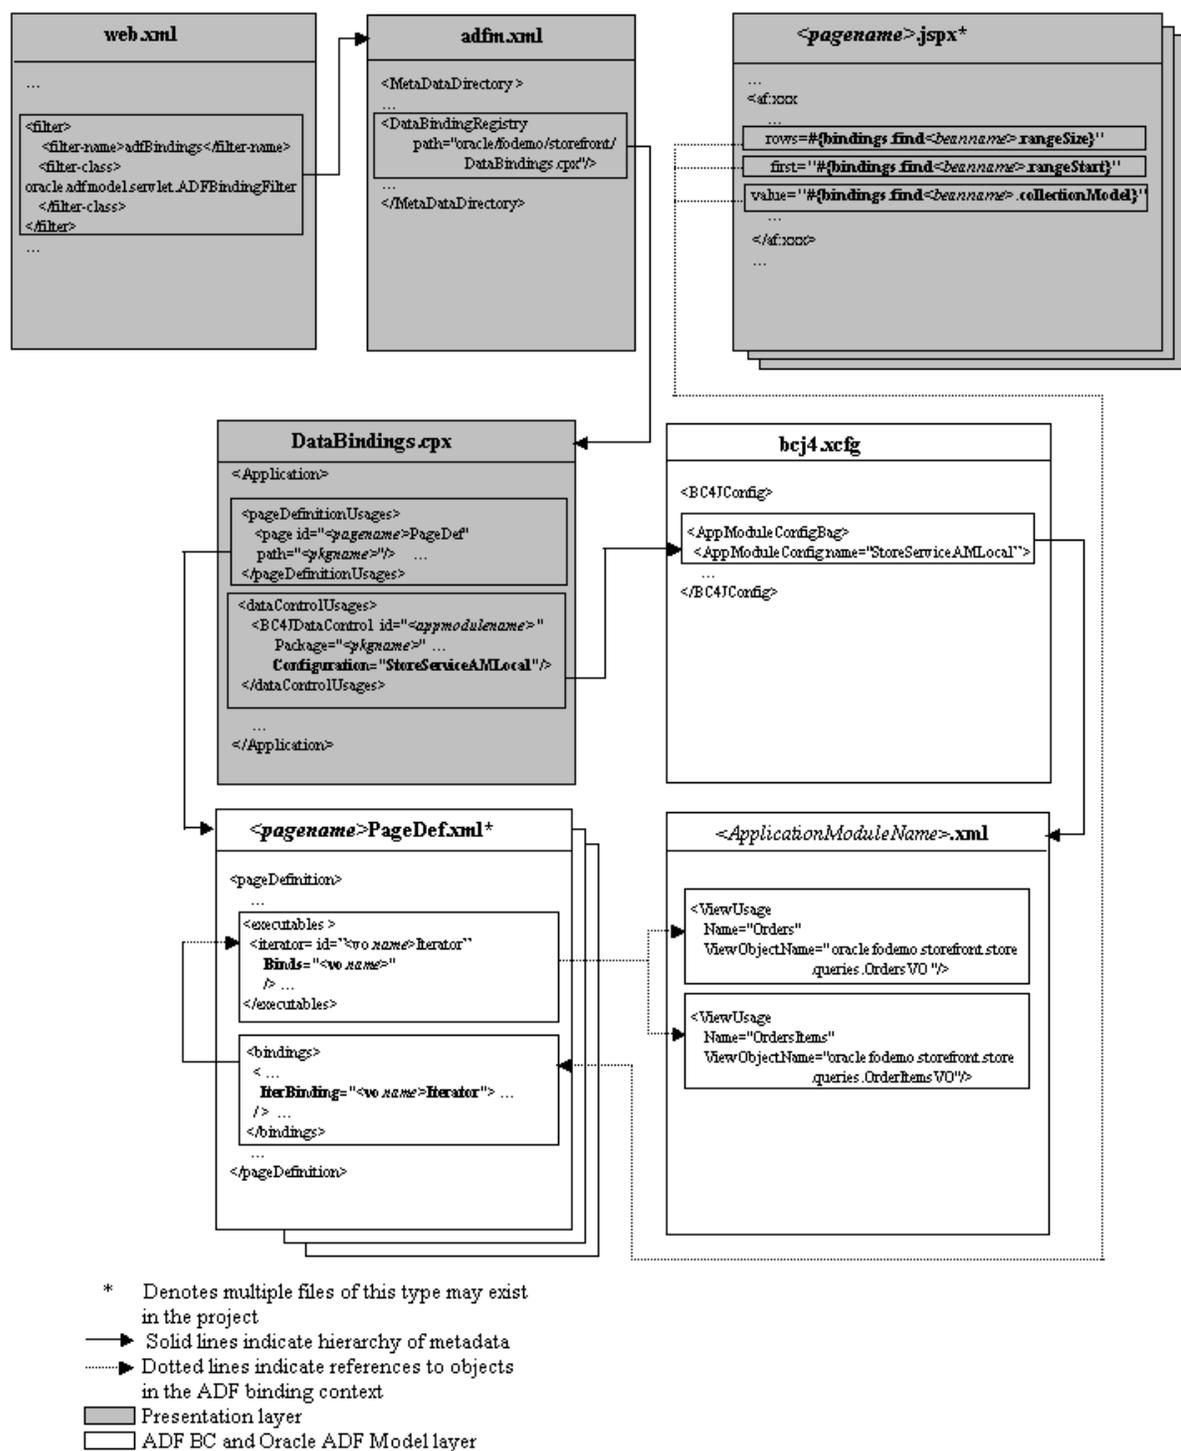

- `adfc-config.xml`: The configuration file for an ADF unbounded task flow. The configuration file contains metadata about the activities and control flows contained in the unbounded task flow. The default name for this file is `adfc-config.xml`, but an end user can change the name.  
For more information, see [Section A.9, "adfc-config.xml"](#).
- `task-flow-definition.xml`: The configuration file for an ADF bounded task flow. The configuration file contains metadata about the activities and control flows contained in the bounded task flow. The default name for this file can be `task-flow-definition.xml` or whatever an end user specifies in the **Create ADF Task Flow** dialog. The same application can contain multiple task flow definition files.  
For more information, see [Section A.10, "task-flow-definition.xml"](#).

### A.3 ADF File Syntax Diagram

[Figure A-2](#) illustrates the hierarchical relationship of the XML metadata files that you might work with in a web application that uses an ADF application module as a service interface to ADF Business Components. At runtime, the objects created from these files interact in this sequence:

1. When the first request for an ADF databound web page occurs, the servlet registers the Oracle ADF servlet filter `ADFBindingFilter` named in the `web.xml` file.
2. The binding filter creates an empty binding context.
3. When a page is rendered, the binding filter asks the binding context to load a corresponding `PageDef.xml` for the page.
4. The binding context creates the binding container by loading the `<page>` file as referenced by the `<pagemap>` element in the `DataBindings.cpx` file.
5. The `adfm.xml` file loads the `DataBindings.cpx` contents and finds the right `PageDef.xml` based on the `<pagemap>` element reference to the `<pageDefinitionUsage>` element.
6. The binding container's `prepareModel` phase prepares and refreshes all relevant executables (most are marked `deferred` by default).
7. An iterator binding gets executed by referencing the named method on the data control found through the data control factory named in the case of ADF Business Components in the `bc4j.xcfg` file.
8. The binding container also creates the bindings defined in the `<bindings>` section of the `pagenamePageDef.xml` file for the mapped web page.
9. The web page references to ADF bindings through EL using the expression `{bindings}` are resolved by accessing the binding container of the page.
10. The page pulls the available data from the bindings in the binding container.

Figure A-2 Oracle ADF File Hierarchy and Syntax Diagram for an ADF BC-based Web Application

## A.4 adfm.xml

The `adfm.xml` file contains the classpath-relative paths for the `.cpx`, `.dcx`, `.jspx`, and `.xcfg` files in each design time project that is included in the runtime deployed application. The `adfm.xml` file operates as a dynamically maintained "Registry of

Registries" that is used to quickly find all .cpx, .dcx, .jspx, and .xcfg files (which are themselves registries of metadata).

The file registry is used extensively by the ADF Library resource catalog browsing implementations, by the ADF model layer design time, and at runtime during merge and discovery.

When a developer creates a binding on a page, JDeveloper adds metadata files (for example, page definitions) in the project source tree. The `adfm.xml` file then notes the location of each.

When a project is built, the `adfm.xml` file is put in `project-root/adfmsrc/META-INF/adfm.xml`. The project-level archive deployment profiles locate the file at `META-INF/adfm.xml`.

At runtime, the application classpath is scanned to build the list of .cpx files that comprise the application. The application then loads each .cpx as needed to create the binding context. For details about the ADF model layer usage, see [Section 13.4.2, "What Happens When You Use the Data Controls Panel"](#).

Four types of sub registries are recorded by the `adfm.xml` file:

- `DataBindingRegistry (.cpx)`
- `DataControlRegistry (.dcx)`
- `BusinessComponentServiceRegistry (.xcfg)`
- `BusinessComponentProjectRegistry (.jspx)`

## A.5 modelProjectName.jpx

The .jspx file contains configuration information that JDeveloper uses in the design time to allow you to create the data model project with ADF Business Components. It also contains metadata that defines how a shared application module is used at runtime. Because the shared application module can be accessed by any data model project in the same Fusion web application, JDeveloper maintains the scope of the shared application module in the ADF Business Components project configuration file.

This file is saved in the `src` directory of the project. For example, if you look at the `StoreFrontService.jpx` file in the `./src/model` subdirectory of the Fusion Order Demo application's `StoreFrontService` project, you will see the `SharedLookupService` application module's usage definition. For details about the shared application module usage, see [Section 10.2.2, "What Happens When You Define a Shared Application Module"](#).

[Example A-2](#) displays a sample default .jspx file.

### Example A-1 Sample .jspx File

```
<JboProject

</JboProject>

```

## A.6 bc4j.xcfg

The `bc4j.xcfg` file contains metadata information about application module names, the database connection used by the application module, and the runtime parameters the user has configured for the application module.

The `bc4j.xcfg` file is located in the `./common` subdirectory relative to the application module's XML component definition. All of the configurations for all of the application modules in a single Java package are saved in that same file. For example, if you look at the `bc4j.xcfg` file in the `./classes/oracle/fodemo/storefront/store/service/common` directory of the Fusion Order Demo application's `StoreFront` project, you will see the three named configurations for its `StoreServiceAM` application module. For details about editing the configurations, see [Section 9.3.4, "How to Change Your Application Module's Runtime Configuration"](#) and [Section 44.2, "Setting Pool Configuration Parameters"](#).

[Example A–2](#) displays a sample `bc4j.xcfg` file from the Fusion Order Demo application.

### Example A–2 Sample bc4j.xcfg File

```

<BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/configuration">
 <AppModuleConfigBag ApplicationName="oracle.fodemo.storefront.store.service.StoreServiceAM">
 <AppModuleConfig
 DeployPlatform="LOCAL"

 <Security AppModuleJndiName="oracle.fodemo.storefront.store.service.StoreServiceAM"/>
 <Custom JDBCDataSource="java:comp/env/jdbc/FODDS"/>
</AppModuleConfig>
</AppModuleConfigBag>
</BC4JConfig>

```

## A.7 DataBindings.cpx

The `DataBindings.cpx` file is created in the user interface project the first time you drop a data control usage onto a web page in the visual editor. The `DataBindings.cpx` file defines the Oracle ADF binding context for the entire application and provides the metadata from which the Oracle ADF binding objects are created at runtime. It is used extensively by the ADF Library Resource Palette browsing implementations, and also by the `.cpx` and `.dcx` design time and runtime merge and discovery. When you insert a databound UI component into your document, the page will contain binding expressions that access the Oracle ADF binding objects at runtime.

If you are familiar with building Fusion web applications in earlier releases of JDeveloper, you'll notice that the `.cpx` file no longer contains all the information copied from the `DataControls.dcx` file, but only a reference to it. If you need to make changes to the `.cpx` file, you must edit the `DataControls.dcx` file.

The `DataBindings.cpx` file appears in the `/src` directory of the user interface project. When you double-click the file node, the binding context description appears in the XML source editor. (To edit the binding context parameters, use the Property Inspector and select the desired parameter in the Structure window.)

### A.7.1 DataBindings.cpx Syntax

The top level element of the `DataBindings.cpx` file is `<DataControlConfigs>`:

```

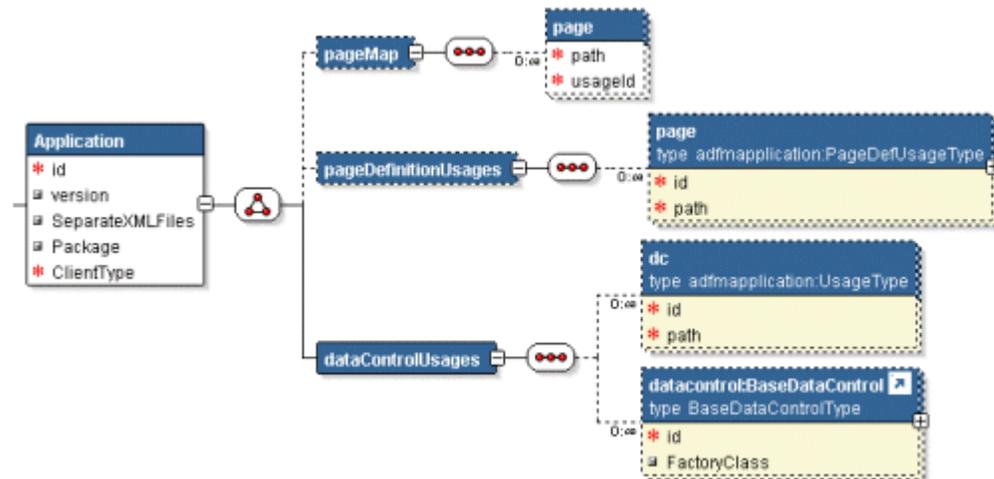

<?xml version = '1.0' encoding = 'UTF-8'?>
<BC4JConfig version="11.0" xmlns="http://xmlns.oracle.com/bc4j/configuration">

```

where the XML namespace attribute (`xmlns`) specifies the URI to which the data controls bind at runtime. Only the package name is editable; all other attributes should have the values shown.

Figure A-3 displays the child element hierarchy of the `<DataControlConfigs>` element. Note that each business service for which you have created a data control will have its own `<dataControlUsages>` definition.

**Figure A-3 Schema for the Structure Definition of the DataBindings.cpx File**

The child elements have the following usages:

- `<definitionFactories>` registers a factory class to create the ADF binding objects associated with a particular namespace at runtime. The factory class is specific to the namespace associated with the type of ADF binding (for instance, a task flow binding).
- `<pageMap>` maps all user interface URLs and the corresponding page definition usage name. This map is used at runtime to map a URL to its page definition.
- `<pageDefinitionUsages>` maps a page definition usage (`BindingContainer` instance) name to the corresponding page definition. The `id` attribute represents the usage ID. The `path` attribute represents the full path to the page definition.
- `<dataControlUsages>` declares a list of data control usages (shortnames) and corresponding path to the data control definition entries in the `.dcx` or `.xcfg` file.

Table A-1 describes the attributes of the `DataBindings.cpx` elements.

**Table A-1 Attributes of the DataBindings.cpx File Elements**

Element Syntax	Attributes	Attribute Description
<code>&lt;definitionFactories&gt;</code> <code>&lt;factory/&gt;</code> <code>&lt;/definitionFactories&gt;</code>	<code>nameSpace</code>	A URI. Identifies the location of the executable elements in the page definition usage.
	<code>className</code>	The fully qualified class name. Identifies the location of the factory class that creates the page definition usage objects.
<code>&lt;pageMap&gt;</code> <code>&lt;page /&gt;</code> <code>&lt;/pageMap&gt;</code>	<code>path</code>	The full directory path. Identifies the location of the user interface page.

**Table A-1 (Cont.) Attributes of the DataBindings.cpx File Elements**

Element Syntax	Attributes	Attribute Description
	usageId	A unique qualifier. Names the page definition ID that appears in the ADF page definition file. The ADF binding servlet looks at the incoming URL requests and checks that the bindings variable is pointing to the ADF page definition associated with the URL of the incoming HTTP request.
<pageDefinitionUsages> <page/> </pageDefinitionUsages>	id	A unique qualifier. References the page definition ID that appears in the ADF page definition file.
	path	The fully qualified package name. Identifies the location of the user interface page's ADF page definition file.
<dataControlUsages> <dc.../> </dataControlUsages>	id	A unique qualifier. Identifies the data control usage as is defined in the DataControls.dcx file.
	path	The fully qualified package name. Identifies the location of the data control.

## A.7.2 DataBindings.cpx Sample

[Example A-3](#) shows the syntax for the DataBindings.cpx file in the Fusion Order Demo application.

The ADF executable definition factory (factory element) is named by a className attribute and is associated with a namespace. At runtime, the factory class creates the executable definition objects that leads to the creation of the binding objects for the ADF binding container associated with a particular page definition. The factory locates the page definition through two DataBindings.cpx file elements: the pageMap element that maps the page URL to the page definition ID (usageId attribute) assigned at design time and the pageDefinitionUsages element that maps the ID to the location of the page definition from the project or project classpath.

Additionally, the ADF Business Components data control (BC4JDataControl element) is named by the id attribute. The combination of the Package attribute and the Configuration attribute is used to locate the bc4j.xcfg file in the ./common subdirectory of the indicated package. The configuration contains the information of the application module name and all the runtime parameters the user has configured.

### Example A-3 Sample DataBindings.cpx File

```
<Application xmlns="http://xmlns.oracle.com/adfm/application"
 version="11.1.1.44.61" id="DataBindings" SeparateXMLFiles="false"
 Package="oracle.fodemo.storefront" ClientType="Generic"
 ErrorHandlerClass="oracle.fodemo.frmwkext.FODCustomErrorHandler">
 <definitionFactories>
 <factory namespace="http://xmlns.oracle.com/adf/controller/binding"
 className="oracle.adf.controller.internal.binding.
 TaskFlowBindingDefFactoryImpl"/>
 <factory namespace="http://xmlns.oracle.com/adfm/dvt"
 className="oracle.adfinternal.view.faces.dvt.model.binding.
 FacesBindingFactory"/>
 </definitionFactories>
 <pageMap>
 <page path="/home.jspx" usageId="homePageDef"/>
 </pageMap>
</Application>
```

```

...
</pageMap>
<pageDefinitionUsages>
 <page id="homePageDef"
 path="oracle.fodemo.storefront.pageDefs.homePageDef"/>
...
</pageDefinitionUsages>
<dataControlUsages>
 <BC4JDataControl id="StoreServiceAMDataControl"
 Package="oracle.fodemo.storefront.store.service"
 FactoryClass="oracle.adf.model.bc4j.DataControlFactoryImpl"
 SupportsTransactions="true" SupportsFindMode="true"
 SupportsRangesize="true" SupportsResetState="true"
 SupportsSortCollection="true"
 Configuration="StoreServiceAMLocalWeb" syncMode="Immediate"
 xmlns="http://xmlns.oracle.com/adfm/datacontrol"/>
...
</dataControlUsages>
</Application>

```

## A.8 pageNamePageDef.xml

The `pageNamePageDef.xml` files are created each time you insert a databound component into a web page using the Data Controls Palette or Structure window. These XML files define the Oracle ADF binding container for each web page in the application. The binding container provides access to the bindings within the page. You will have one XML file for each databound web page.

---

**Caution:** The `DataBindings.cpx` file maps JSF pages to their corresponding page definition files. If you change the name of a page definition file or a JSF page, JDeveloper does *not* automatically refactor the `DataBindings.cpx` file. You must manually update the page mapping in the `DataBindings.cpx` file.

---

The `PageDef.xml` file appears in the `/src/view` directory of the user interface project. The Application Navigator displays the file in the view package of the Application Sources node. When you double-click the file node, the page description appears in the XML source editor. To edit the page description parameters, use the Property Inspector and select the desired parameter in the Structure window.

For more information, see [Chapter 13.7, "Working with Page Definition Files"](#).

There are important differences in how the page definitions are generated for methods that return a single value and a collection.

### A.8.1 PageDef.xml Syntax

The top-level element of the `PageDef.xml` file is `<pageDefinition>`:

```

<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uiamodel"
 version="10.1.3.35.83" id="<pagename>PageDef"
 Package="oracle.fod.view.pageDefs">

```

where the XML namespace attribute (`xmlns`) specifies the URI to which the ADF binding container binds at runtime. Only the package name is editable; all other attributes should have the values shown.

[Example A-4](#) displays the child element hierarchy of the `<pageDefinition>` element. Note that each business service for which you have created a data control will have its own `<AdapterDataControl>` definition.

**Example A-4 PageDef.xml Element Hierarchy**

```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition>
 <parameters>
 ...
 </parameters>
 <executables>
 ...
 </executables>
 <bindings>
 ...
 </bindings>
</pageDefinition>
```

The child elements have the following usages:

- `<parameters>` defines page-level parameters that are EL accessible. These parameters store information local to the web page request and may be accessed in the binding expressions.
- `<executables>` defines the list of items (methods, view objects, and accessors) to execute during the `prepareModel` phase of the ADF page lifecycle. Methods to be executed are defined by `<methodIterator>`. The lifecycle performs the execute in the sequence listed in the `<executables>` section. Whether or not the method or operation is executed depends on its `refresh` or `refreshCondition` attribute value. Built-in operations on the data control are defined by:
  - `<page>` - definition for a nested page definition (binding container)
  - `<iterator>` - definition to a named collection in `DataControls`
  - `<accessorIterator>` - definition to get an accessor in a data control hierarchy
  - `<methodIterator>` - definition to get to an iterator returned by an invoked method defined by a `methodAction` in the same file
  - `<variableIterator>` - internal iterator that contains variables declared for the binding container
  - `<invokeAction>` - definition of which method to invoke as an executable
- `<bindings>` refers to an entry in `<executables>` to get to the collection from which bindings extract/submit attribute level data.

[Table A-2](#) describes the attributes of the top-level `<pageDefinition>` element.

**Table A-2 Attributes of the PageDef.xml File <pageDefinition> Element**

Element Syntax	Attributes	Attribute Description
<pageDefinition>	ControllerClass	Fully qualified class name to create when controller requests a PageController object for this bindingContainer.
	EnableTokenValidation	Enables currency validation for this bindingContainer when a postback occurs. This is to confirm that the web tier state matches the state that particular page was rendered with.
	FindMode	FindMode is for legacy (10.1.2) use only and indicates whether this bindingContainer should start out in findMode when initially prepared.
	MsgBundleClass	Fully qualified package name. Identifies the class which contains translation strings for any bindings.
	SkipValidation	Determines if data validation occurs. The supported values are: <ul style="list-style-type: none"> <li>■ true: skips data validation. Note that client-side binding level attribute validation still occurs. For example, validates non-null and type conversion errors.</li> <li>■ false: validates all rows for all data controls referenced in the current page. This is the default value.</li> <li>■ skipDataControls: validates the current rows of iterator bindings modified in the current page.</li> <li>■ custom: set to custom if your application implements an instance of the <code>oracle.binding.BindingContainerValidator</code> interface and references it through an EL expression entry named <code>CustomValidator</code> in the binding container.</li> </ul> <p>Setting a value for this attribute can be useful if you want to skip data validation on, for example, a train component. For more information see the "How to Create the Train Model" section of the <i>Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework</i></p>
	Viewable	An EL expression that should resolve at runtime to whether this binding and the associated component should be rendered or not.

Table A-3 describes the attributes of the child element of <parameters>.

**Table A-3 Attributes of the PageDef.xml File <parameters> Element**

Element Syntax	Attributes	Attribute Description
<parameter>	evaluate	Specifies when the parameter should be evaluated: <code>eachUse</code> , <code>firstUse</code> , or <code>inPrepareModel</code> .
	id	Unique identifier. May be referenced by ADF bindings.
	option	Indicates the usage of the variable within the binding container: <ul style="list-style-type: none"> <li>▪ <code>Final</code> indicates that this parameter cannot be passed in by a usage of this binding container. It must use the default value in the definition.</li> <li>▪ <code>Optional</code> indicates that the variable value need not be provided.</li> <li>▪ <code>Mandatory</code> indicates that the variable value must be provided or a binding container exception will be thrown.</li> </ul>
	readonly	Indicates whether the parameter value may be modified or not. Set to <code>true</code> when you do not want the application to modify the parameter value.
	value	A default value, which can be an EL expression.

Table A-4 describes the attributes of the PageDef.xml <executables> elements.

**Table A-4 Attributes of the PageDef.xml File <executables> Element**

Element Syntax	Attributes	Attribute Description
<accessorIterator>	Accessor	Specifies any other accessor defined by this binding.
	Binds	Specifies the view or action to which the iterator is bound.
	BeanClass	Identifies the Java type of beans in the associated iterator or collection.
	CacheResults	If <code>true</code> , manages the data collection between requests.
	ChangeEventRate	Specifies the rate of events when a component is wired to data via this iterator and is in polling event mode.
	DataControl	Interprets and returns the collection referred to by this iterator binding.
	id	Unique identifier. May be referenced by any ADF value binding.
	MasterBinding	Reference to the <code>methodIterator</code> (or <code>iterator</code> ) that binds the data collection that serves as the master to the accessor iterator's detail collection.
	ObjectType	Used for ADF Business Components only. A boolean value determines whether the collection is an object type or not.
	RangeSize	Specifies the number of data objects in a range to fetch from the bound collection. The range defines a window you can use to access a subset of the data objects in the collection. By default, the range size is set to a range that fetches just ten data objects. Use <code>RangeSize</code> when you want to work with an entire set or when you want to limit the number of data objects to display in the page. Note that the values <code>-1</code> and <code>0</code> have specific meaning: the value <code>-1</code> returns all available objects from the collection, while the value <code>0</code> will return the same number of objects as the collection uses to retrieve from its data source.

**Table A-4 (Cont.) Attributes of the PageDef.xml File <executables> Element**

Element Syntax	Attributes	Attribute Description
	Refresh	<p>Determines when and whether the executable should be invoked. Set one of the following properties as required:</p> <ul style="list-style-type: none"> <li>■ <code>always</code> - causes the executable to be invoked each time the binding container is prepared. This will occur when the page is displayed and when the user submits changes, or when the application posts back to the page.</li> <li>■ <code>deferred</code> (default for ADF faces applications) - refresh occurs when another binding requires or refers to this executable. Since refreshing an executable may be a performance concern, you can set the refresh to occur only if <code>deferred</code> is used in a binding that is being rendered.</li> <li>■ <code>&lt;default&gt;</code> - Always set to <code>Deferred</code> by default.</li> <li>■ <code>ifNeeded</code> (default for all view technologies other than ADF Faces) - whenever the framework needs to refresh the executable because it has not been refreshed to this point. For example, when you have an accessor hierarchy such that a detail is listed first in the page definition, the master could be refreshed twice (once for the detail and again for the master's iterator). Using <code>ifNeeded</code> gives the mean to avoid duplicate refreshes. This is the default behavior for executables.</li> <li>■ <code>never</code> - when the application itself will call refresh on the executable during one of the controller phases and does not want the framework to refresh it at all.</li> <li>■ <code>prepareModel</code> - causes the executable to be invoked each time the page's binding container is prepared.</li> <li>■ <code>prepareModelIfNeeded</code> - causes the executable to be invoked during the <code>prepareModel</code> phase if this executable has not been refreshed to this point. See also <code>ifNeeded</code> above.</li> <li>■ <code>renderModel</code> - causes the executable to be invoked each time the page is rendered.</li> <li>■ <code>renderModelIfNeeded</code> - causes the executable to be invoked during the page's <code>renderModel</code> phase on the condition that it is needed. See also <code>ifNeeded</code> above.</li> <li>■ <code>refreshAfter</code> - Use to handle dependencies between executables. For example, you can set the condition so that this executable refreshes after another executable.</li> </ul>
	RefreshCondition	<p>An EL expression that when resolved, determines when and whether the executable should be invoked. For example,  <code>\${!bindings.findAllServiceRequestIter.findModel}</code> resolves the value of the <code>findModel</code> on the iterator in the ADF binding context <code>AllServiceRequest</code>. Hint: Use the Property Inspector to create expressions from the available objects of the binding context (bindings namespace) or binding context (data namespace), JSF managed beans, and JSP objects.</p>
	RefreshAfter	<p>Specifies the condition after which the page should be refreshed.</p>

**Table A-4 (Cont.) Attributes of the PageDef.xml File <executables> Element**

Element Syntax	Attributes	Attribute Description
	RowCountThreshold	<p>Specify a value to determine if a result set returns the number of rows you specify as a value. If you set RowCountThreshold to 0, the iterator returns the estimated row count in the result set by executing the count query. If you set RowCountThreshold to less than 0, the iterator does not execute the count query.</p> <p>Set RowCountThreshold to a value greater than 0 if you want the iterator to execute the count query with the maximum value equal to the value you specify for RowCountThreshold. If the estimated row count is less than the value of RowCountThreshold, return the number of rows in the estimated row count. If the estimated row count is greater than the value of RowCountThreshold, return -1.</p>
	Sortable	Specifies whether the iterator is sortable or not.
<invokeAction>	Binds	<p>Determines the action to invoke. This may be on any actionBinding. Additionally, in the case, of the EJB session facade data control, you may bind to the finder method exposed by the data control. Built-in actions supported by the EJB session facade data control include:</p> <ul style="list-style-type: none"> <li>▪ Execute executes the bound action defined by the data collection.</li> <li>▪ Find retrieves a data object from a collection.</li> <li>▪ First navigates to the first data object in the data collection range.</li> <li>▪ Last navigates to the first data object in the data collection range.</li> <li>▪ Next navigates to the first data object in the data collection range. If the current range position is already on the last data object, then no action is performed.</li> <li>▪ Previous navigates to the first data object in the data collection range. If the current position is already on the first data object, then no action is performed.</li> <li>▪ setCurrentRowWithKey passes the row key as a String converted from the value specified by the input field. The row key is used to set the currency of the data object in the bound data collection. When passing the key, the URL for the form will not display the row key value. You may use this operation when the data collection defines a multipart attribute key.</li> <li>▪ setCurrentRowWithKeyValue is used as above, but when you want to use a primary key value instead of the stringified key.</li> </ul>
	id	Unique identifier. May be referenced by any ADF action binding.
	Refresh	See Refresh for <accessorIterator>.
	RefreshCondition	See RefreshCondition for <accessorIterator>.
<iterator> and <methodIterator>	BeanClass	Identifies the Java type of beans in the associated iterator or collection.

**Table A-4 (Cont.) Attributes of the PageDef.xml File <executables> Element**

Element Syntax	Attributes	Attribute Description
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. Not used in current JDeveloper release.
	Binds	See Binds for <invokeAction>.
	CacheResults	See CacheResults for <accessorIterator>.
	ChangeEventRate	Specifies the rate of events when a component is wired to data via this iterator and is in polling event mode.
	DataControl	Name of the DataControl usage in the bindingContext (.cpx) which this iterator is associated with.
	DefClass	Used internally by ADF.
	id	Unique identifier. May be referenced by any ADF value binding.
	ObjectType	Not used by EJB session facade data control (used by ADF Business Components only).
	RangeSize	See RangeSize for <accessorIterator>.
	Refresh	See Refresh for <accessorIterator>.
	RefreshAfter	Specifies the condition after which the page should be refreshed.
	RefreshCondition	See RefreshCondition for <accessorIterator>.
	RowCountThreshold	See RowCountThreshold for <accessorIterator>.
<page> and <variableIterator>	id	Unique identifier. In the case of <page>, refers to nested page or region that is included in this page. In the case of the <variableIterator> executable, the identifier may be referenced by any ADF value binding.
	ChangeEventRate	Specifies the rate of events when a component is wired to data via this iterator and is in polling event mode.
	path	Used by <page> executable only. Advanced, a fully qualified path that may reference another page's binding container.
	Refresh	See Refresh for <accessorIterator>.
	RefreshAfter	Specifies the condition after which the page should be refreshed.
	RefreshCondition	See RefreshCondition for <accessorIterator>.

Table A-5 describes the attributes of the PageDef.xml <bindings> element.

**Table A-5 Attributes of the PageDef.xml File <bindings> Element**

Element Syntax	Attributes	Attribute Description
<action>	Action	Fully qualified package name. Identifies the class for which the data control is created. In the case of the EJB session facade, this is the session bean.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	DataControl	Name of the DataControl usage in the bindingContext (.cpx) which this iteratorBinding or actionBinding is associated with.
	Execute	Used by default when you drop an operation from the Data Controls Panel in the automatically configured ActionListener property. It results in executing the action binding's operation at runtime.
	InstanceName	Specifies the instance name for the action.
	IterBinding	Specifies the iteratorBinding instance in this bindingContainer to which this binding is associated.
	Outcome	Use if you want to use the result of a method action binding (once converted to a String) as a JSF navigation outcome name.
<attributeValues>	ApplyValidation	Set to true by default. When true, controlBinding executes validators defined on the binding. You can set to false in the case of ADF Business Components, when running in local mode and the same validators are already defined on the corresponding attribute.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	ChangeEventPolicy	Specifies the event strategy for the component when run with ADS (Active Data Services). Can be specified as push poll ppr none
	ControlClass	Used internally by ADF.
	CustomInputHandler	This is the class name for a oracle.jbo.uicli.binding.JUCtrlValueHandler implementation that is used to process the inputValue for a given value binding.
	DefClass	Used internally by ADF.
	id	Unique identifier. May be referenced by any ADF action binding.
	IterBinding	Refers to the iteratorBinding instance in this bindingContainer to which this binding is associated.
	NullValueId	Refers to the entry in the message bundle for this bindingContainer that contains the String to indicate the null value in a list display.

**Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element**

Element Syntax	Attributes	Attribute Description
<button>	ApplyValidation	Set to true by default. When true, <code>controlBinding</code> executes validators defined on the binding. You can set to false in the case of ADF Business Components, when running in local mode and when the same validators are already defined on the corresponding attribute.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	BoolVal	Identifies whether the value at the zero index in the static value list in this boolean list binding represents true or false.
	ControlClass	Used internally by ADF.
	CustomInputHandler	This is the class name for a <code>oracle.jbo.uicli.binding.JUCtrlValueHandler</code> implementation that is used to process the <code>inputValue</code> for a given value binding.
	DefClass	Used internally by ADF.
	id	Unique identifier. May be referenced by any ADF action binding.
	IterBinding	Refers to the <code>iteratorBinding</code> instance in this <code>bindingContainer</code> to which this binding is associated.
	ListIter	Refers to the <code>iteratorBinding</code> that is associated with the source list of this <code>listBinding</code> .
	ListOperMode	Determines whether this list binding is for navigation, contains a static list of values or is an LOV type list.
	NullValueFlag	Describes whether this list binding has a null value and, if so, whether it should be displayed at the beginning or the end of the list.
	NullValueId	Refers to the entry in the message bundle for this <code>bindingContainer</code> that contains the <code>String</code> to indicate the null value in a list display.
	<gantDataMap>	
<gaugeDataMap>		Maps the data binding XML for an ADF Faces gauge component.
<graph>	ApplyValidation	Set to true by default. When true, <code>controlBinding</code> executes validators defined on the binding. You can set to false in the case of ADF Business Components, when running in local mode and when the same validators are already defined on the corresponding attribute.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	BoolVal	Identifies whether the value at the zero index in the static value list in this boolean list binding represents true or false.
	ChildAccessorName	The name of the accessor to invoke to get the next level of nodes for a given hierarchical node type in a tree.

**Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element**

Element Syntax	Attributes	Attribute Description
	ControlClass	Used internally by ADF.
	CustomInputHandler	This is the class name for a <code>oracle.jbo.uicli.binding.JUCtrlValueHandler</code> implementation that is used to process the <code>inputValue</code> for a given value binding.
	DefClass	Used internally by ADF.
	GraphPropertiesFile Name	An XML file that specifies the type of graph to use, for example, pie chart or bar graph. This XML file can be used to customize the visual properties of the graph. It contains graph attributes such as title, subtitle, footnote, graph type, legend area, and plot area. The default filename is <code>BIGraphDef.xml</code> .
	GroupLabel	For master-detail forms, specifies the attribute that will be used to group data.
	id	Unique identifier. May be referenced by any ADF action binding.
	IterBinding	Refers to the <code>iteratorBinding</code> instance in this <code>bindingContainer</code> to which this binding is associated.
	NullValueId	Refers to the entry in the message bundle for this <code>bindingContainer</code> that contains the <code>String</code> to indicate the null value in a list display.
	SeriesLabel	Defines the attribute, based on which data will be clubbed.
	SeriesType	Determines whether graph is for <code>SingleView(SINGLE_SERIES)</code> , or for <code>MASTER_DETAIL</code> .
<graphDataMap>		Wraps the data binding XML for an ADF Faces graph component.
<list>	ApplyValidation	Set to true by default. When true, <code>controlBinding</code> executes validators defined on the binding. You can set to false in the case of ADF Business Components, when running in local mode and when the same validators are already defined on the corresponding attribute.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	ControlClass	Used internally by ADF.
	CustomInputHandler	This is the class name for a <code>oracle.jbo.uicli.binding.JUCtrlValueHandler</code> implementation that is used to process the <code>inputValue</code> for a given value binding.
	DefClass	Used internally by ADF.
	id	Unique identifier. May be referenced by any ADF action binding.
	IterBinding	Refers to the <code>iteratorBinding</code> instance in this <code>bindingContainer</code> to which this binding is associated.
	ListIter	Refers to the <code>iteratorBinding</code> that is associated with the source list of this <code>listBinding</code> .

**Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element**

Element Syntax	Attributes	Attribute Description
	ListOperMode	Determines whether this list binding is for navigation, contains a static list of values, or is an LOV type list.
	Mode	The value of this attribute determines if the list binding passes the actual value ( <code>Object</code> ) or the location of the value in an index ( <code>Index</code> ). For more information about setting this attribute, see <a href="#">Section 30.3.6, "What You May Need to Know About Values in a Selection List."</a>
	MRUCount	Specifies the number of items to display in a choice list when you want to provide a shortcut for the end-user to display their most recent selections. For example, a form might display a choice list of supplier ID values to drive a purchase order form. In this case, you can allow users to select from a list of their most recently view suppliers, where the number of supplier choices is determined by the count you enter. The default for the choice list is to display all values for the attribute and is specified by the count 0 (zero)."
	MRUId	Specifies the <code>String</code> that will be the discriminator line for the MRU list.
	NullValueFlag	Describes whether this list binding has a null value and, if so, whether it should be displayed at the beginning of the list or the end.
	NullValueId	Refers to the entry in the message bundle for this <code>bindingContainer</code> that contains the <code>String</code> to indicate the null value in a list display.
	StaticList	Defines a static list of values that will be rendered in the bound list component.
<mapThemeDataMap>		Wraps the data binding XML for an ADF Data Visualization geographic map component.
<methodAction>	Action	Fully qualified package name. Identifies the class for which the data control is created. In the case of the EJB session facade, this is the session bean.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	ClassName	This is the class to which the method being invoked belongs.
	DataControl	Name of the <code>DataControl</code> usage in the <code>bindingContext (.cpx)</code> which this <code>iteratorBinding</code> or <code>actionBinding</code> is associated with.
	DefClass	Used internally by ADF.
	id	Unique identifier. May be referenced by any ADF action binding.
	InstanceName	A dot-separated EL path to a Java object instance on which the associated method is to be invoked.
	IsLocalObjectReference	Set to <code>true</code> if the <code>instanceName</code> contains an EL path relative to this <code>bindingContainer</code> .
	IsViewObjectMethod	Set to <code>true</code> if the <code>instanceName</code> contains an instance path relative to the associated data control's application module.

**Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element**

Element Syntax	Attributes	Attribute Description
	MethodName	Indicates the name of the operation on the given instance or class that needs to be invoked for this methodActionBinding.
	RequiresUpdateModel	Whether this action requires that the model be updated before the action is to be invoked.
	ReturnName	The EL path of the result returned by the associated method.
<pivotTableDataMap>		Wraps the data binding XML for an ADF Faces pivot table component.
<table> and <tree>	ApplyValidation	Set to true by default. When true, controlBinding executes validators defined on the binding. You can set to false in the case of ADF Business Components, when running in local mode and when the same validators are already defined on the corresponding attribute.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	CollectionModel	Accesses the CollectionModel object, the data model that is used by ADF table components. A table's value is bound to the CollectionModel attribute. The table wraps the result set from the iterator binding in a CollectionModel object. The CollectionModel attribute allows each item in the collection to be available within the table component using the var attribute.
	ControlClass	Used internally for testing purposes.
	CustomInputHandler	This is the class name for a oracle.jbo.uicli.binding.JUctrlValueHandler implementation that is used to process the inputValue for a given value binding.
	DefClass	Used internally by ADF.
	DiscrValue	Indicates the discriminator value for a hierarchical type binding (type definition for a tree node). This value is used to determine whether a given row in a collection being rendered in a polymorphic tree binding should be rendered using the containing hierarchical type binding.
	id	Unique identifier. May be referenced by any ADF action binding.
	IterBinding	Refers to the iteratorBinding instance in this bindingContainer to which this binding is associated.
	TreeModel	The data model used by ADF Tree components. TreeModel extends CollectionModel to add support for container rows. Rows in the TreeModel may (recursively) contain other rows.

## A.9 adfc-config.xml

The adfc-config.xml file is the source file for the ADF unbounded task flow that JDeveloper creates by default when you create an application using the Fusion Web Application (ADF) template. By default, JDeveloper stores the adfc-config.xml file in the following directory:

```
application_root\ViewController\Web Content\WEB-INF
```

If you create additional unbounded task flows, JDeveloper proposes the following file name for the source files of the additional unbounded task flows:

```
adfc-configN.xml
```

where *N* is a number that increments each time you create a new unbounded task flow. Alternatively, you choose the file name you want for an unbounded task flow's source file.

Each source file for an unbounded task flow contains the metadata for activities, control flow rules, and managed beans that you added to an unbounded task flow so that end users can interact with the Fusion web application to complete a task.

The XML schema definition file (XSD) that defines valid metadata entries for the `adfc-config.xml` file is `adfc-config_1_0.xsd`. The `adfc-config_1_0.xsd` file is stored in the `adf-controller-schema.jar` file in the following directory of your JDeveloper installation:

```
jdev_install\oracle_common\modules\oracle.adf.model_11.1.1
```

Use JDeveloper's XSD Visual Editor to view the `adfc-config_1_0.xsd` file. Using this editor, you can identify the valid metadata elements and attributes for the `adfc-config.xml` file.

[Example A-5](#) shows the source file for an unbounded task flow where view activities, control flow rules, and so on have yet to be added.

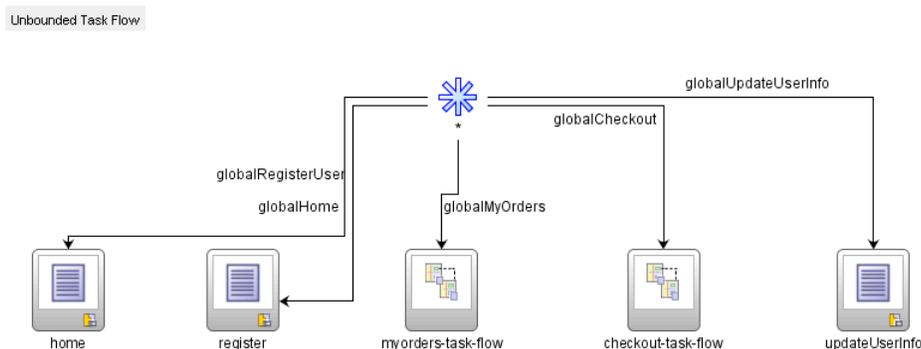

#### **Example A-5 Sample adfc-config.xml file with no entries**

```
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
</adfc-config>
```

[Figure A-4](#) shows the Diagram view of the Fusion Order Demo application's `adfc-config.xml` file. [Example A-6](#) shows the corresponding source view of the unbounded task flow that appears in [Figure A-4](#). For brevity, many metadata entries have been removed from [Example A-6](#). However, instances of metadata that identify view activities (`<view id>`), a task flow call activity (`<task-flow-call>`), control flow rules (`<control-flow-rule>`), and managed beans (`<managed-bean>`) remain.

For more information about unbounded task flows, [Chapter 18, "Getting Started with ADF Task Flows."](#)

**Figure A-4 Diagram View of Fusion Order Demo Application's adfc-config.xml File**

**Example A-6 Source View of Fusion Order Demo Application's adfc-config.xml file**

```

<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller">
 <metadata-resource>/WEB-INF/adfc-config.xml</metadata-resource>
 <view id="home">
 <page>/home.jsp</page>
 </view>
 <task-flow-call id="checkout-task-flow">
 <task-flow-reference>
 <document>/WEB-INF/checkout-task-flow.xml</document>
 <id>checkout-task-flow</id>
 </task-flow-reference>
 </task-flow-call>
 <view id="updateUserInfo">
 <page>/account/updateUserInfo.jsp</page>
 </view>
 ...
 <task-flow-call id="myorders-task-flow">
 <task-flow-reference>
 <document>/WEB-INF/myorders-task-flow.xml</document>
 <id>myorders-task-flow</id>
 </task-flow-reference>
 </task-flow-call>
 <control-flow-rule>
 <from-activity-id>*</from-activity-id>
 <control-flow-case>
 <from-outcome>globalHome</from-outcome>
 <to-activity-id>home</to-activity-id>
 </control-flow-case>
 <!-- removed control flow cases for brevity -->
 </control-flow-rule>
 <managed-bean>
 <managed-bean-name>homePageBean</managed-bean-name>
 <managed-bean-class>oracle.fodemo.storefront.store.view.managed.HomeBean</managed-bean-class>
 <managed-bean-scope>request</managed-bean-scope>
 </managed-bean>
 <!-- removed managed beans for brevity -->
</adfc-config>

```

**A.10 task-flow-definition.xml**

The default file name that JDeveloper proposes for the source file of the first ADF bounded task flow that you create is `task-flow-definition.xml`. This file stores the metadata for a bounded task flow. It contains entries for each view activity, method call activity, task flow call, and so on that you add to the bounded task flow.

JDeveloper proposes the following file name for subsequent bounded task flows that you create:

```
task-flow-definitionN.xml
```

where *N* is a number that increments each time you create a new bounded task flow. Alternatively, you choose the file name you want for a bounded task flow's source file. By default, JDeveloper stores the `task-flow-definition.xml` file in the following directory:

```
application_root\ViewController\Web Content\WEB-INF
```

The XML schema definition files (XSD) that define the valid metadata entries for the source file of a bounded task flow are stored in the `adf-controller-schema.jar` file in the following directory of your JDeveloper installation:

```
jdev_install\oracle_common\modules\oracle.adf.model_11.1.1
```

Use JDeveloper's XSD Visual Editor to view these XSD files and identify the valid metadata elements and attributes for the source file of a bounded task flow.

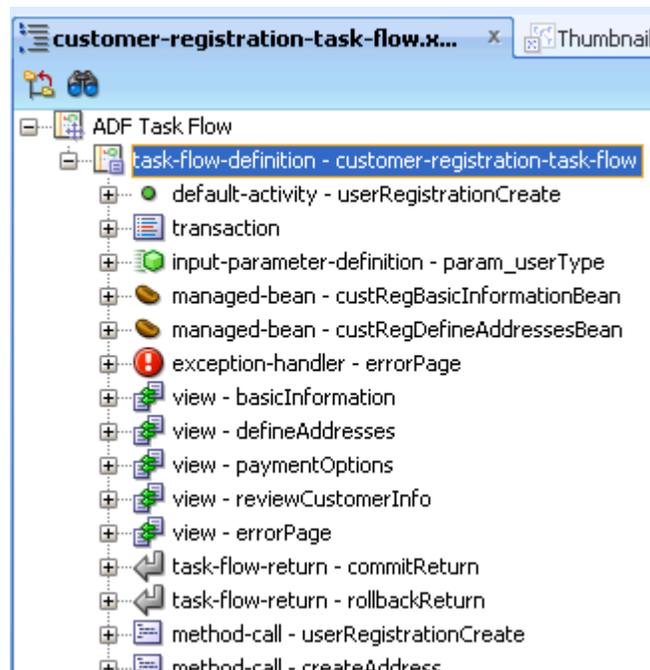

[Example A-7](#) shows the content of a source file when you create a new bounded task flow using the Create Task Flow dialog. The `<task-flow-definition>` element identifies this file as a bounded task flow. JDeveloper generates the `<task-flow-definition>` element when you select the **Create as Bounded Task Flow** check box in the Create Task Flow dialog. The value of the `<task-flow-definition>` element's `id` attribute (`task-flow-definition`) corresponds to the value that you enter in the **Task Flow ID** field of the Create Task Flow dialog. The `<use-page-fragments/>` element indicates that all view activities in this bounded task flow must be associated with page fragments. JDeveloper generates this entry when you select the **Create with Page Fragments** check box in the Create Task Flow dialog.

**Example A-7 Sample task-flow-definition.xml with no entries**

```
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
 <task-flow-definition id="task-flow-definition">
 <use-page-fragments/>
 </task-flow-definition>
</adfc-config>
```

[Example A-8](#) shows an abbreviated version of the Fusion Order Demo application's `customer-registration-task-flow.xml` file. Many metadata entries have been removed for brevity. However, you can view entries for the activities shown in the Structure window in [Figure A-5](#).

For more information about bounded task flows, see [Chapter 18, "Getting Started with ADF Task Flows"](#).

**Figure A-5 Abbreviated Structure View of the customer-registration-task-flow.xml File****Example A-8 Abbreviated Source View of the customer-registration-task-flow.xml File**

```

<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.0">
 <task-flow-definition id="customer-registration-task-flow">

 <to-activity-id>basicInformation</to-activity-id>
 </control-flow-case>
</control-flow-rule>
<use-page-fragments/>
</task-flow-definition>
</adfc-config>

```

## A.11 adf-config.xml

JDeveloper generates the `adf-config.xml` file when you create an application using the Fusion Web Application (ADF) template. It stores the file in the following directory:

```
application_root\.adf\META-INF
```

The `adf-config.xml` file specifies application-level settings that are usually determined at deployment and are often changed at runtime. You can use a deployment profile to specify settings that are used at application deploy time. You can change some of the settings at runtime using Oracle Enterprise Manager.

Examples of tasks that you can accomplish by changing settings in the `adf-config.xml` file include the following:

- Enable or disable the validation of ADF Controller metadata
- Replicate memory scope if you deploy your Fusion web application in a clustered environment

- Configure properties to manage the caching of resource bundles where your application uses EL expressions to retrieve strings at runtime from resource bundles

The properties that you can configure are:

- `initial-size`

Specifies the initial number of resource bundles that your application can cache. The default value is 100.

- `max-size`

Specifies the maximum number of resource bundles that your application can cache. The default value is 100.

- `load-factor`

The default value is 0.75.

- `expire-time`

The default value is 43200 seconds (12 hours).

You specify these properties as attribute values of the

`<resource-bundle-cache>` element in the `adf-config.xml` file.

[Example A-9](#) demonstrates how you might configure these values for your application in the `adf-config.xml` file.

As an alternative to configuring the caching of resource bundles in the `adf-config.xml` file, you can specify the resource bundle caching properties as parameters for the Java Virtual Machine (JVM). If you specify the properties as parameters for the JVM, the changes apply to all applications managed by the JVM. For this reason, we recommend that you configure the resource bundle caching properties in the `adf-config.xml` file for your application. Use the following property names if you decide to specify the resource bundle caching properties as parameters for the JVM:

- `resource-bundle-cache-initial-size`
- `resource-bundle-cache-max-size`
- `resource-bundle-cache-load-factor`
- `resource-bundle-cache-expire-time`

At runtime, the Fusion web application loads the `adf-config.xml` file from the `META-INF` directory. If the Fusion web application finds more than one `adf-config.xml` file, it stops loading the file and logs a warning.

The following tasks modify or require you to modify the `adf-config.xml` file:

- Creating task flows

For more information, see [Chapter 18, "Getting Started with ADF Task Flows"](#).

- Enabling implicit save points

For more information, see [Section 22.6.7, "How to Enable Implicit Save Points"](#).

- Disable automatic partial page rendering as the default behavior for an application. This requires you to change the value for the `changeEventPolicy` attribute from the default value of `ppr`:

```
<defaults changeEventPolicy="ppr" />
```

For more information, see [Section 25.2.1, "What You May Need to Know About Partial Page Rendering and Iterator Bindings."](#)

- Persisting saved searches in MDS  
For more information, see [Section 31.2.4, "How to Persist Saved Searches into MDS"](#).
- Configuring ADF Business Components global settings  
For more information, see [Section 42.1.1, "Limiting the View Object Max Fetch Size to Fetch the First n Rows"](#) and [Section 3.3.1, "Choosing a Connection, SQL Platform, and Data Type Map."](#)
- Enabling Oracle ADF Security  
For more information, see [Section 35.3.2, "What Happens When You Enable ADF Security"](#).
- Enabling seeded customizations  
For more information, [Section 39.2.4, "How to Enable Seeded Customizations for View Projects"](#) and [Section 39.2.5, "How to Enable Seeded Customizations in Existing Pages"](#).
- Configuring change persistence  
For more information, see [Section 40.2.1, "How to Enable User Customizations"](#).
- Enabling user customizations  
For more information, see [Section 40.2.2, "What Happens When You Enable User Customizations"](#).

[Example A-9](#) shows example entries for an application's `adf-config.xml` file.

#### **Example A-9 Sample adf-config.xml File**

```
<?xml version="1.0" encoding="windows-1252" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"

## A.12 adf-settings.xml

The `adf-settings.xml` file holds project-level and library-level settings such as ADF Faces help providers and ADF Controller phase listeners.

The configuration settings for `adf-settings.xml` are fixed and cannot be changed during or after application deployment. There can be multiple `adf-settings.xml` files in an application. The users of `adf-settings.xml` files are responsible for merging the contents of their configuration.

JDeveloper creates an `adf-settings.xml` file when you:

- Create an application using the Fusion Web Application (ADF) template
- Add ADF Page Flow (ADF Controller) to the technology scope of an existing project

By default, JDeveloper stores the `adf-settings.xml` file in the following directory:  
`application_root\ViewController\src\META-INF`

The following tasks modify or require you to modify the `adf-settings.xml` file:

- Registering a phase listener  
 For more information, see [Section 25.4.2, "How to Register a Listener Globally"](#).
- Creating help for ADF Faces components  
 For more information, see the "Displaying Help for Components" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

[Example A-10](#) shows a sample `adf-setting.xml` file with settings configured for a phase listener and a help provider.

#### Example A-10 Sample `adf-settings.xml` File

```
<?xml version="1.0" encoding="windows-1252" ?>
<adf-settings xmlns="http://xmlns.oracle.com/adf/config">
 <adfc-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
 <lifecycle>
 <phase-listener>
 <listener-id>FODPhaseListener</listener-id>
 <class>oracle.fodemo.storefront.listeners.FODPhaseListener</class>
 </phase-listener>
 </lifecycle>
 </adfc-controller-config>
 <adf-faces-config>
 <help-provider prefix="MYAPP">
 <help-provider-class>oracle.fodemo.storefront.MyHelpProvider</help-provider-class>
 <property>
 <property-name>myCustomProperty</property-name>
 <value>someValue</value>
 </property>
 </help-provider>
 </adf-faces-config>
</adf-settings>
```

## A.13 web.xml

Oracle ADF has specific configuration settings for the standard `web.xml` deployment descriptor file.

When you create a project in JDeveloper that uses JSF technology, a starter `web.xml` file with default settings is created for you in the `/WEB-INF` folder. To edit the file, double-click **web.xml** in the Application Navigator to open it in the XML editor.

The following must be configured in `web.xml` for all applications that use JSF and ADF Faces:

- ADF Library resource servlet and mapping: Serves up web application resources (images, style sheets, JavaScript libraries) from ADF Library JAR files on the application class path.

By default, static web application resources (including resources in ADF Libraries), such as images, have a staleness period setting of 364 days. This staleness period setting requests that the client not make a request to the server to validate the static web application resources until one of the following events occur:

- Staleness period expires
- Browser cache no longer contains the static resource
- User executes a page refresh

If the client does make a request to the server and the resources have not changed, the server returns a HTTP 304 response (Not Modified) with no body.

You can override the staleness period setting of 364 days for all static web application resources in ADF Libraries by adding initialization parameters to the `web.xml` file. [Example A-11](#) demonstrates how to set these initialization parameters using a number of examples.

#### **Example A-11 Staleness Settings for Static Resources in web.xml**

```
<!-- Expires all static resources in 30 days -->
<init-param>
 <param-name>expires</param-name>
 <param-value>60*60*24*30</param-value>
</init-param>

<!-- Expires static resources with the .js file extension in 1 day -->
<init-param>
 <param-name>expires.js</param-name>
 <param-value>60*60*24</param-value>
</init-param>

<!-- Turns off staleness setting. Use for testing -->
<init-param>
 <param-name>expires</param-name>
 <param-value>OFF</param-value>
</init-param>
```

[Example A-12](#) shows the default file extensions. You can add additional file extensions by configuring the `extensions` parameter value to include the file extensions that you want. Note that you must prepend and append "." to the file extension. [Example A-12](#) also shows how you specify visibility for cache control.

#### **Example A-12 Specifying Additional File Extensions and Cache Control**

```
<!-- Specify file extensions for a number of different file formats -->
<init-param>
 <param-name>extensions</param-name>
 <param-value>.png.jpg.jpeg.gif.js.css.</param-value>
</init-param>

<!-- Specify visibility for cache control, for example -->
<init-param>
 <param-name>visibility</param-name>
 <param-value>Public</param-value>
</init-param>
```

- JSF servlet and mapping: The servlet `javax.faces.webapp.FacesServlet` that manages the request-processing lifecycle for web applications utilizing JSF to construct the user interface.
- ADF Faces filter and mapping: A servlet filter to ensure that ADF Faces is properly initialized by establishing a `AdfFacesContext` object. This filter also processes file uploads.

The JSF servlet and mapping configuration settings are automatically added to the starter `web.xml` file when you first create a JSF project. When you insert an ADF Faces component into a JSF page for the first time, JDeveloper automatically inserts the configuration settings for ADF Faces filter and mapping, and resource servlet and mapping.

For more information, see the "ADF Faces Configuration" appendix in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

## A.14 logging.xml

ADF Logger is a diagnostic tool that you can use in JDeveloper to capture runtime traces messages when you debug an application. You configure the use of this tool by editing the `logging.xml` file.

For more information about the `logging.xml` file and using the ADF Logger, see [Section 36.6, "Using the ADF Logger"](#).

## Oracle ADF Binding Properties

This appendix provides a reference for the properties of the ADF bindings.

[Table B-1](#) shows the properties that you can use in EL expressions to access values of the ADF binding objects at runtime. The properties appear in alphabetical order.

**Table B-1** EL Properties of Oracle ADF Bindings

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
actionEnabled	Use operationEnabled instead.	n/a	yes	n/a	n/a	n/a	n/a	n/a
allRowsInRange	Returns an array of the current set of rows from the associated collection. Calls getAllRowsInRange () on the RowSetIterator object.	yes	n/a	n/a	n/a	n/a	n/a	n/a
attributeDef	Returns the attribute definition for the first attribute with which the binding is associated.	n/a	n/a	yes	yes	yes	n/a	n/a
attributeDefs	Returns the attribute definitions for all the attributes to which the binding is associated.	n/a	n/a	yes	yes	yes	n/a	n/a
attributeValue	Returns an unformatted and typed (appropriate Java type) value in the current row, for the attribute to which the control binding is bound.	n/a	n/a	yes	yes	yes	n/a	n/a
attributeValues	Returns the value of all the attributes to which the binding is associated in an ordered array. Returns an array of unformatted and typed (appropriate Java type) values in the current row for all the attributes to which the control binding is bound.	n/a	n/a	yes	yes	yes	n/a	n/a
bindings	Returns a new binding for each cell or attribute exposed under the rows of a tree node binding.	no	no	no	no	no	no	yes
children	Returns the child nodes of a tree node binding.	n/a	n/a	n/a	n/a	n/a	n/a	yes

**Table B-1 (Cont.) EL Properties of Oracle ADF Bindings**

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
currentRow	Returns the current row on an action binding bound to an iterator (for example, built-in navigation actions).	n/a	yes	n/a	n/a	n/a	n/a	n/a
dataControl	Returns the iterator's associated data provider.	yes	n/a	n/a	n/a	n/a	n/a	n/a
displayData	Returns a list of map elements. Each map entry contains the following elements: <ul style="list-style-type: none"><li>■ selected: A boolean true if the current entry should be selected.</li><li>■ index: The index value of the current entry.</li><li>■ prompt: A string value that may be used to render the entry in the UI.</li><li>■ displayValues: An ordered list of display attribute values for all display attributes in the list binding.</li></ul>	n/a	n/a	n/a	n/a	yes	n/a	n/a
displayHint	Returns the display hint for the first attribute to which the binding is associated. The hint identifies whether the attribute should be displayed or not. For more information, see <code>oracle.jbo.AttributeHints.displayHint</code> .	n/a	n/a	n/a	n/a	yes	n/a	n/a

**Table B-1 (Cont.) EL Properties of Oracle ADF Bindings**

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
displayHints	Returns a list of name-value pairs for UI hints for all display attributes to which the binding is associated. The map contains the following elements: <ul style="list-style-type: none"> <li>▪ label: The label to display for the current attribute.</li> <li>▪ tooltip: The tooltip to display for the current attribute.</li> <li>▪ displayHint: The display hint for the current attribute.</li> <li>▪ displayHeight: The height in lines for the current attribute.</li> <li>▪ displayWidth: The width in characters for the current attribute.</li> <li>▪ controlType: The control type hint for the current attribute.</li> <li>▪ format: The format to be used for the current attribute.</li> </ul>	n/a	n/a	n/a	yes	yes	n/a	n/a
enabled	Use the operationEnabled property.	n/a	n/a	n/a	n/a	n/a	n/a	n/a
enabledString	Returns disabled if the action binding is not ready to be invoked. Otherwise, returns an empty string (" ").	n/a	yes	n/a	n/a	n/a	n/a	n/a
error	Returns any exception that was cached while updating the associated attribute value for a value binding or when invoking an operation bound by an operation binding.	yes	yes	yes	yes	yes	yes	yes
estimatedRowCount	Returns the maximum row count of the rows in the collection with which this iterator binding is associated	yes	n/a	n/a	n/a	n/a	yes	yes
findMode	Returns true if the iterator is currently operating in find mode. Otherwise, returns false.	yes	n/a	n/a	n/a	n/a	n/a	n/a
fullName	Returns the fully qualified name of the binding object in the Oracle ADF binding context.	yes	yes	yes	yes	yes	yes	yes

**Table B-1 (Cont.) EL Properties of Oracle ADF Bindings**

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
hints	Returns the value of the UI hint indicated for the binding. See <code>displayHints</code> for the list of UI hint keywords.	yes	yes	yes	yes	yes	yes	yes
inputValue	Returns the value of the first attribute to which the binding is associated. If the binding was used to set the value on the attribute and the set operation failed, this method returns the invalid value that was being set.	n/a	n/a	yes	yes	yes	yes	yes
iteratorBinding	Returns the iterator binding that provides access to the data collection.	n/a	yes	yes	yes	yes	yes	yes
label	Returns the label (if supplied by control hints) for the first attribute of the binding.	n/a	n/a	yes	yes	yes	n/a	n/a
labels	Returns a map of labels (if supplied by control hints) keyed by attribute name for all attributes to which the binding is associated.	n/a	n/a	yes	yes	yes	yes	n/a
labelSet	Returns an ordered set of labels for all the attributes to which the binding is associated.	n/a	n/a	yes	yes	yes	yes	n/a
mandatory	Returns whether the first attribute to which the binding is associated is required.	n/a	n/a	yes	yes	yes	n/a	n/a
name	Returns the name of the binding object in the context of the binding container to which it is registered. Note this property is not visible in the EL expression builder dialog.	yes	yes	yes	yes	yes	yes	yes
operationEnabled	Returns <code>true</code> or <code>false</code> , depending on the state of the action binding. For example, the action binding may be enabled ( <code>true</code> ) or disabled ( <code>false</code> ) based on the currency (as determined, for example, when the user clicks the First, Next, Previous, Last navigation buttons).	n/a	yes	n/a	n/a	n/a	n/a	n/a

**Table B-1 (Cont.) EL Properties of Oracle ADF Bindings**

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
rangeSet	<p>Returns a list of map elements over the range of rows from the associated iterator binding. The elements in this list are wrapper objects over the indexed row in the range that restricts access to the attributes to which the binding is bound. The properties returned on the reference object are:</p> <ul style="list-style-type: none"> <li>▪ index: The range index of the row this reference is pointing to.</li> <li>▪ key: The key of the row this reference is pointing to.</li> <li>▪ keyStr: The string format of the key of the row this reference is pointing to.</li> <li>▪ currencyString: The current indexed row as a string. Returns "*" if the current entry belongs to the current row; otherwise, returns ". This property is useful in JSP applications to display the current row.</li> <li>▪ attributeValues: The array of applicable attribute values from the row.</li> </ul> <p>You may also access an attribute value by name on a range set like <code>rangeSet.dname</code> if <code>dname</code> is a bound attribute in the range binding.</p>	n/a	n/a	n/a	n/a	n/a	yes	yes
rangeSize	Returns the range size of the ADF iterator binding's row set. This allows you to determine the number of data objects to bind from the data source.	yes	n/a	n/a	n/a	n/a	yes	yes
rangeStart	Returns the absolute index in a collection of the first row in range. See the javadoc for <code>oracle.jbo.RowSetIterator.getRangeStart()</code> .	yes	n/a	n/a	n/a	n/a	yes	yes
result	Returns the result of a method that is bound and invoked by a method action binding.	n/a	yes	n/a	n/a	n/a	n/a	n/a
rootNodeBinding	Returns the root node of a tree binding.	n/a	n/a	n/a	n/a	n/a	n/a	yes

---

**Table B-1 (Cont.) EL Properties of Oracle ADF Bindings**

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
selectedValue	Returns the value corresponding to the current selected index in the list or button binding.	n/a	n/a	n/a	yes	yes	n/a	n/a
tooltip	Returns the tooltip hint for the first attribute to which the binding is associated.	n/a	n/a	yes	yes	yes	n/a	n/a
updateable	Returns <code>true</code> if the first attribute to which the binding is associated is updateable. Otherwise, returns <code>false</code> .	n/a	n/a	yes	yes	yes	n/a	n/a

---

## ADF Security Permission Grants

This appendix lists the security-aware components of Oracle Application Development Framework (Oracle ADF) and the actions that their `Permission` implementation classes define.

[Table C-1](#) shows the ADF components and their permission grants that you can define to create ADF security policies. You add grants to the policy store using the overview editor for ADF security policies. A permission grant specifies the fully qualified permission class name, the fully qualified resource name, the action that can be performed against the resource, and the application role target of the grant. When you enable ADF security to enforce permission checking, the operations supported by ADF components will be inaccessible to users who do not possess sufficient access rights as defined by grants to their application role.

For complete details about defining ADF security policies in Fusion web applications, see [Chapter 35, "Enabling ADF Security in a Fusion Web Application."](#)

---

**Note:** JDeveloper displays grantable actions for Fusion web applications including actions for the Oracle WebCenter Framework. Oracle WebCenter Framework supports creating personalizable web pages. For details about securing WebCenter applications, see the *Oracle Fusion Middleware Developer's Guide for Oracle WebCenter*.

---

**Table C-1 ADF Security Permission Grants**

ADF Component	Grantable Action	Corresponding Implementation
ADF bounded task flow	View	The view action controls who can read and execute a bounded task flow. Pages that the user accesses within the process of executing a bounded task flow will not be individually security checked and will run under the permission of the task flow.
	Customize	Reserved for future use. This action is not checked at runtime.
	Grant	Reserved for future use. This action is not checked at runtime.
	Personalize	Reserved for future use. This action is not checked at runtime.
ADF page definition	View	The view action controls who can view the page. Page-level security is checked for pages that have an associated page definition binding file <i>only</i> if the page is accessed in the process of an unbounded task flow. There is a one-to-one relationship between the page definition file and the web page it secures.
ADF Business Components entity objects	read	The read action controls who can view a row of the bound collection.

---

**Table C-1 (Cont.) ADF Security Permission Grants**

<b>ADF Component</b>	<b>Grantable Action</b>	<b>Corresponding Implementation</b>
	update	The update action controls who can update any attribute of the bound collection.
	removeCurrentRow/delete	The delete action controls who can delete a row from the bound collection.
ADF Business Components attributes of entity objects	update	The update action controls who can update a specific attribute of the bound collection.

---

---

## Most Commonly Used ADF Business Components Methods

This appendix highlights the most commonly used methods in the interfaces and classes of ADF Business Components.

This appendix contains the following sections:

- [Section D.1, "Methods for Creating Your Own Layer of Framework Base Classes"](#)
- [Section D.2, "Methods Used in the Client Tier"](#)
- [Section D.3, "Methods Used in the Business Service Tier"](#)

### D.1 Methods for Creating Your Own Layer of Framework Base Classes

Before you begin to develop application-specific business components, you can create a layer of classes that extend all of the ADF Business Components framework base implementation classes described in this appendix. An example of a customized framework base class for application module components might look like this:

```
package com.yourcompany.adfextensions;
import oracle.jbo.server.ApplicationModuleImpl;
public class CustomApplicationModuleImpl extends ApplicationModuleImpl {
 /*
 * We might not yet have any custom code to put here yet, but
 * the first time we need to add a generic feature that all of
 * our company's application modules need, we will be very happy
 * that we thought ahead to leave ourselves a convenient place
 * in our class hierarchy to add it so that all of the application
 * modules we have created will instantly benefit by that new feature,
 * behavior change, or even perhaps, bug workaround.
 */
}
```

A common set of customized framework base classes in a package name of your own choosing like `com.yourcompany.adfextensions`, each importing the `oracle.jbo.server.*` package, would consist of the following classes:

- `public class CustomEntityImpl extends EntityImpl`
- `public class CustomEntityDefImpl extends EntityDefImpl`
- `public class CustomViewObjectImpl extends ViewObjectImpl`
- `public class CustomViewRowImpl extends ViewRowImpl`
- `public class CustomApplicationModuleImpl extends ApplicationModuleImpl`

- `public class CustomDBTransactionImpl extends DBTransactionImpl2`
- `public class CustomDatabaseTransactionFactory extends DatabaseTransactionFactory`

For completeness, you may also want to create customized framework classes for the following classes as well:

- `public class CustomViewDefImpl extends ViewDefImpl`
- `public class CustomEntityCache extends EntityCache`
- `public class CustomApplicationModuleDefImpl extends ApplicationModuleDefImpl`

Overriding anything in these classes would be a fairly rare requirement.

## D.2 Methods Used in the Client Tier

All of the interfaces described in this section are designed for use by client-layer code and are part of the `oracle.jbo.*` package.

This section provides a summary of the most frequently called, written, and overridden methods for the key ADF Business Components interfaces.

---

---

**Note:** The corresponding implementation classes for these `oracle.jbo.*` interfaces are intentionally designed to *not* be directly accessed by client code. [Section D.3, "Methods Used in the Business Service Tier"](#) shows that the implementation classes reside in the `oracle.jbo.server.*` package and generally have the suffix `Impl` in their name to help remind you not to use them in your client-layer code.

---

---

### D.2.1 ApplicationModule Interface

An application module is a business service component that acts as a transactional container for other ADF components and coordinates *with* them to implement a number of Java EE design patterns important to business application developers. These design pattern implementations enable your client code to work easily with updatable collections of value objects, based on fast-lane reader SQL queries that retrieve only the data needed by the client, in the way the client wants to view it. Changes made to these value objects are automatically coordinated with your persistent business domain objects in the business service tier to enforce business rules consistently and save changes back to the database. [Table D-1](#) describes the operations that you can perform on an application module using the `ApplicationModule` interface.

---

---

**Note:** For the complete list of design patterns that ADF Business Components implements, see [Appendix E, "ADF Business Components Java EE Design Pattern Catalog."](#)

---

---

**Table D-1 ApplicationModule Interface**

If you want to...	Call this ApplicationModule interface method
Access an existing view object instance using the assigned instance name (for example, MyVOInstanceName)	findViewObject()
Create a new view object instance from an existing definition	createViewObject()
Create a new view object instance from a SQL Statement	createViewObjectFromQueryStmt()
	<p><b>Notes:</b></p> <p>This incurs runtime overhead to describe the "shape" of the dynamic query's SELECT list. Use this method only when you cannot know the SELECT list for the query at design time. Furthermore, if you are creating the dynamic query based on some kind of custom runtime repository, you can follow the steps to create (both read-only and updatable) dynamic view objects without the runtime-describe overhead, as described in <a href="#">Section 42.9, "Creating a View Object with Multiple Updatable Entities."</a> If only the WHERE needs to be dynamic, create the view object at design time, then set the WHERE clause dynamically as needed using ViewObject APIs.</p>
Access a nested application module instance by name	findApplicationModule()
Create a new nested application module instance from an existing definition	createApplicationModule()
Find a view object instance in a nested application module using a dot-notated name (for example, MyNestedAMInstanceName.OneOfItsVONames)	<p>findViewObject()</p> <p><b>Notes:</b></p> <p>You can use this method to find an instance of a view object belonging to a nested application module in a single method call. This way you do not need to first call findApplicationModule() to find the nested application module, before calling findViewObject() on that nested application module.</p>
Access the current transaction object	getTransaction()

In addition to generic application module access, JDeveloper can generate a custom *YourApplicationModuleName* interface containing service-level custom methods that you've chosen to expose to the client. You use the **Client Interface** page of the Edit Application Module dialog to select the methods that you want to appear in your client interface.

## D.2.2 Transaction Interface

The `Transaction` interface exposes methods allowing the client to manage pending changes in the current transaction. [Table D-2](#) describes the operations that you can perform on the transaction using the `Transaction` interface.

**Table D-2 Transaction Interface**

<b>If you want to...</b>	<b>Call this Transaction interface method</b>
Commit pending changes	<code>commit()</code>
Roll back pending changes	<code>rollback()</code>
Execute a one-time database command or block of PL/SQL	<code>executeCommand()</code> <b>Notes:</b> Do not use this command with methods that require retrieving OUT parameters and that will be executed more than once, or that could benefit from using bind variables. Instead, expose a custom method on your application module.
Validate all pending invalid changes in the transaction	<code>validate()</code>
Change the default locking mode	<code>setLockingMode()</code> <b>Notes:</b> You can set the locking mode in your configuration by setting the property <code>jbo.locking.mode</code> to one of the four supported values: <code>none</code> , <code>optimistic</code> , <code>pessimistic</code> , <code>optupdate</code> . If you don't explicitly set the locking mode, it will default to <code>optimistic</code> . For Fusion web applications, use <code>optimistic</code> or <code>optupdate</code> modes.
Decide whether to use bundled exception reporting mode or not	<code>setBundledExceptionMode()</code> <b>Notes:</b> ADF Controller layer support sets this parameter to <code>true</code> automatically for Fusion web applications.
Decide whether entity caches will be cleared upon a successful commit of the transaction	<code>setClearCacheOnCommit()</code> <b>Notes:</b> Default is <code>false</code> .
Decide whether entity caches will be cleared upon a rollback of the transaction	<code>setClearCacheOnRollback()</code> <b>Notes:</b> Default is <code>true</code> .
Clear the entity cache for a specific entity object	<code>clearEntityCache()</code>

### D.2.3 ViewObject Interface

A view object is a component that encapsulates a database query and simplifies working with the row set of results it produces. You use view objects to project, filter, join, or sort business data using SQL from one or more tables to cast the data into exactly the format that the user should see on the page or panel. You can create "master-detail" hierarchies of any depth or complexity by connecting view objects together using view links. View objects can produce read-only query results, or when associated with one or more entity objects at design time, can be fully updatable. Updatable view objects can support insertion, modification, and deletion of rows in the result collection, with automatic delegation to the correct business domain objects.

Every view object contains a "default row set" for simplifying the 90 percent of use cases where you work with a single row set of results for the view object's query. A view object implements all the methods on the `RowSet` interface by delegating them to this default `RowSet`. That means you can invoke any `RowSet` methods on any view object as well.

Every view object implements the `StructureDef` interface to provide information about the number and types of attributes in a row of its row sets. So you can call `StructureDef` methods directly on any view object.

[Table D-3](#) describes the operations that you can perform on a view object using the `ViewObject` interface

**Table D-3 ViewObject Interface**

If you want to...	Call this ViewObject interface method
Set an additional runtime <code>WHERE</code> clause on the row set	<code>setWhereClause()</code>  <b>Notes:</b> This <code>WHERE</code> clause augments any <code>WHERE</code> clause specified at design time in the base view object. It does not replace it.
Set a dynamic <code>ORDER BY</code> clause	<code>setOrderByClause()</code>
Create a Query-by-Example criteria collection	<code>createViewCriteria()</code>  <b>Notes:</b> You then create one or more <code>ViewCriteriaRow</code> objects using the <code>createViewCriteriaRow()</code> method on the <code>ViewCriteria</code> object you created. Then you <code>add()</code> these view criteria rows to the view criteria collection and apply the criteria using the <code>applyViewCriteria()</code> method.
Apply a Query-by-Example criteria collection	<code>applyViewCriteria()</code>
Set a query optimizer hint	<code>setQueryOptimizerHint()</code>
Access the attribute definitions for the key attributes in the view object	<code>getKeyAttributeDefs()</code>
Add a dynamic attribute to rows in this view object's row sets	<code>addDynamicAttribute()</code>
Clear all row sets produced by a view object	<code>clearCache()</code>
Remove a view object instance and its resources	<code>remove()</code>
Set an upper limit on the number of rows that the view object will attempt to fetch from the database	<code>setMaxFetchSize()</code>  <b>Notes:</b> Default is -1, which means to impose no limit on how many rows would be retrieved from the database if you iterated through them all. By default, as you iterate through them, they are fetched lazily.

In addition to generic `ViewObject` access, JDeveloper can generate you a custom `YourViewObjectName` interface containing view object-level custom methods that you've chosen to expose to the client. You use the **Client Interface** page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

## D.2.4 RowSet Interface

A row set is an object that contains a set of rows, typically produced by executing a view object's query.

Every RowSet aggregates a "default row set iterator" for simplifying the 90 percent of use cases where you need only a single iterator over the row set. A RowSet object implements all the methods on the RowSetIterator interface by delegating them to this default RowSetIterator. This means you can invoke any RowSetIterator method on any RowSet object (or view object, since it implements RowSet, as well for its default RowSet).

[Table D-4](#) describes the operations that you can perform on a row set using the RowSet interface.

**Table D-4 RowSet Interface**

If you want to...	Call this RowSet interface method
Set a WHERE clause bind variable value	setWhereClauseParam() <b>Notes:</b> Bind variable ordinal positions are zero-based.
Avoid view object row caching if data is being read only once	setForwardOnly()
Force a row set's query to be (re)executed	executeQuery() <b>Notes:</b> Do not use executeQuery() when you want to reuse the cached query collection. See refreshCollection() to reuse a query collection without forcing a query reexecution.
Estimate the number of rows in a view object's query result	getEstimatedRowCount()
Produce an XML document for rows in a view object row set	writeXML()
Process all rows from an incoming XML document	readXML()
Set whether a row set will automatically see new rows based on the same entity object created through other row sets	setAssociationConsistent()
Create a secondary iterator to use for programmatic iteration	createRowSetIterator() <b>Notes:</b> If you plan to find and use the secondary iterator by name later, then pass in a string name as the argument; otherwise, pass null for the name and make sure to close the iterator when done iterating by calling its closeRowSetIterator() method.

## D.2.5 RowSetIterator Interface

A row set iterator is an iterator over the rows in a row set. By default it allows you to iterate both forward and backward through the rows. [Table D-5](#) describes the operations that you can perform on a row set using the RowSetIterator interface.

**Table D-5 RowSetIterator Interface**

<b>If you want to...</b>	<b>Call this RowSetIterator interface method</b>
Get the first row of the iterator's row set	<code>first()</code>
Test whether there are more rows to iterate	<code>hasNext()</code>
Get the next row of an iterator's row set	<code>next()</code>
Find a row in this iterator's row set with a given key value	<code>findByKey()</code> <b>Notes:</b> It's important that the <code>Key</code> object that you pass to <code>findByKey</code> be created using the <i>exact</i> same data types as the attributes that comprise the key of the rows in the view object you're working with.
Create a new row to populate for insertion	<code>createRow()</code> <b>Notes:</b> The new row will already have default values set for attributes which either have a static default value supplied at the entity object or view object level, or if the values have been populated in an overridden <code>create()</code> method of the underlying entity object(s).
Create a view row with an initial set of foreign key and/or discriminator attribute values	<code>createAndInitRow()</code> <b>Notes:</b> You use this method when working with view objects that can return one of a "family" of entity object subtypes. By passing in the correct discriminator attribute value in the call to create the row, the framework can create you the correct matching entity object subtype underneath.
Insert a new row into the iterator's row set	<code>insertRow()</code> <b>Notes:</b> It's a good habit to always immediately insert a newly created row into the rowset. That way you will avoid a common gotcha of creating the row but forgetting to insert it into the rowset.
Get the last row of the iterator's row set	<code>last()</code>
Get the previous row of the iterator's row set	<code>previous()</code>
Reset the current row pointer to the slot before the first row	<code>reset()</code>
Close an iterator when done iterating	<code>closeRowSetIterator()</code>
Set a given row to be the current row	<code>setCurrentRow()</code>
Remove the current row	<code>removeCurrentRow()</code>
Remove the current row to later insert it at a different location in the same iterator	<code>removeCurrentRowAndRetain()</code>
Remove the current row from the current collection but do not remove it from the transaction.	<code>removeCurrentRowFromCollection()</code>
Set/change the number of rows in the range (a "page" of rows the user can see)	<code>setRangeSize()</code>

**Table D-5 (Cont.) RowSetIterator Interface**

If you want to...	Call this RowSetIterator interface method
Scroll to view the <i>n</i> th page of rows (1-based)	<code>scrollToRangePage()</code>
Scroll to view the range of rows starting with row number <i>n</i>	<code>scrollRangeTo()</code>
Set row number <i>n</i> in the range to be the current row	<code>setCurrentRowAtRangeIndex()</code>
Get all rows in the range as a row array	<code>getAllRowsInRange()</code>

## D.2.6 Row Interface

A row is generic value object. It contains attributes appropriate in name and Java type for the view object that it is related to. [Table D-6](#) describes the operations that you can perform on a view object row using the Row interface.

**Table D-6 Row Interface**

If you want to...	Call this Row interface method
Get the value of an attribute by name	<code>getAttribute()</code>
Set the value of an attribute by name	<code>setAttribute()</code>
Produce an XML document for a single row	<code>writeXML()</code>
Eagerly validate a row	<code>validate()</code>
Read row attribute values from XML	<code>readXML()</code>
Remove the row	<code>remove()</code>
Flag a newly created row as temporary (until updated again)	<code>setNewRowState(Row.STATUS_INITIALIZED)</code>
Retrieve the attribute structure definition information for a row	<code>getStructureDef()</code>
Get the Key object for a row	<code>getKey()</code>

In addition to generic Row access, JDeveloper can generate a custom *YourViewObjectNameRow* interface containing your type-safe attribute getter and setter methods, as well as any desired row-level custom methods that you've chosen to expose to the client. You use the **Client Row Interface** page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

## D.2.7 StructureDef Interface

The StructureDef interface provides access to runtime metadata about the structure of a Row object.

In addition, for convenience every view object implements the StructureDef interface as well, providing access to metadata about the attributes in the resulting view rows that its query will produce.

[Table D-7](#) describes the operations that you can perform on a view object row using the StructureDef interface.

**Table D-7 StructureDef Interface**

If you want to...	Call this StructureDef interface method
Access attribute definitions for all attributes in the view object row	<code>getAttributeDefs()</code>
Find an attribute definition by name	<code>findAttributeDef()</code>
Get attribute definition by index	<code>getAttributeDef()</code>
Get number of attributes in a row	<code>getAttributeCount()</code>

## D.2.8 AttributeDef Interface

The `AttributeDef` interface provides attribute definition information for any attribute of a view object row or entity object instance like attribute name, Java type, and SQL type. It also provides access to custom attribute-specific metadata properties that can be inspected by generic code you write, as well as UI hints that can assist in rendering an appropriate user interface display for the attribute and its value. [Table D-8](#) describes the operations that you can perform on an attribute using the `AttributeDef` interface.

**Table D-8 AttributeDef Interface**

If you want to...	Call this AttributeDef interface method
Get the Java type of the attribute	<code>getJavaType()</code>
Get the SQL type of the attribute	<code>getSQLType()</code>
	<b>Notes:</b> The <code>int</code> value corresponds to constants in the JDBC class <code>java.sql.Types</code> .
Determine the kind of attribute	<code>getAttributeKind()</code>
	<b>Notes:</b> A simple attribute is one that returns one of the constants <code>ATTR_PERSISTENT</code> , <code>ATTR_SQL_DERIVED</code> , <code>ATTR_TRANSIENT</code> , <code>ATTR_DYNAMIC</code> , <code>ATTR_ENTITY_DERIVED</code> . If the attribute is a 1-to-1 or many-to-1 association/viewlink accessor, it returns <code>ATTR_ASSOCIATED_ROW</code> . If the attribute is a 1-to-many or many-to-many association/viewlink accessor, it returns <code>ATTR_ASSOCIATED_ROWITERATOR</code>
Get the Java type of elements contained in an Array-valued attribute	<code>getElemJavaType()</code>
Get the SQL type of elements contained in an Array-valued attribute	<code>getElemSQLType()</code>
Get the name of the attribute	<code>getName()</code>
Get the index position of the attribute	<code>getIndex()</code>
Get the precision of a numeric attribute or the maximum length of a string attribute	<code>getPrecision()</code>
Get the scale of a numeric attribute	<code>getScale()</code>
Get the underlying column name corresponding to the attribute	<code>getColumnNameForQuery()</code>
Get attribute-specific custom property values	<code>getProperty()</code> , <code>getProperties()</code>

**Table D–8 (Cont.) AttributeDef Interface**

If you want to...	Call this AttributeDef interface method
Get the UI <code>AttributeHints</code> object for the attribute	<code>getUIHelper()</code>
Test whether the attribute is mandatory	<code>isMandatory()</code>
Test whether the attribute is querable	<code>isQueryable()</code>
Test whether the attribute is part of the primary key for the row	<code>isPrimaryKey()</code>

## D.2.9 AttributeHints Interface

The `AttributeHints` interface exposes UI hint information that you can use to render an appropriate user interface display for the attribute and its value. [Table D–9](#) describes the operations that you can perform on an attribute using the `AttributeHints` interface.

**Table D–9 AttributeHints Interface**

If you want to...	Call this AttributeHints interface method
Get the UI label for the attribute	<code>getLabel()</code>
Get the tooltip for the attribute	<code>getTooltip()</code>
Get the formatted value of the attribute, using any format mask supplied	<code>getFormattedAttribute()</code>
Get the display hint for the attribute	<code>getDisplayHint()</code>
	<b>Notes:</b> The display hint will have a string value of either <code>Display</code> or <code>Hide</code> .
Get the preferred control type for the attribute	<code>getControlType()</code>
Parse a formatted string value using any format mask supplied for the attribute	<code>parseFormattedAttribute()</code>

## D.3 Methods Used in the Business Service Tier

The implementation classes corresponding to the `oracle.jbo.*` interfaces, as described in [Section D.2, "Methods Used in the Client Tier,"](#) are intentionally designed to *not* be directly accessed by client code. They reside in a different package named `oracle.jbo.server.*` and have the `Impl` suffix in their name to help remind you not to use them in your client-layer code.

In your business service tier implementation code, you can use any of the same methods that are available to clients, but in addition you can also:

- Safely cast any `oracle.jbo.*` interface to its `oracle.jbo.server.*` package implementation class and use any methods on that `Impl` class as well.
- Override any of the `public` or `protected` methods for the base framework implementation classes and write custom code in your component subclass before or after calling `super.methodName()` to augment or change the default functionality.

This section provides a summary of the most frequently called, written, and overridden methods for the key ADF Business Components classes.

### D.3.1 Controlling Custom Java Files for Your Components

Before examining the specifics of individual classes, it's important to understand how you can control which custom Java files each of your components will use. When you don't need a customized subclass for a given component, you can just let the base framework class handle the implementation at runtime.

Each business component you create comprises a single XML component descriptor, and zero or more related custom Java implementation files. Each component that supports Java customization has a Java page in its component overview editor in the JDeveloper IDE. By selecting or deselecting the different Java classes, you control which ones will be created for your component. If none of the classes is specified, then your component will be an XML-only component, which simply uses the base framework class as its Java implementation. Otherwise, tick the checkbox of the related Java classes for the current component that you need to customize. JDeveloper will create a custom *subclass* of the framework base class in which you can add your code.

---

**Note:** You can set up global IDE preferences for the Java classes to be generated by default for each ADF business component type by choosing **Tools > Preferences > Business Components** and ticking the checkboxes to indicate what you want your defaults to be.

---

A best practice is to *always* generate entity object and view row classes, even if you don't require any custom code in them other than the automatically generated getter and setter methods. These getter and setter methods offer you compile-time type checking that prevents errors surfacing at runtime in response to an attribute having been set to an incorrect kind of value.

### D.3.2 ApplicationModuleImpl Class

The `ApplicationModuleImpl` class is the base class for application module components. Since the application module is the ADF component used to implement a business service, think of the application module class as the place where you can write your service-level application logic. The application module coordinates with view object instances to support updatable collections of value objects that are automatically "wired" to business domain objects. The business domain objects are implemented as ADF entity objects.

#### D.3.2.1 Methods You Typically Call on ApplicationModuleImpl

Table D-10 describes the operations that you can perform on an application module using the `ApplicationModuleImpl` class.

**Table D-10** *Methods You Typically Call on ApplicationModuleImpl*

If you want to...	Call this method of the <code>ApplicationModuleImpl</code> class
Perform any of the common application module operations from inside your class, which can also be done from the client	For a list of these methods, see <a href="#">Section D.2.1, "ApplicationModule Interface."</a>

**Table D–10 (Cont.) Methods You Typically Call on ApplicationModuleImpl**

If you want to...	Call this method of the ApplicationModuleImpl class
Access a view object instance that you added to the application module's data model at design time	<code>getViewObjectName()</code> <b>Notes:</b> JDeveloper generates this type-safe view object instance getter method for you to reflect each view object instance in the application module's design time data model.
Access the current DBTransaction object	<code>getDBTransaction()</code>
Access a nested application module instance that you added to the application module at design time	<code>getAppModuleName()</code> <b>Notes:</b> JDeveloper generates this type-safe application module instance getter method for you to reflect each nested application module instance added to the current application module at design time.

### D.3.2.2 Methods You Typically Write in Your Custom ApplicationModuleImpl Subclass

[Table D–11](#) describes the operations that you can perform on an application module using your custom `ApplicationModuleImpl` class.

**Table D–11 Methods You Typically Write in Your Custom ApplicationModuleImpl Subclass**

If you want to...	Write a method like this in your custom ApplicationModuleImpl class
Invoke a database stored procedure	<code>someCustomMethod()</code> <b>Notes:</b> Use the appropriate method on the <code>DBTransaction</code> interface to create a <code>JDBC PreparedStatement</code> . If the stored procedure has <code>OUT</code> parameters, then create a <code>CallableStatement</code> instead.  For sample code that demonstrates encapsulating a call to a PL/SQL stored procedure inside your application module, see <a href="#">Section 12.6, "Invoking Stored Procedures and Functions."</a>
Expose custom business service methods on your application module	<code>someCustomMethod()</code> <b>Notes:</b> Select the method name on the <b>Client Interface</b> page of the Edit Application Module dialog to expose it for client access if required.

JDeveloper can generate a custom `YourApplicationModuleName` interface containing service-level custom methods that you've chosen to expose to the client. You can use the **Client Interface** page of the Edit Application Module dialog to select the methods that you want to appear in your client interface.

### D.3.2.3 Methods You Typically Override in Your Custom ApplicationModuleImpl Subclass

Table D–12 describes the operations that you can override on an application module using your custom ApplicationModuleImpl class.

**Table D–12 Methods You Typically Override in Your Custom ApplicationModuleImpl Subclass**

If you want to...	Override this method in your custom ApplicationModuleImpl class
Perform custom setup code the first time an application module is created and each subsequent time it gets used by a different client session.	<p><code>prepareSession()</code></p> <p><b>Notes:</b></p> <p>This is the method you'd use to set up per-client context info for the current user in order to use Oracle's Virtual Private Database (VPD) features. It can also be used to set other kinds of PL/SQL package global variables, whose values might be client-specific, on which other stored procedures might rely.</p> <p>This method is also useful to perform setup code that is specific to a given view object <i>instance</i> in the application module. If instead of the view object setup code being instance-specific, you want it to be initialized for every instance ever created of that view object component, then put the setup logic in an overridden <code>create()</code> method in your <code>ViewObjectImpl</code> subclass instead.</p>
Perform custom setup code after the application module's transaction is associated with a database connection from the connection pool	<p><code>afterConnect()</code></p> <p><b>Notes:</b></p> <p>Can be a useful place to write a line of code that uses <code>getDBTransaction().executeCommand()</code> to perform an <code>ALTER SESSION SET SQL TRACE TRUE</code> to enable database SQL trace logging for the current application connection. These logs can then be processed with the TKPROF utility to study the SQL statements being performed and the query optimizer plans that are getting used.</p> <p>For details about the TKPROF utility, see the "Understanding SQL Trace and TKPROF" section in the <i>Oracle Database Performance Tuning Guide</i>.</p>
Perform custom setup code before the application module's transaction releases its database connection back to the database connection pool	<p><code>beforeDisconnect()</code></p> <p><b>Notes:</b></p> <p>If you have set <code>jbo.doconnectionpooling</code> to <code>true</code>, then the connection is released to the database connection pool each time the application module is returned to the application module pool.</p>
Write custom application module state to the state management XML snapshot	<p><code>passivateState()</code></p>
Read and restore custom application module state from the state management XML snapshot	<p><code>activateState()</code></p>

### D.3.3 DBTransactionImpl2 Class

The `DBTransactionImpl2` class — which extends the base `DBTransactionImpl` class, and is constructed by the `DatabaseTransactionFactory` class — is the base class that implements the `DBTransaction` interface, representing the unit of pending work in the current transaction.

#### D.3.3.1 Methods You Typically Call on DBTransaction

[Table D–13](#) describes the operations that you can perform on a transaction using the `DBTransaction` class.

**Table D–13** *Methods You Typically Call on DBTransaction*

If you want to...	Call this method on the <code>DBTransaction</code> class
Commit the transaction	<code>commit()</code>
Roll back the transaction	<code>rollback()</code>
Eagerly validate any pending invalid changes in the transaction	<code>validate()</code>
Create a JDBC <code>PreparedStatement</code> using the transaction's <code>Connection</code> object	<code>createPreparedStatement()</code>
Create a JDBC <code>CallableStatement</code> using the transaction's <code>Connection</code> object	<code>createCallableStatement()</code>
Create a JDBC <code>Statement</code> using the transaction's <code>Connection</code> object	<code>createStatement()</code>
Add a warning to the transaction's warning list	<code>addWarning()</code>

#### D.3.3.2 Methods You Typically Override in Your Custom `DBTransactionImpl2` Subclass

[Table D–14](#) describes the operations that you can perform on a transaction using your custom `DBTransactionImpl2` subclass.

**Table D–14** *Methods You Typically Override in Your Custom `DBTransactionImpl2` Subclass*

If you want to...	Override this method in your custom <code>DBTransactionImpl2</code> class
Perform custom code before or after the transaction commit operation	<code>commit()</code>
Perform custom code before or after the transaction rollback operation	<code>rollback()</code>

In order for your custom `DBTransactionImpl2` subclass to be used at runtime, there are you must follow these steps:

1. Create a custom subclass of `DatabaseTransactionFactory` that overrides the `create` method to return an instance of your custom `DBTransactionImpl2` subclass like this:

```
package com.yourcompany.adfextensions;
import oracle.jbo.server.DBTransactionImpl2;
import oracle.jbo.server.DatabaseTransactionFactory;
import com.yourcompany.adfextensions.CustomDBTransactionImpl;
```

```

public class CustomDatabaseTransactionFactory
 extends DatabaseTransactionFactory {
 /**
 * Return an instance of our custom CustomDBTransactionImpl class
 * instead of the default implementation.
 *
 * @return An instance of our custom DBTransactionImpl2 implementation.
 */
 public DBTransactionImpl2 create() {
 return new CustomDBTransactionImpl();
 }
}

```

2. Tell the framework to use your custom transaction factory class by setting the value of the `TransactionFactory` configuration property to the fully qualified class name of your custom transaction factory. As with other configuration properties, if not supplied in the configuration XML file, it can be provided alternatively as a Java system parameter of the same name.

## D.3.4 EntityImpl Class

The `EntityImpl` class is the base class for entity objects, which encapsulate the data, validation rules, and business behavior for your business domain objects.

### D.3.4.1 Methods You Typically Call on EntityImpl

[Table D-15](#) describes the operations that you can perform on an entity object using the `EntityImpl` class.

**Table D-15** *Methods You Typically Call on EntityImpl*

If you want to...	Call this method in the EntityImpl class
Get the value of an attribute	<code>getAttributeName()</code> <b>Notes:</b> This code-generated getter method calls <code>getAttributeInternal()</code> , but provides compile-time type checking.
Set the value of an attribute	<code>setAttributeName()</code> <b>Notes:</b> This code-generated setter method calls <code>setAttributeInternal()</code> , but provides compile-time type checking.
Get the value of an attribute by name	<code>getAttributeInternal()</code>
Set the value of an attribute by name	<code>setAttributeInternal()</code>
Eagerly perform entity object validation	<code>validate()</code>
Refresh the entity from the database	<code>refresh()</code>
Populate the value of an attribute without <i>marking</i> it as being changed, but sending <i>notification</i> of its being changed so that the UI refreshes the value on the screen/page	<code>populateAttributeAsChanged()</code>
Access the <code>Definition</code> object for an entity	<code>getDefinitionObject()</code>
Get the <code>Key</code> object for an entity	<code>getKey()</code>

**Table D–15 (Cont.) Methods You Typically Call on EntityImpl**

If you want to...	Call this method in the EntityImpl class
Determine the state of the entity instance, irrespective of whether it has already been posted (but not yet committed) in the current transaction	<p><code>getEntityState()</code></p> <p><b>Notes:</b> This method will return one of the constants <code>STATUS_UNMODIFIED</code>, <code>STATUS_INITIALIZED</code>, <code>STATUS_NEW</code>, <code>STATUS_MODIFIED</code>, <code>STATUS_DELETED</code>, or <code>STATUS_DEAD</code>, indicating the status of the entity instance in the current transaction.</p>
Determine the state of the entity instance	<p><code>getPostState()</code></p> <p><b>Notes:</b> This method is typically relevant only if you are programmatically using the <code>postChanges()</code> method to post but not yet commit, entity changes to the database and need to detect the state of an entity with regard to its posting state.</p>
Get the value originally read from the database for a given attribute	<code>getPostedAttribute()</code>
Eagerly lock the database row for an entity instance	<code>lock()</code>

### D.3.4.2 Methods You Typically Write in Your Custom EntityImpl Subclass

Table D–16 describes the operations that you can perform on an entity object using your custom `EntityImpl` subclass.

**Table D–16 Methods You Typically Write in Your Custom EntityImpl Subclass**

If you want to...	Write a method like this in your custom EntityImpl subclass
Perform attribute-specific validation	<p><code>public boolean validateSomething(AttrTypevalue)</code></p> <p><b>Notes:</b> Register the attribute validator method by adding a <code>MethodValidator</code> rule on the correct attribute in the <b>Validation</b> page of the Edit Entity Object dialog.</p>
Perform entity-level validation	<p><code>public boolean validateSomething()</code></p> <p><b>Notes:</b> Register the entity-level validator method by adding a <code>MethodValidator</code> rule on the entity in the <b>Validation</b> panel of the Edit Entity Object dialog.</p>
Calculate the value of a transient attribute	Add your calculation code to the generated <code>getAttributeName()</code> method.

### D.3.4.3 Methods You Typically Override in Your Custom EntityImpl Subclass

Table D–17 describes the operations that you can override on an entity object using your custom `EntityImpl` subclass.

**Table D–17 Methods You Typically Override in Your Custom EntityImpl Subclass**

If you want to...	Override this method in your EntityImpl subclass
Set calculated default attribute values, including programmatically populating the primary key attribute value of a new entity instance	<p><code>create()</code></p> <p><b>Notes:</b> After calling <code>super.create()</code>, call the appropriate <code>setAttributeName()</code> method(s) to set the default values for the attributes.</p>
Modify attribute values before changes are posted to the database	<code>prepareForDML()</code>
Augment or change the standard INSERT, UPDATE, or DELETE DML operation that the framework will perform on your entity object's behalf to the database	<p><code>doDML()</code></p> <p><b>Notes:</b> This method checks the value of the operation flag to the constants <code>DML_INSERT</code>, <code>DML_UPDATE</code>, or <code>DML_DELETE</code> to test what DML operation is being performed.</p>
Perform complex, SQL-based validation after all entity instances have been posted to the database but before those changes are committed	<code>beforeCommit()</code>
Insure that a related, newly-created, parent entity gets posted to the database <i>before</i> the current child entity on which it depends	<p><code>postChanges()</code></p> <p><b>Notes:</b> If the parent entity is related to this child entity via a composition association, then the framework already handles posting the changes automatically. If they are only associated (but not composed), then you need to override <code>postChanges()</code> to force a newly created parent entity to post before the current, dependent child entity. For an example of the code you typically write in your overridden <code>postChanges()</code> method to accomplish this, see <a href="#">Section 4.14.7.3, "Overriding postChanges() to Control Post Order."</a></p>

---

**Note:** It is possible to write attribute-level validation code directly inside the appropriate `setAttributeName` method of your `EntityImpl` class; however, adopting the `MethodValidator` approach suggested in [Table D–16](#) conveniently places all the validations in effect on the **Validation Rules** page of the overview editor for the attributes of the entity object.

---

---

**WARNING:** It is also possible to override the `validateEntity()` method to write entity-level validation code; however, if you want to maintain the benefits of the ADF bundled exception mode — where the framework collects and reports a *maximal* set of validation errors back to the client user interface — use the `MethodValidator` approach suggested in [Table D-16](#). This allows the framework to automatically collect all of your exceptions that your validation methods throw without your having to understand the bundled exception implementation mechanism. Overriding the `validateEntity()` method directly shifts the responsibility onto your *own* code to correctly catch and bundle the exceptions that Oracle ADF would have caught by default, which is non-trivial and a chore to remember and hand-code each time.

---

## D.3.5 EntityDefImpl Class

The `EntityDefImpl` class is a singleton, shared metadata object for all entity objects of a given type in a single Java VM. For instance, if the Java VM contains two instances of the `EntityDefImpl` class, one with the customers XML data and one with the orders, there would only ever be one instance of each. This class defines the structure of the entity instances and provides methods to create new entity instances and find existing instances by their primary key.

### D.3.5.1 Methods You Typically Call on EntityDefImpl

[Table D-18](#) describes the operations that you can perform on an entity object using the `EntityDefImpl` class.

**Table D-18** *Methods You Typically Call on EntityDefImpl*

If you want to...	Call this method in the EntityDefImpl class
Find an entity object of a given type by its primary key	<code>findByPrimaryKey()</code> <b>Notes:</b> For a tip about getting <code>findByPrimaryKey()</code> to find entity instances of subtype entities as well, see <a href="#">Section 4.19.4.2, "Subtype Entity Objects and the findByPrimaryKey() Method."</a>
Access the current <code>DBTransaction</code> object	<code>getDBTransaction()</code>
Find any <code>EntityDefImpl</code> object by its fully qualified name	<code>findDefObject()</code> (static method)
Retrieve the value of an entity object's custom property	<code>getProperty()</code> , <code>getProperties()</code>
Set the value of an entity object's custom property	<code>setProperty()</code>
Create a new instance of an entity object	<code>createInstance2()</code> <b>Notes:</b> Alternatively, you can expose custom <code>createXXX()</code> methods with your own expected signatures in that same custom <code>EntityDefImpl</code> subclass. See <a href="#">Section D.3.5.2, "Methods You Typically Write in Your Custom EntityDefImpl Class"</a> for details.

**Table D–18 (Cont.) Methods You Typically Call on EntityDefImpl**

If you want to...	Call this method in the EntityDefImpl class
Iterate over the entity instances in the cache of this entity type	<code>getAllEntityInstancesIterator()</code>
Access an array list of entity definition objects for entities that extend the current one.	<code>getExtendedDefObjects()</code>

### D.3.5.2 Methods You Typically Write in Your Custom EntityDefImpl Class

Table D–19 describes the operations that you can perform on an entity object using your custom `EntityDefImpl` class.

**Table D–19 Methods You Typically Write on EntityDefImpl**

If you want to...	Write a method like this in your custom EntityDefImpl class
Allow other classes to create an entity instance with an initial type-safe set of attribute values or setup information	<pre>createXXX(Type1arg1, . . . , TypeNargN)</pre> <p><b>Notes:</b></p> <p>Internally, using this method would create and populate an instance of a <code>NameValuePairs</code> object (which implements <code>AttributeList</code>) and call the protected method <code>createInstance()</code>, passing that <code>NameValuePairs</code> object. Make sure that the method is <code>public</code> if other classes need to be able to call it.</p>

### D.3.5.3 Methods You Typically Override in Your Custom EntityDefImpl

Table D–20 describes the operations that you can perform on an entity object using the `EntityDefImpl` class.

**Table D–20 Methods You Typically Override on EntityDefImpl**

If you want to...	Override this method in your custom EntityDefImpl class
Perform custom metadata initialization when this singleton metaobject is loaded	<code>createDef()</code>
Avoid using the <code>RETURNING INTO</code> clause to support refresh-on-insert or refresh-on-update attributes	<pre>isUseReturningClause()</pre> <p><b>Notes:</b></p> <p>Set this method to return <code>false</code> to disable the use of <code>RETURNING INTO</code>, necessary sometimes when your entity object is based on a view with <code>INSTEAD OF</code> triggers that don't support <code>RETURNING INTO</code> at the database level.</p>
Control whether the <code>UPDATE</code> statements issued for this entity update only changed columns or for all columns	<pre>isUpdateChangedColumns()</pre> <p><b>Notes:</b></p> <p>Defaults to <code>true</code>.</p>
Find any <code>EntityDefImpl</code> object by its fully qualified name	<pre>findDefObject()</pre> <p><b>Notes:</b></p> <p>Static method.</p>

**Table D–20 (Cont.) Methods You Typically Override on EntityDefImpl**

<b>If you want to...</b>	<b>Override this method in your custom EntityDefImpl class</b>
Set the value of an entity object's custom property	<code>setProperty()</code>
Allow other classes to create a new instance of an entity object without doing so implicitly via a view object	<code>createInstance()</code> <b>Notes:</b> If you don't write a custom create method as noted in <a href="#">Section D.3.5.2, "Methods You Typically Write in Your Custom EntityDefImpl Class"</a> , you'll need to override this method and widen the visibility from <code>protected</code> to <code>public</code> to allow other classes to construct an entity instance.

## D.3.6 ViewObjectImpl Class

The `ViewObjectImpl` class is the base class for view objects.

### D.3.6.1 Methods You Typically Call on ViewObjectImpl

[Table D–21](#) describes the operations that you can perform on a view object using the `ViewObjectImpl` class.

**Table D–21 Methods You Typically Call on ViewObjectImpl**

<b>If you want to...</b>	<b>Call this method in the ViewObjectImpl class</b>
Perform any of the common view object, row set, or row set iterator operations from inside your class, which can also be done from the client	For more information about operations at the view object, row set, or row set iterator-level, see <a href="#">Section D.2.3, "ViewObject Interface,"</a> <a href="#">Section D.2.4, "RowSet Interface,"</a> and <a href="#">Section D.2.5, "RowSetIterator Interface."</a>
Set an additional runtime <code>WHERE</code> clause on the default row set	<code>setWhereClause()</code>
Define a named bind parameter	<code>defineNamedWhereClauseParam()</code>
Remove a named bind parameter	<code>removeNamedWhereClauseParam()</code>
Set bind variable values on the default row set by name	<code>setNamedWhereClauseParam()</code> <b>Notes:</b> Only works when you have formally defined named bind variables on your view object.
Set bind variable values on the default row set	<code>setWhereClauseParam()</code> <b>Notes:</b> Use this method for view objects with binding style of "Oracle Positional" or "JDBC Positional" when you have not formally defined named bind variables.
Retrieve a subset of rows in a view object's row set based on evaluating an in-memory filter expression	<code>getFilteredRows()</code>
Retrieve a subset of rows in the current range of a view object's row set based on evaluating an in-memory filter expression	<code>getFilteredRowsInRange()</code>

**Table D–21 (Cont.) Methods You Typically Call on ViewObjectImpl**

If you want to...	Call this method in the ViewObjectImpl class
Override the runtime display of criteria items that appear inside an ADF query component. Subclasses may override to return custom <code>AttributeHints</code> implementation for the given criteria item. Returns null by default.	<code>getCriteriaItemAttributeHints()</code>
Set the number of rows that will be fetched from the database per roundtrip for this view object	<code>setFetchSize()</code> <b>Notes:</b> The default fetch size is a single row at a time. This is definitely not optimal if your view object intends to retrieve many rows, so you should either set the fetch size higher at design time on the <b>Tuning</b> page of the Edit View Object dialog, or set it at runtime using this method.
Access a cached query collection without reexecuting the query (useful for view instances of a shared application module)	<code>refreshCollection()</code> <b>Notes:</b> When you cache lookup data in a shared application module, you should not reexecute the lookup view object query since reexecuting forces a new query collection and prevents the cache from being used. Instead of using <code>executeQuery()</code> , use this pattern to reuse the cached query collection: <pre data-bbox="954 1003 1446 1108">if (!lookupVO.isExecuted()) {     ((ViewObjectImpl)lookupVO).         refreshCollection(null, true, true); }</pre>

### D.3.6.2 Methods You Typically Write in Your Custom ViewObjectImpl Subclass

Table D–22 describes the operations that you can perform on a view object using your custom `ViewObjectImpl` subclass.

**Table D–22 Methods You Typically Write in Your Custom ViewObjectImpl Subclass**

If you want to...	Write a method like this in your custom ViewObjectImpl subclass
Provide clients with type-safe methods to set bind variable values without exposing positional details of the bind variables themselves	<code>someMethodName(Type1arg1, ..., TypeNargN)</code> <b>Notes:</b> Internally, this method would call the <code>setWhereClauseParam()</code> method to set the correct bind variables with the values provided in the type-safe method arguments.

JDeveloper can generate a custom `YourViewObjectName` interface containing view object custom methods that you've chosen to expose to the client. You can use the **Client Interface** page of the Edit View Object to select the methods that you want to appear in your client interface.

### D.3.6.3 Methods You Typically Override in Your Custom ViewObjectImpl Subclass

Table D–23 describes the operations that you can perform on a view object using your custom ViewObjectImpl subclass.

**Table D–23 Methods You Typically Override in Your Custom ViewObjectImpl Subclass**

If you want to...	Override this method in your custom ViewObjectImpl subclass
Initialize custom view object class members (not row attributes) when the view object instance is created for the first time	<p><code>create()</code></p> <p><b>Notes:</b></p> <p>This method is useful to perform set up logic that is applicable to every instance of a view object that will ever get created, in the context of any application module.</p> <p>If instead of <i>generic</i> view object setup logic, you need to perform logic specific to a given view object <i>instance</i> in an application module, then override the <code>prepareSession()</code> method of your application module's <code>ApplicationModuleImpl</code> subclass and perform the logic there after calling <code>findViewObject()</code> to find the view object instance whose properties you want to set.</p>
Write custom view object instance state to the state management XML snapshot	<code>passivateState()</code>
Read and restore custom view object instance state from the state management XML snapshot	<code>activateState()</code>
Customize the execution of the view object query to utilize an alternative data source	<p><code>executeQueryForCollection()</code></p> <p><b>Notes:</b></p> <p>By default view objects read their data from the database and automate the task of working with the JDBC layer to process the database result sets. However, by overriding appropriate methods in its custom Java class, you can create a view object that programmatically retrieves data from alternative data sources, as described in <a href="#">Section 42.8, "Using Programmatic View Objects for Alternative Data Sources."</a></p>
Customize the programmatic view object to utilize an alternative data source and determine whether the query collection has more rows to fetch from the query execution	<code>hasNextForCollection()</code>
Customize the programmatic view object to utilize an alternative data source and populate each row of the retrieved data	<code>createRowFromResultSet()</code>
Customize the programmatic view object to utilize an alternative data source and return a count of the number of rows that will be retrieved	<code>getQueryHitCount()</code>
Customize the programmatic view object to utilize an alternative data source and release any resources that may be associated with a row set that is being closed	<code>releaseUserDataForCollection()</code>

**Table D–23 (Cont.) Methods You Typically Override in Your Custom ViewObjectImpl**

If you want to...	Override this method in your custom ViewObjectImpl subclass
Change or augment the way that the ViewCriteria collection of ViewCriteriaRows is converted into a Query-by-Example WHERE clause	getViewCriteriaClause(boolean)

## D.3.7 ViewRowImpl Class

The ViewRowImpl class is the base class for view row objects.

### D.3.7.1 Methods You Typically Call on ViewRowImpl

Table D–24 describes the operations that you can perform on a view object row using your custom ViewRowImpl class.

**Table D–24 Methods You Typically Call on ViewRowImpl**

If you want to...	Call this method in your custom ViewRowImpl class
Perform any of the common view row operations from inside your class, which can also be done from the client	For more information about the row-level operations, see <a href="#">Section D.2.6, "Row Interface."</a>
Get the value of an attribute	getAttrName()
Set the value of an attribute	setAttrName()
Access the underlying entity instance to which this view row is delegating attribute storage	getEntityUsageAliasName() <b>Notes:</b> You can change the name of the entity usage alias name on the <b>Entity Objects</b> page of the Edit View Object dialog.

### D.3.7.2 Methods You Typically Write in Your Custom ViewRowImpl Class

Table D–25 describes the operations that you can perform on a view object row using your custom ViewRowImpl class.

**Table D–25 Methods You Typically Write on ViewRowImpl**

If you want to...	Write a method like this in your custom ViewRowImpl class
Calculate the value of a view object-level transient attribute	getAttrName() <b>Notes:</b> JDeveloper generates the skeleton of the method for you, but you need to write the custom calculation logic inside the method body.
Perform custom processing of the setting of a view row attribute	setAttrName() <b>Notes:</b> JDeveloper generates the skeleton of the method for you, but you need to write the custom logic inside the method body if required.
Determine the updateability of an attribute in a conditional way	isAttributeUpdateable()

**Table D–25 (Cont.) Methods You Typically Write on ViewRowImpl**

If you want to...	Write a method like this in your custom ViewRowImpl class
Expose logical operations on the current row, optionally callable by clients	<pre>doSomething()</pre> <p><b>Notes:</b></p> <p>Often these view-row-level custom methods simply turn around and delegate to a method call on the underlying entity object related to the current row.</p>

JDeveloper can generate a custom *YourViewObjectNameRow* interface containing view row custom methods that you've chosen to expose to the client. You can use the **Client Row Interface** page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

### D.3.7.3 Methods You Typically Override in Your Custom ViewRowImpl Subclass

Table D–26 describes the operations that you can perform on a view object row using your custom *ViewRowImpl* subclass.

**Table D–26 Methods You Typically Override in Your Custom ViewRowImpl Subclass**

If you want to...	Write a method like this in your ViewRowImpl subclass
Determine the updateability of an attribute in a conditional way	<pre>isAttributeUpdateable()</pre>

---

# ADF Business Components Java EE Design Pattern Catalog

This appendix provides a brief summary of the Java Platform, Enterprise Edition (Java EE) design patterns that the ADF Business Components layer implements for you.

By using the Oracle Application Development Framework's business components building-blocks and related design time extensions to JDeveloper, you get a prescriptive architecture for building richly functional and cleanly layered Java EE business services with great performance.

[Table E-1](#) provides a brief overview of the numerous design patterns that the ADF Business Components layer implements for you. Some are the familiar patterns from Sun's Java EE BluePrints and some are design patterns that ADF Business Components adds to the list. For details about Java EE BluePrints, see the BluePrints page at the Oracle Technology Network web site at <http://www.oracle.com/technetwork/java/index-jsp-136701.html>.

**Table E-1 Java EE Design Patterns Implemented by ADF Business Components**

Pattern Name and Description	How ADF Business Components Implements It
<p><b>Model/View/Controller</b></p> <p>Cleanly separates the roles of data and presentation, allowing multiple types of client displays to work with the same business information.</p>	<p>The ADF application module provides a generic implementation of a Model/View/Controller "application object" that simplifies exposing the application data model for any application or service, and facilitates declaratively specifying the boundaries of a logical unit of work. Additional UI-centric frameworks and tag libraries provided in JDeveloper help you implement the view and controller layers.</p>
<p><b>Interface / Implementation Separation</b></p> <p>Cleanly separates the API or Interface for components from their implementation class.</p>	<p>ADF Business Components enforces a logical separation of client-tier accessible functionality (via interfaces) and its business tier implementation. JDeveloper handles the creation of custom interfaces and client proxy classes automatically.</p>
<p><b>Service Locator</b></p> <p>Abstracts the technical details of locating a service so that the client can use it more easily.</p>	<p>ADF application modules are looked up using a simple configuration object which hides the low-level details of finding the service instance behind the scenes. For Fusion web applications, it also hides the implementation of the application module pool usage, a lightweight pool of service components that improves application scalability.</p>

**Table E-1 (Cont.) Java EE Design Patterns Implemented by ADF Business Components**

<b>Pattern Name and Description</b>	<b>How ADF Business Components Implements It</b>
<p><b>Inversion of Control</b></p> <p>A containing component orchestrates the lifecycle of the components it contains, invoking specific methods that you can override at the appropriate times, so as to be able to focus more on what the code should do, instead of when it should be executed.</p>	<p>ADF components contain a number of easy-to-override methods that the framework invokes as needed during the course of application processing.</p>
<p><b>Dependency Injection</b></p> <p>Simplifies application code, and increases configuration flexibility by deferring component configuration and assembly to the container.</p>	<p>ADF Business Components configures all its components from externalized XML metadata definition files. At runtime, the framework automatically injects dependent objects like view object instances into your application module service component and entity objects into your view rows, implementing lazy loading. It supports runtime factory substitution of components by any customized subclass of that component to simplify onsite application customization scenarios. Much of the ADF Business Components functionality is implemented via dynamic injection of validator and listener subscriptions that coordinate the framework interactions depending on what declarative features have been configured for each component in their XML metadata.</p>
<p><b>Active Record</b></p> <p>Avoids the complexity of "anything to anything" object/relational mapping, by providing an object that wraps a row in a database table or view, encapsulates the database access, and adds domain logic on that data.</p>	<p>ADF entity objects handle the database mapping functionality you use most frequently, including inheritance, association, and composition support, so you don't have to focus on object/relational mapping. They also provide a place to encapsulate both declarative business rules and one-off programmatic business domain.</p>
<p><b>Data Access Objects</b></p> <p>Prevents unnecessary marshalling overhead by implementing dependent objects as lightweight, persistent classes instead of each as an individual enterprise bean. Isolates persistence details into a single, easy-to-maintain class.</p>	<p>ADF view objects automate the implementation of data access for reading data using SQL statements. ADF entity objects automate persistent storage of lightweight business entities. ADF view objects and entity objects cooperate to provide a sophisticated, performant data access objects layer, where any data queried through a view object can optionally be made fully updatable without requiring that you write any "application plumbing" code.</p>
<p><b>Session Facade</b></p> <p>Prevents inefficient client access of entity beans and inadvertent exposure of sensitive business information by wrapping entity beans with a session bean.</p>	<p>ADF application modules are designed to implement a coarse-grained "service facade" architecture in any of their supported deployment modes. When deployed as EJB session beans or as a service interface, they provide an implementation of the Session Facade pattern automatically.</p>

---

**Table E-1 (Cont.) Java EE Design Patterns Implemented by ADF Business Components**

---

<b>Pattern Name and Description</b>	<b>How ADF Business Components Implements It</b>
<p><b>Value Object</b></p> <p>Prevents unnecessary network roundtrips by creating one-off "transport" objects to group a set of related attributes needed by a client program.</p>	<p>ADF Business Components provides an implementation of a generic Row object, which is a metadata-driven container of any number and kind of attributes that need to be accessed by a client. The developer can work with the generic Row interface and do late-bound <code>getAttribute("Price")</code> and <code>setAttribute("Quantity")</code> calls, or optionally generate early-bound row interfaces like <code>OverdueOrdersRow</code>, to enable type-safe method calls like <code>getPrice()</code> and <code>setQuantity()</code>. Smarter than just a simple "bag 'o attributes", the ADF Row object can be introspected at runtime to describe the number, names, and types of the attributes in the row, enabling sophisticated, generic solutions to be implemented.</p>
<p><b>Page-by-Page Iterator</b></p> <p>Prevents sending unnecessary data to the client by breaking a large collection into page-sized "chunks" for display.</p>	<p>ADF Business Components provides an implementation of a generic RowSet interface which manages result sets produced by executing view object SQL queries. The RowSet interface allows you to set a desired page size, for example 10 rows, and page up and down through the query results in these page-sized chunks. Since data is retrieved lazily, only data the user actually visits will ever be retrieved from the database on the backend, and in the client tier the number of rows in the page can be returned over the network in a single roundtrip.</p>
<p><b>Fast-Lane Reader</b></p> <p>Prevents unnecessary overhead for read-only data by accessing JDBC APIs directly. This allows an application to retrieve only the attributes that need to be displayed, instead of finding all of the attributes by primary key when only a few are required by the client. Typically, implementations of this pattern sacrifice data consistency for performance, since queries performed at the raw JDBC level do not "see" pending changes made to business information represented by enterprise beans.</p>	<p>ADF view objects read data directly from the database for best performance; however, they give you a choice regarding data consistency. If updateability and/or consistency with pending changes is desired, you need only associate your view object with the appropriate entity objects whose business data is being presented. If consistency is not a concern, view objects can simply perform the query with no additional overhead. In either case, you never have to write JDBC data access code. You need only provide appropriate SQL statements in XML descriptors.</p>
<p><b>(Bean) Factory</b></p> <p>Allows runtime instantiation and configuration of an appropriate subclass of a given interface or superclass based on externally configurable information.</p>	<p>All ADF component instantiation is done based on XML configuration metadata through factory classes allowing runtime substitution of specialized components to facilitate application customization.</p>
<p><b>Entity Facade</b></p> <p>Provides a restricted view of data and behavior of one or more business entities.</p>	<p>ADF view objects can surface any set of attributes and methods from any combination of one or more underlying entity objects to furnish the client with a single, logical value object to work with.</p>

---

---

**Table E-1 (Cont.) Java EE Design Patterns Implemented by ADF Business Components**

<b>Pattern Name and Description</b>	<b>How ADF Business Components Implements It</b>
<p><b>Value Messenger</b> Keeps client value object attributes in sync with the middle-tier business entity information that they represent in a bidirectional fashion.</p>	<p>The ADF Business Components value object implementation coordinates with a client-side value object cache to batch attribute changes to the EJB tier and receive batch attribute updates which occur as a result of middle-tier business logic. The ADF Value Messenger implementation is designed to not require any kind of asynchronous messaging to achieve this effect.</p>
<p><b>Continuations</b> Gives you the simplicity and productivity of a stateful programming model with the scalability of a stateless web solution.</p>	<p>ADF Business Components application module pooling and state management functionality combine to deliver this value-add. Application module pooling eliminates the need to dedicate application server tier resources to individual users and supports a "stateless with user affinity" optimization that you can tune.</p>

## ADF Equivalents of Common Oracle Forms Triggers

This appendix provides a quick summary of how basic tasks performed with the most common Oracle Forms triggers are accomplished using Oracle ADF.

This appendix includes the following sections:

- [Section F.1, "Validation and Defaulting \(Business Logic\)"](#)
- [Section F.2, "Query Processing"](#)
- [Section F.3, "Database Connection"](#)
- [Section F.4, "Transaction "Post" Processing \(Record Cache\)"](#)
- [Section F.5, "Error Handling"](#)

### F.1 Validation and Defaulting (Business Logic)

**Table F-1 ADF Equivalents for Oracle Forms Validation and Defaulting Triggers**

Forms Trigger	ADF Equivalent
WHEN-VALIDATE-RECORD Execute validation code at the record level	In the custom <code>EntityImpl</code> class for your entity object, write a public method returning a <code>boolean</code> type with a method name like <code>validateXXXX()</code> and have it return <code>true</code> if the validation succeeds or <code>false</code> if the validation fails. Then, add a Method validator for this validation method to your entity object at the entity level. When doing that, you can associate a validation failure message with the rule.
WHEN-VALIDATE-ITEM Execute validation code at the field level	In the custom <code>EntityImpl</code> class for your entity object, write a public method returning a <code>boolean</code> type and accepting a single argument of the same data type as your attribute, having a method name like <code>validateXXXX()</code> . Have it return <code>true</code> if the validation succeeds or <code>false</code> if the validation fails. Then, add a Method validator for this validation method to the entity object at the attribute level for the appropriate attribute. When doing that, you can associate a validation failure message with the rule.
WHEN-DATABASE-RECORD Execute code when a row in the data block is marked for insert or update	Override the <code>addToTransactionManager()</code> method of your entity object. Write code after calling the super.

**Table F-1 (Cont.) ADF Equivalents for Oracle Forms Validation and Defaulting Triggers**

Forms Trigger	ADF Equivalent
<p>WHEN-CREATE-RECORD</p> <p>Execute code to populate complex default values when a new record in the data block is created, without changing the modification status of the record</p>	<p>Override the <code>create()</code> method of your entity object and after calling the super, use appropriate <code>setAttribute()</code> methods to set default values for attributes as necessary.</p> <p>To immediately set a primary key attribute to the value of a sequence, construct an instance of the <code>SequenceImpl</code> helper class and call its <code>getSequenceNumber()</code> method to get the next sequence number. Assign this value to your primary key attribute.</p> <p>If you want to wait to assign the sequence number until the new record is saved, but still without using a database trigger, you can use this technique in an overridden <code>prepareForDML()</code> method in your entity object.</p> <p>If instead you want to assign the primary key from a sequence using your own <code>BEFOREINSERTFOREACHROW</code> database trigger, then use the special data type called <code>DBSequence</code> for your primary key attribute instead of the regular <code>Number</code> type.</p>
<p>WHEN-REMOVE-RECORD</p> <p>Execute code whenever a row is removed from the data block</p>	<p>Override the <code>remove()</code> method of your entity object and write code either before or after calling the super.</p>

## F.2 Query Processing

**Table F-2 ADF Equivalents for Oracle Forms Query Processing Triggers**

Forms Trigger	ADF Equivalent
<p>PRE-QUERY</p> <p>Execute logic before executing a query in a data block, typically to set up values for Query-by-Example criteria in the "example record"</p>	<p>Override the <code>executeQueryForCollection()</code> method on your view object class and write code before calling the super.</p>
<p>ON-COUNT</p> <p>Override default behavior to count the query hits for a data block</p>	<p>Override the <code>getQueryHitCount()</code> method in your view object and do something instead of calling the super.</p>
<p>POST-QUERY</p> <p>Execute logic after retrieving each row from the data source for a data block.</p>	<p>Generally instead of using a <code>POST-QUERY</code> style technique to fetch descriptions from other tables based on foreign key values in the current row, in ADF it's more efficient to build a view object that has multiple participating entity objects, joining in all the information you need in the query from the main table, as well as any auxiliary or lookup-value tables. This way, in a single roundtrip to the database you get all the information you need. If you still need a per-fetched-row trigger like <code>POST-QUERY</code>, override the <code>createInstanceFromResultSet()</code> method in your view object class.</p>
<p>ON-LOCK</p> <p>Override default behavior to attempt to acquire a lock on the current row in the data block</p>	<p>Override the <code>lock()</code> method in your entity object class and do something instead of calling the super.</p>

## F.3 Database Connection

**Table F-3 ADF Equivalents for Oracle Forms Database Connection Triggers**

Forms Trigger	ADF Equivalent
POST-LOGON Execute logic after logging into the database	Override the <code>afterConnect()</code> method on your custom application module. Since application module instances can stay connected while serving different logical client sessions, you can override the <code>prepareSession()</code> method, which is fired after initial login, as well as after any time the application module is accessed by a user that was different from the one that accessed it last time.
PRE-LOGOUT Execute logic before logging out of the database	Override the <code>beforeDisconnect()</code> method on your custom application module class.

## F.4 Transaction "Post" Processing (Record Cache)

**Table F-4 ADF Equivalents for Oracle Forms Transactional Triggers**

Forms Trigger	ADF Equivalent
PRE-COMMIT Execute code before commencing processing of the changed rows in all data blocks in the transaction	Override the <code>commit()</code> method in a custom <code>DBTransactionImpl</code> class and write code before calling the super.  <b>Note:</b> For an overview of creating and using a custom <code>DBTransaction</code> implementation, see <a href="#">Section 12.8.4.1, "Creating a Custom Database Transaction Framework Extension Class."</a>
PRE-INSERT Execute code before a new row in the data block is inserted into the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_INSERT</code> , then write code <i>before</i> calling the super.
ON-INSERT Override default processing for inserting a new row into the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_INSERT</code> , then write code <i>instead of</i> calling the super.
POST-INSERT Execute code after new row in the data block is inserted into the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_INSERT</code> , then write code <i>after</i> calling the super.
PRE-DELETE Execute code before a row removed from the data block is deleted from the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_DELETE</code> , then write code <i>before</i> calling the super.
ON-DELETE Override default processing for deleting a row removed from the data block from the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_DELETE</code> , then write code <i>instead of</i> calling the super.

**Table F-4 (Cont.) ADF Equivalents for Oracle Forms Transactional Triggers**

<b>Forms Trigger</b>	<b>ADF Equivalent</b>
POST-DELETE Execute code after a row removed from the data block is deleted from the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_DELETE</code> , then write code <i>after</i> calling the <code>super</code> .
PRE-UPDATE Execute code before a row changed in the data block is updated in the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_UPDATE</code> , then write code <i>before</i> calling the <code>super</code> .
ON-UPDATE Override default processing for updating a row changed in the data block from the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_UPDATE</code> , then write code <i>instead of</i> calling the <code>super</code> .
POST-UPDATE Execute code after a row changed in the data block is updated in the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_UPDATE</code> , then write code <i>after</i> calling the <code>super</code> .
POST-FORMS-COMMIT Execute code after Forms has "posted" all necessary rows to the database, but before issuing the data commit to end the transaction	If you want a single block of code for the whole transaction, you can override the <code>doCommit()</code> method in a custom <code>DBTransactionImpl</code> object and write code before calling the <code>super</code> .  To execute entity-specific code before commit for each affected entity in the transaction, override the <code>beforeCommit()</code> method on your entity object, and write code there.
POST-DATABASE-COMMIT Execute code after database transaction has been committed	Override the <code>commit()</code> method in a custom <code>DBTransactionImpl</code> class, and write code <i>after</i> calling the <code>super</code> .

## F.5 Error Handling

**Table F-5 ADF Equivalents for Oracle Forms Error Handling Triggers**

<b>Forms Trigger</b>	<b>ADF Equivalent</b>
ON-ERROR Override default behavior for handling an error	Install a custom error handler ( <code>DCErrorHandler</code> ) on the ADF <code>BindingContext</code> .

---

---

# Performing Common Oracle Forms Tasks in Oracle ADF

This appendix describes how some common Oracle Forms tasks are implemented in Oracle ADF. In Oracle Forms, you do some tasks in the data block, and others in the UI. For this reason, the appendix is divided into two sections: tasks that relate to data, and tasks that relate to the UI.

This appendix includes the following sections:

- [Section G.1, "Performing Tasks Related to Data"](#)
- [Section G.2, "Performing Tasks Related to the User Interface"](#)

## G.1 Performing Tasks Related to Data

In Oracle Forms, tasks that relate solely to data are performed in the data block. In Oracle ADF, these tasks are done on the business components that persist data (entity objects) and on the objects that query data (view objects).

### G.1.1 How to Retrieve Lookup Display Values for Foreign Keys

In Oracle Forms, an editable table often has foreign key lookup columns to other tables. The user-friendly display values corresponding to the foreign key column values exist in related tables. You often need to present these related display values to the user.

In Oracle Forms, this was a complicated task that required adding nondatabase items to the data block, adding a block-level `POST-QUERY` trigger to the data block, and writing a SQL select statement for each foreign key attribute. Additionally, if the user changed the data, you needed to sync the foreign key values with an item-level `WHEN-VALIDATE-ITEM` trigger. This process is much easier in Oracle ADF.

#### Implementation of the task in Oracle ADF

1. Create a view object that includes the following:
  - The main, editable entity object as the primary entity usage
  - Secondary "reference" entity usages for the one or more associated entities whose underlying tables contain the display text

For more information, see [Section 5.5.1, "How to Create Joins for Entity-Based View Objects."](#)

2. Select the desired attributes (at least the display text) from the secondary entity usages as described in [Section 5.5.2, "How to Select Additional Attributes from Reference Entity Usages."](#)

At runtime, the data for the main entity and all related lookup display fields is retrieved from the database in a single join.

If the user can change the data, no additional steps are required. If the user changes the value of a foreign key attribute, the reference information is automatically retrieved for the new, related row in the associated table.

## G.1.2 How to Get the Sysdate from the Database

In Oracle Forms, when you wanted to get the current date and time, you retrieved the `sysdate` from the database. In Oracle ADF, you also have the option of getting the system date using a Java method or a Groovy expression.

### Implementation of the task in Oracle ADF

To get the system date from the database, you can use the following Groovy expression at the entity level:

```
DBTransaction.currentDbTime
```

---

---

**Note:** The `DBTransaction` reference is for entity-level Groovy expressions only.

---

---

If you want to assign a default value to an attribute using this Groovy expression, see [Section 4.10.7, "How to Define a Default Value Using a Groovy Expression."](#)

To get the system date from Java, you call the `getCurrentDate()` method. For more information, see [Section 8.10, "Accessing the Current Date and Time."](#)

## G.1.3 How to Implement an Isolation Mode That Is Not Read Consistent

In Oracle Forms, you might have been concerned with *read consistency*, that is, the ability of the database to deliver the state of the data at the time the SQL statement was issued.

### Implementation of the task in Oracle ADF

If you use an entity-based view object, the query sees the changes currently in progress by the current user's session in the pending transaction. This is the default behavior, and the most accurate.

If instead, you want a snapshot of the data on the database without considering the pending changes made by the current user, you can use a read-only view object and reexecute the query to see the latest committed database values. For more information on read-only view objects, see [Section 5.2.3, "How to Create an Expert Mode, Read-Only View Object."](#)

## G.1.4 How to Implement Calculated Fields

Calculated fields are often used to show the sum of two values, but they could also be used for the concatenated value of two or more fields, or the result of a method call.

### Implementation of the task in Oracle ADF

Calculated attributes are usually not stored in the database, as their values can easily be obtained programmatically. Attributes that are used in the middle tier, but that are not stored in the database are called *transient attributes*. Transient attributes can be defined at the entity object level or the view object level.

If a transient attribute will be used by more than one view object that might be based on an entity object, then define the attribute at the entity object level. Otherwise, define the transient attribute at the view object level for a particular view object.

To define transient attributes at the entity object level, see [Section 4.11, "Adding Transient and Calculated Attributes to an Entity Object."](#) To define transient attributes at the view object level, see [Section 5.14, "Adding Calculated and Transient Attributes to a View Object."](#)

## G.1.5 How to Implement Mirrored Items

In Oracle Forms, you may be used to using mirrored items to show two or more fields that share identical values.

### Implementation of the task in Oracle ADF

There is no need to have mirrored items in Oracle ADF, because the UI and data are separated. The same view object can appear on any number of pages, so you don't need to create mirrored items that have the same value. Likewise, a form could have the same field represented in more than one place and it would not have to be mirrored.

## G.1.6 How to Use Database Columns of Type CLOB or BLOB

If you are used to working with standard database types, you may be wondering how to use the CLOB and BLOB types in Oracle ADF.

### Implementation of the task in Oracle ADF

In Oracle ADF, use the built-in data types `ClobDomain` or `BlobDomain`. These are automatically created when you reverse-engineer entity objects or view objects from existing tables with these column types. ADF Business Components also supports data types for Intermedia column types: `OrdImage`, `OrdAudio`, `OrdDoc`, and `OrdVideo`. For more information, see [Section 4.10.1, "How to Set Database and Java Data Types for an Entity Object Attribute."](#)

## G.2 Performing Tasks Related to the User Interface

In Oracle ADF, common UI-related tasks (such as master-detail screens, popup list of values, and page layout) are handled quite differently than they were in Oracle Forms. This section describes how to perform some common Oracle Forms tasks that relate to the UI with Oracle ADF.

### G.2.1 How to Lay Out a Page

Oracle Forms is based on an absolute pixel or point-based layout, as compared to the container-based approach of JSF, and the Layout Manager approach in ADF Swing.

### **Implementation of the task in Oracle ADF**

See the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework* for information on how to lay out a page in Oracle ADF.

## **G.2.2 How to Stack Canvases**

In Oracle Forms, stacked canvases were often used to hide and display areas of the screen.

### **Implementation of the task in Oracle ADF**

The analog of stacked canvases in Oracle ADF is panels (layout containers) with the rendered property set to `true` or `false`. See the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework* for more information.

## **G.2.3 How to Implement a Master-Detail Screen**

Master-detail relationships in Oracle ADF are coordinated through a view link. A view link is conceptually similar to a Oracle Forms *relation*.

### **Implementation of the task in Oracle ADF**

For information on how create view links, see [Section 5.6, "Working with Multiple Tables in a Master-Detail Hierarchy."](#) Once you have established a relationship between two view objects with a view link, see [Section 5.6.4, "How to Enable Active Master-Detail Coordination in the Data Model."](#)

## **G.2.4 How to Implement an Enter Query Screen**

In Oracle Forms, another common task was creating an *enter query screen*. That is, a screen that starts in Find mode.

### **Implementation of the task in Oracle ADF**

In Oracle ADF, this accomplished with a search form. Complete information on how to create a search form is covered in [Chapter 31, "Creating ADF Databound Search Forms."](#) In particular, you may want to look at [Section 31.3.1, "How to Set Search Form Properties on the View Criteria."](#)

## **G.2.5 How to Implement an Updatable Multi-Record Table**

In Oracle Forms, you may be used to creating tables where you can edit and insert many records at the same time. This can be slightly more complicated when using a JSF page in Oracle ADF, because the operations to edit an existing record and to create a new record are not the same.

### **Implementation of the task in Oracle ADF**

In Oracle ADF, this is done using an input table. To create an input table, see [Section 27.4, "Creating an Input Table."](#)

## **G.2.6 How to Create a Popup List of Values**

In Oracle Forms, it was simple to create a list of values (LOV) object and then associate that object with a field in a declarative manner. This LOV would display a popup window and provide the following capabilities:

- Selection of modal values
- Query area at the top of the LOV dialog
- Display of multiple columns
- Automatic reduction of LOV contents, possibly based on the contents of the field that launched the LOV
- Automatic selection of the list value when only one value matches the value in the field when the LOV function is invoked
- Validation of the field value based on the values cached by the LOV
- Automatic popup of the LOV if the field contents are not valid

#### **Implementation of the task in Oracle ADF**

To implement a popup list in Oracle ADF, you configure one of the view object's attributes to be of LOV type, and select **Input Text with List of Values** as the style for its UI hint. For a description of how to do this, see [Section 5.12, "Working with List of Values \(LOV\) in View Object Attributes."](#)

### **G.2.7 How to Implement a Dropdown List as a List of Values**

In Oracle Forms, you could create a list of values (LOV) object and then associate that object with a field in a declarative manner. In Oracle ADF, you can implement an LOV (lookup-value) screen with a search item, usable for a lookup field with many possible values.

#### **Implementation of the task in Oracle ADF**

To implement a dropdown list in Oracle ADF, you configure one of the view object's attributes to be of LOV type, and select **Input Text with List of Values** as the style for its UI hint. For a description of how to do this, see [Section 5.12, "Working with List of Values \(LOV\) in View Object Attributes."](#)

### **G.2.8 How to Implement a Dropdown List with Values from Another Table**

In Oracle Forms, you could create a list of values (LOV) object and then associate that object with a field in a declarative manner. In Oracle ADF, you can implement a dropdown list with string values from a different table. These string values populate the field with an id code that is valid input in the table that the screen is based on.

#### **Implementation of the task in Oracle ADF**

To implement a dropdown list of this type in Oracle ADF, you configure one of the view object's attributes to be of LOV type, and select **Choice List** as the style for its UI hint. For a description of how to do this, see [Section 5.12, "Working with List of Values \(LOV\) in View Object Attributes."](#)

### **G.2.9 How to Implement Immediate Locking**

In Oracle ADF, you can lock a record in the database at the first moment it is obvious that the user is going to change a specific record.

#### **Implementation of the task in Oracle ADF**

Immediate row locking can be configured in ADF Business Components, although it is not the default and is typically not used in web application scenarios. For web applications, use the default configuration setting

`jbo.locking.mode=optimistic`. For more information, see [Section 43.11.1, "How to Confirm That Applications Use Optimistic Locking."](#)

## G.2.10 How to Throw an Error When a Record Is Locked

When a record has been locked by a user, it's helpful to throw an error to let other users know that the record is not currently updatable.

### Implementation of the task in Oracle ADF

Locking rows and throwing an exception if the row is already locked is built-in ADF Business Components functionality. There are a couple of different ways that you can handle the error message, depending on whether you want a static error message or a custom message with information about the current row.

- To throw a static message, register a custom message bundle in your data model project to substitute the default `RowAlreadyLockedException`'s error message with something more meaningful or user-friendly.
- To throw a message that contains information about the row, override the `lock()` method on the entity object, using a try/catch block to catch the `RowAlreadyLocked` exception. After you catch the exception, you can throw an error message that might contain more specific information about the current row.

# Data Controls in Fusion Web Applications

This appendix provides a brief description of the various types of data controls available for Fusion web applications built with Oracle ADF. It also presents a brief comparison of how data access features are implemented for each type of data control.

This appendix contains the following sections:

- [Section H.1, "Introduction to Data Controls"](#)
- [Section H.2, "Data Control Feature Implementation Comparison"](#)
- [Section H.3, "Data Control Objects"](#)

## H.1 Introduction to Data Controls

A data control is essentially a bridge that makes data from a source available to the user interface in a Fusion web application. You can use the objects in the data control to create databound user interface components.

The most commonly used types of data controls include the following:

- **ADF Business Components Data Control**

This type of data control is generated by JDeveloper when you create an application module in your ADF Business Components application.

For more information, see [Section 13.4, "Using the Data Controls Panel."](#)
- **JavaBean Data Control**

This type of data control obtains the structure of the data from POJOs (plain, old Java objects).

To create a JavaBean data control, right-click a Java class file (in the Application Navigator), and choose Create Data Control.

For information about the data control objects available in a JavaBean data control, see [Section H.3, "Data Control Objects."](#)
- **EJB Data Control**

The EJB data control is essentially the same as the JavaBean data control, except that it uses features inherent in the EJB architecture to obtain the structure of the data.

You can create an EJB data control from the New Gallery. Expand the **Business Tier** node, select **Data Controls**, choose **EJB Data Control**, and click **OK**.

For information about the data control objects available in an EJB data control, see the *Oracle Fusion Middleware Java EE Developer's Guide for Oracle Application Development Framework*.

- URL Service Data Control

A URL service data control lets you access and consume the data stream from a specified URL. This type of data control is not updateable.

You can create a URL Service data control from the New Gallery. Expand the **Business Tier** node, select **Data Controls**, choose **URL Service Data Control**, and click **OK**.

For information about the data control objects available in a URL Service data control, see [Section 15.2, "Exposing URL Services with ADF Data Controls."](#)

- Web Service Data Control

A Web Service data control obtains the structure of the data from the WSDL for a web service.

You can create a Web Service data control from the New Gallery. Expand the **Business Tier** node, select **Data Controls**, choose **Web Service Data Control**, and click **OK**.

For more information, see [Section 14.2, "Creating Web Service Data Controls."](#)

- JMX Data Control

A JMX data control obtains the structure of the JMX MBeans from an MBean Server.

You can create a JMX data control from the New Gallery. Expand the **Business Tier** node, select **Data Controls**, choose **JMX Data Control**, and click **OK**. For more information about creating a JMX data control, see the online help for the Create JMX Data Control wizard.

Before you can create a JMX data control, you must first have a JMX connection. For more information about JMX connections, see the online help for the Create JMX Connection dialog.

For information about the data control objects available in a JMX data control, see [Section H.3, "Data Control Objects."](#)

- Placeholder Data Control

A placeholder data control is a special type of data control that doesn't require a traditional data structure. As the name implies, it is a placeholder that can be used during UI development, and then replaced with the real data control when it becomes available.

You can create a Placeholder data control from the New Gallery. Expand the **Business Tier** node, select **Data Controls**, choose **Placeholder Data Control**, and click **OK**.

For more information, see [Chapter 17, "Designing a Page Using Placeholder Data Controls."](#)

## H.2 Data Control Feature Implementation Comparison

The type of data control that you choose to use will impact how you implement data access features. [Table H-1](#) provides a comparison of how you implement some commonly used data access features for each type of data control.

**Table H–1 Comparison of Feature Implementation in Data Controls**

	<b>ADF Business Components Data Control</b>	<b>JavaBean Data Control</b>	<b>EJB Data Control</b>	<b>Web Services Data Control</b>	<b>URL Service Data Control</b>	<b>JMX Data Control</b>	<b>Placeholder Data Control</b>
af:Query	Declarative	Declarative	Declarative	Implemented programmatically	Not available	Not available	Not available
af:quickQuery	Declarative	Declarative	Declarative	Implemented programmatically	Not available	Not available	Not available
af:inputCombo ListOfValues	Declarative	Declarative	Declarative	Implemented programmatically	Not available	Not available	Declarative
af:Calendar	Declarative	Implemented programmatically	Implemented programmatically	Implemented programmatically	Not available	Not available	Not available
af:Media	Declarative	Implemented programmatically	Implemented programmatically	Implemented programmatically	Not available	Not available	Not available

The features that are listed in the table as "implemented programmatically" can be implemented using the necessary Java classes required to implement a business model that can be used by the specific data-entry component. For more information, refer to the Javadoc for the appropriate classes.

### H.3 Data Control Objects

In the Data Controls panel, each data control object is represented by an icon. [Table H–2](#) describes what each icon represents, where it appears in the Data Controls panel hierarchy, and what components it can be used to create.

You can design a databound user interface by dragging an item from the Data Controls panel and dropping it on a page as a specific UI component.

The objects described in [Table H–2](#) are applicable to the JavaBean data control, the EJB data control, and the JMX data control, unless otherwise noted. For information about the data control objects available in the other types of data controls, refer to the documentation for the desired type of data control, as listed in [Section H.1, "Introduction to Data Controls."](#)

**Table H-2 Data Controls Panel Icons and Object Hierarchy for JavaBeans and EJBs**

Icon	Name	Description	Used to Create...
	Data Control	Represents a data control. You cannot use the data control itself to create UI components, but you can use the child objects listed under the data control. There may be more than one data control, each representing a logical grouping of data functions.  Typically, there is one data control for a given source (bean or EJB). However, you may have additional data controls that were created for other types of objects (for example, application modules or web services).	Serves as a container for the other objects. Not used to create anything.
	Create Method	Represents a built-in method that creates a new instance of an object in a data collection using the new Java constructor call. Create method icons are located in a node named after the data collection to which they belong. These data collection nodes are located in the <b>Constructors</b> node under the data control. The <b>Attributes</b> node, which appears as a child under a create method, contains all the attributes of the data collection. If the collection contains an attribute from another collection (called a <i>foreign key</i> in relational databases), that attribute is represented by an accessor return icon. In this case, the accessor returns a single object.  This object is not available in the JMX data control.	Creation forms.
	Method	Represents a custom method on the data control that may accept parameters, perform some action or business logic, and return data or data collections. If the method is a <i>get</i> method of a map and returns a data collection, a method return icon appears as a child under it. If a method requires a parameter, a folder appears under the method, which lists the required parameters.	UI actions such as buttons or links.
	Method Return	Represents a data collection that is returned by a custom method. A method return appears as a child under the method that returns it. The objects that appear as children under a method return may be attributes of the collection, accessor returns that represent collections related to the parent collection, other methods that perform actions related to the parent collection, and operations that can be performed on the parent collection.	Forms, tables, trees, and range navigation components.

**Table H-2 (Cont.) Data Controls Panel Icons and Object Hierarchy for JavaBeans and EJBs**

Icon	Name	Description	Used to Create...
	Accessor Return	<p>Represents an object returned by a bean-style accessor method on the business service. An accessor method is used when the objects returned are JavaBeans. Accessor returns appear as children under method returns, other accessor returns, or in the <b>Attributes</b> node under built-in create methods. Accessor returns are objects that are related to the current object in the parent collection. This relationship is usually based on a common unique attribute in both objects. For example, if a method returns a collection of users, an accessor return that is a child of that collection might be a collection of service requests that are assigned to a particular user. In ADF, the relationship between parent and child collections is called a master-detail relationship. For more information about master-detail objects, see <a href="#">Chapter 29, "Displaying Master-Detail Data."</a></p> <p>Accessor returns can be either collections or single objects. For example, if a method returns a collection of service requests, one accessor return under that method might be a collection of service history details for the current service request, while another accessor return might be a single user assigned to the current service request. By default, when data controls are created from session beans over POJOs, the names of accessors that return collections end in <code>Collection</code> (for example, <code>OrderCollection</code>). The UI components available from the Data Controls panel context menu differ depending on whether the accessor return is a collection or a single object.</p> <p>The children under an accessor return may be attributes of the collection or object, other accessor returns, custom methods that return a value from the collection or object, and operations that can be performed on the collection or object. The accessor returns under a built-in create method are always a single object and never have any children.</p>	<p>For collections: Forms, tables, trees, range navigation components, and master-detail widgets.</p> <p>For single objects: Forms, master-detail widgets, and selection lists.</p> <p>For single objects under a constructor: selection lists only.</p>
	Attribute	Represents a discrete data element in an object. Attributes appear as children under method returns or accessor returns.	Label, text field, and selection list components.
	Operation	Represents a built-in data control operation that performs actions on the parent object. If an operation requires a parameter, a folder appears under the method, which lists the required parameters. Data control operations are located in an <b>Operations</b> node under method returns or accessor returns and under the root data control node. The operations that are children of a particular method or accessor return operate on that return object only, while operations under the data control node operate on all the objects represented by the data control.	UI actions such as buttons or links.
	Parameter	Represents a parameter value that is declared by the method or operation under which it appears. Parameters appear in a folder under a method or operation.	Label, text, and selection list components.

---

---

# Glossary

## **action binding**

A binding for command components, such as buttons or links, to built-in or custom methods on the [data control](#), or to built-in collection-level operations (such as, Create, Delete, Next, or Previous). An action binding object encapsulates the details of how to invoke a method and what parameters (if any) the method is expecting.

## **activity**

A piece of work that is performed when an ADF Controller [task flow](#) runs, for example, a method call or view.

## **ADF**

See [Oracle ADF](#).

## **ADF binding filter**

A servlet filter that ADF web applications use to preprocess any HTTP requests that may require access to the binding context.

## **ADF Business Components**

A framework that simplifies the development, delivery, and customization of business applications for the Java 2 Platform. You use ADF Business Components to define associations between [entity objects](#), [view objects](#), and [application modules](#) to reflect the foreign keys present in the underlying tables.

## **ADF Controller layer**

A mechanism that provides an enhanced navigation and state management model on top of JSF. This mechanism declaratively defines navigation using control flow rules.

## **ADF Faces Rich Client (RC)**

A set of standard JSF components that include built-in AJAX functionality.

## **ADF Model layer**

A layer that implements JSR-227 service abstraction called the [data control](#).

## **application module**

A transactional component that UI clients use to work with application data. It defines an updatable data model and top-level procedures and functions (called *service methods*) related to a logical unit of work. This unit of work is related to an end-user task.

**binding context**

A container object that holds a list of available [data controls](#) and data binding objects. The `DataBindings.cpx` files define the binding context for the application. See also [data control](#).

**bounded task flow**

A specialized form of ADF Controller task flow that has a single entry point and zero or more exit points. It contains its own set of private, [control flow](#) rules, activities, and managed beans. A bounded task flow allows reuse, parameters, transaction management, and reentry. When dropped on a page, it becomes a [region](#).

**control flow**

An ADF Controller activity that enables navigation between other activities in an ADF task flow. The control flow links one [activity](#) to another in a [task flow](#).

**data control**

XML configuration files that describe a service. At design time, visual tools like JDeveloper can leverage that metadata to UI component to be declaratively bound to an operation or data collection.

**Data Controls panel**

A panel in JDeveloper that lists all the [data controls](#) that have been created for the application's business services and exposes all the collections (row sets of data objects), methods, and built-in operations that are available for binding to UI components.

**entity object**

An object that represents a row in a database table and that simplifies modifying its data by handling all data manipulation language operations for you. Entity objects are [ADF Business Components](#) that provide the mapping to underlying data structures.

**invoke action**

An action that binds to a method that invokes the operations or methods defined in an action or a method action binding during any phase of the page lifecycle. See also [action binding](#).

**iterator binding**

A binding to an iterator that iterates over view object collections. There is one iterator binding for each collection used on the page. All of the value bindings on the page must refer to an iterator binding in order for the component values to be populated with data at runtime.

Contrast with [variable iterator](#) and [method iterator](#).

**list of values (LOV)**

See [LOV](#).

**LOV**

Input components that allow a user to enter values by picking from a list that is generated by a query

**MDS**

An application server and Oracle relational database that keep metadata in these areas: a file-based repository data, dictionary tables (accessed by built-in functions) and a

---

metadata registry. One of the primary uses of MDS is to store customizations and persisted personalization for Oracle applications

**method iterator**

A binding to an iterator that iterates over the collections returned by custom methods in the data control. An iterator binding that is always related to a method [action binding](#) object. The method action binding encapsulates the details about how to invoke the method and what parameters the method is expecting. The method action binding is itself bound to the method iterator, which provides the data.

**Oracle ADF**

An end-to-end application framework that builds on Java Platform, Enterprise Edition standards and open-source technologies to simplify and accelerate implementing service-oriented applications.

**Oracle Application Development Framework (Oracle ADF)**

See [Oracle ADF](#).

**Oracle Metadata Services (MDS)**

See [MDS](#).

**page definition file**

A file that defines the binding objects that populate the data in UI components at runtime. For every page that has ADF bindings, there must be a corresponding page definition file that defines the binding objects used by that page.

**region**

An ADF Controller UI component whose content is based on a [task flow](#) definition. When first rendered, the region's content is that of the first view activity in a task flow. See also [activity](#).

**task flow**

A set of ADF Controller activities, [control flow](#) rules and managed beans that interact to allow a user to complete a task.

**unbounded task flow**

A set of activities, ADF [control flow](#) rules, and managed beans that interact to allow a user to complete a task. An unbounded task flow has a single point of entry.

**value binding**

A binding used by ADF view UI components that display data. Value bindings range from the most basic variety that work with a simple text field to more sophisticated list and tree bindings that support the additional needs of list, table, and tree UI controls.

**value iterator**

An ADF Model iterator pointing to a collection that contains only one data object whose attributes are the binding container variable. Contrast with [method iterator](#) and [value iterator](#) iterator.

**variable iterator**

A binding to an iterator that exposes all the variables in the binding container to the other bindings. While there is an iterator binding for each collection, there is only one

variable iterator binding for all variables used on the page. Contrast with [method iterator](#) and [value iterator](#) iterator.

**view accessor**

An ADF Business Components object that points from an entity object attribute (or [view object](#)) to a destination view object or shared view instance in the same application workspace. The view accessor returns a row set that by default contains all the rows from the destination view object.

**view object**

An ADF Business Components object that represents a SQL query and simplifies working with its results. The SQL language is used to join, project, filter, sort, and aggregate data into the shape required by the end-user task being represented in the user interface.
