Preface

The Modular Debugger (MDB) is a new general purpose debugging tool for the Solaris™ Operating Environment. Its primary feature is its extensibility. The Solaris Modular Debugger Guide describes how to use MDB to debug complex software systems, with a particular emphasis on the facilities available for debugging the Solaris kernel and associated device drivers and modules. It also includes a complete reference for and discussion of the MDB language syntax, debugger features, and MDB Module Programming API.

Who Should Use This Book

If you were a detective and were investigating at the scene of a crime, you might interview the witnesses and ask them to describe what happened and who they saw. However, if there were no witnesses or these descriptions proved insufficient, you might consider collecting fingerprints and forensic evidence that could be examined for DNA to help solve the case. Often, software program failures divide into analogous categories: problems that can be solved with source-level debugging tools, and problems that require low-level debugging facilities, examination of core files, and knowledge of assembly language to diagnose and correct. MDB is a debugger designed to facilitate analysis of this second class of problems.

It might not be necessary to use MDB in every case, just as a detective doesn’t need a microscope and DNA evidence to solve every crime. However, when programming a complex low-level software system such as an operating system, these situations can occur frequently. As a result, MDB is designed as a debugging framework that allows you to construct your own custom analysis tools to aid in the diagnosis of these problems. MDB also provides a powerful set of built-in commands that allow you to analyze the state of your program at the assembly language level.
If you are not familiar with assembly language programming and debugging, “Related Books and Papers” on page 11 provides references to materials that you might find useful.

You should also disassemble various functions of interest in the programs you will be debugging in order to familiarize yourself with the relationship between your program’s source code and the corresponding assembly language code. If you are planning to use MDB for debugging Solaris kernel software, you should read carefully Chapter 7 and Chapter 8. These chapters provide more detailed information on the MDB commands and facilities provided for debugging Solaris kernel software.

How This Book Is Organized

Chapter 1 provides an overview of the debugger. This chapter is intended for all users.

Chapter 2 describes the MDB architecture and explains the terminology for the debugger concepts used throughout this book. This chapter is intended for all users.

Chapter 3 describes the syntax, operators and evaluation rules for the MDB language. This chapter is intended for all users.

Chapter 4 describes the MDB interactive command-line editing facilities and output pager. This chapter is intended for all users.

Chapter 5 describes the set of built-in debugger commands that are always available. This chapter is intended for all users.

Chapter 6 describes the MDB facilities for controlling the execution of live running user processes. This chapter is intended for user application programmers and system administrators.

Chapter 7 describes the set of loadable debugger commands that are provided for debugging the Solaris kernel. This chapter is intended for users who intend to examine Solaris kernel crash dumps and for kernel software developers.

Chapter 8 describes the debugging features of the Solaris kernel memory allocator and the MDB commands provided to take advantage of these features. This chapter is intended for advanced programmers and kernel software developers.

Chapter 9 describes the facilities for writing loadable debugger modules. This chapter is intended for advanced programmers and software developers who intend to develop custom debugging support for MDB.

Appendix A provides a reference for MDB command-line options.

Appendix B provides warnings and notes about using the debugger.
Appendix C provides a reference for `adb(1M)` commands and their MDB equivalents.

Appendix D provides a reference for `crash(1M)` commands and their MDB equivalents.

### Related Books and Papers

These books and papers are recommended and related to the tasks that you need to perform:

- **Writing Device Drivers.** Sun Microsystems, 2000.

---

**Note** – In this document, the term “IA” refers to the Intel 32-bit processor architecture, which includes the Pentium, Pentium Pro, Pentium II, Pentium II Xeon, Celeron, Pentium III, and Pentium III Xeon processors, and compatible microprocessor chips made by AMD and Cyrix.
Note – The Solaris operating environment runs on two types of hardware, or platforms—SPARC™ and IA. The Solaris operating environment also runs on both 64-bit and 32-bit address spaces. The information in this document pertains to both platforms and address spaces unless called out in a special chapter, section, note, bullet, figure, table, example, or code example.

Accessing Sun Documentation Online

The docs.sun.comSM Web site enables you to access Sun technical documentation online. You can browse the docs.sun.com archive or search for a specific book title or subject. The URL is http://docs.sun.com.

What Typographic Conventions Mean

The following table describes the typographic changes used in this book.

CHAPTER 1

Modular Debugger Overview

The Modular Debugger (MDB) is a general purpose debugging tool for Solaris whose primary feature is its extensibility. This book describes how to use MDB to debug complex software systems, with a particular emphasis on the facilities available for debugging the Solaris kernel and associated device drivers and modules. The book also includes a complete reference for and discussion of the MDB language syntax, debugger features, and MDB Module Programming API.

Introduction

Debugging is the process of analyzing the execution and state of a software program in order to remove defects. Traditional debugging tools provide facilities for execution control so that programmers can re-execute programs in a controlled environment and display the current state of program data or evaluate expressions in the source language used to develop the program. Unfortunately, these techniques are often inappropriate for debugging complex software systems such as:

- An operating system, where bugs might not be reproducible and program state is massive and distributed
- Programs that are highly optimized or have had their debug information removed
- Programs that are themselves low-level debugging tools
- Customer situations where the developer can only access post-mortem information

MDB is a tool that provides a completely customizable environment for debugging these programs and scenarios, including a dynamic module facility that programmers can use to implement their own debugging commands to perform program-specific analysis. Each MDB module can be used to examine the program in several different contexts, including live and post-mortem. The Solaris Operating Environment
includes a set of MDB modules designed to aid programmers in debugging the Solaris
kernel and related device drivers and kernel modules. Third-party developers might
find it useful to develop and deliver their own debugging modules for supervisor or
user software.

**MDB Features**

MDB provides an extensive collection of features for analyzing the Solaris kernel and
other target programs. You can:

- Perform post-mortem analysis of Solaris kernel crash dumps and user process core
dumps: MDB includes a collection of debugger modules that facilitate
sophisticated analysis of kernel and process state, in addition to standard data
display and formatting capabilities. The debugger modules allow you to formulate
complex queries to:
  - Locate all the memory allocated by a particular thread
  - Print a visual picture of a kernel STREAM
  - Determine what type of structure a particular address refers to
  - Locate leaked memory blocks in the kernel
  - Analyze memory to locate stack traces

- Use a first-class programming API to implement your own debugger commands
  and analysis tools without having to recompile or modify the debugger itself. In
  MDB, debugging support is implemented as a set of loadable modules (shared
  libraries that the debugger can dlopen(3DL)), each of which provides a set of
  commands that extends the capabilities of the debugger itself. The debugger in
  turn provides an API of core services, such as the ability to read and write memory
  and access symbol table information. MDB provides a framework for developers to
  implement debugging support for their own drivers and modules; these modules
can then be made available for everyone to use.

- Learn to use MDB if you are already familiar with the legacy debugging tools
  adb(1) and crash(1M): MDB provides backward compatibility with these
  existing debugging solutions. The MDB language itself is designed as a superset of
  the adb language; all existing adb macros and commands work within MDB so
developers who use adb can immediately use MDB without knowing any
MDB-specific commands. MDB also provides commands that surpass the
functionality available from the crash utility.

- Benefit from enhanced usability features. MDB provides a host of usability
  features, including:
  - Command-line editing
  - Command history
  - Built-in output pager
  - Syntax error checking and handling
Future Enhancements

MDB provides a stable foundation for developing advanced post-mortem analysis tools. In the future, the Solaris operating environment will include additional MDB modules that provide even more sophisticated functionality for debugging the kernel and other software programs. You can use MDB to debug existing software programs, and develop your own modules to improve your ability to debug your own Solaris drivers and applications.
Debugger Concepts

This section discusses the significant aspects of MDB’s design, and the benefits derived from this architecture.

Architecture

FIGURE 2–1 MDB architecture
Building Blocks

The target is the program being inspected by the debugger. MDB currently provides support for the following types of targets:

- User processes
- User process core files
- Live operating system (through /dev/kmem and /dev/ksyms)
- Operating system crash dumps
- User process images recorded inside an operating system crash dump
- ELF object files
- Raw data files

Each target exports a standard set of properties, including one or more address spaces, one or more symbol tables, a set of load objects, and a set of threads. Figure 2–1 shows an overview of the MDB architecture, including two of the built-in targets and a pair of sample modules.

A debugger command, or dcmd (pronounced dee-command) in MDB terminology, is a routine in the debugger that can access any of the properties of the current target. MDB parses commands from standard input, then executes the corresponding dcmds. Each dcmd can also accept a list of string or numerical arguments, as shown in “Syntax” on page 23. MDB contains a set of built-in dcmds described in Chapter 5, that are always available. The programmer can also extend the capabilities of MDB itself by writing dcmds using a programming API provided with MDB.

A walker is a set of routines that describe how to walk, or iterate, through the elements of a particular program data structure. A walker encapsulates the data structure’s implementation from dcmds and from MDB itself. You can use walkers interactively, or use them as a primitive to build other dcmds or walkers. As with dcmds, the programmer can extend MDB by implementing additional walkers as part of a debugger module.

A debugger module, or dmod (pronounced dee-mod), is a dynamically loaded library containing a set of dcmds and walkers. During initialization, MDB attempts to load dmods corresponding to the load objects present in the target. You can subsequently load or unload dmods at any time while running MDB. MDB provides a set of standard dmods for debugging the Solaris kernel.

A macro file is a text file containing a set of commands to execute. Macro files are typically used to automate the process of displaying a simple data structure. MDB provides complete backward compatibility for the execution of macro files written for adb. The set of macro files provided with the Solaris installation can therefore be used with either tool.
Modularity

The benefit of MDB’s modular architecture extends beyond the ability to load a shared library containing additional debugger commands. The MDB architecture defines clear interface boundaries between each of the layers shown in Figure 2–1. Macro files execute commands written in the MDB or adb language. Dcmds and walkers in debugger modules are written using the MDB Module API, and this forms the basis of an application binary interface that allows the debugger and its modules to evolve independently.

The MDB name space of walkers and dcmds also defines a second set of layers between debugging code that maximizes code sharing and limits the amount of code that must be modified as the target program itself evolves. For example, one of the primary data structures in the Solaris kernel is the list of proc_t structures representing active processes in the system. The ::ps dcmd must iterate over this list in order to produce its output. However, the code to iterate over the list is not in the ::ps dcmd, it is encapsulated in the genunix module’s proc walker.

MDB provides both ::ps and ::ptree dcmds, but neither has any knowledge of how proc_t structures are accessed in the kernel. Instead, they invoke the proc walker programmatically and format the set of returned structures appropriately. If the data structure used for proc_t structures ever changed, MDB could provide a new proc walker and none of the dependent dcmds would need to change. The proc walker can also be accessed interactively using the ::walk dcmd in order to create novel commands as you work during a debugging session.

In addition to facilitating layering and code sharing, the MDB Module API provides dcmds and walkers with a single stable interface for accessing various properties of the underlying target. The same API functions are used to access information from user process or kernel targets, simplifying the task of developing new debugging facilities.

In addition, a custom MDB module can be used to perform debugging tasks in a variety of contexts. For example, you might want to develop an MDB module for a user program you are developing. Once you have done so, you can use this module when MDB examines a live process executing your program, a core dump of your program, or even a kernel crash dump taken on a system where your program was executing.

The Module API provides facilities for accessing the following target properties:

Address Spaces The module API provides facilities for reading and writing data from the target’s virtual address space. Functions for reading and writing using physical addresses are also provided for kernel debugging modules.
Symbol Tables
The module API provides access to the static and dynamic symbol tables of the target’s primary executable file, its runtime link-editor, and a set of load objects (shared libraries in a user process or loadable modules in the Solaris kernel).

External Data
The module API provides a facility for retrieving a collection of named external data buffers associated with the target. For example, MDB provides programmatic access to the proc(4) structures associated with a user process or user core file target.

In addition, you can use built-in MDB dcmds to access information about target memory mappings, load objects, register values, and control the execution of user process targets.
This chapter describes the MDB language syntax, operators, and rules for command and symbol name resolution.

Syntax

The debugger processes commands from standard input. If standard input is a terminal, MDB provides terminal editing capabilities. MDB can also process commands from macro files and from dcmd pipelines, described below. The language syntax is designed around the concept of computing the value of an expression (typically a memory address in the target), and applying a dcmd to that address. The current address location is referred to as dot, and "." is used to reference its value.

A metacharacter is one of the following characters:

```
[ ] | ! / \ ? = > $ ; NEWLINE SPACE TAB
```

A blank is a TAB or a SPACE. A word is a sequence of characters separated by one or more non-quoted metacharacters. Some of the metacharacters function only as delimiters in certain contexts, as described below. An identifier is a sequence of letters, digits, underscores, periods, or back quotes beginning with a letter, underscore, or period. Identifiers are used as the names of symbols, variables, dcmds, and walkers. Commands are delimited by a NEWLINE or semicolon ( ; ).

A dcmd is denoted by one of the following words or metacharacters:

```
/ \ ? = > $ character : character :: identifier
```

dcmds named by metacharacters or prefixed by a single $ or : are provided as built-in operators, and implement complete compatibility with the command set of the legacy adb(1) utility. After a dcmd has been parsed, the /, \, ?, =, >, $, and : characters are no longer recognized as metacharacters until the termination of the argument list.
A simple-command is a dcmd followed by a sequence of zero or more blank-separated words. The words are passed as arguments to the invoked dcmd, except as specified under “Arithmetic Expansion” on page 25 and “Quoting” on page 27. Each dcmd returns an exit status that indicates it was either successful, failed, or was invoked with invalid arguments.

A pipeline is a sequence of one or more simple commands separated by |. Unlike the shell, dcmds in MDB pipelines are not executed as separate processes. After the pipeline has been parsed, each dcmd is invoked in order from left to right. Each dcmd’s output is processed and stored as described in “dcmd Pipelines” on page 31. After the left-hand dcmd is complete, its processed output is used as input for the next dcmd in the pipeline. If any dcmd does not return a successful exit status, the pipeline is aborted.

An expression is a sequence of words that is evaluated to compute a 64-bit unsigned integer value. The words are evaluated using the rules described in “Arithmetic Expansion” on page 25.

Commands

A command is one of the following:

pipeline [ ! word ... ] [ ; ]
A simple-command or pipeline can be optionally suffixed with the ! character, indicating that the debugger should open a pipe(2) and send the standard output of the last dcmd in the MDB pipeline to an external process created by executing $SHELL -c followed by the string formed by concatenating the words after the ! character. For more details, refer to “Shell Escapes” on page 28.

expression pipeline [ ! word ... ] [ ; ]
A simple-command or pipeline can be prefixed with an expression. Before execution of the pipeline, the value of dot (the variable denoted by “.”) is set to the value of the expression.

expression, expression pipeline [ ! word ... ] [ ; ]
A simple-command or pipeline can be prefixed with two expressions. The first is evaluated to determine the new value of dot, and the second is evaluated to determine a repeat count for the first dcmd in the pipeline. This dcmd will be executed count times before the next dcmd in the pipeline is executed. The repeat count applies only to the first dcmd in the pipeline.

expression pipeline [ ! word ... ] [ ; ]
If the initial expression is omitted, dot is not modified; however, the first dcmd in the pipeline will be repeated according to the value of the expression.
expression [ ! word ... ] [ ; ]

A command can consist only of an arithmetic expression. The expression is evaluated and the dot variable is set to its value, then the previous dcmd and arguments are executed using the new value of dot.

eexpression , expression [ ! word ... ] [ ; ]

A command can consist only of a dot expression and repeat count expression. After dot is set to the value of the first expression, the previous dcmd and arguments are repeatedly executed the number of times specified by the value of the second expression.

, expression [ ! word ... ] [ ; ]

If the initial expression is omitted, dot is not modified but the previous dcmd and arguments are repeatedly executed the number of times specified by the value of the count expression.

! word ... [ ; ]

If the command begins with the ! character, no dcmds are executed and the debugger executes $SHELL -c followed by the string formed by concatenating the words after the ! character.

Comments

A word beginning with // causes that word and all the subsequent characters up to a NEWLINE to be ignored.

Arithmetic Expansion

Arithmetic expansion is performed when an MDB command is preceded by an optional expression representing a start address, or a start address and a repeat count. Arithmetic expansion can also be performed to compute a numerical argument for a dcmd. An arithmetic expression can appear in an argument list enclosed in square brackets preceded by a dollar sign ($[ expression ]), and will be replaced by the value of the expression.

Expressions can contain any of the following special words:

integer

The specified integer value. Integer values can be prefixed with 0i or 0I to indicate binary values, 0o or 0O to indicate octal values, 0t or 0T to indicate decimal values, and 0x or 0X to indicate hexadecimal values (the default).
The specified decimal floating point value, converted to its IEEE double-precision floating point representation

The integer value computed by converting each character to a byte equal to its ASCII value. Up to eight characters can be specified in a character constant. Characters are packed into the integer in reverse order (right-to-left), beginning at the least significant byte.

The value of the variable named by identifier

The value of the symbol named by identifier

The value of expression

The value of dot

The most recent value of dot used to execute a dcmd

The value of dot incremented by the current increment

The value of dot decremented by the current increment

The increment is a global variable that stores the total bytes read by the last formatting dcmd. For more information on the increment, refer to the discussion of “Formatting dcmds” on page 32.

### Unary Operators

Unary operators are right associative and have higher precedence than binary operators. The unary operators are:

- `#expression` Logical negation
- `~expression` Bitwise complement
- `-expression` Integer negation
- `%expression` Value of a pointer-sized quantity at the object file location corresponding to virtual address \( \text{expression} \) in the target’s virtual address space
- `%/[csil]/expression` Value of a char-, short-, int-, or long-sized quantity at the object file location corresponding to virtual address \( \text{expression} \) in the target’s virtual address space
- `%/[1248]/expression` Value of a one-, two-, four-, or eight-byte quantity at the object file location corresponding to virtual address \( \text{expression} \) in the target’s virtual address space
- `*expression` Value of a pointer-sized quantity at virtual address \( \text{expression} \) in the target’s virtual address space
Binary Operators

Binary operators are left associative and have lower precedence than unary operators. The binary operators, in order of precedence from highest to lowest, are:

- `*` Integer multiplication
- `%` Integer division
- `#` Left-hand side rounded up to next multiple of right-hand side
- `+` Integer addition
- `-` Integer subtraction
- `<<` Bitwise shift left
- `>>` Bitwise shift right
- `==` Logical equality
- `!=` Logical inequality
- `&` Bitwise AND
- `^` Bitwise exclusive OR
- `|` Bitwise inclusive OR

Quoting

Each metacharacter described previously (see “Syntax” on page 23) terminates a word unless quoted. Characters can be quoted (forcing MDB to interpret each character as itself without any special significance) by enclosing them in a pair of single (‘) or double (”) quotation marks. A single quote cannot appear within single quotes. Inside double quotes, MDB recognizes the C programming language character escape sequences.
Shell Escapes

The ! character can be used to create a pipeline between an MDB command and the user’s shell. If the $SHELL environment variable is set, MDB will fork and exec this program for shell escapes; otherwise /bin/sh is used. The shell is invoked with the -c option followed by a string formed by concatenating the words after the ! character.

The ! character takes precedence over all other metacharacters, except semicolon (;) and NEWLINE. After a shell escape is detected, the remaining characters up to the next semicolon or NEWLINE are passed “as is” to the shell. The output of shell commands cannot be piped to MDB dcmds. Commands executed by a shell escape have their output sent directly to the terminal, not to MDB.

Variables

A variable is a variable name, a corresponding integer value, and a set of attributes. A variable name is a sequence of letters, digits, underscores, or periods. A variable can be assigned a value using the > dcmd or ::typeset dcmd, and its attributes can be manipulated using the ::typeset dcmd. Each variable’s value is represented as a 64-bit unsigned integer. A variable can have one or more of the following attributes: read-only (cannot be modified by the user), persistent (cannot be unset by the user), and tagged (user-defined indicator).

The following variables are defined as persistent:

0 Most recent value printed using the /, \, ?, or = dcmd
9 Most recent count used with the $< dcmd
b Virtual address of the base of the data section
d Size of the data section in bytes
e Virtual address of the entry point
hits The count of the number of times the matched software event specifier has been matched. See “Event Callbacks” on page 56.
m Initial bytes (magic number) of the target’s primary object file, or zero if no object file has been read yet
t Size of the text section in bytes
The thread identifier of the current representative thread. The value of the identifier depends on the threading model used by the current target. See “Thread Support” on page 56.

In addition, the MDB kernel and process targets export the current values of the representative thread’s register set as named variables. The names of these variables depend on the target’s platform and instruction set architecture.

Symbol Name Resolution

As explained in “Syntax” on page 23, a symbol identifier present in an expression context evaluates to the value of this symbol. The value typically denotes the virtual address of the storage associated with the symbol in the target’s virtual address space. A target can support multiple symbol tables including, but not limited to,

- Primary executable symbol table
- Primary dynamic symbol table
- Runtime link-editor symbol table
- Standard and dynamic symbol tables for each of a number of load objects (such as shared libraries in a user process, or kernel modules in the Solaris kernel)

The target typically searches the primary executable’s symbol tables first, then one or more of the other symbol tables. Notice that ELF symbol tables contain only entries for external, global, and static symbols; automatic symbols do not appear in the symbol tables processed by MDB.

Additionally, MDB provides a private user-defined symbol table that is searched prior to any of the target symbol tables. The private symbol table is initially empty, and can be manipulated using the ::nmadd and ::nmdel dcmds.

The ::nm -P option can be used to display the contents of the private symbol table. The private symbol table allows the user to create symbol definitions for program functions or data that were either missing from the original program or stripped out. These definitions are then used whenever MDB converts a symbolic name to an address, or an address to the nearest symbol.

Because targets contain multiple symbol tables, and each symbol table can include symbols from multiple object files, different symbols with the same name can exist. MDB uses the backquote “‘ ” character as a symbol-name scoping operator to allow the programmer to obtain the value of the desired symbol in this situation.
You can specify the scope used to resolve a symbol name as either: object `name`, or file `name`, or object `file` `name`. The object identifier refers to the name of a load object. The file identifier refers to the basename of a source file that has a symbol of type STT_FILE in the specified object’s symbol table. The object identifier’s interpretation depends on the target type.

The MDB kernel target expects object to specify the base name of a loaded kernel module. For example, the symbol name:

`specfs` `init`

evaluates to the value of the _init symbol in the specfs kernel module.

The mdb process target expects object to specify the name of the executable or of a loaded shared library. It can take any of the following forms:

- Exact match (that is, a full pathname): `/usr/lib/libc.so.1`
- Exact basename match: `libc.so.1`
- Initial basename match up to a ‘.’ suffix: `libc.so` or `libc`
- Literal string `a.out` which is accepted as an alias for the executable

The process target will also accept any of the four forms described above preceded by an optional link-map id (`lmid`). The `lmid` prefix is specified by an initial `LM` followed by the link-map id in hexadecimal followed by an additional backquote. For example, the symbol name:

`LM0` `libc.so.1` `init`

will evaluate to the value of the _init symbol in the libc.so.1 library that is loaded on link-map 0 (LM_ID_BASE). The link-map specifier may be necessary to resolve symbol naming conflicts in the event that the same library is loaded on more than one link map. For more information on link maps, refer to the Linker and Libraries Guide and the dlopen(3DL) man page. Link-map identifiers will be displayed when symbols are printed according to the setting of the `showlmid` option, as described under “Summary of Command-line Options” on page 137.

In the case of a naming conflict between symbols and hexadecimal integer values, MDB attempts to evaluate an ambiguous token as a symbol first, before evaluating it as an integer value. For example, the token `f` can refer either to the decimal integer value 15 specified in hexadecimal (the default base), or to a global variable named `f` in the target’s symbol table. If a symbol with an ambiguous name is present, the integer value can be specified by using an explicit `0x` or `0X` prefix.
dcmd and Walker Name Resolution

As described earlier, each MDB dmod provides a set of dcmds and walkers. dcmds and walkers are tracked in two distinct, global namespaces. MDB also keeps track of a dcmd and walker namespace associated with each dmod. Identically named dcmds or walkers within a given dmod are not allowed: a dmod with this type of naming conflict will fail to load.

Name conflicts between dcmds or walkers from different dmods are allowed in the global namespace. In the case of a conflict, the first dcmd or walker with that particular name to be loaded is given precedence in the global namespace. Alternate definitions are kept in a list in load order.

The backquote character "`" can be used in a dcmd or walker name as a scoping operator to select an alternate definition. For example, if dmods m1 and m2 each provide a dcmd d, and m1 is loaded prior to m2, then:

::d  Executes m1’s definition of d
::m1’d  Executes m1’s definition of d
::m2’d  Executes m2’s definition of d

If module m1 were now unloaded, the next dcmd on the global definition list (m2 ‘d) would be promoted to global visibility. The current definition of a dcmd or walker can be determined using the ::which dcmd, described below. The global definition list can be displayed using the ::which -v option.

dcmd Pipelines

dcmds can be composed into a pipeline using the | operator. The purpose of a pipeline is to pass a list of values, typically virtual addresses, from one dcmd or walker to another. Pipeline stages might be used to map a pointer from one type of data structure to a pointer to a corresponding data structure, to sort a list of addresses, or to select the addresses of structures with certain properties.

MDB executes each dcmd in the pipeline in order from left to right. The left-most dcmd is executed using the current value of dot, or using the value specified by an explicit expression at the start of the command. When a | operator is encountered, MDB creates a pipe (a shared buffer) between the output of the dcmd to its left and the MDB parser, and an empty list of values.
As the dcmd executes, its standard output is placed in the pipe and then consumed and evaluated by the parser, as if MDB were reading this data from standard input. Each line must consist of an arithmetic expression terminated by a newline or semicolon (;). The value of the expression is appended to the list of values associated with the pipe. If a syntax error is detected, the pipeline is aborted.

When the dcmd to the left of a | operator completes, the list of values associated with the pipe is then used to invoke the dcmd to the right of the | operator. For each value in the list, dot is set to this value and the right-hand dcmd is executed. Only the rightmost dcmd in the pipeline has its output printed to standard output. If any dcmd in the pipeline produces output to standard error, these messages are printed directly to standard error and are not processed as part of the pipeline.

### Formatting dcmds

The /, \, ?, and = metacharacters are used to denote the special output formatting dcmds. Each of these dcmds accepts an argument list consisting of one or more format characters, repeat counts, or quoted strings. A format character is one of the ASCII characters shown in the table below.

Format characters are used to read and format data from the target. A repeat count is a positive integer preceding the format character that is always interpreted in base 10 (decimal). A repeat count can also be specified as an expression enclosed in square brackets preceded by a dollar sign ($[ ]$). A string argument must be enclosed in double-quotes (" "). No blanks are necessary between format arguments.

The formatting dcmds are:

- `/` Display data from the target’s virtual address space starting at the virtual address specified by dot.
- `\` Display data from the target’s physical address space starting at the physical address specified by dot.
- `?` Display data from the target’s primary object file starting at the object file location corresponding to the virtual address specified by dot.
- `=` Display the value of dot itself in each of the specified data formats. The = dcmd is therefore useful for converting between bases and performing arithmetic.

In addition to dot, MDB keeps track of another global value called the *increment*. The increment represents the distance between dot and the address following all the data read by the last formatting dcmd.
For example, if a formatting dcmd is executed with dot equal to address A, and displays a 4-byte integer, then after this dcmd completes, dot is still A, but the increment is set to 4. The + character, described in “Arithmetic Expansion” on page 25, would now evaluate to the value A + 4, and could be used to reset dot to the address of the next data object for a subsequent dcmd.

Most format characters increase the value of the increment by the number of bytes corresponding to the size of the data format, shown in the table. The table of format characters can be displayed from within MDB using the ::formats dcmd.

The format characters are:

+ Increment dot by the count (variable size)
- Decrement dot by the count (variable size)
B Hexadecimal int (1 byte)
C Character using C character notation (1 byte)
D Decimal signed int (4 bytes)
E Decimal unsigned long long (8 bytes)
F Double (8 bytes)
G Octal unsigned long long (8 bytes)
H Swap bytes and shorts (4 bytes)
I Address and disassembled instruction (variable size)
J Hexadecimal long long (8 bytes)
K Hexadecimal uintptr_t (4 or 8 bytes)
N Newline
O Octal unsigned int (4 bytes)
P Symbol (4 or 8 bytes)
Q Octal signed int (4 bytes)
R Binary int (8 bytes)
S String using C string notation (variable size)
T Horizontal tab
U Decimal unsigned int (4 bytes)
V Decimal unsigned int (1 byte)
W Default radix unsigned int (4 bytes)
X Hexadecimal int (4 bytes)
Y Decoded time32_t (4 bytes)
The /, \, and ? formatting dcmds can also be used to write to the target’s virtual address space, physical address space, or object file by specifying one of the following modifiers as the first format character, and then specifying a list of words that are either immediate values or expressions enclosed in square brackets preceded by a dollar sign ($[ ]).

The write modifiers are:

v Write the lowest byte of the value of each expression to the target beginning at the location specified by dot

w Write the lowest 2 bytes of the value of each expression to the target beginning at the location specified by dot
W  Write the lowest 4 bytes of the value of each expression to the target beginning at
   the location specified by dot
Z  Write the complete 8 bytes of the value of each expression to the target beginning
   at the location specified by dot

The /, \, and ? formatting dcmds can also be used to search for a particular integer
value in the target’s virtual address space, physical address space, and object file,
respectively, by specifying one of the following modifiers as the first format character,
then specifying a value and optional mask. The value and mask are each specified as
either immediate values or expressions enclosed in square brackets preceded by a
dollar sign.

If only a value is specified, MDB reads integers of the appropriate size and stops at the
address containing the matching value. If a value $v$ and mask $m$ are specified, MDB
reads integers of the appropriate size and stops at the address containing a value $x$
where $(x \& m) == v$. At the completion of the dcmd, dot is updated to the address
containing the match. If no match is found, dot is left at the last address that was read.

The search modifiers are:
  l  Search for the specified 2-byte value
  L  Search for the specified 4-byte value
  M  Search for the specified 8-byte value

For both user and kernel targets, an address space is typically composed of a set of
discontiguous segments. It is not legal to read from an address that does not have a
corresponding segment. If a search reaches a segment boundary without finding a
match, it aborts when the read past the end of the segment boundary fails.
Interaction

This chapter describes the MDB interactive command-line editing and history functions, the output pager, and debugger signal handling.

Command Re-entry

The text of the last HISTSIZE (default 128) commands entered from a terminal device are saved in memory. The in-line editing facility, described next, provides key mappings for searching and fetching elements from the history list.

In-line Editing

If standard input is a terminal device, MDB provides some simple emacs-style facilities for editing the command line. The search, previous, and next commands in edit mode provide access to the history list. Only strings, not patterns, are matched when searching. In the list below, the notation for control characters is caret (^) followed by a character shown in upper case. The notation for escape sequences is M-followed by a character. For example, M-f (pronounced meta- eff) is entered by depressing <ESC> followed by 'f', or by depressing Meta followed by 'f' on keyboards that support a Meta key. A command line is committed and executed using RETURN or NEWLINE. The edit commands are:

- ^F  Move cursor forward (right) one character.
- M-f  Move cursor forward one word.
- ^B  Move cursor backward (left) one character.
M-b  Move cursor backward one word.
^A  Move cursor to start of line.
^E  Move cursor to end of line.
^D  Delete current character, if the current line is not empty. If the current line is empty, ^D denotes EOF and the debugger will exit.
M-^H  (Meta-backspace) Delete previous word.
^K  Delete from the cursor to the end of the line.
^L  Reprint the current line.
^T  Transpose current character with next character.
^N  Fetch the next command from the history. Each time ^N is entered, the next command forward in time is retrieved.
^P  Fetch the previous command from the history. Each time ^P is entered, the next command backward in time is retrieved.
^R[string]  Search backward in the history for a previous command line containing string. The string should be terminated by a RETURN or NEWLINE. If string is omitted, the previous history element containing the most recent string is retrieved.

The editing mode also interprets the following user-defined sequences as editing commands. User defined sequences can be read or modified using the stty(1) command.

erase  User defined erase character (usually ^H or ^?). Delete previous character.
intr  User defined interrupt character (usually ^C). Abort the current command and print a new prompt.
kill  User defined kill character (usually ^U). Kill the entire current command line.
quit  User defined quit character (usually ^\). Quit the debugger.
suspend  User defined suspend character (usually ^Z). Suspend the debugger.
werase  User defined word erase character (usually ^W). Erase the preceding word.

On keyboards that support an extended keypad with arrow keys, mdb will interpret these keystrokes as editing commands:

up-arrow  Fetch the previous command from the history (same as ^P).
down-arrow  Fetch the next command from the history (same as ^N).
left-arrow  Move cursor backward one character (same as ^B).
Output Pager

mdb provides a built-in output pager. The output pager is enabled if the debugger’s standard output is a terminal device. Each time a command is executed, mdb will pause after one screenful of output is produced and will display a pager prompt:

>> More [<space>, <cr>, q, n, c, a] ?

The following key sequences are recognized by the pager:

- **SPACE**: Display the next screenful of output.
- **a, A**: Abort the current top-level command and return to the prompt.
- **c, C**: Continue displaying output without pausing at each screenful until the current top-level command is complete.
- **n, N, NEWLINE, RETURN**: Display the next line of output.
- **q, Q, ^C, ^\**: Quit (abort) the current dcmd only.

Signal Handling

The debugger ignores the PIPE and QUIT signals. The INT signal aborts the command that is currently executing. The debugger intercepts and provides special handling for the ILL, TRAP, EMT, FPE, BUS, and SEGV signals. If any of these signals are generated asynchronously (that is, delivered from another process using `kill(2)`), mdb will restore the signal to its default disposition and dump core. However, if any of these signals are generated synchronously by the debugger process itself and a dcmd from an externally loaded dmod is currently executing, and standard input is a terminal, mdb will provide a menu of choices allowing the user to force a core dump, quit without producing a core dump, stop for attach by a debugger, or attempt to resume. The resume option will abort all active commands and unload the dmod whose dcmd was active at the time the fault occurred. It can then be subsequently re-loaded by the user. The resume option provides limited protection against buggy dcmds. Refer to “Warnings” on page 145, Use of the Error Recovery Mechanism, for information about the risks associated with the resume option.
Built-in Commands

MDB provides a set of built-in dcmds that are always defined. Some of these dcmds are applicable only to certain targets: if a dcmd is not applicable to the current target, it fails and prints a message indicating “command is not supported by current target”.

In many cases, MDB provides a mnemonic equivalent (::identifier) for the legacy adb(1) dcmd names. For example, ::quit is provided as the equivalent of $q. Programmers who are experienced with adb(1) or who appreciate brevity or arcana might prefer the $ or : forms of the built-ins. Programmers who are new to MDB might prefer the more verbose :: form. The built-ins are shown in alphabetical order. If a $ or : form has a ::identifier equivalent, it is shown under the ::identifier form.

Built-in dcmds

> variable-name
> /modifier/ variable-name
Assign the value of dot to the specified named variable. Some variables are read-only and cannot be modified. If the > is followed by a modifier character surrounded by //, then the value is modified as part of the assignment. The modifier characters are:

c  Unsigned char quantity (1-byte)
s  Unsigned short quantity (2-byte)
i  Unsigned int quantity (4-byte)
l  Unsigned long quantity (4-byte in 32-bit, 8-byte in 64-bit)
Notice that these operators do not perform a cast; they instead fetch the specified number of low-order bytes (on little-endian architectures) or high-order bytes (big-endian architectures). These modifiers are provided for backward compatibility; the MDB */modifier/ and %/modifier/ syntax should be used instead.

$< \text{macro-name}
Read and execute commands from the specified macro file. The file name can be given as an absolute or relative path. If the file name is a simple name (that is, if it does not contain a ‘/’), MDB searches for it in the macro file include path. If another macro file is currently being processed, this file is closed and replaced with the new file.

$<< \text{macro-name}
Read and execute commands from the specified macro file (as with $<), but do not close the current open macro file.

$?
Print the process-ID and current signal of the target if it is a user process or core file, and then print the general register set of the representative thread.

$[ \text{address} ] \%C [ \text{count} ]
Print a C stack backtrace, including stack frame pointer information. If the dcmd is preceded by an explicit address, a backtrace beginning at this virtual memory address is displayed. Otherwise, the stack of the representative thread is displayed. If an optional count value is given as an argument, no more than count arguments are displayed for each stack frame in the output.

64-bit SPARC only – The biased frame pointer value (that is, the virtual address minus 0x7ffe) should be used as the address when requesting a stack trace.

$[ \text{base} ] \%d
Get or set the default output radix. If the dcmd is preceded by an explicit expression, the default output radix is set to the given base; otherwise, the current radix is printed in base 10 (decimal). The default radix is base 16 (hexadecimal).

$e
Print a list of all known external (global) symbols of type object or function, the value of the symbol, and the first 4 (32-bit) or 8 (64-bit) bytes stored at this location in the target’s virtual address space. The :nm dcmd provides more flexible options for displaying symbol tables.

$P \text{prompt-string}
Set the prompt to the specified prompt-string. The default prompt is ‘>’. The prompt can also be set using :set -P or the -P command-line option.

distance $s
Get or set the symbol matching distance for address-to-symbol-name conversions. The symbol matching distance modes are discussed along with the -s
command-line option in Appendix A. The symbol matching distance can also be modified using the ::set -s option. If no distance is specified, the current setting is displayed.

$v$
Print a list of the named variables that have non-zero values. The ::vars dcmd provides other options for listing variables.

$w$
Set the output page $width$ to the specified value. Typically, this command is not necessary, as MDB queries the terminal for its width and handles resize events.

$W$
Reopen the target for writing, as if MDB had been executed with the -w option on the command line. Write mode can also be enabled with the ::set -w option.

[ pid ] ::attach [ core | pid ]
[ pid ] ::A [ core | pid ]
If the user process target is active, attach to and debug the specified process-ID or core file. The core file path name should be specified as a string argument. The process-ID can be specified as the string argument, or as the value of the expression preceding the dcmd. Recall that the default base is hexadecimal, so decimal PIDs obtained using pgrep(1) or ps(1) should be preceded with "0t" when specified as expressions.

::cat filename ...
Concatenate and display files. Each file name can be specified as a relative or absolute path name. The file contents will print to standard output, but will not pass through the output pager. This dcmd is intended to be used with the | operator; the programmer can initiate a pipeline using a list of addresses stored in an external file.

address ::context
address $p$
Context switch to the specified process. A context switch operation is valid only when using the kernel target. The process context is specified using the address of its proc structure in the kernel’s virtual address space. The special context address "0" is used to denote the context of the kernel itself. MDB can only perform a context switch when examining a crash dump if the dump contains the physical memory pages of the specified user process (as opposed to just kernel pages). The kernel crash dump facility can be configured to dump all pages or the pages of the current user process using dumpadm(1M). The ::status dcmd can be used to display the contents of the current crash dump.

When the user requests a context switch from the kernel target, MDB constructs a new target representing the specified user process. After the switch occurs, the new target interposes its dcmds at the global level: thus the / dcmd can now format and display data from the virtual address space of the user process, the ::mappings dcmd can display the mappings in the address space of the user process, and so on. The kernel target can be restored by executing 0::context.
::dcmás
List the available dcmds and print a brief description for each one.

[ address ] ::dis [ -fw ] [ -n count ] [ address ]
Disassemble starting at or around the address specified by the final argument, or the
current value of dot. If the address matches the start of a known function, the entire
function is disassembled; otherwise, a “window” of instructions before and after
the specified address is printed in order to provide context. By default, instructions
are read from the target’s virtual address space; if the -f option is present,
instructions are read from the target’s object file instead. The -f option is enabled
by default if the debugger is not currently attached to a live process, core file, or
crash dump. The -w option can be used to force window-mode, even if the address
is the start of a known function. The size of the window defaults to ten instructions;
the number of instructions can be specified explicitly using the -n option.

::disasms
List the available disassembler modes. When a target is initialized, MDB attempts
to select the appropriate disassembler mode. The user can change the mode to any
of the modes listed using the ::dismode dcmd.

::dismode [ mode ]
SV [ mode ]
Get or set the disassembler mode. If no argument is specified, print the current
disassembler mode. If a mode argument is specified, switch the disassembler to the
specified mode. The list of available disassemblers can be displayed using the
::disasms dcmd.

::dmods [-l ] [ module-name ]
List the loaded debugger modules. If the -l option is specified, the list of the
dcmds and walkers associated with each dmod is printed below its name. The
output can be restricted to a particular dmod by specifying its name as an
additional argument.

[address] ::dump [-eqrstu] [-f|-p] [-g bytes] [-w paragraphs]
Print a hexadecimal and ASCII memory dump of the 16-byte aligned region of
virtual memory containing the address specified by dot. If a repeat count is
specified for ::dump, this is interpreted as a number of bytes to dump rather than a
number of iterations. The ::dump dcmd also recognizes the following options:

-e Adjust for endian-ness. The -e option assumes 4-byte words; the
-g option can be used to change the default word size.

-f Read data from the object file location corresponding to the given
virtual address instead of from the target’s virtual address space.
The -f option is enabled by default if the debugger is not
currently attached to a live process, core file, or crash dump.

-g group Display bytes in groups of bytes. The default group size is 4 bytes.
The group size must be a power of two that divides the line width

-p Interpret address as a physical address location in the target’s
address space instead of a virtual address.

44 Solaris Modular Debugger Guide • May 2002
-q    Do not print an ASCII decoding of the data.
-r    Number lines relative to the start address instead of with the explicit address of each line. This option implies the -u option.
-s    Elide repeated lines.
-t    Only read from and display the contents of the specified addresses, instead of reading and printing entire lines.
-u    Unalign output instead of aligning the output at a paragraph boundary.
-w paragraphs Display paragraphs 16-byte paragraphs per line. The default number of paragraphs is one. The maximum value accepted for -w is 16.
::echo [string | value ... ]
    Print the arguments separated by blanks and terminated by a NEWLINE to standard output. Expressions enclosed in $[ ] will be evaluated to a value and printed in the default base.
::eval command
    Evaluate and execute the specified string as a command. If the command contains metacharacters or white space, it should be enclosed in double or single quotes.
::files
    $f
    Print a list of the known source files (symbols of type STT_FILE present in the various target symbol tables).
[address] ::findsym [-g] [ address | symbol ...]
    Search instruction text for instructions that refer to the specified symbols or addresses. The search list should consist of one or more addresses or symbol names specified as an address preceding the dcmd or one or more symbol names or expressions following the dcmd. If the -g option is specified, the search is restricted to instruction text that is part of a globally visible function in the target’s symbol table.

Note – SPARC only. The ::findsym dcmd is only available when debugging a target that uses the SPARC instruction set architecture.

::formats
    List the available output format characters for use with the /, \, ?, and = formatting dcmds. The formats and their use is described in “Formatting dcmds” on page 32.
[ thread ] ::fpregs [-dqs]
[ thread ] $x, $X, $y, $Y
Print the floating-point register set of the representative thread. If a thread is specified, the floating point registers of that thread are displayed. The thread expression should be one of the thread identifiers described under “Thread Support” on page 56.

**Note** – SPARC only. The `-d`, `-q`, and `-s` options can be used to display the floating point registers as a collection of double-precision (`-d`), quad-precision (`-q`), or single-precision (`-s`) floating point values.

```
::grep command
Evaluate the specified command string, then print the old value of dot if the new value of dot is non-zero. If the `command` contains white space or metacharacters, it must be quoted. The `::grep` dcmd can be used in pipelines to filter a list of addresses.

::help [ dcmd-name ]
With no arguments, the `::help` dcmd prints a brief overview of the help facilities available in MDB. If a `dcmd-name` is specified, MDB prints a usage summary for that dcmd.

[ address ] ::list type member [ variable-name ]
Walk through the elements of a linked list data structure and print the address of each element in the list. The address of the first element in the list can be specified using an optional `address`; otherwise the list is assumed to start at the current value of dot. The `type` parameter must name a C struct or union type and is used to describe the type of the list elements so that MDB can read in objects of the appropriate size. The `member` parameter is used to name the member of `type` that contains a pointer to the next list element. The `::list` dcmd will continue iterating until a NULL pointer is encountered, the first element is reached again (a circular list), or an error occurs while reading an element. If the optional `variable-name` is specified, the specified variable will be assigned the value returned at each step of the walk when MDB invokes the next stage of a pipeline.

**Note** – This dcmd may only be used with objects that contain compressed symbolic debugging information designed for use with `mdb`. This information is currently only available for certain Solaris kernel modules. The SUNWzlib (32-bit) or SUNWzlibx (64-bit) decompression software must be installed in order to process the symbolic debugging information.

```
::load [-s] module-name
Load the specified dmod. The module name can be given as an absolute or relative path. If `module-name` is a simple name (that is, does not contain a `'/'), MDB searches for it in the module library path. Modules with conflicting names cannot be loaded;
the existing module must be unloaded first. If the -s option is present, MDB will remain silent and not issue any error messages if the module is not found or could not be loaded.

::log [ -d | [ -e ] filename ]
$> [ filename ]
Enable or disable the output log. MDB provides an interactive logging facility where both the input commands and standard output can be logged to a file while still interacting with the user. The -e option enables logging to the specified file, or re-enables logging to the previous log file if no file name is given. The -d option disables logging. If the $> dcmd is used, logging is enabled if a file name argument is specified; otherwise, logging is disabled. If the specified log file already exists, MDB appends any new log output to the file.

::map command
Map the value of dot to a corresponding value using the command specified as a string argument, then print the new value of dot. If the command contains white space or metacharacters, it must be quoted. The ::map dcmd can be used in pipelines to transform the list of addresses into a new list of addresses.

[ address ] ::mappings [ name ]
[ address ] ::nm [ name ]
Print a list of each mapping in the target’s virtual address space, including the address, size, and description of each mapping. If the dcmd is preceded by an address, MDB shows only the mapping that contains the given address. If a string name argument is given, MDB shows only the mapping that matched the description.

[ address ] ::nm [ -D | -P | -d ] [ -t types ] [ -f format ] [ object ]
Print the symbol tables associated with the current target. If an optional address preceding the dcmd is specified, only the symbol table entry for the symbol corresponding to address is displayed. If an object name is specified, only the symbol table for this load object is displayed. The ::nm dcmd also recognizes the following options:

-D Prints .dynsym (dynamic symbol table) instead of .symtab.
-P Prints the private symbol table instead of .symtab.
-d Prints value and size fields in decimal.
-f format[,format...]
Print only the specified symbol information. The valid format argument strings are:
ndx symbol table index
val symbol table
size size in bytes
type symbol type
bind binding
oth other
shndx section index
name symbol name
cctype C type for symbol (if known)
obj object which defines symbol

-g Prints only global symbols.
-h Suppresses the header line.
-n Sorts symbols by name.
-o Prints value and size fields in octal.
-p Prints symbols as a series of ::nmadd commands. This option can be used with -P to produce a macro file that can be subsequently read into the debugger with $<.
-t type [,type...] Prints only symbols of the specified type(s). The valid type argument strings are:
  noty STT_NOTYPE
  objt STT_OBJECT
  func STT_FUNC
  sect STT_SECTION
  file STT_FILE
  comm STT_COMMON
  tls STT_TLS
  regi STT_SPARC_REGISTER
-u Prints only undefined symbols.
-v Sorts symbols by value.
-x Prints value and size fields in hexadecimal.

value ::nmadd [-fo] [-e end] [-s size] name
Add the specified symbol name to the private symbol table. MDB provides a private, configurable symbol table that can be used to interpose on the target’s symbol table, as described in “Symbol Name Resolution” on page 29. The ::nmadd dcmsg also recognizes the following options:

-e Set the size of the symbol to end - value.
-f Set the type of the symbol to STT_FUNC.
-o Set the type of the symbol to STT_OBJECT.
-s Set the size of the symbol to size.

::nmdel name
Delete the specified symbol name from the private symbol table.

::objects
Print a map of the target’s virtual address space, showing only those mappings that correspond to the primary mapping (usually the text section) of each of the known load objects.

::offsetof type member
Print the offset of the specified member of the specified type. The type should be the name of a C structure. The offset is printed in bytes, unless the member is a bit-field in which case the offset may be printed in bits. The output is always suffixed with the appropriate units for clarity. The type name may use the backquote (‘) scoping operator described in “Symbol Name Resolution” on page 29.

Note – This dcmd may only be used with objects that contain compressed symbolic debugging information designed for use with mdb. This information is currently only available for certain Solaris kernel modules. The SUNWzlib (32-bit) or SUNWzlibx (64-bit) decompression software must be installed in order to process the symbolic debugging information.

[address] ::print [-aCdLptx] [-c lim] [-l lim] [type [member ... ] ]
Print the data structure at the specified virtual address using the given type information. The type parameter may name a C struct, union, enum, fundamental integer type, or a pointer to any of these types. If the type name contains whitespace (for example, ‘struct foo’) it must be enclosed in single or double quotes. The type name may use the backquote (‘) scoping operator described under “Symbol Name Resolution” on page 29. If the type is a structured type, the ::print dcmd will recursively print each member of the struct or union. If the type argument is not present and a static or global STT_OBJECT symbol matches the address, ::print will infer the appropriate type automatically. If the type argument is specified, it may be followed by an optional list of member expressions, in which case only those members and submembers of the specified type are displayed. If type contains other structured types, each member string may refer to a sub-structure element by forming a list of member names separated by period (‘.’) delimiters. The ::print dcmd may only be used with objects that contain symbolic debugging information designed for use with MDB. After displaying the data structure, ::print increments dot by the size of type in bytes.
Note – This dcmd may only be used with objects that contain compressed symbolic debugging information designed for use with mdb. This information is currently only available for certain Solaris kernel modules. The SUNWzlib (32-bit) or SUNWzlibx (64-bit) decompression software must be installed in order to process the symbolic debugging information.

If the -a option is present, the address of each member is displayed. If the -p option is present, ::print interprets address as a physical memory address instead of a virtual memory address. If the -t option is present, the type of each member is displayed. If the -d or -x options are present, all integers are displayed in decimal (-d) or hexadecimal (-x); by default a heuristic is used to determine if the value should be displayed in decimal or hexadecimal. The number of characters in a character array that will be read and displayed as a string can be limited with the -c option. If the -C option is present, no limit is enforced. The number of elements in a standard array that will be read and displayed can be limited with the -l option. If the -L option is present, no limit is enforced and all array elements are shown. The default values for -c and -l can be modified using ::set or the -o command-line option as described in Appendix A.

::quit
$q
Quit the debugger.

[ thread ] ::regs
[ thread ] $r
Print the general-purpose register set of the representative thread. If a thread is specified, the general purpose register set of that thread is displayed. The thread expression should be one of the thread identifiers described under “Thread Support” on page 56.

::release [-a]
::R [-a]
Release the previously attached process or core file. If the -a option is present, the process is released and left stopped and abandoned. It can subsequently be continued by prun(1) or it can be resumed by applying MDB or another debugger. By default, a released process is forcibly terminated if it was created by MDB using ::run, or it is released and set running if it was attached to by MDB using the -p option or using the ::attach or :A dcmds.

::set [-wF] [+/-o option] [-s distance] [-L path] [-P path] [-P prompt]
Get or set miscellaneous debugger properties. If no options are specified, the current set of debugger properties is displayed. The ::set dcmd recognizes the following options:

- $F Forcibly take over the next user process that ::attach is applied to, as if mdb had been executed with the -F option on the command line.
-I Set the default path for locating macro files. The path argument can contain any of the special tokens described for the -I command-line option in Appendix A.

-L Set the default path for locating debugger modules. The path argument can contain any of the special tokens described for the -I command-line option in Appendix A.

-o Enable the specified debugger option. If the +o form is used, the option is disabled. The option strings are described along with the -o command-line option in Appendix A.

-P Set the command prompt to the specified prompt string.

-s Set the symbol matching distance to the specified distance. Refer to the description of the -s command-line option in Appendix A for more information.

-w Re-open the target for writing, as if mdb had been executed with the -w option on the command line.

::sizeof type
Print the size of the specified type in bytes. The type parameter may name a C struct, union, enum, fundamental integer type, or a pointer to any of these types. The type name may use the backquote (‘) scoping operator described in “Symbol Name Resolution” on page 29.

Note – This dcmd may only be used with objects that contain compressed symbolic debugging information designed for use with mdb. This information is currently only available for certain Solaris kernel modules. The SUNWzlib (32-bit) or SUNWzlibx (64-bit) decompression software must be installed in order to process the symbolic debugging information.

[ address ] ::stack [ count ]
[ address ] ::s [ count ]
Print a C stack back trace. If the dcmd is preceded by an explicit address, a back trace beginning at this virtual memory address is displayed. Otherwise, the stack of the representative thread is displayed. If an optional count value is given as an argument, no more than count arguments are displayed for each stack frame in the output.

64-bit SPARC only – The biased frame pointer value (that is, the virtual address minus 0x7ff) should be used as the address when requesting a stack trace.

::status
Print a summary of information related to the current target.
thread ::tls symbol
Print the address of the storage for the specified thread-local storage (TLS) symbol in the context of the specified thread. The thread expression should be one of the thread identifiers described under “Thread Support” on page 56. The symbol name may use any of the scoping operators described under “Symbol Name Resolution” on page 29.

::typeset [+/-t] variable-name ...
Set attributes for named variables. If one or more variable names are specified, they are defined and set to the value of dot. If the -t option is present, the user-defined tag associated with each variable is set. If the +t option is present, the tag is cleared. If no variable names are specified, the list of variables and their values is printed.

::unload module-name
Unload the specified dmod. The list of active dmods can be printed using the ::dmods dcmd. Built-in modules cannot be unloaded. Modules that are busy (that is, provide dcmds that are currently executing) cannot be unloaded.

::unset variable-name ...
Unset (remove) the specified variable(s) from the list of defined variables. Some variables are exported by MDB are marked as persistent, and cannot be unset by the user.

::vars [-npt]
Print a listing of named variables. If the -n option is present, the output is restricted to variables that currently have non-zero values. If the -p option is present, the variables are printed in a form suitable for re-processing by the debugger using the $< dcmd. This option can be used to record the variables to a macro file, then restore these values later. If the -t option is present, only the tagged variables are printed. Variables can be tagged using the -t option of the ::typeset dcmd.

::version
Print the debugger version number.

address ::vtop [-a as]
Print the physical address mapping for the specified virtual address, if possible. The ::vtop dcmd is only available when examining a kernel target, or when examining a user process inside a kernel crash dump (after a ::context dcmd has been issued).

When examining a kernel target from the kernel context, the -a option can be used to specify the address (as) of an alternate address space structure that should be used for the virtual to physical translation. By default, the kernel’s address space is used for translation. This option is available for active address spaces even when the dump content only contains kernel pages.

[ address ] ::walk walker-name [ variable-name ]
Walk through the elements of a data structure using the specified walker. The available walkers can be listed using the ::walkers dcmd. Some walkers operate on a global data structure and do not require a starting address. For example, walk
the list of proc structures in the kernel. Other walkers operate on a specific data structure whose address must be specified explicitly. For example, given a pointer to an address space, walk the list of segments.

When used interactively, the :w walk dcmd will print the address of each element of the data structure in the default base. The dcmd can also be used to provide a list of addresses for a pipeline. The walker name can use the backquote "'" scoping operator described in “dcmd and Walker Name Resolution” on page 31. If the optional variable-name is specified, the specified variable will be assigned the value returned at each step of the walk when MDB invokes the next stage of the pipeline.

::walkers
List the available walkers and print a brief description for each one.

::whence [-v] name ...
::which [-v] name ...
Print the dmod that exports the specified dcmds and walkers. These dcmds can be used to determine which dmod is currently providing the global definition of the given dcmd or walker. Refer to “dcmd and Walker Name Resolution” on page 31 for more information on global name resolution. The -v option causes the dcmd to print the alternate definitions of each dcmd and walker in order of precedence.

::xdata
List the external data buffers exported by the current target. External data buffers represent information associated with the target that cannot be accessed through standard target facilities (that is, an address space, symbol table, or register set). These buffers can be consumed by dcmds; for more information, refer to “mdb_get_xdata()” on page 135.
CHAPTER 6

Execution Control

MDB provides facilities for controlling and tracing the execution of a live running program. Currently, only the user process target provides support for execution control. This chapter describes the built-in dcmds that can be used to control target execution.

Execution Control

MDB provides a simple model of execution control: a target process can be started from within the debugger using ::run, or MDB can attach to an existing process using ::attach, or the -p command-line option (see Chapter 5). A list of traced software events can be specified by the user. Each time a traced event occurs in the target process, all threads in the target stop, the thread that triggered the event is chosen as the representative thread, and control returns to the debugger. Once the target program is set running, control can be asynchronously returned to the debugger by typing the user-defined interrupt character (typically ^C).

A software event is a state transition in the target program that is observed by the debugger. For example, the debugger may observe the transition of a program counter register to a value of interest (a breakpoint) or the delivery of a particular signal.

A software event specifier is a description of a class of software events that is used by the debugger to instrument the target program in order to observe these events. The ::events dcmd is used to list the software event specifiers. A set of standard properties is associated with each event specifier, as described under ::events in “Built-in dcmds” on page 57.

The debugger can observe a variety of different software events, including breakpoints, watchpoints, signals, machine faults, and system calls. New specifiers can be created using ::bp, ::fltbp, ::sigbp, ::sysbp, or ::wp. Each specifier has an associated callback (an MDB command string to execute as if it had been typed at the
command prompt) and a set of properties, as described under ::events in “Built-in dcmds” on page 57. Any number of specifiers for the same event may be created, each with different callbacks and properties. The current list of traced events and the properties of the corresponding event specifiers can be displayed using the ::events dcmd. The event specifier properties are defined as part of the description of the ::events and ::evset dcmds, in “Built-in dcmds” on page 57.

The execution control built-in dcmds, described in “Built-in dcmds” on page 57, are always available, but will issue an error message indicating they are not supported if applied to a target that does not support execution control.

---

**Event Callbacks**

The ::evset dcmd and event tracing dcmds allow you to associate an event callback (using the -c option) with each event specifier. The event callbacks are strings that represent MDB commands to execute when the corresponding event occurs in the target. These commands are executed as if they had been typed at the command prompt. Prior to executing each callback, the dot variable is set to the value of the representative thread’s program counter and the hits variable is set to the number of times this specifier has been matched, including the current match.

If the event callbacks themselves contain one or more commands to continue the target (for example, ::cont or ::step), these commands do not immediately continue the target and wait for it to stop again. Instead, inside of an event callback, the continue dcmds note that a continue operation is now pending, and then return immediately. Therefore, if multiple dcmds are included in an event callback, the step or continue dcmd should be the last command specified. Following the execution of all event callbacks, the target will immediately resume execution if all matching event callbacks requested a continue. If conflicting continue operations are requested, the operation with the highest precedence determines what type of continue will occur. The order of precedence from highest to lowest is: step, step-over (next), step-out, continue.

---

**Thread Support**

MDB provides facilities to examine the stacks and registers of each thread associated with the target. The persistent “thread” variable contains the current representative thread identifier. The format of the thread identifier depends on the target. The ::regs and ::fpregs dcmds can be used to examine the register set of the representative thread, or of another thread if its register set is currently available. In
addition, the register set of the representative thread is exported as a set of named variables. The user can modify the value of one or more registers by applying the `>` dcmd to the corresponding named variable.

The MDB kernel target exports the virtual address of the corresponding internal thread structure as the identifier for a given thread.

The MDB process target provides proper support for examination of multi-threaded user processes that use the native lwp_* interfaces, /usr/lib/libthread.so, or /usr/lib/libpthread.so. When debugging a live user process, MDB will detect if a single threaded process dlopen or closes libthread and will automatically adjust its view of the threading model on-the-fly. The process target thread identifiers will correspond to either the lwpid_t, thread_t, or pthread_t of the representative, depending on the threading model used by the application.

If MDB is debugging a user process target and the target makes use of compiler-supported thread-local storage, MDB will automatically evaluate symbol names referring to thread-local storage to the address of the storage corresponding to the current representative thread. The `::tls` built-in dcmd can be used to display the value of the symbol for threads other than the representative thread.

### Built-in dcmds

\[ addr \]:b [+/dDestT] [-c cmd] [-n count] sym ...

Set a breakpoint at the specified locations. The `:bp` dcmd sets a breakpoint at each address or symbol specified, including an optional address specified by an explicit expression preceding the dcmd, and each string or immediate value following the dcmd. The arguments may either be symbol names or immediate values denoting a particular virtual address of interest. If a symbol name is specified, it may refer to a symbol that cannot yet be evaluated in the target process: that is, it may consist of an object name and function name in a load object that has not yet been opened. In this case, the breakpoint is deferred and it will not be active in the target until an object matching the given name is loaded. The breakpoint will be automatically enabled when the load object is opened. Breakpoints on symbols defined in a shared library should always be set using a symbol name and not using an address expression, as the address may refer to the corresponding Procedure Linkage Table (PLT) entry instead of the actual symbol definition. Breakpoints set on PLT entries may be overwritten by the run-time link-editor when the PLT entry is subsequently resolved to the actual symbol definition. The `-d`, `-D`, `-e`, `-s`, `-t`, `-T`, `-c`, and `-n` options have the same meaning as they do for the `:evset` dcmd, as described later in this section. If the `:b` form of the dcmd is used, a breakpoint is only set at the virtual address specified by the expression preceding the dcmd. The arguments following the `:b` dcmd are concatenated together to form the callback string. If this string contains meta-characters, it must be quoted.
::cont [SIG]
:c [SIG]
Suspend the debugger, continue the target program, and wait for it to terminate or stop following a software event of interest. If the target is already running because the debugger was attached to a running program with the -onostop option enabled, this dcmd simply waits for the target to terminate or stop after an event of interest. If an optional signal name or number (see the signal (3HEAD) man page) is specified as an argument, the signal is immediately delivered to the target as part of resuming its execution. If the SIGINT signal is traced, control may be asynchronously returned to the debugger by typing the user-defined interrupt character (usually ^C). This SIGINT signal will be automatically cleared and will not be observed by the target the next time it is continued. If no target program is currently running, ::cont will start a new program running as if by ::run.

addr ::delete [id | all]
addr ::d [id | all]
Delete the event specifiers with the given id number. The id number argument is interpreted in decimal by default. If an optional address is specified preceding the dcmd, all event specifiers that are associated with the given virtual address are deleted (e.g. all breakpoints or watchpoints affecting that address). If the special argument "all" is given, all event specifiers are deleted, except those that are marked sticky (T flag). The ::events dcmd displays the current list of event specifiers.

::events [-av]
$b [-av]
Display the list of software event specifiers. Each event specifier is assigned a unique ID number that can be used to delete or modify it at a later time. The debugger may also have its own internal events enabled for tracing; these will only be displayed if the -a option is present. If the -v option is present, a more verbose display including the reason for any specifier inactivity will be shown. The following ::events dcmd shows example output:

```
> ::events
  ID  S  TA  HT  LM  Description  Action
  ----  --  --  --  --  ------------------  ----------
[  1] -  T  1  0  stop on SIGINT   -
[  2] -  T  0  0  stop on SIGHUP   -
[  3] -  T  0  0  stop on SIGILL   -
...[ 11] -  T  0  0  stop on SIGXCPU -
[ 12] -  T  0  0  stop on SIGXFSZ -
[ 13] -  T  2  0  stop at libc'printf ::echo printf
```

The following discussion explains the meaning of each column. A summary of this information is available using ::help events.

ID The event specifier identifier. The identifier will be shown in square brackets [ ] if the specifier is enabled, in parentheses ( ) if the
specifier is disabled, or in angle brackets <> if the target program is currently stopped on an event that matches the given specifier.

**S**
The event specifier state. The state will be one of the following symbols:

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>-</td>
<td>The event specifier is idle. When no target program is running, all specifiers are idle. When the target program is running, a specifier may be idle if it cannot be evaluated (such as a deferred breakpoint in a shared object that is not yet loaded).</td>
</tr>
<tr>
<td>+</td>
<td>The event specifier is active. When the target is continued, events of this type will be detected by the debugger.</td>
</tr>
<tr>
<td>*</td>
<td>The event specifier is armed. This state means that the target is currently running with instrumentation for this type of event. This state is only visible if the debugger is attached to a running program with the <code>-o nostop</code> option.</td>
</tr>
<tr>
<td>!</td>
<td>The event specifier was not armed due to an operating system error. The <code>::events -v</code> option can be used to display more information about the reason the instrumentation failed.</td>
</tr>
</tbody>
</table>

**TA**
The Temporary, Sticky, and Automatic event specifier properties. One or more of the following symbols may be shown:

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>t</td>
<td>The event specifier is temporary, and will be deleted the next time the target stops, regardless of whether it is matched.</td>
</tr>
<tr>
<td>T</td>
<td>The event specifier is sticky, and will be not be deleted by <code>::delete all</code> or <code>::z</code>. The specifier can be deleted by explicitly specifying its id number to <code>::delete</code>.</td>
</tr>
<tr>
<td>d</td>
<td>The event specifier will be automatically disabled when the hit count is equal to the hit limit.</td>
</tr>
<tr>
<td>D</td>
<td>The event specifier will be automatically deleted when the hit count is equal to the hit limit.</td>
</tr>
<tr>
<td>s</td>
<td>The target will automatically stop when the hit count is equal to the hit limit.</td>
</tr>
</tbody>
</table>

**HT**
The current hit count. This column displays the number of times the corresponding software event has occurred in the target since the creation of this event specifier.
LM The current hit limit. This column displays the limit on the hit count at which the auto-disable, auto-delete, or auto-stop behavior will take effect. These behaviors can be configured using the ::evset dcmd.

Description A description of the type of software event that is matched by the given specifier.

Action The callback string to execute when the corresponding software event occurs. This callback is executed as if it had been typed at the command prompt.

id ::evset [+/-dDestT] [-c cmd] [-n count] id ...

Modify the properties of one or more software event specifiers. The properties are set for each specifier identified by the optional expression preceding the dcmd and an optional list of arguments following the dcmd. The argument list is interpreted as a list of decimal integers, unless an explicit radix is specified. The ::evset dcmd recognizes the following options:

-\(d\) Disable the event specifier when the hit count reaches the hit limit. If the +\(d\) form of the option is given, this behavior is disabled. Once an event specifier is disabled, the debugger will remove any corresponding instrumentation and will ignore the corresponding software events until the specifier is subsequently re-enabled. If the -\(n\) option is not present, the specifier is disabled immediately.

-\(D\) Delete the event specifier when the hit count reaches the hit limit. If the +\(D\) form of the option is given, this behavior is disabled. The -\(D\) option takes precedence over the -\(d\) option. The hit limit can be configured using the -\(n\) option.

-\(e\) Enable the event specifier. If the +\(e\) form of the option is given, the specifier is disabled.

-\(s\) Stop the target program when the hit count reaches the hit limit. If the +\(s\) form of the option is given, this behavior is disabled. The -\(s\) behavior tells the debugger to act as if ::cont were issued following each execution of the specifier’s callback, except for the Nth execution, where N is the current value of the specifier’s hit limit. The -\(s\) option takes precedence over both the -\(D\) option and the -\(d\) option.

-\(t\) Mark the event specifier as temporary. Temporary specifiers are automatically deleted the next time the target stops, regardless of whether it stopped as the result of a software event corresponding to the given specifier. If the +\(t\) form of the option is given, the temporary marker is removed. The -\(t\) option takes precedence over the -\(T\) option.

-\(T\) Mark the event specifier as sticky. Sticky specifiers will not be deleted by ::delete all or :z. They can be deleted by specifying the corresponding specifier ID as an explicit argument to ::delete. If the +\(T\) form of the
option is given, the sticky property is removed. The default set of event
specifiers are all initially marked sticky.

-c Execute the specified cmd string each time the corresponding software event
occurs in the target program. The current callback string can be displayed
using ::events.

-n Set the current value of the hit limit to count. If no hit limit is currently set
and the -n option does not accompany -s or -D, the hit limit will be set to
one.

A summary of this information is available using ::help evset.

flt ::fltbp [+-dDestT] [-c cmd] [-n count] flt ...
Trace the specified machine faults. The faults are identified using an optional fault
number preceding the dcmd, or a list of fault names or numbers (see
/sys/fault.h) following the dcmd. The -d, -D, -e, -s, -t, -T, -c, and -n
options have the same meaning as they do for the ::evset dcmd.

signal :i
If the target is a live user process, ignore the specified signal and allow it to be
delivered transparently to the target. All event specifiers that are tracing delivery of
the specified signal will be deleted from the list of traced events. By default, the set
of ignored signals is initialized to the complement of the set of signals that cause a
process to dump core by default (see the signal(3HEAD) man page), except for
SIGINT, which is traced by default.

$i
Display the list of signals that are ignored by the debugger and will be handled
directly by the target. More information on traced signals can be obtained using the
::events dcmd.

::kill
:k
Forcibly terminate the target if it is a live user process. The target will also be
forcibly terminated when the debugger exits if it was created by the debugger using
::run.

$l
Print the LWID of the representative thread, if the target is a user process.

$L
Print the LWIDs of each LWP in the target, if the target is a user process.

::next [SIG]
:e [SIG]
Step the target program one instruction, but step over subroutine calls. If an
optional signal name or number (see signal(3HEAD) man page) is specified as an
argument, the signal is immediately delivered to the target as part of resuming its
execution. If no target program is currently running, ::next will start a new
program running as if by ::run and stop at the first instruction.
::run [args ... ]
::r [args ... ]
Start a new target program running with the specified arguments and attach to it. The arguments are not interpreted by the shell. If the debugger is already examining a live running program, it will first detach from this program as if by ::release.

[signal] ::sigbp [+/-DestT] [-c cmd] [-n count] SIG ...
[signal] ::t [+/-DestT] [-c cmd] [-n count] SIG ...
Trace delivery of the specified signals. The signals are identified using an optional signal number preceding the dcmd, or a list of signal names or numbers (see signal(3HEAD)) following the dcmd. The -d, -D, -e, -s, -t, -T, -c, and -n options have the same meaning as they do for the ::evset dcmd. Initially, the set of signals that cause the process to dump core by default (see signal(3HEAD)) and SIGINT are traced.

::step [over | out] [SIG]
::s SIG
::u SIG
Step the target program one instruction. If an optional signal name or number (see the signal(3HEAD) man page) is specified as an argument, the signal is immediately delivered to the target as part of resuming its execution. If the optional "over" argument is specified, ::step will step over subroutine calls. The ::step over argument is the same as the ::next dcmd. If the optional "out" argument is specified, the target program will continue until the representative thread returns from the current function. If no target program is currently running, ::step over will start a new program running as if by ::run and stop at the first instruction. The ::s dcmd is the same as ::step. The ::u dcmd is the same as ::step out.

[syscall] ::sysbp [+/-DestT] [-i] [-c cmd] [-n count] syscall ...
Trace entry to or exit from the specified system calls. The system calls are identified using an optional system call number preceding the dcmd, or a list of system call names or numbers (see <sys/syscall.h>) following the dcmd. If the -i option is specified (the default), the event specifiers trigger on entry into the kernel for each system call. If the -o option is specified, the event specifiers trigger on exit out from the kernel. The -d, -D, -e, -s, -t, -T, -c, and -n options have the same meaning as they do for the ::evset dcmd.

addr [len]: wp [+/-DestT] [-rwx] [-c cmd] [-n count]
addr [len]: a [cmd... ]
addr [len]: w [cmd... ]
Set a watchpoint at the specified address. The length in bytes of the watched region may be set by specifying an optional repeat count preceding the dcmd. If no length is explicitly set, the default is one byte. The ::wp dcmd allows the watchpoint to be configured to trigger on any combination of read (-r option), write (-w option), or execute (-x option) access. The -d, -D, -e, -s, -t, -T, -c, and -n options have the same meaning as they do for the ::evset dcmd. The :a dcmd sets a read access watchpoint at the specified address. The :p dcmd sets an execute access watchpoint at the specified address. The :w dcmd sets a write access watchpoint at
the specified address. The arguments following the :a, :p, and :w dcmds are concatenated together to form the callback string. If this string contains meta-characters, it must be quoted.

:z
Delete all event specifiers from the list of traced software events. Event specifiers can also be deleted using ::delete.

---

Interaction With exec

When a controlled process performs a successful exec(2), the behavior of the debugger is controlled by the ::set -o follow_exec_mode option, as described in “Summary of Command-line Options” on page 137. If the debugger and victim process have the same data model, then the "stop" and "follow" modes determine whether MDB automatically continues the target or returns to the debugger prompt following the exec. If the debugger and victim process have a different data model, then the "follow" behavior causes MDB to automatically re-exec the MDB binary with the appropriate data model and re-attach to the process, still stopped on return from the exec. Not all debugger state is preserved across this re-exec.

If a 32-bit victim process execs a 64-bit program, then "stop" will return to the command prompt, but the debugger will no longer be able to examine the process because it is now using the 64-bit data model. To resume debugging, execute the ::release -a dcmd, quit MDB, and then execute mdb -p pid to re-attach the 64-bit debugger to the process.

If a 64-bit victim process execs a 32-bit program, then "stop" will return to the command prompt, but the debugger will only provide limited capabilities for examining the new process. All built-in dcmds will work as advertised, but loadable dcmds will not since they do not perform data model conversion of structures. The user should release and reattach the debugger to the process as described above in order to restore full debugging capabilities.

---

Interaction with Job Control

If the debugger is attached to a process that is stopped by job control (that is, it stopped in response to SIGTSTP, SIGTTIN, or SIGTTOU), the process may not be able to be set running again when it is continued by a continue dcmd. If the victim process is a member of the same session (that is, it shares the same controlling terminal as MDB), MDB will attempt to bring the associated process group to the foreground and
continue the process with SIGCONT to resume it from job control stop. When MDB is detached from such a process, it will restore the process group to the background before exiting. If the victim process is not a member of the same session, MDB cannot safely bring the process group to the foreground, so it will continue the process with respect to the debugger but the process will remain stopped by job control. MDB will print a warning in this case, and the user must issue a `fg` command from the appropriate shell in order to resume the process.

Process Attach and Release

When MDB attaches to a running process, the process is stopped and remains stopped until one of the continue dcmds is applied, or the debugger quits. If the `-nostop` option is enabled prior to attaching the debugger to a process with `-p` or prior to issuing an `:attach` or `:A` command, MDB will attach to the process but not stop it. While the process is still running, it may be inspected as usual (albeit with inconsistent results) and breakpoints or other tracing flags may be enabled. If the `:c` or `:cont` dcmds are executed while the process is running, the debugger will wait for the process to stop. If no traced software events occur, the user can send an interrupt (^C) after `:c` or `:cont` to force the process to stop and return control to the debugger.

MDB releases the current running process (if any) when the `:R`, `:release`, `:r`, `:run`, `:q`, or `:quit` dcmds are executed, or when the debugger terminates as the result of an EOF or signal. If the process was originally created by the debugger using `:r` or `:run`, it will be forcibly terminated as if by SIGKILL when it is released. If the process was already running prior to attaching MDB to it, it will be set running again when it is released. A process may be released and left stopped and abandoned using the `:release -a` option.
Kernel Debugging Modules

This chapter describes the debugger modules, dcmds, and walkers provided to debug the Solaris kernel. Each kernel debugger module is named after the corresponding Solaris kernel module, so that it will be loaded automatically by MDB. The facilities described here reflect the current Solaris kernel implementation and are subject to change in the future; writing shell scripts that depend on the output of these commands is not recommended. In general, the kernel debugging facilities described in this chapter are meaningful only in the context of the corresponding kernel subsystem implementation. See “Related Books and Papers” on page 11 for a list of references that provide more information about the Solaris kernel implementation.

Note – This guide reflects the Solaris 9 operating environment implementation; these modules, dcmds, and walkers may not be relevant, correct, or applicable to past or future releases, since they reflect the current kernel implementation. They do not define a permanent public interface of any kind. All of the information provided about modules, dcmds, walkers, and their output formats and arguments is subject to change in future releases of the Solaris operating environment.

Generic Kernel Debugging Support (genunix)

Kernel Memory Allocator

This section discusses the dcmds and walkers used to debug problems identified by the Solaris kernel memory allocator and to examine memory and memory usage. The dcmds and walkers described here are discussed in more detail in Chapter 8.
dcmds

thread ::allocdby
Given the address of a kernel thread, print a list of memory allocations it has performed in reverse chronological order.

bufctl ::bufctl [-a address] [-c caller] [-e earliest] [-l latest] [-t thread]
Print a summary of the bufctl information for the specified bufctl address. If one or more options are present, the bufctl information is printed only if it matches the criteria defined by the option arguments; in this way, the dcmd can be used as a filter for input from a pipeline. The -a option indicates that the bufctl’s corresponding buffer address must equal the specified address. The -c option indicates that a program counter value from the specified caller must be present in the bufctl’s saved stack trace. The -e option indicates that the bufctl’s timestamp must be greater than or equal to the specified earliest timestamp. The -l option indicates that the bufctl’s timestamp must be less than or equal to the specified latest timestamp. The -t option indicates that the bufctl’s thread pointer must be equal to the specified thread address.

[ address ] ::findleaks [-v]
The ::findleaks dcmd provides powerful and efficient detection of memory leaks in kernel crash dumps where the full set of kmem debug features has been enabled. The first execution of ::findleaks processes the dump for memory leaks (this can take a few minutes), then coalesces the leaks by the allocation stack trace. The findleaks report shows a bufctl address and the topmost stack frame for each memory leak that was identified.

If the -v option is specified, the dcmd prints more verbose messages as it executes. If an explicit address is specified prior to the dcmd, the report is filtered and only leaks whose allocation stack traces contain the specified function address are displayed.

thread ::freedby
Given the address of a kernel thread, print a list of memory frees it has performed, in reverse chronological order.

value ::kgrep
Search the kernel address space for pointer-aligned addresses that contain the specified pointer-sized value. The list of addresses that contain matching values is then printed. Unlike MDB’s built-in search operators, ::kgrep searches every segment of the kernel’s address space and searches across discontiguous segment boundaries. On large kernels, ::kgrep can take a considerable amount of time to execute.

::kmalog [ slab | fail ]
Display events in a kernel memory allocator transaction log. Events are displayed in time-reverse order, with the most recent event displayed first. For each event, ::kmalog displays the time relative to the most recent event in T-minus notation (for example, T-0.000151879), the bufctl, the buffer address, the kmem cache name, and the stack trace at the time of the event. Without arguments, ::kmalog displays the kmem transaction log, which is present only if KMF_AUDIT is set in
::kmalogfail displays the allocation failure log, which is always present; this can be useful in debugging drivers that don’t cope with allocation failure correctly. ::kmalogslab displays the slab create log, which is always present. ::kmalogslab can be useful when searching for memory leaks.

::kmastat
Display the list of kernel memory allocator caches and virtual memory arenas, along with corresponding statistics.

::kmausers [-ef][cache ...]
Print information about the medium and large users of the kernel memory allocator that have current memory allocations. The output consists of one entry for each unique stack trace specifying the total amount of memory and number of allocations that was made with that stack trace. This dcmd requires that the KM_F_AUDIT flag is set in kmem_flags.

If one or more cache names (for example, kmem_alloc_256) are specified, the scan of memory usage is restricted to those caches. By default all caches are included. If the -e option is used, the small users of the allocator are included. The small users are allocations that total less than 1024 bytes of memory or for which there are less than 10 allocations with the same stack trace. If the -f option is used, the stack traces are printed for each individual allocation.

[ address ] ::kmem_cache
Format and display the kmem_cache structure stored at the specified address, or the complete set of active kmem_cache structures.

::kmem_log
Display the complete set of kmem transaction logs, sorted in reverse chronological order. This dcmd uses a more concise tabular output format than ::kmalog.

[ address ] ::kmem_verify
Verify the integrity of the kmem_cache structure stored at the specified address, or the complete set of active kmem_cache structures. If an explicit cache address is specified, the dcmd displays more verbose information regarding errors; otherwise, a summary report is displayed. The ::kmem_verify dcmd is discussed in more detail in “Kernel Memory Caches” on page 93.

[ address ] ::vmem
Format and display the vmem structure stored at the specified address, or the complete set of active vmem structures. This structure is defined in <sys/vmem_impl.h>.

address ::vmem_seg
Format and display the vmem_seg structure stored at the specified address. This structure is defined in <sys/vmem_impl.h>.

address ::whatis [-abv]
Report information about the specified address. In particular, ::whatis will attempt to determine if the address is a pointer to a kmem-managed buffer or another type of special memory region, such as a thread stack, and report its findings. If the -a option is present, the dcmd reports all matches instead of just the
first match to its queries. If the `-b` option is present, the dcmd also attempts to determine if the address is referred to by a known kmem_bufctl. If the `-v` option is present, the dcmd reports its progress as it searches various kernel data structures.

**Walkers**

- **allocdby**
  Given the address of a `kthread_t` structure as a starting point, iterate over the set of `bufctl` structures corresponding to memory allocations performed by this kernel thread.

- **bufctl**
  Given the address of a `kmem_cache_t` structure as a starting point, iterate over the set of allocated `bufctl` structures associated with this cache.

- **freectl**
  Given the address of a `kmem_cache_t` structure as a starting point, iterate over the set of free `bufctl` structures associated with this cache.

- **freedby**
  Given the address of a `kthread_t` structure as a starting point, iterate over the set of `bufctl` structures corresponding to memory deallocations performed by this kernel thread.

- **freemem**
  Given the address of a `kmem_cache_t` structure as a starting point, iterate over the set of free buffers associated with this cache.

- **kmem**
  Given the address of a `kmem_cache_t` structure as a starting point, iterate over the set of allocated buffers associated with this cache.

- **kmem_cache**
  Iterate over the active set of `kmem_cache_t` structures. This structure is defined in `<sys/kmem_impl.h>`.

- **kmem_cpu_cache**
  Given the address of a `kmem_cache_t` structure as a starting point, iterate over the per-CPU `kmem_cpu_cache_t` structures associated with this cache. This structure is defined in `<sys/kmem_impl.h>`.

- **kmem_slab**
  Given the address of a `kmem_cache_t` structure as a starting point, iterate over the set of associated `kmem_slab_t` structures. This structure is defined in `<sys/kmem_impl.h>`.

- **kmem_log**
  Iterate over the set of `bufctl` structures stored in the kmem allocator transaction log.

- **leak**
  Given the address of a `bufctl` structure, iterate over the set of `bufctl` structures corresponding to leaked memory buffers with similar allocation stack traces. The `::findleaks` dcmd must be applied to locate memory leaks before the leak walker can be used.
leakbuf

Given the address of a bufctl structure, iterate over the set of buffer addresses corresponding to leaked memory buffers with similar allocation stack traces. The ::findleaks dcmd must be applied to locate memory leaks before the leakbuf walker can be used.

File Systems

The MDB file systems debugging support includes a built-in facility to convert vnode pointers to the corresponding file system path name. This conversion is performed using the Directory Name Lookup Cache (DNLC); because the cache does not hold all active vnodes, some vnodes might not be able to be converted to path names and “??” is displayed instead of a name.

dcmds

::fsinfo

Display a table of mounted file systems, including the vfs_t address, ops vector, and mount point of each file system.

::lminfo

Display a table of vnodes with active network locks registered with the lock manager. The pathname corresponding to each vnode is shown.

address ::vnode2path [-v]

Display the pathname corresponding to the given vnode address. If the -v option is specified, the dcmd prints a more verbose display, including the vnode pointer of each intermediate path component.

Walkers

buf

Iterate over the set of active block I/O transfer structures (buf_t structures). The buf structure is defined in <sys/buf.h> and is described in more detail in buf(9S).

Virtual Memory

This section describes the debugging support for the kernel virtual memory subsystem.
dcmds

`address :: addr2smap [offset]`  Print the smap structure address that corresponds to the given address in the kernel’s segmap address space segment.

`as :: as2proc`  Display the proc_t address for the process corresponding to the as_t address as.

`[ address ] :: memlist [-aiv]`  Display the specified memlist structure or one of the well-known memlist structures. If no memlist address and options are present or if the -i option is present, the memlist representing physically installed memory is displayed. If the -a option is present, the memlist representing available physical memory is displayed. If the -v option is present, the memlist representing available virtual memory is displayed.

`::memstat`  Display a system-wide memory usage summary. The amount and percentage of system memory consumed by different classes of pages (kernel, anonymous memory, executables and libraries, page cache, and free lists) are displayed, along with the total amount of system memory.

`[ address ] :: page`  Display the properties of the specified page_t. If no page_t address is specified, the dcmd displays the properties of all system pages.

`seg :: seg`  Format and display the specified address space segment (seg_t address).

`[ address ] :: swapinfo`  Display information on all active swapinfo structures or about the specified struct swapinfo. The vnode, filename, and statistics for each structure are displayed.

`vnode :: vnode2smap [offset]`  Print the smap structure address that corresponds to the given vnode_t address and offset.

Walkers

`anon`  Given the address of an anon_map structure as a starting point, iterate over the set of related anon structures. The anon map implementation is defined in `<vm/anon.h>`.

`memlist`  Iterate over the spans of the specified memlist structure. This walker can be used in conjunction with the `::memlist` dcmd to display each span.
page Iterate over all system page structures. If an explicit address is specified for the walk, this is taken to be the address of a vnode and the walker iterates over only those pages associated with the vnode.

seg Given the address of an as_t structure as a starting point, iterate over the set of address space segments (seg structures) associated with the specified address space. The seg structure is defined in <vm/seg.h>.

swapinfo Iterate over the list of active swapinfo structures. This walker may be used in conjunction with the ::swapinfo dcmd.

CPUs and the Dispatcher

This section describes the facilities for examining the state of the cpu structures and the kernel dispatcher.

dcmds
::callout Display the callout table. The function, argument, and expiration time for each callout is displayed.
::class Display the scheduling class table.
[ cpuid ] ::cpuinfo [-v] Display a table of the threads currently executing on each CPU. If an optional CPU ID number or CPU structure address is specified prior to the dcmd name, only the information for the specified CPU is displayed. If the -v option is present, ::cpuinfo also displays the runnable threads waiting to execute on each CPU as well as the active interrupt threads.

Walkers

cpu Iterate over the set of kernel CPU structures. The cpu_t structure is defined in <sys/cpuvar.h>.

Device Drivers and DDI Framework

This section describes dcmds and walkers that are useful for kernel developers as well as third-party device driver developers.

dcmds

address ::binding_hash_entry
   Given the address of a kernel name-to-major number binding hash table entry
   (struct bind), display the node binding name, major number, and pointer to the
   next element.

::devbindings device-name
   Display the list of all instances of the named driver. The output consists of an entry
   for each instance, beginning with the pointer to the struct dev_info (viewable
   with $<devinfo or ::devinfo), the driver name, the instance number, and the
   driver and system properties associated with that instance.

address ::devinfo [-q]
   Print the system and driver properties associated with a devinfo node. If the -q
   option is specified, only a quick summary of the device node is shown.

address ::devinfo2driver
   Print the name of the driver (if any) associated with the devinfo node.

[ address ] ::devnames [-v]
   Display the kernel’s devnames table along with the dn_head pointer, which points
   at the driver instance list. If the -v flag is specified, additional information stored at
   each entry in the devnames table is displayed.

[ devinfo ] ::prtconf [-cpv]
   Display the kernel device tree starting at the device node specified by devinfo. If
   devinfo is not provided, the root of the device tree is assumed by default. If the -c
   option is specified, only children of the given device node are displayed. If the -p
   option is specified, only ancestors of the given device node are displayed. If -v is
   specified, the properties associated with each node are displayed.

[ major-num ] ::major2name [ major-num ]
   Display the driver name corresponding to the specified major number. The major
   number can be specified as an expression preceding the dcmd or as a
   command-line argument.

[ address ] ::modctl2devinfo
   Print all of the device nodes that correspond to the specified modctl address.

::name2major driver-name
   Given a device driver name, display its major number.

[ address ] ::softstate [ instance-number ]
   Given a softstate state pointer (see ddi_soft_state_init(9F)) and a device
   instance number, display the soft state for that instance.

Walkers

binding_hash
   Given the address of an array of kernel binding hash table entries
   (struct bind **), walk all entries in the hash table and return the
   address of each struct bind.
devinfo

First, iterate over the parents of the given devinfo and return them in order of seniority from most to least senior. Second, return the given devinfo itself. Third, iterate over the children of the given devinfo in order of seniority from most to least senior. The dev_info struct is defined in <sys/ddi_impldefs.h>.

devinfo_children

First, return the given devinfo, then iterate over the children of the given devinfo in order of seniority from most to least senior. The dev_info struct is defined in <sys/ddi_impldefs.h>.

devinfo_parents

Iterate over the parents of the given devinfo in order of seniority from most to least senior, and then return the given devinfo. The dev_info struct is defined in <sys/ddi_impldefs.h>.

devi_next

Iterate over the siblings of the given devinfo. The dev_info struct is defined in <sys/ddi_impldefs.h>.

devnames

Iterate over the entries in the devnames array. This structure is defined in <sys/autoconf.h>.

softstate

Given a softstate pointer (see ddi_soft_state_init(9F)) display all non-NULL pointers to driver state structures.

softstate_all

Given a softstate pointer (see ddi_soft_state_init(9F)) display all pointers to driver state structures. Note that the pointers for unused instances will be NULL.

STREAMEs

This section describes dcmds and walkers that are useful for kernel developers as well as developers of third-party STREAMS modules and drivers.

dcmds

address :: mblk2dblk

Given the address of an mblk_t, print the address of the corresponding dblk_t.

[address] :: mblk_verify

Verify the integrity of one or more message blocks. If an explicit message block address is specified, the integrity of this message block is checked. If no address is specified, the integrity of all active message blocks are checked. This dcmd produces output for any invalid message block state that is detected.

address :: queue [-v] [-f flag] [-F flag] [-s syncq]

Filter and display the specified queue_t data structure. With no options, various properties of the queue_t are shown. If the -v option is present, the queue flags are decoded in greater detail. If the -f, -F, or -m options are present, the queue is displayed only if it matches the criteria defined by the arguments to these options;
in this way, the dcmd can be used as a filter for input from a pipeline. The -f option indicates that the specified flag (one of the Q flag names from <sys/stream.h>) must be present in the queue flags. The -F option indicates that the specified flag must be absent from the queue flags. The -m option indicates that the module name associated with the queue must match the specified modname. The -s option indicates that the syncq_t associated with the queue must match the specified syncq_t address.

address :: q2syncq
Given the address of a queue_t, print the address of the corresponding syncq_t data structure.

address :: q2otherq
Given the address of a queue_t, print the address of the peer read or write queue structure.

address :: q2rdq
Given the address of a queue_t, print the address of the corresponding read queue.

address :: q2wrq
Given the address of a queue_t, print the address of the corresponding write queue.

[ address ] :: stream
Display a visual picture of a kernel STREAM data structure, given the address of the stdata_t structure representing the STREAM head. The read and write queue pointers, byte count, and flags for each module are shown, and in some cases additional information for the specific queue is shown in the margin.

address :: sync [-v] [-f flag] [-F flag] [-t type] [-T type]
Filter and display the specified syncq_t data structure. With no options, various properties of the syncq_t are shown. If the -v option is present, the syncq flags are decoded in greater detail. If the -f, -F, -t, or -T options are present, the syncq is displayed only if it matches the criteria defined by the arguments to these options; in this way, the dcmd can be used as a filter for input from a pipeline. The -f option indicates that the specified flag (one of the SQ_flag names from <sys/strsubr.h>) must be present in the syncq flags. The -F option indicates that the specified flag must be absent from the syncq flags. The -t option indicates that the specified type (one of the SQ_CI or SQ_CO type names from <sys/strsubr.h>) must be present in the syncq type bits. The -T option indicates that the specified type must be absent from the syncq type bits.

address :: syncq2q
Given the address of a syncq_t, print the address of the corresponding queue_t data structure.

Walkers

b_cont  Given the address of an mblk_t, iterate over the set of associated message structures by following the b_cont pointer. The b_cont pointer is used to
link a given message block to the next associated message block that is the
continuation of the same message. The message block is described in more
detail in msgb(9S).

b_next Given the address of an mblk_t, iterate over the set of associated message
structures by following the b_next pointer. The b_next pointer is used to
link a given message block to the next associated message block on a given
queue. The message block is described in more detail in msgb(9S).

qlink Given the address of a queue_t structure, walk the list of related queues
using the q_link pointer. This structure is defined in <sys/stream.h>.

qnext Given the address of a queue_t structure, walk the list of related queues
using the q_next pointer. This structure is defined in <sys/stream.h>.

readq Given the address of an stdata_t structure, walk the list of read-side
queue structures.

writeq Given the address of an stdata_t structure, walk the list of write-side
queue structures.

Networking
The following dcmds and walkers are provided to help debug the core kernel
networking stack protocols.

dcmds

address :: mi [-p] [-d | -m]
Given the address of a kernel MI_O, filter and display the MI_O or its payload. If
the -p option is specified, then the address of the corresponding payload of the
MI_O is displayed, otherwise the MI_O itself is displayed. Specifying filter -d or -m
enables the dcmd to filter device or module MI_O objects respectively.

:: netstat [-av] [-f inet | inet6 | unix] [-P tcp | udp]
Show network statistics and active connections. If the -a option is present, the state
of all sockets is displayed. If the -v option is present, more verbose output is
displayed. If the -f option is present, only connections associated with the
specified address family are displayed. If the -P option is present, only connections
associated with the specified protocols are displayed.

[ address ] :: sonode [-f inet | inet6 | unix | id] [-t stream | dgram | raw |
id] [-p id]
Filters and displays sonode objects. If no address is given, then the list of AF_UNIX
sockets is displayed, otherwise only the specified sonode is displayed. If the -f
option is present, then only sockets of the given family will be output. If the -t
option is present, then only sonodes of the given type will be output. If the -p
option is present, then only sockets of the given protocol will be displayed.
[address] ::tcpb [-av] [-P v4 | v6]
Filters and displays tcpb objects. If no address is specified, all connections are walked, otherwise only the specified tcpb is filtered/displayed. Specifying -a filters for only active connections and -P can be used to filter for TCP IPv4 or IPv6 connections. The tcpb dcmd is intelligent about filtering TCP connections, and if a IPv6 TCP connection is in a state that would still facilitate a IPv4 connection, the -P filter considers the connection as both IPv4 and IPv6 in much the same way that ::netstat does. If the dcmd is not being used as a filter and the -v option is specified, then the output of the dcmd will be verbose.

Walkers
ar     Given the address of an ar, this walker walks all ar objects from the given ar to the final ar. If no address is specified, all ar objects are walked.
icmp   Given the address of an icmp, this walker walks all icmp objects from the given icmp to the final icmp. If no address is specified, all icmp objects are walked.
ill     Given the address of an interface link layer structure (ill), this walker walks all ill objects from the given ill to the final. If no address is specified, all ill objects are walked.
ipc     Given the address of an ipc, this walker walks all ipc objects from the given ipc to the final ipc. If no address is specified, all ipc objects are walked.
mi     Given the address of a MI_O, walk all the MI_O's in this MI.
sonode Given the address of a AF_UNIX sonode, walk the associated list of AF_UNIX sonodes beginning with the given sonode. If no address is specified, this walker walks the list of all AF_UNIX sockets.
tcpb   Given the address of a tcpb, this walker walks all TCP connections from the given tcpb to the final TCP connection. If no address is specified, all tcpb objects are walked.
udp     Given the address of a udp, this walker walks all udp objects from the given udp to the final udp. If no address is specified, all udp objects are walked.

Files, Processes, and Threads
This section describes dcmds and walkers used to format and examine various fundamental file, process, and thread structures in the Solaris kernel.
dcmds

process : fd fd-num
Print the file_t address corresponding to the file descriptor fd-num associated
with the specified process. The process is specified using the virtual address of its
proc_t structure.

thread : findstack [ command ]
Print the stack trace associated with the given kernel thread, identified by the
virtual address of its kthread_t structure. The dcmd employs several different
algorithms to locate the appropriate stack backtrace. If an optional command string
is specified, the dot variable is reset to the frame pointer address of the topmost
stack frame, and the specified command is evaluated as if it had been typed at the
command line. The default command string is “<. $C0”; that is, print a stack trace
including frame pointers but no arguments.

pid : pid2proc
Print the proc_t address corresponding to the specified PID. Recall that MDB’s
default base is hexadecimal, so decimal PIDs obtained using pgrep(1) or ps(1)
should be prefixed with 0t.

process : pmap [-q]
Print the memory map of the process indicated by the given process address. The
dcmd displays output using a format similar to pmap(1). If the -q option is present,
the dcmd displays an abbreviated form of its output that requires less processing
time.

[ address ] : ps [-fltTP]
Print a summary of the information related to the specified process, or all active
system processes, similar to ps(1). If the -f option is specified, the full command
name and initial arguments are printed. If the -l option is specified, the LWPs
associated with each process are printed. If the -t option is specified, the kernel
threads associated with each process LWP are printed. If the -T option is specified,
the task ID associated with each process is displayed. If the -P option is specified,
the project ID associated with each process is displayed.

::ptree
Print a process tree, with child processes indented from their respective parent
processes. The dcmd displays output using a format similar to ptree(1).

address :: task
Print a list of the active kernel task structures and their associated ID numbers and
attributes. The process task ID is described in more detail in settaskid(2).

[ address ] :: thread [-bdfimps]
Display properties of the specified kernel kthread_t structure. If no kthread_t
address is specified, the properties of all kernel threads are displayed. The dcmd
options are used to control which output columns are shown. If no options are
present, the -i option is enabled by default. If the -b option is present, information
relating to the thread’s turnstile and blocking synchronization object is shown. If
the -d option is present, the thread’s dispatcher priority, binding, and last dispatch
time is shown. If the -t option is present, threads whose state is TS_FREE are
elided from the output. If the -i option is present (the default), thread state, flags,
priority, and interrupt information is shown. If the -m option is present, all of the
other output options are merged together on to a single output line. If the -p option
is present, the thread’s process, LWP, and credential pointers are displayed. If the
-s option is present, the thread’s signal queue and masks of pending and held
signals are shown.

vnode ::whereopen
Given a vnode_t address, print the proc_t addresses of all processes that have
this vnode currently open in their file table.

Walkers

file Given the address of a proc_t structure as a starting point, iterate over the
set of open files (file_t structures) associated with the specified process.
The file_t structure is defined in <sys/file.h>.

proc Iterate over the active process (proc_t) structures. This structure is defined
in <sys/proc.h>.

task Given a task pointer, iterate over the list of proc_t structures for processes
that are members of the given task

thread Iterate over a set of kernel thread (kthread_t) structures. If the global
walk is invoked, all kernel threads are returned by the walker. If a local
walk is invoked using a proc_t address as the starting point, the set of
threads associated with the specified process is returned. The kthread_t
structure is defined in <sys/thread.h>.

Synchronization Primitives

This section describes dcmds and walkers used to examine particular kernel
synchronization primitives. The semantics of each primitive are discussed in the
 corresponding (9F) section of the manual pages.

dcmds

rwlock :: rwlock
Given the address of a readers-writers lock (see
rwlock(9F)), display the current state of the lock
and the list of waiting threads.

address :: sobj2ts
Convert the address of a synchronization object to
the address of the corresponding turnstile and print
the turnstile address.
Display the properties of the specified turnstile_t. If no turnstile_t address is specified, the dcmd displays the properties of all turnstiles.

Given the address of a condition variable (see condvar(9F)) or semaphore (see semaphore(9F)), display the current number of waiters on this object. If no explicit address is specified, display all such objects that have waiting threads. If the -v option is specified, display the list of threads that are blocked on each object.

Walkers

- **blocked**: Given the address of a synchronization object (such as a mutex(9F) or rwlock(9F)), iterate over the list of blocked kernel threads.
- **wchan**: Given the address of a condition variable (see condvar(9F)) or semaphore (see semaphore(9F)), iterate over the list of blocked kernel threads.

Cyclics

The cyclic subsystem is a low-level kernel subsystem that provides high resolution, per-CPU interval timer facilities to other kernel services and programming interfaces.

dcmds

- **::cycinfo[-vV]**: Display the cyclic subsystem per-CPU state for each CPU. If the -v option is present, a more verbose display is shown. If the -V option is present, an even more verbose display than -v is shown.
- **address ::cyclic**: Format and display the cyclic_t at the specified address.
- **::cyccover**: Display cyclic subsystem code coverage information. This information is available only in a DEBUG kernel.
- **::cyctrace**: Display cyclic subsystem trace information. This information is available only in a DEBUG kernel.
Walkers

cyc CPU Iterate over the per-CPU cyc_cpu_t structures. This structure is defined in <sys/cyclic_impl.h>.

cyctrace Iterate over the cyclic trace buffer structures. This information is only available in a DEBUG kernel.

Task Queues

The task queue subsystem provides general-purpose asynchronous task scheduling for a variety of clients in the kernel.

dcmds

address :::taskq_entry Print the contents of the specified struct taskq_entry.

Walkers
taskq_entry Given the address of a taskq structure, iterate over the list of taskq_entry structures.

Error Queues

The error queue subsystem provides general-purpose asynchronous error event processing for platform-specific error handling code.

dcmds

[ address ] :::errorq Display a summary of information relating to the specified error queue. If no address is given, display information relating to all system error queues. The address, name, queue length, and data element size for each queue are displayed, along with various queue statistics.

Walkers

errorq Walk the list of system error queues and return the address of each individual error queue.
errorq_data  Given the address of an error queue, return the address of each pending error event data buffer.

Configuration
This section describes dcmds that can be used to examine system configuration data.

dcmds
::system  Display the contents of the system(4) configuration file at the time the kernel parsed the file during system initialization.

Interprocess Communication Debugging Support (ipc)
The ipc module provides debugging support for the implementation of the message queue, semaphore, and shared memory interprocess communication primitives.

dcmds
::ipcs [-l]  Display a listing of system-wide IPC identifiers, corresponding to known message queues, semaphores, and shared memory segments. If the -l option is specified, a longer listing of information is shown.

address ::msg [-l] [-t type]  Display the properties of the specified message queue element (struct msg). If the -l option is present, the raw contents of the message are displayed in hexadecimal and ASCII. If the -t option is present, it can be used to filter the output and only display messages of the specified type. This can be useful when piping the output of the msgqueue walker to ::msg.

id ::msqid [-k]  Convert the specified message queue IPC identifier to a pointer to the corresponding kernel implementation
structure and print the address of this kernel structure. If the -k option is present, the id is instead interpreted as a message queue key to match (see msgget(2)).

[address] : : msqid_ds [-l] Print the specified msqid_ds structure or a table of the active msqid_ds structures (message queue identifiers). If the -l option is specified, a longer listing of information is displayed.

id : : semid [-k] Convert the specified semaphore IPC identifier to a pointer to the corresponding kernel implementation structure and print the address of this kernel structure. If the -k option is present, the id is instead interpreted as a semaphore key to match (see semget(2)).

[address] : : semid_ds [-l] Print the specified semid_ds structure or a table of the active semid_ds structures (semaphore identifiers). If the -l option is specified, a longer listing of information is displayed.

id : : shmid [-k] Convert the specified shared memory IPC identifier to a pointer to the corresponding kernel implementation structure and print the address of this kernel structure. If the -k option is present, the id is instead interpreted as a shared memory key to match (see shmget(2)).

[address] : : shmid_ds [-l] Print the specified shmid_ds structure or a table of the active shmid_ds structures (shared memory segment identifiers). If the -l option is specified, a longer listing of information is displayed.

Walkers

msg Walk the active msqid_ds structures corresponding to message queue identifiers. This structure is defined in <sys/msg.h>.

msgqueue Iterate over the message structures that are currently enqueued on the specified message queue.

sem Walk the active semid_ds structures corresponding to semaphore identifiers. This structure is defined in <sys/sem.h>.

shm Walk the active shmid_ds structures corresponding to shared memory segment identifiers. This structure is defined in <sys/shm.h>.
Loopback File System Debugging Support (lofs)

The lofs module provides debugging support for the lofs(7FS) file system.

**dcmds**

- **[address] :: lnode**
  Print the specified lnode_t, or a table of the active lnode_t structures in the kernel.

- **address :: lnode2dev**
  Print the dev_t (vfs_dev) for the underlying loopback mounted filesystem corresponding to the given lnode_t address.

- **address :: lnode2rdev**
  Print the dev_t (li_rdev) for the underlying loopback mounted file system corresponding to the given lnode_t address.

**Walkers**

- **lnode**
  Walk the active lnode_t structures in the kernel. This structure is defined in `<sys/fs/lofs_node.h>`.

Internet Protocol Module Debugging Support (ip)

The ip module provides debugging support for the ip(7P) driver.

**dcmds**

- **[address] :: ire [-q]**
  Print the specified ire_t, or a table of the active ire_t structures in the kernel. If the -q flag is specified, the send and receive queue pointers are printed instead of the source
and destination addresses.

Walkers

ire  Walk the active ire (Internet Route Entry) structures in the kernel. This structure is defined in <inet/ip.h>.

Kernel Runtime Link Editor Debugging Support (krtld)

This section describes the debugging support for the kernel runtime link editor, which is responsible for loading kernel modules and drivers.

dcmds

[ address ] ::modctl  Print the specified modctl, or a table of the active modctl structures in the kernel.

address ::modhdrs  Given the address of a modctl structure, print the module’s ELF executable header and section headers.

::modinfo  Print information about the active kernel modules, similar to the output of the /usr/sbin/modinfo command.

Walkers

modctl  Walk the list of active modctl structures in the kernel. This structure is defined in <sys/modctl.h>.
USB Framework Debugging Support (uhci)

The *uhci* module provides debugging support for the host controller interface portion of the Universal Serial Bus (USB) framework.

**dcmds**

`address :: uhci_qh [-bd]` Given the address of a USB UHCI controller Queue Head (QH) structure, print the contents of the structure. If the `-b` option is present iterate over the `link_ptr` chain, printing all QHs found. If the `-d` option is present, iterate over the `element_ptr` chain, printing all TDs found.

`address :: uhci_td [-d]` Given the address of a USB UHCI controller Transaction Descriptor (TD) structure, print the contents of the structure. Note this only works for Control and Interrupt TDs. If the `-d` option is present, iterate over the `element_ptr` chain, printing all TDs found.

**Walkers**

`uhci_qh` Given the address of a USB UHCI controller Queue Head (QH) structure, iterate over the list of such structures.

`uhci_td` Given the address of a USB UHCI controller Queue Head Descriptor (TD) structure, iterate over the list of such structures.

USB Framework Debugging Support (usba)

The *usba* module provides debugging support for the platform-independent Universal Serial Bus (USB) framework.
dcmds

::usb_debug_buf
Print the USB debugging information buffer.

address ::usb_hcdi_cb
Given the address of a host controller callback structure (struct usb_hcdi_cb), print summary information for this callback.

[ address ] ::usb_device [-pv]
Given the address of a usb_device structure, print summary information. If no address is supplied, this dcmd walks the global list of usb_device structures. If the -p option is present, also list information for all open pipes on this device. If the -v option is present, list verbose information for each device.

address ::usb_pipe_handle
Given the address of a USB pipe handle structure (struct usb_pipe_handle_impl), print summary information for this handle.

Walkers

usb_hcdi_cb
Given the address of a USB host controller devinfo node, iterate over the list of usb_hcdi_cb_t structs for the controller.

usba_list_entry
Given the address of a usba_list_entry structure, iterate over the chain of such structures.

IA: Platform Debugging Support (unix)
These dcmds and walkers are specific to IA.

dcmds

[ cpuid | address ] ::ttrace [-x]
Display trap trace records in reverse chronological order. The trap trace facility is available only in DEBUG kernels. If an explicit dot value is specified, this is interpreted as either a CPU ID number or a trap trace record address, depending on the precise value. If a CPU ID is specified, the output is restricted to the buffer from that CPU. If a record address is specified, only that record is formatted. If the -x option is specified, the complete raw record is displayed.
Walkers

ttrace    Walk the list of trap trace record addresses in reverse chronological order.
The trap trace facility is available only in DEBUG kernels.

SPARC: sun4m Platform Debugging Support (unix)

These dcmds and walkers are specific to the SPARC sun4m platform.

dcmds

[ cpuid | address ] : ttrace [-x]
Display trap trace records in reverse chronological order. The trap trace facility is
available only in DEBUG kernels. If an explicit dot value is specified, this is
interpreted as either a CPU ID number or a trap trace record address, depending on
the precise value. If a CPU ID is specified, the output is restricted to the buffer from
that CPU. If a record address is specified, only that record is formatted. If the -x
option is specified, the complete raw record is displayed.

Walkers

rtrace    Walk the list of trap trace record addresses in reverse chronological order.
The trap trace facility is only available in DEBUG kernels.

SPARC: sun4u Platform Debugging Support (unix)

These dcmds and walkers are specific to the SPARC sun4u platform.
**dcmds**

[address]::softint Display the soft interrupt vector structure at the specified address, or display all the active soft interrupt vectors. The pending count, PIL, argument, and handler function for each structure is displayed.

::ttctl Display trap trace control records. The trap trace facility is available only in DEBUG kernels.

[cpuid]::ttrace[-x] Display trap trace records in reverse chronological order. The trap trace facility is available only in DEBUG kernels. If an explicit dot value is specified, this is interpreted as a CPU ID number, and the output is restricted to the buffer from that CPU. If the -x option is specified, the complete raw record is displayed.

[address]::xc_mbox Display the cross-call mailbox at the specified address, or format all the cross-call mailboxes that have pending requests.

::xctrace Format and display cross-call trace records in reverse chronological order that are related to CPU cross-call activity. The cross-call trace facility is available only in DEBUG kernels.

**Walkers**

softint Iterate over the soft interrupt vector table entries.

ttrace Iterate over the trap trace record addresses in reverse chronological order. The trap trace facility is only available in DEBUG kernels.

xc_mbox Iterate over the mailboxes used for CPU handshake and cross-call (x-call) requests.
Debugging With the Kernel Memory Allocator

The Solaris kernel memory (kmem) allocator provides a powerful set of debugging features that can facilitate analysis of a kernel crash dump. This chapter discusses these debugging features, and the MDB dcmds and walkers designed specifically for the allocator. Bonwick (see “Related Books and Papers” on page 11) provides an overview of the principles of the allocator itself. Refer to the header file `<sys/kmem_impl.h>` for the definitions of allocator data structures. The kmem debugging features can be enabled on a production system to enhance problem analysis, or on development systems to aid in debugging kernel software and device drivers.

Note – This guide reflects Solaris 9 implementation; this information might not be relevant, correct, or applicable to past or future releases, since it reflects the current kernel implementation. It does not define a public interface of any kind. All of the information provided about the kernel memory allocator is subject to change in future Solaris releases.

Getting Started: Creating a Sample Crash Dump

This section shows you how to obtain a sample crash dump, and how to invoke MDB in order to examine it.
Setting kmem_flags

The kernel memory allocator contains many advanced debugging features, but these are not enabled by default because they can cause performance degradation. In order to follow the examples in this guide, you should turn on these features. You should enable these features only on a test system, as they can cause performance degradation or expose latent problems.

The allocator’s debugging functionality is controlled by the kmem_flags tunable. To get started, make sure kmem_flags is set properly:

```
# mdb -k
> kmem_flags/X
kmem_flags:
  kmem_flags:  f
```

If kmem_flags is not set to ‘f’, you should add the line:

```
set kmem_flags=0xf
```

to /etc/system and reboot the system. When the system reboots, confirm that kmem_flags is set to ‘f’. Remember to remove your /etc/system modifications before returning this system to production use.

Forcing a Crash Dump

The next step is to make sure crash dumps are properly configured. First, confirm that dumpadm is configured to save kernel crash dumps and that savecore is enabled. See dumpadm(1M) for more information on crash dump parameters.

```
# dumpadm
Dump content: kernel pages
Dump device: /dev/dsk/c0t0d0s1 (swap)
Savecore directory: /var/crash/testsystem
Savecore enabled: yes
```

Next, reboot the system using the ‘-d’ flag to reboot(1M), which forces the kernel to panic and save a crash dump.

```
# reboot -d
Sep 28 17:51:18 testsystem reboot: rebooted by root
panic[cpu0]/thread=70aacde0: forced crash dump initiated at user request
401fbb10 genunix:uadmin=55c (1, 1, 0, 6d700000, 5, 0)
  %10-7: 00000000 00000000 00000000 00000000 00000000 00000000 00000000
  ... 00000000
```

When the system reboots, make sure the crash dump succeeded:
If the dump is missing from your dump directory, it could be that the partition is out of space. You can free up space and run `savecore(1M)` manually as root to subsequently save the dump. If your dump directory contains multiple crash dumps, the one you just created will be the `unix.[n]` and `vmcore.[n]` pair with the most recent modification time.

## Starting MDB

Now, run `mdb` on the crash dump you created, and check its status:

```
$ mdb unix.1 vmcore.1
Loading modules: [ unix krtld genunix ip nfs ipc ]
> ::status
debugging crash dump vmcore.1 (32-bit) from testsystem
operating system: 5.9 Generic (sun4u)
panic message: forced crash dump initiated at user request
```

In the examples presented in this guide, a crash dump from a 32-bit kernel is used. All of the techniques presented here are applicable to a 64-bit kernel, and care has been taken to distinguish pointers (sized differently on 32- and 64-bit systems) from fixed-sized quantities, which are invariant with respect to the kernel data model.

A Sun Ultra-1 workstation was used to generate the example presented. Your results can vary depending on the architecture and model of system you use.

---

## Allocator Basics

The kernel memory allocator’s job is to parcel out regions of virtual memory to other kernel subsystems (these are commonly called clients). This section explains the basics of the allocator’s operation and introduces some terms used later in this guide.

## Buffer States

The functional domain of the kernel memory allocator is the set of buffers of virtual memory that make up the kernel heap. These buffers are grouped together into sets of uniform size and purpose, known as caches. Each cache contains a set of buffers. Some of these buffers are currently free, which means that they have not yet been allocated to any client of the allocator. The remaining buffers are allocated, which means that a
pointer to that buffer has been provided to a client of the allocator. If no client of the allocator holds a pointer to an allocated buffer, this buffer is said to be *leaked*, because it cannot be freed. Leaked buffers indicate incorrect code that is wasting kernel resources.

**Transactions**

A *kmem transaction* is a transition on a buffer between the allocated and free states. The allocator can verify that the state of a buffer is valid as part of each transaction. Additionally, the allocator has facilities for logging transactions for post-mortem examination.

**Sleeping and Non-Sleeping Allocations**

Unlike the Standard C Library’s `malloc(3C)` function, the kernel memory allocator can block (or *sleep*), waiting until enough virtual memory is available to satisfy the client’s request. This is controlled by the ‘flag’ parameter to `kmem_alloc(9F)`. A call to `kmem_alloc(9F)` which has the `KM_SLEEP` flag set can never fail; it will block forever waiting for resources to become available.

**Kernel Memory Caches**

The kernel memory allocator divides the memory it manages into a set of *caches*. All allocations are supplied from these caches, which are represented by the `kmem_cache_t` data structure. Each cache has a fixed *buffer size*, which represents the maximum allocation size satisfied by that cache. Each cache has a string name indicating the type of data it manages.

Some kernel memory caches are special purpose and are initialized to allocate only a particular kind of data structure. An example of this is the “thread_cache,” which allocates only structures of type `kthread_t`. Memory from these caches is allocated to clients by the `kmem_cache_alloc()` function and freed by the `kmem_cache_free()` function.

---

*Note* – `kmem_cache_alloc()` and `kmem_cache_free()` are not public DDI interfaces. Do NOT write code that relies on them, because they are subject to change or removal in future releases of Solaris.

Caches whose name begins with “`kmem_alloc_`” implement the kernel’s general memory allocation scheme. These caches provide memory to clients of `kmem_alloc(9F)` and `kmem_zalloc(9F)`. Each of these caches satisfies requests whose size is between the buffer size of that cache and the buffer size of the next
smallest cache. For example, the kernel has `kmem_alloc_8` and `kmem_alloc_16` caches. In this case, the `kmem_alloc_16` cache handles all client requests for 9-16 bytes of memory. Remember that the size of each buffer in the `kmem_alloc_16` cache is 16 bytes, regardless of the size of the client request. In a 14 byte request, two bytes of the resulting buffer are unused, since the request is satisfied from the `kmem_alloc_16` cache.

The last set of caches are those used internally by the kernel memory allocator for its own bookkeeping. These include those caches whose names start with “kmem_magazine_” or “kmem_va_”, the `kmem_slab_cache`, the `kmem_bufctl_cache` and others.

### Kernel Memory Caches

This section explains how to find and examine kernel memory caches. You can learn about the various `kmem` caches on the system by issuing the `::kmastat` command:

```bash
> ::kmastat

<table>
<thead>
<tr>
<th>cache name</th>
<th>buf</th>
<th>buf</th>
<th>buf</th>
<th>memory</th>
<th>alloc alloc</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>

<td>368</td>
<td>107</td>
<td>126</td>
<td>49152</td>
<td>669881</td>
</tr>
<tr>
<td>lwp_cache</td>
<td>576</td>
<td>107</td>
<td>117</td>
<td>73728</td>
<td>182</td>
</tr>
<tr>
<td>turnstile_cache</td>
<td>36</td>
<td>149</td>
<td>292</td>
<td>16384</td>
<td>670506</td>
</tr>
<tr>
<td>cred_cache</td>
<td>96</td>
<td>6</td>
<td>73</td>
<td>8192</td>
<td>2677787</td>
</tr>
<tr>
<td>...</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

If you run `::kmastat` you get a feel for what a “normal” system looks like. This will help you to spot excessively large caches on systems that are leaking memory. The results of `::kmastat` will vary depending on the system you are running on, how many processes are running, and so forth.

Another way to list the various `kmem` caches is with the `::kmem_cache` command:

```bash
> ::kmem_cache

<table>
<thead>
<tr>
<th>ADDR</th>
<th>NAME</th>
<th>FLAG</th>
<th>CFLAG</th>
<th>BUFSIZE</th>
<th>BUFTOTL</th>
</tr>
</thead>
<tbody>
<tr>
<td>70036028</td>
<td>kmem_magazine_1</td>
<td>0020</td>
<td>0e0000</td>
<td>8</td>
<td>1020</td>
</tr>
<tr>
<td>700362a8</td>
<td>kmem_magazine_3</td>
<td>0020</td>
<td>0e0000</td>
<td>16</td>
<td>510</td>
</tr>
</tbody>
</table>
```

Chapter 8 • Debugging With the Kernel Memory Allocator 93
This command is useful because it maps cache names to addresses, and provides the debugging flags for each cache in the FLAG column. It is important to understand that the allocator’s selection of debugging features is derived on a per-cache basis from this set of flags. These are set in conjunction with the global kmem_flags variable at cache creation time. Setting kmem_flags while the system is running has no effect on the debugging behavior, except for subsequently created caches (which is rare after boot-up).

Next, walk the list of kmem caches directly using MDB’s kmem_cache walker:

```bash
> ::walk kmem_cache
```

This produces a list of pointers that correspond to each kmem cache in the kernel. To find out about a specific cache, apply the kmem_cache macro:

```bash
> 0x70039928$<kmem_cache
```

```
lock
owner/waiters
0
flags freelist offset
20f 707c86a0 24
global Alloc global_FREE alloc_FAIL
523 0 0
hash_shift hash_mask hash_table
5 1ff 70444858
nullslab
```

```
cache base next
70039928 0 702d5de0
prev head tail
707c86a0 0 0
refcnt chunks
-1 0
constructor destructor reclaim
0 0 0
private arena cflags
0 104444f0 0
buFSIZE align chunksize
24 8 40
slabsize color maxcolor
8192 24 32
```
<table>
<thead>
<tr>
<th>Address</th>
<th>Symbol</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0x700399ac</td>
<td>slab_create</td>
<td>slab_destroy buftotal</td>
</tr>
<tr>
<td></td>
<td></td>
<td>3 0 612</td>
</tr>
<tr>
<td>0x700399b8</td>
<td>bufmax</td>
<td>rescale lookup_depth</td>
</tr>
<tr>
<td></td>
<td></td>
<td>612 1 0</td>
</tr>
<tr>
<td>0x700399c4</td>
<td>kstat</td>
<td>next prev</td>
</tr>
<tr>
<td></td>
<td></td>
<td>702c8608 70039ba8 700396a8</td>
</tr>
<tr>
<td>0x700399d0</td>

<td>kmem_alloc_24</td>
</tr>
<tr>
<td>0x700399f0</td>
<td>buftcl_cache</td>
<td>magazine_cache magazine_size</td>
</tr>
<tr>
<td></td>
<td></td>
<td>70037ba8 700367a8 15</td>
</tr>
</tbody>
</table>

Important fields for debugging include 'bufsize', 'flags' and 'name'. The name of the kmem_cache (in this case “kmem_alloc_24”) indicates its purpose in the system. Bufsize indicates the size of each buffer in this cache; in this case, the cache is used for allocations of size 24 and smaller. 'flags' indicates what debugging features are turned on for this cache. You can find the debugging flags listed in `<sys/kmem_impl.h>`. In this case 'flags' is 0x20f, which is KMF_AUDIT | KMF_DEADBEEF | KMF_REDZONE | KMF_CONTENTS | KMF_HASH. This document explains each of the debugging features in subsequent sections.

When you are interested in looking at buffers in a particular cache, you can walk the allocated and freed buffers in that cache directly:

```bash
> 0x70039928::walk kmem
704ba010 702ba008 704ba038 702ba030 ...
> 0x70039928::walk freemem
70a9ae50 70a9ae28 704bb710 704bb2f8 ...

MDB provides a shortcut to supplying the cache address to the kmem walker: a specific walker is provided for each kmem cache, and its name is the same as the name of the cache. For example:

```bash
> ::walk kmem_alloc_24
704ba010 702ba008 704ba038 702ba030 ...
> ::walk thread_cache
70b38080 70aac060 705c4020 70aac1e0 ...
```
Now you know how to iterate over the kernel memory allocator’s internal data structures and examine the most important members of the kmem_cache data structure.

Detecting Memory Corruption

One of the primary debugging facilities of the allocator is that it includes algorithms to recognize data corruption quickly. When corruption is detected, the allocator immediately panics the system.

This section describes how the allocator recognizes data corruption; you must understand this to be able to debug these problems. Memory abuse typically falls into one of the following categories:

- Writing past the end of a buffer
- Accessing uninitialized data
- Continuing to use a freed buffer
- Corrupting kernel memory

Keep these problems in mind as you read the next three sections. They will help you to understand the allocator’s design, and enable you to diagnose problems more efficiently.

Freed Buffer Checking: 0xdeadbeef

When the KMF_DEADBEEF (0x2) bit is set in the flags field of a kmem_cache, the allocator tries to make memory corruption easy to detect by writing a special pattern into all freed buffers. This pattern is 0xdeadbeef. Since a typical region of memory contains both allocated and freed memory, sections of each kind of block will be interspersed; here is an example from the “kmem_alloc_24” cache:

```
0x70a9aadd8:  deadbeef  deadbeef
0x70a9aade0:  deadbeef  deadbeef
0x70a9ade8:  deadbeef  deadbeef
0x70a9adf0:  feedface  feedface
0x70a9adf8:  70ae3260  8440c68e
0x70a9ae00:  5  4ef83
0x70a9ae08:  0  0
0x70a9ae10:  1  bbddcafe
0x70a9ae18:  feedface  139d
0x70a9ae20:  70ae1200  d1befaed
0x70a9ae28:  deadbeef  deadbeef
0x70a9ae30:  deadbeef  deadbeef
0x70a9ae38:  deadbeef  deadbeef
0x70a9ae40:  feedface  feedface
```
The buffer beginning at 0x70a9add8 is filled with the 0xdeadbeef pattern, which is an immediate indication that the buffer is currently free. At 0x70a9ae28 another free buffer begins; at 0x70a9ae00 an allocated buffer is located between them.

**Note** – You might have observed that there are some holes on this picture, and that 324-byte regions should occupy only 72 bytes of memory, instead of the 120 bytes shown here. This discrepancy is explained in the next section “Redzone: 0xfeedface” on page 97.

### Redzone: 0xfeedface

The pattern 0xfeedface appears frequently in the buffer above. This pattern is known as the “redzone” indicator. It enables the allocator (and a programmer debugging a problem) to determine if the boundaries of a buffer have been violated by “buggy” code. Following the redzone is some additional information. The contents of that data depends upon other factors (see “Memory Allocation Logging” on page 100). The redzone and its suffix are collectively called the *buftag* region. Figure 8–1 summarizes this information.

![FIGURE 8–1 The Redzone](image)

The buftag is appended to each buffer in a cache when any of the KMF_AUDIT, KMF_DEADBEEF, or KMF_REDZONE flags are set in that buffer’s cache. The contents of the buftag depend on whether KMF_AUDIT is set.

Decomposing the memory region presented above into distinct buffers is now simple:

- 0x70a9add8: 70ae31a0 8440c54e
- 0x70a9ae28: 5 4ef83
- 0x70a9ae08: 0 0
- 0x70a9ae10: 1 bbddcafe
- 0x70a9ae18: feedface 139d
- 0x70a9ae20: 70ae3200 d1bea3

Chapter 8 • Debugging With the Kernel Memory Allocator 97
In the free buffers at 0x70a9add8 and 0x70a9ae28, the redzone is filled with 0xfeedfacefeedface. This a convenient way of determining that a buffer is free.

In the allocated buffer beginning at 0x70a9ae00, the situation is different. Recall from “Allocator Basics” on page 91 that there are two allocation types:

1) The client requested memory using kmem_cache_alloc(), in which case the size of the requested buffer is equal to the bufsize of the cache.

2) The client requested memory using kmem_alloc(9F), in which case the size of the requested buffer is less than or equal to the bufsize of the cache. For example, a request for 20 bytes will be filled from the kmem_alloc_24 cache. The allocator enforces the buffer boundary by placing a marker, the redzone byte, immediately following the client data:

0x70a9ae00: 5 4ef83 \n0x70a9ae08: 0 0 +- User Data (allocated)\n0x70a9ae10: 1 bbddcafe /\n0x70a9ae18: feedface 139d -- REDZONE\n0x70a9ae20: 70ae3200 d1befaed -- Debugging Data

0xfeedface at 0x70a9ae18 is followed by a 32-bit word containing what seems to be a random value. This number is actually an encoded representation of the size of the buffer. To decode this number and find the size of the allocated buffer, use the formula:

\[ \text{size} = \frac{\text{redzone\_value}}{251} \]

So, in this example,

\[ \text{size} = \frac{0x139d}{251} = 20 \text{ bytes}. \]

This indicates that the buffer requested was of size 20 bytes. The allocator performs this decoding operation and finds that the redzone byte should be at offset 20. The redzone byte is the hex pattern 0xbb, which is present at 0x729084e4 (0x729084d0 + 0x20) as expected.
Valid User Data

FIGURE 8-2 Sample kmem_alloc(9F) Buffer

Figure 8–3 shows the general form of this memory layout.

FIGURE 8-3 Redzone Byte

If the allocation size is the same as the bufsize of the cache, the redzone byte overwrites the first byte of the redzone itself, as shown in Figure 8–4.

FIGURE 8-4 Redzone Byte at the Beginning of the Redzone

This overwriting results in the first 32-bit word of the redzone being 0xbbedface, or 0xfedfabb depending on the endianness of the hardware on which the system is running.

Note – Why is the allocation size encoded this way? To encode the size, the allocator uses the formula (251 * size + 1). When the size decode occurs, the integer division discards the remainder of ’+1’. However, the addition of 1 is valuable because the allocator can check whether the size is valid by testing whether (size % 251 == 1). In this way, the allocator defends against corruption of the redzone byte index.
Uninitialized Data: 0xbaddcafe

You might be wondering what the suspicious 0xbaddcafe at address 0x729084d4 was before the redzone byte got placed over the first byte in the word. It was 0xbaddcafe. When the KMF_DEADBEEF flag is set in the cache, allocated but uninitialized memory is filled with the 0xbaddcafe pattern. When the allocator performs an allocation, it loops across the words of the buffer and verifies that each word contains 0xdeadbeef, then fills that word with 0xbaddcafe.

A system can panic with a message such as:

```
panic[cpu1]/thread=e1979420: BAD TRAP: type=e (Page Fault)
rp=ef641e88 addr=baddcafe occurred in module "unix" due to an illegal access to a user address
```

In this case, the address that caused the fault was 0xbaddcafe: the panicking thread has accessed some data that was never initialized.

Associating Panic Messages With Failures

The kernel memory allocator emits panic messages corresponding to the failure modes described earlier. For example, a system can panic with a message such as:

```
kernel memory allocator: buffer modified after being freed
modification occurred at offset 0x30
```

The allocator was able to detect this case because it tried to validate that the buffer in question was filled with 0xdeadbeef. At offset 0x30, this condition was not met. Since this condition indicates memory corruption, the allocator panicked the system.

Another example failure message is:

```
kernel memory allocator: redzone violation: write past end of buffer
```

The allocator was able to detect this case because it tried to validate that the redzone byte (0xbb) was in the location it determined from the redzone size encoding. It failed to find the signature byte in the correct location. Since this indicates memory corruption, the allocator panicked the system. Other allocator panic messages are discussed later.

Memory Allocation Logging

This section explains the logging features of the kernel memory allocator and how you can employ them to debug system crashes.
Buftag Data Integrity

As explained earlier, the second half of each buftag contains extra information about the corresponding buffer. Some of this data is debugging information, and some is data private to the allocator. While this auxiliary data can take several different forms, it is collectively known as “Buffer Control” or bufctl data.

However, the allocator needs to know whether a buffer’s bufctl pointer is valid, since this pointer might also have been corrupted by malfunctioning code. The allocator confirms the integrity of its auxiliary pointer by storing the pointer and an encoded version of that pointer, and then cross-checking the two versions.

As shown in Figure 8–5, these pointers are the bcp (buffer control pointer) and bxstat (buffer control XOR status). The allocator arranges bcp and bxstat so that the expression bcp XOR bxstat equals a well-known value.

In the event that one or both of these pointers becomes corrupted, the allocator can easily detect such corruption and panic the system. When a buffer is allocated, bcp XOR bxstat = 0xa110c8ed (“allocated”). When a buffer is free, bcp XOR bxstat = 0xf4eef4ee (“freefree”).

Note – You might find it helpful to re-examine the example provided in “Freed Buffer Checking: 0xdeadbeef” on page 96, in order to confirm that the buftag pointers shown there are consistent.

In the event that the allocator finds a corrupt buftag, it panics the system and produces a message similar to the following:

```
kernel memory allocator: boundary tag corrupted
  bcp ^ bxstat = 0xffeef4ee, should be f4eef4ee
```

Remember, if bcp is corrupt, it is still possible to retrieve its value by taking the value of bxstat XOR 0xf4eef4ee or bxstat XOR 0xa110c8ed, depending on whether the buffer is allocated or free.
The bufctl Pointer

The buffer control (bufctl) pointer contained in the buftag region can have different meanings, depending on the cache’s kmf_flags. The behavior toggled by the KMF_AUDIT flag is of particular interest: when the KMF_AUDIT flag is not set, the kernel memory allocator allocates a kmem_bufctl_t structure for each buffer. This structure contains some minimal accounting information about each buffer. When the KMF_AUDIT flag is set, the allocator instead allocates a kmem_bufctl_audit_t, an extended version of the kmem_bufctl_t.

This section presumes the KMF_AUDIT flag is set. For caches that do not have this bit set, the amount of available debugging information is reduced.

The kmem_bufctl_audit_t (bufctl_audit for short) contains additional information about the last transaction that occurred on this buffer. The following example shows how to apply the bufctl_audit macro to examine an audit record. The buffer shown is the example buffer used in “Detecting Memory Corruption” on page 96:

```
> 0x70a9ae00,5/KKn
0x70a9ae00: 5 4ef83
 0 0
 1 bbddcafe
  feedface 139d
  70ae3200 d1befaed
```

Using the techniques presented above, it is easy to see that 0x70ae3200 points to the bufctl_audit record: it is the first pointer following the redzone. To examine the bufctl_audit record it points to, apply the bufctl_audit macro:

```
> 0x70ae3200$<bufctl_audit
0x70ae3200: next addr slab
  70378000 70a9ae00 707c86a0
0x70ae320c: cache timestamp thread
  70039928 elbd0e26afe 70aac4e0
0x70ae321c: lastlog contents stackdepth
  7011c7c0 7018a0b0 4
0x70ae3228:
  kmem_zalloc+0x30
  pid_assign+8
  getpid+0x68
  cfork+0x60
```

The ‘addr’ field is the address of the buffer corresponding to this bufctl_audit record. This is the original address: 0x70a9ae00. The ‘cache’ field points at the kmem_cache that allocated this buffer. You can use the ::kmem_cache dcmd to examine it as follows:

```
> 0x70039928::kmem_cache
ADDR NAME  FLAG  CFLAG BUFSIZE BUFTOTL
70039928 kmem_alloc_24  020f 000000  24 612
```
The ‘timestamp’ field represents the time this transaction occurred. This time is expressed in the same manner as gethrtimer(3C).

‘thread’ is a pointer to the thread that performed the last transaction on this buffer. The ‘lastlog’ and ‘contents’ pointers point to locations in the allocator’s transaction logs. These logs are discussed in detail in “Allocator Logging Facility” on page 106.

Typically, the most useful piece of information provided by bufctl_audit is the stack trace recorded at the point at which the transaction took place. In this case, the transaction was an allocation called as part of executing fork(2).

Advanced Memory Analysis

This section describes facilities for performing advanced memory analysis, including locating memory leaks and sources of data corruption.

Finding Memory Leaks

The ::findleaks dcmd provides powerful and efficient detection of memory leaks in kernel crash dumps where the full set of kmem debug features has been enabled. The first execution of ::findleaks processes the dump for memory leaks (this can take a few minutes), and then coalesces the leaks by the allocation stack trace. The findleaks report shows a bufctl address and the topmost stack frame for each memory leak that was identified:

```
> ::findleaks
CACHE LEAKED BUFCTL CALLER
70039ba8 1 703746c0 pm_autoconfig+0x708
70039ba8 1 703748a0 pm_autoconfig+0x708
7003a028 1 70d3b1a0 sigaddq+0x108
7003c7a8 1 70515200 pm_ioctl+0x187c
```

```
Total 4 buffers, 376 bytes
```

Using the bufctl pointers, you can obtain the complete stack backtrace of the allocation by applying the bufctl_audit macro:

```
> 70d3b1a0$<bufctl_audit
0x70d3b1a0:  next     addr    slab
70a049c0    70d03b28  70bb7480
0x70d3b1ac:  cache    timestamp    thread
7003a028    13f7cf63b3  70b38380
0x70d3b1bc:  lastlog    contents    stackdepth
700d6e60  0  5
```

Chapter 8 • Debugging With the Kernel Memory Allocator 103
The programmer can usually use the \texttt{bufctl\_audit} information and the allocation stack trace to quickly track down the code path that leaks the given buffer.

Finding References to Data

When trying to diagnose a memory corruption problem, you should know what other kernel entities hold a copy of a particular pointer. This is important because it can reveal which thread accessed a data structure after it was freed. It can also make it easier to understand which kernel entities are sharing knowledge of a particular (valid) data item. The \texttt{::whatis} and \texttt{::kgrep} dcmds can be used to answer these questions. You can apply \texttt{::whatis} to a value of interest:

```bash
> 0x705d8640::whatis
705d8640 is 705d8640+0, allocated from streams_mblk
```

In this case, 0x705d8640 is revealed to be a pointer to a STREAMS \texttt{mblk} structure. To see the entire allocation tree, use \texttt{::whatis\_a} instead:

```bash
> 0x705d8640::whatis\_a
705d8640 is 705d8640+0, allocated from streams_mblk
705d8640 is 705d8000+640, allocated from kmem_va_8192
705d8640 is 705d8000+640 from kmem\_default vmem arena
705d8640 is 705d2000+2640 from kmem\_va vmem arena
705d8640 is 705d2000+2640 from heap vmem arena
```

This reveals that the allocation also appears in the \texttt{kmem\_va\_8192} cache—a \texttt{kmem} cache that is fronting the \texttt{kmem\_va} vmem arena. It also shows the full stack of vmem allocations.

The complete list of \texttt{kmem} caches and vmem arenas is displayed by the \texttt{::kmastat} dcmd. You can use \texttt{::kgrep} to locate other kernel addresses that contain a pointer to this \texttt{mblk}. This illustrates the hierarchical nature of memory allocations in the system; in general, you can determine the type of object referred to by the given address from the name of the most specific \texttt{kmem} cache.

```bash
> 0x705d8640::kgrep
400a3720
705b0d24
705d9d7f0
706a37ec
706add34
```

and investigate them by applying \texttt{::whatis} again:

```bash
> 400a3720::whatis
400a3720 is in thread 7095b240’s stack
```
> 706add34::what.is
706add34 is 706add20+14, allocated from streams_dblk_120

Here one pointer is located on the stack of a known kernel thread, and another is the
mblk pointer inside of the corresponding STREAMS dblk structure.

Finding Corrupt Buffers With ::kmem_verify

MDB’s ::kmem_verify dcmd implements most of the same checks that the kmem
allocator does at runtime. ::kmem_verify can be invoked in order to scan every
kmem cache with appropriate kmem_flags, or to examine a particular cache.

Here is an example of using ::kmem_verify to isolate a problem:

> ::kmem_verify
Cache Name      Addr      Cache Integrity
kmem_alloc_8    70039428  clean
kmem_alloc_16   700396a8  clean
kmem_alloc_24   70039928  1 corrupt buffer
kmem_alloc_32   70039ba8  clean
kmem_alloc_40   7003a028  clean
kmem_alloc_48   7003a2a8  clean
...

It is easy to see here that the kmem_alloc_24 cache contains what ::kmem_verify
believes to be a problem. With an explicit cache argument, the ::kmem_verify dcmd
provides more detailed information about the problem:

> 70039928::kmem_verify
Summary for cache ‘kmem_alloc_24’
buffer 702babc0 (free) seems corrupted, at 702babc0

The next step is to examine the buffer which ::kmem_verify believes to be corrupt:

> 0x702babc0,5/KKn
0x702babc0: 0      deadbeef
deadbeef  deadbeef
deadbeef  deadbeef
feedback  feedback
703785a0    84d9714e

The reason that ::kmem_verify flagged this buffer is now clear: The first word in the
buffer (at 0x702babc0) should probably be filled with the 0xdeadbeef pattern, not
with a 0. At this point, examining the bufctl_audit for this buffer might yield clues
about what code recently wrote to the buffer, indicating where and when it was freed.

Another useful technique in this situation is to use ::kgrep to search the address
space for references to address 0x702babc0, in order to discover what threads or data
structures are still holding references to this freed data.
Allocator Logging Facility

When KMF_AUDIT is set for a cache, the kernel memory allocator maintains a log that records the recent history of its activity. This transaction log records bufctl_audit records. If the KMF_AUDIT and the KMF_CONTENTS flags are both set, the allocator generates a contents log that records portions of the actual contents of allocated and freed buffers. The structure and use of the contents log is outside the scope of this document. The transaction log is discussed in this section.

MDB provides several facilities for displaying the transaction log. The simplest is ::walk kmem_log, which prints out the transaction in the log as a series of bufctl_audit_t pointers:

```
> ::walk kmem_log
70128340
701282e0
70128280
70128220
701281c0...
```

```
> 70128340$<bufctl_audit
0x70128340: next addr slab
70acld40 70bc4ea8 70bb7c00
0x7012834c: cache timestamp thread
70039428 e1bd7abe721 70aacde0
0x7012835c: lastlog contents stackdepth
701282e0 7018f340 4
0x70128368:
    kmem_cache_free+0x24
    nfs3_sync+0x3c
    vfs_sync+0x84
    syssync+4
```

A more elegant way to view the entire transaction log is by using the ::kmem_log command:

```
> ::kmem_log
CPU ADDR BUFADDR TIMESTAMP THREAD
 0 70128340 70bc4ea8 e1bd7abe721 70aacde0
 0 701282e0 70bc4ea8 e1bd7aa86fa 70aacde0
 0 70128280 70bc4ea8 e1bd7aa27dd 70aacde0
 0 70128220 70bc4ea8 e1bd7a98a6e 70aacde0
 0 701281c0 70d03738 e1bd7a8e3e0 70aacde0...
```

```
106
Solaris Modular Debugger Guide • May 2002
```
The output of `::kmem_log` is sorted in descending order by timestamp. The `ADDR` column is the `bufctl_audit` structure corresponding to that transaction; `BUFADDR` points to the actual buffer.

These figures represent transactions on buffers (both allocations and frees). When a particular buffer is corrupted, it can be helpful to locate that buffer in the transaction log, then determine in which other transactions the transactioning thread involved. This can help to assemble a picture of the sequence of events that occurred prior to and after the allocation (or free) of a buffer.

You can employ the `::bufctl` command to filter the output of walking the transaction log. The `::bufctl -a` command filters the buffers in the transaction log by buffer address. This example filters on buffer `0x70b09578`:

```bash
> ::walk kmem_log | ::bufctl -a 0x70b09578
ADDR   BUFADDR   TIMESTAMP   THREAD   CALLER
70127020 70b09578 e1bd5fc1791 40033e60 biodone+0x108
70127640 70b09578 e1bd55062da 70aadce0 pageio_setup+0x268
701276de 70b09578 e1bd52b317 40033e60 biodone+0x108
70127600 70b09578 e1bd497ee8e 70aadce0 pageio_setup+0x268
70127040 70b09578 e1bd21c5e2a 70aadce0 elfexec+0x9f0
70127000 70b09578 e1bd20f5ab5 70aadce0 pageio_setup+0x268
7011ef20 70b09578 e1bd1e9a1dd 70aadce0 ufs_getpage_miss+0x354
7011d720 70b09578 e1bd1170dc4 70aadce0 pageio_setup+0x268
7011d780 70b09578 e1bcff6ff27 70bc2480 elfexec+0x9f0
70117960 70b09578 e1bcf64a9f 70bc2480 getelfhead+0x100
...
```

This example illustrates that a particular buffer can be used in numerous transactions.

---

**Note** – Remember that the kmem transaction log is an incomplete record of the transactions made by the kernel memory allocator. Older entries in the log are evicted as needed in order to keep the size of the log constant.

The `::allocdby` and `::freedby` dcmds provide a convenient way to summarize transactions associated with a particular thread. Here is an example of listing the recent allocations performed by thread `0x70aadce0`:

```bash
> 0x70aadce0::allocdby
BUFCTL      TIMESTAMP  CALLER
70d4d8c0    e1edb14511a allocb+0x88
70d4e8a0    e1edb142472 dblk_constructor+0xc
70d4a240    e1edb13dd4f allocb+0x88
70d4e840    e1edb13aeec dblk_constructor+0xc
70d4d860    e1ed8340071 allocb+0x88
70d4e7e0    e1ed8342536 dblk_constructor+0xc
70d4a1e0    e1ed82b3a3c allocb+0x88
70a5f8f0    e1ed82b0b91 dblk_constructor+0xc
70d4d800    e1e9b663b92 allocb+0x88
```
By examining bufctl_audit records, you can understand the recent activities of a particular thread.
Module Programming API

This chapter describes the structures and functions contained in the MDB debugger module API. The header file `<sys/mdb_modapi.h>` contains prototypes for these functions, and the SUNWmdbdm package provides source code for an example module in the directory `/usr/demo/mdb`.

Debugger Module Linkage

```c
 mdb_init()

const mdb_modinfo_t *mdb_init(void);
```

Each debugger module is required to provide, for linkage and identification purposes, a function named `_mdb_init()`. This function returns a pointer to a persistent (that is, not declared as an automatic variable) `mdb_modinfo_t` structure, as defined in `<sys/mdb_modapi.h>`:

```c
typedef struct mdb_modinfo {
    ushort_t mi_dvers;  /* Debugger API version number */
    const mdb_dcmd_t *mi_dcmds; /* NULL-terminated list of dcmds */
    const mdb_walker_t *mi_walkers; /* NULL-terminated list of walks */
} mdb_modinfo_t;
```

The `mi_dvers` member is used to identify the API version number, and should always be set to `MDB_API_VERSION`. The current version number is therefore compiled into each debugger module, allowing the debugger to identify and verify the application binary interface used by the module. The debugger does not load modules that are compiled for an API version that is more recent than the debugger itself.
The `mi_dcmds` and `mi_walkers` members, if not NULL, point to arrays of `dcmd` and walker definition structures, respectively. Each array must be terminated by a NULL element. These `dcmds` and walkers are installed and registered with the debugger as part of the module loading process. The debugger will refuse to load the module if one or more `dcmds` or walkers are defined improperly or if they have conflicting or invalid names. `Dcmd` and walker names are prohibited from containing characters that have special meaning to the debugger, such as quotation marks and parentheses.

The module can also execute code in `_mdb_init()` using the module API to determine if it is appropriate to load. For example, a module can only be appropriate for a particular target if certain symbols are present. If these symbols are not found, the module can return NULL from the `_mdb_init()` function. In this case, the debugger will refuse to load the module and an appropriate error message is printed.

```c
void _mdb_fini(void);
```

If the module performs certain tasks prior to unloading, such as freeing persistent memory previously allocated with `mdb_alloc()`, it can declare a function named `_mdb_fini()` for this purpose. This function is not required by the debugger. If declared, it is called once prior to unloading the module. Modules are unloaded when the user requests that the debugger terminate or when the user explicitly unloads a module using the `::unload` built-in dcmd.

### Dcmd Definitions

```c
int dcmd(uintptr_t addr, uint_t flags, int argc, const mdb_arg_t *argv);
```

A `dcmd` is implemented with a function similar to the `dcmd()` declaration. This function receives four arguments and returns an integer status. The function arguments are:

- `addr` Current address, also called dot. At the start of the `dcmd`, this address corresponds to the value of the dot "$\cdot$" variable in the debugger.
- `flags` Integer containing the logical OR of one or more of the following flags:
  - `DCMD_ADDRSPEC` An explicit address was specified to the left of `::dcmd`.
  - `DCMD_LOOP` The `dcmd` was invoked in a loop using the `,count` syntax, or the `dcmd` was invoked in a loop by a pipeline.
DCMD_LOOPFIRST
This invocation of the dcmd function corresponds to the first loop or pipeline invocation.

DCMD_PIPE
The dcmd was invoked with input from a pipeline.

DCMD_PIPE_OUT
The dcmd was invoked with output set to a pipeline.

As a convenience, the DCMD_HDRSPEC() macro is provided to allow a dcmd to test its flags to determine if it should print a header line (that is, it was not invoked as part of a loop, or it was invoked as the first iteration of a loop or pipeline).

 argc  Number of arguments in the argv array.
 argv  Array of arguments specified to the right of ::dcmd on the command line. These arguments can be either strings or integer values.

The dcmd function is expected to return one of the following integer values, defined in <sys/mdb_modapi.h>.

DCMD_OK  The dcmd completed successfully.
DCMD_ERR  The dcmd failed for some reason.
DCMD_USAGE  The dcmd failed because invalid arguments were specified. When this value is returned, the dcmd usage message (described below) prints automatically.
DCMD_NEXT  The next dcmd definition (if one is present) is automatically invoked with the same arguments.
DCMD_ABORT  The dcmd failed, and the current loop or pipeline should be aborted. This is like DCMD_ERR, but indicates that no further progress is possible in the current loop or pipe.

Each dcmd consists of a function defined according to the example dcmd() prototype, and a corresponding mdb_dcmd_t structure, as defined in <sys/mdb_modapi.h>. This structure consists of the following fields:

const char *dc_name  The string name of the dcmd, without the leading "::". The name cannot contain any of the MDB meta-characters, such as $ or '.

const char *dc_usage  An optional usage string for the dcmd, to be printed when the dcmd returns DCMD_USAGE. For example, if the dcmd accepts options -a and -b, dc_usage might be specified as "[-ab]". If the dcmd accepts no arguments, dc_usage can be set to NULL. If the usage string begins with "::", this is shorthand for indicating that the dcmd requires an explicit address
(that is, it requires DCMD_ADDRSPEC to be set in its flags parameter). If the usage string begins with “?”,
this indicates that the dcmd optionally accepts an address. These hints modify the usage message
accordingly.

const char *dc_descr
A mandatory description string, briefly explaining the purpose of the dcmd. This string should consist of
only a single line of text.

mdb_dcmd_f *dc_funcp
A pointer to the function that will be called to execute the dcmd.

void (*dc_help)(void)
An optional function pointer to a help function for the dcmd. If this pointer is not NULL, this function will be
called when the user executes ::help dcmd. This function can use mdb_printf() to display further information or examples.

---

**Walker Definitions**

```c
int walk_init(mdb_walk_state_t *wsp);
int walk_step(mdb_walk_state_t *wsp);
void walk_fini(mdb_walk_state_t *wsp);
```

A walker is composed of three functions, `init`, `step`, and `fini`, which are defined according to the example prototypes above. A walker is invoked by the debugger when one of the walk functions (such as `mdb_walk()`) is called, or when the user executes the `::walk` built-in dcmd. When the walk begins, MDB calls the walker's `init` function, passing it the address of a new `mdb_walk_state_t` structure, as defined in `<sys/mdb_modapi.h>`:

```c
typedef struct mdb_walk_state {
    mdb_walk_cb_t walk_callback; /* Callback to issue */
    void *walk_cbdata; /* Callback private data */
    uintptr_t walk_addr; /* Current address */
    void *walk_data; /* Walk private data */
    void *walk_arg; /* Walk private argument */
    void *walk_layer; /* Data from underlying layer */
} mdb_walk_state_t;
```
A separate `mdb_walk_state_t` is created for each walk, so that multiple instances of the same walker can be active simultaneously. The state structure contains the callback the walker should invoke at each step (`walk_callback`), and the private data for the callback (`walk_cbdata`), as specified to `mdb_walk()`, for example. The `walk_cbdata` pointer is opaque to the walker: it must not modify or dereference this value, nor can it assume it is a pointer to valid memory.

The starting address for the walk is stored in `walk_addr`. This is either NULL if `mdb_walk()` was called, or the address parameter specified to `mdb_pwalk()`. If the `::walk` built-in was used, `walk_addr` will be non-NULL if an explicit address was specified on the left-hand side of `::walk`. A walk with a starting address of NULL is referred to as `global`. A walk with an explicit non-NULL starting address is referred to as `local`.

The `walk_data` and `walk_arg` fields are provided for use as private storage for the walker. Complex walkers might need to allocate an auxiliary state structure and set `walk_data` to point to this structure. Each time a walk is initiated, `walk_arg` is initialized to the value of the `walk_init_arg` member of the corresponding walker’s `mdb_walker_t` structure.

In some cases, it is useful to have several walkers share the same init, step, and fini routines. For example, the MDB genunix module provides walkers for each kernel memory cache. These share the same init, step, and fini functions, and use the `walk_init_arg` member of the `mdb_walker_t` to specify the address of the appropriate cache as the `walk_arg`.

If the walker calls `mdb_layered_walk()` to instantiate an underlying layer, then the underlying layer will reset `walk_addr` and `walk_layer` prior to each call to the walker’s step function. The underlying layer sets `walk_addr` to the target virtual address of the underlying object, and set `walk_layer` to point to the walker’s local copy of the underlying object. For more information on layered walks, refer to the discussion of `mdb_layered_walk()` below.

The walker init and step functions are expected to return one of the following status values:

- **WALK_NEXT**  Proceed to the next step. When the walk init function returns `WALK_NEXT`, MDB invokes the walk step function. When the walk step function returns `WALK_NEXT`, this indicates that MDB should call the step function again.

- **WALK_DONE**  The walk has completed successfully. `WALK_DONE` can be returned by either the step function to indicate that the walk is complete, or by the init function to indicate that no steps are needed (for example, if the given data structure is empty).

- **WALK_ERR**   The walk has terminated due to an error. If `WALK_ERR` is returned by the init function, `mdb_walk()` (or any of its counterparts) returns −1 to indicate that the walker failed to initialize. If
WALK_ERR is returned by the step function, the walk terminates but mdb_walk() returns success.

The walk_callback is also expected to return one of the values above. Therefore, the walk step function's job is to determine the address of the next object, read in a local copy of this object, call the walk_callback function, then return its status. The step function can also return WALK_DONE or WALK_ERR without invoking the callback if the walk is complete or if an error occurred.

The walker itself is defined using the mdb_walker_t structure, defined in:

```c
typedef struct mdb_walker {
    const char *walk_name; /* Walk type name */
    const char *walk_descr; /* Walk description */
    int (*walk_init)(mdb_walk_state_t *); /* Walk constructor */
    int (*walk_step)(mdb_walk_state_t *); /* Walk iterator */
    void (*walk_fini)(mdb_walk_state_t *); /* Walk destructor */
    void *walk_init_arg; /* Constructor argument */
} mdb_walker_t;
```

The walk_name and walk_descr fields should be initialized to point to strings containing the name and a brief description of the walker, respectively. A walker is required to have a non-NULL name and description, and the name cannot contain any of the MDB meta-characters. The description string is printed by the ::walkers and ::dmods built-in dcmds.

The walk_init, walk_step, and walk_fini members refer to the walk functions themselves, as described earlier. The walk_init and walk_fini members can be set to NULL to indicate that no special initialization or cleanup actions need to be taken. The walk_step member cannot be set to NULL. The walk_init_arg member is used to initialize the walk_arg member of each new mdb_walk_state_t created for the given walker, as described earlier. Figure 9–1 shows a flowchart for the algorithm of a typical walker.
The walker is designed to iterate over the list of \texttt{proc_t} structures in the kernel. The head of the list is stored in the global \texttt{practive} variable, and each element’s \texttt{p_next} pointer points to the next \texttt{proc_t} in the list. The list is terminated with a NULL pointer. In the walker’s init routine, the \texttt{practive} symbol is located using \texttt{mdb_lookup_by_name()} step (1), and its value is copied into the \texttt{mdb_walk_state_t} pointed to by \texttt{wsp}.

In the walker’s step function, the next \texttt{proc_t} structure in the list is copied into the debugger’s address space using \texttt{mdb_vread()} step (2), the callback function is invoked with a pointer to this local copy, step (3), and then the \texttt{mdb_walk_state_t} is updated with the address of the \texttt{proc_t} structure for the next iteration. This update corresponds to following the pointer, step (4), to the next element in the list.
These steps demonstrate the structure of a typical walker: the init routine locates the global information for a particular data structure, the step function reads in a local copy of the next data item and passes it to the callback function, and the address of the next element is read. Finally, when the walk terminates, the fini function frees any private storage.

API Functions

**mdb_pwalk()**

```c
int mdb_pwalk(const char *name, mdb_walk_cb_t func, void *data,
              uintptr_t addr);
```

Initiate a local walk starting at `addr` using the walker specified by `name`, and invoke the callback function `func` at each step. If `addr` is NULL, a global walk is performed (that is, the `mdb_pwalk()` invocation is equivalent to the identical call to `mdb_walk()` without the trailing `addr` parameter). This function returns 0 for success, or -1 for error. The `mdb_pwalk()` function fails if the walker itself returns a fatal error, or if the specified walker name is not known to the debugger. The walker name may be scoped using the backquote (``) operator if there are naming conflicts. The `data` parameter is an opaque argument that has meaning only to the caller; it is passed back to `func` at each step of the walk.

**mdb_walk()**

```c
int mdb_walk(const char *name, mdb_walk_cb_t func, void *data);
```

Initiate a global walk starting at `addr` using the walker specified by `name`, and invoke the callback function `func` at each step. This function returns 0 for success, or -1 for error. The `mdb_walk()` function fails if the walker itself returns a fatal error, or if the specified walker name is not known to the debugger. The walker name can be scoped using the backquote (``) operator if there are naming conflicts. The data parameter is an opaque argument that has meaning only to the caller; it is passed back to `func` at each step of the walk.
mdb_pwalk_dcmd()

```
int mdb_pwalk_dcmd(const char *wname, const char *dcname, int argc,
                   const mdb_arg_t *argv, uintptr_t addr);
```

Initiate a local walk starting at `addr` using the walker specified by `wname`, and invoke the dcmd specified by `dcname` with the specified `argc` and `argv` at each step. This function returns 0 for success, or -1 for error. The function fails if the walker itself returns a fatal error, if the specified walker name or dcmd name is not known to the debugger, or if the dcmd itself returns DCMD_ABORT or DCMD_USAGE to the walker. The walker name and dcmd name can each be scoped using the backquote (``) operator if there are naming conflicts. When invoked from `mdb_pwalk_dcmd()`, the dcmd will have the DCMD_LOOP and DCMD_ADDRSPEC bits set in its flags parameter, and the first call will have DCMD_LOOPFIRST set.

mdb_walk_dcmd()

```
int mdb_walk_dcmd(const char *wname, const char *dcname, int argc,
                  const mdb_arg_t *argv);
```

Initiate a global walk using the walker specified by `wname`, and invoke the dcmd specified by `dcname` with the specified `argc` and `argv` at each step. This function returns 0 for success, or -1 for error. The function fails if the walker itself returns a fatal error, if the specified walker name or dcmd name is not known to the debugger, or if the dcmd itself returns DCMD_ABORT or DCMD_USAGE to the walker. The walker name and dcmd name can each be scoped using the backquote (``) operator if there are naming conflicts. When invoked from `mdb_walk_dcmd()`, the dcmd will have the DCMD_LOOP and DCMD_ADDRSPEC bits set in its flags parameter, and the first call will have DCMD_LOOPFIRST set.

mdb_call_dcmd()

```
int mdb_call_dcmd(const char *name, uintptr_t addr, uint_t flags,
                  int argc, const mdb_arg_t *argv);
```

Invoke the specified dcmd name with the given parameters. The dot variable is reset to `addr`, and `addr`, `flags`, `argc`, and `argv` are passed to the dcmd. The function returns 0 for success, or -1 for error. The function fails if the dcmd returns DCMD_ERR, DCMD_ABORT, or DCMD_USAGE, or if the specified dcmd name is not known to the debugger. The dcmd name can be scoped using the backquote (``) operator if there are naming conflicts.
mdb_layered_walk()

int mdb_layered_walk(const char *name, mdb_walk_state_t *wsp);

Layer the walk denoted by wsp on top of a walk initiated using the specified walker name. The name can be scoped using the backquote (') operator if there are naming conflicts. Layered walks can be used, for example, to facilitate constructing walkers for data structures that are embedded in other data structures.

For example, suppose that each CPU structure in the kernel contains a pointer to an embedded structure. To write a walker for the embedded structure type, you could replicate the code to iterate over CPU structures and dereference the appropriate member of each CPU structure, or you could layer the embedded structure’s walker on top of the existing CPU walker.

The mdb_layered_walk() function is used from within a walker’s init routine to add a new layer to the current walk. The underlying layer is initialized as part of the call to mdb_layered_walk(). The calling walk routine passes in a pointer to its current walk state; this state is used to construct the layered walk. Each layered walk is cleaned up after the caller’s walk fini function is called. If more than one layer is added to a walk, the caller’s walk step function will step through each element returned by the first layer, then the second layer, and so forth.

The mdb_layered_walk() function returns 0 for success, or -1 for error. The function fails if the specified walker name is not known to the debugger, if the wsp pointer is not a valid, active walk state pointer, if the layered walker itself fails to initialize, or if the caller attempts to layer the walker on top of itself.

mdb_add_walker()

int mdb_add_walker(const mdb_walker_t *w);

Register a new walker with the debugger. The walker is added to the module’s namespace, and to the debugger’s global namespace according to the name resolution rules described in “dcmd and Walker Name Resolution” on page 31. This function returns 0 for success, or -1 for error if the given walker name is already registered by this module, or if the walker structure w is improperly constructed. The information in the mdb_walker_t w is copied to internal debugger structures, so the caller can reuse or free this structure after the call to mdb_add_walker().

mdb_remove_walker()

int mdb_remove_walker(const char *name);
Remove the walker with the specified name. This function returns 0 for success, or -1 for error. The walker is removed from the current module’s namespace. The function fails if the walker name is unknown, or is registered only in another module’s namespace. The mdb_remove_walker() function can be used to remove walkers that were added dynamically using mdb_add_walker(), or walkers that were added statically as part of the module’s linkage structure. The scoping operator cannot be used in the walker name; it is not legal for the caller of mdb_remove_walker() to attempt to remove a walker exported by a different module.

**mdb_vread() and mdb_vwrite()**

```
ssize_t mdb_vread(void *buf, size_t nbytes, uintptr_t addr);
ssize_t mdb_vwrite(const void *buf, size_t nbytes, uintptr_t addr);
```

These functions provide the ability to read and write data from a given target virtual address, specified by the addr parameter. The mdb_vread() function returns nbytes for success, or -1 for error; if a read is truncated because only a portion of the data can be read from the specified address, -1 is returned. The mdb_vwrite() function returns the number of bytes actually written upon success; -1 is returned upon error.

**mdb_fread() and mdb_fwrite()**

```
ssize_t mdb_fread(void *buf, size_t nbytes, uintptr_t addr);
ssize_t mdb_fwrite(const void *buf, size_t nbytes, uintptr_t addr);
```

These functions provide the ability to read and write data from the object file location corresponding to the given target virtual address, specified by the addr parameter. The mdb_fread() function returns nbytes for success, or -1 for error; if a read is truncated because only a portion of the data can be read from the specified address, -1 is returned. The mdb_fwrite() function returns the number of bytes actually written upon success; -1 is returned upon error.

**mdb_pread() and mdb_pwrite()**

```
ssize_t mdb_pread(void *buf, size_t nbytes, uint64_t addr);
ssize_t mdb_pwrite(const void *buf, size_t nbytes, uint64_t addr);
```

These functions provide the ability to read and write data from a given target physical address, specified by the addr parameter. The mdb_pread() function returns nbytes for success, or -1 for error; if a read is truncated because only a portion of the data can be read from the specified address, -1 is returned. The mdb_pwrite() function returns the number of bytes actually written upon success; -1 is returned upon error.
mdb_readstr()

ssize_t mdb_readstr(char *s, size_t nbytes, uintptr_t addr);

The `mdb_readstr()` function reads a null-terminated C string beginning at the target virtual address `addr` into the buffer addressed by `s`. The size of the buffer is specified by `nbytes`. If the string is longer than can fit in the buffer, the string is truncated to the buffer size and a null byte is stored at `s[nbytes - 1]`. The length of the string stored in `s` (not including the terminating null byte) is returned upon success; otherwise, -1 is returned to indicate an error.

mdb_writestr()

ssize_t mdb_writestr(const char *s, uintptr_t addr);

The `mdb_writestr()` function writes a null-terminated C string from `s` (including the trailing null byte) to the target’s virtual address space at the address specified by `addr`. The number of bytes written (not including the terminating null byte) is returned upon success; otherwise, -1 is returned to indicate an error.

mdb_readsym()

ssize_t mdb_readsym(void *buf, size_t nbytes, const char *name);

`mdb_readsym()` is similar to `mdb_vread()`, except that the virtual address at which reading begins is obtained from the value of the symbol specified by `name`. If no symbol by that name is found or a read error occurs, -1 is returned; otherwise, `nbytes` is returned for success.

The caller can first look up the symbol separately if it is necessary to distinguish between symbol lookup failure and read failure. The primary executable’s symbol table is used for the symbol lookup; if the symbol resides in another symbol table, you must first apply `mdb_lookup_by_obj()`, then `mdb_vread()`.

mdb_writesym()

ssize_t mdb_writesym(const void *buf, size_t nbytes, const char *name);

`mdb_writesym()` is identical to `mdb_vwrite()`, except that the virtual address at which writing begins is obtained from the value of the symbol specified by `name`. If no symbol by that name is found, -1 is returned. Otherwise, the number of bytes
successfully written is returned on success, and -1 is returned on error. The primary executable’s symbol table is used for the symbol lookup; if the symbol resides in another symbol table, you must first apply mdb_lookup_by_obj(), then mdb_vwrite().

mdb_readvar() and mdb_writevar()

ssize_t mdb_readvar(void *buf, const char *name);
ssize_t mdb_writevar(const void *buf, const char *name);

mdb_readvar() is similar to mdb_vread(), except that the virtual address at which reading begins and the number of bytes to read are obtained from the value and size of the symbol specified by name. If no symbol by that name is found, -1 is returned. The symbol size (the number of bytes read) is returned on success; -1 is returned on error. This is useful for reading well-known variables whose sizes are fixed. For example:

```
int hz; /* system clock rate */
mdb_readvar(&hz, "hz");
```

The caller can first look up the symbol separately if it is necessary to distinguish between symbol lookup failure and read failure. The caller must also carefully check the definition of the symbol of interest in order to make sure that the local declaration is the exact same type as the target’s definition. For example, if the caller declares an int, and the symbol of interest is actually a long, and the debugger is examining a 64-bit kernel target, mdb_readvar() copies back 8 bytes to the caller’s buffer, corrupting the 4 bytes following the storage for the int.

mdb_writevar() is identical to mdb_vwrite(), except that the virtual address at which writing begins and the number of bytes to write are obtained from the value and size of the symbol specified by name. If no symbol by that name is found, -1 is returned. Otherwise, the number of bytes successfully written is returned on success, and -1 is returned on error.

For both functions, the primary executable’s symbol table is used for the symbol lookup; if the symbol resides in another symbol table, you must first apply mdb_lookup_by_obj(), then mdb_vread() or mdb_vwrite().

mdb_lookup_by_name() and mdb_lookup_by_obj()

int mdb_lookup_by_name(const char *name, GElf_Sym *sym);
int mdb_lookup_by_obj(const char *object, const char *name, GElf_Sym *sym);
Look up the specified symbol name and copy the ELF symbol information into the GElf_Sym pointed to by sym. If the symbol is found, the function returns 0; otherwise, -1 is returned. The name parameter specifies the symbol name. The object parameter tells the debugger where to look for the symbol. For the mdb_lookup_by_name() function, the object file defaults to MDB_OBJ_EXEC. For mdb_lookup_by_obj(), the object name should be one of the following:

- **MDB_OBJ_EXEC**: Look in the executable's symbol table (.symtab section). For kernel crash dumps, this corresponds to the symbol table from the unix.X file or from /dev/ksyms.
- **MDB_OBJ_RTLD**: Look in the runtime link-editor's symbol table. For kernel crash dumps, this corresponds to the symbol table for the krtld module.
- **MDB_OBJ_EVERY**: Look in all known symbol tables. For kernel crash dumps, this includes the .symtab and .dynsym sections from the unix.X file or /dev/ksyms, as well as per-module symbol tables if these have been processed.

object If the name of a particular load object is explicitly specified, the search is restricted to the symbol table of this object. The object can be named according to the naming convention for load objects described in “Symbol Name Resolution” on page 29.

### mdb_lookup_by_addr()

int mdb_lookup_by_addr(uintptr_t addr, uint_t flag, char *buf, size_t len, GElf_Sym *sym);

Locate the symbol corresponding to the specified address and copy the ELF symbol information into the GElf_Sym pointed to by sym and the symbol name into the character array addressed by buf. If a corresponding symbol is found, the function returns 0; otherwise -1 is returned.

The flag parameter specifies the lookup mode and should be one of the following:

- **MDB_SYM_FUZZY**: Allow fuzzy matching to take place, based on the current symbol distance setting. The symbol distance can be controlled using the ::set -s built-in. If an explicit symbol distance has been set (absolute mode), the address can match a symbol if the distance from the symbol’s value to the address does not exceed the absolute symbol distance. If smart mode is enabled (symbol distance = 0), then the address can match the symbol if it is in the range [symbol value, symbol value + symbol size).

- **MDB_SYM_EXACT**: Disallow fuzzy matching. The symbol can match only the address if the symbol value exactly equals the specified address.
If a symbol match occurs, the name of the symbol is copied into the \texttt{buf} supplied by the caller. The \texttt{len} parameter specifies the length of this buffer in bytes. The caller's \texttt{buf} should be at least of size \texttt{MDB_SYM_NAMLEN} bytes. The debugger copies the name to this buffer and appends a trailing null byte. If the name length exceeds the length of the buffer, the name is truncated but always includes a trailing null byte.

\textbf{mdb_getopts()}

\begin{verbatim}
int mdb_getopts(int argc, const mdb_arg_t *argv, ...);
\end{verbatim}

Parse and process options and option arguments from the specified argument array (\texttt{argv}). The \texttt{argc} parameter denotes the length of the argument array. This function processes each argument in order, and stops and returns the array index of the first argument that could not be processed. If all arguments are processed successfully, \texttt{argc} is returned.

Following the \texttt{argc} and \texttt{argv} parameters, the \texttt{mdb_getopts()} function accepts a variable list of arguments describing the options that are expected to appear in the \texttt{argv} array. Each option is described by an option letter (char argument), an option type (uint\_t argument), and one or two additional arguments, as shown in the table below. The list of option arguments is terminated with a NULL argument. The type should be one of the following:

- \textbf{MDB\_OPT\_SETBITS} The option will \texttt{OR} the specified bits into a flag word. The option is described by these parameters:
  \begin{verbatim}
  char c, uint_t type, uint_t bits, uint_t *p
  \end{verbatim}
  If type is \texttt{MDB\_OPT\_SETBITS} and option \texttt{c} is detected in the \texttt{argv} list, the debugger will \texttt{OR} bits into the integer referenced by pointer \texttt{p}.

- \textbf{MDB\_OPT\_CLRBITS} The option clears the specified bits from a flag word. The option is described by these parameters:
  \begin{verbatim}
  char c, uint_t type, uint_t bits, uint_t *p
  \end{verbatim}
  If type is \texttt{MDB\_OPT\_CLRBITS} and option \texttt{c} is detected in the \texttt{argv} list, the debugger clears bits from the integer referenced by pointer \texttt{p}.

- \textbf{MDB\_OPT\_STR} The option accepts a string argument. The option is described by these parameters:
  \begin{verbatim}
  char c, uint_t type, const char **p
  \end{verbatim}
If type is `MDB_OPT_STR` and option `c` is detected in the `argv` list, the debugger stores a pointer to the string argument following `c` in the pointer referenced by `p`.

**MDB_OPT_UINTPTR**

The option accepts a `uintptr_t` argument. The option is described by these parameters:

```c
char c, uint_t type, uintptr_t *p
```

If type is `MDB_OPT_UINTPTR` and option `c` is detected in the `argv` list, the debugger stores the integer argument following `c` in the `uintptr_t` referenced by `p`.

**MDB_OPT_UINT64**

The option accepts a `uint64_t` argument. The option is described by these parameters:

```c
char c, uint_t type, uint64_t *p
```

If type is `MDB_OPT_UINT64` and option `c` is detected in the `argv` list, the debugger stores the integer argument following `c` in the `uint64_t` referenced by `p`.

For example, the following source code:

```c
int
dcmd(uintptr_t addr, uint_t flags, int argc, const mdb_arg_t *argv)
{
    uint_t opt_v = FALSE;
    const char *opt_s = NULL;

    if (mdb_getopts(argc, argv,
                    'v', MDB_OPT_SETBITS, TRUE, &opt_v,
                    's', MDB_OPT_STR, &opt_s, NULL) != argc)
        return (DCMD_USAGE);

    /* ... */
}
```

demonstrates how `mdb_getopts()` might be used in a `dcmd` to accept a boolean option “-v” that sets the `opt_v` variable to TRUE, and an option “-s” that accepts a string argument that is stored in the `opt_s` variable. The `mdb_getopts()` function also automatically issues warning messages if it detects an invalid option letter or missing option argument before returning to the caller. The storage for argument strings and the `argv` array is automatically garbage-collected by the debugger upon completion of the `dcmd`.

**mdb_strtoull()**

```c
u_longlong_t mdb_strtoull(const char *s);
```
Convert the specified string \( s \) to an unsigned long long representation. This function is intended for use in processing and converting string arguments in situations where \( \text{mdb getopt}(s) \) is not appropriate. If the string argument cannot be converted to a valid integer representation, the function fails by printing an appropriate error message and aborting the dcmd. Therefore, error checking code is not required. The string can be prefixed with any of the valid base specifiers (0i, 0I, 0o, 0O, 0t, 0T, 0x, or 0X); otherwise, it is interpreted using the default base. The function will fail and abort the dcmd if any of the characters in \( s \) are not appropriate for the base, or if integer overflow occurs.

### mdb_alloc() \( \rightarrow \) mdb_zalloc() \( \rightarrow \) mdb_free()

- ```c
   void *mdb_alloc(size_t size, uint_t flags);
   void *mdb_zalloc(size_t size, uint_t flags);
   void mdb_free(void *buf, size_t size);
```

- \( \text{mdb alloc()} \) allocates \( \text{size} \) bytes of debugger memory and returns a pointer to the allocated memory. The allocated memory is at least double-word aligned, so it can hold any C data structure. No greater alignment can be assumed. The \( \text{flags} \) parameter should be the bitwise OR of one or more of the following values:
  - **UM\_NOSLEEP** If sufficient memory to fulfill the request is not immediately available, return NULL to indicate failure. The caller must check for NULL and handle this case appropriately.
  - **UM\_SLEEP** If sufficient memory to fulfill the request is not immediately available, sleep until such time as the request can be fulfilled. As a result, \( \text{UM\_SLEEP} \) allocations are guaranteed to succeed. The caller need not check for a NULL return value.
  - **UM\_GC** Garbage-collect allocation automatically at the end of this debugger command. The caller should not subsequently call \( \text{mdb free()} \) on this block, as the debugger will take care of de-allocation automatically. All memory allocation from within a dcmd must use **UM\_GC** so that if the dcmd is interrupted by the user, the debugger can garbage-collect the memory.

- \( \text{mdb zalloc()} \) is like \( \text{mdb alloc()} \), but the allocated memory is filled with zeroes before returning it to the caller. No guarantees are made about the initial contents of memory returned by \( \text{mdb alloc()} \). \( \text{mdb free()} \) is used to free previously allocated memory (unless it was allocated **UM\_GC**). The buffer address and size must exactly match the original allocation. It is not legal to free only a portion of an allocation with \( \text{mdb free()} \). It is not legal to free an allocation more than once. An allocation of zero bytes always returns NULL; freeing a NULL pointer with size zero always succeeds.
mdb_printf()

```c
void mdb_printf(const char *format, ...);
```

Print formatted output using the specified format string and arguments. Module writers should use `mdb_printf()` for all output, except for warning and error messages. This function automatically triggers the built-in output pager when appropriate. The `mdb_printf()` function is similar to `printf(3C)`, with certain exceptions: the `%C`, `%S`, and `%ws` specifiers for wide character strings are not supported, the `%f` floating-point format is not supported, the `%e`, `%E`, `%g`, and `%G` specifiers for alternative double formats produce only a single style of output, and precision specifications of the form `% . n` are not supported. The list of specifiers that are supported follows:

Flag Specifiers

- `%#` If the `#` sign is found in the format string, this selects the alternate form of the given format. Not all formats have an alternate form; the alternate form is different depending on the format. Refer to the format descriptions below for details on the alternate format.
- `%+` When printing signed values, always display the sign (prefix with either `'+'` or `'-'`). Without `%+`, positive values have no sign prefix, and negative values have a `'-'` prefix prepended to them.
- `%-` Left-justify the output within the specified field width. If the width of the output is less than the specified field width, the output will be padded with blanks on the right-hand side. Without `%-`, values are right-justified by default.
- `%0` Zero-fill the output field if the output is right-justified and the width of the output is less than the specified field width. Without `%0`, right-justified values are prepended with blanks in order to fill the field.

Field Width Specifiers

- `%n` Field width is set to the specified decimal value.
- `%?` Field width is set to the maximum width of a hexadecimal pointer value. This is 8 in an ILP32 environment, and 16 in an LP64 environment.
- `%*` Field width is set to the value specified at the current position in the argument list. This value is assumed to be an `int`. Note that in the 64-bit compilation environment, it may be necessary to cast `long` values to `int`. 

126  Solaris Modular Debugger Guide • May 2002
Integer Specifiers

%h  Integer value to be printed is a short.
%l  Integer value to be printed is a long.
%ll Integer value to be printed is a long long.

Terminal Attribute Specifiers

If standard output for the debugger is a terminal, and terminal attributes can be obtained by the terminfo database, the following terminal escape constructs can be used:

%<n>  Enable the terminal attribute corresponding to n. Only a single attribute can be enabled with each instance of %<.
%</n>  Disable the terminal attribute corresponding to n. Note that in the case of reverse video, dim text, and bold text, the terminal codes to disable these attributes might be identical. Therefore, it might not be possible to disable these attributes independently of one another.

If no terminal information is available, each terminal attribute construct is ignored by mdb_printf(). For more information on terminal attributes, see terminfo(4). The available terminfo attributes are:

a  Alternate character set
b  Bold text
d  Dim text
r  Reverse video
s  Best standout capability
u  Underlining

Format Specifiers

%%  The ‘%’ symbol is printed.
%a  Prints an address in symbolic form. The minimum size of the value associated with %a is a uintptr_t; specifying %la is not necessary. If address-to-symbol conversion is on, the debugger will attempt to convert the address to a symbol name followed by an offset in the current output radix and print this string; otherwise, the value is printed in the default output radix. If %#a is used, the alternate format adds a ‘:’ suffix to the output.
%A  This format is identical to %a, except when an address cannot be converted to a symbol name plus an offset, nothing is printed. If %#A is used, the alternate format prints a '?' when address conversion fails.

%b  Decode and print a bit field in symbolic form. This specifier expects two consecutive arguments: the bit field value (int for %b, long for %#b, and so forth), and a pointer to an array of mdb_bitmask_t structures:

```c
typedef struct mdb_bitmask {
    const char *bm_name;  /* String name to print */
    u_longlong_t bm_mask;  /* Mask for bits */
    u_longlong_t bm_bits;  /* Result for value & mask */
} mdb_bitmask_t;
```

The array should be terminated by a structure whose bm_name field is set to NULL. When %b is used, the debugger reads the value argument, then iterates through each mdb_bitmask structure checking to see if:

```c
(value & bitmask->bm_mask) == bitmask->bm_bits
```

If this expression is true, the bm_name string is printed. Each string printed is separated by a comma. The following example shows how %b can be used to decode the t_flag field in a kthread_t:

```c
const mdb_bitmask_t t_flag_bits[] = {
    { "T_INTR_THREAD", T_INTR_THREAD, T_INTR_THREAD },
    { "T_WAKEABLE", T_WAKEABLE, T_WAKEABLE },
    { "T_TOMASK", T_TOMASK, T_TOMASK },
    { "T_TALLOCSTK", T_TALLOCSTK, T_TALLOCSTK },
    ...
    { NULL, 0, 0 }
};

void
thr_dump(kthread_t *t)
{
    mdb_printf("t_flag = <%hb>\n", t->t_flag, t_flag_bits);
    ...
}
```

If t_flag was set to 0x000a, the function would print:

```c
t_flag = <T_WAKEABLE,T_TALLOCSTK>
```

If %#b is specified, the union of all bits that were not matched by an element in the bitmask array is printed as a hexadecimal value following the decoded names.

%c  Print the specified integer as an ASCII character.

%\d  Print the specified integer as a signed decimal value. Same as %i. If %#d is specified, the alternate format prefixes the value with '0t'.
%e  Print the specified double in the floating-point format
    [+/-] d. ddddde [+/-] d, where there is one digit before the radix
    character, seven digits of precision, and at least two digits following
    the exponent.

%E  Print the specified double using the same rules as %e, except that the
    exponent character will be ‘E’ instead of ‘e’.

%g  Print the specified double in the same floating-point format as %e, but with
    sixteen digits of precision. If %lg is specified, the argument is expected to
    be of type long double (quad-precision floating-point value).

%G  Print the specified double using the same rules as %g, except that the
    exponent character will be ‘E’ instead of ‘e’.

%i  Print the specified integer as a signed decimal value. Same as %d. If %#i is
    specified, the alternate format prefixes the value with ‘0t’.

%i  Print the specified 32-bit unsigned integer as an Internet IPv4 address in
    dotted-decimal format (for example, the hexadecimal value 0xffffffff
    would print as 255.255.255.255).

%m  Print a margin of whitespace. If no field is specified, the default output
    margin width is used; otherwise, the field width determines the number
    of characters of white space that are printed.

%o  Print the specified integer as an unsigned octal value. If %#o is used, the
    alternate format prefixes the output with ‘0’.

%p  Print the specified pointer (void *) as a hexadecimal value.

%q  Print the specified integer as a signed octal value. If %#o is used, the
    alternate format prefixes the output with ‘0’.

%r  Print the specified integer as an unsigned value in the current output radix.
    The user can change the output radix using the $d dcmd. If %#x is
    specified, the alternate format prefixes the value with the appropriate base
    prefix: ‘0i’ for binary, ‘0o’ for octal, ‘0t’ for decimal, or ‘0x’ for
    hexadecimal.

%R  Print the specified integer as a signed value in the current output radix. If
    %#r is specified, the alternate format prefixes the value with the
    appropriate base prefix.

%s  Print the specified string (char *). If the string pointer is NULL, the string
    ‘<NULL>’ is printed.

%t  Advance one or more tab stops. If no width is specified, output advances to
    the next tab stop; otherwise the field width determines how many tab stops
    are advanced.
Advance the output column to the next multiple of the field width. If no field width is specified, no action is taken. If the current output column is not a multiple of the field width, white space is added to advance the output column.

Print the specified integer as an unsigned decimal value. If %u is specified, the alternate format prefixes the value with '0'.

Print the specified integer as a hexadecimal value. The characters a-f are used as the digits for the values 10-15. If %%x is specified, the alternate format prefixes the value with '0x'.

Print the specified integer as a hexadecimal value. The characters A-F are used as the digits for the values 10-15. If %x is specified, the alternate format prefixes the value with '0x'.

The specified time_t is printed as the string 'year month day
HH:MM:SS'.

mdb_snprintf()

size_t mdb_snprintf(char *buf, size_t len, const char *format, ...);

Construct a formatted string based on the specified format string and arguments, and store the resulting string into the specified buf. The mdb_snprintf() function accepts the same format specifiers and arguments as the mdb_printf() function. The len parameter specifies the size of buf in bytes. No more than len - 1 formatted bytes are placed in buf; mdb_snprintf() always terminates buf with a null byte. The function returns the number of bytes required for the complete formatted string, not including the terminating null byte. If the buf parameter is NULL and len is set to zero, the function will not store any characters to buf and returns the number of bytes required for the complete formatted string; this technique can be used to determine the appropriate size of a buffer for dynamic memory allocation.

mdb_warn()

void mdb_warn(const char *format, ...);

Print an error or warning message to standard error. The mdb_warn() function accepts a format string and variable argument list that can contain any of the specifiers documented for mdb_printf(). However, the output of mdb_warn() is sent to standard error, which is not buffered and is not sent through the output pager or processed as part of a dcmd pipeline. All error messages are automatically prefixed with the string “mdb:”.

130 Solaris Modular Debugger Guide • May 2002
In addition, if the \texttt{format} parameter does not contain a newline (\texttt{\textbackslash n}) character, the format string is implicitly suffixed with the string "\texttt{:%s\textbackslash n}" where \texttt{%s} is replaced by the error message string corresponding to the last error recorded by a module API function. For example, the following source code:

\begin{verbatim}
if (mdb_lookup_by_name("no_such_symbol", &sym) == -1)
    mdb_warn("lookup_by_name failed");
\end{verbatim}

produces this output:

\texttt{mdb: lookup_by_name failed: unknown symbol name}

\texttt{mdb\_flush()}

\begin{verbatim}
void mdb_flush(void);
\end{verbatim}

Flush all currently buffered output. Normally, mdb's standard output is line-buffered; output generated using \texttt{mdb\_printf()} is not flushed to the terminal (or other standard output destination) until a newline is encountered, or at the end of the current dcmd. However, in some situations you might want to explicitly flush standard output prior to printing a newline; \texttt{mdb\_flush()} can be used for this purpose.

\texttt{mdb\_nhconvert()}

\begin{verbatim}
void mdb_nhconvert(void *dst, const void *src, size_t nbytes);
\end{verbatim}

Convert a sequence of \texttt{nbytes} bytes stored at the address specified by \texttt{src} from network byte order to host byte order and store the result at the address specified by \texttt{dst}. The \texttt{src} and \texttt{dst} parameters may be the same, in which case the object is converted in place. This function may be used to convert from host order to network order or from network order to host order, since the conversion is the same in either case.

\texttt{mdb\_dumpptr()} and \texttt{mdb\_dump64()}

\begin{verbatim}
int mdb_dumpptr(uintptr_t addr, size_t nbytes, uint_t flags, 
                mdb_dumpptr_cb_t func, void *data);
int mdb_dump64(uint64_t addr, uint64_t nbytes, uint_t flags, 
               mdb_dump64_cb_t func, void *data);
\end{verbatim}

These functions can be used to generate formatted hexadecimal and ASCII data dumps that are printed to standard output. Each function accepts an \texttt{addr} parameter specifying the starting location, a \texttt{nbytes} parameter specifying the number of bytes to
display, a set of flags described below, a func callback function to use to read the data to display, and a data parameter that is passed to each invocation of the callback func as its last argument. The functions are identical in every regard except that mdb_dumpptr uses uintptr_t for its address parameters and mdb_dump64 uses uint64_t. This distinction is useful when combining mdb_dump64 with mdb_pread, for example. The built-in ::dump dcmd uses these functions to perform its data display.

The flags parameter should be the bitwise OR of one or more of the following values:

- **MDB_DUMP_RELATIVE**: Number lines relative to the start address instead of with the explicit address of each line.
- **MDB_DUMP_ALIGN**: Align the output at a paragraph boundary.
- **MDB_DUMP_PEDANT**: Display full-width addresses instead of truncating the address to fit the output in 80 columns.
- **MDB_DUMP_ASCII**: Display ASCII values next to the hexadecimal data.
- **MDB_DUMP_HEADER**: Display a header line about the data.
- **MDB_DUMP_TRIM**: Only read from and display the contents of the specified addresses, instead of reading and printing entire lines.
- **MDB_DUMP_SQUISH**: Elide repeated lines by placing a "*" on a line that is a repeat of the previous line.
- **MDB_DUMP_NEWDOT**: Update the value of dot to the address beyond the last address read by the function.
- **MDB_DUMP_ENDIAN**: Adjust for endian-ness. This option assumes that the word size is equal to the current group size, specified by MDB_DUMP_GROUP(). This option will always turn off alignment, headers, and ASCII display to avoid confusing output. If MDB_DUMP_TRIM is set with MDB_DUMP_ENDIAN, the number of bytes dumped will be rounded down to the nearest word size bytes.

### mdb_dumpwidth(width)

Increase the number of 16-byte paragraphs per line that are displayed. The default value of width is one, and the maximum value is 16.

### mdb_dumpgroup(group)

Set the byte group size to group. The default group size is four bytes. The group size must be a power of two that divides the line width.

### mdb_one_bit()

const char *mdb_one_bit(int width, int bit, int on);
The `mdb_one_bit()` function can be used to print a graphical representation of a bit field in which a single bit of interest is turned on or off. This function is useful for creating verbose displays of bit fields similar to the output from `snoop(1M) -v`. For example, the following source code:

```c
#define FLAG_BUSY 0x1
uint_t flags;
/* ... */

mdb_printf("%s = BUSY\n", mdb_one_bit(8, 0, flags & FLAG_BUSY));
```

produces this output:

```
.... ...1 = BUSY
```

Each bit in the bit field is printed as a period (.), with each 4-bit sequence separated by a white space. The bit of interest is printed as 1 or 0, depending on the setting of the `on` parameter. The total width of the bit field in bits is specified by the width parameter, and the bit position of the bit of interest is specified by the `bit` parameter. Bits are numbered starting from zero. The function returns a pointer to an appropriately sized, null-terminated string containing the formatted bit representation. The string is automatically garbage-collected upon completion of the current dcmd.

### `mdb_inval_bits()`

```c
const char *mdb_inval_bits(int width, int start, int stop);
```

The `mdb_inval_bits()` function is used, along with `mdb_one_bit()`, to print a graphical representation of a bit field. This function marks a sequence of bits as invalid or reserved by displaying an ‘x’ at the appropriate bit location. Each bit in the bit field is represented as a period (.), except for those bits in the range of bit positions specified by the start and stop parameters. Bits are numbered starting from zero. For example, the following source code:

```c
mdb_printf("%s = reserved\n", mdb_inval_bits(8, 7, 7));
```

produces this output:

```
x... ..... = reserved
```

The function returns a pointer to an appropriately sized, null-terminated string containing the formatted bit representation. The string is automatically garbage-collected upon completion of the current dcmd.
mdb_inc_indent() and mdb_dec_indent()

ulong_t mdb_inc_indent(ulong_t n);
ulong_t mdb_dec_indent(ulong_t n);

These functions increment and decrement the numbers of columns that MDB will auto-indent with white space before printing a line of output. The size of the delta is specified by \( n \), a number of columns. Each function returns the previous absolute value of the indent. Attempts to decrement the indent below zero have no effect. Following a call to either function, subsequent calls to mdb_printf() are indented appropriately. If the dcmd completes or is forcibly terminated by the user, the indent is restored automatically to its default setting by the debugger.

mdb_eval()

int mdb_eval(const char *s);

Evaluate and execute the specified command string \( s \), as if it had been read from standard input by the debugger. This function returns 0 for success, or -1 for error. mdb_eval() fails if the command string contains a syntax error, or if the command string executed by mdb_eval() is forcibly aborted by the user using the pager or by issuing an interrupt.

mdb_set_dot() and mdb_get_dot()

void mdb_set_dot(uintmax_t dot);
uintmax_t mdb_get_dot(void);

Set or get the current value of dot (the “.” variable). Module developers might want to reposition dot so that, for example, it refers to the address following the last address read by the dcmd.

mdb_get_pipe()

void mdb_get_pipe(mdb_pipe_t *p);

Retrieve the contents of the pipeline input buffer for the current dcmd. The mdb_get_pipe() function is intended to be used by dcms that want to consume the complete set of pipe input and execute only once, instead of being invoked repeatedly by the debugger for each pipe input element. Once mdb_get_pipe() is invoked, the dcmd will not be invoked again by the debugger as part of the current command. This can be used, for example, to construct a dcmd that sorts a set of input values.
The pipe contents are placed in an array that is garbage-collected upon termination of the dcmd, and the array pointer is stored in `p->pipe_data`. The length of the array is placed in `p->pipe_len`. If the dcmd was not executed on the right-hand side of a pipeline (that is, the DCMD_PIPE flag was not set in its flags parameter), `p->pipe_data` is set to NULL and `p->pipe_len` is set to zero.

**mdb_set_pipe()**

```c
void mdb_set_pipe(const mdb_pipe_t *p);
```

Set the pipeline output buffer to the contents described by the pipe structure `p`. The pipe values are placed in the array `p->pipe_data`, and the length of the array is stored in `p->pipe_len`. The debugger makes its own copy of this information, so the caller must remember to free `p->pipe_data` if necessary. If the pipeline output buffer was previously non-empty, its contents are replaced by the new array. If the dcmd was not executed on the left side of a pipeline (that is, the DCMD_PIPE_OUT flag was not set in its flags parameter), this function has no effect.

**mdb_get_xdata()**

```c
ssize_t mdb_get_xdata(const char *name, void *buf, size_t nbytes);
```

Read the contents of the target external data buffer specified by name into the buffer specified by `buf`. The size of `buf` is specified by the `nbytes` parameter; no more than `nbytes` will be copied to the caller’s buffer. The total number of bytes read will be returned upon success; -1 will be returned upon error. If the caller wants to determine the size of a particular named buffer, `buf` should be specified as NULL and `nbytes` should be specified as zero. In this case, `mdb_get_xdata()` will return the total size of the buffer in bytes but no data will be read. External data buffers provide module writers access to target data that is not otherwise accessible through the module API. The set of named buffers exported by the current target can be viewed using the `::xdata` built-in dcmd.

### Additional Functions

Additionally, module writers can use the following `string(3C)` and `bstring(3C)` functions. They are guaranteed to have the same semantics as the functions described in the corresponding Solaris man page.

- `strcat()`
- `strcpy()`
- `strncpy()`
- `strchr()`
- `strrchr()`
- `strcmp()`
- `strncmp()`
- `strncasecmp()`
- `strlen()`
- `bcmp()`
- `bcopy()`
bzero()  bsearch()  qsort()
Options

This appendix provides a reference for MDB command-line options.

Summary of Command-line Options

mdb [ -fkmuyAPMS ] [ +o option ] [ -p pid ] [ -s distance ]
[ -I path ] [ -L path ] [ -P prompt ] [ -R root ]
[ -V dis-version ] [ object [ core ] | core | suffix ]

The following options are supported:

- **-A** Disables automatic loading of mdb modules. By default, mdb attempts to load debugger modules corresponding to the active shared libraries in a user process or core file, or to the loaded kernel modules in the live operating system or an operating system crash dump.

- **-F** Forcibly takes over the specified user process, if necessary. By default, mdb refuses to attach to a user process that is already under the control of another debugging tool, such as truss(1). With the -F option, mdb attaches to these processes anyway. This can produce unexpected interactions between mdb and the other tools attempting to control the process.

- **-f** Force raw file debugging mode. By default, mdb attempts to infer whether the object and core file operands refer to a user executable and core dump or to a pair of operating system crash dump files. If the file type cannot be inferred, the debugger will default to examining the files as plain binary data. The -f option forces mdb to interpret the arguments as a set of raw files to examine.

- **-I** Sets default path for locating macro files. Macro files are read using the $< or $<< dcmds. The path is a sequence of directory
names delimited by colon (:) characters. The -I include path and -L library path (see below) can also contain any of the following tokens:

%-i Expands to the current instruction set architecture (ISA) name ('sparc', 'sparcv9', or 'i386').
%-o Expands to the old value of the path being modified. This is useful for appending or prepending directories to an existing path.
%-p Expands to the current platform string (either `uname -i` or the platform string stored in the process core file or crash dump).
%-r Expands to the path name of the root directory. An alternate root directory can be specified using the -R option. If no -R option is present, the root directory is derived dynamically from the path to the `mdb` executable itself. For example, if `/bin/mdb` is executed, the root directory is `/`. If `/net/hostname/bin/mdb` were executed, the root directory would be derived as `/net/hostname`.
%-t Expands to the name of the current target. This is either the literal string 'proc' (a user process or user process core file), or 'kvm' (a kernel crash dump or the live operating system).

The default include path for 32-bit mdb is:

```
%r/usr/platform/%p/lib/adb:%r/usr/lib/adb
```

The default include path for 64-bit mdb is:

```
%r/usr/platform/%p/lib/adb/%i:%r/usr/lib/adb/%i
```

-k Forces kernel debugging mode. By default, mdb attempts to infer whether the object and core file operands refer to a user executable and core dump, or to a pair of operating system crash dump files. The -k option forces mdb to assume these files are operating system crash dump files. If no object or core operand is specified, but the -k option is specified, mdb defaults to an object file of `/dev/ksyms` and a core file of `/dev/kmem`. Access to `/dev/kmem` is restricted to group sys.

-L Sets default path for locating debugger modules. Modules are loaded automatically on startup or by using the :load dcmd.
The path is a sequence of directory names delimited by colon (:) characters. The -L library path can also contain any of the tokens shown for -I above.

-m Disables demand-loading of kernel module symbols. By default, mdb processes the list of loaded kernel modules and performs demand loading of per-module symbol tables. If the -m option is specified, mdb does not attempt to process the kernel module list or provide per-module symbol tables. As a result, mdb modules corresponding to active kernel modules are not loaded on startup.

-M Preloads all kernel module symbols. By default, mdb performs demand-loading for kernel module symbols: the complete symbol table for a module is read when an address is that module’s text or data section is referenced. With the -M option, mdb loads the complete symbol table of all kernel modules during startup.

-o option Enables the specified debugger option. If the +o form of the option is used, the specified option is disabled. Unless noted below, each option is off by default. mdb recognizes the following option arguments:

adb Enable stricter adb(1) compatibility. The prompt is set to the empty string and many mdb features, such as the output pager, are disabled.

array_mem_limit=limit Set the default limit on the number of array members that ::print will display. If limit is the special token none, all array members will be displayed by default.

array_str_limit=limit Set the default limit on the number of characters that ::print will attempt to display as an ASCII string when printing a char array. If limit is the special token none, the entire char array will be displayed as a string by default.

follow_exec_mode=mode Set the debugger behavior for following an exec(2) system call. The mode should be one of the following named constants:

| ask | If stdout is a terminal device, the debugger will stop after the exec(2) system call has returned and then prompt the user to decide whether to follow the exec or stop. If stdout is not a terminal device, the ask mode will default to stop. |

Appendix A • Options 139
<table>
<thead>
<tr>
<th>follow</th>
<th>The debugger will follow the exec by automatically continuing the target process and resetting all of its mappings and symbol tables based on the new executable. The follow behavior is discussed in more detail under “Interaction With exec” on page 63.</th>
</tr>
</thead>
<tbody>
<tr>
<td>stop</td>
<td>The debugger will stop following return from the exec system call. The stop behavior is discussed in more detail under “Interaction With exec” on page 63.</td>
</tr>
</tbody>
</table>

**follow_fork_mode=mode**
Set the debugger behavior for following a fork(2), fork1(2), or vfork(2) system call. The mode should be one of the following named constants:

<table>
<thead>
<tr>
<th>ask</th>
<th>If stdout is a terminal device, the debugger will stop after the fork system call has returned and then prompt the user to decide whether to follow the parent or child. If stdout is not a terminal device, the ask mode will default to parent.</th>
</tr>
</thead>
<tbody>
<tr>
<td>parent</td>
<td>The debugger will follow the parent process, and will detach from the child process and set it running.</td>
</tr>
<tr>
<td>child</td>
<td>The debugger will follow the child process, and will detach from the parent process and set it running.</td>
</tr>
</tbody>
</table>

**ignoreeof**
The debugger does not exit when an EOF sequence (^D) is entered at the terminal. The ::quit dcmd must be used to quit.

**nostop**
Do not stop a user process when attaching to it when the -p option is specified or when the ::attach or :A cmds are applied. The nostop behavior is described in more detail under “Process Attach and Release” on page 64.

**pager**
The output pager is enabled (default).

**repeatlast**
If a NEWLINE is entered as the complete command at the terminal, mdb repeats the previous command with the current value of dot. This option is implied by -o adb.

**showlmid**
MDB provides support for symbol naming and identification in user applications that make use of link maps other than LM_ID_BASE and LM_ID_LDSO, as described in “Symbol
Name Resolution” on page 29. Symbols on link maps other than LM_ID_BASE or LM_ID_LDSO will be shown as LMlmid'library'symbol, where lmid is the link-map ID in the default output radix (16). The user may optionally configure MDB to show the link-map ID scope of all symbols and objects, including those associated with LM_ID_BASE and LM_ID_LDSO, by enabling the showlmid option. Built-in dcmds that deal with object file names will display link-map IDs according to the value of showlmid above, including ::nm, ::mappings, $m, and ::objects.

-p pid
Attaches to and stops the specified process id. mdb uses the /proc/pid/object/a.out file as the executable file path name.

-P
Sets the command prompt. The default prompt is ‘>’.

-R
Sets root directory for path name expansion. By default, the root directory is derived from the path name of the mdb executable itself. The root directory is substituted in place of the %r token during path name expansion.

-s distance
Sets the symbol matching distance for address-to-symbol-name conversions to the specified distance. By default, mdb sets the distance to zero, which enables a smart-matching mode. Each ELF symbol table entry includes a value V and size S, representing the size of the function or data object in bytes. In smart mode, mdb matches an address A with the given symbol if A is in the range [V, V + S). If any non-zero distance is specified, the same algorithm is used, but S in the given expression is always the specified absolute distance and the symbol size is ignored.

-S
Suppresses processing of the user’s ~/.mdbrc file. By default, mdb reads and processes the macro file .mdbrc if one is present in the user’s home directory, as defined by $HOME. If the -S option is present, this file is not read.

-u
Forces user debugging mode. By default, mdb attempts to infer whether the object and core file operands refer to a user executable and core dump, or to a pair of operating system crash dump files. The -u option forces mdb to assume these files are not operating system crash dump files.

-V
Sets disassembler version. By default, mdb attempts to infer the appropriate disassembler version for the debug target. The disassembler can be set explicitly using the -V option. The ::disasms dcmd lists the available disassembler versions.

-w
Opens the specified object and core files for writing.

-y
Sends explicit terminal initialization sequences for tty mode. Some terminals require explicit initialization sequences to switch into a
tty mode. Without this initialization sequence, terminal features such as standout mode might not be available to mdb.

Operands

The following operands are supported:

object Specifies an ELF format object file to examine. mdb provides the ability to examine and edit ELF format executables (ET_EXEC), ELF dynamic library files (ET_DYN), ELF relocatable object files (ET_REL), and operating system unix.X symbol table files.

core Specifies an ELF process core file (ET_CORE), or an operating system crash dump vmcore.X file. If an ELF core file operand is provided without a corresponding object file, mdb will attempt to infer the name of the executable file that produced the core using several different algorithms. If no executable is found, mdb will still execute, but some symbol information may be unavailable.

suffix Specifies the numerical suffix representing a pair of operating system crash dump files. For example, if the suffix is ‘3’, mdb infers that it should examine the files ‘unix.3’ and ‘vmcore.3’. The string of digits will not be interpreted as a suffix if an actual file of the same name is present in the current directory.

Exit Status

The following exit values are returned:

0 Debugger completed execution successfully.
1 A fatal error occurred.
2 Invalid command line options were specified.
Environment Variables

The following environment variables are supported:

**HISTSIZE**  This variable is used to determine the maximum length of the command history list. If this variable is not present, the default length is 128.

**HOME**  This variable is used to determine the pathname of the user’s home directory, where a `.mdbrc` file may reside. If this variable is not present, no `.mdbrc` processing will occur.

**SHELL**  This variable is used to determine the pathname of the shell used to process shell escapes requested using the `!` meta-character. If this variable is not present, `/bin/sh` is used.
Notes

Warnings
The following warning information applies to the use of MDB.

Use of the Error Recovery Mechanism
The debugger and its dmods execute in the same address space, and thus it is quite possible that a buggy dmod can cause MDB to dump core or otherwise misbehave. The MDB _resume_ capability, described in “Signal Handling” on page 39, provides a limited recovery mechanism for these situations. However, it is not possible for MDB to know definitively whether the dmod in question has corrupted only its own state, or the debugger’s global state. Therefore a _resume_ operation cannot be guaranteed to be safe, or to prevent a subsequent crash of the debugger. The safest course of action following a _resume_ is to save any important debug information, and then quit and restart the debugger.

Use of the Debugger to Modify the Live Operating System
The use of the debugger to modify (that is, write to) the address space of live running operating system is extremely dangerous, and may result in a system panic in the event the user damages a kernel data structure.
Notes

Limitations on Examining Process Core Files
MDB does not provide support for examining process core files that were generated by a release of the Solaris operating environment preceding Solaris 2.6. If a core file from one operating system release is examined on a different operating system release, the run-time link-editor debugging interface (librtld_db) may not be able to initialize. In this case, symbol information for shared libraries will not be available. Furthermore, since shared mappings are not present in user core files, the text section and read-only data of shared libraries may not match the data that was present in the process at the time it dumped core. Core files from Solaris Intel systems may not be examined on Solaris SPARC systems, and vice-versa.

Limitations on Examining Crash Dump Files
Crash dumps from Solaris 7 and earlier releases may only be examined with the aid of the libkvm from the corresponding operating system release. If a crash dump from one operating system release is examined using the dmods from a different operating system release, changes in the kernel implementation may prevent some dcmds or walkers from working properly. MDB will issue a warning message if it detects this condition. Crash dumps from Solaris Intel systems may not be examined on Solaris SPARC systems, and vice-versa.

Relationship Between 32-bit and 64-bit Debugger
MDB provides support for debugging both 32-bit and 64-bit programs. Once it has examined the target and determined its data model, MDB will automatically re-execute the mdb binary that has the same data model as the target, if necessary. This approach simplifies the task of writing debugger modules, because the modules that are loaded will use the same data model as the primary target. Only the 64-bit debugger may be used to debug 64-bit target programs. The 64-bit debugger can only be used on a system that is running the 64-bit operating environment.

Developer Information
The mdb(1) man page provides a detailed description of built-in mdb features for easy developer reference. The header file <sys/mdb_modapi.h> contains prototypes for the functions in the MDB Module API, and the SUNWmdbdm package provides source code for an example module in the directory /usr/demo/mdb.
Transition From `adb`

The transition from using the legacy `adb` utility to using `mdb` is relatively simple: MDB provides evolutionary compatibility for the `adb` syntax, built-in commands, and command-line options. MDB attempts to provide compatibility for all existing `adb` features, but it is not bug-for-bug compatible with `adb`. This appendix briefly discusses several features of `adb` that are not precisely emulated by `mdb` in order to guide users to the new functionality.

Command-line Options

MDB provides a superset of the command-line options recognized by `adb`. All the `adb` options are supported and have the same meaning as before. The `/usr/bin/adb` pathname is delivered as a link that invokes `mdb`, and automatically enables enhanced `adb` compatibility mode. Executing the `/usr/bin/adb` link is equivalent to executing `mdb` with the `-o adb` option, or executing `::set -o adb` once the debugger has started.

Syntax

The MDB language adheres to the same syntax as the `adb` language, in order to provide compatibility for legacy macros and script files. New MDB dcmds use the extended form `::name`, in order to distinguish them from legacy commands that are prefixed with either `:` or `$`. Expressions can also be evaluated on the right-hand side of a dcmd name by enclosing them in square brackets preceded by a dollar sign (`$`). Similar to `adb`, an input line that begins with an exclamation mark (`) indicates
that the command line should be executed by the user’s shell. In MDB, a debugger command may also be suffixed with an exclamation mark to indicate that its output should be piped to the shell command following the exclamation mark.

In `adb(1)`, binary operators are left associative and have lower precedence than unary operators. Binary operators are evaluated in strict left-to-right order on the input line. In MDB, binary operators are left associative and have lower precedence than unary operators, but the binary operators operate in order of precedence according to the table in “Binary Operators” on page 27. The operators conform to the order of precedence in ANSI C. Legacy `adb(1)` macro files that do not explicitly parenthesize ambiguous expressions may need to be updated to work with MDB. For example, in `adb` the following command evaluates to the integer value nine:

```
$ echo "4-1*3=X" | adb
9
```

In MDB, as in ANSI C, operator "*" has higher precedence than "-" and therefore the result is the integer value one:

```
$ echo "4-1*3=X" | mdb
1
```

Watchpoint Length Specifier

The watchpoint length specifier syntax recognized by MDB is different from the syntax described in `adb(1)`. In particular, the `adb` watchpoint commands `:w`, `:a`, and `:p` allow an integer length in bytes to be inserted between the colon and the command character. In MDB, the count should be specified following the initial address as a repeat count. Stated simply, these `adb(1)` commands:

```
123:456w
123:456a
123:456p
```

are specified in MDB as

```
123,456:w
123,456:a
123,456:p
```

The MDB `::wp` dcmd provides more complete facilities for creating user process watchpoints.
Address Map Modifier

The adb(1) commands to modify segments of the virtual address map and object file map are not present in MDB. Specifically, the /m, /*m, ?m, and ?*m format specifiers are not recognized or supported by MDB. These specifiers were used to manually modify the valid addressable range of the current object and core files. MDB properly recognizes the addressable range of such files automatically, and updates the ranges when a live process is being debugged, so these commands are no longer necessary.

Output

The precise text output form of some commands is different in MDB. Macro files are formatted using the same basic rules, but shell scripts that depend on the precise character-by-character output of certain commands may need to change. Users who have shell scripts that parse the output of adb commands will need to revalidate and update such scripts as part of the transition to MDB.
Transition From \texttt{crash}

The transition from using the legacy \texttt{crash(1M)} utility to using \texttt{mdb(1)} is relatively simple: MDB provides most of the “canned” \texttt{crash} commands. The additional extensibility and interactive features of MDB allow the programmer to explore aspects of the system not examined by the current set of commands.

This appendix briefly discusses several features of \texttt{crash(1M)} and provides pointers to equivalent MDB functionality.

Command-line Options

The \texttt{crash -d}, \texttt{-n}, and \texttt{-w} command-line options are not supported by \texttt{mdb}. The \texttt{crash} dump file and name list (symbol table file) are specified as arguments to \texttt{mdb} in the order of name list, crash dump file. To examine the live kernel, the \texttt{mdb -k} option should be specified with no additional arguments. Users who want to redirect the output of \texttt{mdb} to a file or other output destination, should either employ the appropriate shell redirection operator following the \texttt{mdb} invocation on the command line, or use the \texttt{: :log} built-in \texttt{dcmd}.

Input in MDB

In general, input in MDB is similar to \texttt{crash}, except that function names (in MDB, \texttt{dcmd} names) are prefixed with ”\texttt{::}”. Some MDB \texttt{dcmds} accept a leading expression argument that precedes the \texttt{dcmd} name. Like \texttt{crash}, string options can follow the \texttt{dcmd} name. If a ! character follows a function invocation, MDB will also create a
pipeline to the specified shell pipeline. All immediate values specified in MDB are interpreted in hexadecimal by default. The radix specifiers for immediate values are different in crash and MDB as shown in Table D-1:

**TABLE D-1 Radix Specifiers**

<table>
<thead>
<tr>
<th>crash</th>
<th>mdb</th>
<th>Radix</th>
</tr>
</thead>
<tbody>
<tr>
<td>0x</td>
<td>0x</td>
<td>hexadecimal (base 16)</td>
</tr>
<tr>
<td>0d</td>
<td>0t</td>
<td>decimal (base 10)</td>
</tr>
<tr>
<td>0b</td>
<td>0i</td>
<td>binary (base 2)</td>
</tr>
</tbody>
</table>

Many crash commands accepted slot numbers or slot ranges as input arguments. The Solaris operating environment is no longer structured in terms of slots, so MDB dcmds do not provide support for slot-number processing.

**Functions**

<table>
<thead>
<tr>
<th>crash function</th>
<th>mdb dcmd</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>?</td>
<td>::dcmds</td>
<td>List available functions.</td>
