Preface

The STREAMS Programming Guide describes how to use STREAMS in designing and implementing applications and STREAMS modules and drivers, for architectures that conform to the Solaris™ 7 DDI/DDK.

Who Should Use This Book

This manual is a guide for application, driver, and module developers. The reader must know C programming in a UNIX™ environment, and be familiar with the system interfaces. Driver and module developers should also be familiar with the book Writing Device Drivers.

How This Book Is Organized

This guide is divided into three parts. Part 1, Application Programming Interface, describes how to use STREAMS facilities in applications. Part 2, Kernel Interface, describes how to design STREAMS modules and STREAMS drivers. Part 3, Advanced Topics, contains advanced topics. Every developer should read Chapter 1.

Part 1, Application Programming Interface

- Chapter 1 is a general overview of STREAMS concepts and mechanisms.
- Chapter 2 describes the basic operations to assemble, use, and dismantle streams.
- Chapter 3 details the operations of messages, the flow of streams, and how to manipulate Streams from applications.
Chapter 4 describes putting messages into and receiving them from a stream.
Chapter 5 identifies and describes tools to monitor names and modules, and gather statistics.
Chapter 6 describes pipes and named pipes (FIFOs).

Part 2, Kernel Interface
- Chapter 7 describes STREAMS modules, drivers, and how they relate.
- Chapter 8 describes message types, structure, and linkage in detail. Flow control is also covered.
- Chapter 9 describes specific STREAMS drivers, using code samples.
- Chapter 10 describes how specific examples of modules work based on code samples.
- Chapter 11 describes configuring modules and drivers into the OS.
- Chapter 12 describes the multithreaded environment and how to make modules and drivers MT-safe.
- Chapter 13 describes how to implement multiplexing in a driver.

Part 3, Advanced Topics
- Chapter 14 addresses commonly encountered problems and their resolution.

Part 4, Appendixes
- Appendix A describes STREAMS messages and their use.
- Appendix B describes STREAMS utility routines and their use.
- Appendix C explains how to set up a terminal subsystem, and how to keep track of processes and handle interrupts.
- Appendix D contains answers to a variety of commonly asked questions about STREAMS.
- Glossary defines terms unique to STREAMS.

Related Books
You can obtain more information on STREAMS system calls and utilities from the on-line manual pages. For more information on driver-related issues, including autoconfiguration, see Writing Device Drivers.

You can also find STREAMS described to some extent in the System V Interface Definition, and in the following publications:
Accessing Sun Documentation Online

The docs.sun.com™ Web site enables you to access Sun technical documentation online. You can browse the docs.sun.com archive or search for a specific book title or subject. The URL is http://docs.sun.com.

Typographic Conventions

Overview of STREAMS

This chapter provides a foundation for later chapters. Background and simple definitions are followed by an overview of the STREAMS mechanisms. Because the application developer is concerned with a different subset of STREAMS interfaces than the kernel-level developer, application and kernel levels are described separately.

- “STREAMS Definitions” on page 20
- “When to Use STREAMS” on page 23
- “How STREAMS Works—Application Interface” on page 24
- “How STREAMS Works at the Kernel Level” on page 26
- “Service Interfaces” on page 33

What Is STREAMS?

STREAMS is a general, flexible programming model for UNIX system communication services. STREAMS defines standard interfaces for character input/output (I/O) within the kernel, and between the kernel and the rest of the UNIX system. The mechanism consists of a set of system calls, kernel resources, and kernel routines.

STREAMS enables you to create modules to provide standard data communications services and then manipulate the modules on a stream. From the application level, modules can be dynamically selected and interconnected. No kernel programming, compiling, and link editing are required to create the interconnection.

STREAMS provides an effective environment for kernel services and drivers requiring modularity. STREAMS parallels the layering model found in networking protocols. For example, STREAMS is suitable for:

- Implementing network protocols
- Developing character device drivers
- Developing network controllers (for example, for an Ethernet card)
I/O terminal services

The fundamental STREAMS unit is the stream. A stream is a full-duplex bidirectional data-transfer path between a process in user space and a STREAMS driver in kernel space. A stream has three parts: a stream head, zero or more modules, and a driver.

![Simple Stream Diagram](image)

**FIGURE 1–1 Simple Stream**

**STREAMS Definitions**

The capitalized word “STREAMS” refers to the STREAMS programming model and facilities. The word “stream” refers to an instance of a full-duplex path using the model and facilities between a user application and a driver.

**Stream as a Data Path**

A stream is a data path that passes data in both directions between a STREAMS driver in kernel space, and a process in user space. An application creates a stream by opening a STREAMS device (see Figure 1–1).
Stream Head

A stream head is the end of the stream nearest the user process. It is the interface between the stream and the user process. When a STREAMS device is first opened, the stream consists of only a stream head and a STREAMS driver.

STREAMS Module

A STREAMS module is a defined set of kernel-level routines and data structures. A module does “black-box” processing on data that passes through it. For example, a module converts lowercase characters to uppercase, or adds network routing information. A STREAMS module is dynamically pushed on the stream from the user level by an application. Full details on modules and their operation are covered in Chapter 10.

STREAMS Device Driver

A STREAMS device driver is a character device driver that implements the STREAMS interface. A STREAMS device driver exists below the stream head and any modules. It can act on an external I/O device, or it can be an internal software driver, called a pseudo-device driver. The driver transfers data between the kernel and the device. The interfaces between the driver and kernel are known collectively as the Solaris operating environment Device Driver Interface/Driver Kernel Interface (Solaris operating environment DDI/DKI). The relationship between the driver and the rest of the UNIX kernel is explained in Writing Device Drivers. Details of device drivers are explained in Chapter 9.

STREAMS Data

Data on a stream is passed in the form of messages. Messages are the means by which all I/O is done under STREAMS. Each stream head, STREAMS module, and driver has a read side and a write side. When messages go from one module’s read side to the next module’s read side, they are said to be traveling upstream. Messages passing from one module’s write side to the next module’s write side are said to be traveling downstream. Kernel-level operation of messages is discussed in “Message Components” on page 29.
Message Queues

Each stream head, driver, and module has its own pair of queues, one queue for the read side and one queue for the write side. Messages are ordered into queues, generally on a first-in, first-out basis (FIFO), according to priorities associated with them. Kernel-level details of queues are covered in “Structure of a Message Queue” on page 31.

![Diagram of Message Queues]

FIGURE 1–2 Messages Passing Using Queues

Communicating With a STREAMS Device

To communicate with a STREAMS device, an application’s process uses read(2), write(2), getmsg(2), getpmsg(2), putmsg(2), putpmsg(2), and ioctl(2) to transmit or receive data on a stream.

From the command line, configure a stream with autopush(1M). From within an application, configure a stream with ioctl(2) as described in streamio(7I).

The ioctl(2) interface performs control operations on and through device drivers that cannot be done through the read(2) and write(2) interfaces. ioctl(2) operations include pushing and popping modules on and off the stream, flushing the stream, and manipulating signals and options. Certain ioctl(2) commands for STREAMS operate on the whole stream, not just the module or driver. The streamio(7I) manual page describes STREAMS ioctl(2) commands. Chapter 4 details interstream communications.
STREAMS Multiplexing

The modularity of STREAMS allows one or more upper streams to route data into one or more lower streams. This process is defined as multiplexing (mux). Example configurations of multiplexers are described in “Configuring Multiplexed Streams” on page 32.

STREAMS Polling

Polling within STREAMS enables a user process to detect events occurring at the stream head, specifying the event to look for and the amount of time to wait for it to happen. An application might need to interact with multiple streams. The poll(2) system call enables applications to detect events that occur at the head of one or more streams. Chapter 3 describes polling.

Message Transfer Flow Control

Flow control regulates the rate of message transfer between the user process, stream head, modules, and driver. With flow control, a module that cannot process data at the rate being sent can queue the data to avoid flooding modules upstream. Flow control is local to each module or driver, and is voluntary. Chapter 8 describes flow control.

When to Use STREAMS

The STREAMS framework is most useful when modularity and configurability are issues. For instance, network drivers, terminal drivers, and graphics I/O device drivers benefit from using STREAMS. Modules can be pushed (added) and popped (removed) to create desired program behavior.

STREAMS is general enough to provide modularity between a range of protocols. It is a major component in networking support utilities for UNIX System V because it facilitates communication between network protocols.
How STREAMS Works—Application Interface

An application opens a STREAMS device, which creates the stream head to access the device driver. The stream head packages the data from the user process into STREAMS messages, and passes it downstream into kernel space. One or more cooperating modules can be pushed on a stream between the stream head and driver to customize the stream and perform any of a range of tasks on the data before passing it on. On the other hand, a stream might consist solely of the stream head and driver, with no module at all.

Opening a Stream

To a user application, a STREAMS device resembles an ordinary character I/O device, as it has one or more nodes associated with it in the file system, and is opened by calling `open(2)`.

The file system represents each device as a special file. There is an entry in the file for the major device number, identifying the actual device driver that will activate the device. There are corresponding separate minor device numbers for each instance of a particular device, for example, for a particular port on a serial card, or a specific pseudo-terminal such as those used by a windowing application.

Different minor devices of a driver cause a separate stream to be connected between a user process and the driver. The first open call creates the stream; subsequent open calls respond with a file descriptor referencing that stream. If the same minor device is opened more than once, only one stream is created.

However, drivers can support a user process getting a dedicated stream without the application distinguishing which minor device is used. In this case, the driver selects any unused minor device to be used by the application. This special use of a minor device is called cloning. Chapter 9 describes properties and behavior of clone devices.

Once a device is opened, a user process can send data to the device by calling `write(2)`, and receive data from the device by calling `read(2)`. Access to STREAMS drivers using read and write is compatible with the traditional character I/O mechanism. STREAMS-specific applications also can call `getmsg(2)`, `getpmsg(2)`, `putmsg(2)`, and `putpmsg(2)` to pass data to and from the stream.
Closing a Stream

The close(2) interface closes a device and dismantles the associated stream when the last open reference to the stream is closed. The exit(2) interface terminates the user process and closes all open files.

Controlling Data Flow

If the stream exerts flow control, the write(2) call blocks until flow control has been relieved, unless the file has been specifically advised not to. open(2) or fcntl(2) can be used to control this nonblocking behavior.

Simple Stream Example

Example 1–1 shows how an application might use a simple stream. Here, the user program interacts with a communications device that provides point-to-point data transfer between two computers. Data written to the device is transmitted over the communications line, and data arriving on the line is retrieved by reading from the device.

EXAMPLE 1–1 Simple Stream

```c
#include <sys/fcntl.h>
#include <stdio.h>

int main()
{
    char buf[1024];
    int fd, count;

    if ((fd = open("/dev/ttya", O_RDWR)) < 0) {
        perror("open failed");
        exit(1);
    }

    while ((count = read(fd, buf, sizeof(buf))) > 0) {
        if (write(fd, buf, count) != count) {
            perror("write failed");
            break;
        }
    }

    exit(0);
}
```
In this example, /dev/ttya identifies an instance of a serial communications device driver. When this file is opened, the system recognizes the device as a STREAMS device and connects a stream to the driver. Figure 1–3 shows the state of the stream following the call to open(2).

This example illustrates a simple loop, with the application reading data from the communications device, then writing the input back to the same device, echoing all input back over the communications line. The program reads up to 1024 bytes at a time, and then writes the number of bytes just read.

read(2) returns the available data, which can contain fewer than 1024 bytes. If no data is currently available at the stream head, read(2) blocks until data arrives.

Note – The application program must loop on read(2) until the desired number of bytes are read. The responsibility for the application getting all the bytes it needs is that of the application developer, not the STREAMS facilities.

Similarly, the write(2) call attempts to send the specified number of bytes to /dev/ttya. The driver can implement a flow-control mechanism that prevents a user from exhausting system resources by flooding a device driver with data.

How STREAMS Works at the Kernel Level

Developers implementing STREAMS device drivers and STREAMS modules use a set of STREAMS-specific functions and data structures. This section describes some basic kernel-level STREAMS concepts.
Creating the Stream Head

The stream head is created when a user process opens a STREAMS device. It translates the interface calls of the user process into STREAMS messages, which it sends to the stream. The stream head also translates messages originating from the stream into a form that the application can process. The stream head contains a pair of queues; one queue passes messages upstream from the driver, and the other passes messages to the driver. The queues are the pipelines of the stream, passing data between the stream head, modules, and driver.

Message Processing

A STREAMS module does processing operations on messages passing from a stream head to a driver or from a driver to a stream head. For example, a TCP module might add header information to the front of data passing downstream through it. Not every stream requires a module. There can be zero or more modules in a stream.

Modules are stacked (pushed) onto and unstacked (popped) from a stream. Each module must provide open(), close(), and put() entries and provides a service() entry if the module supports flow control.

Like the stream head, each module contains a pair of queue structures, although a module only queues data if it is implementing flow control. Figure 1–4 shows the queue structures Au/Ad associated with Module A (“u” for upstream “d” for downstream) and Bu/Bd associated with Module B.

The two queues operate completely independently. Messages and data can be shared between upstream and downstream queues only if the module functions are specifically programed to share data.

Within a module, one queue can refer to the messages and data of the opposing queue. A queue can directly refer to the queue of the successor module (adjacent in the direction of message flow). For example, in Figure 1–4, Au (the upstream queue from Module A) can reference Bu (the upstream queue from Module B). Similarly Queue Bd can reference Queue Ad.
Both queues in a module contain messages, processing procedures, and private data.

Messages: Blocks of data that pass through, and can be operated on by, a module.

Processing procedures: Individual put and service routines on the read and write queues process messages. The put procedure passes messages from one queue to the next in a stream and is required for each queue. It can do additional message processing. The service procedure is optional and does deferred processing of messages. These procedures can send messages either upstream or downstream. Both procedures can also modify the private data in their module.

Private data: Data private to the module (for example, state information and translation tables).

Open and close: Entry points must be provided. The open routine is invoked when the module is pushed onto the stream or the stream is reopened. The close is invoked when the module is popped or the stream is closed.
A module is initialized by either an `I_PUSH ioctl(2)`, or pushed automatically during an `open` if a stream has been configured by the `autopush(1M)` mechanism, or if that stream is reopened.

A module is disengaged by `close` or the `I_POP ioctl(2)`.

**Structure of a STREAMS Device Driver**

STREAMS device drivers are structurally similar to STREAMS modules and character device drivers. The STREAMS interfaces to driver routines are identical to the interfaces used for modules. For instance they must both declare `open`, `close`, `put`, and `service` entry points.

There are some significant differences between modules and drivers.

A driver:

- Must be able to handle interrupts from the device.
- Is represented in file system by a character-special file.
- Is initialized and disengaged using `open(2)` and `close(2)`. `open(2)` is called when the device is first opened and for each reopen of the device. `close(2)` is only called when the last reference to the stream is closed.

Both drivers and modules can pass signals, error codes, and return values to processes using message types provided for that purpose.

**Message Components**

All kernel-level input and output under STREAMS is based on messages. STREAMS messages are built in sets of three:

- a message header structure (`msgb(9S)`) that identifies the message instance.
- a data block structure (`datab(9S)`) points to the data of the message.
- the data itself

Each data block and data pair can be referenced by one or more message headers. The objects passed between STREAMS modules are pointers to messages. Messages are sent through a stream by successive calls to the `put` procedure of each module or driver in the stream. Messages can exist as independent units, or on a linked list of messages called a `message queue`. STREAMS utility routines enable developers to manipulate messages and message queues.
All STREAMS messages are assigned message types to indicate how they will be used by modules and drivers and how they will be handled by the stream head. Message types are assigned by the stream head, driver, or module when the message is created. The stream head converts the system calls `read`, `write`, `putmsg`, and `putpmsg` into specified message types, and sends them downstream. It responds to other calls by copying the contents of certain message types that were sent upstream.

**Message Queueing Priority**

Sometimes messages with urgent information, such as a break or alarm conditions, must pass through the stream quickly. To accommodate them, STREAMS uses message queuing priority, and high-priority message types. All messages have an associated priority field. Normal (ordinary) messages have a priority of zero, while priority messages have a priority band greater than zero. High-priority messages have a high priority by virtue of their message type, are not blocked by STREAMS flow control, and are processed ahead of all ordinary messages on the queue.

Nonpriority, ordinary messages are placed at the end of the queue following all other messages that can be waiting. Priority messages can be either high priority or priority band messages. High-priority messages are placed at the head of the queue but after any other high-priority messages already in the queue. Priority band messages enable support of urgent, expedited data. Priority band messages are placed in the queue in the following order:

- after high-priority messages but before ordinary messages.
- below all messages that have a priority greater than or equal to their own.
- above any messages with a lesser priority.

Figure 1–5 shows the message queueing priorities.
High-priority message types cannot be changed into normal or priority band message types. Certain message types come in equivalent high-priority or ordinary pairs (for example, M_PCPROTO and M_PROTO), so that a module or device driver can choose between the two priorities when sending information.

**Structure of a Message Queue**

* A *queue* is an interface between a STREAMS driver or module and the rest of the stream (see `queue(9S)`). The queue structure holds the messages, and points to the STREAMS processing routines that should be applied to a message as it travels through a module. STREAMS modules and drivers must explicitly place messages on a queue, for example, when flow control is used.

Each open driver or pushed module has a pair of queues allocated, one for the read side and one for the write side. Queues are always allocated in pairs. Kernel routines are available to access each queue's mate. The queue's `put` or `service` procedure can add a message to the current queue. If a module does not need to queue messages, its `put` procedure can call the neighboring queue's `put` procedure.
The queue’s `service` procedure deals with messages on the queue, usually by removing successive messages from the queue, processing them, and calling the `put` procedure of the next module in the stream to pass the message to the next queue. Chapter 7 discusses the `service` and `put` procedures in more detail.

Each queue also has a pointer to an `open` and `close` routine. The `open` routine of a driver is called when the driver is first opened and on every successive open of the stream. The `open` routine of a module is called when the module is first pushed on the stream and on every successive open of the stream. The `close` routine of the module is called when the module is popped (removed) off the stream, or at the time of the final close. The `close` routine of the driver is called when the last reference to the stream is closed and the stream is dismantled.

### Configuring Multiplexed Streams

Previously, streams were described as stacks of modules, with each module (except the head) connected to one upstream module and one downstream module. While this can be suitable for many applications, others need the ability to multiplex streams in a variety of configurations. Typical examples are terminal window facilities, and internetworking protocols (that might route data over several subnetworks).

An example of a multiplexer is a module that multiplexes data from several upper streams to a single lower stream. An upper stream is one that is upstream from the multiplexer, and a lower stream is one that is downstream from the multiplexer. A terminal windowing facility might be implemented in this fashion, where each upper stream is associated with a separate window.

A second type of multiplexer might route data from a single upper stream to one of several lower streams. An internetworking protocol could take this form, where each lower stream links the protocol to a different physical network.

A third type of multiplexer might route data from one of many upper streams to one of many lower streams.

The STREAMS mechanism supports the multiplexing of streams through special pseudo-device drivers. A user can activate a linking facility mechanism within the STREAMS framework to dynamically build, maintain, and dismantle multiplexed stream configurations. Simple configurations like those shown previously can be combined to form complex, multilevel multiplexed stream configurations.

STREAMS multiplexing configurations are created in the kernel by interconnecting multiple streams. Conceptually, a multiplexer can be divided into two components—the upper multiplexer and the lower multiplexer. The lower multiplexer
acts as a stream head for one or more lower streams. The upper multiplexer acts as a
device for one or more upper streams. How data is passed between the upper and
lower multiplexer is up to the implementation. Chapter 13 covers implementing
multiplexers.

Multithreading the Kernel

The Solaris operating environment kernel is multithreaded to make effective use of
symmetric shared-memory multiprocessor computers. All parts of the kernel,
including STREAMS modules and drivers, must ensure data integrity in a
multiprocessing environment. For the most part, developers must ensure that
concurrently running kernel threads do not attempt to manipulate the same data at
the same time. The STREAMS framework provides multithreaded (MT) STREAMS
perimeters, which provides the developer with control over the level of concurrency
allowed in a module. The DDI/DKI provides several advisory locks for protecting
data. See Chapter 12 for more information.

Service Interfaces

Using STREAMS, you can create modules that present a service interface to any
neighboring module or device driver, or between the top module and a user
application. A service interface is defined in the boundary between two neighbors.

In STREAMS, a service interface is a set of messages and the rules that allow these
messages to pass across the boundary. A module using a service interface, for example,
receives a message from a neighbor and responds with an appropriate action (perhaps
sending back a request to retransmit) depending on the circumstances.

You can stack a module anywhere in a stream, but connecting sequences of modules
with compatible protocol service interfaces is better. For example, a module that
implements an X.25 protocol layer, as shown in Figure 1–6, presents a protocol service
interface at its input and output sides. In this case, other modules should be connected
to the input and output side if they have the compatible X.25 service interface only.
Manipulating Modules

With STREAMS, you can manipulate modules from the user application level, interchange modules with common service interfaces, and change the service interface to a STREAMS user process. These capabilities yield further benefits when working with networking services and protocols:

- User-level programs can be independent of underlying protocols and physical communication media.
- Network architectures and higher-level protocols can be independent of underlying protocols, drivers, and physical communication media.
- Higher-level services can be created by selecting and connecting lower-level services and protocols.

The following examples show the benefits of STREAMS capabilities for creating service interfaces and manipulating modules. These examples are only illustrations and do not necessarily reflect real situations.

Protocol Portability

Figure 1–6 shows how an X.25 protocol module can work with different drivers on different machines by using compatible service interfaces. The X.25 protocol module interfaces are Connection Oriented Network Service (CONS) and Link Access Protocol – Balanced (LAPB).

![Diagram of Protocol Module Portability](image)

**FIGURE 1–6** Protocol Module Portability
Protocol Substitution

You can alternate protocol modules and device drivers on a system if the alternates are implemented to an equivalent service interface.

Protocol Migration

Figure 1–7 shows how STREAMS can move functions between kernel software and front-end firmware. A common downstream service interface lets the transport protocol module be independent of the number or type of modules below it. The same transport module will connect without modification to either an X.25 module or X.25 driver that has the same service interface.

By shifting functions between software and firmware, you can produce cost-effective, functionally equivalent systems over a wide range of configurations. This means you can swiftly incorporate technological advances. The same transport protocol module can be used on a lower-capacity machine, where economics preclude the use of front-end hardware, and also on a larger scale system where a front-end is economically justified.

![Diagram of Protocol Migration](image)

**FIGURE 1–7** Protocol Migration
Module Reusability

Figure 1-8 shows the same canonical module (for example, one that provides delete and kill processing on character strings) reused in two different streams. This module would typically be implemented as a filter, with no service interface. In both cases, a TTY interface is presented to the stream’s user process because the module is nearest the stream head.

FIGURE 1–8 Module Reusability
STREAMS Application-Level Components

This chapter shows how to construct, use, and dismantle a stream using STREAMS-related system calls. It provides a general discussion of the relationship between STREAMS components in a simple streams example.

- “Opening a STREAMS Device File” on page 39
- “Queue Allocation” on page 40
- “Adding and Removing Modules” on page 40
- “Closing the Stream” on page 41
- “Stream Construction Example” on page 41

STREAMS Interfaces

The stream head provides the interface between the stream and an application program. After a stream has been opened, STREAMS-related system calls enable a user process to insert and delete (push and pop) modules. That process can then communicate with and control the operation of the stream head, modules, and drivers. The stream head handles most system calls so that the related processing does not have to be incorporated in a module or driver.

STREAMS System Calls

Table 2-1 offers an overview of some basic STREAMS-related system calls.
TABLE 2-1 Summary of Basic STREAMS-related System Calls

| poll(2)    | Identifies files on which a user can send or receive messages, or on
            | which certain events have occurred (not restricted to STREAMS, although historically it was) |
| pipe(2)    | Creates a bidirectional channel that provides a communication path between multiple processes |

Note – Sections 1, 2, 3, 7, and 9 of the online manual pages (man pages) contain all the STREAMS information.

Action Summary

The open(2) system call recognizes a STREAMS special file and creates a stream to the specified driver. A user process can receive and send data on STREAMS files using read(2) and write(2) in the same way as with traditional character files. ioctl(2) lets users perform functions specific to a particular device. STREAMS ioctl(2) commands (see the streamio(7I) man page) support a variety of functions to access and control streams. The final close(2) on a stream dismantles it.

The poll(2) system call provides a mechanism for multiplexing input/output over a set of file descriptors that reference open files. putmsg(2) and getmsg(2) and the putpmsg(2) and getpmsg(2) send and receive STREAMS messages, and can act on STREAMS modules and drivers through a service interface.
Opening a STREAMS Device File

One way to construct a stream is to call `open(2)` to open a STREAMS special file. If the open call is the initial file open, a stream is created. (There is one stream for each major or minor device pair.) If this open is not the initial open of this stream, the open procedures of the driver and all pushable modules on the stream are called.

Sometimes a user process needs to connect a new stream to a driver regardless of which minor device is used to access the driver. Instead of the user process polling for an available minor device node, STREAMS provides a facility called `clone open`. If a STREAMS driver is implemented as a clone device, a single node in the file system may be opened to access any unused device that the driver controls. This special node guarantees that the user is allocated a separate stream to the driver for every open call. Each stream is associated with an unused major or minor device, so the total number of streams that can connect to a particular clone driver is limited to the number of minor devices configured for the driver.

Clone devices are used, for example, in a networking environment where a protocol pseudo-device driver requires each user to open a separate stream to establish communication.

You can open a clone device in two ways. The first is to create a node with the major number of the clone device (−) and a minor number corresponding to the major number of the device to be cloned. For example `/dev/ps0` might have a major number of 50 and a minor number of 0 for normal opens. The clone device may have a major number of 40. By creating a node `/dev/ps` with a major number of 40 and a minor number of 50, a clonable device is created. In this case, the driver is passed a special flag (`CLONEOPEN`) that tells it to return a unique minor device number.

The second way is to have the driver open itself as a clone device, that is, the driver returns a unique minor number.

When a stream is already open, further opens of the same device call the open routines of all modules and the driver on that stream. In this case, a driver is opened and a module is pushed on a stream. When a push occurs, the module open routine is called. If another open of the same device is made, the open routine of the module is called, followed by the open routine of the driver. This is opposite to the initial order of opens when the stream is created.

STREAMS also offers `autopush`. On an `open(2)` system call, a preconfigured list is checked for modules to be pushed. All modules in this list are pushed before the `open(2)` returns. For more information see the `autopush(1M)` and `sad(7D)` man pages.
Initializing Details

There is one stream head per stream. The stream head, which is initiated by the first open call, is created from a data structure and a pair of queue structures. The content of the stream head and queues is initialized with predetermined values, including the stream head processing procedures.

Queue Allocation

STREAMS queues are allocated in pairs. One queue is always the upstream or read-side; the other is the downstream or write-side. These queues hold the messages, and tell the kernel which processing routines apply to each message passing through a module. The queue structure type is queue_t. Fields in the queue data structure are detailed in queue(9S).

Adding and Removing Modules

As part of constructing a stream, a module can be added (pushed) with an I_PUSH ioctl(2) (see streamio(7I)) call. The push inserts a module beneath the stream head. Because of the similarity of STREAMS components, the push operation is similar to the driver open.

Each push of a module is independent, even in the same stream. If the same module is pushed more than once on a stream, there are multiple occurrences of the module in the stream. The total number of pushable modules that may be contained on any one stream is limited by the kernel parameter nstrpush.

An I_POP ioctl(2) (see streamio(7I)) system call removes (pops) the module immediately below the stream head. The pop calls the module close procedure. On return from the module close, any messages left on the module’s message queues are freed (deallocated). The stream head then connects to the component previously below the popped module and releases the module’s queue pair.

I_PUSH and I_POP enable a user process to dynamically alter the configuration of a stream by pushing and popping modules as required. For example, a module may be removed and a new one inserted below the stream head. Then the original module can be pushed back after the new module has been pushed.
You can also restrict which modules can be popped with \_\_POP calls by placing an anchor in the stream at any module you want to “lock down.” The \_\_ANCHOR ioctl prevents a module from being popped except by a privileged process. See “STREAMS Anchors” on page 243 for more information about working with anchors.

---

**Closing the Stream**

The last close to a STREAMS device dismantles the stream. Dismantling consists of popping any modules on the stream and closing the driver. Before a module is popped, the close(2) may delay to allow any messages on the write message queue of the module to be drained by module processing. Similarly, before the driver is closed, the close(2) may delay to allow any messages on the write message queue of the driver to be drained by driver processing. If O_NDELAY (or O_NONBLOCK) is clear, close(2) waits up to 15 seconds for each module to drain and up to 15 seconds for the driver to drain, see open(2) and fcntl(2). The default close delay is 15 seconds, but this can be changed on a per-stream basis with the \_\_SETCLTIME ioctl(2).

The close delay is independent of any delay that the module or driver’s close routine itself chooses to impose. If O_NDELAY (or O_NONBLOCK) is set, the pop is performed immediately and the driver is closed without delay.

Messages can remain queued, for example, if flow control is inhibiting execution of the write queue service procedure. When all modules are popped and any wait for the driver to drain is completed, the driver close routine is called. On return from the driver close, any messages left on the driver’s queues are freed, and the queue and stream head structures are released.

---

**Stream Construction Example**

This example extends the communications device-echoing example shown in “Simple Stream Example” on page 25. The module in this example converts (change case, delete, duplicate) selected alphabetic characters.

**Note** – The complete listing of the module is on the CD.
Inserting Modules

An application can insert various modules into a stream to process and manipulate data that pass between a user process and the driver. In the example, the character conversion module receives a command and a corresponding string of characters from the user. All data passing through the module is inspected for instances of characters in this string. Whatever operation the command requires is performed on all characters that match the string.

EXAMPLE 2-1 Module Header File Definition

```c
#include <string.h>
#include <fcntl.h>
#include <stropts.h>
#define BUFLEN 1024
/*
 * These definitions would typically be
 * found in a header file for the module
 */
#define XCASE 1 /* change alphabetic case of char */
#define DELETE 2 /* delete char */
#define DUPLICATE 3 /* duplicate char */
main()
{
    char buf[BUFLEN];
    int fd, count;
    struct strioctl strioctl;
```

The first step is to establish a stream to the communications driver and insert the character conversion module. This is accomplished by first opening (`fd = open`) then calling `ioctl` to push the chconv module, as shown in the sequence of system calls in Example 2-2.

EXAMPLE 2-2 Pushing a Module

```c
if ((fd = open("/dev/term/a", O_RDWR)) < 0) {
    perror("open failed");
    exit(1);
}
if (ioctl(fd, I_PUSH, "chconv") < 0) {
    perror("ioctl I_PUSH failed");
    exit(2);
}
```

The `I_PUSH` `ioctl` call directs the stream head to insert the character conversion module between the driver and the stream head. The example illustrates an important difference between STREAMS drivers and modules. Drivers are accessed through a node or nodes in the file system (in this case `/dev/term/a`) and are opened just like
other devices. Modules, on the other hand, are not devices. Identify modules through a separate naming convention, and insert them into a stream using _I_PUSH or autopush. Figure 2-1 shows creation of the stream.

Modules are stacked onto a stream and removed from a stream in last-in, first-out (LIFO) order. Therefore, if a second module is pushed onto this stream, it is inserted between the stream head and the character conversion module.

**Module and Driver Control**

The next step in this example is to pass the commands and corresponding strings to the character conversion module. This can be accomplished by calling _ioctl(2) to invoke the character conversion module.

Example 2–3 uses the conventional _I_STR _ioctl(2), an indirect way of passing commands and data pointers. Example 2–4 shows the data structure for _I_STR.

Instead of _I_STR, some systems support transparent _ioctl in which calls can be made directly. For example, a module calls _I_PUSH. Both modules and drivers can process _ioctl without requiring user programs to first encapsulate them with
I_STR (that is, the ioctl's in the examples would look like
ioctl(fd, DELETE, "AEIOU");). This style of call works only for modules and
drivers that have been converted to use the new facilities that also accept the I_STR
form.

EXAMPLE 2-3 Processing ioctl(2)

/* change all uppercase vowels to lowercase */
struct strioctl ic_cmd = XCASE; /* default timeout (15 sec) */
structi ic_timout = 0;
structi ic_dp = "AEIOU";
structi ic_len = strlen(strioctl.ic_dp);
if (ioctl(fd, I_STR, &strioctl) < 0) {
  perror("ioctl I_STR failed");
  exit(3);
}
/* delete all instances of the chars ‘X’ and ‘X’ */
structi ic_cmd = DELETE;
structi ic_dp = "Xx";
structi ic_len = strlen(strioctl.ic_dp);
if (ioctl(fd, I_STR, &strioctl) < 0) {
  perror("ioctl I_STR failed");
  exit(4);
}

In Example 2-3, the module changes all uppercase vowels to lowercase, and deletes all
instances of either uppercase or lowercase “x.” ioctl(2) requests are issued indirectly,
using I_STR ioctl(2) (see streamio(7I)). The argument to I_STR must be a pointer
to a strioctl structure, which specifies the request to be made to a module or driver.
This structure is described in streamio(7I) and has the format shown in the
following example.

EXAMPLE 2-4 strioctl Structure

struct strioctl {
    int ic_cmd; /* ioctl request */
    int ic_timout; /* ACK/NAK timeout */
    int ic_len; /* length of data argument */
    char *ic_dp; /* ptr to data argument */
};

where:

ic_cmd Identifies the command intended for a module or driver.
ic_vtimeout Specifies the number of seconds an I_STR request should wait for
an acknowledgement before timing out.
ic_len The number of bytes of data to accompany the request.
ic_dp Points to the data. In the example, two separate commands are
sent to the character-conversion module:
The first command sets `ic_Cmd` to the command `XCASE` and sends as data the string “AEIOU.” It converts all uppercase vowels in data passing through the module to lowercase.

The second command sets `ic_Cmd` to the command `DELETE` and sends as data the string “xX.” It deletes all occurrences of the characters “x” and “X” from data passing through the module.

For each command, the value of `icTimeout` is set to zero, which specifies the system default timeout value of 15 seconds. `ic_dp` points to the beginning of the data for each command; `ic_len` is set to the length of the data.

`I_Str` is intercepted by the stream head, which packages it into a message using information contained in the `stroctl` structure, then sends the message downstream. Any module that cannot process the command in `ic_Cmd` passes the message further downstream. The request is processed by the module or driver closest to the stream head that understands the command specified by `ic_Cmd`. `ioctl(2)` blocks up to `icTimeout` seconds, waiting for the target module or driver to respond with either a positive or negative acknowledgement message. If an acknowledgement is not received in `icTimeout` seconds, `ioctl(2)` fails.

**Note** – Only one `ioctl(2)` can be active on a stream at one time, regardless of whether it is issued with `I_Str`. Further requests will block until the active `ioctl(2)` is acknowledged and the system call concludes.

The `stroctl` structure is also used to retrieve the results, if any, of an `I_Str` request. If data is returned by the target module or driver, `ic_dp` must point to a buffer large enough to hold that data, and `ic_len` is set on return to indicate the amount of data returned. The remainder of this example is identical to Example 1–1 in Chapter 1.

**EXAMPLE 2–5 Process Input**

```c
while ((count = read(fd, buf, BUFLEN)) > 0) {
    if (write(fd, buf, count) != count) {
        perror("write failed");
        break;
    }
}
exit(0);
```

Notice that the character-conversion processing was realized with no change to the communications driver.
exit(2) dismantles the stream before terminating the process. The character
conversion module is removed from the stream automatically when it is closed.
Alternatively, remove modules from a stream using I_POP ioctl(2) which is
described in streamio(7I). This call removes the topmost module on the stream, and
enables a user process to alter the configuration of a stream dynamically by popping
modules as needed.

Several other ioctl(2) requests support STREAMS operations, such as determining if
a given module is on a stream, or flushing the data on a stream. streamio(7I)
describes these requests.
STREAMS Application-Level Mechanisms

The previous chapters described the components of a stream from an application level. This chapter explains how those components work together. It shows how the kernel interprets system calls being passed from an application, so that driver and module developers can know what structures are being passed.

- “Message Handling” on page 47
- “Message Queueing and Priorities” on page 49
- “Input and Output Polling” on page 57
- “Stream as a Controlling Terminal” on page 63

Message Handling

Messages are the communication medium between the user application process and the various components of the stream. This chapter describes the path they travel and the changes that occur to them. Chapter 8 covers the underlying mechanics of the kernel.

Modifying Messages

The put(9E) and srv(9E) interfaces process messages as they pass through the queue. Messages are generally processed by type, resulting in a modified message, one or more new messages, or no message at all. The message usually continues in the same direction it was passing through the queue, but can be sent in either direction. A put(9E) procedure can place messages on its queue as they arrive, for later processing by the srv(9E) procedure. For a more detailed explanation of put(9E) and srv(9E), see Chapter 8.

Some kernel operations are explained here to show you how to manipulate the driver or module appropriately.
Message Types

STREAMS messages differ according to their intended purpose and their queueing priority. The contents of certain message types can be transferred between a process and a stream using system calls. Appendix A describes message types in detail.

Control of Stream Head Processing

The stream head responds to a message by altering the processing associated with certain system calls. Six stream head characteristics can be modified. Four characteristics correspond to fields contained in queue (packet sizes — minimum and maximum, and watermarks — high and low). Packet sizes are discussed in this chapter. Watermarks are discussed in “Flush Handling” on page 77 in Chapter 4.

Read Options

The read options (so_readopt) specify two sets of three modes that can be set by the I_SRDOPT ioctl(2) (see streamio(7I)). Byte-stream mode approximately models pipe data transfer. Message nondiscard mode is similar to a TTY in canonical mode.

The first set of bits, RMODEMASK, deals with data and message boundaries, as shown in Table 3–1.

<table>
<thead>
<tr>
<th>RMODEMASK</th>
<th>RMSGN</th>
<th>RMSGD</th>
</tr>
</thead>
<tbody>
<tr>
<td>RNORM</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Byte-stream (RNORM)**

The read(2) call finishes when the byte count is satisfied, the stream head read queue becomes empty, or a zero length message is encountered. A zero length message is put back in the queue. A subsequent read returns 0 bytes.

**Message non-discard (RMSGN)**

The read(2) call finishes when the byte count is satisfied or a message boundary is found, whichever comes first. Any data remaining in the message is put back on the stream head read queue.

**Message discard (RMSGD)**

The read(2) call finishes when the byte count is satisfied or a message boundary is found. Any data remaining in the message is discarded up to the message boundary.

The second set of bits, RPROTMASK, specifies the treatment of protocol messages by the read(2) system call as shown in Table 3–2.
TABLE 3-2 How read(2) Treats Protocol Messages

<table>
<thead>
<tr>
<th>RPROTNAME</th>
<th>RPROTDIS</th>
<th>RPROTDATA</th>
</tr>
</thead>
<tbody>
<tr>
<td>RPROTNORM</td>
<td>RPROTDIS</td>
<td>RPROTDATA</td>
</tr>
</tbody>
</table>

Normal protocol (RPROTNORM) The read(2) call fails with EBADMSG if an M_PROTO or M_PCPROTO message is at the front of the stream head read queue. This is the default operation protocol.

Protocol discard (RPROTDIS) The read(2) call discards any M_PROTO or M_PCPROTO blocks in a message, delivering the M_DATA blocks to the user.

Protocol data (RPROTDAT) The read(2) call converts the M_PROTO and M_PCPROTO message blocks to M_DATA blocks, treating the entire message as data.

Write Options

Send zero (I_SWROPT) The write(2) mode is set using the value of the argument arg. Legal bit settings for arg are: SNDZERO—Send a zero-length message downstream when the write of 0 bytes occurs. To avoid sending a zero-length message when a write of 0 bytes occurs, this bit must not be set in arg. On failure, errno can be set to EINVAL—arg is above the legal value.

Message Queueing and Priorities

Any delay in processing messages causes message queues to grow. Normally, queued messages are handled in a first-in, first-out (FIFO) manner. However, certain conditions can require that associated messages (for instance, an error message) reach their stream destination as rapidly as possible. For this reason messages are assigned priorities using a priority band associated with each message. Ordinary messages have a priority of zero. High-priority messages are high priority by nature of their message type. Their priority band is ignored. By convention, they are not affected by flow control. Figure 3–1 shows how messages are ordered in a queue according to priority.
When a message is queued, it is placed after the messages of the same priority already in the queue (in other words, FIFO within their order of queueing). This affects the flow-control parameters associated with the band of the same priority. Message priorities range from 0 (normal) to 255 (highest). This provides up to 256 bands of message flow within a stream. Expedited data can be implemented with one extra band of flow (priority band 1) of data. This is shown in Figure 3–2.

### Controlling Data Flow and Priorities

The `I_FLUSHBAND`, `I_CKBAND`, `I_GETBAND`, `I_CANPUT`, and `I_ATMARK` ioctl(2)s support multiple bands of data flow. The `I_FLUSHBAND` ioctl(2) allows a user to flush a particular band of messages. “Flush Handling” on page 77 discusses it in more detail.

The `I_CKBAND` ioctl(2) checks if a message of a given priority exists on the stream head read queue. Its interface is:

```c
ioctl (fd, I_CKBAND, pri);
```

The call returns 1 if a message of priority `pri` exists on the stream head read queue and 0 if no message of priority `pri` exists. If an error occurs, -1 is returned. Note that `pri` should be of type int.

The `I_GETBAND` ioctl(2) checks the priority of the first message on the stream head read queue. The interface is:

```c
ioctl (fd, I_GETBAND, prip);
```

The call results in the integer referenced by `prip` being set to the priority band of the message on the front of the stream head read queue.
The \texttt{I\_CANPUT ioctl(2)} checks if a certain band is writable. Its interface is:
\begin{verbatim}
ioctl (fd, I\_CANPUT, pri);
\end{verbatim}

The return value is 0 if the priority band \texttt{pri} is flow controlled, 1 if the band is writable, and -1 on error.

A module or driver can mark a message. This supports the ability of the Transmission Control Protocol (TCP) to indicate to the user the last byte of out-of-band data. Once marked, a message sent to the stream head causes the stream head to remember the message. A user can check whether the message on the front of its stream head read queue is marked with the \texttt{I\_ATMARK ioctl(2)}. If a user is reading data from the stream head, there are multiple messages on the read queue, and one of those messages is marked, the \texttt{read(2)} terminates when it reaches the marked message and returns the data only up to the marked message. Successive reads can return the rest of the data. Chapter 4 discusses this in more detail.

The \texttt{I\_ATMARK ioctl(2)} has the format:
\begin{verbatim}
ioctl (fd, I\_ATMARK, flag);
\end{verbatim}

where \texttt{flag} can be either \texttt{ANYMARK} or \texttt{LASTMARK}. \texttt{ANYMARK} indicates that the user wants to check whether any message is marked. \texttt{LASTMARK} indicates that the user wants to see whether the message is the one and only one marked in the queue. If the test succeeds, 1 is returned. On failure, 0 is returned. If an error occurs, -1 is returned.

**Accessing the Service Provider**

The first routine presented, \texttt{inter_open}, opens the protocol driver device file specified by \texttt{path} and binds the protocol address contained in \texttt{addr} so that it can receive data. On success, the routine returns the file descriptor associated with the open stream; on failure, it returns -1 and sets \texttt{errno} to indicate the appropriate UNIX system error value. Example 3–1 shows the \texttt{inter_open} routine.

**EXAMPLE 3–1 inter_open Routine**

\begin{verbatim}
inter_open (char *path, oflags, addr)
{
    int fd;
    struct bind_req bind_req;
    struct strbuf ctlbuf;
    union primitives rcvbuf;
    struct error_ack *error_ack;
    int flags;
    if ((fd = open(path, oflags)) < 0)
        return(-1);
    /* send bind request msg down stream */
}  
\end{verbatim}
After opening the protocol driver, `inter_open` packages a bind request message to send downstream. `putmsg` is called to send the request to the service provider. The bind request message contains a control part that holds a `bind_req` structure, but it has no data part. `ctlbuf` is a structure of type `strbuf`, and it is initialized with the primitive type and address. Notice that the `maxlen` field of `ctlbuf` is not set before calling `putmsg`. That is because `putmsg` ignores this field. The `dataptr` argument to `putmsg` is set to `NULL` to indicate that the message contains no data part. The `flags` argument is 0, which specifies that the message is not a high-priority message.

After `inter_open` sends the bind request, it must wait for an acknowledgement from the service provider, as Example 3–2 shows.

**EXAMPLE 3–2 Service Provider**

```c
/* wait for ack of request */

ctlbuf.maxlen = sizeof(union primitives);
ctlbuf.len = 0;
ctlbuf.buf = (char *)&rcvbuf;
flags = RS_HIPRI;
if (getmsg(fd, &ctlbuf, NULL, &flags) < 0) {
    close(fd);
    return(-1);
}

/* did we get enough to determine type? */
if (ctlbuf.len < sizeof(long)) {
    close(fd);
    errno = EPROTO;
    return(-1);
}

/* switch on type (first long in rcvbuf) */
switch(rcvbuf.type) {
    default:
        close(fd);
        errno = EPROTO;
        return(-1);
}
```
EXAMPLE 3-2 Service Provider  (Continued)

```c
return(-1);

case OK_ACK:
    return(fd);

case ERROR_ACK:
    if (ctlbuf.len < sizeof(struct error_ack)) {
        close(fd);
        errno = EPROTO;
        return(-1);
    }
    error_ack = (struct error_ack *)&rcvbuf;
    close(fd);
    errno = error_ack->UNIX_error;
    return(-1);
}
```

getmsg is called to retrieve the acknowledgement of the bind request. The acknowledgement message consists of a control part that contains either an OK_ACK or an error_ack structure, and no data part.

The acknowledgement primitives are defined as high-priority messages. Messages are queued in a first-in, first-out (FIFO) manner within their priority at the stream head. The STREAMS mechanism allows only one high-priority message per stream at the stream head at one time. Any additional high-priority messages are discarded on reaching the stream head. (There can be only one high-priority message present on the stream head read queue at any time.) High-priority messages are particularly suitable for acknowledging service requests when the acknowledgement should be placed ahead of any other messages at the stream head.

Before calling getmsg, this routine must initialize the strbuf structure for the control part. buf should point to a buffer large enough to hold the expected control part, and maxlen must be set to indicate the maximum number of bytes this buffer can hold.

Because neither acknowledgement primitive contains a data part, the dataptr argument to getmsg is set to NULL. The flagsp argument points to an integer containing the value RS_HIPRI. This flag indicates that getmsg should wait for a STREAMS high-priority message before returning. This catches the acknowledgement primitives that are priority messages. Otherwise, if the flag is zero, the first message is taken. With RS_HIPRI set, even if a normal message is available, getmsg blocks until a high-priority message arrives.
On return from getmsg, check the len field to ensure that the control part of the retrieved message is an appropriate size. The example then checks the primitive type and takes appropriate actions. An OK_ACK indicates a successful bind operation, and inter_open returns the file descriptor of the open stream. An error_ack indicates a bind failure, and errno is set to identify the problem with the request.

Closing the Service Provider
The next routine in the service interface library example is inter_close, which closes the stream to the service provider.

```c
inter_close(fd)
{
    close(fd);
}
```

The routine closes the given file descriptor. This causes the protocol driver to free any resources associated with that stream. For example, the driver can unbind the protocol address that had previously been bound to that stream, thereby freeing that address for use by another service user.

Sending Data to the Service Provider
The third routine, inter_snd, passes data to the service provider for transmission to the user at the address specified in addr. The data to be transmitted is contained in the buffer pointed to by buf and contains len bytes. On successful completion, this routine returns the number of bytes of data passed to the service provider; on failure, it returns −1.

**EXAMPLE 3-3 inter_snd**

```c
inter_snd(int fd, char *buf, int len, long *addr)
{
    struct strbuf ctlbuf;
    struct strbuf databuf;
    struct unitdata_req unitdata_req;

    unitdata_req.PRIM_type = UNITDATA_REQ;
    unitdata_req.DEST_addr = addr;

    ctlbuf.len = sizeof(struct unitdata_req);
    ctlbuf.buf = (char *)&unitdata_req;
    databuf.len = len;
    databuf.buf = buf;

    if (putmsg(fd, &ctlbuf, &databuf, 0) < 0)
        return(-1);
}
```
EXAMPLE 3–3 inter_snd  (Continued)

    return(len);
}

In this example, the data request primitive is packaged with both a control part and a data part. The control part contains a unitdata_req structure that identifies the primitive type and the destination address of the data. The data to be transmitted is placed in the data part of the request message.

Unlike the bind request, the data request primitive requires no acknowledgement from the service provider. In the example, this choice was made to minimize the overhead during data transfer. If the putmsg call succeeds, this routine returns the number of bytes passed to the service provider.

Receiving Data

The final routine in Example 3–4, inter_rcv, retrieves the next available data. buf points to a buffer where the data should be stored, len indicates the size of that buffer, and addr points to a long integer where the source address of the data is placed. On successful completion, inter_rcv returns the number of bytes of retrieved data; on failure, it returns -1 and an appropriate UNIX system error value.

EXAMPLE 3–4 Receiving Data

int inter_rcv (int fd, char *buf, int len, long *addr, int *errorp) {
    struct strbuf ctlbuf;
    struct strbuf databuf;
    struct unitdata_ind unitdata_ind;
    int retval;
    int flagsp;

    ctlbuf.maxlen = sizeof(struct unitdata_ind);
    ctlbuf.len = 0;
    ctlbuf.buf = (char *)&unitdata_ind;
    databuf.maxlen = len;
    databuf.len = 0;
    databuf.buf = buf;
    flagsp = 0;

    if((retval=getmsg(fd,&ctlbuf,&databuf,&flagsp))<0) {
        *errorp = EIO;
        return(-1);
    }
    if (retval) {
        *errorp = EIO;
        return(-1)
EXAMPLE 3-4 Receiving Data

(Continued)

```c
}
if (unitdata_ind.PRIM_type != UNITDATA_IND) {
    *errorp = EPROTO;
    return(-1);
}
*addr = unitdata_ind.SRC_addr;
return(databuf.len);
```

getmsg is called to retrieve the data indication primitive, where that primitive contains both a control and data part. The control part consists of a unitdata_ind structure that identifies the primitive type and the source address of the data sender. The data part contains the data itself. In ctlbuf, buf points to a buffer containing the control information, and maxlen indicates the maximum size of the buffer. Similar initialization is done for databuf.

The integer pointed to by flagsp in the getmsg call is set to zero, indicating that the next message should be retrieved from the stream head regardless of its priority. Data arrives in normal priority messages. If there is no message at the stream head, getmsg blocks until a message arrives.

The user’s control and data buffers should be large enough to hold any incoming data. If both buffers are large enough, getmsg processes the data indication and returns 0, indicating that a full message was retrieved successfully. However, if neither buffer is large enough, getmsg only returns the part of the message that fits into each user buffer. The remainder of the message is saved for subsequent retrieval (in message non-discard mode), and a positive, nonzero value is returned to the user. A return value of MORECTL indicates that more control information is waiting for retrieval. A return value of MOREDATA indicates that more data is waiting for retrieval. A return value of (MORECTL | MOREDATA) indicates that data from both parts of the message remain. In the example, if the user buffers are not large enough (that is, getmsg returns a positive, nonzero value), the function sets errno to EIO and fails.

The type of the primitive returned by getmsg is checked to make sure it is a data indication (UNITDATA_IND in the example). The source address is then set and the number of bytes of data is returned.

The example presented is a simplified service interface. It shows typical uses of putmsg(2) and getmsg(2). The state transition rules for the interface are not presented and this example does not handle expedited data.
Input and Output Polling

This section describes the synchronous polling mechanism and asynchronous event notification in STREAMS.

User processes can efficiently monitor and control multiple streams with two system calls: `poll(2)` and the `I_SETSIG ioctl(2)` command. These calls enable a user process to detect events that occur at the stream head on one or more streams, including receipt of data or messages on the read queue and cessation of flow control on the write queue. Note that `poll(2)` is usable on any character device file descriptor, not just STREAMS.

To monitor streams with `poll(2)`, a user process issues that system call and specifies the streams and other files to be monitored, the events to check, and the amount of time to wait for an event. `poll(2)` blocks the process until the time expires or until an event occurs. If an event occurs, it returns the type of event and the descriptor on which the event occurred.

Instead of waiting for an event to occur, a user process can monitor one or more streams while processing other data. To do so, issue the `I_SETSIG ioctl(2)`, specifying a stream and events (as with `poll(2)`). This `ioctl(2)` does not block the process and force the user process to wait for the event, but returns immediately and issues a signal when an event occurs. The process calls one of `sigaction(2)`, `signal(3C)`, or `sigset(3C)` to catch the resulting `SIGPOLL` signal.

If any selected event occurs on any of the selected streams, STREAMS sends `SIGPOLL` to all associated requesting processes. The processes have no information on what event occurred on what stream. A signaled process can get more information by calling `poll(2)`.

Synchronous Input and Output

`poll(2)` provides a mechanism to identify the streams over which a user can send or receive data. For each stream of interest, users can specify one or more events about which they should be notified. The types of events that can be polled are `POLLIN`, `POLLRDNORM`, `POLLRDBAND`, `POLLPRI`, `POLLOUT`, `POLLWRNORM`, `POLLWRBAND`, which are detailed in Table 3–3.
TABLE 3-3 Events That Can Be Polled

<table>
<thead>
<tr>
<th>Event</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>POLLIN</td>
<td>A message other than high-priority data can be read without blocking. This event is maintained for compatibility with the previous releases of the Solaris operating environment.</td>
</tr>
<tr>
<td>POLLRDNORM</td>
<td>A normal (nonpriority) message is at the front of the stream head read queue.</td>
</tr>
<tr>
<td>POLLRDBAND</td>
<td>A priority message (band &gt; 0) is at the front of the stream head queue.</td>
</tr>
<tr>
<td>POLLPRI</td>
<td>A high-priority message is at the front of the stream head read queue.</td>
</tr>
<tr>
<td>POLLOUT</td>
<td>The normal priority band of the queue is writable (not flow controlled).</td>
</tr>
<tr>
<td>POLLWRNORM</td>
<td>The same as POLLOUT.</td>
</tr>
<tr>
<td>POLLWRBAND</td>
<td>A priority band greater than 0 of a queue downstream.</td>
</tr>
</tbody>
</table>

Some of the events may not be applicable to all file types. For example, the POLLPRI event usually is not generated when polling a non-STREAMS character device. POLLIN, POLLRDNORM, POLLRDBAND, and POLLPRI are set even if the message is of zero length.

poll(2) checks each file descriptor for the requested events and, on return, indicates which events have occurred for each file descriptor. If no event has occurred on any polled file descriptor, poll(2) blocks until a requested event or timeout occurs.

poll(2) takes the following arguments:
- An array of file descriptors and events to be polled.
- The number of file descriptors to be polled.
- The number of milliseconds poll should wait for an event if no events are pending (-1 specifies wait forever).

Example 3-5 shows the use of poll(2). Two separate minor devices of the communications driver are opened, thereby establishing two separate streams to the driver. The pollfd entry is initialized for each device. Each stream is polled for incoming data. If data arrive on either stream, data is read and then written back to the other stream.

EXAMPLE 3-5 Polling

```c
#include <sys/stropts.h>
#include <fcntl.h>
#include <poll.h>

#define NPOLL 2 /* number of file descriptors to poll */
int main()
{
    struct pollfd pollfds[NPOLL];
}   
```
EXAMPLE 3-5 Polling  (Continued)

```c
char buf[1024];
int count, i;

if ((pollfds[0].fd = open("/dev/ttya", O_RDWR|O_NONBLOCK)) < 0) {
    perror("open failed for /dev/ttya");
    exit(1);
}
if ((pollfds[1].fd = open("/dev/ttyb", O_RDWR|O_NONBLOCK)) < 0) {
    perror("open failed for /dev/ttyb");
    exit(2);
}
```

The variable `pollfds` is declared as an array of the `pollfd` structure, defined in `<poll.h>`, and has the format:

```c
struct pollfd {
    int fd; /* file descriptor */
    short events; /* requested events */
    short revents; /* returned events */
}
```

For each entry in the array, `fd` specifies the file descriptor to be polled and `events` is a bitmask that contains the bitwise inclusive OR of events to be polled on that file descriptor. On return, the `revents` bitmask indicates which of the requested events has occurred.

The example continues to process incoming data, as shown below:

```c
pollfds[0].events = POLLIN; /* set events to poll */
pollfds[1].events = POLLIN; /* for incoming data */
while (1) {
    /* poll and use -1 timeout (infinite) */
    if (poll(pollfds, NPOLL, -1) < 0) {
        perror("poll failed");
        exit(3);
    }
    for (i = 0; i < NPOLL; i++) {
        switch (pollfds[i].revents) {
        default: /* default error case */
            fprintf(stderr,"error event
");
            exit(4);
        case 0: /* no events */
            break;
        case POLLIN:
            /*echo incoming data on "other" Stream*/
            while ((count = read(pollfds[i].fd, buf, 1024)) > 0) {
                /*
                    * write loses data if flow control
                    * prevents the transmit at this time
                */
            }
        }
    }
}
```

Chapter 3 • STREAMS Application-Level Mechanisms  59
if (write(pollfds[(i+1) % NPOLL].fd buf, count) != count)
    fprintf(stderr, "writer lost data");
break;
}
}

The user specifies the polled events by setting the events field of the pollfd structure to POLLIN. This request tells poll(2) to notify the user of any incoming data on each stream. The bulk of the example is an infinite loop, where each iteration polls both streams for incoming data.

The second argument of poll(2) specifies the number of entries in the pollfds array (2 in this example). The third argument indicates the number of milliseconds poll(2) waits for an event if none has occurred. On a system where millisecond accuracy is not available, timeout is rounded up to the nearest value available on that system. If the value of timeout is 0, poll(2) returns immediately. Here, timeout is set to -1, specifying that poll(2) blocks until a requested event occurs or until the call is interrupted.

If poll(2) succeeds, the program checks each entry in the pollfds array. If revents is set to 0, no event has occurred on that file descriptor. If revents is set to POLLIN, incoming data is available, so all available data is read from the polled minor device and written to the other minor device.

If revents is set to a value other than 0 or POLLIN, an error event must have occurred on that stream because POLLIN was the only requested event. Table 3–4 shows poll error events.

<table>
<thead>
<tr>
<th>Error</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>POLLERR</td>
<td>A fatal error has occurred in a module or driver on the stream associated</td>
</tr>
<tr>
<td></td>
<td>with the specified file descriptor. Further system calls fail.</td>
</tr>
<tr>
<td>POLLHUP</td>
<td>A hangup condition exists on the stream associated with the specified file</td>
</tr>
<tr>
<td></td>
<td>descriptor. This event and POLLOUT are mutually exclusive; a stream</td>
</tr>
<tr>
<td></td>
<td>is not writable if a hangup has occurred.</td>
</tr>
<tr>
<td>POLLNVAL</td>
<td>The specified file descriptor is not associated with an open stream.</td>
</tr>
</tbody>
</table>

These events cannot be polled for by the user but are reported in revents when they occur. They are only valid in the revents bitmask.

The example attempts to process incoming data as quickly as possible. However, when writing data to a stream, write(2) can block if the stream is exerting flow control. To prevent the process from blocking, the minor devices of the communications driver are opened with the O_NDELAY (or O_NONBLOCK) flag set, see note. write(2) cannot send
all the data if flow control is on and \texttt{O\_NDELAY} (\texttt{O\_NONBLOCK}) is set. This can happen if the communications driver processes characters slower than the user transmits. If the stream becomes full, the number of bytes \texttt{write(2)} sends is less than the requested count. For simplicity, the example ignores the data if the stream becomes full, and a warning is printed to \texttt{stderr}.

\begin{quote}
\textbf{Note} – To conform with the IEEE operating system interface standard, POSIX, new applications should use the \texttt{O\_NONBLOCK} flag. Its behavior is the same as that of \texttt{O\_NDELAY} unless otherwise noted.
\end{quote}

This program continues until an error occurs on a stream, or until the process is interrupted.

\section*{Asynchronous Input and Output}
\texttt{poll(2)} enables a user to monitor multiple streams synchronously. \texttt{poll(2)} normally blocks until an event occurs on any of the polled file descriptors. In some applications, however, you want to process incoming data asynchronously. For example, an application can attempt to do some local processing and be interrupted when a pending event occurs. Some time-critical applications must not block, and must have immediate success or failure indication.

The \texttt{I\_SETSIG ioctl(2)} (see \texttt{streamio(7I)}) is used to request that a \texttt{SIGPOLL} signal be sent to a user process when a specific event occurs. Table 3-5 lists events for \texttt{I\_SETSIG}. These are similar to those described for \texttt{poll(2)}.

\begin{table}[h]
\centering
\caption{I\_SETSIG ioctl(2) Events}
\begin{tabular}{|ll|}
\hline
\textbf{Event} & \textbf{Description} \\
\hline
\texttt{S\_INPUT} & A message other than a high-priority message has arrived on a stream head read queue. This event is maintained for compatibility with the previous releases of the Solaris operating environment. \\
\texttt{S\_RDNORM} & A normal (nonpriority) message has arrived on the stream head read queue. \\
\texttt{S\_RDBAND} & A priority message (\texttt{band} > 0) has arrived on the stream head read queue. \\
\texttt{S\_HIPRI} & A high-priority message has arrived on the stream head read queue. \\
\texttt{S\_OUTPUT} & A write queue for normal data (\texttt{priority band} = 0) is no longer full (not flow controlled). This notifies a user that there is space on the queue for sending or writing normal data downstream. \\
\hline
\end{tabular}
\end{table}
### TABLE 3–5 `I_SETSIGioctl(2)` Events (Continued)

<table>
<thead>
<tr>
<th>Event</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>S_WRNORM</code></td>
<td>The same as <code>S_OUTPUT</code>.</td>
</tr>
<tr>
<td><code>S_WRBAND</code></td>
<td>A priority band greater than 0 of a queue downstream exists and is</td>
</tr>
<tr>
<td></td>
<td>writable. This notifies a user that there is space on the queue for sending</td>
</tr>
<tr>
<td></td>
<td>or writing priority data downstream.</td>
</tr>
<tr>
<td><code>S_MSG</code></td>
<td>A signal message sent from a module or driver has arrived on the stream</td>
</tr>
<tr>
<td></td>
<td>head read queue.</td>
</tr>
<tr>
<td><code>S_ERROR</code></td>
<td>An error message reaches the stream head.</td>
</tr>
<tr>
<td><code>S_HANGUP</code></td>
<td>A hangup message sent from a module or driver has arrived at the stream</td>
</tr>
<tr>
<td></td>
<td>head.</td>
</tr>
<tr>
<td><code>S_BANDURG</code></td>
<td>When used with <code>S_RDBAND</code>, <code>SIGURG</code> is generated instead of <code>SIGPOLL</code></td>
</tr>
<tr>
<td></td>
<td>when a priority message reaches the front of the stream head read queue.</td>
</tr>
</tbody>
</table>

`S_INPUT`, `S_RDNORM`, `S_RDBAND`, and `S_HIPRI` are set even if the message is of zero length. A user process can handle only high-priority messages by setting the `arg` to `S_HIPRI`.

**signal Message**

STREAMS enables modules and drivers to send a signal to user processes through a special signal message. If the signal specified by the module or driver is not `SIGPOLL` (see `signal(3C)`), the signal is sent to the process group associated with the stream. If the signal is `SIGPOLL`, the signal is only sent to processes that have registered for the signal by using the `I_SETSIGioctl(2)`.

**Extended Signals**

So that a process can obtain the band and event associated with `SIGPOLL` more readily, STREAMS supports extended signals. For the given events, a special code is defined in `<sys/siginfo.h>` that describes the reason `SIGPOLL` was generated. Table 3–6 describes the data available in the `siginfo_t` structure passed to the signal handler.
Stream as a Controlling Terminal

The controlling terminal can receive signals and send signals. If a foreground process group has the stream as a controlling terminal stream, drivers and modules can use _M_SIG messages to send signals to processes.

Job Control

An overview of Job Control is provided here because it interacts with the STREAMS-based terminal subsystem. You can obtain more information on Job Control from the following manual pages: exit(2), getpgid(2), getpgrp(2), getsid(2), kill(2), setpgid(2), setpgrp(2), setsid(2), sigaction(2), signal(3C), sigsend(2), termios(3C), waitid(2), waitpid(2), and termio(7I).

Job Control breaks a login session into smaller units called jobs. Each job consists of one or more related and cooperating processes. The foreground job, is given complete access to the controlling terminal. The other background jobs are denied read access to the controlling terminal and given conditional write and _ioctl(2) access to it. The user can stop the executing job and resume the stopped job either in the foreground or in the background.

Under Job Control, background jobs do not receive events generated by the terminal and are not informed with a hangup indication when the controlling process exits. Background jobs that linger after the login session has been dissolved are prevented from further access to the controlling terminal, and do not interfere with the creation of new login sessions.

The following list defines terms associated with Job Control:

</tr>
<tr>
<td>Process group lifetime</td>
<td>A time period that begins when a process group is created by its process group leader and ends when the last process that is a member in the group leaves the group.</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Process ID</td>
<td>A positive integer that uniquely identifies each process in the system. A process ID cannot be reused by the system until the process lifetime, process group lifetime, and session lifetime end for any process ID, process group ID, and session ID sharing that value.</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
Process lifetime  A period that begins when the process is forked and ends after the process exits, when its termination has been acknowledged by its parent process.

Session  Each process group is a member of a session that is identified by a session ID.

Session ID  A positive integer that uniquely identifies each session in the system. It is the same as the process ID of its session leader (POSIX).

Session leader  A process whose session ID is the same as its process and process group ID.

Session lifetime  A period that begins when the session is created by its session leader and ends when the lifetime of the last process group that is a member of the session ends.

The following signals manage Job Control: (see also signal(3C)) :

SIGCONT  Sent to a stopped process to continue it.

SIGSTOP  Sent to a process to stop it. This signal cannot be caught or ignored.

SIGTSTP  Sent to a process to stop it. It is typically used when a user requests to stop the foreground process.

SIGTTIN  Sent to a background process to stop it when it attempts to read from the controlling terminal.

SIGTTOU  Sent to a background process to stop it when a user attempts to write to or modify the controlling terminal.

A session can be allocated a controlling terminal. For every allocated controlling terminal, Job Control elevates one process group in the controlling process’s session to the status of foreground process group. The remaining process groups in the controlling process’s session are background process groups. A controlling terminal gives a user the ability to control execution of jobs within the session. Controlling terminals are critical in Job Control. A user can cause the foreground job to stop by typing a predefined key on the controlling terminal. A user can inhibit access to the controlling terminal by background jobs. Background jobs that attempt to access a terminal that has been so restricted is sent a signal that typically causes the job to stop. (See “Accessing the Controlling Terminal” on page 67.)

Job Control requires support from a line-discipline module on the controlling terminal’s stream. The TCSETA, TCSETAW, and TCSETAF commands of termio(7I) allow a process to set the following line discipline values relevant to Job Control:

SUSP character  A user-defined character that, when typed, causes the line discipline module to request that the stream head send a SIGTSTP signal to the foreground process, which by default stops the
members of that group. If the value of SUSP is zero, the SIGTSTP signal is not sent, and the SUSP character is disabled.

**TOSTOP flag**

If TOSTOP is set, background processes are inhibited from writing to their controlling terminal. A line discipline module must record the SUSP suspend character and notify the stream head when the user has typed it, and record the state of the TOSTOP bit and notify the stream head when the user has changed it.

### Allocation and Deallocation of Streams

A stream is allocated as a controlling terminal for a session if it:

- Is acting as a terminal.
- Is not already allocated as a controlling terminal.
- Is opened by a session leader that does not have a controlling terminal.

Controlling terminals are allocated with `open(2)`. The device must inform the stream head that it is acting as a terminal.

### Hungup Streams

When a stream head receives a hangup message from a device or module, it is marked as hung up. A stream that is marked as hung up is allowed to be reopened by its session leader if it is allocated as a controlling terminal, and by any process if it is not allocated as a controlling terminal. This way, the hangup error can be cleared without forcing all file descriptors to be closed first.

If the reopen is successful, the hangup condition is cleared.

### Hangup Signals

When the SIGHUP signal is generated by a hangup message instead of a signal message, the signal is sent to the controlling process instead of the foreground process group. The allocation and deallocation of controlling terminals to a session is the responsibility of that process group.
Accessing the Controlling Terminal

If a process attempts to access its controlling terminal after it has been deallocated, access is denied. If the process is not holding or ignoring SIGHUP, it is sent a SIGHUP signal. Otherwise, the access fails with an EIO error.

Members of background process groups have limited access to their controlling terminals:

- If the background process is ignoring or holding the SIGTTIN signal or is a member of an orphaned process group, an attempt to read from the controlling terminal fails with an EIO error. Otherwise, the process is sent a SIGTTIN signal, which by default stops the process.
- If the process is attempting to write to the terminal and if the terminal’s TOSTOP flag is clear, the process is allowed access.
- If the terminal’s TOSTOP flag is set and a background process is attempting to write to the terminal, the write succeeds if the process is ignoring or holding SIGTTOU. Otherwise, the process stops except when it is a member of an orphaned process group, in which case it is denied access to the terminal and it is returned an EIO error.

If a background process is attempting to perform a destructive ioctl(2) (one that modifies terminal parameters), the ioctl(2) call succeeds if the process is ignoring or holding SIGTTOU. Otherwise, the process stops except when the process is a member of the orphaned process group. In that case the access to the terminal is denied and an EIO error is returned.
Application Access to the STREAMS Driver and Module Interfaces

This chapter describes getting messages into and out of the driver from an application level. It shows the relationship between messages overall and the specific ioctl(2) calls that pertain to application-level operations.

- “System Calls Used” on page 69
- “Module and Driver ioctl Calls” on page 70
- “Flush Handling” on page 77

System Calls Used

Table 4-1 summarizes the system calls commonly used in controlling and transferring data and messages within a stream.

TABLE 4–1 System Calls Used

Module and Driver ioctl Calls

STREAMS is a special type of character device driver that is different from the historical character input/output (I/O) mechanism. In this section, the phrases character I/O mechanism and I/O mechanism refer only to that part of the mechanism that existed before STREAMS.

The character I/O mechanism handles all ioctl(2) calls transparently. That is, the kernel expects all ioctl(2) to be handled by the device driver associated with the character special file on which the call is sent. All ioctl(2) calls are sent to the driver, which is expected to perform all validation and processing other than file descriptor validity checking. The operation of any specific ioctl(2) is dependent on the device driver. If the driver requires data to be transferred in from user space, it will use the kernel ddi_copyin function. It may also use ddi_copyout to transfer any data results to user space.

With STREAMS, there are a number of differences from the character I/O mechanism that impart ioctl(2) processing.

First, there is a set of generic STREAMS ioctl(2) command values recognized and processed by the stream head. This is described in streamio(7I). The operation of the generic STREAMS ioctl(2) is generally independent of the presence of any specific module or driver on the stream.

The second difference is the absence of user context in a module and driver when the information associated with the ioctl(2) is received. This prevents use of ddi_copyin(9F) or ddi_copyout(9F) by the module. This also prevents the module and driver from associating any kernel data with the currently running process. (By the time the module or driver receives the ioctl(2), the process generating it probably will no longer be running.)
A third difference is that for the character I/O mechanism, all ioctl(2) are handled by the single driver associated with the file. In STREAMS, there can be multiple modules on a stream and each one can have its own set of ioctl(2) calls. That is, the ioctl(2) that can be used on a stream can change as modules are pushed and popped.

STREAMS provides the capability for user processes to perform control functions on specific modules and drivers in a stream with ioctl(2) calls. Most streamio(7I) ioctl(2) commands go no further than the stream head. They are fully processed there and no related messages are sent downstream. However, certain commands and all unrecognized commands cause the stream head to create an M_IOCTL message, which includes the ioctl(2) arguments, and send the message downstream to be received and processed by a specific module or driver. The M_IOCTL message is the initial message type that carries ioctl(2) information to modules. Other message types are used to complete the ioctl(2) processing in the stream. In general, each module must uniquely recognize and act on specific M_IOCTL messages.

STREAMS ioctl(2) handling is equivalent to the transparent processing of the character I/O mechanism. STREAMS modules and drivers can process ioctl(2) generated by applications that are implemented for a non-STREAMS environment.

General ioctl Processing

STREAMS blocks a user process that issues an ioctl(2) and causes the stream head to generate an M_IOCTL message. The process remains blocked until one of the following occurs:

- A module or a driver responds with an M_IOCACK (ack, positive acknowledgement) message or an M_IOCNAK (nak, negative acknowledgement) message.
- No message is received and the request times out.
- The ioctl(2) is interrupted by the user process.
- An error condition occurs. For the I_STR ioctl(2), the timeout period can be a user-specified interval or a default. For the other ioctl(2) calls, the default value (infinite) is used.

For an I_STR, the STREAMS module or driver that generates a positive acknowledgement message can also return data to the process in the message. An alternate means to return data is provided with transparent ioctl(2). If the stream head does not receive a positive or negative acknowledgement message in the specified time, the ioctl(2) call fails.

A module that receives an unrecognized M_IOCTL message must pass it on unchanged. A driver that receives an unrecognized M_IOCTL must produce a negative acknowledgement.
The two STREAMS ioctl(2) mechanisms, I_STR and transparent, are described next. (Here, I_STR means the streamio(7I) I_STR command and implies the related STREAMS processing unless noted otherwise.) I_STR has a restricted format and restricted addressing for transferring ioctl(2)-related data between user and kernel space. It requires only a single pair of messages to complete ioctl(2) processing. The transparent mechanism is more general and has almost no restrictions on ioctl(2) data format and addressing. The transparent mechanism generally requires that multiple pairs of messages be exchanged between the stream head and module to complete the processing.

This is a rather simplistic view. Nothing prevents a given ioctl(2) from being issued either directly (transparent) or by means of I_STR. Furthermore, ioctl(2) calls issued through I_STR potentially can require further processing of the form typically associated with transparent ioctl(2).

**I_STR ioctl Processing**

The I_STR ioctl(2) provides a capability for user applications to perform module and driver control functions on STREAMS files. I_STR allows an application to specify the ioctl(2) timeout. It encourages that all user ioctl(2) data (to be received by the destination module) be placed in a single block that is pointed to from the user strioctl structure. The module can also return data to this block.

**Transparent ioctl Processing**

The transparent STREAMS ioctl(2) mechanism enables application programs to perform module and driver control functions with ioctl(2) calls other than I_STR. It transparently supports applications developed prior to the introduction of STREAMS. It alleviates the need to recode and recompile the user-level software to run over STREAMS files. More importantly, applications do not have to package their ioctl(2) requests into the form demanded by I_STR.

The mechanism extends the data transfer capability for STREAMS ioctl(2) calls beyond those provided in the I_STR form. Modules and drivers can transfer data between their kernel space and user space in any ioctl(2) that has a value of the command argument not defined in streamio(7I). These ioctl(2) are known as transparent ioctl(2) to differentiate them from the I_STR form. Existing applications that use non-STREAMS character devices require transparent processing for ioctl(2) if the device driver is converted to STREAMS. The ioctl(2) data can be in any format mutually understood by the user application and module.

The transparent mechanism also supports STREAMS applications that send ioctl(2) data to a driver or module in a single call, where the data may not be in a form readily embedded in a single user block. For example, the data may be contained in nested structures and different user space buffers.
**I_LIST ioctl**

The I_LIST ioctl(2) supports the strconf(1) and strchg(1) commands that are used to query or change the configuration of a stream. Only the root user or an owner of a STREAMS device can alter the configuration of that stream.

strchg(1) does the following:
- Pushes one or more modules on the stream.
- Pops the topmost module off the stream.
- Pops all the modules off the stream.
- Pops all modules up to but not including a specified module.

strconf(1) does the following:
- Checks if the specified module is present on the stream.
- Prints the topmost module of the stream.
- Prints a list of all modules and the topmost driver on the stream. If the stream contains a multiplexing driver, the strchg and strconf commands will not recognize any modules below that driver.

The I_LIST ioctl(2), illustrated in Example 4–1, performs two functions. When the third argument of the ioctl(2) call is NULL,

```c
if ((mods = ioctl(s, I_LIST, 0)) < 0) {
    the return value of the call indicates the number of modules, plus the driver, present on the stream. For example, if there are two modules above the driver, 3 is returned. On failure, errno may be set to a value specified in streamio(7I). The second function of the I_LIST ioctl(2) is to copy the module names found on the stream to the user-supplied buffer. The address of the buffer in user space and the size of the buffer are passed to the ioctl(2) through a structure str_mlist that is defined as:

```c
struct str_mlist {
    char l_name[FMNAMESZ+1]; /* space for holding a module name*/
}

```c
struct str_list {
    int sl_nmods; /* #of modules for which space is allocated */
    struct str_mlist *sl_modlist; /*addr of buf for names*/
}
```

Here sl_nmods is the number of modules in the sl_modlist array that the user has allocated. Each element in the array must be at least FMNAMESZ+1 bytes long. The array is FMNAMESZ+1 so the extra byte can hold the NULL character at the end of the string. FMNAMESZ is defined by <sys/conf.h>.

The amount of space to allocate for module names is indicated by the number of modules in the STREAM. This is not completely reliable because another module might be pushed onto the stream after the application invokes the I_LIST ioctl(2) with the NULL argument and before it invokes the I_LIST ioctl(2) with the structure argument.
The `I_LIST` call with `arg` pointing to the `str_list` structure returns the number of entries that have been filled into the `sl_modlist` array (the number represents the number of modules including the driver). If there is not enough space in the `sl_modlist` array or `sl_nmods` is less than 1, the `I_LIST` call fails and `errno` is set to `EINVAL`. If `arg` or the `sl_modlist` array points outside the allocated address space, `EFAULT` is returned.

**EXAMPLE 4-1 I_LIST ioctl**

```c
#include <stdio.h>
#include <string.h>
#include <stropts.h>
#include <sys/types.h>
#include <sys/socket.h>
#include <sys/socket.h>

main(int argc, const char **argv)
{
    int s, i;
    unsigned int mods;
    struct str_list mod_list; struct str_mlist *mlist;
    /* Get a socket... */
    if ((s = socket(AF_INET, SOCK_STREAM, 0)) <= 0) {
        perror("socket: ");
        exit(1);
    }

    /* Determine the number of modules in the stream */
    if ((mods = ioctl(s, I_LIST, 0)) < 0) {
        perror("I_LIST ioctl");
    }
    if (mods == 0) {
        printf("No modules\n");
        exit(1);
    } else {
        printf("%d modules\n", mods);
    }

    /* Allocate memory for all of the module names */
    mlist = (struct str_mlist *)
    calloc(mods, sizeof (struct str_mlist));
    if (mlist == 0) {
        perror("calloc failure");
        exit(1);
    }
    mod_list.sl_modlist = mlist;
    mod_list.sl_nmods = mods;
    /* Do the ioctl and get the module names... */
    if (ioctl(s, I_LIST, &mod_list) < 0) {
        exit(1);
    }
}
```
EXAMPLE 4-1 I_LIST ioctl  (Continued)

/* Print out the name of the modules... */
for (i = 0; i < mods; i++) {
    printf("s: %s\n", mod_list.sl_modlist[i].l_name);
}
/* Free the calloc’d structures... */
free(mlist);
return(0);
}

Other ioctl Commands

streamio(7I) details the ioctl(2) commands shown in Table 4-2.

TABLE 4-2 Other ioctl Commands

<table>
<thead>
<tr>
<th>ioctl Calls</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>I_ANCHOR</td>
<td>Prevents the removal of a STREAMS module with an I_POP call. Any process can place an anchor on a stream, but once placed, an anchor can only be removed by a privileged process.</td>
</tr>
<tr>
<td>I.Look</td>
<td>Retrieves the name of the module just below the stream head</td>
</tr>
<tr>
<td>I_FLUSH</td>
<td>Flushes all input or output queues</td>
</tr>
<tr>
<td>I_FLUSHBAND</td>
<td>Flushes a band of messages</td>
</tr>
<tr>
<td>I.Find</td>
<td>Compares the names of all modules present in the stream to a specific name</td>
</tr>
<tr>
<td>I.Peek</td>
<td>Enables the user to look at information in the first message on the stream head read queue without taking the message off the queue</td>
</tr>
<tr>
<td>I_SRDOPT</td>
<td>Sets the read mode using a series of flag options in the argument</td>
</tr>
<tr>
<td>I_GRDOPT</td>
<td>Indicates the read mode in an int</td>
</tr>
<tr>
<td>I_NREAD</td>
<td>Counts the data bytes in data blocks in the first message on the stream head read queue</td>
</tr>
<tr>
<td>I_FDINSERT</td>
<td>Creates a message from a user buffer, adds information about another stream, and sends the message downstream</td>
</tr>
<tr>
<td>I_SWROPT</td>
<td>Sets the write mode using the value of the argument</td>
</tr>
<tr>
<td>I_GWROPT</td>
<td>Returns the current write mode setting</td>
</tr>
<tr>
<td>I_SENDFD</td>
<td>Requests that the stream send a message with file pointer to the stream head at the other end of a STREAMS pipe</td>
</tr>
</tbody>
</table>
TABLE 4–2 Other ioctl Commands (Continued)

<table>
<thead>
<tr>
<th>ioctl Calls</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>I_RECVFD</td>
<td>Retrieves the file descriptor of the message sent by an I_SENDFD ioctl(2) over a STREAMS pipe</td>
</tr>
<tr>
<td>I_ATMARK</td>
<td>Lets the application see if the current message on the stream head read queue is marked by a module downstream</td>
</tr>
<tr>
<td>I_CKBAND</td>
<td>Checks if the message of a given priority band exists on the stream head read queue</td>
</tr>
<tr>
<td>I_GETBAND</td>
<td>Returns the priority band of the first message on the stream head read queue</td>
</tr>
<tr>
<td>I_CANPUT</td>
<td>Checks if a certain band is writable</td>
</tr>
<tr>
<td>I_SETCLTIME</td>
<td>Enables the user to set the time the stream head will delay when a stream is closing if data exists on the write queues</td>
</tr>
<tr>
<td>I_GETCLTIME</td>
<td>Returns the close time delay</td>
</tr>
<tr>
<td>I_LINK</td>
<td>Connects two streams</td>
</tr>
<tr>
<td>I_UNLINK</td>
<td>Disconnects two streams</td>
</tr>
<tr>
<td>I_PLINK</td>
<td>Connects two streams with a persistent link below a multiplexing driver</td>
</tr>
<tr>
<td>I_PUNLINK</td>
<td>Disconnects two streams that have been connected with a persistent link</td>
</tr>
</tbody>
</table>

Message Direction

Various system calls let the user create messages and send them downstream and prioritize the messages.

TABLE 4–3 Send and Receive Messages

<table>
<thead>
<tr>
<th>System Call</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>putmsg(2)</td>
<td>Creates a message from the caller supplied control and data buffers and sends the message downstream</td>
</tr>
<tr>
<td>putpmsg(2)</td>
<td>Does the same as putmsg(2) and enables the caller to specify a priority band for the message</td>
</tr>
<tr>
<td>getmsg(2)</td>
<td>Retrieves M_DATA, M_PROTO, or M_PCPROTO or high priority messages from the stream head, and places the contents into two user buffers</td>
</tr>
<tr>
<td>getpmsg(2)</td>
<td>Does the same as getmsg(2) and enables the caller to specify a priority band for the message</td>
</tr>
</tbody>
</table>

The stream head guarantees that the control part of a message generated by putmsg(2) is at least 64 bytes long. This promotes reusability of the buffer. When the buffer is a reasonable size, modules and drivers may reuse the buffer for other headers.
stropts.h contains the specification of strbuf, which describes the control and data buffers.

Flush Handling

All modules and drivers are expected to handle the flushing of messages. The user may cause data to be flushed of queued messages from a stream by the submission of an I_FLUSH ioctl(2). Data may be flushed from the read side, write side, or both sides of a stream.

ioctl (fd, I_FLUSH, arg);

Table 4–4 describes the arguments that may be passed to M_FLUSH.

<table>
<thead>
<tr>
<th>Flag</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>FLUSHR</td>
<td>Flushes read side of stream</td>
</tr>
<tr>
<td>FLUSHW</td>
<td>Flushes write queue</td>
</tr>
<tr>
<td>FLUSHRW</td>
<td>Flushes both read and write queues</td>
</tr>
</tbody>
</table>

In addition to being able to flush all the data from a queue, a specific band may be flushed using the I_FLUSHBAND ioctl(2).

ioctl (fd, I_FLUSHBAND, bandp);

The ioctl(2) is passed a pointer to a bandinfo structure. The bi_pri field indicates the band priority to be flushed (values from 0 to 255). The bi_flag field indicates the type of flush to do. The legal values for bi_flag are defined in Table 4–4. bandinfo has the following format:

```c
struct bandinfo {
    unsigned char bi_pri;
    int bi_flag;
};
```

See “Flushing Priority Band” on page 167, which describes M_FLUSHBAND processing, for details on how modules and drivers should handle flush band requests.
CHAPTER 5

STREAMS Administration

This chapter describes the tools available to administer STREAMS. It shows how to keep track of names, where to find modules, and how to monitor statistics. Kernel debugging is covered in Chapter 14.

- “Administration Tools” on page 79
- “Autopush Facility” on page 80
- “Administration Tool Description” on page 82

Administration Tools

Table 5-1 identifies some common tools available for monitoring, logging, and administering STREAMS.

<table>
<thead>
<tr>
<th>Tool</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>autopush(1M)</td>
<td>Configures list of modules to be automatically pushed</td>
</tr>
<tr>
<td>crash</td>
<td>Examines system memory images</td>
</tr>
<tr>
<td></td>
<td><strong>Note</strong> – crash has reached EOL and is not supported in the Solaris 9 operating environment. For information about how to transition from crash to mdb, see the Solaris Modular Debugger Guide.</td>
</tr>
<tr>
<td>fdetach(1M)</td>
<td>Detaches a name from a file descriptor</td>
</tr>
<tr>
<td>strace(1M)</td>
<td>Prints STREAMS trace messages</td>
</tr>
<tr>
<td>strchg(1), strconf(1)</td>
<td>Changes or queries a stream configuration</td>
</tr>
</tbody>
</table>
Autopush Facility

The autopush facility (see autopush(1M)) enables administrators to specify a list of modules to be automatically pushed onto the stream whenever a STREAMS device is opened. A prespecified list (/etc/iu.ap) of modules can be pushed onto the stream if the STREAMS device is not already open.

The STREAMS Administrative Driver (SAD) (see sad(7D)) provides an interface to the autopush mechanism. System administrators can open the SAD and set or get autopush information on other drivers. The SAD caches the list of modules to push for each driver. When the driver is opened, if not already open, the stream head checks the SAD’s cache to determine if the device is configured to have modules automatically pushed. If an entry is found, the modules are pushed. If the device is open, another open does not cause the list of the prespecified modules to be pushed again.

The autopush SAD_SAP command ap_cmd field specifies the configuration options:

- SAP_ONE Configure each minor device (that is, a specific major and minor device number).
- SAP_RANGE Configure a range of minor devices within a major device.
- SAP_ALL Configure all minor devices within a major device.
- SAP_CLEAR Undo configuration information for a driver.

In addition, when configuring the module list, an optional anchor can be placed within the list. (See “STREAMS Anchors” on page 243 for more information.)

When the configuration list is cleared, a range of minor devices has to be cleared as a range and not in parts.

---

**TABLE 5-1 Tools Available for STREAMS Administration (Continued)**

<table>
<thead>
<tr>
<th>Tool</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>strerr(1M)</td>
<td>Logs STREAMS errors</td>
</tr>
<tr>

<td>Loads a kernel module</td>
</tr>
<tr>
<td>modunload(1M)</td>
<td>Unloads a kernel module</td>
</tr>
<tr>
<td>modinfo(1M)</td>
<td>Displays information about loaded kernel modules</td>
</tr>
</tbody>
</table>
Application Interface

The SAD is accessed through /dev/sad/admin or /dev/sad/user. After the device is initialized, a program can be run to perform any needed autopush configuration. The program should open the SAD, read a configuration file to find out what modules must be configured for which devices, format the information into strapush structures, and perform the necessary SAD_SAP ioctl(2)s. See sad(7D) for more information.

All autopush operations are performed through an ioctl(2) command to set or get autopush information. Only the root user can set autopush information, but any user can get the autopush information for a device.

In the ioctl(2) call, the parameters are the file descriptor of the SAD, either SAD_SAP (set autopush information) or SAD_GAP (get autopush information), and a pointer to a strapush structure.

strapush is defined as:

```c
/*
 * maximum number of modules that can be pushed on a
 * Stream using the autopush feature should be no greater
 * than nstrpush
 */
#define MAXAPUSH 8

/* autopush information common to user and kernel */
struct apcommon {
    uint apc_cmd; /* command - see below */
    major_t apc_major; /* major device number */
    minor_t apc_minor; /* minor device number */
    minor_t apc_lastminor; /* last minor dev # for range */
    uint apc_npush; /* number of modules to push */
};

/* ap_cmd - various options of autopush */
#define SAP_CLEAR 0 /* remove configuration list */
#define SAP_ONE 1 /* configure one minor device */
#define SAP_RANGE 2 /* config range of minor devices */
#define SAP_ALL 3 /* configure all minor devices */

/* format of autopush ioctls */
struct strapush {
    struct apcommon sap_common;
    char sap_list[MAXAPUSH] [FMNAMESZ + 1]; /* module list */
};

#define sap_cmd sap_common.apc_cmd
#define sap_major sap_common.apc_major
#define sap_minor sap_common.apc_minor
#define sap_lastminor sap_common.apc_lastminor
```
A device is identified by its major device number, `sap_major`. A SAD_CMD ioctl(2) is one of the following commands:

- **SAP_CLEAR**: Clears the previous settings by removing the entry with the matching `sap_major` and `sap_minor` fields.
- **SAP_ONE**: Configures a single minor device, `sap_minor`, of a driver.  
- **SAP_RANGE**: Configures a range of minor devices from `sap_minor` to `sap_lastminor`, inclusive.
- **SAP_ALL**: Configures all minor devices of a device.

The list of modules is specified as a list of module names in `sap_list`. The maximum number of modules to push automatically is defined by `MAXAPUSH`.

A user can query the current configuration status of a given major or minor device by issuing the SAD_GAP ioctl(2) with `sap_major` and `sap_minor` values of the device set. On successful return from this system call, the `strapush` structure will be filled in with the corresponding information for that device. The maximum number of entries the SAD driver can cache is determined by the tunable parameter `NAUTOPUSH` found in the SAD driver’s master file.

The following is an example of an autopush configuration file in `/etc/iu.ap`:

```
# major  minor  lastminor  modules
wc      0      0          ldterm ttcompat
zs      0      1          ldterm ttcompat
ptsl    0      15         ldterm ttcompat
```

The first line is the configuration of a single minor device whose major name is `wc` and minor numbers start at 0 and end at 0, creating only one minor number. The modules automatically pushed are `ldterm` and `ttcompat`. The second line represents the configuration of the `zs` driver. The minor device numbers are 0 and 1. The last line allows minor device numbers from 0 to 15 for the `ptsl` driver.

---

**Administration Tool Description**

STREAMS error and trace loggers are provided for debugging and for administering STREAMS modules and drivers. This facility consists of `log(7D)`, `strace(1M)`, `strclean(1M)`, `strerr(1M)`, and the `strlog(9F)` function.
strace Command

strace(1M) is a utility that displays the messages in a specified STREAMS log. The log to display is identified by STREAMS module ID number, a sub-ID number, and the priority level.

strlog Command

strlog(9F) sends formatted text to log(7D) driver. Required definitions are contained in <sys/strlog.h> and <sys/log.h>. The call specifies the STREAMS module ID number, a sub-ID number, and the priority level. A flag parameter can specify any combination of:

- SL_ERROR The message is for the error logger
- SL_TRACE The message is for the tracer
- SL_FATAL Advisory notification of a fatal error
- SL_NOTIFY Modifies the SL_ERROR flag to request that a copy of the message be mailed to the system administrator
- SL_CONSOLE Log the message to the console
- SL_WARN Warning message
- SL_NOTE Notice the message

The flags are followed by a printf(3S)-style format string, but %s, %e, %E, %g, and %G conversion specifications are not recognized. Up to NLOGARGS of numeric or character arguments can be specified.

strqget Command

strqget(9F) gets information about a queue or band of a queue. The information is returned in a long. The stream must be frozen by the caller when calling strqget.

strqset Command

strqset(9F) changes information about a queue or band of the queue. The updated information is provided in an int. If the field is read-only, EPERM is returned and the field is left unchanged. See <sys/stream.h> for valid values. The stream must be frozen by the caller when calling strqset(9F).
strerr Daemon

strerr(1M) is the STREAMS error logger daemon.
Pipes and Queues

This chapter covers communication between processes using STREAMS-based pipes and named pipes. Discussion is limited to communications between applications.

- “Overview of Pipes and FIFOs” on page 85
- “Creating and Opening Pipes and FIFOs” on page 86

Overview of Pipes and FIFOs

A pipe in the SunOS 5.6 system provides a communication path between multiple processes. Prior to the SunOS 5.0 release, SunOS had standard pipes and named pipes (also called FIFOs). With standard pipes, one end was opened for reading and the other end for writing, so data flow was unidirectional. FIFOs had only one end and typically one process opened the file for reading and another process opened the file for writing. Data written into the FIFO by the writer could then be read by the reader.

To provide greater support and development flexibility for networked applications, pipes and FIFOs are STREAMS-based in the SunOS 5 software. The interface is unchanged but the underlying implementation is changed. When a pipe is created through the pipe(2) interface, two streams are opened and connected. Data flow is serial.

The remainder of this chapter uses the terms pipe and STREAMS-based pipe interchangeably to mean a STREAMS-based pipe.
Note – After both ends of a FIFO have been opened, there is no guarantee that further calls to open O_RDONLY (O_WRONLY) will synchronize with later calls to open O_WRONLY (O_RDONLY) until both ends of the FIFO have been closed by all readers and writers. Any data written into a FIFO will be lost if both ends of the FIFO are closed before the data is read.

Creating and Opening Pipes and FIFOs

A named pipe, also called a FIFO, is a pipe identified by an entry in a file system’s name space. FIFOs are created using mknod(2), mkfifo(3C), or the mknod(1M) command. They are removed using unlink(2) or the rm(1) command.

FIFOs look like regular file system nodes, but are distinguished from them by a p in the first column when the ls -l command is run.

    /usr/sbin/mknod xxx pls -l xxx
    prw-r--r-- 1 guest other 0 Aug 26 10:55 xxx
    echoput> hello.world>xxx & put>
    [1] 8733
    cat xxx
    hello world
    [1] + Done
    rm xxx

FIFOs are unidirectional: that is, one end of the FIFO is used for writing data, the other for reading data. FIFOs allow simple one-way interprocess communication between unrelated processes. Modules may be pushed onto a FIFO. Data written to the FIFO is passed down the write side of the module and back up the read side as shown in Figure 6–1.
FIFOs are opened in the same manner as other file system nodes with `open(2)`. Any data written to the FIFO can be read from the same file descriptor in the first-in, first-out manner (serial, sequentially). Modules can also be pushed on the FIFO. See `open(2)` for the restrictions that apply when opening a FIFO. If `O_NDELAY` or `O_NONBLOCK` is not specified, an `open` on a FIFO blocks until both a reader and a writer are present.

Named or mounted streams provide a more powerful interface for interprocess communications than does a FIFO. See “Named Streams” on page 90 for details.

A STREAMS-based pipe, also referred to as an anonymous pipe, is created using `pipe(2)`, which returns two file descriptors, `fd[0]` and `fd[1]`, each with its own stream head. The ends of the pipe are constructed so that data written to either end of a pipe may be read from the opposite end.

STREAMS modules can be added to a pipe with `I_PUSH ioctl(2)`. A module can be pushed onto one or both ends of the pipe (see Figure 6–2). However, if a module is pushed onto one end of the pipe, that module cannot be popped from the other end.
Using Pipes and FIFOs

Pipes and FIFOs can be accessed through the operating system routines `read(2)`, `write(2)`, `ioctl(2)`, `close(2)`, `putmsg(2)`, `putpmsg(2)`, `getmsg(2)`, `getpmsg(2)`, and `poll(2)`. For FIFOs, `open(2)` is also used.

Reading From a Pipe or FIFO

`read(2)` or `getmsg(2)` are used to read from a pipe or FIFO. Data can be read from either end of a pipe. On success, the `read(2)` returns the number of bytes read and buffered. When the end of the data is reached, `read(2)` returns 0.

When a user process attempts to read from an empty pipe (or FIFO), the following happens:

- If one end of the pipe is closed, 0 is returned, indicating the end of the file.
- If the `write` side of the FIFO has closed, `read(2)` returns 0 to indicate the end of the file.
- If some process has the FIFO open for writing, or both ends of the pipe are open, and `O_NDELAY` is set, `read(2)` returns 0.
- If some process has the FIFO open for writing, or both ends of the pipe are open, and `O_NONBLOCK` is set, `read(2)` returns -1 and sets `errno` to `EAGAIN`.
- If `O_NDELAY` and `O_NONBLOCK` are not set, the `read` call blocks until data is written to the pipe, until one end of the pipe is closed, or the FIFO is no longer open for writing.
Writing to a Pipe or FIFO

When a user process calls write(2), data is sent down the associated stream. If the pipe or FIFO is empty (no modules pushed), the data that is written is placed on the read queue of the other stream for pipes, and on the read queue of the same stream for FIFOs. Since the size of a pipe is the number of unread data bytes, the written data is reflected in the size of the other end of the pipe.

Zero-Length Writes

If a user process issues write(2) with 0 as the number of bytes to send a pipe or FIFO, 0 is returned, and, by default, no message is sent down the stream. However, if a user must send a zero-length message downstream, SNDZERO ioctl(2) can be used to change this default behavior. If SNDZERO is set in the stream head, write(2) requests of 0 bytes generate a zero-length message and send the message down the stream. If SNDZERO is not set, no message is generated and 0 is returned to the user.

The SNDZERO bit may be changed by the I_SWROPT ioctl(2). If the arg in the ioctl(2) has SNDZERO set, the bit is turned on. If the arg is set to 0, the SNDZERO bit is turned off.

The I_GWROPT ioctl(2) is used to get the current write settings.

Atomic Writes

If multiple processes simultaneously write to the same pipe, data from one process can be interleaved with data from another process, if modules are pushed on the pipe or the write is greater than PIPE_BUF. The order of data that is written is not necessarily the order of data that is read. To ensure that writes of less than PIPE_BUF bytes are not interleaved with data written by other processes, any modules pushed on the pipe should have a maximum packet size of at least PIPE_BUF.

Note – PIPE_BUF is an implementation-specific constant that specifies the maximum number of bytes that are atomic when writing to a pipe. When writing to a pipe, write requests of PIPE_BUF or fewer bytes are not interleaved with data from other processes doing writes to the same pipe. However, write requests of more than PIPE_BUF bytes may have data interleaved on arbitrary byte boundaries with writes by other processes whether or not the O_NONBLOCK or O_NDELAY flag is set.

If the module packet size is at least the size of PIPE_BUF, the stream head packages the data in such a way that the first message is at least PIPE_BUF bytes. The remaining data may be packaged into smaller or equal-sized blocks depending on buffer availability. If the first module on the stream cannot support a packet of PIPE_BUF, atomic writes on the pipe cannot be guaranteed.
Closing a Pipe or FIFO

`close(2)` closes a pipe or FIFO and dismantles its associated streams. On the last close of one end of a pipe, an `M_HANGUP` message is sent to the other end of the pipe. Subsequent `read(2)` or `getmsg(2)` calls on that stream head return the number of bytes read and zero when there are no more data. Subsequent `write(2)` or `putmsg(2)` requests fail with `errno` set to `EPIPE`. If the other end of the pipe is mounted, the last close of the pipe forces it to be unmounted.

Flushing Pipes and FIFOs

When the flush request is initiated from an `ioctl(2)` or from `flushq(9F)`, the `FLUSHR` or the `FLUSHW` bits of an `M_FLUSH` message must be switched. Bits are switched at the point where the `M_FLUSH` message is passed from a write queue to a read queue. This point is also known as the midpoint of the pipe.

The midpoint of a pipe is not always easily detectable, especially if there are numerous modules pushed on either end of the pipe. In that case, some mechanism needs to intercept all messages passing through the stream. If the message is an `M_FLUSH` message and it is at the stream midpoint, the flush bits need to be switched.

This bit switching is handled by the `pipemod` module. `pipemod` should be pushed onto a pipe or FIFO where flushing of any kind will take place. The `pipemod(7M)` module can be pushed on either end of the pipe. The only requirement is that it is pushed onto an end that previously did not have modules on it. That is, `pipemod(7M)` must be the first module pushed onto a pipe so that it is at the midpoint of the pipe itself.

The `pipemod(7M)` module handles only `M_FLUSH` messages. All other messages are passed to the next module using the `putnext(9F)` utility routine. If an `M_FLUSH` message is passed to `pipemod(7M)` and the `FLUSHR` and `FLUSHW` bits are set, the message is not processed but is passed to the next module using `putnext(9F)`. If only the `FLUSHR` bit is set, it is turned off and the `FLUSHW` bit is set. The message is then passed to the next module, using `putnext(9F)`. Similarly, if the `FLUSHW` bit was the only bit set in the `M_FLUSH` message, it is turned off and the `FLUSHR` bit is turned on. The message is then passed to the next module on the stream.

The `pipemod(7M)` module can be pushed on any stream if it requires the bit switching.

Named Streams

The name of a stream or STREAMS-based pipe often associates the stream with an existing node in the file system name space. This allows unrelated processes to open the pipe and exchange data with the application. The following interfaces support naming a stream or STREAMS-based pipe.
fattach(3C) Attaches a stream file descriptor to a node in the file system name space, thus naming the stream.

fdetach(3C) Detaches a named stream file descriptor from its node in the file system name space, thus unnaming the stream.

isastream(3C) Tests whether a file descriptor is associated with a stream.

Named streams are useful for passing file descriptors between unrelated processes on the same machine. A user process can send a file descriptor to another process by invoking the I_SENDFD ioctl(2) on one end of a named stream. This sends a message containing a file pointer to the stream head at the other end of the pipe. Another process can retrieve the message containing the file pointer by an I_RECVFD ioctl(2) call on the other end of the pipe.

Unique Connections

With named pipes, client processes may communicate with a server process using the connld module which lets a client process get a unique, non-multiplexed connection to a server. connld(7M) is a STREAMS-based module that has open, close, and put procedures.

When the named stream is opened, the open routine of connld(7M) is called. The open fails if:
- The pipe ends cannot be created.
- A file pointer and file descriptor cannot be allocated.
- The stream head cannot stream the two pipe ends.

The open is not complete and will block until the server process has received the file descriptor using the I_RECVFD ioctl. The setting of the O_NDELAY or O_NONBLOCK flag has no impact on the open routine.

connld(7M) does not process messages. All messages are passed to the next object in the stream. The read, write, and put routines call putnext(9F) to send the message up or down the stream.

The connld(7M) module can be pushed onto the named end of the pipe. If the named end of the pipe is then opened by a client, a new pipe is created. One file descriptor for the new pipe is passed back to a client (named stream) as the file descriptor from open(2) and the other file descriptor is passed to the server using I_RECVFD ioctl(2). The server and the client may then communicate through a new pipe.

Figure 6–3 shows a server process that has created a pipe and pushed the connld module on the other end. The server then invokes the fattach(3C) routine to name the other end /usr/toserv.
When process X (procx) opens /usr/toserv, it gains a unique connection to the server process that was at one end of the original STREAMS-based pipe. When process Y (procy) does the same, it also gains a unique connection to the server. As shown in Figure 6–4, the server process has access to three separate pipes through three file descriptors.

Because the STREAMS subsystem of UNIX® provides a framework on which communications services can be built, it is often called the STREAMS framework. This framework consists of the stream head and a series of utilities (put, putnext), kernel structures (mblk, dblk), and linkages (queues) that facilitate the interconnections between modules, drivers, and basic system calls. This chapter describes the STREAMS components from the kernel developer’s perspective.

Overview of Streams in Kernel Space

Chapter 1 describes a stream as a full-duplex processing and data transfer path between a STREAMS driver in kernel space and a process in user space. In the kernel, a stream consists of a stream head, a driver, and zero or more modules between the driver and the stream head.

The stream head is the end of the stream nearest the user process. All system calls made by user-level applications on a stream are processed by the stream head.

Messages are the containers in which data and control information is passed between the stream head, modules, and drivers. The stream head is responsible for translating the appropriate messages between the user application and the kernel. Messages are simply pointers to structures (mblk, dblk) that describe the data contained in them. Messages are categorized by type according to the purpose and priority of the message.
Queues are the basic elements by which the stream head, modules, and drivers are connected. Queues identify the open, close, put, and service entry points. Additionally, queues specify parameters and private data for use by modules and drivers, and are the repository for messages destined for deferred processing.

In the rest of this chapter, the word “modules” refers to modules, drivers, or multiplexers, except where noted.

Stream Head

The stream head interacts between applications in the user space and the rest of the stream in kernel space. The stream head is responsible for configuring the plumbing of the stream through open, close, push, pop, link, and unlink operations. It also translates user data into messages to be passed down the stream, and translates messages that arrive at the stream head into user data. Any characteristics of the stream that can be modified by the user application or the underlying stream are controlled by the stream head, which also informs users of data arrival and events such as error conditions.

If an application makes a system call with a STREAMS file descriptor, the stream head routines are invoked, resulting in data copying, message generation, or control operations. Only the stream head can copy data between the user space and kernel space. All other parts of the stream pass data by way of messages and are thus isolated from direct interaction with users of the stream.

Kernel–Level Messages

Chapter 3 discusses messages from the application perspective. The following sections discuss message types, message structure and linkage; how messages are sent and received; and message queues and priority from the kernel perspective.

Message Types

Several STREAMS messages differ in their purpose and queueing priority. The message types are briefly described and classified, according to their queueing priority, in Table 7–1 and Table 7–2. A detailed discussion of message types is in Chapter 8.
Some message types are defined as high-priority types. Ordinary or normal messages can have a normal priority of 0, or a priority (also called a $band$) from 1 to 255.

### Message Structure

A STREAMS message in its simplest form contains three elements—a message block, a data block, and a data buffer. The data buffer is the location in memory where the actual data of the message is stored. The data block (datab(9S)) describes the data buffer—where it starts, where it ends, the message types, and how many message blocks reference it. The message block (msgb(9S)) describes the data block and how the data is used.

The data block has a typedef of dblk_t and has the following public elements:

```c
struct datab {
    unsigned char *db_base; /* first byte of buffer */
    unsigned char *db_lim; /* last byte+1 of buffer */
    unsigned char db_ref; /* msg count ptg to this blk */
    unsigned char db_type; /* msg type */
};

typedef struct datab dblk_t;
```

The datab structure specifies the data buffers' fixed limits (db_base and db_lim), a reference count field (db_ref), and the message type field (db_type). db_base points to the address where the data buffer starts, db_lim points one byte beyond where the data buffer ends, and db_ref maintains a count of the number of message blocks sharing the data buffer.

**Caution** – db_base, db_lim, and db_ref should not be modified directly. db_type is modified under carefully monitored conditions, such as changing the message type to reuse the message block.

In a simple message, the message block references the data block, identifying for each message the address where the message data begins and ends. Each simple message block refers to the data block to identify these addresses, which must be within the confines of the buffer such that db_base ≥ b_rptr ≥ b_wptr ≥ db_lim. For ordinary messages, a priority band can be indicated, and this band is used if the message is queued.
Figure 7–1 shows the linkages between msgb, datab, and the data buffer in a simple message.

![Diagram of message block and data buffer linkages](image)

**FIGURE 7–1 Simple Message Referencing the Data Block**

The message block (see `msgb(9S)`) has a typedef of `mblk_t` and has the following public elements:

```c
struct msgb {  
    struct msgb *b_next;  /*next msg in queue*/  
    struct msgb *b_prev;  /*previous msg in queue*/  
    struct msgb *b_cont;  /*next msg block of message*/  
    unsigned char *b_rptr;  /*1st unread byte in bufr*/  
    unsigned char *b_wptr;  /*1st unwritten byte in bufr*/  
    struct datab *b_datap;  /*data block*/  
    unsigned char b_band;  /*message priority*/  
    unsigned short b_flag;  /*message flags*/
};
```

The STREAMS framework uses the `b_next` and `b_prev` fields to link messages into queues. `b_rptr` and `b_wptr` specify the current read and write pointers respectively, in the data buffer pointed to by `b_datap`. The fields `b_rptr` and `b_wptr` are maintained by drivers and modules.

The field `b_band` specifies a priority band where the message is placed when it is queued using the STREAMS utility routines. This field has no meaning for high-priority messages and is set to zero for these messages. When a message is allocated using `allocb(9F)`, the `b_band` field is initially set to zero. Modules and drivers can set this field to a value from 0 to 255 depending on the number of priority bands needed. Lower numbers represent lower priority. The kernel incurs overhead in maintaining bands if nonzero numbers are used.
Caution – Message block data elements must not modify b_next, b_prev, or b_datap. The first two fields are modified by utility routines such as putq(9F) and getq(9F). Message block data elements can modify b_cont, b_rptr, b_wptr, b_band (for ordinary messages types), and b_flag.

The SunOS environment places b_band in the msgb structure. Some other STREAMS implementations place b_band in the datab structure. The SunOS implementation is more flexible because each message is independent. For shared data blocks, the b_band can differ in the SunOS implementation, but not in other implementations.

Message Linkage

A complex message can consist of several linked message blocks. If buffer size is limited or if processing expands the message, multiple message blocks are formed in the message, as shown in Figure 7–2. When a message is composed of multiple message blocks, the type associated with the first message block determines the overall message type, regardless of the types of the attached message blocks.

Queued Messages

A put procedure processes single messages immediately and can pass the message to the next module’s put procedure using put or putnext. Alternatively, the message is linked on the message queue for later processing, to be processed by a module’s service procedure (putq(9F)). Note that only the first module of a set of linked modules is linked to the next message in the queue.
Think of linked message blocks as a concatenation of messages. Queued messages are a linked list of individual messages that can also be linked message blocks.

[Diagram of linked message blocks]

**FIGURE 7-3 Queued Messages**

In Figure 7–3 messages are queued: Message 1 being the first message on the queue, followed by Message 2 and Message 3. Notice that Message 1 is a linked message consisting of more than one mblk.

---

**Caution** – Modules or drivers must not modify b_next and b_prev. These fields are modified by utility routines such as putq(9F) and getq(9F).

---

**Shared Data**

In Figure 7–4, two message blocks are shown pointing to one data block. db_ref indicates that there are two references (mblks) to the data block. db_base and db_lim point to an address range in the data buffer. The b_rptr and b_wptr of both message blocks must fall within the assigned range specified by the data block.
Data blocks are shared using utility routines (see `dupmsg(9F)` or `dupb(9F)`). STREAMS maintains a count of the message blocks sharing a data block in the `db_ref` field.

These two `mblk`s share the same data and datablock. If a module changes the contents of the data or message type, it is visible to the owner of the message block.

When modifying data contained in the `dblk` or data buffer, if the reference count of the message is greater than one, the module should copy the message using `copymsg(9F)`, free the duplicated message, and then change the appropriate data.

---

**Note – Hardening Information.** At Sun, it is assumed that a message with a `db_ref` > 1 is a “read-only” message and can be read but not modified. If the module wishes to modify the data, it should first copy the message, and free the original:

```c
if ( dbp->db_ref > 1 ) {
    dblk_t *newdbp;
    
    /* Get a copy of the message */
    newdbp = copymsg(dbp);
    
    /* Free the original */
    freemsg(dbp);
    
    /* make sure that we are now using the new dbp */
    dbp = newdbp;
}
```
STREAMS provides utility routines and macros (identified in Appendix B) to assist in managing messages and message queues, and in other areas of module and driver development. Always use utility routines to operate on a message queue or to free or allocate messages. If messages are manipulated in the queue without using the STREAMS utilities, the message ordering can become confused and cause inconsistent results.

Caution – Not adhering to the DDI/DKI can result in panics and system crashes.

Sending and Receiving Messages

Among the message types, the most commonly used messages are M_DATA, M_PROTO, and M_PCPROTO. These messages can be passed between a process and the topmost module in a stream, with the same message boundary alignment maintained between user and kernel space. This allows a user process to function, to some degree, as a module above the stream and maintain a service interface.

M_PROTO and M_PCPROTO messages carry service interface information among modules, drivers, and user processes.

Modules and drivers do not interact directly with any interfaces except open(2) and close(2). The stream head translates and passes all messages between user processes and the uppermost STREAMS module. Message transfers between a process and the stream head can occur in different forms. For example, M_DATA and M_PROTO messages can be transferred in their direct form by getmsg(2) and putmsg(2). Alternatively, write(2) creates one or more M_DATA messages from the data buffer supplied in the call. M_DATA messages received at the stream head are consumed by read(2) and copied into the user buffer.

Any module or driver can send any message in either direction on a stream. However, based on their intended use in STREAMS and their treatment by the stream head, certain messages can be categorized as upstream, downstream, or bidirectional. For example, M_DATA, M_PROTO, or M_PCPROTO messages can be sent in both directions. Other message types such as M_IOACK are sent upstream to be processed only by the stream head. Messages to be sent downstream are silently discarded if received by the stream head. Table 7–1 and Table 7–2 indicate the intended direction of message types.

STREAMS enables modules to create messages and pass them to neighboring modules. read(2) and write(2) are not enough to enable a user process to generate and receive all messages. In the first place, read(2) and write(2) are byte-stream oriented with no concept of message boundaries. The message boundary of each service primitive must be preserved so that the start and end of each primitive can be located in order to support service interfaces. Furthermore, read(2) and write(2) offer only one buffer to the user for transmitting and receiving STREAMS messages. If
control information and data is placed in a single buffer, the user has to parse the contents of the buffer to separate the data from the control information. Furthermore, read(2) and write(2) offer only one buffer to the user for transmitting and receiving STREAMS messages. If control information and data is placed in a single buffer, the user has to parse the contents of the buffer to separate the data from the control information.

getmsg(2) and putmsg(2) enable a user process and the stream to pass data and control information between one another while maintaining distinct message boundaries.

Data Alignment

**Note – Hardening Information.** There is no guarantee in STREAMS that a b_rptr or b_wptr will fall on a proper bit alignment. Most modules that pass data structures with pointers try to retain the desired bit alignment. If the module is in a stream where this is reasonably guaranteed, it does not need to check data alignment. However, for the purpose of hardening, modules that are concerned about data alignment should verify that pointers are properly aligned, or copy data in mblk's to local structures that are properly aligned (see bcopy(3C)).

**Note – Hardening Information.** Ensure that the changing of pointers is uniform (b_rptr <= b_rptr). Keep pointers inside db_base and db_lim. It is easier to recover from an error if b_rptr and b_wptr are inside db_base and db_lim.

When a module changes the b_rptr and/or the b_wptr, it should verify the following relationship:

\[ \text{db_base} < \text{b_rptr} < \text{b_wptr} < \text{db_lim} \]

and

\[ \text{db_base} < \text{db_lim} \]

Message Queues and Message Priority

Message queues grow when the STREAMS scheduler is delayed from calling a service procedure by system activity, or when the procedure is blocked by flow control. When called by the scheduler, a module’s service procedure processes queued messages in a FIFO manner (getq(9F)). However, some messages associated with certain conditions, such as M_ERROR, must reach their stream destination as rapidly as possible. This is accomplished by associating priorities with the messages. These priorities imply a certain ordering of messages in the queue, as shown in Figure 7–5.
Each message has a priority band associated with it. Ordinary messages have a priority band of zero. The priority band of high-priority messages is ignored since they are high priority and thus not affected by flow control. `putq(9F)` places high-priority messages at the head of the message queue, followed by priority band messages (expedited data) and ordinary messages.

<table>
<thead>
<tr>
<th>normal (band 0) messages</th>
<th>priority (band 1) messages</th>
<th>priority (band 2) messages</th>

<td></td>
<td>head</td>
</tr>
</tbody>
</table>

**FIGURE 7–5 Message Ordering in a Queue**

When a message is queued, it is placed after the messages of the same priority already in the queue (in other words, FIFO within their order of queueing). This affects the flow-control parameters associated with the band of the same priority. Message priorities range from 0 (normal) to 255 (highest). This provides up to 256 bands of message flow within a stream. An example of how to implement expedited data would be with one extra band of data flow (priority band 1), as shown in Figure 7–6. Queues are explained in detail in the next section.

**FIGURE 7–6 Message Ordering with One Priority Band**

High-priority messages are not subject to flow control. When they are queued by `putq(9F)`, the associated queue is always scheduled, even if the queue has been disabled (`noenable(9F)`). When the service procedure is called by the stream’s scheduler, the procedure uses `getq(9F)` to retrieve the first message on queue, which is a high-priority message. Service procedures must be implemented to act on high-priority messages immediately. The mechanisms just mentioned—priority message queueing, absence of flow control, and immediate processing by a procedure—result in rapid transport of high-priority messages between the originating and destination components in the stream.

In general, high-priority messages should be processed immediately by the module’s `put` procedure and not placed on the `service` queue.
Caution – A service procedure must never queue a high-priority message on its own queue because an infinite loop results. The enqueuing triggers the queue to be immediately scheduled again.

Message Queues

The queue is the fundamental component of a stream. It is the interface between a STREAMS module and the rest of the stream, and is the repository for deferred message processing. For each instance of an open driver or pushed module or stream head, a pair of queues is allocated, one for the read side of the stream and one for the write side.

The RD(9F), WR(9F), and OTHERQ(9F) routines allow reference of one queue from the other. Given a queue, RD(9F) returns a pointer to the read queue, WR(9F) returns a pointer to the write queue and OTHERQ(9F) returns a pointer to the opposite queue of the pair (see QUEUE(9S)).

By convention, queue pairs are depicted graphically as side-by-side blocks, with the write queue on the left and the read queue on the right (see Figure 7-7).

queue(9S) Structure

As previously discussed, messages are ordered in message queues. Message queues, message priority, service procedures, and basic flow control all combine in STREAMS. A service procedure processes the messages in its queue. If there is no service procedure for a queue, putq(9F) does not schedule the queue to be run. The module developer must ensure that the messages in the queue are processed. Message priority and flow control are associated with message queues.

The queue structure is defined in stream.h as a typedef queue_t, and has the following public elements:

```c
struct qinit *q_qinfo; /* procs and limits for queue */
struct msgb *q_first; /* first data block */
struct msgb *q_last; /* last data block */
struct queue *q_next; /* Q of next stream */
```
struct queue *q_link; /* to next Q for scheduling */
void *q_ptr; /* to private data structure */
size_t q_count; /* number of bytes on Q */
uint q_flag; /* queue state */
ssize_t q_minpsz; /* min packet size accepted by this module */
ssize_t q_maxpsz; /* max packet size accepted by this module */
size_t q_hiwat; /* queue high-water mark */
size_t q_lowat; /* queue low-water mark */

q_first points to the first message on the queue, and q_last points to the last message on the queue. q_count is used in flow control and contains the total number of bytes contained in normal and high-priority messages in band 0 of this queue. Each band is flow controlled individually and has its own count. For more details, see “qband Structure” on page 121. qsize(9F) can be used to determine the total number of messages on the queue. q_flag indicates the state of the queue. See Table 7–3 for the definitions of these flags.

q_minpsz contains the minimum packet size accepted by the queue, and q_maxpsz contains the maximum packet size accepted by the queue. These are suggested limits, and some implementations of STREAMS may not enforce them. The SunOS stream head enforces these values but they are voluntary at the module level. You should design modules to handle messages of any size.

q_hiwat indicates the limiting maximum number of bytes that can be put on a queue before flow control occurs. q_lowat indicates the lower limit where STREAMS flow control is released.

q_ptr is the element of the queue structure where modules can put values or pointers to data structures that are private to the module. This data can include any information required by the module for processing messages passed through the module, such as state information, module IDs, routing tables, and so on. Effectively, this element can be used any way the module or driver writer chooses. q_ptr can be accessed or changed directly by the driver, and is typically initialized in the open(9E) routine.

When a queue pair is allocated, streamtab initializes q_qinfo, and module_info initializes q_minpsz, q_maxpsz, q_hiwat, and q_lowat. Copying values from the module_info structure enables them to be changed in the queue without modifying the streamtab and module_info values.

Table 7–3 lists the queue(9S) flags.

**Table 7–3 Queue Flags**

Using Queue Information

The q_first, q_last, q_count, and q_flags components must not be modified by the module, and should be accessed using strqget(9F). The values of q_minpsz, q_maxpsz, q_hiwat, and q_lowat are accessed through strqget(9F), and are modified by strqset(9F). q_ptr can be accessed and modified by the module and contains data private to the module.

All other accesses to fields in the queue(9S) structure should be made through STREAMS utility routines (see Appendix B, “STREAMS Utilities”). Modules and drivers should not change any fields not explicitly listed previously.

strqget(9F) enables modules and drivers to get information about a queue or particular band of the queue. This insulates the STREAMS data structures from the modules and drivers. The prototype for the strqget(9F) routine is:

```c
int strqget(queue_t *q, qfields_t what, unsigned char pri, void *valp)
```

q specifies from which queue the information is to be retrieved; what defines the queue_t field value to obtain (see the following structure fields). pri identifies a specific priority band. The value of the field is returned in valp. The fields that can be obtained are defined in <sys/stream.h> and shown here as:

- QHIWAT /* high-water mark */
- QLOWAT /* low-water mark */
- QMAXPSZ /* largest packet accepted */
- QMINPSZ /* smallest packet accepted */
- QCOUNT /* approx. size (in bytes) of data */
- QFIRST /* first message */
- QLAST /* last message */
- QFLAG /* status */

strqset(9F) enables modules and drivers to change information about a queue or a band of the queue. This also insulates the STREAMS data structures from the modules and drivers. Its prototype is:

```c
int strqset(queue_t *q, qfields_t what, unsigned char pri, intptr_t val)
```
The q, what, and pri fields are the same as in strqget(9F), but the information to be updated is provided in val instead of through a pointer. If the field is read-only, EPERM is returned and the field is left unchanged. The following fields are read-only: QCOUNT, QFIRST, QLAST, and QFLAG.

---

**Note – Hardening Information.** Access queue structure information, through strqget() and strqset() only. Do not access the queue structure directly.

---

### Entry Points

The q_qinfo component points to a qinit structure. This structure defines the module’s entry point procedures for each queue, which include the following:

```c
int (*qi_putp)(); /* put procedure */
int (*qi_srvp)(); /* service procedure */
int (*qi_qopen)(); /* open procedure */
int (*qi_qclose)(); /* close procedure */
struct module_info *qi_minfo; /* module information structure */
```

There is generally a unique q_init structure associated with the read queue and the write queue. qi_putp identifies the put procedure for the module. qi_srvp identifies the optional service procedure for the module.

The open and close entry points are required for the read-side queue. The put procedure is generally required on both queues and the service procedure is optional.

---

**Note – Hardening Information.** If the put procedure is not defined and a subsequent put is done to the module, a panic occurs. As a precaution, putnext should be declared as the module’s put procedure.

If a module only requires a service procedure, putq(9F) can be used as the module’s put procedure. If the service procedure is not defined, the module’s put procedure must not queue data (putq).

---

The qi_qopen member of the read-side qinit structure identifies the open(9E) entry point of the module. The qi_qclose member of the read-side qinit structure identifies the close(9E) entry point of the module.

The qi_minfo member points to the module_info(9S) structure.

```c
struct module_info {
    ushort mi_idnum; /* module id number */
};
```
mi_idnum is the module’s unique identifier defined by the developer and used in `strlog(9F)`. mi_idname is an ASCII string containing the name of the module. mi_minpsz is the initial minimum packet size of the queue. mi_maxpsz is the initial maximum packet size of the queue. mi_hiwat is the initial high-water mark of the queue. mi_lowat is the initial low-water mark of the queue.

open Routine

The `open(9E)` routine of a device is called once for the initial `open` of the device, then is called again on subsequent reopens of the stream. Module `open` routines are called once for the initial push onto the stream and again on subsequent reopens of the stream.

The stream is analogous to a stack. Initially the driver is opened and as modules are pushed onto the stream, their `open` routines are invoked. Once the stream is built, this order reverses if a reopen of the stream occurs. For example, while building the stream shown in Figure 7–8, device A’s `open` routine is called, followed by B’s and C’s when they are pushed onto the stream. If the stream is reopened, Module C’s `open` routine is called first, followed by B’s, and finally by A’s.
Usually the module or driver does not check this, but the issue is raised so that dependencies on the order of open routines are not introduced by the programmer. Note that although an open can happen more than once, close is only called once. See the next section on the close routine for more details. If a file is duplicated (dup(2)) the stream is not reopened.

The prototype for the open entry point is:

```c
int prefix_open(queue_t *q, dev_t *devp, int oflag, int sflag,
                 cred_t *cred_p)
```

- `q` Pointer to the read queue of this module.
- `devp` Pointer to a device number that is always associated with the device at the end of the stream. Modules cannot modify this value, but drivers can, as described in Chapter 9.
- `oflag` For devices, oflag can contain the following bit mask values: FEXCL, FNDELAY, FREAD, and FWRITE. See Chapter 9 for more information on drivers.
- `sflag` When the open is associated with a driver, sflag is set to 0 or CLONEOPEN, see Chapter 9, “Cloning STREAMS Drivers” on page 199 for more details. If the open is associated with a module, sflag contains the value MODOPEN.
- `cred_p` Pointer to the user credentials structure.

The open routines to devices are serialized. If more than one process attempts to open the device, only one proceeds and the others wait until the first finishes. Interrupts are not blocked during an open. The driver’s interrupt routine must continue to handle interrupts when multiple processes are opening the same device. See Chapter 9 for more information.

The open routines for both drivers and modules have user context. For example, they can do blocking operations, but the blocking routine should return in the event of a signal. In other words, q_wait_sig is allowed, but q_wait is not.

If the module or driver is to allocate a controlling terminal, it should send an M_SETOPTS message with SO_ISTTY set to the stream head.

The open routine usually initializes the q_ptr member of the queue. q_ptr is generally initialized to some private data structure that contains various state information private to the module or driver. The module’s close routine is responsible for freeing resources allocated by the module including q_ptr. Example 7–1 shows a simple open routine.

**EXAMPLE 7–1 A Simple open Routine**

```c
/* example of a module open */
int xx_open(queue_t *q, dev_t *devp, int oflag, int sflag, cred_t *crp)
{
    struct xxstr *xx_ptr;
```
A module receiving this data before its open routine finishes initialization can panic. To eliminate this problem, modules and drivers are not linked into the stream until qprocson(9F) is called (messages flow around the module). Figure 7-9 illustrates this process. See Chapter 12 for more information on the multithreaded environment and the use of perimeters.

The module or driver instance is guaranteed to be single-threaded before qprocson(9F) is called, except for interrupts or callbacks that must be handled separately.

**Note – Hardening Information.** qprocson must be called before calling qbufcall(9F), qtimeout(9F), qwait(9F), or qwait_sig(9F).

Before a module calls qprocson, it must be ready to accept data via the module’s put procedure so all data structures must be fully initialized (see “put Procedure” on page 114). The most common method for calling qprocson is to call this function just before returning from a successful open (see Example 7-1).
Note – For a multithreaded environment, verify you are using the correct perimeter before accessing data. See Chapter 12 for more information on the multithreaded environment and the use of perimeters.

close Routine

The close routine of devices is called only during the last close of the device. Module close routines are called during the last close or if the module is popped.

The prototype for the close entry point is:

```c
int prefix_close (queue *q, int flag, cred_t * cred_p)
```

- `q` is a pointer to the read queue of the module.
- `flag` is analogous to the `oflag` parameter of the open entry point. If `FNBLOCK` or `FNDELAY` is set, then the module should attempt to avoid blocking during the close.
- `cred_p` is a pointer to the user credential structure.

Like open, the close entry point has user context and can block. Likewise, the blocking routines should return in the event of a signal. Device drivers must take into consideration that interrupts are not blocked during close. The close routine must cancel all pending and qbufcall callbacks, and process any remaining messages on its service queue.

The open and close procedures are only used on the read side of the queue and can be set to NULL in the write-side qinit structure initialization. Example 7–2 shows an example of a module close routine.

EXAMPLE 7-2 Example of a Module Close

```c
/* example of a module close */
static int
xx_close(queue_t *rq, int flag, cred_t *credp)
{
    struct xxstr  *xxp;

    /*
     * Disable xxput() and xxsrv() procedures on this queue.
     */
    qprocsoff(xq);
    xxp = (struct xxstr *) rq->q_ptr;

    /*
     * Cancel any pending timeout.
     * This example assumes that the timeout was issued
```
EXAMPLE 7–2 Example of a Module Close  (Continued)

* against the write queue.
*/

if (xxp->xx_timeoutid != 0) {
    (void) quntimeout(WR(rq), xxp->xx_timeoutid);
    xxp->xx_timeoutid=0;
}

/*
* Cancel any pending bufcalls.
* This example assumes that the bufcall was issued
* against the write queue.
*/

if (xxp->xx_bufcallid !=0) {
    (void) qunbufcall(WR(rq), xxp->xx_bufcallid);
    xxp->xx_bufcallid = 0;
}

rq->q_ptr = WR(rq)->q_ptr = NULL;

/*
* Free resources allocated during open
*/

kmem_free (xxp, sizeof (struct xxstr));
return (0);
}

qprocsoff does the inverse operation shown in Figure 7–9. This supports the need
for cancelling callbacks before a qprocsoff.

qprocsoff is typically called at the beginning of the close routine. The module can
no longer receive messages from adjoining modules. The queue, however, still has
pointers to it’s adjoining modules and can putnext. However, as the queue is no
longer inserted into the stream, these messages may be out of order from other
messages in the stream, so it is best to process these messages before qprocsoff.

qwait is used because a module needs to get some response from another module or
driver in the STREAM (i.e. a DLPI disconnect message sent downstream). qwait and
qwait_sig must also be called before qprocsoff because once the queue is
removed from the stream, there will be no way for the reply message to reach the
queue.

put Procedure

The put procedure is the mechanism that other modules use to pass messages into
this module. This procedure is called via the put or putnext routines on behalf of
other modules. The queue’s put procedure is invoked by the preceding module to
process a message immediately (see put(9F) and putnext(9F)). Most modules will have a put routine. The common exception is on the read-side of drivers because there will not typically be a module downstream to the driver.

**Note – Hardening Information.** putnext is used by adjoining modules to ensure that the next module’s queue is intact. Use of put cannot guarantee that the queue being called is currently valid and inserted into a stream; you must ensure that the queue is valid when using put.

A driver’s put procedure must do one of the following:
- Process and free the message.
- Process and route the message back upstream.
- Queue the message to be processed by the driver’s service procedure.

All M_IOCTL type messages must be acknowledged through M_IOACK or rejected through M_IOCNACK. M_IOCTL messages should not be freed. Drivers must free any unrecognized message.

A module’s put procedure must do one of the following as shown in Figure 7-10:
- Process and free the message.
- Process the message and pass it to the next module or driver.
- Queue the message to be processed later by the module’s service procedure.

Unrecognized messages are passed to the next module or driver. The stream operates more efficiently when messages are processed in the put procedure. Processing a message with the service procedure imposes some latency on the message.
If the next module is flow controlled (see canput(9F) and canputnext(9F)), the put procedure can queue the message for processing by the next service procedure (see putq(9F)). The put routine is always called before the component’s corresponding srv(9E) service routine, so always use put for immediate message processing.

Note – Hardening Information. canput and canputnext operate similar to put and putnext; that is the next functions verify the integrity of the next queue. Not using the next functions can cause panics as the queue being referenced might have already been closed.

The preferred naming convention for a put procedure reflects the direction of the message flow. The read put procedure is suffixed by r (rput), and the write procedure by w (wput). For example, the read-side put procedure for module xx is declared as int xxrput (queue_t *q, mblk_t *mp). The write-side put procedure is declared as int xxwput (queue_t *q, mblk_t *mp), where q points to the corresponding read or write queue and mp points to the message to be processed.
Although high-priority messages can be placed on the service queue, processing them immediately in the put procedure is better. (See the stub code in Example 7–3.) Place ordinary or priority-band messages on the service queue (putq(9F)) if:

- The stream has been flow controlled; that is, canput fails.
- There are already messages on the service queue, that is, q_first is not NULL.
- Deferred processing is desired.

If other messages already exist on the queue and the put procedure does not queue new messages (provided they are not high-priority), messages are reordered. If the next module is flow controlled (see canput(9F) and canputnext(9F)), the put procedure can queue the message for processing by the service procedure (see putq(9F)).

**EXAMPLE 7–3 Example of a Module put Procedure**

```c
/*example of a module put procedure */
int
xxrput(queue_t *,mblk_t, *mp)
{
/*
 * If the message is a high-priority message or
 * the next module is not flow controlled and we have not
 * already deferred processing, then:
 */

if (mp->b_datap->db_type >= QPCTL ||
    (canputnext(q) && q->q_first == NULL)) {
    /*
     * Process message
     */
    ...
    ...
    putnext(q,mp);
} else {
    /*
     * put message on service queue
     */
    putq(q,mp);
}
return (0);
}
```

Put procedures must never call putq, putbq, or qenable if the module does not have a service procedure.
**Note – Hardening Information.** Once a message is passed using a `putq`, `put`, `putnext`, as well as the perimeter function `qwriter`, it cannot be accessed again because the use of this message has been given to the new routine. If a reference needs to be retained by the module, it should copy it by using `copyb`, `copymsg`, `dupb`, or `dupmsg`.

A module need not process the message immediately, and can queue it for later processing by the `service` procedure (see `putq(9F)`).

The SunOS STREAMS framework is multithreaded. Unsafe (nonmultithreaded) modules are not supported. To make multithreading of modules easier, the SunOS STREAMS framework uses perimeters (see “MT STREAMS Perimeters” on page 252 for more information).

**Caution –** Mutex locks must not be held across a call to `put(9F)`, `putnext(9F)`, or `qreply(9F)`. Because of the asynchronous nature of STREAMS, do not assume that a module’s `put` procedure has been called just because `put(9F)`, `putnext(9F)`, or `qreply(9F)` has returned.

**Queue service Procedure**

A queue’s `service` procedure is invoked to process messages on the queue. It removes successive messages from the queue, processes them, and calls the `put` procedure of the next module in the stream to give the processed message to the next queue.

The `service` procedure is optional. A module or driver can use a `service` procedure for the following reasons:

- Streams flow control is implemented by `service` procedures. If the next component on the stream has been flow controlled, the `put` procedure can queue the message. (See “Flow Control in Service Procedures” on page 125 in Chapter 7 for more on flow control.)
- Resource allocation recovery. If a `put` or `service` procedure cannot allocate a resource, such as memory, the message is usually queued to process later.
- A device driver can queue a message and get out of interrupt context.
- To combine multiple messages into larger messages.
The service procedure is invoked by the STREAMS scheduler. A STREAMS service procedure is scheduled to run if:

- The queue is not disabled (noenable(9F)) and the message being queued is either the first message on the queue, or a priority band message.
- The message being queued (putq(9F) or putbq(9F)) is a high-priority message,
- The queue has been back-enabled because flow control has been relieved,
- The queue has been explicitly enabled (qenable(9F)).

A service procedure usually processes all messages on its queue (getq(9F)) or takes appropriate action to ensure it is re-enabled (qenable(9F)) at a later time. Figure 7-11 shows the flow of a service procedure.

**Caution** – High-priority messages (db_type and MSG_HIPRI) must never be placed back on a service queue (putbq(9F)); this can cause an infinite loop.

Put procedures must never call putq, putbq, or qenable if the module does not have a service procedure.
Example 7–4 shows the stub code for a module service procedure.

EXAMPLE 7–4 Module service Procedure
/* example of a module service procedure */
int
xxrsvr(queue_t *q)
{
    mblk_t *mp;
    /*
     * While there are still messages on our service queue
     */
    while ((mp = getq(q) != NULL) {
        /*
         * We check for high priority messages, but
         * none is ever seen since the put procedure
         * never queues them.
         * If the next module is not flow controlled, then
         */
        if (mp->b_datap->db_type >= QPCTL || (canputnext (q)) {
EXAMPLE 7-4 Module service Procedure (Continued)

    /*
    * process message
    */
    .
    .
    .
    putnext(q, mp);
    }
    else {
    /*
    * put message back on service queue
    */
    putbq(q, mp);
    break;
    }
    }
    return (0);
}

qband Structure

The queue flow information for each band, other than band 0, is contained in a qband(9S) structure. This structure is not visible to other modules. For accessible information see strqget(9F) and strqset(9F). qband is defined as follows:

typedef struct qband {
    struct qband *qb_next; /* next band’s info */
    size_t q_count; /* number of bytes in band */
    struct msgb *qb_first; /* beginning of band’s data */
    struct msgb *qb_last; /* end of band’s data */
    size_t qb_hiwat; /* high-water mark for band */
    size_t qb_lowat; /* low-water mark for band */
    uint qb_flag; /* see below */
} qband_t;

The structure contains pointers to the linked list of messages in the queue. These pointers, qb_first and qb_last, denote the beginning and end of messages for the particular band. The q_count field is analogous to the queue’s q_count field. However, q_count only applies to the messages in the queue in the band of data flow represented by the corresponding qband structure. In contrast, q_count only contains information regarding normal and high-priority messages.

Each band has a separate high and low watermark, qb_hiwat and qb_lowat. These are initially set to the queue’s q_hiwat and q_lowat respectively. Modules and drivers can change these values through the strqset(9F) function. The QB_FULL flag for qb_flag denotes that the particular band is full.
The `qband(9S)` structures are not preallocated per queue. Rather, they are allocated when a message with a priority greater than zero is placed in the queue using `putq(9F)`, `putbq(9F)`, or `insq(9F)`. Since band allocation can fail, these routines return 0 on failure and 1 on success. Once a `qband(9S)` structure is allocated, it remains associated with the queue until the queue is freed. `strqset(9F)` and `strqget(9F)` cause `qband(9S)` allocation. Sending a message to a band causes all bands up to and including that one to be created.

**Using qband Information**

The STREAMS utility routines should be used when manipulating the fields in the queue and `qband(9S)` structures. `strqget(9F)` and `strqset(9F)` are used to access band information.

Drivers and modules can change the `qb_hiwat` and `qb_lowat` fields of the `qband` structure. Drivers and modules can only read the `qb_count`, `qb_first`, `qb_last`, and `qb_flag` fields of the `qband` structure. Only the fields listed previously can be referenced.

---

**Caution** – There are fields in the `qband` structure that are reserved and are not documented. These fields are subject to undocumented, unnotified change at any time.

---

Figure 7–12 shows a queue with two extra bands of flow.
Several routines are provided to aid you in controlling each priority band of data flow. These routines are

- `flushband(9F)`
- `bcanputnext(9F)`
- `strqset(9F)`
- `strqset(9F)`

`flushband(9F)` is discussed in “Flushing Priority Band” on page 167. `bcanputnext(9F)` is discussed in “Flow Control in Service Procedures” on page 125, and the other two routines are described in the following section. Appendix B also has a description of these routines.
Message Processing Procedures

Typically, put procedures are required in pushable modules, but service procedures are optional. If the put routine queues messages, a corresponding service routine must be present to handle the queued messages. If the put routine does not queue messages, the service routine is not required.

Figure 7–10 shows typical processing flow for a put procedure which works as follows:

- A message is received by the put procedure associated with the queue, where some processing can be performed on the message.
- The put procedure determines if the message can be sent to the next module by the use of canput(9F) or canputnext(9F).
- If the next module is flow controlled, the put procedure queues the message using putq(9F).
- putq(9F) places the message in the queue based on its priority.
- Then, putq(9F) makes the queue ready for execution by the STREAMS scheduler, following all other queues currently scheduled.
- If the next module is not flow controlled, the put procedure does any processing needed on the message and sends it to the next module using putnext(9F). Note that if the module does not have a service procedure it cannot queue the message, and must process and send the message to the next module.

Figure 7–11 shows typical processing flow for a service procedure that works as follows:

- When the system goes from kernel mode to user mode, the STREAMS scheduler calls the service procedure.
- The service procedure gets the first message (q_first) from the message queue using the getq(9F) utility.
- The put procedure determines if the message can be sent to the next module using canput(9F) or canputnext(9F).
- If the next module is flow controlled, the put procedure requeues the message with putbq(9F), and then returns.
- If the next module is not flow controlled, the service procedure processes the message and passes it to the put procedure of the next queue with putnext(9F).
- The service procedure gets the next message and processes it. This processing continues until the queue is empty or flow control blocks further processing. The service procedure returns to the caller.
**Caution** – A service or put procedure must never block since it has no user context. It must always return to its caller.

If no processing is required in the put procedure, the procedure does not have to be explicitly declared. Rather, putq(9F) can be placed in the qinit(9S) structure declaration for the appropriate queue side to queue the message for the service procedure. For example:

```c
class qinit winit = { putq, modwsrv, ...... };
```

More typically, put procedures process high-priority messages to avoid queueing them.

Device drivers associated with hardware are examples of STREAMS devices that might not have a put procedure. Since there are no queues below the hardware level, another module does not call the module’s put procedure. Data comes into the stream from an interrupt routine, and is either processed or queued for the service procedure.

A STREAMS filter is an example of a module without a service procedure—messages passed to it are either passed or filtered. Flow control is described in “Flow Control in Service Procedures” on page 125.

The key attribute of a service procedure in the STREAMS architecture is delayed processing. When a service procedure is used in a module, the module developer is implying that there are other, more time-sensitive activities to be performed elsewhere in this stream, in other streams, or in the system in general.

**Note** – The presence of a service procedure is mandatory if the flow control mechanism is to be utilized by the queue. If you do not implement flow control, queues can overflow and hang the system.

---

**Flow Control in Service Procedures**

The STREAMS flow control mechanism is voluntary and operates between the two nearest queues in a stream containing service procedures (see Figure 7-13). Messages are held on a queue only if a service procedure is present in the associated queue.
Messages accumulate on a queue when the queue’s service procedure processing does not keep pace with the message arrival rate, or when the procedure is blocked from placing its messages on the following STREAMS component by the flow control mechanism. Pushable modules can contain independent upstream and downstream limits. The stream head contains a preset upstream limit (which can be modified by a special message sent from downstream) and a driver can contain a downstream limit. See M_SETOPTS for more information.

Flow control operates as follows:

- Each time a STREAMS message-handling routine (for example, putq(9F)) adds or removes a message from a message queue, the limits are checked. STREAMS calculates the total size of all message blocks \((bp->b_wptr - bp->b_rptr)\) on the message queue.

**Note** – \(bp\) is a pointer to the buffer header structure allocated by \(bp\) _mapin(), \(b_wptr\) is the first unwritten byte in the buffer, and \(b_rptr\) is the first unread byte in the buffer. See msgb(9S) STREAMS message block structure.

- The total is compared to the queue high and low watermark values. If the total exceeds the high watermark value, an internal full indicator is set for the queue. The operation of the service procedure in this queue is not affected if the indicator is set, and the service procedure continues to be scheduled.

- The next part of flow control processing occurs in the nearest preceding queue that contains a service procedure. In Figure 7–13, if D is full and C has no service procedure, then B is the nearest preceding queue.

- The service procedure in B uses canputnext(9F) to check if a queue ahead is marked full. If messages cannot be sent, the scheduler blocks the service procedure in B from further execution. B remains blocked until the low watermark of the full queue, D, is reached.

- While B is blocked, any messages except high-priority messages arriving at B accumulate on its message queue. High-priority messages are not subject to flow control. Eventually, B can reach a full state and the full condition propagates back to the preceding module in the stream.
When the service procedure processing on D causes the message block total to fall below the low watermark, the full indicator is turned off. STREAMS then schedules the nearest preceding blocked queue (B in this case). This automatic scheduling is called back-enabling a queue.

Modules and drivers need to observe the message priority. High-priority messages, determined by the type of the first block in the message,

\[ mp->b_datap->db_type >= QPCTL \]

are not subject to flow control. They should be processed immediately and forwarded, as appropriate.

For ordinary messages, flow control must be tested before any processing is performed. `canputnext(9F)` determines if the forward path from the queue is blocked by flow control.

This is the general flow control processing of ordinary messages:

- Retrieve the message at the head of the queue with `getq(9F)`.
- Determine if the message type is high priority and not to be processed here.
- If so, pass the message to the put procedure of the following queue with `putnext(9F)`.
- Use `canputnext(9F)` to determine if messages can be sent onward.
- If messages cannot be forwarded, put the message back in the queue with `putbq(9F)` and return from the procedure.

**Caution** – High-priority messages must be processed and not placed back on the queue.

Otherwise, process the message.

The canonical representation of this processing within a service procedure is:

```c
while (getq() != NULL)
    if (high priority message || no flow control) {
        process message
        putnext()
    } else {
        putbq()
        return
    }
```
Expedited data has its own flow control with the same processing method as that of ordinary messages. bcanputnext(9F) provides modules and drivers with a test of flow control in a priority band. It returns 1 if a message of the given priority can be placed in the queue. It returns 0 if the priority band is flow controlled. If the band does not exist in the queue in question, the routine returns 1.

If the band is flow controlled, the higher bands are not affected. However, lower bands are also stopped from sending messages. Without this, lower priority messages can be passed along ahead of the flow-controlled higher priority messages.

The call bcanputnext(q, 0); is equivalent to the call canputnext(q);

---

**Note** – A service procedure must process all messages in its queue unless flow control prevents this.

---

A service procedure must continue processing messages from its queue until getq(9F) returns NULL. When an ordinary message is queued by putq(9F), the service procedure is scheduled only if the queue was previously empty, and a previous getq(9F) call returns NULL (that is, the QWANT flag is set). If there are messages in the queue, putq(9F) presumes the service procedure is blocked by flow control and the procedure is automatically rescheduled by STREAMS when the block is removed. If the service procedure cannot complete processing as a result of conditions other than flow control (for example, no buffers), it must ensure a later return (for example, by bufcall(9F)) or discard all messages in the queue. If this is not done, STREAMS never schedules the service procedure to be run unless the queue’s put procedure queues a priority message with putq(9F).

---

**Note** – High-priority messages are discarded only if there is already a high-priority message on the stream head read queue. That is, there can be only one high-priority message (PC_PROTO) present on the stream head read queue at any time.

---

putbq(9F) replaces a message at the beginning of the appropriate section of the message queue according to its priority. This might not be the same position at which the message was retrieved by the preceding getq(9F). A subsequent getq(9F) might return a different message.

putq(9F) checks only the priority band in the first message. If a high-priority message is passed to putq with a nonzero b_band value, b_band is reset to 0 before placing the message in the queue. If the message is passed to putq(9F) with a b_band value that is greater than the number of qband(9S) structures associated with the queue, putq(9F) tries to allocate a new qband(9S) structure for each band, up to and including the band of the message.
rmvq and insq work similarly. If you try to insert a message out of order in a queue with insq(9F), the message is not inserted and the routine fails.

putq(9F) does not schedule a queue if noenable(9F) was previously called for the queue. noenable(9F) forces putq(9F) to queue the message when called by this queue, but not to schedule the service procedure. noenable(9F) does not prevent the queue from being scheduled by a flow control back-enable. The inverse of noenable(9F) is enableok(9F).

The service procedure is written using the following algorithm:

```c
while ((bp = getq(q)) != NULL) {
    if (queclass(bp) == QPCTL) {
        /* Process the message */
        putnext(q, bp);
    } else if (bcanputnext(q, bp->b_band)) {
        /* Process the message */
        putnext(q, bp);
    } else {
        putbq(q, bp);
        return;
    }
}
```

If the module or driver ignores priority bands, the algorithm is the same as described in the previous paragraphs, except that canputnext(q) is substituted for bcanputnext(q, bp->b_band).

genable(9F), another flow-control utility, enables a module or driver to cause one of its queues, or another module’s queues, to be scheduled. genable(9F) can also be used to delay message processing. An example of this is a buffer module that gathers messages in its message queue and forwards them as a single, larger message. This module uses noenable(9F) to inhibit its service procedure and queues messages with its put procedure until a certain byte count or “in queue” time has been reached. When either of these conditions is met, the module calls genable(9F) to cause its service procedure to run.

Another example is a communication line discipline module that implements end-to-end (for example, to a remote system) flow control. Outbound data is held on the write side message queue until the read side receives a transmit window from the remote end of the network.

**Note** – STREAMS routines are called at different priority levels. Interrupt routines are called at the interrupt priority of the interrupting device. Service routines are called with interrupts enabled (so that service routines for STREAMS drivers can be interrupted by their own interrupt routines).
CHAPTER 8

STREAMS Kernel-Level Mechanisms

This chapter describes the STREAMS kernel-level mechanisms:

- “ioctl Processing” on page 131
- “Message Allocation and Freeing” on page 132
- “Extended STREAMS Buffers” on page 138
- “General ioctl Processing” on page 141
- “M_FLUSH Message Handling” on page 164
- “Driver and Module Service Interfaces” on page 169
- “Common ioctl Interfaces” on page 178
- “signal Message” on page 179

ioctl Processing

STREAMS is a special type of character device driver that is different from the historical character input/output (I/O) mechanism in several ways.

In the classical device driver, all ioctl(2) calls are processed by the single device driver, which is responsible for their resolution. The classical device driver has user context, that is, all data can be copied directly to and from user space.

By contrast, the stream head itself can process some ioctl(2) calls (defined in streamio(7I)). Generally, STREAMS ioctl(2) calls operate independently of any particular module or driver on the stream. This means the valid ioctl(2) calls that are processed on a stream change over time, as modules are pushed and popped on the stream. The stream modules have no user context and must rely on the stream head to perform copyin and copyout requests.
There is no user context in a module or driver when the information associated with the ioctl(2) call is received. This prevents use of ddi_copyin(9F) or ddi_copyout(9F) by the module. No user context also prevents the module and driver from associating any kernel data with the currently running process. In any case, by the time the module or driver receives the ioctl(2) call, the process generating can have exited.

STREAMS enables user processes to control functions on specific modules and drivers in a stream using ioctl(2) calls. In fact, many streamio(7I) ioctl(2) commands go no further than the stream head. They are fully processed there and no related messages are sent downstream. For an I_STR ioctl(2) or an unrecognized ioctl(2) command, the stream head creates an M_IOCTL message, which includes the ioctl(2) argument. This is then sent downstream to be processed by the pertinent module or driver. STREAMS ensures that there is only one user-driven M_IOCTL operating on a stream at a time. The M_IOCTL message is the precursor message type carrying ioctl(2) information to modules. Other message types are used to complete the ioctl processing in the stream. Each module has its own set of M_IOCTL messages it must recognize.

Caution – Hardening Information. Modules and drivers should never assume that user data is correct. Users might be able to pass offsets that exceed the buffers supplied, or data that might be in kernel space. Values should always be checked against the range of data that is requested or supplied. Otherwise, panics or data corruption may occur.

Message Allocation and Freeing

The allocb(9F) utility routine allocates a message and the space to hold the data for the message. allocb(9F) returns a pointer to a message block containing a data buffer of at least the size requested, providing there is enough memory available. The routine returns NULL on failure. allocb(9F) always returns a message of type M_DATA. The type can then be changed if required. b_rptr and b_wptr are set to db_base (see msgb(9S) and datab(9S)), which is the start of the memory location for the message buffer.

Note – STREAMS often provides buffers that are bit aligned, but there is no guarantee that db_base or db_lim reside on bit-aligned boundaries. If bit or page alignment is required on module-supplied buffers use esballoc. For more information about esballoc see “Extended STREAMS Buffers” on page 138.
allocb(9F) can return a buffer larger than the size requested. If allocb(9F) indicates that buffers are not available (allocb(9F) fails), the put or service procedure cannot block to wait for a buffer to become available. Instead, bufcall(9F) defers processing in the module or the driver until a buffer becomes available.

If message space allocation is done by the put procedure and allocb(9F) fails, the message is usually discarded. If the allocation fails in the service routine, the message is returned to the queue. bufcall(9F) is called to set a call to the service routine when a message buffer becomes available, and the service routine returns.

freeb(9F) releases the message block descriptor and the corresponding data block, if the reference count (see datab(9S)) is equal to 1. If the reference count exceeds 1, the data block is not released.

freemsg(9F) releases all message blocks in a message. It uses freeb(9F) to free all message blocks and corresponding data blocks.

In Example 8–1, allocb(9F) is used by the bappend subroutine that appends a character to a message block.

EXAMPLE 8–1 Use of allocb

`/*
 * Append a character to a message block.
 * If (*bpp) is null, it will allocate a new block
 * Returns 0 when the message block is full, 1 otherwise
 */`
#define MODBLKSZ 128 /* size of message blocks */

static int bappend(mblk_t **bpp, int ch)
{
    mblk_t *bp;
    if ((bp = *bpp) != NULL) {
        if ((bp->b_wptr >= bp->b_datap->db_lim)
            return (0);
    } else {
        if ((*bpp = bp = allocb(MODBLKSZ, BPRI_MED)) == NULL)
            return (1);
    }
    *bp->b_wptr++ = ch;
    return 1;
}

bappend receives a pointer to a message block and a character as arguments. If a message block is supplied (*bpp != NULL), bappend checks if there is room for more data in the block. If not, it fails. If there is no message block, a block of at least MODBLKSZ is allocated through allocb(9F).

If allocb(9F) fails, bappend returns success and discards the character. If the original message block is not full or the allocb(9F) is successful, bappend stores the character in the block.
Example 8–2 shows the processing of all the message blocks in any downstream data (type M_DATA) messages. freemsg(9F) frees messages.

EXAMPLE 8–2 Subroutine modwput

```c
/* Write side put procedure */
static int modwput(queue_t *q, mblk_t *mp)
{
    switch (mp->b_datap->db_type) {
    default:
        putnext(q, mp);        /* Don’t do these, pass along */
        break;
    case M_DATA:
    {
        mblk_t *bp;
        struct mblk_t *nmp = NULL, *nbp = NULL;
        for (bp = mp; bp != NULL; bp = bp->b_cont) {
            while (bp->b_rptr < bp->b_wptr) {
                if (*bp->b_rptr == 
                    if (!bappend(&nbp, 
                        if (!bappend(&nbp, bp->b_rptr))
                            goto newblk;
                        nmp = nbp;
                    }
                bp->b_rptr++;
                continue;
            }
            newblk:
            if (nmp == NULL)
                nmep = nbp;
            else {
                /* link msg blk to tail of nmp */
                linkb(nmp, nbp);
                nbp = NULL;
            }
        }
        if (nmp == NULL)
            nmp = nbp;
        else
            linkb(nmp, nbp);
        freemsg(mp); /* de-allocate message */
        if (nmp)
            putnext(q, nmp);
        break;
    }
}
```

Data messages are scanned and filtered. modwput copies the original message into new blocks, modifying as it copies. nbp points to the current new message block. nmp points to the new message being formed as multiple M_DATA message blocks. The outer for loop goes through each message block of the original message. The inner
while loop goes through each byte. bappend is used to add characters to the current or new block. If bappend fails, the current new block is full. If nmp is NULL, nmp is pointed at the new block. If nmp is not NULL, the new block is linked to the end of nmp by use of linkb(9F).

At the end of the loops, the final new block is linked to nmp. The original message (all message blocks) is returned to the pool by freemsg(9F). If a new message exists, it is sent downstream.

Recovering From No Buffers

bufcall(9F) can be used to recover from an allocb(9F) failure. The call syntax is as follows:

```
bufcall_id_t bufcall(int size, int pri, void(*func)(), long arg);
```

**Note** – qbufcall(9F) and qunbufcall(9F) must be used with perimeters.

bufcall(9F) calls (*func)(arg) when a buffer of size bytes is available. When func is called, it has no user context and must return without blocking. Also, there is no guarantee that when func is called, a buffer will still be available.

On success, bufcall returns a nonzero identifier that can be used as a parameter to unbufcall(9F) to cancel the request later. On failure, 0 is returned and the requested function is never called.

**Caution** – Care must be taken to avoid deadlock when holding resources while waiting for bufcall to call (*func(arg)). bufcall should be used sparingly.

Read Device Interrupt Handler

Example 8–3 is an example of a read device interrupt handler.

**EXAMPLE 8-3** Device Interrupt Handler

```c
#include <sys/types.h>
#include <sys/param.h>
#include <sys/stream.h>
buffcall_id_t id; /* hold id val for unbufcall */

dev_rintr(dev)
{
```
EXAMPLE 8-3 Device Interrupt Handler  (Continued)

/* process incoming message ... */
/* allocate new buffer for device */
dev_re_load(dev);
}
/*
 * Reload device with a new receive buffer
 */
dev_re_load(dev)
{
  mblk_t *bp;
  id = 0; /* begin with no waiting for buffers */
  if ((bp = allocb(DEVBLKSZ, BPRI_MED)) == NULL) {
    cmn_err(CE_WARN,"dev:allocbfailure(size%d)\n",
            DEVBLKSZ);
    /* Allocation failed. Use bufcall to
     * schedule a call to ourselves.
     */
    id = bufcall(DEVBLKSZ,BPRI_MED,dev_re_load,dev);
    return;
  }
  /* pass buffer to device ... */
}

See Chapter 12 for more information on the uses of unbufcall(9F). These references
to unbufcall are protected by MT locks.

Because bufcall(9F) can fail, there is still a chance that the device will hang. A better
strategy if bufcall(9F) fails is to discard the current input message and resubmit that
buffer to the device. Losing input data is preferable to the device hanging.

Write Service Procedure

Example 8-4 is an example of a write service procedure.

EXAMPLE 8-4 Write Service Procedure

static int mod_wsrv(queue_t *q)
{
  extern int qenable();
  mblk_t *mp, *bp;
  while (mp = getq(q)) {
    /* check for priority messages and canput ... */
    /* Allocate a header to prepend to the message.
     * If the allocb fails, use bufcall to reschedule.
     */

  }
}
EXAMPLE 8–4 Write Service Procedure  (Continued)

```c
if ((bp = allocb(HDRSZ, BPRI_MED)) == NULL) {
   if (!bufcall(HDRSZ,BPRI_MED,qenable, q)) {
      timeout(qenable, (caddr_t)q, 
      drv_usec_tohz()); 
      /*
       * Put the msg back and exit, we will be
       * re-enabled later
       */
      putbq(q, mp);
      return;
   }
   /* process message .... */
}
```

`mod_wsrv` prefixes each output message with a header.

In this example, `mod_wsrv` illustrates a potential deadlock case. If `allocb(9F)` fails, `mod_wsrv` tends to recover without loss of data and calls `bufcall(9F)`. In this case, the routine passed to `bufcall(9F)` is `qenable(9F)`. When a buffer is available, the service procedure is automatically re-enabled. Before exiting, the current message is put back in the queue. Example 8–4 deals with `bufcall(9F)` failure by calling `timeout(9F)`.

`timeout(9F)` schedules the given function to be run with the given argument in the given number of clock cycles. In this example, if `bufcall(9F)` fails, the system runs `qenable(9F)` after two seconds have passed.

### Releasing Callback Requests

When `allocb(9F)` fails and `bufcall(9F)` is called, a callback is pending until a buffer is actually returned. Because this callback is asynchronous, it must be released before all processing is complete. To release this queued event, use `unbufcall(9F)`.

Pass the `id` returned by `bufcall(9F)` to `unbufcall(9F)`. Then close the driver in the normal way. If this sequence of `unbufcall(9F)` and `xxclose` is not followed, the callback can occur when the driver is already closed. This is one of the most difficult types of problems to find and debug.

---

**Caution** – All `bufcall(9F)` and timeouts must be canceled in the close routine.
Extended STREAMS Buffers

Some hardware using the STREAMS mechanism supports memory-mapped I/O (see `mmap(2)`) which allows the sharing of buffers between users, the kernel, and the I/O card. Modules and drivers that need bit-aligned or page-aligned buffers should use extended STREAMS buffers by calling `esballoc` (also see `ddi_umem_alloc`).

If the hardware supports memory-mapped I/O, data received from the hardware is placed in the DARAM (dual-access RAM) section of the I/O card. Since DARAM is memory that is shared between the kernel and the I/O card, coordinated data transfer between the kernel and the I/O card is eliminated. Once in kernel space, the data buffer is manipulated as if it were a kernel resident buffer. Similarly, data sent downstream is placed in the DARAM and forwarded to the network.

In a typical network arrangement, data is received from the network by the I/O card. The controller reads the block of data into the card’s internal buffer. It interrupts the host computer to notify that data have arrived. The STREAMS driver gives the controller the kernel address where the data block is to go and the number of bytes to transfer. After the controller has read the data into its buffer and verified the checksum, it copies the data into main memory to the address specified by the DMA (direct memory access) memory address. Once in the kernel space, the data is packaged into message blocks and processed in the usual manner.

When data is transmitted from a user process to the network, it is copied from the user space to the kernel space, packaged as a message block, and sent to the downstream driver. The driver interrupts the I/O card, signaling that data is ready to be transmitted to the network. The controller copies the data from the kernel space to the internal buffer on the I/O card, and from there it is placed on the network.

The STREAMS buffer allocation mechanism enables the allocation of message and data blocks to point directly to a client-supplied (non-STREAMS) buffer. Message and data blocks allocated this way are indistinguishable from the normal data blocks. The client-supplied buffers are processed as if they were normal STREAMS data buffers.

Drivers can attach non-STREAMS data buffers and also free them. This is done as follows:

- **Allocation** - If the drivers use DARAM without using STREAMS resources and without depending on upstream modules or need to use privately allocated buffers, a data and message block can be allocated without an allocated data buffer. Use `esballoc(9F)`. This returns a message block and data block without an associated STREAMS buffer. The buffer used is the one supplied by the caller in the calling sequence.

- **Freeing** - Each driver using non-STREAMS resources in a STREAMS environment must manage those resources completely, including freeing them. To make this as transparent as possible, a driver-dependent routine is executed if `freeb(9F)` is
called to free a message and data block with an attached non-STREAMS buffer.

`freeb(9F)` detects when a buffer is a client supplied, non-STREAMS buffer. If it is, `freeb(9F)` finds the `free_rtn(9S)` structure associated with the buffer. After calling the driver-dependent routine (defined in `free_rtn(9S)`) to free the buffer, `freeb(9F)` frees the message and data block.

The `free` routine should not reference any dynamically allocated data structures that are freed when the driver is closed, as messages can exist in a stream after the driver is closed. For example, when a stream is closed, the driver `close` routine is called and its private data structure can be deallocated. If the driver sends a message created by `esballoc` upstream, that message can still be on the stream head read queue. When the stream head read queue is flushed, the message is freed and a call is made to the driver’s `free` routine after the driver has been closed.

The format of the `free_rtn(9S)` structure is as follows:

```c
void (*free_func)();  /* driver dependent free routine */
char *free_arg;       /* argument for free_rtn */
```

The structure has two fields: a pointer to a function and a location for any argument passed to the function. Instead of defining a specific number of arguments, `free_arg` is defined as a `char *`. This way, drivers can pass pointers to structures if more than one argument is needed.

The method by which `free_func` is called is implementation-specific. Do not assume that `free_func` is called directly from STREAMS utility routines like `freeb(9F)`. The `free_func` function must not call another module’s `put` procedure nor try to acquire a private module lock that can be held by another thread across a call to a STREAMS utility routine that could free a message block. Otherwise, lock recursion and deadlock could occur.

`esballoc(9F)`, provides a common interface for allocating and initializing data blocks. It makes the allocation as transparent to the driver as possible and provides a way to modify the fields of the data block, since modification should only be performed by STREAMS. The driver calls this routine to attach its own data buffer to a newly allocated message and data block. If the routine successfully completes the allocation and assigns the buffer, it returns a pointer to the message block. The driver is responsible for supplying the arguments to `esballoc(9F)`, a pointer to its data buffer, the size of the buffer, the priority of the data block, and a pointer to the `free_rtn` structure. All arguments should be non-NULL. See Appendix B, for a description of `esballoc(9F)`.

**esballoc(9F) Example**

Example 8-5 (which will not compile) shows how extended buffers are managed in the multithreaded environment. The driver maintains a pool of special memory that is allocated by `esballoc(9F)`. The allocator `free` routine uses the queue struct assigned
to the driver or other queue private data, so the allocator and the close routine need to coordinate to ensure that no outstanding esballoc(9F) memory blocks remain after the close. The special memory blocks are of type ebm_t, the counter is ebm, and the mutex mp and the condition variable cvp are used to implement the coordination.

**EXAMPLE 8-5  esballoc Example**

```c
void special_new()
{
    mutex_enter(&mp);
    /*
    * allocate some special memory
    */
    esballoc();
    /*
    * increment counter
    */
    ebm++;
    mutex_exit(&mp);
}

void special_free()
{
    mutex_enter(&mp);
    /*
    * de-allocate some special memory
    */
    freeb();
    /*
    * decrement counter
    */
    ebm--;
    if (ebm == 0)
        cv_broadcast(&cvp);
    mutex_exit(&mp);
}
```

```c
open_close(q, .....)
{
    /*
    * do some stuff
    */
    /*
    * Time to decommission the special allocator. Are there
    * any outstanding allocations from it?
    */
    mutex_enter(&mp);
    while (ebm > 0)
        cv_wait(&cvp, &mp);
    mutex_exit(&mp);
}
```
EXAMPLE 8-6 esballoc Example

Example (Continued)

}

Caution – The close routine must wait for all esballoc(9F) memory to be freed.

General ioctl Processing

Note – Please see the ioctl() section in the Writing Device Drivers for information on the 64-bit data structure macros.

When the stream head is called to process an ioctl(2) that it does not recognize, it creates an M_IOCTL message and sends it down the stream. An M_IOCTL message is a single M_IOCTL message block followed by zero or more M_DATA blocks. The M_IOCTL message block has the form of an iocblk(9S) structure. This structure contains the following elements.

int ioc_cmd; /* ioctls command type */
cred_t *ioc_cr; /* full credentials */
uint ioc_id; /* ioctl id */
uint ioc_count; /* byte cnt in data field */
int ioc_error; /* error code */
int ioc_rval; /* return value */

For an I_STR ioctl(2), ioc_cmd contains the command supplied by the user in the ic_cmd member of the striocctl structure defined in streamio(7I). For others, ioc_cmd contains the value of the cmd argument in the call to ioctl(2). The ioc_cr field contains the credentials of the user process.

The ioc_id field is a unique identifier used by the stream head to identify the ioctl and its response messages.

The ioc_count field indicates the number of bytes of data associated with this ioctl request. If the value is greater than zero, there will be one or more M_DATA mblks linked to the M_IOCTL mblk_cont field. If the value of the ioc_count field is zero, there will be no M_DATA mblk associated with the M_IOCTL mblk. If the value
of ioc_count is equal to the special value TRANSPARENT, then there is one M_DATA
mblk linked to this mblk and its contents will be the value of the argument passed to
ioctl(2). This can be a user address or numeric value. (see “Transparent ioctl
Processing” on page 72).

An M_IOCTL message is processed by the first module or driver that recognizes it. If a
module does not recognize the command, it should pass it down. If a driver does not
recognize the command, it should send a negative acknowledgement or M_IOCNAK
message upstream. In all circumstances, a module or driver processing an M_IOCTL
message must acknowledge it.

Modules must always pass unrecognized messages on. Drivers should negatively
acknowledge unrecognized ioctl(2) messages and free any other unrecognized
message.

If a module or driver finds an error in an M_IOCTL message for any reason, it must
produce a negative acknowledgement message. To do this, set the message type to
M_IOCNAK and send the message upstream. No data or return value can be sent. If
ioc_error is set to 0, the stream head causes the ioctl(2) to fail with EINVAL.
Optionally, the module can set ioc_error to an alternate error number.

ioc_error can be set to a nonzero value in both M_IOCACK and M_IOCNAK. This
causes the value to be returned as an error number to the process that sent the
ioctl(2).

If a module checks what the ioctl(2) of other modules below it are doing, the
module should not just search for a specific M_IOCTL on the write side, but also look
for M_IOCACK or M_IOCNAK on the read side. For example, suppose the module’s
write side sees TCSETA (see termio(7I)) and records what is being set. The read-side
processing knows that the module is waiting for an answer for the ioctl(2). When
the read-side processing sees an ack or nak, it checks for the same ioctl(2) by
checking the command (here TCSETA) and the ioc_id. If these match, the module
can use the information previously saved.

If you have the module check, for example, the TCSETA/TCGETA group of ioctl(2)
calls as they pass up or down a stream, you must never assume that because TCSETA
comes down it actually has a data buffer attached to it. The user can form TCSETA as
an I_STR call and accidentally give a NULL data buffer pointer. Always check b_cont
to see if it is NULL before using it as an index to the data block that goes with
M_IOCTL messages.

The TCGETA call, if formed as an I_STR call with a data buffer pointer set to a value
by the user, always has a data buffer attached to b_cont from the main message
block. Do not assume that the data block is missing and allocate a new buffer, then
assign b_cont to point to it, because the original buffer will be lost.
STREAMS ioctl Issues

Regular device drivers have user context in the ioctl(9E) call. However, in a STREAMS driver or module, the only guarantee of user context is in the open(9E) and close(9E) routines. Some indication of the calling context where data is used is therefore necessary.

**Note** – The notion of data models as well as new macros for handling data structure access are discussed in *Writing Device Drivers*. A STREAMS driver or module writer should use these flags and macros when dealing with structures that change size between data models.

A flag value that represents the data model of the entity invoking the operation has been added to the ioc_flag field of the iocblk(9S) structure, the cq_flag of the copyreq(9S) structure, and the cp_flag of the copyresp(9S) structure.

The data model flag is one of these possibilities:

- IOC_ILP32
- IOC_LP64

In addition, IOC_NATIVE is conditionally defined to match the data model of the kernel implementation.

By looking at the data model flag field of the relevant iocblk(9S), copyreq(9S), or copyresp(9S) structures, the STREAMS module can determine the best method of handling the data.

**Caution** – The layout of the iocblk, copyreq, and copyresp structures is different between the 32-bit and 64-bit kernels. Be cautious of any data structure overloading in the cp_private, cq_private, or cq_filler fields because alignment has changed.

I_STR ioctl Processing

The transparent and nontransparent methods implement ioctl(2) in the STREAMS driver or module itself, rather than in the stream head. I_STR ioctl(2) (also referred to as nontransparent ioctl(2)) is created when a user requests an I_STR ioctl(2) and specifies a pointer to a strioctl structure as the argument. For example, assuming that fd is an open lp STREAMS device and LP_CRLF is a valid option, the user could make a request by issuing the struct in the following example:

**EXAMPLE 8-6** Struct for Nontransparent ioctl

```c
struct strioctl *str;
short lp_opt = LP_CRLF;
```
EXAMPLE 8-6 Struct for Nontransparent ioctl (Continued)

```c
str.ic_cmd = SET_OPTIONS;
str.ic_timeout = -1;
str.ic_dp = (char *)&lp_opt;
str.ic_len = sizeof (lp_opt);
ioctl(fd, I_STR, &str);
```

On receipt of the I_STR ioctl(2) request, the stream head creates an M_IOCTL message. ioc_cmd is set to SET_OPTIONS, ioc_count is set to the value contained in ic_len (in this example sizeof (short)). An M_DATA mblk is linked to the M_IOCTL mblk and the data pointed to by ic_dp is copied into it (in this case LP_CRLF).

Example 8-7 illustrates processing associated with an I_STR ioctl(2). lpdoioctl illustrates driver M_IOCTL processing, which also applies to modules. lpdoioctl is called by lp write-side put or service procedure to process M_IOCTL messages. This example is for a driver.

EXAMPLE 8-7 I_STR ioctl(2) Driver

```c
static void
lpdoioctl (queue_t *q, mblk_t *mp)
{
    struct iocblk *iocp;
    struct lp *lp;
    lp = (struct lp *)q->q_ptr;
    /* 1st block contains iocblk structure */
    iocp = (struct iocblk *)mp->b_rptr;
    switch (iocp->ioc_cmd) {
        case SET_OPTIONS:
            /* Count should be exactly one short’s worth
             * (for this example) */
            if (iocp->ioc_count != sizeof(short))
                goto iocnak;
            if (mp->b_cont == NULL)
                goto lognak; /* not shown in this example */
            /* Actual data is in 2nd message block */
            iocp->ioc_error = lpsetopt (lp, *(short *)mp->b_cont->b_rptr);
            /* ACK the ioctl */
            mp->b_datap->db_type = M_IOCACK;
            iocp->ioc_count = 0;
            qreply(q, mp);
            break;
        default:
            iocnak:
            /* NAK the ioctl */
```
This example recognizes only one command, SET_OPTIONS. The ioc_count contains the number of user-supplied data bytes. ioc_count must equal the size of a short.

```
switch (iocp->ioc_cmd) {
    case SET_OPTIONS:
        /* Count should be exactly one short’s worth
         * (for this example) */
        if (iocp->ioc_count != sizeof(short))
            goto iocnak;
        if (mp->b_cont == NULL)
            goto lognak; /* not shown in this example */

        Once the command has been verified, lpsetopt is called to process the request.
        lpsetopt returns 0 if the request is satisfied, otherwise an error number is returned.
        If ioc_error is nonzero, on receipt of the acknowledgement the stream head returns
        -1 to the application’s ioctl request and sets errno to the value of ioc_error.

        /* Actual data is in 2nd message block */
        iocp->ioc_error = lpsetopt (lp, *(short *)mp->b_cont->b_rptr)

        The ioctl(2) is acknowledged. This includes changing the M_IOCTL message type to
        M_IOCACK and setting the ioc_count field to zero to indicate that no data is to be
        returned to the user. Finally, the message is sent upstream using qreply(9F).

        If ioc_count was left nonzero, the stream head would copy that many bytes from the
        second through the nth message blocks into the user buffer. You must set ioc_count
        if you want to pass any data back to the user.

        /* ACK the ioctl */
        mp->b_datap->db_type = M_IOCACK;
        iocp->ioc_count = 0;
        qreply(q, mp);
        break;
```

In the default case for unrecognized commands or malformed requests, a nak is generated. This is done by changing the message type to an M_IOCNAK and sending it back upstream.

```
default:
    iocnak:
        /* NAK the ioctl */
        mp->b_datap->db_type = M_IOCNAK;
        qreply(q, mp);
```

A module does not acknowledge (nak) an unrecognized command, but passes the message on. A module does not acknowledge (nak) a malformed request.
**Transparent ioctl**

Transparent ioctl are used from within a module to tell the stream head to perform a copyin or copyout on behalf of the module. The stream head must have knowledge of the data model of the caller in order to process the copyin and copyout properly. The user should use the ioctl macros as described in *Writing Device Drivers* when coding a STREAMS module that uses Transparent ioctl.

**Transparent ioctl Messages**

The transparent STREAMS ioctl(2) mechanism is needed because user context does not exist in modules and drivers when an ioctl(2) is processed. This prevents them from using the kernel ddi_copyin/ddi_copyout functions.

Transparent ioctl(2) enable you to write an application using conventional ioctl(2) semantics instead of the I_STR ioctl(2) and an strioctl structure. The difference between transparent and nontransparent ioctl(2) processing in a STREAMS driver and module is the way data is transferred from user to kernel space.

The transparent ioctl(2) mechanism allows backward compatibility for older programs. This transparency only works for modules and drivers that support transparent ioctl(2). Trying to use transparent ioctl(2) on a stream that does not support them makes the driver send an error message upstream, causing the ioctl to fail.

The following example illustrates the semantic difference between a nontransparent and transparent ioctl(2). A module that translates arbitrary character is pushed on the stream. The ioctl(2) specifies the translation to do (in this case all uppercase vowels are changed to lowercase). A transparent ioctl(2) uses XCASE instead of I_STR to inform the module directly.

Assume that fd points to a STREAMS device and that the conversion module has been pushed onto it. The semantics of a nontransparent I_STR command to inform the module to change the case of AEIOU are:

```c
strioctl.ic_cmd = XCASE;
strioctl.ic_timeout = 0;
strioctl.ic_dp = "AEIOU"
strioctl.ic_len = strlen(strioctl.ic_dp);
ioctl(fd, I_STR, &strioctl);
```

When the stream head receives the I_STR ioctl(2) it creates an M_IOCTL message with the ioc_cmd set to XCASE and the data specified by ic_dp. AEIOU is copied into the first mblk following the M_IOCTL mblk.

The same ioctl(2) specified as a transparent ioctl(2) is called as follows:

```c
ioctl(fd, XCASE, "AEIOU");
```
The stream head creates an M_IOCTL message with the ioc_cmd set to XCASE, but the data is not copied in. Instead, ioc_count is set to TRANSPARENT and the address of the user data is placed in the first mblk following the M_IOCTL mblk. The module then requests the stream head to copy in the data ("AEIOU") from user space.

Unlike the nontransparent ioctl(2), which can specify a timeout parameter, transparent ioctl(2) s block until processing is complete.

**Caution** – Incorrectly written drivers can cause applications using transparent ioctl(2) to block indefinitely.

Even though this process is simpler in the application, transparent ioctl adds considerable complexity to modules and drivers, and additional overhead to the time required to process the request.

The form of the M_IOCTL message generated by the stream head for a transparent ioctl(2) is a single M_IOCTL message block followed by one M_DATA block. The form of the iocblk(9S) structure in the M_IOCTL block is the same as described under general ioctl(2) processing. However, ioc_cmd is set to the value of the command argument in ioctl(2) and ioc_count is set to the special value of TRANSPARENT. The value TRANSPARENT distinguishes when an I_STR ioctl(2) can specify a value of ioc_cmd that is equivalent to the command argument of a transparent ioctl(2).

The b_cont block of the message contains the value of the arg parameter in the call.

**Caution** – If a module processes a specific ioc_cmd and does not validate the ioc_count field of the M_IOCTL message, the module breaks when transparent ioctl(2) is performed with the same command.

**Note** – Write modules and drivers to support both transparent and I_STR ioctl(2).

All M_IOCTL message types (M_COPYIN, M_COPYOUT, M_IOCDATA, M_IOCACK, and M_IOCNACK) have some similar data structures and sizes. You can reuse these structures instead of reallocating them. Note the similarities in the command type, credentials, and id.

The iocblk(9S) structure is contained in M_IOCTL, M_IOCACK and M_IOCNAK message types. For the transparent case, M_IOCTL has one M_DATA message linked to it. This message contains a copy of the argument passed to ioctl(2). Transparent processing of M_IOCACK and M_IONAK does not allow any messages to be linked to them.
The copyreq(9S) structure is contained in M_COPYIN and M_COPYOUT message types. The M_COPYIN message type must not have any other message linked to it (that is, b_cont == NULL). The M_COPYOUT message type must have one or more M_DATA messages linked to it. These messages contain the data to be copied into user space.

The copyresp(9S) structure is contained in M_IOCDATA response message types. These messages are generated by the stream head in response to an M_COPYIN or M_COPYOUT request. If the message is in response to an M_COPYOUT request, the message has no messages attached to it (b_cont is NULL). If the response is to an M_COPYIN, then zero or more M_DATA message types are attached to the M_IOCDATA message. These attached messages contain a copy of the user data requested by the M_COPYIN message.

The iocblk(9S), copyreq(9S), and copyresp(9S) structures contain a field indicating the type of ioctl(2) command, a pointer to the user’s credentials, and a unique identifier for this ioctl(2). These fields must be preserved.

The structure member cq_private is reserved for use by the module. M_COPYIN and M_COPYOUT request messages contain a cq_private field that can be set to contain state information for ioctl(2) processing (which identifies what the subsequent M_IOCDATA response message contains). This state is returned in cp_private in the M_IOCDATA message. This state information determines the next step in processing the message. Keeping the state in the message makes the message self-describing and simplifies the ioctl(2) processing.

For each piece of data that the module copies from user space, an M_COPYIN message is sent to the stream head. The M_COPYIN message specifies the user address (cq_addr) and number of bytes (cq_size) to copy from user space. The stream head responds to the M_COPYIN request with a M_IOCDATA message. The b_cont field of the M_IOCDATA mblk contains the contents pointed to by the M_COPYIN request. Likewise, for each piece of data that the module copies to user space, an M_COPYOUT message is sent to the stream head. Specify the user address (cq_addr) and number of bytes to copy (cq_size). The data to be copied is linked to the M_COPYOUT message as one or more M_DATA messages. The stream head responds to M_COPYOUT requests with an M_IOCDATA message, but b_cont is null.

After the module has finished processing the ioctl (that is, all M_COPYIN and M_COPYOUT requests have been processed), the ioctl(2) must be acknowledged with an M_IOCACK to indicate successful completion of the command or an M_IOCNAK to indicate failure.

If an error occurs when attempting to copy data to or from user address space, the stream head will set cp_rval in the M_IOCDATA message to the error number. In the event of such an error, the M_IOCDATA message should be freed by the module or driver. No acknowledgement of the ioctl(2) is sent in this case.
Transparent ioctl Examples

Following are three examples of transparent ioctl(2) processing. Example 8-8 and Example 8-9 illustrate how to use M_COPYIN to copy data from user space. Example 8-10 illustrates how to use M_COPYOUT to copy data to user space. Example 8-11 is a more complex example showing state transitions that combine M_COPYIN and M_COPYOUT.

In these examples the message blocks are reused to avoid the overhead of allocating, copying, and releasing messages. This is standard practice.

The stream head guarantees that the size of the message block containing an iocblk(9S) structure is large enough to also hold the copyreq(9S) and copyresp(9S) structures.

M_COPYIN Example

Note – Please see the copyin section in Writing Device Drivers for information on the 64-bit data structure macros.

Example 8-8 illustrates the processing of a transparent ioctl(2) request only (nontransparent request processing is not shown). In this example, the contents of a user buffer are to be transferred into the kernel as part of an ioctl call of the form

```c
ioctl(fd, SET_ADDR, (caddr_t) &bufadd);
```

where bufadd is a struct address whose elements are:

```c
define struct address {
    int ad_len; /* buffer length in bytes */
    caddr_t ad_addr; /* buffer address */
}
```

This requires two pairs of messages (request and response) following receipt of the M_IOCTL message: the first copyin(9F), shown in Example 8-8, copies the structure (address), and the second copyin(9F), shown in Example 8-9, copies the buffer (address.ad.addr). Two states are maintained and processed in this example: GETSTRUCT is for copying the address structure and GETADDR for copying the ad_addr of the structure.

The transparent part of the SET_ADDR M_IOCTL message processing requires that the address structure be copied from user address space. To accomplish this, the M_IOCTL message processing issues an M_COPYIN request to the stream head.

**EXAMPLE 8-8** M_COPYIN: Copy the address Structure

```c
struct address { /* same members as in user space */
    int ad_len; /* length in bytes */
```
EXAMPLE 8-8 M_COPYIN: Copy the address Structure

(Continued)

caddr_t ad_addr; /* buffer address */

/* state values (overloaded in private field) */
#define GETSTRUCT 0 /* address structure */
#define GETADDR 1 /* byte string from ad_addr */

static void xxioc(queue_t *q, mblk_t *mp);

static int
xxwput(queue_t *q, mblk_t *mp)
{
struct iocblk *iocbp;
struct copyreq *cqp;

switch (mp->b_datap->db_type) {
.
.
.
case M_IOCTL:
    /* Process ioctl commands */
    iocbp = (struct iocblk *)mp->b_rptr;
    switch (iocbp->ioc_cmd) {
    case SET_ADDR;
        if (iocbp->ioc_count != TRANSPARENT) {
            /* do non-transparent processing here */
            /* (not shown here) */
        } else {
            /* ioctl command is transparent */
            /* Reuse M_IOCTL block for first M_COPYIN
            request of address structure */
            cqp = (struct copyreq *)mp->b_rptr;
            /* Get user space structure address from linked
            M_DATA block */
            cqp->cq_addr = *(caddr_t *) mp->b_cont->b_rptr;
            cqp->cq_size = sizeof(struct address);
            /* MUST free linked blks */
            freemsg(mp->b_cont);
            mp->b_cont = NULL;
            /* identify response */
            cqp->cq_private = (mblk_t *)GETSTRUCT;
            /* Finish describing M_COPYIN message */
            cqp->cq_flag = 0;
            mp->b_datap->db_type = M_COPYIN;
            mp->b_wptr = mp->b_rptr + sizeof(struct copyreq);
            qreply(q, mp);
        break;
        default: /* M_IOCTL not for us */
    /* if module, pass on */
}
EXAMPLE 8-8 M_COPYIN: Copy the address Structure  
(Continued)

    /* if driver, nak ioctl */
    break;
} /* switch (iocbp->ioc_cmd) */
break;
case M_IOCDATA:
    /* all M_IOCDATA processing done here */
    xxic(q, mp);
    break;
}
return (0);
}

xxwput() verifies that the SET_ADDR is TRANSPARENT to avoid confusion with an I_STR ioctl(2), which uses a value of ioc_cmd equivalent to the command argument of a transparent ioctl(2).

The if else statement checks whether the size count is equal to TRANSPARENT. If it is equal, the message was not generated from an I_STR ioctl(2) and the else clause of the if else executes.

    if (iocbp->ioc_count != TRANSPARENT) {
        /* do non-transparent processing here (not shown here) */
    } else {

The mblk is reused and mapped into a copyreq(9S) structure. The user space address of bufadd is contained in the b_cont of the M_IOCTL mblk. This address and its size are copied into the copyreq(9S) message. The b_cont of the copy request mblk is not needed, so it is freed and then filled with NULL.

    cqp = (struct copyreq *)mp->b_rptr;
    /* Get user space structure address from linked M_DATA block */
    cqp->cq_addr = *(caddr_t *) mp->b_cont->b_rptr;
    cqp->cq_size = sizeof(struct address);
    /* MUST free linked blks */
    freemsg(mp->b_cont);
    mp->b_cont = NULL;

Caution – The layout of the iocblk, copyreq, and copyresp structures is different between 32-bit and 64-bit kernels. Be careful not to overload any data structure in the cp_private or the cq_filler fields because alignment has changed.

EXAMPLE 8-9 M_COPYIN: Copy the Buffer Address

    xxic(queue_t *q, mblk_t *mp) /* M_IOCDATA processing */
    {
        struct iocblk *iocbp;
        struct copyreq *cqp;
        struct copyresp *csp;
        
        Chapter 8 • STREAMS Kernel-Level Mechanisms  151
EXAMPLE 8-9 M_COPYIN: Copy the Buffer Address  (Continued)

```c
struct address *ap;
csp = (struct copyresp *)mp->b_rptr;
iocbp = (struct iocblk *)mp->b_rptr;

/* validate this M_IOCDATA is for this module */
switch (csp->cp_cmd) {
case SET_ADDR:
    if (csp->cp_rval){ /* GETSTRUCT or GETADDR fail */
        freemsg(mp);
        return;
    }
    switch ((int)csp->cp_private){ /* determine state */
        case GETSTRUCT: /* user structure has arrived */
            /* reuse M_IOCDATA block */
            mp->b_datap->db_type = M_COPYIN;
            mp->b_wptr = mp->b_rptr + sizeof (struct copyreq);
            cqp = (struct copyreq *)mp->b_rptr;
            /* user structure */
            ap = (struct address *)mp->b_cont->b_rptr;
            /* buffer length */
            cqp->cq_size = ap->ad_len;
            /* user space buffer address */
            cqp->cq_addr = ap->ad_addr;
            freemsg(mp->b_cont);
            mp->b_cont = NULL;
            cqp->cq_flag = 0;
            cqp->cp_private=(mblk_t *)GETADDR; /*nxt st*/
            qreply(q, mp);
            break;
        case GETADDR: /* user address is here */
            /* hypothetical routine */
            if (xx_set_addr(mp->b_cont) == FAILURE) {
                mp->b_datap->db_type = M_IOCNAK;
                iocbp->ioc_error = EIO;
            } else {
                mp->b_datap->db_type=M_IOCACK;/*success*/
                /* can have been overwritten */
                iocbp->ioc_error = 0;
                iocbp->ioc_count = 0;
                iocbp->ioc_rval = 0;
            }
            mp->b_wptr=mp->b_rptr + sizeof (struct iocblk);
            freemsg(mp->b_cont);
            mp->b_cont = NULL;
            qreply(q, mp);
            break;
        default: /* invalid state: can't happen */
            freemsg(mp->b_cont);
            mp->b_cont = NULL;
            mp->b_datap->db_type = M_IOCNAK;
```
EXAMPLE 8-9 \textit{M\_COPYIN: Copy the Buffer Address} \hspace{1cm} (Continued)

```c
mp->b_wptr = mp->rptr + sizeof (struct iocblk);
/* can have been overwritten */
ioctlbp->ioc_error = EINVAL;
qreply(q, mp);
break;
}
break; /* switch \{cp\_private\} */

default: /* \textit{M\_IOCDATA} not for us */
/* if module, pass message on */
/* if driver, free message */
break;
```

On receipt of the \textit{M\_IOCDATA} message for the \texttt{SET\_ADDR} command, \texttt{xxioc()} checks \texttt{cp\_rval}. If an error occurred during the \texttt{copyin} operation, \texttt{cp\_rval} is set. The \texttt{mblk} is freed and, if necessary, \texttt{xxioc()} cleans up from previous \texttt{M\_IOCTL} requests, freeing memory, resetting state variables, and so on. The stream head returns the appropriate error to the user.

```c
if (csp->cp_rval){ /* \texttt{GETSTRUCT} or \texttt{GETADDR} fail */
freemsg(mp);
return;
```

If no error occurred during the \texttt{copyin} operation, the \texttt{switch} statement determines whether to process the user structure, \texttt{GETSTRUCT}, or user address, \texttt{GETADDR}.

```c
switch ((int)csp->cp_private){ /*determine state*/
```

The \texttt{cp\_private} field set to \texttt{GETSTRUCT} indicates that the linked \texttt{b\_cont mblk} contains a copy of the user’s address structure. The example then copies the actual address specified in \texttt{address.ad\_addr}. The program issues another \texttt{M\_COPYIN} request to the stream head, but this time \texttt{cq\_private} contains \texttt{GETADDR} to indicate that the \texttt{M\_IOCDATA} response will contain a copy of \texttt{address.ad\_addr}. The stream head copies the information at the requested user address and sends it downstream in another, final \texttt{M\_IOCDATA} message.

```c
case GETSTRUCT: /* user structure has arrived */
/* reuse \textit{M\_IOCDATA} block */
mp->b_datap->db_type = M\_COPYIN;
mp->b_wptr = mp->b_rptr + sizeof (struct copyreq);
cqp = (struct copyreq *)mp->b_rptr;
/* user structure */
ap = (struct address *)mp->b_cont->b_rptr;
/* buffer length */
cqp->cq_size = ap->ad_len;
/* user space buffer address */
cqp->cq_addr = ap->ad_addr;
freemsg(mp->b_cont);
mp->b_cont = NULL;
cqp->cq_flag = 0;
cqp->cp_private=(mblk_t *)GETADDR; /*nxt st*/
```
The final `M_IOCDATA` message arrives from the stream head. `cp_private` contains `GETADDR`. The `ad_addr` data is contained in the `b_cont` link of the mblk. If the address is successfully processed by `xx_set_addr()` (not shown here), the message is acknowledged with an `M_IOCACK` message. If `xx_set_addr()` fails, the message is rejected with an `M_IOCNAK` message. `xx_set_addr()` processes the user address from the `ioctl(2)`.

After the final `M_IOCDATA` message is processed, the module acknowledges the `ioctl(2)` to let the stream head know that processing is complete. This is done by sending an `M_IOCACK` message upstream if the request was successfully processed. Always set `ioc_error` to zero, otherwise an error code could be passed to the user application. Set `ioc_rval` and `ioc_count` to zero to reflect that a return value of 0 and no data is to be passed upstream. If the request cannot be processed, either an `M_IOCNAK` or `M_IOCACK` can be sent upstream with an appropriate error number. When sending an `M_IOCNAK` or `M_IOCACK`, freeing the linked `M_DATA` block is not mandatory. It is more efficient to use the stream head handle to free the linked `M_DATA` block.

If `ioc_error` is set in an `M_IOCNAK` or `M_IOCACK` message, this error code will be returned to the user. If no error code is set in an `M_IOCNAK` message, `EINVAL` will be returned to the user.

```c
qreply(q, mp);
break;
```

        iocbp->ioc_error = EIO;
    } else {
        mp->b_datap->db_type=M_IOCACK;/*success*/
        /* can have been overwritten */
        iocbp->ioc_error = 0;
        iocbp->ioc_count = 0;
        iocbp->ioc_rval = 0;
    }
    mp->b_wptr=mp->b_rptr + sizeof (struct ioclk);
freemsg(mp->b_cont);
mp->b_cont = NULL;
qreply(q, mp);
break;
```

---

**M_COPYOUT Example**

**Note** – Please see the copyout section in *Writing Device Drivers* for information on the 64-bit data structure macros.
The following code excerpts return option values for the STREAMS device by placing them in the user’s options structure. This is done by a transparent ioctl(2) call of the form

```
struct options optadd;
ioctl(fd, GET_OPTIONS,(caddr_t) &optadd)
```

or by a nontransparent I_STR call

```
struct strioctl opts_strioctl;
structure options optadd;

opts_strioctl.ic_cmd = GET_OPTIONS;
opts_strioctl.ic_timeout = -1
opts_strioctl.ic_len = sizeof (struct options);
opts_strioctl.ic_dp = (char *)&optadd;
ioctl(fd, I_STR, (caddr_t) &opts_strioctl)
```

In the nontransparent I_STR case, opts_strioctl.ic_dp points to the options structure optadd.

Example 8-7 illustrates support of both the I_STR and transparent forms of ioctl(2). The transparent form requires a single M_COPYOUT message following receipt of the M_IOCTL to copy out the contents of the structure. xxwput() is the write-side put procedure of module or driver xx.

**EXAMPLE 8-10 M_COPYOUT**

```
struct options { /* same members as in user space */
    int     op_one;
    int     op_two;
    short   op_three;
    long    op_four;
};

static int
xxwput (queue_t *q, mblk_t *mp)
{
    struct iocblk *iocbp;
    struct copyreq *cqp;
    struct copyresp *csp;
    int transparent = 0;

    switch (mp->b_datap->db_type) {
        ...
        case M_IOCTL:
            iocbp = (struct iocblk *)mp->b_rptr;
            switch (iocbp->ioc_cmd) {
                case GET_OPTIONS:
                    if (iocbp->ioc_count == TRANSPARENT) {
                        transparent = 1;
                        cqp = (struct copyreq *)mp->b_rptr;
```
cqp->cq_size = sizeof(struct options);
/* Get struct address from 
linked M_DATA block */
cqp->cq_addr = (caddr_t) *(caddr_t *)mp->b_cont->b_rptr;
cqp->cq_flag = 0;
/* No state necessary - we will only ever
* get one M_IOCTLDATA from the Stream head
* indicating success or failure for
* the copyout */
}
if (mp->b_cont)
freemsg(mp->b_cont);
if ((mp->b_cont = allocb(sizeof(struct options),
BPRI_MED)) == NULL) {
mp->b_datap->db_type = M_IOCNAK;
iocbp->ioc_error = EAGAIN;
qreply(q, mp);
break;
}
/* hypothetical routine */
xx_get_options(mp->b_cont);
if (transparent) {
mp->b_datap->db_type = M_COPYOUT;
mp->b_wptr = mp->b_rptr + sizeof(struct copyreq);
} else {
mp->b_datap->db_type = M_IOCACK;
iocbp->ioc_count = sizeof(struct options);
}
qreply(q, mp);
break;

default: /* M_IOCTL not for us */
/*if module, pass on;if driver, nak ioctl*/
break;
} /* switch (iocbp->ioc_cmd) */
break;

case M_IOCTLDATA:
csp = (struct copyresp *)mp->b_rptr;
/* M_IOCTLDATA not for us */
if (csp->cmd != GET_OPTIONS) {
/*if module/pass on, if driver/free message*/
break;
}
if (csp->cp_rval) {
freemsg(mp); /* failure */
return (0);
}
/* Data successfully copied out, ack */
/* reuse M_IOCTLDATA for ack */
EXAMPLE 8–10 M_COPYOUT (Continued)

mp->b_datap->db_type = M_IOCACK;
mp->b_wptr = mp->b_rptr + sizeof(struct iocblk);
/* can have been overwritten */
iocbp->ioc_error = 0;
iocbp->ioc_count = 0;
iocbp->ioc_rval = 0;
qreply(q, mp);
break;
.
.
} /* switch (mp->b_datap->db_type) */
return (0);

xxwput() first checks whether the ioctl(2) command is transparent. If it is, the
message is reused as an M_COPYOUT copy request message. The pointer to the
receiving buffer is in the linked message and is copied into cq_addr. Because only a
single copy out is being done, no state information needs to be stored in cq_private.
The original linked message is freed, in case it isn’t big enough to hold the request.

if (iocbp->ioc_count == TRANSPARENT) {
  transparent = 1;
cqp = (struct copyreq *)mp->b_rptr;
cqp->cq_size = sizeof(struct options);
/* Get struct address from linked M_DATA block */
cqp->cq_addr = *(caddr_t *)(caddr_t *)mp->b_cont->b_rptr;
cqp->cq_flag = 0;
/* No state necessary - we will only ever get one
 * M_IOCDATA from the Stream head indicating
 * success or failure for the copyout */
}
if (mp->b_cont) {
  freemsg(mp->b_cont);
}

As an optimization, the following code checks the size of the message for reuse:

mp->b_cont->b_datap->db_lim
- mp->b_cont->b_datap->db_base >= sizeof (struct options)

**Note — Hardening Information.** After message reuse, make sure to retain the relation:

\[
db_base \leq b_rptr \leq b_wptr \leq db_lim
\]
A new linked message is allocated to hold the option request. When using the transparent ioctl(2) M_COPYOUT command, data contained in the linked message is passed to the stream head. The stream head will copy the data to the user's address space and issue an M_IOCDATA in response to the M_COPYOUT message, which the module must acknowledge in an M_IOCACK message.

```c
/* hypothetical routine */
xx_get_options(mp->b_cont);
if (transparent) {
    mp->b_datap->db_type = M_COPYOUT;
    mp->b_wptr = mp->b_rptr + sizeof(struct copyreq);
} else {
    mp->b_datap->db_type = M_IOCACK;
    iocbp->ioc_count = sizeof(struct options);
}
```

If the message is not transparent (is issued through an I_STR ioctl(2)), the data is sent with the M_IOCACK acknowledgement message and copied into the buffer specified by the stroct data structure, ioc_error, ioc_count, and ioc_rval are cleared to prevent any stale data from being passed back to the stream head.

```c
/* reuse M_IOCDATA for ack */
mp->b_datap->db_type = M_IOCACK;
mp->b_wptr = mp->b_rptr + sizeof(struct iocblk);
// can have been overwritten */
iocbp->ioc_error = 0;
iocbp->ioc_count = 0;
iocbp->ioc_rval = 0;
qreply(q, mp);
break;
```

**Bidirectional Data Transfer Example**

Example 8–11 illustrates bidirectional data transfer between the kernel and application during transparent ioctl(2) processing. It also shows how to use more complex state information.

The user wants to send and receive data from user buffers as part of a transparent ioctl(2) call of the form:

```
ioctl(fd, XX_IOCTL, (caddr_t) &addr_xxdata)
```

**EXAMPLE 8-11 Bidirectional Data Transfer**

```c
struct xxdata {
    int x_inlen; /* number of bytes copied in */
    caddr_t x_inaddr; /* buf addr of data copied in */
    int x_outlen; /* number of bytes copied out */
    caddr_t x_outaddr; /* buf addr of data copied out */
};
/* State information for ioctl processing */
struct state {
```
EXAMPLE 8–11 Bidirectional Data Transfer  (Continued)

```c
int st_state; /* see below */
struct xxdata st_data; /* see above */
}; /* state values */
#define GETSTRUC 0 /* get xxdata structure */
#define GETINDATA 1 /* get data from x_inaddr */
#define PUTOUTDATA 2 /* get response from M_COPYOUT */

static void xxioc(queue_t *q, mblk_t *mp);

static int
xxwput (queue_t *q, mblk_t *mp) {
    struct iocblk *iocbp;
    struct copyreq *cqp;
    struct state *stp;
    mblk_t *tmp;

    switch (mp->b_datap->db_type) {
        case M_IOCTL:
            iocbp = (struct iocblk *)mp->b_rptr;
            switch (iocbp->ioc_cmd) {
                case XX_IOCTL:
                    /* do non-transparent processing. (See I_STR ioctl */
                    /* processing discussed in previous section.) */
                    /*Reuse M_IOCTL block for M_COPYIN request*/
                    cqp = (struct copyreq *)mp->b_rptr;
                    /* Get structure’s user address from */
                    /* linked M_DATA block */
                    cqp->cq_addr = (caddr_t) *(long *)mp->b_cont->b_rptr;
                    freemsg(mp->b_cont);
                    mp->b_cont = NULL;

                    /* Allocate state buffer */
                    if (!tmp = allocb(sizeof(struct state),
                                    BPRI_MED)) == NULL) {
                        mp->b_datap->db_type = M_IOCNAK;
                        iocbp->ioc_error = EAGAIN;
                        qreply(q, mp);
                        break;
                    }
                    tmp->b_wptr += sizeof(struct state);
                    stp = (struct state *)tmp->b_rptr;
                    stp->st_state = GETSTRUCT;
    }
}
```
cqp->cq_private = tmp;
/* Finish describing M_COPYIN message */
cqp->cq_size = sizeof(struct xxdata);
cqp->cq_flag = 0;
mp->b_datap->db_type = M_COPYIN;
mp->b_wptr=mp->b_rptr+sizeof(struct copyreq);
qreply(q, mp);
broadcast;

default: /* M_IOCTL not for us */
/* if module, pass on */
/* if driver, nak ioctl */
break;

} /* switch (iocbp->ioc_cmd) */
broadcast;

case M_IOCDATA:
    xxioc(q, mp); /* all M_IOCDATA processing here*/
broadcast;
    .
    .
    .
} /* switch (mp->b_datap->db_type) */

Three pairs of messages are required following the M_IOCTL message:
1. case GETSTRUCT copies the structure into the message buffer.
2. case GETINDATA copies the user buffer into the message buffer.
3. case PUTOUTDATA copies the second message buffer into the user buffer.

xxwput() is the write-side put procedure for module or driver xx. xxwput allocates a message block to contain the state structure and reuses the M_IOCTL to create an M_COPYIN message to read in the xxdata structure.

M_IOCDATA processing is done in xxioc() as shown in the following example:

EXAMPLE 8-12 M_IOCDATA Processing

xxioc(
    queue_t *q,
    mblk_t *mp)
{
    struct iocblk *iocbp;
    struct copyreq *cqp;
    struct copyresp *csp;
    struct state *stp;
    mblk_t *xx_indata();
EXAMPLE 8–12 M_IOCDATA Processing (Continued)

csp = (struct copyresp *)mp->b_rptr;
iocbp = (struct iocblk *)mp->b_rptr;
switch (csp->cp_cmd) {
  case XX_IOCTL:
    if (csp->cp_rval) { /* failure */
      if (csp->cp_private) /* state structure */
        freemsg(csp->cp_private);
        freemsg(mp);
        return;
    }
    stp = (struct state *)csp->cp_private->b_rptr;
    switch (stp->st_state) {
      case GETSTRUCT: /* xxdata structure copied in */
        /* save structure */
        stp->st_data = *(struct xxdata *)mp->b_cont->b_rptr;
        freemsg(mp->b_cont);
        mp->b_cont = NULL;
        /* Reuse M_IOCDATA to copyin data */
        mp->b_datap->db_type = M_COPYIN;
        cqp = (struct copyreq *)mp->b_rptr;
        cqp->cq_size = stp->st_data.x_inlen;
        cqp->cq_addr = stp->st_data.x_inaddr;
        cqp->cq_flag = 0;
        stp->st_state = GETINDATA; /* next state */
        qreply(q, mp);
        break;
      case GETINDATA: /* data successfully copied in */
        /* Process input, return output */
        if ((mp->b_cont = xx_indata(mp->b_cont))
            == NULL) { /* hypothetical */
          /* fail xx_indata */
          mp->b_datap->db_type = M_IOCNAK;
          mp->b_wptr = mp->b_rptr +
            offsetof(struct iocblk);

          break;
        }
        mp->b_datap->db_type = M_COPYOUT;
        cqp = (struct copyreq *)mp->b_rptr;
        cqp->cq_size = min(msgdsize(mp->b_cont),
                        stp->st_data.x_outlen);
        cqp->cq_addr = stp->st_data.x_outaddr;
        cqp->cq_flag = 0;
        stp->st_state = PUTOUTDATA; /* next state */
        qreply(q, mp);
        break;
    }
  case GETINDATA: /* data successfully copied in */
    /* Process input, return output */
    if ((mp->b_cont = xx_indata(mp->b_cont))
        == NULL) { /* hypothetical */
      /* fail xx_indata */
      mp->b_datap->db_type = M_IOCNAK;
      mp->b_wptr = mp->b_rptr +
        offsetof(struct iocblk);
      iocbp->ioc_error = EIO;
      qreply(q, mp);
      break;
    }
    mp->b_datap->db_type = M_COPYOUT;
    cqp = (struct copyreq *)mp->b_rptr;
    cqp->cq_size = min(msgdsize(mp->b_cont),
                      stp->st_data.x_outlen);
    cqp->cq_addr = stp->st_data.x_outaddr;
    cqp->cq_flag = 0;
    stp->st_state = PUTOUTDATA; /* next state */
    qreply(q, mp);
    break;
}
At case GETSTRUCT, the user xxdata structure is copied into the module’s state structure (pointed to by cp_private in the message) and the M_IOCDATA message is reused to create a second M_COPYIN message to read the user data.

At case GETINDATA, the input user data is processed by xx_indata (not supplied in the example), which frees the linked M_DATA block and returns the output data message block. The M_IOCDATA message is reused to create an M_COPYOUT message to write the user data.

At case PUTOUTDATA, the message block containing the state structure is freed and an acknowledgement is sent upstream.

Care must be taken at the “can’t happen” default case since the message block containing the state structure (cp_private) is not returned to the pool because it might not be valid. This might result in a lost block. The ASSERT helps find errors in the module if a “can’t happen” condition occurs.

I_LIST ioctl(2) Example

The I_LIST ioctl(2) lists the drivers and module in a stream.
EXAMPLE 8-13 List a Stream’s Drivers and Modules

```c
#include <stdio.h>
#include <string.h>
#include <stropts.h>
#include <sys/types.h>
#include <sys/socket.h>
main(int argc, const char **argv) {
    int s, i;
    int mods;
    struct str_list mod_list;
    struct str_mlist *mlist;
    /* Get a socket... */
    if((s = socket(AF_INET, SOCK_STREAM, 0)) <= 0) {
        perror("socket: ");
        exit(1);
    }
    /* Determine the number of modules in the stream. */
    if((mods = ioctl(s, I_LIST, 0)) < 0) {
        perror("I_LIST ioctl");
        exit(1);
    } else {
        printf("%d modules\n", mods);
        mlist = (struct str_mlist *) calloc(mods, sizeof(struct str_mlist));
        if(mlist == 0) {
            perror("malloc failure");
            exit(1);
        }
        mod_list.sl_modlist = mlist;
        mod_list.sl_nmods = mods;
        /* Do the ioctl and get the module names. */
        if(ioctl(s, I_LIST, &mod_list) < 0) {
            perror("I_LIST ioctl fetch");
            exit(1);
        }
        /* Print out the name of the modules */
        for(i = 0; i < mods; i++) {
            printf("s: %s\n", mod_list.sl_modlist[i].l_name);
        }
        free(mlist);
    }
}
```
M_FLUSH Message Handling

All modules and drivers are expected to handle M_FLUSH messages. An M_FLUSH message can originate at the stream head or from a module or a driver. The user can cause data to be flushed from queued messages of a stream by submitting an I_FLUSH ioctl(2). Data can be flushed from the read side, write side, or both sides of a stream.

```c
ioctl(fd, I_FLUSH, arg);
```

The first byte of the M_FLUSH message is an option flag. The following table describes the possible values for this flag.

**TABLE 8-1  M_FLUSH Arguments and bi_flag Values**

<table>
<thead>
<tr>
<th>Flag</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>FLUSHR</td>
<td>Flush read side of stream</td>
</tr>
<tr>
<td>FLUSHW</td>
<td>Flush write queue</td>
</tr>
<tr>
<td>FLUSHRW</td>
<td>Flush both, read and write, queues</td>
</tr>
<tr>
<td>FLUSHBAND</td>
<td>Flush a specified priority band only</td>
</tr>
</tbody>
</table>

Flushing According to Priority Bands

In addition to being able to flush all the data from a queue, a specific band can be flushed using the I_FLUSHBAND ioctl(2).

```c
ioctl(fd, I_FLUSHBAND, bandp);
```

The ioctl(2) is passed a pointer to a bandinfo structure. The bi_pri field indicates the band priority to be flushed (from 0 to 255). The bi_flag field indicates the type of flushing to be done. The legal values for bi_flag are defined in Table 8-1. bandinfo has the following format:

```c
struct bandinfo {
    unsigned char bi_pri;
    in bi_flag;
};
```
See “M_FLUSH” on page 321 for details on how modules and drivers should handle flush band requests.

Figure 8–1 and Figure 8–2 further demonstrate flushing the entire stream due to a line break. Figure 8–1 shows the flushing of the write side of a stream, and Figure 8–2 shows the flushing of the read side of a stream.

The following discussion describes the sequence of events shown in Figure 8–1 (dotted lines mean flushed queues):

1. A break is detected by a driver.
2. The driver generates an M_BREAK message and sends it upstream.
3. The module translates the M_BREAK into an M_FLUSH message with FLUSHW set, then sends it upstream.
4. The stream head does not flush the write queue (no messages are ever queued there).
5. The stream head turns the message around (sends it down the write side).
6. The module flushes its write queue.
7. The message is passed downstream.
8. The driver flushes its write queue and frees the message.

Figure 8–2 shows flushing the read side of a stream.
The following discussion describes the sequence of events.

1. After generating the first M_FLUSH message, the module generates an M_FLUSH with FLUSHR set and sends it downstream.
2. The driver flushes its read queue.
3. The driver turns the message around (sends it up the read side).
4. The module flushes its read queue.
5. The message is passed upstream.
6. The stream head flushes the read queue and frees the message.

The following code shows line discipline module for flush handling.

**EXAMPLE 8-14 Line Discipline Module for Flush Handling**

```c
static int
ld_put(
    queue_t *q,  /* pointer to read/write queue */
    mblk_t *mp)  /* pointer to message being passed */
{
    switch (mp->b_datap->db_type) {
        default:
            putq(q, mp); /* queue everything */
            return (0); /* except flush */
        case M_FLUSH:
            if (*mp->b_rptr & FLUSHW) /* flush write q */
                flushq(WR(q), FLUSHDATA);
            if (*mp->b_rptr & FLUSHR) /* flush read q */
                flushq(RD(q), FLUSHDATA);
            putnext(q, mp); /* pass it on */
            return(0);
    }
}
```

FIGURE 8-2 Flushing the Read Side of a Stream
The above example uses FLUSHDATA as the argument to flushq. This code will flush data type messages (M_DATA, M_DELAY, M_PROTO and M_PCPROTO) only. Flushing non-data messages, such as M_IOCTL, M_IOCACK, and M_IOCNAK, might flush messages that contain critical state in the stream. If an M_IOCACK message is flushed, a thread waiting at the stream head for a non-data message response will never receive it. Care should be taken when using flushq.

The stream head turns around the M_FLUSH message if FLUSHW is set (FLUSHR is cleared). A driver turns around M_FLUSH if FLUSHR is set (should mask off FLUSHW).

### Flushing Priority Band

The bi_flag field is one of FLUSHR, FLUSHW, or FLUSHRW.

The following example shows flushing according to the priority band.

```
EXAMPLE 8–15 Priority Band Data Flush Handling

queue_t *rdq; /* read queue */
queue_t *wrq; /* write queue */

case M_FLUSH:
    if (*bp->b_rptr & FLUSHBAND) {
        if (*bp->b_rptr & FLUSHW)
            flushband(wrq, FLUSHDATA, *(bp->b_rptr + 1));
        if (*bp->b_rptr & FLUSHR)
            flushband(rdq, FLUSHDATA, *(bp->b_rptr + 1));
    } else {
        if (*bp->b_rptr & FLUSHW)
            flushq(wrq, FLUSHDATA);
        if (*bp->b_rptr & FLUSHR)
            flushq(rdq, FLUSHDATA);
    }
/*
 * modules pass the message on;
 * drivers shut off FLUSHW and loop the message
 * up the read-side if FLUSHR is set; otherwise,
 * drivers free the message.
 */
break;
```

Note that modules and drivers are not required to treat messages as flowing in separate bands. Modules and drivers can view the queue as having only two bands of flow, normal and high priority. However, the latter alternative flushes the entire queue whenever an M_FLUSH message is received.
The field `b_flag` of the `msgb` structure provides a way for the stream head to stop `M_FLUSH` messages from being reflected forever when the stream is used as a pipe. When the stream head receives an `M_FLUSH` message, it sets the `MSGNOLOOP` flag in the `b_flag` field before reflecting the message down the write side of the stream. If the stream head receives an `M_FLUSH` message with this flag set, the message is freed rather than reflected.

**FIGURE 8-3 Interfaces Affecting Drivers**

The set of STREAMS utilities available to drivers are listed in Appendix B. No system-defined macros that manipulate global kernel data or introduce structure-size dependencies are permitted in these utilities. So, some utilities that have been implemented as `macros` in the prior Solaris operating environment releases are implemented as `functions` in the SunOS 5 system. This does not preclude the existence of both `macro` and `function` versions of these utilities. Driver source code should include a header file that picks up `function` declarations while the core operating system source should include a header file that defines the `macros`. With the DKI interface, the following STREAMS utilities are implemented as C programming language functions: `datamsg(9F)`, `OTHERQ(9F)`, `putnext(9F)`, `RD(9F)`, and `WR(9F)`.
Replacing macros such as RD with function equivalents in the driver source code allows driver objects to be insulated from changes in the data structures and their size, increasing the useful lifetime of driver source code and objects. Multithreaded drivers are also protected against changes in implementation-specific STREAMS synchronization.

The DKI defines an interface suitable for drivers and there is no need for drivers to access global kernel data structures directly. The kernel function `drv_getparm(9F)` fetches information from these structures. This restriction has an important consequence. Because drivers are not permitted to access global kernel data structures directly, changes in the contents/offsets of information within these structures will not break objects.

### Driver and Module Service Interfaces

STREAMS provides the means to implement a service interface between any two components in a stream, and between a user process and the topmost module in the stream. A service interface is a set of primitives defined at the boundary between a service user and a service provider (see Figure 8–5). Rules define a service and the allowable state transitions that result as these primitives are passed between the user and the provider. These rules are typically represented by a state machine. In STREAMS, the service user and provider are implemented in a module, driver, or user process. The primitives are carried bidirectionally between a service user and provider in `M_PROTO` and `M_PCPROTO` messages.

`PROTO` messages (`M_PROTO` and `M_PCPROTO`) can be multiblock. The second through last blocks are of type `M_DATA`. The first block in a PROTO message contains the control part of the primitive in a form agreed upon by the user and provider. The block is not intended to carry protocol headers. (Upstream PROTO messages can have multiple PROTO blocks at the start of the message, although its use is not recommended. `getmsg(2)` compacts the blocks into a single control part when sending to a user process.) The `M_DATA` block contains any data part associated with the primitive. The data part can be processed in a module that receives it, or it can be sent to the next stream component, along with any data generated by the module. The contents of `PROTO` messages and their allowable sequences are determined by the service interface specification.

`PROTO` messages can be sent bidirectionally (upstream and downstream) on a stream and between a stream and a user process. `putmsg(2)` and `getmsg(2)` system calls are analogous to `write(2)` and `read(2)` except that the former allow both data and control parts to be (separately) passed, and they retain the message boundaries across the user-stream interface. `putmsg(2)` and `getmsg(2)` separately copy the control part (`M_PROTO` or `M_PCPROTO` block) and data part (`M_DATA` blocks) between the stream and user process.
An `M_PCPROTO` message normally is used to acknowledge primitives composed of other messages. `M_PCPROTO` ensures that the acknowledgement reaches the service user before any other message. If the service user is a user process, the stream head will only store a single `M_PCPROTO` message, and discard subsequent `M_PCPROTO` messages until the first one is read with `getmsg(2)`.

![Diagram](image)

**FIGURE 8–4 Protocol Substitution**

By defining a service interface through which applications interact with a transport protocol, you can substitute a different protocol below the service interface that is completely transparent to the application. In Figure 8–4, the same application can run over the Transmission Control Protocol (TCP) and the ISO transport protocol. Of course, the service interface must define a set of services common to both protocols.

The three components of any service interface are the service user, the service provider, and the service interface itself, as seen in Figure 8–5.
Typically, an application makes requests of a service provider using some well-defined service primitive. Responses and event indications are also passed from the provider to the user using service primitives.

Each service interface primitive is a distinct STREAMS message that has two parts, a control part and a data part. The control part contains information that identifies the primitive and includes all necessary parameters. The data part contains user data associated with that primitive.

An example of a service interface primitive is a transport protocol connect request. This primitive requests the transport protocol service provider to establish a connection with another transport user. The parameters associated with this primitive can include a destination protocol address and specific protocol options to be associated with that connection. Some transport protocols also allow a user to send data with the connect request. A STREAMS message is used to define this primitive. The control part identifies the primitive as a connect request and includes the protocol address and options. The data part contains the associated user data.

Service Interface Library Example

The service interface library example presented here includes four functions that enable a user do the following:

- Establish a stream to the service provider and bind a protocol address to the stream
- Send data to a remote user
- Receive data from a remote user
Close the stream connected to the provider

First, the structure and constant definitions required by the library are shown in the following code. These typically reside in a header file associated with the service interface.

The defined structures describe the contents of the control part of each service interface message passed between the service user and service provider. The first field of each control part defines the type of primitive being passed.

EXAMPLE 8-16 Service Interface Library Header File

```c
/*@ * Primitives initiated by the service user. */
#define BIND_REQ 1 /* bind request */
#define UNITDATA_REQ 2 /* unitdata request */

/*@ * Primitives initiated by the service provider. */
#define OK_ACK 3 /* bind acknowledgement */
#define ERROR_ACK 4 /* error acknowledgement */
#define UNITDATA_IND 5 /* unitdata indication */

/*@ * The following structure definitions define the format * of the control part of the service interface message * of the above primitives. */
struct bind_req { /* bind request */
    t_scalar_t PRIM_type; /* always BIND_REQ */
    t_uscalar_t BIND_addr; /* addr to bind */
};
struct unitdata_req { /* unitdata request */
    t_scalar_t PRIM_type; /* always UNITDATA_REQ */
    t_scalar_t DEST_addr; /* destination addr */
};
struct ok_ack { /* positiv acknowledgement*/
    t_scalar_t PRIM_type; /* always OK_ACK */
};
struct error_ack { /* error acknowledgement */
    t_scalar_t PRIM_type; /* always ERROR_ACK */
    t_scalar_t UNIX_error; /* UNIX systemerror code */
};
struct unitdata_ind { /* unitdata indication */
    t_scalar_t PRIM_type; /* always UNITDATA_IND */
    t_scalar_t SRC_addr; /* source addr */
};
/*@ * union of all primitives */
```
EXAMPLE 8–16 Service Interface Library Header File  (Continued)

union primitives {
    t_scalar_t type;
    struct bind_req bind_req;
    struct unitdata_req unitdata_req;
    struct ok_ack ok_ack;
    struct error_ack error_ack;
    struct unitdata_ind unitdata_ind;
};

/* header files needed by library */
#include <stropts.h>
#include <stdio.h>
#include <errno.h>

Five primitives are defined. The first two represent requests from the service user to
the service provider.

BIND_REQ Asks the provider to bind a specified protocol address. It requires
an acknowledgement from the provider to verify that the contents
of the request were syntactically correct.

UNITDATA_REQ Asks the provider to send data to the specified destination
address. It does not require an acknowledgement from the
provider.

The three other primitives represent acknowledgements of requests, or indications of
incoming events, and are passed from the service provider to the service user.

OK_ACK Informs the user that a previous bind request was received
successfully by the service provider.

ERROR_ACK Informs the user that a nonfatal error was found in the previous
bind request. It indicates that no action was taken with the
primitive that caused the error.

UNITDATA_IND Indicates that data destined for the user has arrived.

Module Service Interface Example

The following code is part of a module that illustrates the concept of a service
interface. The module implements a simple service interface and mirrors the service
interface library example. The following rules pertain to service interfaces.

- Modules and drivers that support a service interface must act upon all PROTO
  messages and not pass them through.
- Modules can be inserted between a service user and a service provider to
  manipulate the data part as it passes between them. However, these modules
  cannot alter the contents of the control part (PROTO block, first message block) nor
alter the boundaries of the control or data parts. That is, the message blocks comprising the data part can be changed, but the message cannot be split into separate messages nor combined with other messages.

In addition, modules and drivers must observe the rule that high-priority messages are not subject to flow control and forward them accordingly.

**Service Primitive Declarations**

The service interface primitives are defined in the declarations shown in the following example:

**EXAMPLE 8-17 Service Primitive Declarations**

```c
#include <sys/types.h>
#include <sys/param.h>
#include <sys/stream.h>
#include <sys/errno.h>

/* Primitives initiated by the service user */

#define BIND_REQ 1 /* bind request */
define UNIDATA_REQ 2 /* unitdata request */

/* Primitives initiated by the service provider */

#define OK_ACK 3 /* bind acknowledgement */
define ERROR_ACK 4 /* error acknowledgement */
define UNIDATA_IND 5 /* unitdata indication */

/* The following structures define the format of the stream message block of the above primitives. */

struct bind_req { /* bind request */
  t_scalar_t PRIM_type; /* always BIND_REQ */
  t_uscalar_t BIND_addr; /* addr to bind */
};
struct unitdata_req { /* unitdata request */
  t_scalar_t PRIM_type; /* always UNIDATA_REQ */
  t_scalar_t DEST_addr; /* dest addr */
};
struct ok_ack { /* ok acknowledgement */
  t_scalar_t PRIM_type; /* always OK_ACK */
};
struct error_ack { /* error acknowledgement */
  t_scalar_t PRIM_type; /* always ERROR_ACK */
  t_scalar_t UNIX_error; /* UNIX system error code */
};
struct unitdata_ind { /* unitdata indication */
  t_scalar_t PRIM_type; /* always UNIDATA_IND */
  t_scalar_t SRC_addr; /* source addr */
```
union primitives { /* union of all primitives */
    long type;
    struct bind_req bind_req;
    struct unitdata_req unitdata_req;
    struct ok_ack ok_ack;
    struct error_ack error_ack;
    struct unitdata_ind unitdata_ind;
};

struct dgproto { /* structure minor device */
    short state; /* current provider state */
    long addr; /* net address */
};

/* Provider states */
#define IDLE 0
#define BOUND 1

In general, the M_PROTO or M_PCPROTO block is described by a data structure containing the service interface information in this example, union primitives.

The module recognizes two commands:

**BIND_REQ**  
Give this stream a protocol address (for example, give it a name on the network). After a BIND_REQ is completed, data from other senders will find their way through the network to this particular stream.

**UNITDATA_REQ**  
Send data to the specified address.

The module generates three messages:

**OK_ACK**  
A positive acknowledgement (ack) of BIND_REQ.

**ERROR_ACK**  
A negative acknowledgement (nak) of BIND_REQ.

**UNITDATA_IND**  
Data from the network has been received.

The acknowledgement of a BIND_REQ informs the user that the request was syntactically correct (or incorrect if ERROR_ACK). The receipt of a BIND_REQ is acknowledged with an M_PCPROTO to ensure that the acknowledgement reaches the user before any other message. For example, if a UNITDATA_IND comes through before the bind is completed, the application cannot send data to the proper address.

The driver uses a per-minor device data structure, dgproto, which contains the following:

**state**  
Current state of the service provider IDLE or BOUND.

**addr**  
Network address that has been bound to this stream.
The module open procedure is assumed to have set the write queue q_ptr to point at the appropriate private data structure, although this is not shown explicitly.

**Service Interface Procedure**

The write put procedure, protowput(), is shown in the following example:

**EXAMPLE 8-18 Service Interface protowput Procedure**

```c
static int protowput(queue_t *q, mblk_t *mp) {
    union primitives *proto;
    struct dgproto *dgproto;
    int err;
    dgproto = (struct dgproto *) q->q_ptr; /* priv data struct */
    switch (mp->b_datap->db_type) {
    default:
        /* don’t understand it */
        mp->b_datap->db_type = M_ERROR;
        mp->b_rptr = mp->b_wptr = mp->b_datap->db_base;
        *mp->b_wptr++ = EPROTO;
        qreply(q, mp);
        break;
    case M_FLUSH: /* standard flush handling goes here ... */
        break;
    case M_PROTO:
        /* Protocol message -> user request */
        proto = (union primitives *) mp->b_rptr;
        switch (proto->type) {
            default:
                mp->b_datap->db_type = M_ERROR;
                mp->b_rptr = mp->b_wptr = mp->b_datap->db_base;
                *mp->b_wptr++ = EPROTO;
                qreply(q, mp);
                return;
            case BIND_REQ:
                if (dgproto->state != IDLE) {
                    err = EINVAL;
                    goto error_ack;
                }
                if ((mp->b_wptr - mp->b_rptr) !=
                    sizeof(struct bind_req)) {
                    err = EINVAL;
                    goto error_ack;
                }
                if (err = chkaddr(proto->bind_req.BIND_addr))
                    goto error_ack;
                dgproto->state = BOUND;
                dgproto->addr = proto->bind_req.BIND_addr;
                mp->b_datap->db_type = M_PCPROTO;
                proto->type = OK_ACK;
                mp->b_wptr = mp->b_rptr + sizeof(struct ok_ack);
                break;
            case M_INMSG:
                break;
        }
    }
}
```

May 2002
EXAMPLE 8–18 Service Interface protowput Procedure (Continued)

```c
qreply(q, mp);
break;
error_ack:
    mp->b_datap->db_type = M_PCPROTO;
    proto->type = ERROR_ACK;
    proto->error_ack.UNIX_error = err;
    mp->b_wptr = mp->b_rptr+sizeof(struct error_ack);
    qreply(q, mp);
    break;

case UNITDATA_REQ:
    if (dgproto->state != BOUND)
        goto bad;
    if (mp->b_wptr - mp->b_rptr !=
        sizeof(struct unitdata_req))
        goto bad;
    if (err=chkaddr(proto->unitdata_req.DEST_addr))
        goto bad;
    putq(q, mp);
    /* start device or mux output ... */
    break;
bad:
    freemsg(mp);
    break;
}
return(0);
```

The write put procedure, protowput(), switches on the message type. The only types accepted are M_FLUSH and M_PROTO. For M_FLUSH messages, the driver performs the canonical flush handling (not shown). For M_PROTO messages, the driver assumes that the message block contains a union primitive and switches on the type field. Two types are understood: BIND_REQ and UNITDATA_REQ.

For a BIND_REQ, the current state is checked; it must be IDLE. Next, the message size is checked. If it is the correct size, the passed-in address is verified for legality by calling chkaddr. If everything checks, the incoming message is converted into an OK_ACK and sent upstream. If there was any error, the incoming message is converted into an ERROR_ACK and sent upstream.

For UNITDATA_REQ, the state is also checked; it must be BOUND. As above, the message size and destination address are checked. If there is any error, the message is discarded. If all is well, the message is put in the queue, and the lower half of the driver is started.

If the write put procedure receives a message type that it does not understand, either a bad b_datap->db_type or bad proto->type, the message is converted into an M_ERROR message and is then sent upstream.
The generation of UNITDATA_IND messages (not shown in the example) would normally occur in the device interrupt if this is a hardware driver or in the lower read put procedure if this is a multiplexer. The algorithm is simple: the data part of the message is prefixed by an M_PROTO message block that contains a unitdata_ind structure and is sent upstream.

Message Type Change Rules
To change a message type, use the following rules:

- You can only change the M_IOCTL family of message types to other M_IOCTL message types.
- M_DATA, M_PROTO, and M_PCPROTO are dependent on the modules, driver and service provider interfaces defined.
- A message type should not be changed if the reference count > 1.
- The data of a message should not be modified if the reference count > 1.
- All other message types are interchangeable as long as sufficient space has been allocated in the data buffer of the message.

Common ioctl Interfaces
Many ioctl operations are common to a class of STREAMS drivers or STREAMS modules. Modules that deal with terminals usually implement a subset of the termio(7I) ioctlrs. Similarly, drivers that deal with audio devices usually implement a subset of the audio(7I) interfaces.

Because no data structures have changed size as a result of the LP64 data model for either termio(7I) or audio(7I), you do no need to use any of the structure macros to decode any of these ioctlrs.

FIORDCHK
The FIORDCHK ioctl returns a count (in bytes) of the number of bytes to be read as the return value. Although FIORDCHK should be able to return more than MAXINT bytes, it is constrained to returning an int by the type of the ioctl(2) function.
FIONREAD

The FIONREAD ioctl returns the number of data bytes (in all data messages queued) in the location pointed to by the arg parameter. The ioctl returns a 32-bit quantity for both 32-bit and 64-bit application. Therefore, code that passes the address of a long variable needs to be changed to pass an int variable for 64-bit applications.

I_READ

The I_READ ioctl (streamio(7I)) is an informational ioctl that counts the data bytes as well as the number of messages in the stream head read queue. The number of data bytes is returned in the location pointed to by the arg parameter of the ioctl. The number of messages in the stream head read queue is returned as the return value of the ioctl.

Like FIONREAD, the arg parameter to the I_READ ioctl should be a pointer to an int, not a long. And, like EIORDCHK, the return value is constrained to be less than or equal to MAXINT bytes, even if more data is available.

signal Message

STREAMS modules and drivers send signals to application processes through a special signal message. If the signal specified by the module or driver is not SIGPOLL (see signal(3C)), the signal is delivered to the process group associated with the stream. If the signal is SIGPOLL, the signal is only sent to processes that have registered for the signal by using the I_SETSIG ioctl(2).

Modules or drivers use an M_SIG message to insert an explicit in-band signal into a message stream. For example, a message can be sent to the application process immediately before a particular service interface message. When the M_SIG message reaches the head of the stream read queue, a signal is generated and the M_SIG message is removed. The service interface message is the next message to be processed by the user. (The M_SIG message is usually defined as part of the service interface of the driver or module.)
STREAMS Drivers

This chapter describes the operation of STREAMS drivers and some of the processing typically required in the drivers.

- “STREAMS Device Drivers” on page 181
- “STREAMS Driver Entry Points” on page 182
- “STREAMS Driver Code Samples” on page 186

STREAMS Device Drivers

STREAMS drivers can be considered a subset of device drivers in general and character device drivers in particular. While there are some differences between STREAMS drivers and non-STREAMS drivers, much of the information contained in Writing Device Drivers also applies to STREAMS drivers.

Note – The word module is used differently when talking about drivers. A device driver is a kernel-loadable module that provides the interface between a device and the Device Driver Interface, and is linked to the kernel when it is first invoked.

STREAMS drivers share a basic programming model with STREAMS modules. Information common to both drivers and modules is discussed in Chapter 10. After summarizing some basic device driver concepts, this chapter discusses several topics specific to STREAMS device drivers (and not covered elsewhere) and then presents code samples illustrating basic STREAMS driver processing.
Basic Driver

A device driver is a loadable kernel module that translates between an I/O device and the kernel to operate the device.

Device drivers can also be software-only, implementing a pseudo-device such as RAM disk or a pseudo-terminal that only exists in software.

In the Solaris operating environment, the interface between the kernel and device drivers is called the Device Driver Interface (DDI/DKI). This interface is specified in the Section 9E manual pages that specify the driver entry points. Section 9 also details the kernel data structures (9S) and utility functions (9F) available to drivers.

The DDI protects the kernel from device specifics. Application programs and the rest of the kernel need little (if any) device-specific code to use the device. The DDI makes the system more portable and easier to maintain.

There are three basic types of device drivers corresponding to the three basic types of devices. Character devices handle data serially and transfer data to and from the processor one character at a time, the same as keyboards and low performance printers. Serial block devices and drivers also handle data serially, but transfer data to and from memory without processor intervention, the same as tape drives. Direct access block devices and drivers also transfer data without processor intervention and blocks of storage on the device can be addressed directly, the same as disk drives.

There are two types of character device drivers: standard character device drivers and STREAMS device drivers. STREAMS is a separate programming model for writing a character driver. Devices that receive data asynchronously (such as terminal and network devices) are suited to a STREAMS implementation.

STREAMS drivers share some kinds of processing with STREAMS modules. Important differences between drivers and modules include how the application manipulates drivers and modules and how interrupts are handled. In STREAMS, drivers are opened and modules are pushed. A device driver has an interrupt routine to process hardware interrupts.

STREAMS Driver Entry Points

STREAMS drivers have five different points of contact with the kernel:
TABLE 9-1 Kernel Contact Points

<table>
<thead>
<tr>
<th>Kernel Contact Point</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Configuration entry points</td>
<td>These kernel (dynamically loading) routines enable the kernel to find the driver binary in the file system and load it into, or unload it from, the running kernel. The entry points include _init(9E), _info(9E), and _fini(9E).</td>
</tr>
<tr>
<td>Initialization entry points</td>
<td>Enable the driver to determine a device’s presence and initialize its state. These routines are accessed through the dev_ops(9S) data structure during system initialization. They include getinfo(9E), identify(9E), probe(9E), attach(9E), and detach(9E).</td>
</tr>
<tr>
<td>Table-driven entry points</td>
<td>Accessed through cb_ops(9S), the character and block access table, when an application calls the appropriate interface. The members of the cb_ops(9S) structure include pointers to entry points that perform the device’s functions, such as read(9E), write(9E), ioctl(9E). The cb_ops(9S) table contains a pointer to the streamtab(9S) structure.</td>
</tr>
<tr>
<td>STREAMS queue processing entry points</td>
<td>Contained in the streamtab, read and process the STREAMS messages that travel through the queue structures. Examples of STREAMS queue processing entry points are put(9E) and srv(9E).</td>
</tr>
<tr>
<td>Interrupt routines</td>
<td>Handle the interrupts from the device (or software interrupts). It is added to the kernel by ddi_add_intr(9F) when the kernel configuration software calls attach(9F).</td>
</tr>
</tbody>
</table>

STREAMS Configuration Entry Points

As with other SunOS 5 drivers, STREAMS drivers are dynamically linked and loaded when referred to for the first time. For example, when the system is initially booted, the STREAMS pseudo-tty slave pseudo-driver (pts(7D)) is loaded automatically into the kernel when it is first opened.

In STREAMS, the header declarations differ between drivers and modules. The word “module” is used in two different ways when talking about drivers. There are STREAMS modules, which are pushable nondriver entities, and there are kernel-loadable modules, which are components of the kernel. See the appropriate chapters in Writing Device Drivers.

The kernel configuration mechanism must distinguish between STREAMS devices and traditional character devices because system calls to STREAMS drivers are processed by STREAMS routines, not by the system driver routines. The streamtab pointer in the cb_ops(9S) structure provides this distinction. If it is NULL, there are no STREAMS routines to execute; otherwise, STREAMS drivers initialize streamtab with a pointer to a streamtab(9S) structure containing the driver’s STREAMS queue processing entry points.
STREAMS Initialization Entry Points

The initialization entry points of STREAMS drivers must perform the same tasks as those of non-STREAMS drivers. See Writing Device Drivers for more information.

STREAMS Table-Driven Entry Points

In non-STREAMS drivers, most of the driver’s work is accomplished through the entry points in the cb_ops(9S) structure. For STREAMS drivers, most of the work is accomplished through the message-based STREAMS queue processing entry points.

Figure 9–1 shows multiple streams (corresponding to minor devices) connecting to a common driver. There are two distinct streams opened from the same major device. Consequently, they have the same streamtab and the same driver procedures.

Multiple instances (minor devices) of the same driver are handled during the initial open for each device. Typically, a driver stores the queue address in a driver-private structure that is uniquely identified by the minor device number. (The DDI/DKI provides a mechanism for uniform handling of driver-private structures; see ddi_soft_state(9F)). The q_ptr of the queue points to the private data structure entry. When the messages are received by the queue, the calls to the driver put and service procedures pass the address of the queue, enabling the procedures to determine the associated device through the q_ptr field.
STREAMS guarantees that only one open or close can be active at a time per major/minor device pair.

**STREAMS Queue Processing Entry Points**

STREAMS device drivers have processing routines that are registered with the framework through the `streamtab` structure. The `put` procedure is a driver's entry point, but it is a message (not system) interface. STREAMS drivers and STREAMS modules implement these entry points similarly, as described in “Entry Points” on page 109.

The stream head translates `write(2)` and `ioctl(2)` calls into messages and sends them downstream to be processed by the driver's write queue `put(9E)` procedure. `read` is seen directly only by the stream head, which contains the functions required to process system calls. A STREAMS driver does not check system interfaces other than `open` and `close`, but it can detect the absence of `read` indirectly if flow control propagates from the stream head to the driver and affects the driver's ability to send messages upstream.

For read-side processing, when the driver is ready to send data or other information to a user process, it prepares a message and sends it upstream to the read queue of the appropriate (minor device) stream. The driver's open routine generally stores the queue address corresponding to this stream.

For write-side (or output) processing, the driver receives messages in place of a write call. If the message cannot be sent immediately to the hardware, it may be stored on the driver's write message queue. Subsequent output interrupts can remove messages from this queue.

A driver is at the end of a stream. As a result, drivers must include standard processing for certain message types that a module might be able to pass to the next component. For example, a driver must process all `M_IOCTL` messages; otherwise, the stream head blocks for an `M_IOCNAK`, `M_IOCACK`, or until the timeout (potentially infinite) expires. If a driver does not understand an `ioctl(2)`, an `M_IOCNAK` message is sent upstream.

Messages that are not understood by the drivers should be freed.

The stream head locks up the stream when it receives an `M_ERROR` message, so driver developers should be careful when using the `M_ERROR` message.
STREAMS Interrupt Handlers

Most hardware drivers have an interrupt handler routine. You must supply an interrupt routine for the device’s driver. The interrupt handling for STREAMS drivers is not fundamentally different from that for other device drivers. Drivers usually register interrupt handlers in their attach(9E) entry point, using ddi_add_intr(9F). Drivers unregister the interrupt handler at detach time using ddi_remove_intr(9F).

The system also supports software interrupts. The routines ddi_add_softintr(9F) and ddi_remove_softintr(9F) register and unregister (respectively) soft-interrupt handlers. A software interrupt is generated by calling ddi_trigger_softintr(9F).

See Writing Device Drivers for more information.

Driver Unloading

STREAMS drivers can prevent unloading through the standard driver detach(9E) entry point.

STREAMS Driver Code Samples

The following discussion describes characteristics of a STREAMS driver:

- Basic hardware/pseudo drivers
  This type of driver communicates with a specific piece of hardware (or simulated hardware). The 1p example simulates a simple printer driver.

- Clonable drivers
  The STREAMS framework supports a CLONEOPEN facility, which allows multiple streams to be opened from a single special file. If a STREAMS device driver chooses to support CLONEOPEN, it can be referred to as a clonable device. The attach(9E) routines from two Solaris drivers, ptm(7D) and log(7D), illustrate two approaches to cloning.

- Multiple instances in drivers
  A multiplexer driver is a regular STREAMS driver that can handle multiple streams connected to it instead of just one stream. Multiple connections occur when more than one minor device of the same driver is in use. See “Cloning STREAMS Drivers” on page 199 for more information.
Printer Driver Example

Example 9–1 is a sample print driver for an interrupt-per-character line printer. The driver is unidirectional—it has no read-side processing. It demonstrates some differences between module and driver programming, including the following:

- Declarations for driver configuration
- Open handling
- A driver is passed a device number
- Flush handling
- A driver must loop M_FLUSH messages back upstream
- Interrupt routine
- A driver registers interrupt handler and processes interrupts

Most of the STREAMS processing in the driver is independent of the actual printer hardware; in this example, actual interaction with the printer is limited to the lpoutchar function, which prints one character at a time. For purposes of demonstration, the “printer hardware” is actually the system console, accessed through cmn_err(9F). Since there’s no actual hardware to generate a genuine hardware interrupt, lpoutchar simulates interrupts using ddi_trigger_softintr(9F). For a real printer, the lpoutchar function is rewritten to send a character to the printer, which should generate a hardware interrupt.

The driver declarations follow. After specifying header files (include <sys/ddi.h> and <sys/sunddi.h> as the last two header files), the driver declares a per-printer structure, struct lp. This structure contains members that enable the driver to keep track of each instance of the driver, such as flags (what the driver is doing), msg (the current STREAMS print message), qptr (pointer to the stream’s write queue), dip (the instance’s device information handle), iblock_cookie (for registering an interrupt handler), siid (the handle of the soft interrupt), and lp_lock (a mutex to protect the data structure from multithreaded race conditions). The driver next defines the bits for the flags member of struct lp; the driver defines only one flag, BUSY.

Following function prototypes, the driver provides some standard STREAMS declarations: a module_info(9S) structure (minfo), a qinit(9S) structure for the read side (rinit) that is initialized by the driver’s open and close entry points, a qinit(9S) structure for the write side (winit) that is initialized by the write put procedure, and a streamtab(9S) that points to rinit and winit. The values in the module name and ID fields in the module_info(9S) structure must be unique in the system. Because the driver is unidirectional, there is no read side put or service procedure. The flow control limits for use on the write side are 50 bytes for the low-watermark and 150 bytes for the high-watermark.

The driver next declares lp_state. This is an anchor on which the various “soft-state” functions provided by the DDK operate. The ddi_soft_state(9F) manual page describes how to maintain multiple instances of a driver.
The driver next declares a `cb_ops(9S)` structure, which is required in all device drivers. In non-STREAMS device drivers, `cb_ops(9S)` contains vectors to the table-driven entry points. For STREAMS drivers, however, `cb_ops(9S)` contains mostly nodev entries. The `cb_stream` field, however, is initialized with a pointer to the driver’s `streamtab(9S)` structure. This indicates to the kernel that this driver is a STREAMS driver.

Next, the driver declares a `dev_ops(9S)` structure, which points to the various initialization entry points as well as to the `cb_ops(9S)` structure. Finally, the driver declares a `struct moldrv` and a `struct modlinkage` for use by the kernel linker when the driver is dynamically loaded. `struct moldrv` contains a pointer to `mod_driverops` (a significant difference between a STREAMS driver and a STREAMS module—a STREAMS module would contain a pointer to `mod_strops` instead).

**EXAMPLE 9-1 Simple Line Printer Driver**

```c
#include <sys/types.h>
#include <sys/param.h>
#include <sys/stream.h>
#include <sys/stropts.h>
#include <sys/signal.h>
#include <sys/errno.h>
#include <sys/cred.h>
#include <sys/stat.h>
#include <sys/modctl.h>
#include <sys/conf.h>
#include <sys/ddi.h>
#include <sys/sunddi.h>

/* This is a private data structure, one per minor device number */

struct lp {

};

static struct modlinkage modlinkage = {
    MODREV_1, &modldrv, NULL
};

Example 9-2 shows the required driver configuration entry points _init(9E), _fini(9E), and _info(9E). In addition to installing the driver using mod_install(9F), the _init entry point also initializes the per-instance driver structure using ddi_soft_state_init(9F). _fini(9E) performs the complementary calls to mod_remove(9F) and ddi_soft_state_fini(9F) to unload the driver and release the resources used by the soft-state routines.

EXAMPLE 9-2 Configuration Entry Points

int
_init(void)
{
    int e;

EXAMPLE 9-2 Configuration Entry Points  (Continued)

```c
if ((e = ddi_soft_state_init(&lp_state, sizeof (struct lp), 1)) != 0) {
    return (e);
}
if ((e = mod_install(&modlinkage)) != 0) {
    ddi_soft_state_fini(&lp_state);
    return (e);
}
int _fini(void) {
    int e;
    if ((e = mod_remove(&modlinkage)) != 0) {
        return (e);
    }
    ddi_soft_state_fini(&lp_state);
    return (e);
}
int _info(struct modinfo *modinfop) {
    return (mod_info(&modlinkage, modinfop));
}
```

Example 9-3 shows the lp driver’s implementation of the initialization entry points. In lpidentify, the driver ensures that the name of the device being attached is “lp”.

lpattach first uses ddi_soft_state_zalloc(9F) to allocate a per-instance structure for the printer being attached. Next it creates a node in the device tree for the printer using ddi_create_minor_node(9F); user programs use the node to access the device. lpattach then registers the driver interrupt handler because the sample is driver pseudo-hardware, the driver uses soft interrupts. A driver for a real printer would use ddi_add_intr(9F) instead of ddi_add_softintr(9F). A driver for a real printer would also need to perform any other required hardware initialization in lpattach. Finally, lpattach initializes the per-instance mutex.

In lpdetach, the driver undoes everything it did in lpattach.

lpgetinfo uses the soft-state structures to obtain the required information.

EXAMPLE 9-3 Initialization Entry Points

```c
static int lpidentify(dev_info_t *dip)
```
EXAMPLE 9-3 Initialization Entry Points  (Continued)

```c
\{ 
    if (strcmp(ddi_get_name(dip), "lp") == 0) { 
        return (DDI_IDENTIFIED);
    } else 
        return (DDI_NOT_IDENTIFIED);
\}

The STREAMS mechanism allows only one stream per minor device. The driver open
routine is called whenever a STREAMS device is opened. open matches the correct
private data structure with the stream using ddi_get_soft_state(9F). The driver
open, lpopen in Example 9-4, has the same interface as the module open.

The stream flag, sflag, must have the value 0, indicating a normal driver open. devp
pointers to the major/minor device number for the port. After checking sflag, lpopen uses
devp to find the correct soft-state structure.

The next check, if (q->q_ptr) ... , determines if the printer is already open. q_ptr
is a driver or module private data pointer. It can be used by the driver for any purpose
and is initialized to zero by STREAMS before the first open. In this example, the
driver sets the value of q_ptr, in both the read and write queue structures, to point
to the device’s per-instance data structure. If the pointer is non-NULL, it means the
printer is already open, so lpopen returns EBUSY to avoid merging printouts from
multiple users.

The driver close routine is called by the stream head. Any messages left in the queue
are automatically removed by STREAMS. The stream is dismantled and data
structures are released.

EXAMPLE 9-4 Queue Processing Entry Points

    /*ARGSUSED*/
    static int
    lpopen(
        queue_t *q,  /* read queue */
        dev_t *devp,
        int flag,
        int sflag,
        cred_t *credp)
EXAMPLE 9–4 Queue Processing Entry Points (Continued)

```c
{
    struct lp *lp;
    if (sflag) /* driver refuses to do module or clone open */
        return (ENXIO);
    if ((lp = ddi_get_soft_state(lp_state, getminor(*devp))) == NULL)
        return (ENXIO);
    /* Check if open already. Can’t have multiple opens */
    if (q->q_ptr) {
        return (EBUSY);
    }
    lp->qptr = WR(q);
    q->q_ptr = (char *) lp;
    WR(q)->q_ptr = (char *) lp;
    qprocson(q);
    return (0);
}

/*ARGSUSED*/
static int
lpclose(
    queue_t *q, /* read queue */
    int flag,
    cred_t *credp)
{
    struct lp *lp;
    qprocsoff(q);
    lp = (struct lp *) q->q_ptr;
    /*
     * Free message, queue is automatically
     * flushed by STREAMS
     */
    mutex_enter(&lp->lp_lock);
    if (lp->msg) {
        freemsg(lp->msg);
        lp->msg = NULL;
    }
    lp->flags = 0;
    mutex_exit(&lp->lp_lock);
    return (0);
}
```

Chapter 9 • STREAMS Drivers 195
There are no physical pointers between the read and write queue of a pair. \texttt{WR}(9F) is a queue pointer function. \texttt{WR}(9F) generates the write pointer from the read pointer. \texttt{RD}(9F) and \texttt{OTHERQ}(9F) are additional queue pointer functions. \texttt{RD}(9F) generates the read pointer from the write pointer, and \texttt{OTHERQ}(9F) generates the mate pointer from either.

**Driver Flush Handling**

The write put procedure in Example 9–5, \texttt{lpwput}, illustrates driver \texttt{M\_FLUSH} handling. Note that all drivers are expected to incorporate flush handling.

If \texttt{FLUSHW} is set, the write message queue is flushed, and (in this example) the leading message (\texttt{lp->msg}) is also flushed. \texttt{lp\_lock} protects the driver’s per-instance data structure.

In most drivers, if \texttt{FLUSHR} is set, the read queue is flushed. However, in this example, no messages are ever placed on the read queue, so flushing it is not necessary. The \texttt{FLUSHW} bit is cleared and the message is sent upstream using \texttt{qreply}(9F). If \texttt{FLUSHR} is not set, the message is discarded.

The stream head always performs the following actions on flush requests received on the read side from downstream. If \texttt{FLUSHR} is set, messages waiting to be sent to user space are flushed. If \texttt{FLUSHW} is set, the stream head clears the \texttt{FLUSHR} bit and sends the \texttt{M\_FLUSH} message downstream. In this manner, a single \texttt{M\_FLUSH} message sent from the driver can reach all queues in a stream. A module must send two \texttt{M\_FLUSH} messages to have the same effect.

\texttt{lpwput} queues \texttt{M\_DATA} and \texttt{M\_IOCTL} messages and if the device is not busy, starts output by calling \texttt{lpout}. Message types that are not recognized are discarded (in the default case of the switch).

**EXAMPLE 9–5 Driver Flush Handling**

```c
static int lpwput(
    queue_t *q, /* write queue */
    mblk_t *mp) /* message pointer */
{
    struct lp *lp;

    lp = (struct lp *)q->q_ptr;

    switch (mp->b_datap->db_type) {
    default:
        freemsg(mp);
        break;
    case M\_FLUSH: /* Canonical flush handling */
        if (!mp->b_rptr & FLUSHW) {
            flushq(q, FLUSHDATA);
            mutex_enter(&lp->lp_lock); /* lock any access to lp */
        }
    ```
EXAMPLE 9-5 Driver Flush Handling  (Continued)

```c
if (lp->msg) {
    freemsg(lp->msg);
    lp->msg = NULL;
}
mutex_exit(&lp->lp_lock);
}
if (*mp->b_rptr & FLUSHR) {
    *mp->b_rptr &= ~FLUSHW;
    qreply(q, mp);
} else
    freemsg(mp);
break;
```

print Driver Interrupt

Example 9–6 shows the interrupt handling for the printer driver.

`lpintr` is the driver-interrupt handler registered by the `attach` routine.

`lpout` takes a single character from the queue and sends it to the printer. For convenience, the message currently being output is stored in `lp->msg` in the per-instance structure. This assumes that the message is called with the mutex held.

`lpoutchar` sends a single character to the printer (in this case the system console using `cmn_err(9F)`) and interrupts when complete. Of course, hardware would generate a hard interrupt, so the call to `ddi_trigger_softintr(9F)` would be unnecessary.

EXAMPLE 9-6 Driver Interrupt Handling

```c
/* Device interrupt routine */
static uint
lpintr(caddr_t lp) /* minor device number of lp */
```
EXAMPLE 9-6 Driver Interrupt Handling  (Continued)

default

{struct lp *lpp = (struct lp *)lp;
mutex_enter(&lpp->lp_lock);

if (!(lpp->flags & BUSY)) {
    mutex_exit(&lpp->lp_lock);
    return (DDI_INTR_UNCLAIMED);
}

lpp->flags &= ~BUSY;
lpout(lpp);
mutex_exit(&lpp->lp_lock);

return (DDI_INTRCLAIMED);
}

/* Start output to device - used by put procedure and driver */

static void
lpout(
    struct lp *lp)
{
    mblk_t *bp;
    queue_t *q;
    q = lp->qptr;

    loop:
    if ((bp = lp->msg) == NULL) { /*no current message*/
        if ((bp = getq(q)) == NULL) {
            lp->flags &= ~BUSY;
            return;
        }
        if (bp->b_datap->db_type == M_IOCTL) {
            /* lpdoioctl(lp, bp); */
            goto loop;
        }
        lp->msg = bp; /* new message */
    }
    if (bp->b_rptr >= bp->b_wptr) { /* validate message */
        bp = lp->msg->b_cont;
        lp->msg->b_cont = NULL;
        freeb(lp->msg);
        lp->msg = bp;
        goto loop;
    }
}
EXAMPLE 9-6 Driver Interrupt Handling (Continued)

```c
lpoutchar(lp, *bp->b_rptr++); /* output one character*/
lp->flags |= BUSY;
}
static void
lpoutchar(  
    struct lp *lp,
    char c)
{
    cmn_err(CE_CONT, "%c", c);
    ddi_trigger_softintr(lp->siid);
}
```

Driver Flow Control

The same utilities (described in Chapter 10) and mechanisms used for module flow control are used by drivers.

When the message is queued, putq(9F) increments the value of q_count by the size of the message and compares the result to the driver’s write high-watermark (q_hiwat) value. If the count reaches q_hiwat, putq(9F) sets the internal FULL indicator for the driver write queue. This causes messages from upstream to be halted (canputnext(9F) returns FALSE) until the write queue count drops below q_lowat. The driver messages waiting to be output through lpout are dequeued by the driver output interrupt routine with getq(9F), which decrements the count. If the resulting count is below q_lowat, getq(9F) back-enables any upstream queue that had been blocked.

For priority band data, qb_count, qb_hiwat, and qb_lowat are used.

STREAMS with flow control can be used on the driver read side to handle temporary upstream blocks.

To some extent, a driver or a module can control when its upstream transmission becomes blocked. Control is available through the M_SETOPTS message (see Appendix A) to modify the stream head read-side flow control limits.

Cloning STREAMS Drivers

To eliminate polling, STREAMS drivers can be made clonable. If a STREAMS driver is implemented as a clonable device, a single node in the file system can be opened to access any unused device that the driver controls. This special node guarantees that each user is allocated a separate stream to the driver for each open call. Each stream is associated with an unused minor device, so the total number of streams that may be connected to a particular clonable driver is limited only by the number of minor devices configured for that driver.
In previous examples, each user process connected a stream to a driver by explicitly opening a particular minor device of the driver. Each minor device had its own node in the device tree file system. Often, there is a need for a user process to connect a new stream to a driver regardless of which minor device is used to access the driver. In the past, this forced the user process to poll the various minor device nodes of the driver for an available minor device.

The clone model is useful, for example, in a networking environment where a protocol pseudo-device driver requires each user to open a separate stream over which it establishes communication. (The decision to implement a STREAMS driver as a clonable device is made by the designers of the device driver. Knowledge of the clone driver implementation is not required to use it.)

There are two ways to open as a clone device. The first is to use the STREAMS framework-provided clone device, which arranges to open the device with the CLONEOPEN flag passed in. This method is demonstrated in Example 9–7, which shows the attach and open routines for the pseudo-terminal master ptm(7D) driver. The second way is to have the driver open itself as a clone device, without intervention from the system clone device. This method is demonstrated in the attach and open routines for the log(7D) device in Example 9–8.

The ptm(7D) device, which uses the system-provided clone device, sets up two nodes in the device file system. One has a major number of 23 (ptm’s assigned major number) and a minor number of 0. The other node has a major number of 11 (the clone device’s assigned major number) and a minor number of 23 (ptm’s assigned major number). The driver’s attach routine (see Example 9–7) calls to ddi_create_minor_node(9F) twice. First, to set up the “normal” node (major number 23); second, to specify CLONE_DEV as the last parameter, making the system create the node with major 11.

```
crw-rw-rw- 1 sys 11, 23 Mar 6 02:05 clone:ptmx

crw------- 1 sys 23, 0 Mar 6 02:05 ptm:ptmajor
```

When the special file /devices/pseudo/clone@0:ptmx is opened, the clone driver code in the kernel (accessed by major 11) passes the CLONEOPEN flag in the sflag parameter to the ptm(7D) open routine. ptm’s open routine checks sflag to make sure it is being called by the clone driver. The open routine next attempts to find an unused minor device for the open by searching its table of minor devices. (PT_ENTER_WRITE and PT_EXIT_WRITE are driver-defined macros for entering and exiting the driver’s mutex.) If it succeeds (and following other open processing), the open routine constructs a new dev_t with the new minor number, which it passes back to its caller in the devp parameter. (The new minor number is available to the user program that opened the clonable device through an fstat(2) call.)

**EXAMPLE 9-7 Opening a System Clone Device**

```c
static int
ptm_attach(dev_info_t *devi, ddi_attach_cmd_t cmd)
{
    if (cmd != DDI_ATTACH)
        return (DDI_FAILURE);
```
EXAMPLE 9-7 Opening a System Clone Device  (Continued)

```c
if (ddi_create_minor_node(devi, "ptmajor", S_IFCHR, 0, NULL, 0)
    == DDI_FAILURE) {
    ddi_remove_minor_node(devi, NULL);
    return (DDI_FAILURE);
}
if (ddi_create_minor_node(devi, "ptmx", S_IFCHR, 0, NULL, CLONE_DEV)
    == DDI_FAILURE) {
    ddi_remove_minor_node(devi, NULL);
    return (DDI_FAILURE);
}
ptm_dip = devi;
return (DDI_SUCCESS);
}

static int
ptmopen(
    queue_t *rqp, /* pointer to the read side queue */
    dev_t *devp, /* pointer to stream tail's dev */
    int oflag, /* the user open(2) supplied flags */
    int sflag, /* open state flag */
    cred_t *credp) /* credentials */
{

    struct pt_ttys *ptmp;
    mblk_t *mop; /* ptr to a setopts message block */
    minor_t dev;

    if (sflag != CLONEOPEN) {
        return (EINVAL);
    }
    for (dev = 0; dev < pt_cnt; dev++) {
        ptmp = &ptms_tty[dev];
        PT_ENTER_WRITE(ptmp);
        if (ptmp->pt_state & (PTMOPEN | PTSOPEN | PTLOCK)) {
            PT_EXIT_WRITE(ptmp);
        } else
            break;
    }
    if (dev >= pt_cnt) {
        return (ENODEV);
    }
    ... <other open processing> ...

    /*
     * The input, devp, is a major device number, the output is put into
     * into the same parm as a major,minor pair.
     */
    *devp = makedevice(getmajor(*devp), dev);
    return (0);
}
```

The \texttt{log(7D)} driver uses the second method; it clones itself without intervention from the system clone device. The \texttt{log(7D)} driver's attach routine (in Example 9–8) is similar to the one in \texttt{ptm(7D)}. It creates two nodes using \texttt{ddi_create_minor_node(9F)}, but neither specifies \texttt{CLONE_DEV} as the last parameter. Instead, one of the devices has minor 0, the other minor \texttt{CLONEMIN}. These two devices provide \texttt{log(7D)} two interfaces: the first write-only, the second read-write (see the man page \texttt{log(7D)} for more information). Users open one node or the other. If they open the \texttt{CONSWMIN} (clonable, read-write) node, the open routine checks its table of minor devices for an unused device. If it is successful, it (like the \texttt{ptm(7D)} open routine) returns the new \texttt{dev_t} to its caller in \texttt{devp}.

**EXAMPLE 9–8 Opening the log Driver**

```c
static int
log_attach(dev_info_t *devi, ddi_attach_cmd_t cmd)
{
    if (ddi_create_minor_node(devi, "conslog", S_IFCHR, 0, NULL, NULL)
        == DDI_FAILURE ||
        ddi_create_minor_node(devi, "log", S_IFCHR, 5, NULL, NULL)
        == DDI_FAILURE)
    {
        ddi_remove_minor_node(devi, NULL);
        return (-1);
    }
    log_dip = devi;
    return (DDI_SUCCESS);
}

static int
logopen(
    queue_t *q,
    dev_t *devp,
    int flag,
    int sflag,
    cred_t *cr)
{
    int i;
    struct log *lp;

    /*
     * A MODOPEN is invalid and so is a CLONEOPEN.
     * This is because a clone open comes in as a CLONEMIN device open!!
     */
    if (sflag)
        return (ENXIO);

    mutex_enter(&log_lock);
    switch (getminor(*devp)) {
    case CONSWMIN:
        if (flag & FREAD) { /* you can only write to this minor */
            mutex_exit(&log_lock);
            return (EINVAL);
        }
    }
    if (q->q_ptr) { /* already open */
```
EXAMPLE 9-8 Opening the log Driver  (Continued)

```c
mutex_exit(&log_lock);
return (0);
}
lp = &log_log[CONSWMIN];
break;

case CLONEMIN:
    /*
     * Find an unused minor > CLONEMIN.
     */
    i = CLONEMIN + 1;
    for (lp = &log_log[i]; i < log_cnt; i++, lp++) {
        if (!(lp->log_state & LOGOPEN))
            break;
    }
    if (i >= log_cnt) {
        mutex_exit(&log_lock);
        return (ENXIO);
    }
    *devp = makedevice(getmajor(*devp), i); /* clone it */
    break;

default:
    mutex_exit(&log_lock);
    return (ENXIO);
}

/*
 * Finish device initialization.
 */
lp->log_state = LOGOPEN;
lp->log_rdq = q;
q->q_ptr = (void *) lp;
WR(q)->q_ptr = (void *) lp;
mutex_exit(&log_lock);
qprocson(q);
return (0);
}
```

Loop-Around Driver

The loop-around driver is a pseudo-driver that loops data from one open stream to another open stream. The associated files are almost like a full-duplex pipe to user processes. The streams are not physically linked. The driver is a simple multiplexer that passes messages from one stream’s write queue to the other stream’s read queue.

To create a connection, a process opens two streams, obtains the minor device number associated with one of the returned file descriptors, and sends the device number in an `ioctl(2)` to the other stream. For each open, the driver `open` places the passed queue
pointer in a driver interconnection table, indexed by the device number. When the driver later receives an `M_IOCTL` message, it uses the device number to locate the other stream’s interconnection table entry, and stores the appropriate queue pointers in both of the streams’ interconnection table entries.

Subsequently, when messages other than `M_IOCTL` or `M_FLUSH` are received by the driver on either stream’s write side, the messages are switched to the read queue following the driver on the other stream’s read side. The resultant logical connection is shown in Figure 9–2. Flow control between the two streams must be handled explicitly, since STREAMS do not automatically propagate flow control information between two streams that are not physically connected.

![Diagram](attachment:image.png)

**FIGURE 9–2 Loop-Around Streams**

Example 9–9 shows the loop-around driver code. The `loop` structure contains the interconnection information for a pair of streams. `loop_loop` is indexed by the minor device number. When a stream is opened to the driver, the driver places the address of the corresponding `loop_loop` element in the `q_ptr` (private data structure pointer) of the read-side and write-side queues. Since STREAMS clears `q_ptr` when the queue is allocated, a NULL value of `q_ptr` indicates an initial open. `loop_loop` verifies that this stream is connected to another open stream.

The code presented here for the loop-around driver represents a single-threaded, uniprocessor implementation. Chapter 12 presents multiprocessor and multithreading issues such as locking to prevent race conditions and data corruption.

Example 9–9 contains the declarations for the driver.

    int error;

    switch (infocmd) {
    case DDI_INFO_DEVT2DEVINFO:
        if (loop_dip == NULL) {
            error = DDI_FAILURE;
        } else {
            *result = (void *) loop_dip;
            error = DDI_SUCCESS;
        }
        break;
    case DDI_INFO_DEVT2INSTANCE:
        *result = (void *)0;
        error = DDI_SUCCESS;
        break;
    default:
        error = DDI_FAILURE;
    }
    return (error);
}
The open procedure (in Example 9–11) includes canonical clone processing that enables a single file system node to yield a new minor device/vnode each time the driver is opened. In loopopen, sflag can be CLONEOPEN, indicating that the driver picks an unused minor device. In this case, the driver scans its private loop_loop data structure to find an unused minor device number. If sflag is not set to CLONEOPEN, the passed-in minor device specified by getminor(*devp) is used.

**EXAMPLE 9–11 Opening the Loop-Around Driver**

```c
/*ARGSUSED*/
static int loopopen(
    queue_t *q,
    dev_t *devp,
    int flag,
    int sflag,
    cred_t *credp)
{
    struct loop *loop;
    minor_t newminor;

    if (q->q_ptr) /* already open */
        return(0);

    /*
    * If CLONEOPEN, pick a minor device number to use.
    * Otherwise, check the minor device range.
    */
    if (sflag == CLONEOPEN) {
        for (newminor = 0; newminor < loop_cnt; newminor++) {
            if (loop_loop[newminor].qptr == NULL)
                break;
        }
    } else
        newminor = getminor(*devp);

    if (newminor >= loop_cnt)
        return(ENXIO);

    /*
    * construct new device number and reset devp
    * getmajor gets the major number
    */
    *devp = makedevice(getmajor(*devp), newminor);
    loop = &loop_loop[newminor];
    WR(q)->q_ptr = (char *) loop;
    q->q_ptr = (char *) loop;
    loop->qptr = WR(q);
    loop->oqptr = NULL;
    qprocson(q);

    return(0);
}
```
Because the messages are switched to the read queue following the other stream’s read side, the driver needs a `put` procedure only on its write side. `loopwput` (in Example 9–12) shows another use of an `ioctl(2)`. The driver supports the `ioc_cmd` value `LOOP_SET` in the `iocblk(9S)` of the `M_IOCTL` message. `LOOP_SET` makes the driver connect the current open stream to the stream indicated in the message. The second block of the `M_IOCTL` message holds an integer that specifies the minor device number of the stream to which to connect.

The `LOOP_SET ioctl(2)` processing involves several checks:

- Does the second block have the proper amount of data?
- Is the “to” device in range?
- Is the “to” device open?
- Is the current stream disconnected?
- Is the “to” stream disconnected?

If these checks pass, the read queue pointers for the two streams are stored in the respective `oqptr` fields. This cross-connects the two streams indirectly, through `loop_loop`.

The `put` procedure incorporates canonical flush handling.

`loopwput` queues all other messages (for example, `M_DATA` or `M_PROTO`) for processing by its `service` procedure. A check is made that the stream is connected. If not, `M_ERROR` is sent to the stream head. Certain message types can be sent upstream by drivers and modules to the stream head where they are translated into actions detectable by user processes. These messages may also modify the state of the stream head:

- `M_ERROR` Causes the stream head to lock up. Message transmission between stream and user processes is terminated. All subsequent system calls except `close(2)` and `poll(2)` fail. Also causes `M_FLUSH`, clearing all message queues, to be sent downstream by the stream head.

- `M_HANGUP` Terminates input from a user process to the stream. All subsequent system calls that would send messages downstream fail. Once the stream head read message queue is empty, `EOF` is returned on reads. This can also result in `SIGHUP` being sent to the process group’s session leader.

- `M_SIG/M_PCSIG` Causes a specified signal to be sent to the process group associated with the stream.
putnextctl(9F) and putnextctl1(9F) allocate a non-data (that is, not M_DATA, M_DELAY, M_PROTO, or M_PCPROTO) type message, place one byte in the message (for putnextctl1(9F)), and call the put(9E) procedure of the specified queue.

**EXAMPLE 9–12** Use of ioctl to Copy Data From User Space to Kernel Space

```c
static int loopwput(queue_t *q, mblk_t *mp) {
    struct loop *loop;
    int to;

    loop = (struct loop *)q->q_ptr;

    switch (mp->b_datap->db_type) {
    case M_IOCTL: {
        struct iocblk *iocp;
        int error=0;

        iocp = (struct iocblk *)mp->b_rptr;
        switch (iocp->ioc_cmd) {
        case LOOP_SET: {
            /* if this is a transparent ioctl return an error;
             * the complete solution is to convert the message
             * into an M_COPYIN message so that the data is
             * ultimately copied from user space
             * to kernel space.
             */
            if (iocp->ioc_count == TRANSPARENT) {
                error = EINVAL;
                goto iocnak;
            }
            /* fetch other minor device number */
            to = *(int *)mp->b_cont->b_rptr;

            /* Sanity check. ioc_count contains the amount
             * of user supplied data which must equal the
             * size of an int.
             */
            if (iocp->ioc_count != sizeof(int)) {
                error = EINVAL;
                goto iocnak;
            }
            /* Is the minor device number in range? */
            if (to >= loop_cnt || to < 0) {
                return -EFAULT;
            }
            break;
        }
    }
    }
}
```

Chapter 9 • STREAMS Drivers
error = ENXIO;
goto iocnak;
}

/* Is the other device open? */
if (!loop_loop[to].qptr) {
    error = ENXIO;
goto iocnak;
}

/* Check if either dev is currently connected */
if ((loop->oqptr || loop_loop[to].oqptr) {
    error = EBUSY;
goto iocnak;
}

/* Cross connect the streams through
* the loopstruct
*/
loop->oqptr = RD(loop_loop[to].qptr);
loop_loop[to].oqptr = RD(q);

/*
* Return successful ioctl. Set ioc_count
* to zero, since no data is returned.
*/
mp->b_datap->db_type = M_IOCACK;
iocp->ioc_count = 0;
qreply(q, mp);
break;
}

default:
    error = EINVAL;
    iocnak:

    /*
     * Bad ioctl. Setting ioc_error causes
     * the ioctl call to return that particular errno.
     * By default, ioctl returns EINVAL on failure.
     */
    mp->b_datap->db_type = M_IOCNAK;
iocp->ioc_error = error;
qreply(q, mp);
break;
break;
}

case M_FLUSH: {

if (*mp->b_rptr & FLUSHW) {
    flushq(q, FLUSHALL); /* write */
    if (loop->oqptr)
        flushq(loop->oqptr, FLUSHALL); /* read on other side equals write on this side */
}

if (*mp->b_rptr & FLUSHR) {
    flushq(RD(q), FLUSHALL);
    if (loop->oqptr != NULL)
        flushq(WR(loop->oqptr), FLUSHALL);
}

switch(*mp->b_rptr) {

case FLUSHW:
    *mp->b_rptr = FLUSHR;
    break;

case FLUSHR:
    *mp->b_rptr = FLUSHW;
    break;
}

if (loop->oqptr != NULL)
    (void) putnext(loop->oqptr, mp);
break;
}

default: /* If this Stream isn’t connected, send M_ERROR upstream. */
    if (loop->oqptr == NULL) {
        freemsg(mp);
        (void) putnextctl1(RD(q), M_ERROR, ENXIO);
    }
    (void) putq(q, mp);
}

return (0);
}
Service procedures are required in this example on both the write side and read side for flow control (see Example 9–13). The write service procedure, loopwsrv, takes on the canonical form. The queue being written to is not downstream, but upstream (found through oqptr) on the other stream.

In this case, there is no read-side put procedure so the read service procedure, looprsrv, is not scheduled by an associated put procedure, as has been done previously. looprsrv is scheduled only by being back-enabled when its upstream flow control blockage is released. The purpose of the procedure is to re-enable the writer (loopwsrv) by using oqptr to find the related queue. loopwsrv cannot be directly back-enabled by STREAMS because there is no direct queue linkage between the two streams. Note that no message is queued to the read service procedure. Messages are kept on the write side so that flow control can propagate up to the stream head. qenable(9F) schedules the write-side service procedure of the other stream.

**EXAMPLE 9–13 Loop-Around Driver Flow Control**

```c
static int loopwsrv (queue_t*q)
{
    mblk_t *mp;
    structloop *loop;
    loop = (structloop*) q->q_ptr;

    while ((mp = getq (q)) != NULL){
        /* Check if we can put the message up
         * the other Stream read queue */
        if (mp->b_datap->db_type <= QPCTL && !canputnext (loop->oqptr)) {
            (void) putbq (q,mp); /*read-side is blocked*/
            break;
        }
        /* send message to queue following other Stream read queue */
        (void) putnext (loop->oqptr, mp);
    }
    return (0);
}

static int looprsrv (queue_t*q)
{
    /* Enter only when *backenabled* by flow control */
    structloop *loop;
    loop = (structloop*) q->q_ptr;
    if (loop->oqptr == NULL)
        return (0);

    /*manually enable write service procedure*/
    qenable (WR (loop->oqptr));
    return (0);
}
```

214 STREAMS Programming Guide • May 2002
loopclose breaks the connection between the streams, as shown in Example 9–14. loopclose sends an M_HANGUP message up the connected stream to the stream head.

**EXAMPLE 9–14** Breaking Stream Connections for Loop-Around Device

```c
/*ARGSUSED*/
static int loopclose (queue_t *q, int flag, cred_t *credp)
{
    struct loop *loop;

    loop = (struct loop *)q->q_ptr;
    loop->qptr = NULL;

    /*
     * If we are connected to another stream, break the linkage, and
     * send a hangup message. The hangup message causes the stream head
     * to reject writes, allow the queued data to be read completely,
     * and then return EOF on subsequent reads.
     */
    if (loop->oqptr) {
        (void) putnextctl(loop->oqptr, M_HANGUP);
        ((struct loop *)loop->oqptr->q_ptr)->oqptr = NULL;
        loop->oqptr = NULL;
    }

    qprocsoff(q);
    return (0);
}
```

An application using this driver would first open the clone device node created in the attach routine (/devices/pseudo/clone@0:loopx) two times to obtain two streams. The application can determine the minor numbers of the devices by using fstat(2). Next, it joins the two streams by using the STREAMS I_STR ioctl(2) (see streamio(7)) to pass the LOOP_SET ioctl(2) with one of the stream’s minor numbers as an argument to the other stream. Once this is completed, the data sent to one stream using write(2) or putmsg(2) can be retrieved from the other stream with read(2) or getmsg(2). The application also can interpose STREAMS modules between the stream heads and the driver using the I_PUSH ioctl(2).
Summarizing STREAMS Device Drivers

STREAMS device drivers are in many ways similar to non-STREAMS device drivers. The following points summarize the differences between STREAMS drivers and other drivers:

- Drivers must have `attach(9E)`, `probe(9E)`, and `identify(9E)` entry points to initialize the driver. The `attach` routine initializes the driver. Software drivers usually have little to initialize, because there is no hardware involved.
- Drivers have `open(9E)` and `close(9E)` routines.
- Most drivers have an interrupt handler routine. The driver developer is responsible for supplying an interrupt routine for the device’s driver. In addition to hardware interrupts, the system also supports software interrupts. A software interrupt is generated by calling `ddi_trigger_softintr(9F)`.
- All minor nodes are generated by `ddi_create_minor_node(9F)`.

STREAMS device drivers also are similar to STREAMS modules. The following points summarize some of the differences between STREAMS modules and drivers:

- Messages that are not understood by the drivers should be freed.
- A driver must process all `M_IOCTL` messages. Otherwise, the stream head blocks for an `M_IOCNAK`, `M_IOCACK`, or until the timeout (potentially infinite) expires.
- If a driver does not understand an `ioctl(2)`, an `M_IOCNAK` message must be sent upstream.
- The stream head locks up the stream when it receives an `M_ERROR` message, so driver developers should be careful when using the `M_ERROR` message.
- A hardware driver must provide an interrupt routine.
- Multithreaded drivers must protect their own data structures.

For more information on global driver issues and non-STREAMS drivers, see *Writing Device Drivers*. 
STREAMS Modules

This chapter provides specific examples of how modules work, including code samples.

- “Module Overview” on page 217
- “Data Flow Control” on page 224
- “Design Guidelines” on page 226

Module Overview

STREAMS modules process messages as they flow through the stream between an application and a character device driver. A STREAMS module is a pair of initialized queue structures and the specified kernel-level procedures that process data, status, and control information for the two queues. A stream can contain zero or more modules. Application processes push (stack) modules on a stream using the I_PUSH ioctl(2) and pop (unstack) them using the I_POP ioctl(2).

STREAMS Module Configuration

Like device drivers, STREAMS modules are dynamically linked and can be loaded into and unloaded from the running kernel.

Note – The word module is used differently when talking about drivers. A device driver is a kernel-loadable module that provides the interface between a device and the Device Driver Interface, and is linked to the kernel when it is first invoked.
A loadable module must provide linkage information to the kernel in an initialized modlstrmod(9S) and three entry points: _init(9E), _info(9E), and _fini(9E).

STREAMS modules can be unloaded from the kernel when not pushed onto a stream. A STREAMS module can prevent itself from being unloaded by returning an error (selected from errno.h) from its _fini(9E) routine (EBUSY is a good choice).

Module Procedures

STREAMS module procedures (open, close, put, service) have already been described in the previous chapters. This section shows some examples and further describes attributes common to module put and service procedures.

A module’s put procedure is called by the preceding module, driver, or stream head, and always before that queue’s service procedure. The put procedure does any immediate processing (for example, high-priority messages), while the corresponding service procedure performs deferred processing.

The service procedure is used primarily for performing deferred processing, with a secondary task to implement flow control. Once the service procedure is enabled, it can start but not finish before running user-level code. The put and service procedures must not block because there is no thread synchronization being done.

Example 10-1 shows a STREAMS module read-side put procedure.

**EXAMPLE 10-1 Read-side put Procedure**

```c
static int modrput (queue_t *q, mblk_t *mp)
{
    struct mod_prv *modptr;

    modptr = (struct mod_prv *) q->q_ptr; /*state info*/
    if (mp->b_datap->db_type >= QPCTL){ /*proc pri msg*/
        putnext(q, mp); /* and pass it on */
        return (0);
    }

    switch(mp->b_datap->db_type) {
    case M_DATA: /* can process message data */
        putq(q, mp); /* queue msg for service procedure */
        return (0);

    case M_PROTO: /* handle protocol control message */
        ...

    default:
        putnext(q, mp);
    }
}```
EXAMPLE 10–1 Read-side put Procedure  (Continued)

    return (0);

}

The preceding code does the following:

- A pointer to a queue defining an instance of the module and a pointer to a message are passed to the put procedure.
- The put procedure performs a switch on the type of the message. For each message type, the put procedure either enqueues the message for further processing by the module service procedure, or passes the message to the next module in the stream.
- High-priority messages are typically processed immediately. Immediate processing is not required by the put procedure and the message is passed to the next module.
- Ordinary (or normal) messages are either queued or passed along the stream.

Example 10–2 shows a module write-side put procedure.

EXAMPLE 10–2 Write-side put Procedure

static int modwput (queue_t *q, mblk_t *mp)
{
    struct mod_prv *modptr;
    modptr = (struct mod_prv *) q->q_ptr; /* state info */

    if (mp->b_datap->db_type >= QPCTL) { /* proc pri msg and pass it on */
        putnext(q, mp);
        return (0);
    }

    switch(mp->b_datap->db_type) {
        case M_DATA: /* can process message data queue msg */
            putq(q, mp); /* for service procedure or pass message */
            return (0);
        case M_PROTO:
            /* if cmd in msg is recognized */
            /* process message and send reply back */
            /* else pass message downstream */
            default:
                break;
    }

Chapter 10 • STREAMS Modules  219
EXAMPLE 10-2 Write-side put Procedure  (Continued)

    putnext (q, mp);
    return (0);

}
}

The write-side put procedure, unlike the read side, can be passed M_IOCTL messages. The module must recognize and process the ioctl(2) command, or pass the message downstream if it does not recognize the command.

Example 10-3 shows a general scenario employed by the module’s service procedure.

EXAMPLE 10-3 STREAMS Module Service Procedure

static int
modrsrv (queue_t *q)
{
    mblk_t *mp;

    while ((mp = getq(q)) != NULL) {
        /* flow control check */
        if ((mp->b_datap->db_type >= QPCTL) && !canputnext(q)) {
            putbq(q, mp); /* return message */
            return (0);
        }
        /* process the message */
        .
        .
        putnext(q, mp); /* pass the result */
    }
    return (0);
}

The steps are:

1. Retrieve the first message from the queue using getq(9F).
2. If the message is high priority, process it immediately and pass it along the stream.

   Otherwise, the service procedure should use canputnext(9F) to determine if the next module or driver that enqueues messages is within acceptable flow-control limits. canputnext(9F) searches the stream for the next module, driver, or the stream head with a service procedure. When it finds one, it looks at the total message space currently allocated to the queue for messages. If the amount of space currently used at that queue reaches the high-water mark, canputnext(9F) returns false (zero). If the next queue with a service procedure is within acceptable flow-control limits, canputnext(9F) returns true (nonzero).
3. If canputnext(9F) returns false, the service procedure returns the message to its own queue with putbq(9F). The service procedure can do no further processing at this time, and it returns to the caller.

If canputnext(9F) returns true, the service procedure completes any processing of the message. This can involve retrieving more messages from the queue, allocating and deallocating header and trailer information, and performing control functions for the module.

4. When the service procedure is finished processing the message, it calls putnext(9F) to pass the resulting message to the next queue.

These steps are repeated until getq(9F) returns NULL (the queue is empty) or canputnext(9F) returns false.

Filter Module Example

The module shown next, crmod in Example 10–4, is an asymmetric filter. On the write side, a newline is changed to a carriage return followed by a newline. On the read side, no conversion is done.

EXAMPLE 10–4 Filter Module

/* Simple filter
   * converts newline -> carriage return, newline
   */
#include <sys/types.h>
#include <sys/param.h>
#include <sys/stream.h>
#include <sys/stropts.h>
#include <sys/ddi.h>
#include <sys/sunddi.h>
static struct module_info minfo =
    { 0x09, "crmod", 0, INFPSZ, 512, 128 };
static int modopen (queue_t*, dev_t*, int, int, cred_t*);
static int modrput (queue_t*, mblk_t*);
static int modwput (queue_t*, mblk_t*);
static int modwsrv (queue_t*);
static int modclose (queue_t*, int, cred_t*);
static struct qinit rinit = {
    modrput, NULL, modopen, modclose, NULL, &minfo, NULL};
static struct qinit winit = {
    modwput, modwsrv, NULL, NULL, NULL, &minfo, NULL};
struct streamtab crmdinfo={ &rinit, &winit, NULL, NULL};

stropts.h includes definitions of flush message options common to user applications. modrput is like modput from the null module.
In contrast to the null module example, a single module_info structure is shared by the read side and write side. The module_info includes the flow control high-water and low-water marks (512 and 128) for the write queue. (Though the same module_info is used on the read queue side, the read side has no service procedure so flow control is not used.) The qinit contains the service procedure pointer.

The write-side put procedure, the beginning of the service procedure, and an example of flushing a queue are shown in Example 10–5.

**EXAMPLE 10–5 Flushing a Queue**

```c
static int
modwput(queue_t *q, mblk_t *mp)
{
    if (mp->b_datap->db_type >= QBCTL && mp->b_datap->db_type != M_FLUSH)
        putnext(q, mp);
    else
        putq(q, mp); /* Put it on the queue */
    return (0);
}

static int
modwsvr(queue_t *q)
{
    mblk_t *mp;

    while ((mp = getq(q)) != NULL) {
        switch (mp->b_datap->db_type) {
        default:
            if (canputnext(q)) {
                putnext(q, mp);
            } else {
                putbq(q, mp);
                return (0);
            } break;
        case M_FLUSH:
            if (*mp->b_rptr & FLUSHW)
                flushq(q, FLUSHDATA);
            putnext(q, mp);
            break;
        case M_DATA: {
            mblk_t *nbp = NULL;
            mblk_t *next;
            if (!canputnext(q)) {
                putbq(q, mp);
                return (0);
            }
            /* Filter data, appending to queue */
            for (; mp != NULL; mp = next) {
                while (mp->b_rptr < mp->b_wptr) {
                    if (*mp->b_rptr == '

```

May 2002
EXAMPLE 10–5 Flushing a Queue  (Continued)

    if (!bappend(&nbp, '\r'))
        goto push;
    if (!bappend(&nbp, *mp->b_rptr))
        goto push;
    mp->b_rptr++;
    continue;
push:
    if (nbp)
        putnext(q, nbp);
    nbp = NULL;
    if (!canputnext(q)) {
        if (mp->b_rptr>=mp->b_wptr){
            next = mp->b_cont;
            freeb(mp);
            mp=next;
        }
        if (mp)
            putbq(q, mp);
        return (0);
    }
} /* while */
next = mp->b_cont;
freeb(mp);
if (nbp)
    putnext(q, nbp);
} /* for */
} /* switch */
return (0);

modwsrv() is the write service procedure. It takes a single argument, which is a
pointer to the write queue. modwsrv() switches on the message type, M_FLUSH or
M_DATA. modwsrv() processes only one high-priority message, M_FLUSH. No other
high-priority messages should reach modwsrv. High-priority messages other than
which M_FLUSH use putnext(9F) to avoid scheduling. The others are queued for the
service procedure. An M_FLUSH message is a request to remove messages on one or
both queues. It can be processed in the put or service procedure.

For an M_FLUSH message, modwsrv() checks the first data byte. If FLUSHW is set, the
write queue is flushed by flushq(9F), which takes two arguments, the queue pointer
and a flag. The flag indicates what should be flushed, data messages (FLUSHDATA) or
everything (FLUSHALL). Data includes M_DATA, M_DELAY, M_PROTO, and M_PCPROTO
messages. The choice of what types of messages to flush is specific to each module.

Ordinary messages are returned to the queue if canputnext(9F) returns false,
indicating the downstream path is blocked.

Chapter 10 • STREAMS Modules  223
The differences in M_DATA processing between this and the example in “Message Allocation and Freeing” on page 132 relate to the manner in which the new messages are forwarded and flow controlled. For the purpose of demonstrating alternative means of processing messages, this version creates individual new messages rather than a single message containing multiple message blocks. When a new message block is full, it is immediately forwarded with putnext(9F) rather than being linked into a single large message. This alternative is not desirable because message boundaries are altered, and because of the additional overhead of handling and scheduling multiple messages.

When the filter processing is performed (following push), flow control is checked (with canputnext(9F)) after each new message is forwarded. This is necessary because there is no provision to hold the new message until the queue becomes unblocked. If the downstream path is blocked, the remaining part of the original message is returned to the queue. Otherwise, processing continues.

Data Flow Control

To support the STREAMS flow control mechanism, modules that use service procedures must invoke canputnext(9F) before calling putnext(9F), and use appropriate values for the high-water and low-water marks. If your module has a service procedure, you manage the flow control. If you don’t have a service procedure, then there is no need to do anything.

The queue hiwat and lowat values limit the amount of data that can be placed on a queue. These limits prevent depletion of buffers in the buffer pool. Flow control is advisory in nature and can be bypassed. It is managed by high-water and low-water marks and regulated by the utility routines getq(9F), putq(9F), putbq(9F), insq(9F), rmvq(9F), and canputnext(9F).

The following scenario takes place normally in flow control:

A driver sends data to a module using putnext(9F), and the module’s put procedure queues data using putq(9F). Calling putq(9F) enables the service procedure and executes it at some indeterminate time in the future. When the service procedure runs, it retrieves the data by calling getq(9F).

If the module cannot process data at the rate at which the driver is sending the data, the following happens:

When the message is queued, putq(9F) increments the value of q_count by the size of the message and compares the result to the module’s high-water limit (q_hiwat) value for the queue. If the count reaches q_hiwat, putq(9F) sets the internal FULL indicator for the queue. This causes messages from upstream in the case of a write-side queue or downstream in the case of a read-side queue to be halted.
(canputnext(9F) returns FALSE) until the queue count drops below q_lowat.
getq(9F) decrements the queue count. If the resulting count is below q_lowat,
getq(9F) back-enables and causes the service procedure to be called for any
blocked queue. (Flow control does not prevent reaching q_hiwat on a queue. Flow
control can exceed its maximum value before canputnext(9F) detects QFULL and
flow is stopped.)

The next example shows a line discipline module's flow control. Example 10–6 shows a
read-side line discipline module and a write-side line discipline module. Note that the
read side is the same as the write side but without the M_IOCTL processing.

EXAMPLE 10–6 Read-side Line Discipline Module

/* read side line discipline module flow control */
static mblk_t *read_canon(mblk_t *);
static int
def_queue_t *q)
{
    mblk_t *mp;
    mblk_t *bp;
    while ((mp = getq(q)) != NULL) {
        switch (mp->b_datap->db_type) { /* type of msg */
            case M_DATA: /* data message */
                if (canputnext(q)) {
                    bp = read_canon(mp);
                    putnext(q, bp);
                } else {
                    putbq(q, mp); /* put message back in queue */
                    return (0);
                }
                break;
            default:
                if (mp->b_datap->db_type == QPCTL)
                    putnext(q, mp); /* high-priority message */
                else { /* ordinary message */
                    if (canputnext(q))
                        putnext(q, mp);
                    else {
                        putbq(q, mp);
                        return (0);
                    }
                }
                break;
        }
    }
    return (0);
}

/* write side line discipline module flow control */
static int
EXAMPLE 10–6 Read-side Line Discipline Module  

(Continued)

```c
ld_write_srv(
    queue_t *q) /* pointer to write queue */
{
    mblk_t *mp; /* original message */
    mblk_t *bp; /* canonicalized message */

    while ((mp = getq(q)) != NULL) {
        switch (mp->b_datap->db_type) { /* type of msg */
            case M_DATA: /* data message */
                if (canputnext(q)) {
                    bp = write_canon(mp);
                    putnext(q, bp);
                } else {
                    putbq(q, mp);
                    return (0); // Remove message
                }
            break;
            case M_IOCTL:
                ld_ioctl(q, mp);
                break;
            default:
                if (mp->b_datap->db_type >= QPCTL) /* high priority message */
                    putnext(q, mp);
                else { /* ordinary message */
                    if (canputnext(q))
                        putnext(q, mp);
                    else {
                        putbq(q, mp);
                        return (0);
                    }
                }
            break;
        }
    }
    return (0);
}
```

Design Guidelines

Module developers should follow these guidelines:

- If a module cannot process the message types, the message types must be passed to the next module.
The module that acts on an M_IOCTL message should send an M_IOCACK or M_IOCNAK message in response to the ioctl(2). If the module cannot process the ioctl(2), it should pass the M_IOCTL message to the next module.

Modules should not pertain to any particular driver but should be compatible with all drivers.

In general, modules should not require the data in an M_DATA message to follow a particular format, such as a specific alignment. This means modules can be arbitrarily pushed on top of each other in a sensible fashion. Not following this rule can limit module usability.

Filter modules pushed between a service user and a service provider should not alter the contents of the M_PROTO or M_PCPROTO block in messages. The contents of the data blocks can be changed, but the message boundaries must be preserved.

**htonl(3N) and ntohl(3N)**

The htonl(3N) and ntohl(3N) conversion routines follow the XNS5 publications. The functions continue to convert 32-bit quantities between network byte order and host byte order.
Configuring STREAMS Drivers and Modules

This chapter contains information about configuring STREAMS drivers and modules into the Solaris operating environment. It describes how to configure a driver and a module for the STREAMS framework only. For more in-depth information on the general configuration mechanism, see Writing Device Drivers.

This chapter has the following organization:

- “Kernel Data Structures” on page 229
- “STREAMS Driver Entry Points” on page 233
- “Tunable Parameters” on page 240
- “STREAMS Administrative Driver” on page 241

Kernel Data Structures

The following sections contain descriptions of the pointer relationships maintained by the kernel and the various data structures used in STREAMS drivers. When the kernel accesses a driver, it uses a sequence of pointers in various data structures. It looks first at the data structure relationship, and then the entry point interface for loading the driver into the kernel and accessing the driver from the application level.

The order of data structures the kernel uses to get to a driver is as follows:

- modlinkage(9S) Contains the revision number and a list of drivers to dynamically load. It is used by mod_install in the _init routine to load the module into the kernel. Points to a modldr(9S) or modlstrmod(9S).
- modldr(9S) Contains information about the driver being loaded and points to the devops structure.
modlstrmod(9S) Points to an fmodsw(9S) structure (which points to a streamtab(9S)). Only used by STREAMS modules.

dev_ops(9S) Contains list of entry points for a driver, such as identify, attach, and info. Also points to a cb_ops(9S) structure.

cb_ops(9S) Points to list of threadable entry points to driver, like open, close, read, write, ioctl. Also points to the streamtab.

streamtab(9S) Points to the read and write queue init structures.

ginit(9S) Points to the entry points of the STREAMS portion of the driver, such as put, srv, open, close, as well as the mod_info structure. These entry points only process messages.

Each STREAMS driver or module contains the linkage connections for the various data structures which is a list of pointers to dev_ops(9S) structures. In each dev_ops(9S) structure is a pointer to the cb_ops(9S) structure. In the cb_ops(9S) structure contains a pointer to the streamtab struct. If the driver is not a STREAMS driver, streamtab is NULL. If the driver is a STREAMS driver, streamtab contains initialization routines for the driver.

**modlinkage**

The definition of modlinkage(9S) is:

```c
struct modlinkage {
    int ml_rev; /* rev of loadable modules system */
    void *ml_linkage[4]; /* NULL terminated list of linkage
                                 * structures */
};
```

**modldrv**

The definition of modldrv(9S) is:

```c
struct modldrv {
    struct mod_ops *drv_modops;
    char *drv_linkinfo;
    struct dev_ops *drv_dev_ops;
};
```
**modlstrmod**

The definition of `modlstrmod(9S)` is below. It does not point to `dev_ops(9S)` structures because modules can only be pushed onto an existing stream.

```c
struct modlstrmod {
    struct mod_ops  *strmod_modops;
    char            *strmod_linkinfo;
    struct fmodsw   *strmod_fmodsw;
};
```

**dev_ops**

The `dev_ops(9S)` structure represents a specific class or type of device. Each `dev_ops(9S)` structure represents a unique device to the operating system. Each device has its own `dev_ops(9S)` structure, which in turn contains a `cb_ops(9S)` structure.

```c
struct dev_ops {
    int   devo_rev;    /* Driver build version */
    int   devo_refcnt; /* device reference count */
    int   (*devo_getinfo)(dev_info_t *dip, ddi_info_cmd_t infocmd, 
                           void *arg, void **result);
    int   (*devo_identify)(dev_info_t *dip);
    int   (*devo_probe)(dev_info_t *dip);
    int   (*devo_attach)(dev_info_t *dip, ddi_attach_cmd_t cmd);
    int   (*devo_detach)(dev_info_t *dip, ddi_detach_cmd_t cmd);
    int   (*devo_reset)(dev_info_t *dip, ddi_reset_cmd_t cmd);
    struct cb_ops  *devo_cb_ops; /* cb_ops ptr for leaf driver*/
    struct bus_ops *devo_bus_ops; /* ptr for nexus drivers */
};
```

**cb_ops**

The `cb_ops(9S)` structure is the SunOS 5 version of the `cdevsw` and `bdevsw` tables of previous versions of UNIX System V. It contains character and block device information and the driver entry points for non-STREAMS drivers.

```c
struct cb_ops {
    int   (*cb_open)(dev_t *devp, int flag, int otyp, 
                     cred_t *credp);
    int   (*cb_close)(dev_t dev, int flag, int otyp, 
                      cred_t *credp);
    int   (*cb_strategy)(struct buf *bp);
    int   (*cb_print)(dev_t dev, char *str);
    int   (*cb_dump)(dev_t dev, caddr_t addr, daddr_t blkno, 
                     int nblk);
    int   (*cb_read)(dev_t dev, struct uio *uiop, cred_t *credp);
};
```
int (*cb_write)(dev_t dev, struct uio *uiop, cred_t *credp);
int (*cb_ioctl)(dev_t dev, int cmd, int arg, int mode, 
    cred_t *credp, int *rvalp);
int (*cb_devmap)(dev_t dev, dev_info_t *dip, 
    ddi_devmap_data_t *dvdp, ddi_devmap_cmd_t cmd, 
    off_t offset, unsigned int len, unsigned int prot, 
    cred_t *credp);
int (*cb_mmap)(dev_t dev, off_t off, int prot);
int (*cb_segmap)(dev_t dev, off_t off, struct as *asp, 
    caddr_t *addrp, off_t len, unsigned int prot, 
    unsigned int maxprot, unsigned int flags, 
    cred_t *credp);
int (*cb_chpoll)(dev_t dev, short events, int anyyet, 
    short *reventsp, struct pollhead **phpp);
int (*cb_prop_op)(dev_t dev, dev_info_t *dip, 
    ddi_prop_op_t prop_op, int mod_flags, char *name, 
    caddr_t valuep, int *length);

struct streamtab *cb_str; /* streams information */

/*
 * The cb_flag fields are here to tell the system a bit about
 * the device. The bit definitions are in <sys/conf.h>.
 */
int cb_flag; /* driver compatibility flag */
}

streamtab

The streamtab(9S) structure contains pointers to the structures that hold the routines
that actually initialize the reading and writing for a module.

If streamtab is NULL, there are no STREAMS routines and the entire driver is
treated as though it was a non-STREAMS driver. The streamtab(9S) indirectly
identifies the appropriate open, close, put, service, and administration
routines. These driver and module routines should generally be declared static.

struct streamtab {
    struct qinit *st_rdinit; /* defines read queue */
    struct qinit *st_wrinit; /* defines write queue */
    struct qinit *st_muxrinit; /* for multiplexing */
    struct qinit *st_muxwinit; /* drivers only */
};
qinit

The qinit(9S) structure (also shown in Appendix A) contains pointers to the STREAMS entry points. These routines are called by the module-loading code in the kernel.

```
struct qinit {
    int (*qi_putp)(); /* put procedure */
    int (*qi_srvp)(); /* service procedure */
    int (*qi_qopen)(); /* called on each open or push*/
    int (*qi_qclose)(); /* called on last close or pop*/
    int (*qi_qadmin)(); /* reserved for future use */
    struct module_info  *qi_minfo; /* info struct */
    struct module_stat  *qi_mstat; /* stats struct (opt)*/
};
```

STREAMS Driver Entry Points

As described in Chapter 9 and as seen in the previous data structures, there are four STREAMS driver entry points:

- load kernel module: _init(9E), _fini(9E), _info(9E)
- dev_ops: identify(9E), attach(9E), getinfo(9E)
- cb_ops: open(9E), close(9E), read(9E), write(9E), ioctl(9E)
- streamtab: put(9E), srv(9E)

pts Example

The following real example was taken from the Solaris operating environment. The driver pts(7D) is the pseudo terminal slave driver.

```
EXAMPLE 11–1 Stream Pseudo Terminal Module

    /*
     * Slave Stream Pseudo Terminal Module
     */

    #include <sys/types.h>
    #include <sys/param.h>
    #include <sys/stream.h>
    #include <sys/stropts.h>
    #include <sys/stat.h>
    #include <sys/errno.h>
```

STREAMS Module Configuration

The following example shows the structures you need if you are working with a module instead of a driver. Notice that a modlstrmod(9S) is used in modlinkage(9S), and fmodsw(9S) points to streamtab(9S) instead of going through dev_ops(9S).

EXAMPLE 11–2 Module Structures

extern struct streamtab pteminfo;

static struct fmodsw fsw = {
    "ptem",
    &pteminfo,
    D_NEW | D_MP
};

/*
 * Module linkage information for the kernel.
 */
**EXAMPLE 11-2 Module Structures (Continued)**

```c
extern struct mod_ops mod_strmodops;

static struct modlstrmod modlstrmod = {
    &mod_strmodops,
    "pty hardware emulator",
    &fsw
};

static struct modlinkage modlinkage = {
    MODREV_1,
    (void *)&modlstrmod,
    NULL
};
```

---

**Compilation**

Below are some compile, assemble, and link lines for an example driver with two C source files (example_one.c and example_two.c) and an assembly language source file (example_asm.s).

```
cc -D_KERNEL -c example_one.c
cc -D_KERNEL -c example_two.c
as -P -D_ASM -D_KERNEL -I. -o example_asm.o example_asm.s
ld -r -o example example_one.o example_two.o example_asm.o
```

---

**Kernel Loading**

See *Writing Device Drivers* for more information on the sequence of installing and loading device drivers. The basic procedure is to copy your driver to /kernel/drv and your module to /kernel/strmod. For drivers run `add_drv(1M)`.

**Note** – The autoload facility looks for modules to reside in /kernel/strmod. If the object resides elsewhere the module will not be loaded.
Checking the Module Type

Below is sample code that enables a driver to determine if it is running as a regular driver, a module, or a cloneable driver. The open routine returns sflag, which is checked.

```c
if (sflag == MODOPEN)
    /* then the module is being pushed */
else if (sflag == CLONEOPEN)
    /* then its being opened as a clonable driver */
else
    /* its being opened as a regular driver */
```

Tunable Parameters

Certain system parameters referred to by STREAMS are configurable when building a new operating system (see the file `/etc/system` and the *SunOS User's Guide to System Administration* for further details). These parameters are:

- **nstrpush**: Maximum number (should be at least 8) of modules that can be pushed onto a single stream.
- **strmsgsz**: Maximum number of bytes of information that a single system call can pass to a stream to be placed into the data part of a message (in `M_DATA` blocks). Any `write(2)` exceeding this size is broken into multiple messages. A `putmsg(2)` with a data part exceeding this size fails with `ERANGE`. If `STRMSGSZ` is set to 0, the number of bytes passed to a stream is infinite.
- **strctlsz**: Maximum number of bytes of information that a single system call can pass to a stream to be placed into the control part of a message (in an `M_PROTO` or `M_PCPROTO` block). A `putmsg(2)` with a control part that exceeds this size fails with `ERANGE`.
STREAMS Administrative Driver

The autopush(1M) facility configures the list of modules for a STREAMS device. It automatically pushes a prespecified list (/etc/iu.ap) of modules onto the stream when the STREAMS device is opened and the device is not already open.

The STREAMS Administrative Driver (SAD) (see the sad(7D) man page) provides an interface to the autopush mechanism. System administrators can open the SAD driver and set or get autopush information on other drivers. The SAD driver caches the list of modules to push for each driver. When the driver is opened the stream head checks the SAD’s cache to determine if the device is configured to have modules pushed automatically. If an entry is found, the modules are pushed. If the device has been opened but not closed, another open does not cause the list of the prespecified modules to be pushed again.

Three options configure the module list:
- Configure for each minor device (that is, a specific major and minor device number)
- Configure for a range of minor devices within a major device
- Configure for all minor devices within a major device

In addition, when configuring the module list, an optional anchor can be placed within the module list. See “STREAMS Anchors” on page 243 for more information.

When the module list is cleared, a range of minor devices has to be cleared as a range and not in parts.

Application Interface

The SAD driver is accessed through the /dev/sad/admin or /dev/sad/user node. After the device is initialized, a program can perform any autopush configuration. The program should open the SAD driver, read a configuration file to find out what modules need to be configured for which devices, format the information into strapush structures, and make the SAD_SAP_ioctl(2) calls. See the sad(7D) man page for more information.

All autopush operations are performed through SAD_SAP_ioctl(2) commands to set or get autopush information. Only the root user can set autopush information, but any user can get the autopush information for a device.
The SAD_SAP ioctl is a form of ioctl(fd, cmd, arg), where fd is the file descriptor of the SAD driver, cmd is either SAD_SAP (set autopush information) or SAD_GAP (get autopush information), and arg is a pointer to the structure strapush.

The strapush structure is shown in the following example:

```
/*
 * maximum number of modules that can be pushed on a
 * stream using the autopush feature should be no greater
 * than nstrpush
 */
#define MAXAPUSH 8

/*@ autopush information common to user and kernel */

struct apcommon {
    uint    apc_cmd;    /* command - see below */
    major_t apc_major; /* major device number */
    minor_t apc_minor; /* minor device number */
    minor_t apc_lastminor; /* last minor dev # for range */
    uint    apc_npush; /* number of modules to push */
};

/*@ ap_cmd - various options of autopush */
#define SAP_CLEAR 0 /* remove configuration list */
#define SAP_ONE 1    /* configure one minor device */
#define SAP_RANGE 2   /* config range of minor devices */
#define SAP_ALL 3     /* configure all minor devices */

/*@ format of autopush ioctls */
struct strapush {
    struct apcommon sap_common;
    char sap_list[MAXAPUSH][FMNAMESZ + 1]; /* module list */
};

#define sap_cmd     sap_common.apc_cmd
#define sap_major    sap_common.apc_major
#define sap_minor    sap_common.apc_minor
#define sap_lastminor sap_common.apc_lastminor
#define sap_npush    sap_common.apc_npush
```

A device is identified by its major device number, sap_major. The SAD_SAP ioctl(2) has the following options:

- **SAP_ONE**: Configures a single minor device, sap_minor, of a driver
- **SAP_RANGE**: Configures a range of minor devices from sap_minor to sap_lastminor, inclusive
- **SAP_ALL**: Configures all minor devices of a device
SAP_CLEAR  Clears the previous settings by removing the entry with the matching
          sap_major and sap_minor fields

The list of modules is specified as a list of module names in sap_list. MAXAPUSH
defines the maximum number of modules to push automatically.

A user can query the current configuration status of a given major/minor device by
issuing the SAD_GAP ioctl(2) with sap_major and sap_minor values of the device
set. On successful return from this system call, the strapush structure is filled in with
the corresponding information for the device. The maximum number of entries that
the SAD driver can cache is determined by the tunable parameter NAUTOPUSH which
is found in the SAD driver’s master file.

The following is an example of an autopush configuration file in /etc/iu.ap:

<table>
<thead>
<tr>
<th>#</th>
<th>major</th>
<th>minor</th>
<th>lastminor</th>
<th>modules</th>
</tr>
</thead>
<tbody>
<tr>
<td>wc</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>ldterm ttcompat</td>
</tr>
<tr>
<td>zs</td>
<td>0</td>
<td>1</td>
<td></td>
<td>ldterm ttcompat</td>
</tr>
<tr>
<td>ptsl</td>
<td>0</td>
<td>15</td>
<td></td>
<td>ldterm ttcompat</td>
</tr>
</tbody>
</table>

The first line configures a single minor device whose major name is wc. Minor
numbers start and end at 0, creating only one minor number. The modules
automatically pushed are ldterm and ttcompat. The second line configures the zs
driver whose minor device numbers are 0 and 1, and automatically pushes the same
modules. The last line configures the ptsl driver whose minor device numbers are
from 0 to 15, and automatically pushes the same modules.

STREAMS Anchors

An anchor is a lock that prevents the removal of a STREAMS module with an I_POP
call. You place an anchor in a stream on the module you want to lock. All modules at
or below the anchor are locked, and can only be popped by a privileged process.

An anchor is a lock that prevents the removal of a STREAMS module with an I_POP
call. You place an anchor in a stream on the module you want to lock. All modules at
or below the anchor are locked, and can only be popped by a privileged process.
Anchors and Data Flow

**Note** – *Hardening Information.* Anchors do not affect the flow of data in the stream or any other properties of the stream other than to lock down its plumbing. Any process can place an anchor on a stream, but once placed, it can only be removed by a privileged process.

An anchor is a per-stream entity; that is, there is exactly one per stream, and the anchor is moved upstream or downstream as needed. When a stream is created, the anchor is conceptually at the driver and therefore has no effect on the stream. By issuing the `I_ANCHOR ioctl` on a stream, a process places the anchor at the STREAMS module directly below the stream head. This means that a process can move an existing anchor upstream by pushing additional STREAMS modules and calling `I_ANCHOR` again.

Although anchors conceptually exist at a specific location in the stream, they are not a data processing element and therefore do not physically exist in the stream (for example, you will not find them parsing `q_next` pointers.) This means that anchors will not appear in `ioctl` such as `I_LOOK`, and they are not included in the module count on the stream.

To remove an anchor, a process pops the module at which the anchor was placed. The anchor will only allow a privileged process to pop modules at or below it, which provides security. Once an anchor has been removed, the anchor is not reset to its previous location in the stream, but rather positioned at the STREAMS driver again. When an unprivileged process attempts to pop an anchored module, the `ioctl` returns with `EPERM`.

The `I_ANCHOR ioctl` is processed completely in the stream head, and is never sent downstream. If a module or driver sends an `I_ANCHOR` to the stream head, the anchor is silently discarded.

### Using Anchors

An anchor can be placed on a STREAMS module by adding an `[anchor]` flag to an autopush configuration file or by directly calling the `I_ANCHOR ioctl`.

For example, this configuration file specifies that autopush should place an anchor between `foo` and `babar` in the `bb` stream:

```
# major  minor  lastminor  modules
aa      0    0          foo  babar
bb      0    1          foo  [anchor]  babar
```
The following two examples illustrate the use of anchors in a client/server setting in which file descriptors are being passed. They call the I_ANCHOR ioctl directly.

In this example, the server program, `fd_server.c`, opens a stream, pushes modules on to it, and places an anchor on `rlmod`. The client program, `fd_client.c` attempts to pop modules, but can only pop `rlmod` or any modules below it if the client is run as root. That is, if the client is run as non-root, the I_POP fails.

This example also shows that once the module with the anchor on it is popped by the privileged root process, the anchor is destroyed (technically, it is moved back to the driver, where it has no effect). Subsequent attempts by the client to pop modules will succeed, even if the client is run as non-root.

Finally, this example also illustrates the effect of passing file descriptors, rather than copying modules or the stream as a whole. Specifically, because the stream is not duplicated, all instances of the client operate on the same stream. In this case, running the client repeatedly causes it to work down the list of modules, popping each one off in turn, until all modules have been removed from the stream.

**EXAMPLE 11-4 STREAMS Anchors fd_server.c**

```c
#include <sys/types.h>
#include <sys/socket.h>
#include <netinet/in.h>
#include <fcntl.h>
#include <stdio.h>
#include <stropts.h>
#include <sys/conf.h>
#include <sys/stat.h>
#include <unistd.h>
#include <stdlib.h>
#define SPIPE_PATH "/tmp/mypipe"

int main(void)
{
    int pipefd[2];
    struct strrecvfd strrecvfd;
    int streamfd;

    /*
     * Open a stream to hand back to the client. Since this
     * is just an example, we don’t really care what we open;
     * make a rlmod-->udp-->ip stream. Stick an anchor above
     * rlmod so the client cannot I_POP rlmod unless it’s root.
     */
    streamfd = open("/dev/udp", O_RDWR);
    if (streamfd == -1) {
        perror("open");
    } else {
        /*
         * Open a pipe to communicate with the client. Since
         * this is just an example, we don’t really care what we open;
         * make a pipe to communicate with the client.
         */
        pipefd[0] = pipefd[1] = open(SPIPE_PATH, O_WRONLY);
        if (pipefd[0] == -1) {
            perror("pipe");
            close(pipefd[0]);
            return (1);
        }
        strrecvfd = strrecvfd_create(streamfd, &streamrecvfd);
        if (strrecvfd == NULL) {
            perror("strrecvfd_create");
            close(pipefd[0]);
            close(pipefd[1]);
            return (1);
        }
        strrecvfd_setsockopt(strrecvfd, SOL_SOCKET, 1);
        /*
         * The client will probably want to use our
         * stream so link it over to the client.
         */

Multithreaded STREAMS

This chapter describes how to write a multithreaded STREAMS driver or module. It covers the necessary conversion topics so that new and existing STREAMS modules and drivers run in the multithreaded kernel. It describes STREAMS-specific multithreading issues and techniques. For general information, see Writing Device Drivers.

This chapter contains the following information:

- “Multithreaded (MT) STREAMS Overview” on page 249
- “MT STREAMS Framework” on page 251
- “MT STREAMS Perimeters” on page 252
- “MT SAFE Modules and Drivers” on page 258
- “Routines Used Inside a Perimeter” on page 259
- “MT SAFE Modules Using Explicit Locks” on page 263
- “Preparing to Port” on page 264
- “Sample Multithreaded Device Driver Using a Per Module Inner Perimeter” on page 266
- “Sample Multithreaded Module With Outer Perimeter” on page 273

Multithreaded (MT) STREAMS Overview

The SunOS 5 operating system is fully multithreaded, which means that it can make effective use of the available parallelism of a symmetric shared-memory multiprocessor computer. All kernel subsystems are multithreaded: scheduler, virtual memory, file systems, block/character/STREAMS I/O, networking protocols, and device drivers.
MT STREAMS requires you to use some different concepts and terminology. These concepts apply not only to STREAMS drivers, but to all device drivers in the Solaris operating environment. For a more complete description of these terms, see *Writing Device Drivers*. Additionally, see Chapter 1 of this guide for definitions and Chapter 8 for elements of MT drivers.

Some of the multithreaded terms and ideas are.

<table>
<thead>
<tr>
<th>Term</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Thread</td>

</tbody>
</table>
MT STREAMS Framework

The STREAMS framework consists of the stream head, documented STREAMS data structures (such as queue_t, mblk_t) and STREAMS utility routines including STREAMS facilities documented in the Device Driver Interface (DDI). The STREAMS framework enables multiple kernel threads to concurrently enter and execute code defined by each module, including the open, close, put, and service procedures of each queue within the system.

The first goal of the SunOS 5 system is to preserve the interface and flavor of STREAMS and to shield module code as much as possible from the impact of migrating to the multithreaded kernel. Most of the locking is hidden from the programmer and performed by the STREAMS kernel framework. As long as module code uses the standard, documented programmatic interfaces to shared kernel data structures (such as queue_t, mblk_t, and dblk_t), and adheres to the DDI/DKI, the user does not have to explicitly lock these framework data structures.

The second goal is to make writing MT SAFE modules simple. One of the ways that the framework accomplishes this is by using the MT STREAMS perimeter mechanisms for controlling and restricting concurrent access to a STREAMS module. STREAMS perimeters allow the module writer to select the level of concurrency that a module can tolerate.

STREAMS Framework Integrity

The STREAMS framework ensures the integrity of the STREAMS data structures, such as queue_t, mblk_t, and dblk_t as long as the module conforms to the DDI/DKI, and does not directly access global operating system data structures or facilities not described in the DDI/DKI.

The q_next fields of the queue_t structure are not modified by the framework while a thread is actively executing within a synchronous entry point. However the q_next field might change while a thread is executing within an asynchronous entry point.

The q_ptr field is considered private to the module and the framework will not manipulate its value. When making a module MT Safe, the integrity of the module-private data structures must be ensured by the module itself. This integrity can be guaranteed by creating private locks, or by the control of concurrency within the module by the use of STREAMS perimeters. Knowing what the framework supports is critical in deciding what the module writer must provide.
Note – Hardening Information. As in previous Solaris operating environment releases, a module must not call another module’s put or service procedures directly. The DDI/DKI routines putnext(9F), put(9F), and other routines in Section 9F must be used to pass a message to another queue. Calling another module’s routines directly circumvents the design of the MT STREAMS framework and can yield unknown results.

Note – Hardening Information. Once a message is passed using a putq, put, putnext, as well as the perimeter function qwriter, it cannot be accessed again because the use of this message has been given to the new routine. If a reference needs to be retained by the module, it should copy it by using copyb, copymsg, dupb, or dupmsg.

Message Ordering

The STREAMS framework guarantees the ordering of messages along a stream if all the modules in the stream preserve message ordering internally. This ordering guarantee only applies to messages that are sent along the same stream and produced by the same source.

The STREAMS framework does not guarantee that a message has been seen by the next put procedure when the call to putnext(9F) or qreply(9F) returns.

MT STREAMS Perimeters

Solaris STREAMS uses a facility known as perimeters for handling thread concurrency in STREAMS modules. Perimeters allow the module writer to select conditions that will result in exclusive access to a queue, a pair of queues, or all the queues in a module. This makes multithreading issues easier to work with in STREAMS.

Perimeters work somewhat like reader/writer locks, where there can be many readers, but only one writer. A synchronous access to the perimeter is similar to holding the writer lock, in that only one thread can be in the perimeter at a time. Synchronous entry will hold a perimeter exclusively until the thread eventually unwinds out of the
perimeter (usually when it returns from a put/putnext or a qwriter call that initially invoked the synchronous behavior). While a thread has synchronous access to the perimeter, all other access (synchronous or asynchronous) will be deferred.

An asynchronous access is similar to the reader lock, where many threads can be in the perimeter at a time, including the possible recursive entry of a thread previously entering the perimeter. The asynchronous "claim" is not released until the thread winds out of the put/putnext. Because asynchronous access is similar to the reader lock, any synchronous access will be deferred or blocked until all asynchronous claims are released.

**Caution – Hardening Information.** The perimeter data is private to the STREAMS framework, and should not be modified by the module itself.

STREAMS enables the definition of two synchronous perimeters. One is an inner perimeter, and is used to define synchronous entry points on a queue or a queue pair (the read and write queue’s for a specific module instance). It also identifies an outer perimeter, which is made up of all the inner perimeters for all the queues for a specific module.

There is also a special inner perimeter, PERMOD, that is similar to the outer perimeter, but does not have the overhead of the outer perimeter. PERMOD identifies a single synchronous entry point for all queues for this module. Because PERMOD is like a hybrid of an inner perimeter and outer perimeter, the PERMOD perimeter cannot have an outer perimeter.

**Inner Perimeters**

For the most part, the module writer does not need to specify an inner perimeter, as the STREAMS framework automatically creates it for the module. What needs to be specified is the type of perimeter, and the concurrency of the perimeter.

Inner perimeters come in two types:

- **D_PERQ** Enables synchronous entry to be different between the read queue and the write queue. Therefore, if a synchronous putnext is occurring on the read queue, a synchronous or asynchronous putnext can occur on the write queue (or other (a)synchronous access on the write queue).

- **D_QPAIR** Protects both the read queue and the write queue, so synchronous access to one queue will prevent synchronous or asynchronous access to the other queue.

Another perimeter, D_PERMOD is slightly different, and is discussed in “PERMOD Perimeter” on page 254.
An inner perimeter becomes exclusive (writer) whenever an inner synchronous entry point is encountered. By default all the entry points are considered to be synchronous until enabled as "shared" entry points. As previously stated, synchronous entry points remain exclusive until the thread returns to the caller of the synchronous entry point. If the synchronous function calls putnext, the perimeter remains exclusive across the putnext, up till the synchronous function can return to its caller, and subsequent entries into the perimeter will be deferred.

Inner perimeters can specify additional concurrency on the STREAMS entry points for open/close, put/putnext, service, and callbacks as shown in Table 12-4.

Outer Perimeters

The module writer can also specify an outer perimeter. An outer perimeter is the linked list of all inner perimeters for all queues associated with the specified module. Entering the outer perimeter is equivalent to entering each of the inner perimeters. As this can also be an expensive operation, the outer perimeter is only entered synchronously, and upon successful completion of a qwriter(PERM_OUTER) makes the outer perimeter exclusive. This also has the effect of making each of the inner perimeters exclusive.

Use of outer perimeters is reserved for module data that has an effect on all queue instances of the module, such as module state that might allow messages to pass between other instances of the module, information that allows a driver to configure shared hardware, or at open/close time when information is needed for all open instances for a module.

Outer perimeters, at this time, have only one concurrency modifier. This is D_MTOCEXCL, and instructs the framework to enter the outer perimeter on each open and close of queues for the module.

PERMOD Perimeter

The PERMOD perimeter is a hybrid of the inner and outer perimeter. It is implemented primarily for modules that might have a large number of queue instances, and cannot afford the latency for entering the outer perimeter. Because it is a hybrid, PERMOD perimeters cannot have an outer perimeter, and modules that have D_MTPERMOD and D_MTOUTPERIM defined will fail at open. As PERMOD perimeters are implemented as inner perimeters, they share all the concurrency states as the inner perimeter, see Table 12-2.
Hot Perimeters

All STREAMS modules and drivers in the Solaris operating environment must be D_MTSAFE, and must account for multithreading. Specifying an inner and/or outer perimeter will handle concurrency issues that the module writer may encounter while developing the module or driver. Experienced STREAMS programmers might decide that the perimeter should not have any synchronous entry points, and should run fully hot. To define a fully-hot perimeter, the module writer need only specify the D_MTSAFE flag without an inner perimeter type (D_MTPERQ, D_MTQPAIR, D_MTPERMOD) and without an outer perimeter (D_MTOUPTERIM).

Caution – Hardening Information. All STREAMS entry points run concurrently, and in a multiprocessor environment, there can be a put procedure running simultaneously with a service procedure or even a close procedure. So the writer must take precautions against kernel panics by making sure that other concurrent threads will not reference data the current thread is trying to change or remove.

Defining Perimeter Types

To configure a module with perimeter types and concurrency types, use the f_flag field in fmodsw(9s) with D_MTSAFE or’d with the appropriate perimeter type flags. See Table 12-1.

The easiest method is to initially implement your module and configure it to be per-module single threaded, and increase the level of concurrency as needed. “Sample Multithreaded Device Driver Using a Per Module Inner Perimeter” on page 266 provides a complete example of using a per-module perimeter, and “Sample Multithreaded Module With Outer Perimeter” on page 273 provides a complete example with a higher level of concurrency.

To configure a driver with perimeter and concurrency types, put MT_SAFE and the appropriate perimeter flags in the cb_flag field of the cb_ops structure for the driver.

Choosing a Perimeter Type

Table 12–1 summarizes examples of when to use an inner perimeter, or both an inner and outer perimeter for a STREAMS module.
### TABLE 12–1 Choosing a Perimeter Type

<table>
<thead>
<tr>
<th>Module Description</th>
<th>Perimeter Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>A module where the put procedure reads as well as modifies module global data.  Use a per-module inner perimeter on the single-threaded module.</td>
<td>inner</td>
</tr>
<tr>
<td>A module where all the module private data associated with a queue (or a read/write pair of queues) can be configured to be single-threaded. Use an inner perimeter for each corresponding queue (or queue pair).</td>
<td>inner</td>
</tr>
<tr>
<td>A module where most of the module private data is associated with a queue (or a queue pair); but has some module global data that is mostly read. Use an inner perimeter for the queue (or queue pair) plus an outer perimeter for global data. Use qwriter to protect the sections where it modifies the module’s global data (see “qwriter” on page 260).</td>
<td>inner and outer</td>
</tr>
<tr>
<td>A module that requires higher concurrency for certain message types while not requiring message ordering. Use an inner perimeter for shared access to the put procedures. Use an outer perimeter for put procedures that require exclusive access. Use qwriter when messages are handled in the put procedures that require exclusive access (see “qwriter” on page 260).</td>
<td>inner and outer</td>
</tr>
<tr>
<td>A hardware driver can use an appropriate set of inner and outer perimeters to restrict the concurrency in the open, close, put, and service procedures. With explicit synchronization primitives (mutex, condition variables, readers/writer, semaphore), these drivers restrict the concurrency when accessing the hardware registers in interrupt handlers. When designing such drivers, you need to be aware of the issues listed in “SAFE Modules Using Explicit Locks” on page 263.</td>
<td>inner and outer</td>
</tr>
</tbody>
</table>

Several flags specify the inner and outer perimeters (see Table 12–2 and Table 12–3). These flags fall into three categories:

- Define the presence and scope of the inner perimeter
- Define the presence of the outer perimeter (which can have only one scope)
- Modify the default concurrency for the different entry points

You configure the inner perimeter by choosing one of the mutually exclusive flags shown in Table 12–2.

### TABLE 12–2 Inner Perimeter Flags

<table>
<thead>
<tr>
<th>Flag</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>D_MTPERMOD</td>
<td>The module has an inner perimeter that encloses all the module’s queues</td>
</tr>
<tr>
<td>D_MTAPAIR</td>
<td>The module has an inner perimeter around each read/write pair of queues</td>
</tr>
</tbody>
</table>
### TABLE 12–2 Inner Perimeter Flags (Continued)

<table>
<thead>
<tr>
<th>Flag</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>D_MTPERQ</td>
<td>The module has an inner perimeter around each queue</td>
</tr>
<tr>
<td>none</td>
<td>The module has no inner perimeter</td>
</tr>
</tbody>
</table>

Configure the outer perimeter using the flag shown in Table 12–3.

### TABLE 12–3 Outer Perimeter Flag

<table>
<thead>
<tr>
<th>Flag</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>D_MTOOUTPERIM</td>
<td>In addition to an inner perimeter (or none), the module has an outer perimeter that encloses all the module’s queues. This can be combined with all the inner perimeter options except D_MTPERMOD.</td>
</tr>
</tbody>
</table>

By default all synchronous entry points enter the inner perimeter exclusively and enter the outer perimeter shared. To modify this behavior use the flags shown in Table 12–4.

### TABLE 12–4 Modify Exclusive/Shared Access Flags

<table>
<thead>
<tr>
<th>Flag</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>D_MTOCEXCL</td>
<td>open/close entry points are synchronous.</td>
</tr>
<tr>
<td>D_MTPUTSHARED</td>
<td>put/putnext entry points are asynchronous</td>
</tr>
<tr>
<td>_D_MTOCSHARED</td>
<td>open/close entry points are asynchronous (experimental)</td>
</tr>
<tr>
<td>_D_MTCBSHARED</td>
<td>callbacks (via qtimeout, qbufcall) are asynchronous (experimental)</td>
</tr>
<tr>
<td>_D_MTSVCSSHARED</td>
<td>service procedures are asynchronous (experimental)</td>
</tr>
</tbody>
</table>

**Caution – Hardening Information.** Concurrency flags designated with a preceding underbar "_" are experimental, and their behavior might change in the future and should not be relied upon.
MT SAFE Modules and Drivers

A module or a driver can be either MT SAFE or MT UNSAFE. A module or driver is MT SAFE when its data values are correct regardless of the order that multiple threads access and modify the data. For MT SAFE mode, use MT STREAMS perimeters to restrict the concurrency in a module or driver to:

- Per-module single threading
- Per queue-pair single threading
- Per queue single threading
- Per queue or per queue-pair single threading of the put and service procedures with per module single threading of the open and close routines
- Unrestricted concurrency in the put and service procedures with the ability to restrict the concurrency when handling messages that modify data
- Completely unrestricted concurrency

MT SAFE Module

To configure a module as being MT SAFE, use the f_flag field in fmodsw(9S).

The easiest method is to initially implement your module and configure it to be per-module single threaded, and increase the level of concurrency as needed. “Sample Multithreaded Device Driver Using a Per Module Inner Perimeter” on page 266 provides a complete example of using a per-module perimeter, and “Sample Multithreaded Module With Outer Perimeter” on page 273 provides a complete example with a higher level of concurrency.

MT SAFE modules can use different MT STREAMS perimeters to restrict the concurrency in the module to a concurrency that is natural given the data structures that the module contains, thereby removing the need for module private locks (see “MT STREAMS Perimeters” on page 252 for information on perimeters). A module that requires unrestricted concurrency can be configured to have no perimeters. Such modules have to use explicit locking primitives to protect their data structures. While such modules can exploit the maximum level of concurrency allowed by the underlying hardware platform, they are more complex to develop and support. See “MT SAFE Modules Using Explicit Locks” on page 263.

Independent of the perimeters, there will be at most one thread allowed within any given queue’s service procedure.

Your MT SAFE modules should use perimeters and avoid using module private locks (mutex, condition variables, readers/writer, or semaphore). Should you opt to use module private locks, you need to read “MT SAFE Modules Using Explicit Locks” on page 263 along with this section.
Note – MT UNSAFE mode for STREAMS modules was temporarily supported as an aid in porting SVR4 modules; however, MT UNSAFE is not supported after SVR4. Beginning with the release of the Solaris 7 operating environment, no MT UNSAFE module or driver has been supported.

Note – Upper and lower multiplexors share the same perimeter type and concurrency level.

MT SAFE Driver

To configure a driver as being MT SAFE, initialize the cb_ops(9S) and dev_ops(9S) data structures. This code must be in the header section of your module. For more information, see Example 12–1, and dev_ops(9S).

The driver is configured to be MT SAFE by setting the cb_flag to D_MP. It also specifies any MT STREAMS perimeters by setting flags in the cb_flag field. (See mt-streams(9F).)

Routines Used Inside a Perimeter

This section describes the routines and data fields used after you enter a perimeter.

qprocson/qprocsoff

The routines qprocson(9F) and qprocsoff(9F) respectively enable and disable the put and service procedures of the queue pair. Before calling qprocson(9F) and after calling qprocsoff(9F), the module’s put and service procedures are disabled; messages flow around the module as if it were not present in the stream.

Call qprocson(9F) in the first open of a module, but only after allocating and initializing any module resources on which the put and service procedures depend. Call the qprocsoff routine in the close routine of the module before deallocating any resources on which the put and service procedures depend.
Note – To avoid deadlocks, modules must not hold private locks across the calls to qprocson(9F) or qprocsoff(9F).

qtimeout/qunbufcall

The timeout(9F) and bufcall(9F) callbacks are asynchronous. For a module using MT STREAMS perimeters, the timeout(9F) and bufcall(9F) callback functions execute outside the scope of the perimeters. This makes synchronization of callbacks with the rest of the module complex.

To make timeout(9F) and bufcall(9F) functionality easier to use for modules with perimeters, there are additional interfaces that use synchronous callbacks. These routines are qtimeout(9F), quntimeout(9F), qbufcall(9F), and qunbufcall(9F). When using these routines, the callback functions are executed inside the perimeters, and hence have the same concurrency restrictions as the put and service procedures.

qwriter

Modules can use the qwriter(9F) function to upgrade from shared to exclusive access at a perimeter. For example, a module with an outer perimeter can use qwriter(9F) in the put procedure to upgrade to exclusive access at the outer perimeter. A module where the put procedure runs with shared access at the inner perimeter (D_MTPUTSHARED) can use qwriter(9F) in the put procedure to upgrade to exclusive access at the inner perimeter.

Returning from a qwriter call does not mean that the callback function has executed. If the framework can become exclusive in the qwriter call, it will enter the perimeter synchronously, and execute the callback. If it cannot, the callback will be deferred. It is a good idea for any caller of qwriter to immediately return to its caller as there is little that can be accomplished in this thread of execution.

Caution – Hardening Information. Do not call qwriter with another queue, as qwriter assumes that the caller has already made a claim to the perimeter that the queue is associated with (asynchronous entry), and calling another perimeter will cause problems.
**Note** – qwriter(9F) cannot be used in the open or close procedures. If a module needs exclusive access at the outer perimeter in the open and/or close procedures, it has to specify that the outer perimeter should always be entered exclusively for open and close (using D_MTOCEXCL).

The STREAMS framework guarantees that all deferred qwriter(9F) callbacks associated with a queue have executed before the module’s close routine is called for that queue.

For an example of a driver using qwriter(9F) see Example 12–2.

**qwait**

A module that uses perimeters and must wait in its open or close procedure for a message from another STREAMS module has to wait outside the perimeters; otherwise, the message would never be allowed to enter its put and service procedures. This is accomplished by using the qwait(9F) interface. See qwriter(9F) man page for an example.

**Asynchronous Callback Functions**

Interrupt handlers and other asynchronous callback functions require special care by the module writer, because they can execute asynchronously to threads executing within the module open, close, put, and service procedures.

For modules using perimeters, use qtimeout(9F) and qbufcall(9F) instead of timeout(9F) and bufcall(9F). The qtimeout and qbufcall callbacks are synchronous and consequently introduce no special synchronization requirements.

Because a thread can enter the module at any time, you must ensure that the asynchronous callback function acquires the proper private locks before accessing private module data structures, and releases these locks before returning. You must cancel any outstanding registered callback routines before the data structures on which the callback routines depend are deallocated and the module closed.

- For hardware device interrupts, this involves disabling the device interrupts.
- Outstanding callbacks from timeout(9F) and bufcall(9F) must be canceled by calling untimeout(9F) and unbufcall(9F).
  
  The module cannot hold certain private locks across calls to untimeout(9F) or unbufcall(9F). These locks are those that the module’s timeout(9F) or bufcall(9F) callback functions acquire. See “MT SAFE Modules Using Explicit Locks” on page 263.
If outstanding callbacks from `esballoc(9F)` are associated with a particular stream, they must be allowed to complete before the module `close` routine deallocates the private data structures on which they depend.

**close() Race Conditions**

Because the callback functions are by nature asynchronous, they can be executing or about to execute at the time the module `close` routine is called. You must cancel all outstanding callback and interrupt conditions before deallocating those data structures or returning from the `close` routine.

The callback functions scheduled with `timeout(9F)` and `bufcall(9F)` are guaranteed to have been canceled by the time `untimeout(9F)` and `unbufcall(9F)` return. The same is true for `qtimeout(9F)` and `qbufcall(9F)` by the time `quntimeout(9F)` and `qunbufcall(9F)` return. You must also take responsibility for other asynchronous routines, including `esballoc(9F)` callbacks and hardware, as well as software interrupts.

**Unloading a Module that Uses esballoc**

The STREAMS framework prevents a module or driver text from being unloaded while there are open instances of the module or driver. If a module does not cancel all callbacks in the last `close` routine, it should not be allowed to be unloaded.

This is an issue mainly for modules and drivers using `esballoc` because `esballoc` callbacks cannot be canceled. Thus, modules and drivers using `esballoc` have to be prepared to handle calls to the `esballoc` callback free function after the last instance of the module or driver has been closed.

Modules and drivers can maintain a semaphore count of outstanding callbacks. They can deny an unload by making the `_fini(9E)` routine return `EBUSY` if there are outstanding callbacks.

**Use of the q_next Field**

The `q_next` field in the `queue_t` structure can be referenced in `open`, `close`, `put`, and `service` procedures as well as the synchronous callback procedures (scheduled with `qtimeout(9F)`, `qbufcall(9F)`, and `qwriter(9F)`). However, the value in the `q_next` field should not be trusted. It is relevant to the STREAMS framework, but may not be relevant to a specific module.

All other module code, such as interrupt routines, `timeout(9F)` and `esballoc(9F)` callback routines, cannot dereference `q_next`. Those routines have to use the “next” version of all functions. For instance, use `canputnext(9F)` instead of dereferencing `q_next` and using `canput(9F)`.
MT SAFE Modules Using Explicit Locks

Although the result is not reliable, you can use explicit locks either instead of perimeters or to augment the concurrency restrictions provided by the perimeters.

Caution – Explicit locks cannot be used to preserve message ordering in a module because of the risk of re-entering the module. Use MT STREAMS perimeters to preserve message ordering.

All four types of kernel synchronization primitives are available to the module writer: mutexes, readers/writer locks, semaphores, and condition variables. Because `cv_wait` implies a context switch, it can only be called from the module’s open and close procedures, which are executed with valid process context. You must use the synchronization primitives to protect accesses and ensure the integrity of private module data structures.

Constraints When Using Locks

When adding locks in a module, observe these constraints:

- Avoid holding module private locks across calls to `putnext(9F)`. The module might be re-entered by the same thread that called `putnext(9F)`, causing the module to try to acquire a lock that it already holds. This can cause kernel panic.
- Do not hold module private locks, acquired in `put` or `service` procedures, across the calls to `qprocson(9F)` or `qprocsoff(9F)`. Doing this causes deadlock, since `qprocson(9F)` and `qprocsoff(9F)` wait until all threads leave the inner perimeter.
- Similarly, do not hold locks, acquired in the `timeout(9F)` and `bufcall(9F)` callback procedures, across the calls to `untotimeout(9F)` or `unbufcall(9F)`. Doing this causes deadlock, because `untotimeout(9F)` and `unbufcall(9F)` wait until an already executing callback has completed.

The first restriction deters using module private locks to preserve message ordering. The preferred mechanism is to use MT STREAMS perimeters to preserve message ordering.

Preserving Message Ordering

Module private locks cannot be used to preserve message ordering because they cannot be held across calls to `putnext(9F)` and the other messages that pass routines to other modules. The alternatives for preserving message ordering are:
Use MT STREAMS perimeters.

Pass all messages through the service procedures. The service procedure can drop the locks before calling putnext(9F) or qreply(9F), without reordering messages, because the framework guarantees that at most, one thread will execute in the service procedure for a given queue.

Use perimeters to avoid the performance penalty for using service procedures.

Preparing to Port

When modifying a STREAMS driver to take advantage of the multithreaded kernel, a level of MT safety is selected according to:

- The desired degree of concurrency
- The natural concurrency of the underlying module
- The amount of effort or complexity required

Much of the effort in conversion is simply determining the appropriate degree of data sharing and the corresponding granularity of locking (see Table 12–1). The actual time spent configuring perimeters and/or installing locks should be much smaller than the time spent in analysis.

To port your module, you must understand the data structures used within your module, as well as the accesses to those data structures. You must fully understand the relationship between all portions of the module and private data within that module, and to use the MT STREAMS perimeters (or the synchronization primitives available) to maintain the integrity of these private data structures.

You must explicitly restrict access to private module data structures as appropriate to ensure the integrity of these data structures. You must use the MT STREAMS perimeters to restrict the concurrency in the module so that the parts of the module that modify private data are single-threaded with respect to the parts of the module that read the same data. (For more information about perimeters, see “MT STREAMS Perimeters” on page 252.) Besides perimeters, you can use the synchronization primitives available (mutex, condition variables, readers/writer, semaphore) to explicitly restrict access to module private data appropriate for the operations within the module on that data.

The first step in multithreading a module or driver is to analyze the module, breaking the entire module up into a list of individual operations and the private data structures referenced in each operation. Part of this first step is deciding upon a level of concurrency for the module. Ask yourself which of these operations can be multithreaded and which must be single-threaded. Try to find a level of concurrency
that is “natural” for the module and matches one of the available perimeters (or, alternatively, requires the minimal number of locks), and has a simple and straightforward implementation. Avoid additional unnecessary complexity.

Typical questions to ask are:

- What data structures are maintained within the module?
- What types of accesses are made to each field of these data structures?
- When is each data structure accessed destructively (written) and when is it accessed non-destructively (read)?
- Which operations within the module should be allowed to execute concurrently?
- Is per module single-threading appropriate for the module?
- Is per queue-pair or per queue single-threading appropriate?
- What are the message ordering requirements?

Porting to the SunOS 5 System

When porting a STREAMS module or driver from the SunOS 4 system to the SunOS 5 system, the module should be examined with respect to the following areas:

- The SunOS 5 Device Driver Interface (DDI/DKI)
- The SunOS 5 MT design

For portability and correct operation, each module must adhere to the SunOS DDI/DKI. Several facilities available in previous releases of the SunOS system have changed and can take different arguments, or produce different side effects, or no longer exist in the SunOS 5 system. The module writer should carefully review the module with respect to the DDI/DKI.

Each module that accesses underlying Sun-specific features included in the SunOS 5 system should conform to the Device Driver Interface. The SunOS 5 DDI defines the interface used by the device driver to register device hardware interrupts, access device node properties, map device slave memory, and establish and synchronize memory mappings for DVMA (Direct Virtual Memory Access). These areas are primarily applicable to hardware device drivers. Refer to the Device Driver Interface Specification within the Writing Device Drivers for details on the SunOS 5 DDI and DVMA.

The kernel networking subsystem in the SunOS 5 system is based on STREAMS. Datalink drivers that used the ifnet interface in the SunOS 4 system must be converted to use DLPI for the SunOS 5 system. Refer to the Data Link Provider Interface, Revision 2 specification.

After reviewing the module for conformance to the SunOS 5 DKI and DDI specifications, you should be able to consider the impact of multithreading on the module.
Sample Multithreaded Device Driver Using a Per Module Inner Perimeter

Example 12-1 is a sample multithreaded, loadable, STREAMS pseudo-driver. The driver MT design is the simplest possible based on using a per module inner perimeter. Thus, only one thread can execute in the driver at any time. In addition, a quntimeout(9F) synchronous callback routine is used. The driver cancels an outstanding quntimeout(9F) by calling quntimeout(9F) in the close routine. See “close() Race Conditions” on page 262.

```
Sample Multithreaded Module With Outer Perimeter

Example 12-2 is a sample multithreaded, loadable STREAMS module. The module MT design is a relatively simple one, based on a per queue-pair inner perimeter plus an outer perimeter. The inner perimeter protects per-instance data structure (accessed through the q_ptr field) and the module global data is protected by the outer perimeter. The outer perimeter is configured so that the open and close routines have exclusive access to the outer perimeter. This is necessary because they both modify the global-linked list of instances. Other routines that modify global data are run as qwriter(9F) callbacks, giving them exclusive access to the whole module.

EXAMPLE 12-2 Multithread Module with Outer Perimeter

```c

STREAMS Multiplex Drivers

This chapter describes how STREAMS multiplexing configurations are created and also discusses multiplexing drivers. A STREAMS multiplexer is a driver with multiple streams connected to it. The primary function of the multiplexing driver is to switch messages among the connected streams. Multiplexer configurations are created from the user level by system calls.

This chapter contains the following information:
- “STREAMS Multiplexers” on page 279
- “Connecting And Disconnecting Lower Streams” on page 286
- “Multiplexer Construction Example” on page 288
- “Multiplexing Driver Example” on page 289
- “Persistent Links” on page 298
- “Design Guidelines” on page 300

STREAMS Multiplexers

STREAMS-related system calls are used to set up the “plumbing,” or stream interconnections, for multiplexing drivers. The subset of these calls that allows a user to connect (and disconnect) streams below a driver is referred to as multiplexing. This type of connection is referred to as a one-to-M, or lower, multiplexer configuration. This configuration must always contain a multiplexing driver, which is recognized by STREAMS as having special characteristics.

Multiple streams can be connected above a driver by open(2) calls. This accommodates the loop-around driver and the driver that handled multiple minor devices in Chapter 9. There is no difference between the connections to these drivers. Only the functions performed by the driver are different. In the multiplexing case, the driver routes data between multiple streams. In the device driver case, the driver
routes data between user processes and associated physical ports. Multiplexing with streams connected above is referred to as an N-to-1, or upper, multiplexer. STREAMS does not provide any facilities beyond open and close to connect or disconnect upper streams for multiplexing.

From the driver’s perspective, upper and lower configurations differ only in the way they are initially connected to the driver. The implementation requirements are the same: route the data and handle flow control. All multiplexer drivers require special developer-provided software to perform the multiplexing data routing and to handle flow control. STREAMS does not directly support flow control among multiplexed streams. M-to-N multiplexing configurations are implemented by using both of these mechanisms in a driver.

As discussed in Chapter 9, the multiple streams that represent minor devices are actually distinct streams in which the driver keeps track of each stream attached to it. The STREAMS subsystem does not recognize any relationship between the streams. The same is true for STREAMS multiplexers of any configuration. The multiplexed streams are distinct and the driver must be implemented to do most of the work.

In addition to upper and lower multiplexers, more complex configurations can be created by connecting streams containing multiplexers to other multiplexer drivers. With such a diversity of needs for multiplexers, providing general-purpose multiplexer drivers is not possible. Rather, STREAMS provides a general purpose multiplexing facility. The facility enables you to set up the intermodule or driver plumbing to create multiplexer configurations of generally unlimited interconnection.

Building a Multiplexer

The example in this section builds a protocol multiplexer with the multiplexing configuration shown in Figure 13–1. To free users from the need to know about the underlying protocol structure, a user-level daemon process is built to maintain the multiplexing configuration. Users can then access the transport protocol directly by opening the transport protocol (TP) driver device node.

An internetworking protocol driver (IP) routes data from a single upper stream to one of two lower streams. This driver supports two STREAMS connections beneath it. These connections are to two distinct networks; one for the IEEE 802.3 standard through the 802.3 driver, and another to the IEEE 802.4 standard through the 802.4 driver. The TP driver multiplexes upper streams over a single stream to the IP driver.
Example 13–1 shows how this daemon process sets up the protocol multiplexer. The necessary declarations and initialization for the daemon program follow.

**EXAMPLE 13–1 Protocol Daemon**

```c
#include <fcntl.h>
#include <stropts.h>

void main()
{
    int fd_802_4,
        fd_802_3,
        fd_ip,
        fd_tp;
    /* daemon-ize this process */

    switch (fork()) {  
    case 0:  
        break;
    case -1:
        perror("fork failed");
        exit(2);
    default:
        exit(0);
    }
    (void) setsid();
}
```
This multilevel multiplexed stream configuration is built from the bottom up. The example begins by first constructing the IP multiplexer. This multiplexing device driver is treated like any other software driver. It owns a node in the Solaris file system and is opened just like any other STREAMS device driver.

The first step is to open the multiplexing driver and the 802.4 driver, thus creating separate streams above each driver as shown in Figure 13–2. The stream to the 802.4 driver may now be connected below the multiplexing IP driver using the \texttt{I_LINK ioctl(2)}.

The sequence of instructions to this point is:

```c
if ((fd_802_4 = open("/dev/802_4", O_RDWR)) < 0) {
    perror("open of /dev/802_4 failed");
    exit(1);
}
if ((fd_ip = open("/dev/ip", O_RDWR)) < 0) {
    perror("open of /dev/ip failed");
    exit(2);
}
/* now link 802.4 to underside of IP */
if (ioctl(fd_ip, I_LINK, fd_802_4) < 0) {
    perror("I_LINK ioctl failed");
    exit(3);
}
```

**FIGURE 13–2 Streams Before Link**
I_LINK takes two file descriptors as arguments. The first file descriptor, fd_ip, is the stream connected to the multiplexing driver, and the second file descriptor, fd_802_4, is the stream to be connected below the multiplexer. The complete stream to the 802.4 driver is connected below the IP driver. The stream head’s queues of the 802.4 driver are used by the IP driver to manage the lower half of the multiplexer.

I_LINK returns an integer value, muxid, which is used by the multiplexing driver to identify the stream just connected below it. muxid is ignored in the example, but it is useful for dismantling a multiplexer or routing data through the multiplexer. Its significance is discussed in “Dismantling a Multiplexer” on page 284.

The following sequence of system calls continues building the Internetworking Protocol multiplexer (IP):

```c
if ((fd_802_3 = open("/dev/802_3", O_RDWR)) < 0) {
    perror("open of /dev/802_3 failed");
    exit(4);
}
if (ioctl(fd_ip, I_LINK, fd_802_3) < 0) {
    perror("I_LINK ioctl failed");
    exit(5);
}
```

The stream above the multiplexing driver used to establish the lower connections is the controlling stream and has special significance when dismantling the multiplexing configuration. This is illustrated in “Dismantling a Multiplexer” on page 284. The stream referenced by fd_ip is the controlling stream for the IP multiplexer.

The order in which the streams in the multiplexing configuration are opened is unimportant. If intermediate modules in the stream are necessary between the IP driver and media drivers, these modules must be added to the streams associated with the media drivers (using I_PUSH) before the media drivers are attached below the multiplexer.

The number of streams that can be linked to a multiplexer is restricted by the design of the particular multiplexer. The manual page describing each driver describes such restrictions (see SunOS Reference Manual, Intro(7)). However, only one I_LINK operation is allowed for each lower stream; a single stream cannot be linked below two multiplexers simultaneously.

Continuing with the example, the IP driver is now linked below the transport protocol (TP) multiplexing driver. As seen in Figure 13–1, only one link is supported below the transport driver. This link is formed by the following sequence of system calls:

```c
if ((fd_tp = open("/dev/tp", O_RDWR)) < 0) {
    perror("open of /dev/tp failed");
    exit(6);
}
if (ioctl(fd_tp, I_LINK, fd_ip) < 0) {
    perror("I_LINK ioctl failed");
    exit(7);
}
```
Because the controlling stream of the IP multiplexer has been linked below the TP multiplexer, the controlling stream for the new multilevel multiplexer configuration is the stream above the TP multiplexer.

At this point, the file descriptors associated with the lower drivers can be closed without affecting the operation of the multiplexer. If these file descriptors are not closed, all subsequent read(2), write(2), ioctl(2), poll(2), getmsg(2), and putmsg(2) calls issued to them fail. That is because I_LINK associates the stream head of each linked stream with the multiplexer, so the user may not access that stream directly for the duration of the link.

The following sequence of system calls completes the daemon example:

```c
    close(fd_802_4);
    close(fd_802_3);
    close(fd_ip);
    /* Hold multiplexer open forever or at least til this process
     * is terminated by an external UNIX signal */
    pause();
```

The transport driver supports several simultaneous streams. These streams are multiplexed over the single stream connected to the IP multiplexer. The mechanism for establishing multiple streams above the transport multiplexer is actually a by-product of the way in which streams are created between a user process and a driver. By opening different minor devices of a STREAMS driver, separate streams will be connected to that driver. The driver must be designed with the intelligence to route data from the single lower stream to the appropriate upper stream.

The daemon process maintains the multiplexed stream configuration through an open stream (the controlling stream) to the transport driver. Meanwhile, other users can access the services of the transport protocol by opening new streams to the transport driver; they are freed from the need for any unnecessary knowledge of the underlying protocol configurations and subnetworks that support the transport service.

Multilevel multiplexing configurations should be assembled from the bottom up. That is because the passing of ioctl(2) through the multiplexer is determined by the nature of the multiplexing driver and cannot generally be relied on.

**Dismantling a Multiplexer**

Streams connected to a multiplexing driver from above with open(2), can be dismantled by closing each stream with close(2). The mechanism for dismantling streams that have been linked below a multiplexing driver is less obvious, and is described in “Disconnecting Lower Streams” on page 288.
I_UNLINK ioctl(2) disconnects each multiplexer link below a multiplexing driver individually. This command has the form:

```
ioctl(fd, I_UNLINK, muxid);
```

where `fd` is a file descriptor associated with a stream connected to the multiplexing driver from above, and `muxid` is the identifier that was returned by `I_LINK` when a driver was linked below the multiplexer. Each lower driver may be disconnected individually in this way, or a special `muxid` value of `MUXID_ALL` can be used to disconnect all drivers from the multiplexer simultaneously.

In the multiplexing daemon program, the multiplexer is never explicitly dismantled. That is because all links associated with a multiplexing driver are automatically dismantled when the controlling stream associated with that multiplexer is closed. Because the controlling stream is open to a driver, only the final call of `close` for that stream will close it. In this case, the daemon is the only process that has opened the controlling stream, so the multiplexing configuration will be dismantled when the daemon exits.

For the automatic dismantling mechanism to work in the multilevel, multiplexed stream configuration, the controlling stream for each multiplexer at each level must be linked under the next higher-level multiplexer. In the example, the controlling stream for the IP driver was linked under the TP driver. This resulted in a single controlling stream for the full, multilevel configuration. Because the multiplexing program relied on closing the controlling stream to dismantle the multiplexed stream configuration instead of using explicit `I_UNLINK` calls, the `muxid` values returned by `I_LINK` could be ignored.

An important side effect of automatic dismantling on the close is that a process cannot build a multiplexing configuration with `I_LINK` and then exit. `exit(2)` closes all files associated with the process, including the controlling stream. To keep the configuration intact, the process must exist for the life of that multiplexer. That is the motivation for implementing the multiplexer as a daemon process, see “Multiplexing Driver Example” on page 289.

If the process uses persistent links through `I_PLINK ioctl(2)`, the multiplexer configuration remains intact after the process exits. These links are described in “Persistent Links” on page 298.

### Routing Data Through a Multiplexer

As demonstrated, STREAMS provides a mechanism for building multiplexed stream configurations. However, the criteria by which a multiplexer routes data are driver dependent. For example, the protocol multiplexer might use address information found in a protocol header to determine the subnetwork over which data should be routed. You must define its routing criteria.
One routing option available to the multiplexer is to use the muxid value to determine the stream to which data is routed (remember that each multiplexer link has a muxid). The I_LINK passes the muxid value to the driver and returns this value to the user. The driver can therefore specify that the muxid value accompany data routed through it. For example, if a multiplexer routed data from a single upper stream to one of several lower streams (as did the IP driver), the multiplexer can require the user to insert the muxid of the desired lower stream into the first four bytes of each message passed to it. The driver can then match the muxid in each message with the muxid of each lower stream, and route the data accordingly.

Connecting And Disconnecting Lower Streams

Multiple streams are created above a driver/multiplexer by use of the open system call on either different minor device, or on a cloneable device file. Note that any driver that handles more than one minor device is considered an upper multiplexer.

To connect streams below a multiplexer requires additional software in the multiplexer. The main difference between STREAMS lower multiplexers and STREAMS device drivers is that multiplexers are pseudo-devices and multiplexers have two additional qinit structures, pointed to by fields in streamtab(9S): the lower half read-side qinit(9S) and the lower half write-side qinit(9S).

The multiplexer is divided into two parts: the lower half and the upper half. The multiplexer queue structures allocated when the multiplexer was opened use the usual qinit entries from the multiplexer’s streamtab(9S). This is the same as any open of the STREAMS device. When a lower stream is linked beneath the multiplexer, the qinit structures at the stream head are substituted by the lower half qinit(9S) structures identified in the streamtab for the multiplexers. Once the linkage is made, the multiplexer switches messages between upper and lower streams. When messages reach the top of the lower stream, they are handled by put and service routines specified in the bottom half of the multiplexer.

Connecting Lower Streams

A lower multiplexer is connected as follows: the initial open to a multiplexing driver creates a stream, as in any other driver. open uses the st_rdinit and st_wrinit elements of the streamtab structure to initialize the driver queues. At this point, the only distinguishing characteristics of this stream are non-NULL entries in the streamtab(9S) st_muxrinit and st_muxwinit fields.
These fields are ignored by open. Any other stream subsequently opened to this driver will have the same streamtab and thereby the same mux fields.

Next, another file is opened to create a (soon-to-be) lower stream. The driver for the lower stream is typically a device driver. This stream has no distinguishing characteristics. It can include any driver compatible with the multiplexer. Any modules required on the lower stream must be pushed onto it now.

Next, this lower stream is connected below the multiplexing driver with an _I_LINK ioctl(2) (see streamio(7I)). The stream head points to the stream head routines as its procedures (through its queue). An _I_LINK to the upper stream, referencing the lower stream, causes STREAMS to modify the contents of the stream head’s queues in the lower stream. The pointers to the stream head routines, and other values, in the stream head’s queues are replaced with those contained in the mux fields of the multiplexing driver’s streamtab. Changing the stream head routines on the lower stream means that all subsequent messages sent upstream by the lower stream’s driver are passed to the put procedure designated in st_muxrinit, the multiplexing driver. The _I_LINK also establishes this upper stream as the control stream for this lower stream. STREAMS remembers the relationship between these two streams until the upper stream is closed or the lower stream is unlinked.

Finally, the stream head sends an M_IOCTL message with ioc_cmd set to _I_LINK to the multiplexing driver. The M_DATA part of the M_IOCTL contains a linkblk(9S) structure. The multiplexing driver stores information from the linkblk(9S) structure in private storage and returns an M_IOCACK acknowledgement. _I_index is returned to the process requesting the _I_LINK. This value is used later by the process to disconnect the stream.

An _I_LINK is required for each lower stream connected to the driver. Additional upper streams can be connected to the multiplexing driver by open calls. Any message type can be sent from a lower stream to user processes along any of the upper streams. The upper streams provide the only interface between the user processes and the multiplexer.

No direct data structure linkage is established for the linked streams. The read queue’s q_next is NULL and the write queue’s q_next points to the first entity on the lower stream. Messages flowing upstream from a lower driver (a device driver or another multiplexer) will enter the multiplexing driver’s put procedure with the queue represented in l_qbot as the queue_t for the put procedure. The multiplexing driver has to route the messages to the appropriate upper (or lower) stream. Similarly, a message coming downstream from user space on any upper stream has to be processed and routed, if required, by the driver.

---

**Note** – It is the responsibility of the driver to handle routing of messages between the upper and lower streams, or between any lateral stream that is part of the multiplexer. This operation is not handled by the STREAMS framework.
In general, multiplexing drivers should be implemented so that new streams can be dynamically connected to (and existing streams disconnected from) the driver without interfering with its ongoing operation. The number of streams that can be connected to a multiplexer is implementation dependent.

**Disconnecting Lower Streams**

Dismantling a lower multiplexer is accomplished by disconnecting (unlinking) the lower streams. Unlinking can be initiated in three ways:

- An `I_UNLINK` ioctl referencing a specific stream
- An `I_UNLINK` indicating all lower streams
- The last close of the control stream

As in the link, an unlink sends a `linkblk(9S)` structure to the driver in an `M_IOCTL` message. The `I_UNLINK` call, which unlinks a single stream, uses the `l_index` value returned in the `I_LINK` to specify the lower stream to be unlinked. The latter two calls must designate a file corresponding to a control stream, which causes all the lower streams that were previously linked by this control stream to be unlinked. However, the driver sees a series of individual unlinks.

If no open references exist for a lower stream, a subsequent unlink will automatically close the stream. Otherwise, the lower stream must be closed by `close(2)` following the unlink. STREAMS automatically dismantles all cascaded multiplexers (below other multiplexing streams) if their controlling stream is closed. An `I_UNLINK` leaves lower, cascaded multiplexing streams intact unless the stream file descriptor was previously closed.

---

**Multiplexer Construction Example**

This section describes an example of multiplexer construction and usage. Multiple upper and lower streams interface to the multiplexer driver.

The Ethernet, LAPB, and IEEE 802.2 device drivers terminate links to other nodes. The multiplexer driver is an Internet Protocol (IP) multiplexer that switches data among the various nodes or sends data upstream to users in the system. The net modules typically provide a convergence function that matches the multiplexer driver and device driver interface.

Streams A, B, and C are opened by the process, and modules are pushed as needed. Two upper streams are opened to the IP multiplexer. The rightmost stream represents multiple streams, each connected to a process using the network. The stream second
from the right provides a direct path to the multiplexer for supervisory functions. The control stream, leading to a process, sets up and supervises this configuration. It is always directly connected to the IP driver. Although not shown, modules can be pushed on the control stream.

After the streams are opened, the supervisory process typically transfers routing information to the IP drivers (and any other multiplexers above the IP), and initializes the links. As each link becomes operational, its stream is connected below the IP driver. If a more complex multiplexing configuration is required, the IP multiplexer stream with all its connected links can be connected below another multiplexer driver.

### Multiplexing Driver Example

This section contains an example of a multiplexing driver that implements an N-to-1 configuration. This configuration might be used for terminal windows, where each transmission to or from the terminal identifies the window. This resembles a typical device driver, with two differences: the device-handling functions are performed by a separate driver, connected as a lower stream, and the device information (that is, relevant user process) is contained in the input data rather than in an interrupt call.

Each upper stream is created by `open(2)`. A single lower stream is opened and then it is linked by use of the multiplexing facility. This lower stream might connect to the TTY driver. The implementation of this example is a foundation for an M-to-N multiplexer.

As in the loop-around driver (Chapter 9), flow control requires the use of standard and special code because physical connectivity among the streams is broken at the driver. Different approaches are used for flow control on the lower stream, for messages coming upstream from the device driver, and on the upper streams, for messages coming downstream from the user processes.

---

**Note** – The code presented here for the multiplexing driver represents a single-threaded, uniprocessor implementation. See Chapter 12 for details on multiprocessor and multithreading issues such as locking for data corruption and to prevent race conditions.

Example 13–2 is of multiplexer declarations:

```c
EXAMPLE 13-2 Multiplexer Declarations
#include <sys/types.h>
#include <sys/param.h>
#include <sys/stream.h>
```

Chapter 13 • STREAMS Multiplex Drivers 289
EXAMPLE 13–2 Multiplexer Declarations  (Continued)

#include <sys/stropts.h>
#include <sys/errno.h>
#include <sys/cred.h>
#include <sys/ddi.h>
#include <sys/sunddi.h>

static int muxopen (queue_t*, dev_t*, int, int, cred_t*);
static int muxclose (queue_t*, int, cred_t*);
static int muxuwput (queue_t*, mblk_t*);
static int muxlwsrv (queue_t*);
static int muxlrput (queue_t*, mblk_t*);
static int muxuwsrv (queue_t*);

static struct module_info info = {
    0xaabb, "mux", 0, INFPSZ, 512, 128
};

static struct qinit urinit = {
    muxopen, muxclose, NULL, NULL, &info, NULL
};
static struct qinit uwinit = {
    muxuwput, muxuwsrv, NULL, NULL, &info, NULL
};
static struct qinit lrinit = {
    muxlrput, NULL, NULL, NULL, &info, NULL
};
static struct qinit lwinit = {
    muxlwsrv, NULL, NULL, NULL, &info, NULL
};

struct streamtab muxinfo = {
    &urinit, &uwinit, &lrinit, &lwinit
};

struct mux {
    queue_t *qptr; /* back pointer to read queue */
    int bufcid; /* bufcall return value */
};
extern struct mux mux_mux[];
extern int mux_cnt; /* max number of muxes */

static queue_t *muxbot; /* linked lower queue */
static int muxerr; /* set if error of hangup on lower strm */

The four streamtab entries correspond to the upper read, upper write, lower read,
and lower write qinit structures. The multiplexing qinit structures replace those in
each lower stream head (in this case there is only one) after the I_LINK has concluded
successfully. In a multiplexing configuration, the processing performed by the
multiplexing driver can be partitioned between the upper and lower queues. There
must be an upper-stream write put procedure and lower-stream read put procedure.
If the queue procedures of the opposite upper/lower queue are not needed, the queue
can be skipped, and the message put to the following queue.

290  STREAMS Programming Guide • May 2002
In the example, the upper read-side procedures are not used. The lower-stream read queue put procedure transfers the message directly to the read queue upstream from the multiplexer. There is no lower write put procedure because the upper write put procedure directly feeds the lower write queue downstream from the multiplexer.

The driver uses a private data structure, `mux`. `mux_mux[dev]` points back to the opened upper read queue. This is used to route messages coming upstream from the driver to the appropriate upper queue. It is also used to find a free major or minor device for a CLONEOPEN driver open case.

Example 13–3, the upper queue open, contains the canonical driver open code.

**EXAMPLE 13–3 Upper Queue Open**

```c
static int muxopen(queue_t *q, dev_t *devp, int flag,
                     int sflag, cred_t *credp)
{
    struct mux *mux;
    minor_t device;

    if (q->q_ptr)
        return(EBUSY);

    if (sflag == CLONEOPEN) {
        for (device = 0; device < mux_cnt; device++)
            if (mux_mux[device].qptr == 0)
                break;

        *devp=makedevice(getmajor(*devp), device);
    }
    else {
        device = getminor(*devp);
        if (device >= mux_cnt)
            return ENXIO;
    }

    mux = &mux_mux[device];
    mux->qptr = q;
    q->q_ptr = (char *) mux;
    WR(q)->q_ptr = (char *) mux;
    qprocson(q);
    return (0);
}
```

`muxopen` checks for a clone or ordinary open call. It initializes `q_ptr` to point at the `mux_mux[]` structure.
The core multiplexer processing is as follows: downstream data written to an upper stream is queued on the corresponding upper write message queue if the lower stream is flow controlled. This allows flow control to propagate toward the stream head for each upper stream. A lower write service procedure, rather than a write put procedure, is used so that flow control, coming up from the driver below, may be handled.

On the lower read side, data coming up the lower stream are passed to the lower read put procedure. The procedure routes the data to an upper stream based on the first byte of the message. This byte holds the minor device number of an upper stream. The put procedure handles flow control by testing the upper stream at the first upper read queue beyond the driver.

Upper Write put Procedure Sample

muxuwput, the upper-queue write put procedure, traps ioctl calls, in particular I_LINK and I_UNLINK:

EXAMPLE 13-4 bufcall Callback Routine

```c
static int
/*
 * This is our callback routine used by bufcall() to inform us
 * when buffers become available
 */
static void mux_qenable(long ql)
{
    queue_t *q = (queue_t *)ql;
    struct mux *mux;

    mux = (struct mux *)(q->q_ptr);
    mux->bufcid = 0;
    qenable(q);
}

muxuwput(queue_t *q, mblk_t *mp)
{
    struct mux *mux;

    mux = (struct mux *)(q->q_ptr);
    switch (mp->b_datap->db_type) {
    case M_IOCTL: {
        struct iocblk *iocp;
        struct linkblk *linkp;
        /*
         * ioctl. Only channel 0 can do ioctls. Two
         * calls are recognized: LINK, and UNLINK
         */
        if (mux != mux_mux)
            goto iocnak;

        iocp = (struct iocblk *) mp->b_rptr;

        /*...
```

292   STREAMS Programming Guide • May 2002
switch (iocp->ioc_cmd) {
    case I_LINK:
        /* Link. The data contains a linkblk structure
         * Remember the bottom queue in muxbot.
         */
        if (muxbot != NULL)
            goto iocnak;
        linkp=(struct linkblk *) mp->b_cont->b_rptr;
        muxbot = linkp->l_qbot;
        muxerr = 0;
        mp->b_datap->db_type = M_IOCACK;
        iocp->ioc_count = 0;
        qreply(q, mp);
        break;
    case I_UNLINK:
        /* Unlink. The data contains a linkblk struct.
         * Should not fail an unlink. Null out muxbot.
         */
        linkp=(struct linkblk *) mp->b_cont->b_rptr;
        muxbot = NULL;
        mp->b_datap->db_type = M_IOCACK;
        iocp->ioc_count = 0;
        qreply(q, mp);
        break;
    default:
        iocnak:
        /* fail ioctl */
        mp->b_datap->db_type = M_IOCNAK;
        qreply(q, mp);
    }
break;
}

case M_FLUSH:
    if (*mp->b_rptr & FLUSHW)
        flushq(q, FLUSHDATA);
    if (*mp->b_rptr & FLUSHR) {
        *mp->b_rptr &= ~FLUSHW;
        qreply(q, mp);
    } else
        freemsg(mp);
    break;

case M_DATA:{
    /* Data. If we have no lower queue --> fail
    */
}
EXAMPLE 13-4 bufcall Callback Routine  (Continued)

* Otherwise, queue the data and invoke the lower
* service procedure.

mblk_t *bp;
    if (muxerr || muxbot == NULL)
        goto bad;
    if ((bp = allocb(1, BPRI_MED)) == NULL) {
        putbq(q, mp);
        mux->bufcid = bufcall(1, BPRI_MED,
                                mux_qenable, (long)q);
        break;
    }
    *bp->b_wptr++ = (struct mux *)q->ptr - mux_mux;
    bp->b_cont = mp;
    putq(q, bp);
    break;

default:
bad:
    /*
    * Send an error message upstream.
    */
    mp->b_datap->db_type = M_ERROR;
    mp->b_rptr = mp->b_wptr = mp->b datap->db_base;
    mp->b_wptr++ = EINVAL;
    qreply(q, mp);
}

First, there is a check to enforce that the stream associated with minor device 0 will be
the single, controlling stream. The ioctl's are only accepted on this stream. As
described previously, a controlling stream is the one that issues the I_LINK. There
should be only a single control stream. I_LINK and I_UNLINK include a linkblk
structure containing the following fields:

1_qtop is the upper write queue from which the ioctl(2) comes. It always equals q
for an I_LINK, and NULL for I_PLINK.

1_qbot is the new lower write queue. It is the former stream head write queue and is
where the multiplexer gets and puts its data.

1_index is a unique (system-wide) identifier for the link. It can be used for routing or
during selective unlinks. Since the example only supports a single link, 1_index is
not used.

For I_LINK, 1_qbot is saved in muxbot and a positive acknowledgement is
generated. From this point on, until an I_UNLINK occurs, data from upper queues will
be routed through muxbot. Note that when an I_LINK, is received, the lower stream
has already been connected. This enables the driver to send messages downstream to perform any initialization functions. Returning an M_IOCNAK message (negative acknowledgement) in response to an I_LINK causes the lower stream to be disconnected.

The I_UNLINK handling code nulls out muxbot and generates a positive acknowledgement. A negative acknowledgement should not be returned to an I_UNLINK. The stream head ensures that the lower stream is connected to a multiplexer before sending an I_UNLINK M_IOCTL.

Drivers can handle the persistent link requests I_PLINK and I_PUNLINK ioctl(2) in the same manner, except that l_qtop in the linkblk structure passed to the put routine is NULL instead of identifying the controlling stream.

muxuwsput handles M_FLUSH messages as a normal driver does, except that there are no messages queued on the upper read queue, so there is no need to call flushq if FLUSHR is set.

M_DATA messages are not placed on the lower write message queue. They are queued on the upper write message queue. When flow control subsides on the lower stream, the lower service procedure, muxlwsrv, is scheduled to start output. This is similar to starting output on a device driver.

Upper Write service Procedure Sample

The following example shows the code for the upper multiplexer write service procedure:

```c
EXAMPLE 13-5 Upper Multiplexer Write Service Procedure

static int muxuwsrv(queue_t *q)
{
    mblk_t *mp;
    struct mux *muxp;
    muxp = (struct mux *)q->q_ptr;

    if (!muxbot) {
        flushq(q, FLUSHALL);
        return (0);
    }
    if (muxerr) {
        flushq(q, FLUSHALL);
        return (0);
    }
    while (mp = getq(q)) {
        if (canputnext(muxbot))
            putnext(muxbot, mp);
        else {
            putbq(q, mp);
            return(0);
        }
    }
    return (0);
}
```

Chapter 13 • STREAMS Multiplex Drivers 295
As long as there is a stream still linked under the multiplexer and there are no errors, the service procedure will take a message off the queue and send it downstream, if flow control allows.

**Lower Write service Procedure**

`muxlwsrv`, the lower (linked) queue write service procedure is scheduled as a result of flow control subsiding downstream (it is back-enabled).

```c
static int muxlwsrv(queue_t *q)
{
    int i;
    for (i = 0; i < mux_cnt; i++)
        if (mux_mux[i].qptr && mux_mux[i].qptr->q_first)
            qenable(mux_mux[i].qptr);
    return (0);
}
```

`muxlwsrv` steps through all possible upper queues. If a queue is active and there are messages on the queue, then its upper write service procedure is enabled through `qenable`.

**Lower Read put Procedure**

The lower (linked) queue read put procedure is shown in the following example:

```c
static int muxlrput(queue_t *q, mblk_t *mp)
{
    queue_t *uq;
    int device;
    if (muxerr) {
        freemsg(mp);
        return (0);
    }
```
switch(mp->b_datap->db_type) {
  case M_FLUSH:
    /*
     * Flush queues. NOTE: sense of tests is reversed
     * since we are acting like a "stream head"
     */
    if (*mp->b_rptr & FLUSHW) {
      *mp->b_rptr &= ~FLUSHR;
      qreply(q, mp);
    } else
      freemsg(mp);
    break;
  case M_ERROR:
  case M_HANGUP:
    muxerr = 1;
    freemsg(mp);
    break;
  case M_DATA:
    /*
     * Route message. First byte indicates
     * device to send to. No flow control.
     * Extract and delete device number. If the
     * leading block is now empty and more blocks
     * follow, strip the leading block.
     */
    device = *mp->b_rptr++;
    /* Sanity check. Device must be in range */
    if (device < 0 || device >= mux_cnt) {
      freemsg(mp);
    } else
    /*
     * If upper stream is open and not backed up,
     * send the message there, otherwise discard it.
     */
    uq = mux_mux[device].qptr;
    if (uq != NULL && canputnext(uq))
      putnext(uq, mp);
    else
      freemsg(mp);
    break;
    default:
      freemsg(mp);
    }
  return (0);
}
muxlrput receives messages from the linked stream. In this case, it is acting as a stream head and handles M_FLUSH messages. The code is the reverse of a driver, handling M_FLUSH messages from upstream. There is no need to flush the read queue because no data is ever placed in it.

muxlrput also handles M_ERROR and M_HANGUP messages. If one is received, it locks up the upper streams by setting muxerr.

M_DATA messages are routed by checking the first data byte of the message. This byte contains the minor device of the upper stream. Several checks examine whether:

- The device is in range
- The upper stream is open
- The upper stream is full

This multiplexer does not support flow control on the read side; it is merely a router. If the message passes all checks, it is put to the proper upper queue. Otherwise, the message is discarded.

The upper stream close routine clears the mux entry so this queue will no longer be found. Outstanding bufcalls are not cleared.

```c
/*
 * Upper queue close
 */
static int
muxclose(queue_t *q, int flag, cred_t *credp)
{
    struct mux *mux;

    mux = (struct mux *) q->q_ptr;
    qprocsoff(q);
    if (mux->bufcid != 0)
        unbufcall(mux->bufcid);
    mux->bufcid = 0;
    mux->ptr = NULL;
    q->q_ptr = NULL;
    WR(q)->q_ptr = NULL;
    return(0);
}
```

Persistent Links

Keeping a process running merely to hold the multiplexer configuration together is not always desirable, so, “free standing” links below a multiplexer are needed. A persistent link is such a link. It is similar to a STREAMS multiplexer link except that a process is not needed to hold the links together. After the multiplexer has been set up, the process may close all file descriptors and exit, and the multiplexer remains intact.
With `I_LINK` and `I_UNLINK` `ioctl(2)` the file descriptor associated with the stream above the multiplexer used to set up the lower multiplexer connections must remain open for the duration of the configuration. Closing the file descriptor associated with the controlling stream dismantles the whole multiplexing configuration.

Two `ioctl(2)`s, `I_PLINK` and `I_PUNLINK`, are used to create and remove persistent links that are associated with the stream above the multiplexer. `close(2)` and `I_UNLINK` are not able to disconnect the persistent links (see `strconf(1)` and `strchg(1)`).

The format of `I_PLINK` is:
```
ioctl(fd0, I_PLINK, fd1)
```

The first file descriptor, `fd0`, must reference the stream connected to the multiplexing driver and the second file descriptor, `fd1`, must reference the stream to be connected below the multiplexer. The persistent link can be created as follows:
```
upper_stream_fd = open("/dev/mux", O_RDWR);
lower_stream_fd = open("/dev/driver", O_RDWR);
muxid = ioctl(upper_stream_fd, I_PLINK, lower_stream_fd);
/*
 * save muxid in a file
 */
exit(0);
```

The persistent link can still exist even if the file descriptor associated with the upper stream to the multiplexing driver is closed. The `I_PLINK ioctl(2)` returns an integer value, `muxid`, that can be used for dismantling the multiplexing configuration. If the process that created the persistent link still exists, it may pass the `muxid` value to some other process to dismantle the link, if the dismantling is desired, or it can leave the `muxid` value in a file so that other processes may find it later.

Several users can open the MUX driver and send data to Driver1 since the persistent link to Driver1 remains intact.

The `I_PUNLINK ioctl(2)` is used to dismantle the persistent link. Its format is:
```
ioctl(fd0, I_PUNLINK, muxid)
```

where `fd0` is the file descriptor associated with stream connected to the multiplexing driver from above. The `muxid` is returned by the `I_PLINK ioctl(2)` for the stream that was connected below the multiplexer. `I_PUNLINK` removes the persistent link between the multiplexer referenced by `fd0` and the stream to the driver designated by the `muxid`. Each of the bottom persistent links can be disconnected individually. An `I_PUNLINK ioctl(2)` with the `muxid` value of `MUXID_ALL` will remove all persistent links below the multiplexing driver referenced by `fd0`.

The following code example shows how to dismantle the previously given configuration:
fd = open("/dev/mux", O_RDWR);
/*
 * retrieve muxid from the file
 */
ioctl(fd, I_PUNLINK, muxid);
exit(0);

Do not use the I_PLINK and I_PUNLINK ioctl's with I_LINK and I_UNLINK. Any attempt to unlink a regular link with I_PUNLINK or to unlink a persistent link with the I_UNLINK ioctl(2) causes the errno value of EINVAL to be returned.

Because multilevel multiplexing configurations are allowed in STREAMS, persistent links could exist below a multiplexer whose stream is connected to the above multiplexer by regular links. Closing the file descriptor associated with the controlling stream will remove the regular link but not the persistent links below it. On the other hand, regular links are allowed to exist below a multiplexer whose stream is connected to the above multiplexer with persistent links. In this case, the regular links will be removed if the persistent link above is removed and no other references to the lower streams exist.

The construction of cycles is not allowed when creating links. A cycle could be constructed by:
1. Creating a persistent link of multiplexer 2 below multiplexer 1
2. Closing the controlling file descriptor associated with the multiplexer 2
3. Reopening the file descriptor again
4. Linking the multiplexer 1 below the multiplexer 2

This is not allowed. The operating system prevents a multiplexer configuration from containing a cycle to ensure that messages cannot be routed infinitely, which would create an infinite loop or overflow the kernel stack.

Design Guidelines

The following are general multiplexer design guidelines:

- The upper half of the multiplexer acts like the end of the upper stream. The lower half of the multiplexer acts like the head of the lower stream. Service procedures are used for flow control.
- Message routing is based on multiplexer-specific criteria.
- When one stream is being fed by many streams, flow control may have to take place. Then all feeding streams on the other end of the multiplexer have to be enabled when the flow control is relieved.
- When one stream is feeding many streams, flow control may also have to take place. Be careful not to starve other streams when one becomes flow controlled.
Upper and lower multiplexers share the same perimeter type and concurrency level. (See “MT STREAMS Perimeters” on page 252 for information about perimeters.)
Chapter 14, Debugging

Describes the tools available for debugging STREAMS-based applications.
Debugging STREAMS-based Applications

This chapter describes some of the tools available to assist in debugging STREAMS-based applications. It contains the following information:

- “Kernel Debug Printing” on page 305
- “STREAMS Error and Trace Logging” on page 306
- “Kernel Examination Tools” on page 307

Kernel Debug Printing

The kernel routine cmn_err(9F) enables printing of formatted strings on a system console. It displays a specified message on the console and can also store it in the msgbuf that is a circular array in the kernel. The format of cmn_err(9F) is:

```c
#include <sys/cmn_err.h>

void cmn_err (int level, char *fmt, int args)
```

where level can take the following values:

- CE_CONT — may be used as simple printf(3S). It is used to continue another message or to display an informative message not associated with an error.
- CE_NOTE — reports system events. It is used to display a message preceded by NOTICE:. This message is used to report system events that do not necessarily require user action, but may interest the system administrator. An example is a sector on a disk needing to be accessed repeatedly before it can be accessed correctly.
- CE_WARN — reports system events that require user action. This is used to display a message preceded by WARNING:. This message is used to report system events that require immediate attention, such as those where, if an action is not taken, the system may panic. For example, when a peripheral device does not initialize
correctly, this level should be used.

- **CE_PANIC** — reports system panic. This is used to display a message preceded with `PANIC:`. Drivers should specify this level only under the most severe conditions. A valid use of this level is when the system cannot continue to function.

  If the error is recoverable and not essential to continued system operation, do not panic the system. This level halts all processing.

`fmt` and `args` are passed to the kernel routine `printf` that runs at splhi and should be used sparingly. If the first character of `fmt` is `!` (an exclamation point), output is directed to `msgbuf`. `msgbuf` can be accessed with the `crash` command. If the destination character begins with `^` (a caret) output goes to the console. If no destination character is specified, the message is directed to both the `msgbuf` array and the console.

`cmn_err(9F)` appends each `fmt` with `\n`, except for the **CE_CONT** level, even when a message is sent to the `msgbuf` array. `args` specifies a set of arguments passed when the message is displayed. Valid specifications are `%s` (string), `%u` (unsigned decimal), `%d` (decimal), `%o` (octal), and `%x` (hexadecimal). `cmn_err(9F)` does not accept length specifications in conversion specifications. For example, `%3d` is ignored.

---

**Note** — `crash` has reached EOL and is not supported in the Solaris 9 operating environment. For information about how to transition from `crash` to `mdb`, see the *Solaris Modular Debugger Guide*.

---

**STREAMS Error and Trace Logging**

STREAMS error and trace loggers are provided for debugging and for administering STREAMS modules and drivers. This facility consists of `log(7D)`, `strace(1M)`, `strclean(1M)`, `strerr(1M)`, and `strlog(9F)`.

Any module or driver in any stream can call the STREAMS logging function `strlog(9F)` (see also `log(7D)`). `strlog(9F)` sends formatted text to the error logger `strerr(1M)`, the trace logger `strace(1M)`, or the console logger.

`strerr(1M)` runs as a daemon process initiated at system startup. A call to `strlog(9F)` requesting an error to be logged causes an `M_PROTO` message to be sent to `strerr(1M)`, which formats the contents and places them in a daily file.

`strclean(1M)` purges daily log files that have not been modified for three days.

`strlog(9F)` also sends a similar `M_PROTO` message to `strace(1M)`, which places it in a user-designated file. `strace(1M)` is initiated by a user. The user designates the modules and drivers and the severity level of the messages accepted for logging by `strace(1M)`. 
A user process can submit its own M_PROTO messages to the log driver for inclusion in the logger of its choice through putmsg(2). The messages must be in the same format required by the logging processes and are switched to the loggers requested in the message.

The output to the log files is formatted ASCII text. The files can be processed by standard system commands such as grep(1) or by developer-provided routines.

---

**Kernel Examination Tools**

Use crash, adb, and kadb(1M) to examine the kernel.

**crash Command**

`crash` examines kernel structures interactively. It can be used on a system dump and on an active system.

**Note** – `crash` has reached EOL and is not supported in the Solaris 9 operating environment. For information about how to transition from `crash` to `mdb`, see the *Solaris Modular Debugger Guide*.

The following `crash` functions are related to STREAMS:

- `dbfree` — Print data block header free list.
- `dblock` — Print allocated STREAMS data block headers.
- `linkblk` — Print the `linkblk(9S)` table.
- `mbfree` — Print free STREAMS message block headers.
- `mblock` — Print allocated STREAMS message block headers.
- `pty` — Print pseudo-TTYs now configured. The `l` option gives information on the line discipline module. `l@term(7M)`, the `h` option provides information on the pseudo-TTY emulation module `ptem(7M)`. The `s` option gives information on the packet module `pckt(7M)`.
- `qrun` — Print a list of scheduled queues.
- `queue` — Print the STREAMS queues.
- `stream` — Print the stdata table.
- `strstat` — Print STREAMS statistics.
- `tty` — Print the tty table. The `l` option prints details about the line-discipline module.
The crash functions dblock, linkblk, mblock, queue, and stream take an optional table entry argument or address that is the address of the data structure. The strstat command gives information about STREAMS event cells and linkblks in addition to message blocks, data blocks, queues, and streams. On the output report, the CONFIG column represents the number of structures currently configured. It may change because resources are allocated as needed.

adb Command

adb is an interactive general-purpose debugger. It can be used to examine files and provides a controlled environment for the execution of programs. It has no support built in for any STREAMS functionality.

Note – adb has reached EOL and is not supported in the Solaris 9 operating environment. For information about how to transition from adb to mdb, see the Solaris Modular Debugger Guide.

kadb Command

kadb(1M) is an interactive debugger with a user interface similar to adb(1), but it runs in the same virtual address space as the program being debugged. It also has no specific STREAMS support.
Part IV of this manual contains appendixes that summarize message types, kernel utility interfaces, the STREAMS-based terminal subsystem, and frequently asked questions.

</table>
Message Types

STREAMS message types differ in their intended purposes, their treatment at the stream head, and their message-queueing priority.

STREAMS does not prevent a module or driver from generating any message type and sending it in any direction on the stream. However, established processing and direction rules should be observed. Stream head processing according to message type is fixed, although certain parameters can be altered.

- “Ordinary Messages” on page 311
- “High-Priority Messages” on page 319

Ordinary Messages

The message types found in sys/stream.h are described in this appendix, classified according to their message queueing priority. Ordinary messages are described first, with high-priority messages following. In certain cases, two message types may perform similar functions, differing only in priority. Message construction is described in Chapter 3. The use of the word module generally implies module or driver.

Ordinary messages are also called normal or nonpriority messages. Ordinary messages are subject to flow control whereas high-priority messages are not.

M_BREAK

Sent to a driver to request that BREAK be transmitted on whatever media the driver is controlling.
The message format is not defined by STREAMS and its use is developer dependent. This message may be considered a special case of an M_CTL message. An M_BREAK message cannot be generated by a user-level process and is always discarded if passed to the stream head.

**M_CTL**

Generated by modules that send information to a particular module or type of module. M_CTL messages are typically used for intermodule communication, as when adjacent STREAMS protocol modules negotiate the terms of their interface. An M_CTL message cannot be generated by a user-level process and is always discarded if passed to the stream head.

**M_DATA**

Contains ordinary data. Messages allocated by alloca(9F) are M_DATA type by default. M_DATA messages are generally sent bidirectionally on a stream and their contents can be passed between a process and the stream head. In the getmsg(2) and putmsg(2) system calls, the contents of M_DATA message blocks are referred to as the data part. Messages composed of multiple message blocks typically have M_DATA as the message type for all message blocks following the first.

**M_DELAY**

Sent to a media driver to request a real-time delay on output. The data buffer associated with this message is expected to contain an integer to indicate the number of machine cycles of delay desired. M_DELAY messages are typically used to prevent transmitted data from exceeding the buffering capacity of slower terminals.

The message format is not defined by STREAMS and its use is developer dependent. Not all media drivers may understand this message. This message may be considered a special case of an M_CTL message. An M_DELAY message cannot be generated by a user-level process and is always discarded if passed to the stream head.

**M_IOCTL**

Generated by the stream head in response to I_STR, I_LINK, I_UNLINK, I_PLINK, and I_PUNLINK ioctl's (see streamio(7I)). This message is also generated in response to ioctl calls that contain a command argument value not defined in streamio(7I). When one of these ioctl(2) is received from a user process, the stream head uses values supplied in the call and values from the process to create an M_IOCTL message containing them, then sends the message downstream. M_IOCTL messages perform the general ioctl(2) functions of character device drivers.
For an _I_STR ioctl(2), the user values are supplied in a structure of the following form, provided as an argument to the ioctl(2) call (see _I_STR in streamio(7I)):

```c
struct strioctl {
    int   ic_cmd; /* downstream request */
    int   ic_timout; /* ACK/NAK timeout */
    int   ic_len; /* length of data arg */
    char *ic_dp; /* ptr to data arg */
};
```

where `ic_cmd` is the request (or command) defined by a downstream module or driver, `ic_timout` is the time the stream head waits for acknowledgement to the _M_IOCTL message before timing out, and `ic_dp` points to an optional data buffer. On input, `ic_len` contains the length of the data in the buffer that was passed in. On return from the call, it contains the length of the data, if any, being returned to the user in the same buffer.

The _M_IOCTL message format is one _M_IOCTL message block followed by zero or more _M_DATA message blocks. STREAMS constructs an _M_IOCTL message block by placing an iocblk(9S) structure, defined in `<sys/stream.h>`, in its data buffer. The iocblk(9S) structure differs for 64–bit and 32–bit architectures.

```c
#if defined(_LP64)
struct iocblk {
    int   ioc_cmd; /* ioctl command type */
    cred_t *ioc_cr; /* full credentials */
    uint  ioc_id; /* ioctl id */
    uint  ioc_flag; /* see below */
    size_t ioc_count; /* count of bytes in data field */
    int   ioc_rval; /* return value */
    int   ioc_error; /* error code */
};
#else
struct iocblk {
    int   ioc_cmd; /* ioctl command type */
    cred_t *ioc_cr; /* full credentials */
    uint  ioc_id; /* ioctl id */
    size_t ioc_count; /* count of bytes in data field */
    int   ioc_rval; /* return value */
    int   ioc_error; /* error code */
    int   ioc_fill1;
    uint  ioc_flag; /* see below */
    int   ioc_filler[2]; /* reserved for future use */
};
#endif /* _LP64 */
```

For an _I_STR ioctl(2), `ioc_cmd` corresponds to `ic_cmd` of the strioctl structure. `ioc_cr` points to a credentials structure defining the user process’s permissions (see cred.h). Its contents can be tested to determine whether the user issuing the ioctl(2) call is authorized to do so. For an _I_STR ioctl(2), `ioc_count` is the number of data bytes, if any, contained in the message and corresponds to `ic_len`. 

Appendix A • Message Types 313
ioc_id is an identifier generated internally, and is used by the stream head to match each M_IOCTL message sent downstream with response messages sent upstream to the stream head. The response message that completes the stream-head processing for the ioctl(2) is an M_IOCACK (positive acknowledgement) or an M_IOCNAK (negative acknowledgement) message.

For an I_STR ioctl(2), if a user supplies data to be sent downstream, the stream head copies the data (pointed to by ic_dp in the strioctl structure) into M_DATA message blocks and links the blocks to the initial M_IOCTL message block. ioc_count is copied from ic_len. If there are no data, ioc_count is zero.

If the stream head does not recognize the command argument of an ioctl(2), the head creates a transparent M_IOCTL message. The format of a transparent M_IOCTL message is one M_IOCTL message block followed by one M_DATA block. The form of the iocblk structure is the same as above. However, ioc_cmd is set to the value of the command argument in the ioctl(2) and ioc_count is set to TRANSPARENT, defined in <sys/stream.h>. TRANSPARENT distinguishes the case where an I_STR ioctl(2) specifies a value of ioc_cmd equivalent to the command argument of a transparent ioctl(2). The M_DATA block of the message contains the value of the arg parameter in the ioctl(2).

The first module or driver that understands the ioc_cmd request contained in the M_IOCTL acts on it. For an I_STR ioctl(2), this action generally includes an immediate upstream transmission of an M_IOCACK message. For transparent M_IOCTLs, this action generally includes the upstream transmission of an M_COPYIN or M_COPYOUT message.

Intermediate modules that do not recognize a particular request must pass the message on. If a driver does not recognize the request, or the receiving module cannot acknowledge it, an M_IOCNAK message must be returned.

M_IOCACK and MIOCNAK message types have the same format as an M_IOCTL message and contain an iocblk structure in the first block. An M_IOCACK block may be linked to following M_DATA blocks. If one of these messages reaches the stream head with an identifier that does not match that of the currently outstanding M_IOCTL message, the response message is discarded. A common means of ensuring that the correct identifier is returned is for the replying module to convert the M_IOCTL message into the appropriate response type and set ioc_count to 0 if no data is returned. Then, qreply(9F) is used to send the response to the stream head.

In an M_IOCACK or M_IOCNAK message, ioc_error holds any return error condition set by a downstream module. If this value is non-zero, it is returned to the user in errno. Note that both an M_IOCNAK and an M_IOCACK can return an error. However, only an M_IOCACK can have a return value. For an M_IOCACK, ioc_rval holds any return value set by a responding module. For an M_IOCNAK, ioc_rval is ignored by the stream head.
If a module processing an I_STR ioctl(2) is sending data to a user process, it must use the M_IOCACK message that it constructs such that the M_IOCACK block is linked to one or more following M_DATA blocks containing the user data. The module must set ioc_count to the number of data bytes sent. The stream head places the data in the address pointed to by ic_dp in the user I_STR strioctl structure.

A module processing a transparent ioctl(2) that is sending data to a user process can use only an M_COPYOUT message. For a transparent ioctl(2), no data can be sent to the user process in an M_IOCACK message. All data must be sent in a preceding M_COPYOUT message. The stream head ignores any data contained in an M_IOCACK message (in M_DATA blocks) and frees the blocks.

No data can be sent with an M_IOCNAK message for any type of M_IOCTL. The stream head ignores and frees any M_DATA blocks.

The stream head blocks the user process until an M_IOCACK or M_IOCNAK response to the M_IOCTL (same ioc_id) is received. For an M_IOCTL generated from an I_STR ioctl(2), the stream head times out if no response is received in ic_timout interval (the user can specify an explicit interval or specify use of the default interval). For M_IOCTL messages generated from all other ioctl(2)s, the default (infinite) is used.

**M_PASSFP**

The M_PASSFP message passes a file pointer from the stream head at one end of a stream pipe to the stream head at the other end of the same stream pipe.

The message is generated as a result of an I_SENDFD ioctl(2) (see streamio(7I)) issued by a process to the sending stream head. STREAMS places the M_PASSFP message directly on the destination stream head’s read queue to be retrieved by an _RECVFD ioctl(2) (see streamio(7I)). The message is placed without passing it through the stream (that is, it is not seen by any modules or drivers in the stream). This message should never be present on any queue except the read queue of a stream head. Consequently, modules and drivers do not need to recognize this message, and it can be ignored by module and driver developers.

**M_PROTO**

The M_PROTO message contains control information and associated data. The message format is one or more M_PROTO message blocks followed by zero or more M_DATA message blocks. The semantics of the M_DATA and M_PROTO message blocks are determined by the STREAMS module that receives the message.
Note — On the write side, the user can only generate M_PROTO messages containing one M_PROTO message block.

The M_PROTO message block typically contains implementation dependent control information. M_PROTO messages are generally sent bidirectionally on a stream, and their contents can be passed between a process and the stream head. The contents of the first message block of an M_PROTO message is generally referred to as the control part, and the contents of any following M_DATA message blocks are referred to as the data part. In the getmsg(2) and putmsg(2), the control and data parts are passed separately.

The format of M_PROTO and M_PCPROTO (generically PROTO) messages sent upstream to the stream head allows multiple PROTO blocks at the beginning of the message although its use is not recommended. getmsg(2)) compacts the blocks into a single control part when passing them to the user process.

M_RSE

This message is reserved for internal use. Modules that do not recognize this message must pass it on. Drivers that do not recognize it must free it.

M_SETOPTS

This message is used to alter some characteristics of the stream head. It is generated by any downstream module, and is interpreted by the stream head. The data buffer of the message has the following structure, as defined in stream.h:

```c
struct stroptions {
    uint so_flags; /* options to set */
    short so_readopt; /* read option */
    ushort so_wroff; /* write offset */
    ssize_t so_minpsz; /* minimum read packet size */
    ssize_t so_maxpsz; /* maximum read packet size */
    size_t so_hiwat; /* read queue high-water mark */
    size_t so_lowat; /* read queue low-water mark */
    unsigned char so_band; /* band for water marks */
    ushort so_erropt; /* error option */
    ssize_t so_maxblk; /* maximum message block size */
    ushort so_copyopt; /* copy options (see stropts.h) */
};
```

where so_flags specifies which options are to be altered, and can be any combination of the following:

- **SO_ALL** — Update all options according to the values specified in the remaining fields of the stroptions structure.
- **SO_READOPT** — Set the read mode (see `read(2)`) as specified by the value of `so_readopt` to:
  - **RNORM** — Byte stream
  - **RMSGD** — Message discard
  - **RMSGN** — Message non-discard
  - **RPROTNORM** — Normal protocol
  - **RPROTDAT** — Turn `MPROTO` and `M_PCPROTO` msgs into `M_DATA` msgs
  - **RPROTDIS** — Discard `M_PROTO` and `M_PCPROTO` blocks in a `msg` and retain any linked `M_DATA` blocks
- **SO_WROFF** — Direct the stream head to insert an offset (unwritten area), specified by `so_wroff` into the first message block of all `M_DATA` messages created as a result of a `write(2)`. The same offset is inserted into the first `M_DATA` message block, if any, of all messages created by a `putmsg` system call. The default offset is zero.

The offset must be less than the maximum message buffer size (system dependent). Under certain circumstances, a write offset may not be inserted. A module or driver must test that `b_rptr` in the `msgb(9S)` structure is greater than `db_base` in the `datab(9S)` structure to determine that an offset has been inserted in the first message block.

- **SO_MINPSZ** — Change the minimum packet size value associated with the stream head read queue to `so_minpsz`. This value is advisory for the module immediately below the stream head. It should limit the size of `M_DATA` messages that the module should put to the stream head. There is no intended minimum size for other message types. The default value in the stream head is zero.
- **SO_MAXPSZ** — Change the maximum packet size value associated with the stream head read queue to `so_maxpsz`. This value is advisory for the module immediately below the stream head. It should limit the size of `M_DATA` messages that the module should put to the stream head. There is no intended maximum size for other message types. The default value in the stream head is `INFPSZ`, the maximum STREAMS allows.
- **SO_HIWAT** — Change the flow control high–water mark (`q_hiwat` in the `queue(9S)` structure, `qb_hiwat` in the `qband(9S)` structure) on the stream-head read queue to the value specified in `so_hiwat`.
- **SO_LOWAT** — Change the flow control low–water mark (`q_lowat` in the `queue(9S)` structure, `qb_lowat` in the `qband(9S)` structure) on the stream-head read queue to the value specified in `so_lowat`.
- **SO_MREADON** — Enable the stream head to generate `M_READ` messages when processing a `read(2)` system call. If both `SO_MREADON` and `SO_MREADOFF` are set in `so_flags`, `SO_MREADOFF` takes precedence.
- **SO_MREADOFF** — Disable the stream head generation of `M_READ` messages when processing a `read(2)` system call. This is the default. If both `SO_MREADON` and `SO_MREADOFF` are set in `so_flags`, `SO_MREADOFF` takes precedence.
SO_NDELON — Set non-STREAMS TTY semantics for O_NDELAY (or O_NONBLOCK) processing on read(2) and write(2). If O_NDELAY (or O_NONBLOCK) is set, a read(2) returns 0 if no data is waiting to be read at the stream head. If O_NDELAY (or O_NONBLOCK) is clear, a read(2) blocks until data become available at the stream head. (See note below)

Regardless of the state of O_NDELAY (or O_NONBLOCK), a write(2) blocks on flow control and blocks if buffers are not available.

If both SO_NDELON and SO_NDELOFF are set in so_flags, SO_NDELOFF takes precedence.

Note — For conformance with the POSIX standard, new applications should use the O_NONBLOCK flag whose behavior is the same as that of O_NDELAY unless otherwise noted.

SO_NDELOFF — Set STREAMS semantics for O_NDELAY (or O_NONBLOCK) processing on read(2) and write(2) system calls. If O_NDELAY (or O_NONBLOCK) is set, a read(2) will return -1 and set EAGAIN if no data is waiting to be read at the stream head. If O_NDELAY (or O_NONBLOCK) is clear, a read(2) blocks until data become available at the stream head. (See note above.)

If O_NDELAY (or O_NONBLOCK) is set, a write(2) returns -1 and sets EAGAIN if flow control is in effect when the call is received. It blocks if buffers are not available. If O_NDELAY (or O_NONBLOCK) is set, part of the buffer has been written, and a flow control or “buffers not available” condition is encountered, write(2) terminates and returns the number of bytes written.

If O_NDELAY (or O_NONBLOCK) is clear, a write(2) will block on flow control and will block if buffers are not available.

This is the default. If both SO_NDELON and SO_NDELOFF are set in so_flags, SO_NDELOFF takes precedence.

In the STREAMS-based pipe mechanism, the behavior of read(2) and write(2) is different for the O_NDELAY and O_NONBLOCK flags.

SO_BAND — Set watermarks in a band. If the SO_BAND flag is set with the SO_HIWAT or SO_LOWAT flag, the so_band field contains the priority band number related to the so_hiwat and so_lowat fields.

If the SO_BAND flag is not set and the SO_HIWAT and SO_LOWAT flags are on, the normal high-water and low-water marks are affected. The SO_BAND flag has no effect if SO_HIWAT and SO_LOWAT flags are off.

Only one band’s water marks can be updated with a single M_SETOPTS message.

SO_ISTTY — Inform the stream head that the stream is acting like a controlling terminal.

SO_ISNTTY — Inform the stream head that the stream is no longer acting like a controlling terminal.
For **SO_ISTTY**, the stream may be allocated as a controlling terminal via an **M_SETOPTS** message arriving upstream during open processing. If the stream head is opened before receiving this message, the stream will not be allocated as a controlling terminal until it is queued again by a session leader.

- **SO_TOSTOP** — Stop on background writes to the stream.
- **SO_TONSTOP** — Do not stop on background writes to the stream. **SO_TOSTOP** and **SO_TONSTOP** are used in conjunction with job control.
- **SO_DELIM** — Messages are delimited.
- **SO_NODELIM** — Messages are not delimited.
- **SO_STRHOLD** — Enable **strwrite** message coalescing.

**M_SIG**

The **M_SIG** message is sent upstream by modules or drivers to post a signal to a process. When the message reaches the front of the stream-head read queue, it evaluates the first data byte of the message as a signal number, defined in `<sys/signal.h>`. (The signal is not generated until it reaches the front of the stream-head read queue.) The associated signal will be sent to processes under the following conditions:

- If the signal is **SIGPOLL**, it is sent only to those processes that have explicitly registered to receive the signal (see **I_SETSIG** in `streamio(7I)`).
- If the signal is not **SIGPOLL** and the stream containing the sending module or driver is a controlling TTY, the signal is sent to the associated process group. A stream becomes the controlling TTY for its process group if, on **open**(2) a module or driver sends an **M_SETOPTS** message to the stream head with the **SO_ISTTY** flag set.
- If the signal is not **SIGPOLL** and the stream is not a controlling TTY, no signal is sent, except in case of **SIOCSPGRP** and **TIOCSPGRP**. These two ioctl's set the process group field in the stream head so the stream can generate signals even if it is not a controlling TTY.

---

**High-Priority Messages**

High-priority messages are particularly suitable for acknowledging service requests when the acknowledgement should be placed ahead of any other messages at the stream head. High-priority messages are not subject to flow control.
M_COPYIN

The M_COPYIN message is generated by a module or driver and sent upstream to request that the stream head perform a copyin(9F) on behalf of the module or driver. It is valid only after receiving an M_IOCTL message and before an M_IOCACK or M_IOCNAK.

The message format is one M_COPYIN message block containing a copyreq(9S) structure, defined in <sys/stream.h>. Different structures are defined for 64-bit and 32-bit architectures.

```c
#if defined(_LP64)
struct copyreq {
    int cq_cmd; /* ioctl command (from ioc_cmd) */
    cred_t *cq_cr; /* full credentials (from ioc_cmd) */
    uint cq_id; /* ioctl id (from ioc_id) */
    uint cq_flag; /* see below */
    mblk_t *cq_private; /* private state information */
    caddr_t cq_addr; /* address to copy data to/from */
    size_t cq_size; /* number of bytes to copy */
};
#else
struct copyreq {
    int cq_cmd; /* ioctl command (from ioc_cmd) */
    cred_t *cq_cr; /* full credentials */
    uint cq_id; /* ioctl id (from ioc_id) */
    caddr_t cq_addr; /* address to copy data to/from */
    size_t cq_size; /* number of bytes to copy */
    uint cq_flag; /* see below */
    mblk_t *cq_private; /* private state information */
    int cq_filler[4]; /* reserved for future use */
};
#endif /* _LP64 */
```

The first four members of the structure correspond to those of the iocblk(9S) structure in the M_IOCTL message that allows the same message block to be reused for both structures. The stream head guarantees that the message block allocated for the M_IOCTL message is large enough to contain a copyreq(9S). The cq_addr field contains the user space address from which the data is to be copied. The cq_size field is the number of bytes to copy from user space. The cq_flag field is reserved for future use and should be set to zero.

This message should not be queued by a module or driver unless it intends to process the data for the ioctl(2).

M_COPYOUT

The M_COPYOUT message is generated by a module or driver and sent upstream to request that the stream head perform a copyout(9F) on behalf of the module or driver. It is valid only after receiving an M_IOCTL message and before an M_IOCACK or M_IOCNAK.
The message format is one M_COPYOUT message block followed by one or more M_DATA blocks. The M_COPYOUT message block contains a copyreq(9S) as described in the M_COPYIN message with the following differences: the cq_addr field contains the user space address to which the data is to be copied. The cq_size field is the number of bytes to copy to user space.

Data to be copied to user space is contained in the linked M_DATA blocks.

This message should not be queued by a module or driver unless it processes the data for the ioctl in some way.

Note – For more information, see copyin and copyout in the Writing Device Drivers manual.

**M_ERROR**

The M_ERROR message is sent upstream by modules or drivers to report a downstream error condition. When the message reaches the stream head, the stream is marked so that all subsequent system calls issued to the stream, excluding close(2) and poll(2), fail with errno set to the first data byte of the message. POLLERR is set if the stream is being polled. All processes sleeping on a system call to the stream are awakened. An M_FLUSH message with FLUSHRW is sent downstream.

The stream head maintains two error fields, one for the read side and one for the write side. The one-byte format M_ERROR message sets both of these fields to the error specified by the first byte in the message.

There is also a two-byte format of the M_ERROR message. The first byte is the read error and the second byte is the write error. This enables modules to set a different error on the read side and write side. If one of the bytes is set to NOERROR, then the field for the corresponding side of the stream is unchanged. The module can then ignore an error on one side of the stream. For example, if the stream head was not in an error state and a module sent an M_ERROR message upstream with the first byte set to EPROTO and the second byte set to NOERROR, all subsequent read-like system calls (such as read(2) and getmsg(2)) fail with EPROTO, but all write-like system calls (such as write(2) and putmsg(2)) still succeed. If a byte is set to 0, the error state is cleared for the corresponding side of the stream. The values NOERROR and 0 are not valid for the one-byte form of the M_ERROR message.

**M_FLUSH**

The M_FLUSH message requests all modules and drivers that receive it to flush their message queues (discard all messages in those queues) as indicated in the message. An M_FLUSH can originate at the stream head, or in any module or driver. The first byte of the message contains flags that specify one of the following actions:
- FLUSHR — Flush the read queue of the module
- FLUSHW — Flush the write queue of the module
- FLUSHRW — Flush both the read queue and the write queue of the module
- FLUSHBAND — Flush the message according to the priority associated with the band

Each module passes this message to its neighbor after flushing its appropriate queues until the message reaches one of the ends of the stream.

Drivers are expected to include the following processing for M_FLUSH messages. When an M_FLUSH message is sent downstream through the write queues in a stream, the driver at the stream end discards it if the message action indicates that the read queues in the stream are not to be flushed (only FLUSHW set). If the message indicates that the read queues are to be flushed, the driver shuts off the FLUSHW flag, and sends the message up the stream’s read queues.

When a flush message is sent up a stream’s read side, the stream head checks to see if the write side of the stream is to be flushed. If only FLUSHR is set, the stream head discards the message. However, if the write side of the stream is to be flushed, the stream head sets the M_FLUSH flag to FLUSHW and sends the message down the stream’s write side. All modules that queue messages must identify and process this message type.

If FLUSHBAND is set, the second byte of the message contains the value of the priority band to flush.

M_HANGUP

The M_HANGUP message is sent upstream by a driver to report that it can no longer send data upstream. For example, this might be due to an error, or to a remote line connection being dropped. When the message reaches the stream head, the stream is marked so that all subsequent write(2) and putmsg(2) calls issued to the stream will fail and return an ENXIO error. Those ioctl(2) calls that cause messages to be sent downstream are also failed. POLLHUP is set if the stream is being polled.

Subsequent read(2) or getmsg(2) calls to the stream will not generate an error. These calls will return any messages (according to their function) that were on, or in transit to, the stream-head read queue before the M_HANGUP message was received. When all such messages have been read, read(2) returns 0 and getmsg(2) will set each of its two length fields to 0.

This message also causes a SIGHUP signal to be sent to the controlling process instead of the foreground process group, as the allocation and deallocation of controlling terminals to a session is the responsibility of the controlling process.
M_IOCACK

The M_IOCACK message signals the positive acknowledgement of a previous M_IOCTL message. The message format is one M_IOCACK block (containing an iocblk(9S) structure, see M_IOCTL) followed by zero or more M_DATA blocks. The iocblk(9S) may contain a value in ioc_rval to be returned to the user process. It may also contain a value in ioc_error to be returned to the user process in errno.

If this message is responding to an I_STR ioctl (see streamio(7I)), it may contain data from the receiving module or driver to be sent to the user process. In this case, message format is one M_IOCACK block followed by one or more M_DATA blocks containing the user data. The stream head returns the data to the user if there is a corresponding outstanding M_IOCTL request. Otherwise, the M_IOCACK message is ignored and all blocks in the message are freed.

Data cannot be returned in an M_IOCACK message responding to a transparent M_IOCTL. The data must have been sent with preceding M_COPYOUT messages. If any M_DATA blocks follow the M_IOCACK block, the stream head ignores and frees them.

The format and use of this message type is described further under M_IOCTL.

M_IOCDATA

The M_IOCDATA message is generated by the stream head and sent downstream as a response to an M_COPYIN or M_COPYOUT message. The message format is one M_IOCDATA message block followed by zero or more M_DATA blocks. The M_IOCDATA message block contains a copyresp(9S), defined in sys/stream.h.

```c
#if defined(_LP64)
struct copyresp {
    int cp_cmd; /* ioctl command (from ioc_cmd) */
    cred_t *cp_cr; /* full credentials (from ioc_cmd) */
    uint cp_id; /* ioctl id (from ioc_id) */
    uint cp_flag; /* see above */
    mblk_t *cp_private; /* private state information */
    caddr_t cp_rval; /* status of request: 0 -> success */
        /* non-zero -> failure */
};
#else
struct copyresp {
    int cp_cmd; /* ioctl command (from ioc_cmd) */
    cred_t *cp_cr; /* full credentials */
    uint cp_id; /* ioctl id (from ioc_id) */
    caddr_t cp_rval; /* status of request: 0 -> success */
        /* non-zero -> failure */
    size_t cp_pad1;
    uint cp_pad2;
    mblk_t *cp_private; /* private state information */
    uint cp_flag; /* see above */
    int cp_filler[3];
```

Appendix A • Message Types 323
The first three members of the structure correspond to those of the iocblk(9S) in the M_IOCTL message that allows the same message blocks to be reused for all of the related transparent messages (M_COPYIN, M_COPYOUT, M_IOCACK, M_IOCNAK). The cp_rval field contains the result of the request at the stream head. Zero indicates success and non-zero indicates failure. If failure is indicated, the module should not generate an M_IOCNAK message. It must abort all ioctl(2) processing, clean up its data structures, and return.

The cp_private field is copied from the cq_private field in the associated M_COPYIN or M_COPYOUT message. It is included in the M_IOCDATA message so the message can be self-describing. This is intended to simplify ioctl(2) processing by modules and drivers.

If the message is in response to an M_COPYIN message and success is indicated, the M_IOCDATA block is followed by M_DATA blocks containing the data copied in.

If an M_IOCDATA block is reused, any unused fields defined for the resultant message block should be cleared (particularly in an M_IOCACK or M_IOCNAK).

This message should not be queued by a module or driver unless it processes the data for the ioctl in some way.

M_IOCNAK

The M_IOCNAK message signals the negative acknowledgement (failure) of a previous M_IOCTL message. Its form is one M_IOCNAK block containing an iocblk(9S). The iocblk(9S) can contain a value in ioc_error to be returned to the user process in errno. Unlike the M_IOCACK, no user data or return value can be sent with this message. If any M_DATA blocks follow the M_IOCNAK block, the stream head ignores and frees them. When the stream head receives an M_IOCNAK, the outstanding ioctl(2) request, if any, fails. The format and use of this message type is described further under M_IOCTL.

M_PCPROTO

The M_PCPROTO message is the same as the M_PROTO message type, except for the priority and the following additional attributes. When an M_PCPROTO message is placed on a queue, its service procedure is always enabled. The stream head allows only one M_PCPROTO message to be placed in its read queue at a time. If an M_PCPROTO message is already in the queue when another arrives, the second message is discarded and its message blocks freed.

This message is intended to allow data and control information to be sent outside the normal flow control constraints.
getmsg(2) and putmsg(2) refer to messages as high priority messages.

M_PCRSE
The M_PCRSE message is reserved for internal use. Modules that do not recognize this message must pass it on. Drivers that do not recognize it must free it.

M_PCSIG
The M_PCSIG message is the same as the M_SIG message, except for the priority. M_PCSIG is often preferable to M_SIG especially in TTY applications, because M_SIG may be queued while M_PCSIG is more likely to get through quickly. For example, if an M_SIG message is generated when the DEL (delete) key is pressed on the terminal and the user has already typed ahead, the M_SIG message becomes queued and the user does not get the call until too late, becoming impossible to kill or interrupt a process by pressing a delete key.

M_READ
The M_READ message is generated by the stream head and sent downstream for a read(2) if no messages are waiting to be read at the stream head and if read notification has been enabled. Read notification is enabled with the SO_MREADON flag of the M_SETOPTS message and disabled by use of the SO_MREADOFF flag.

The message content is set to the value of the nbyte parameter (the number of bytes to be read) in read(2).

M_READ notifies modules and drivers of the occurrence of a read. It also supports communication between streams that reside in separate processors. The use of the M_READ message is developer dependent. Modules may take specific action and pass on or free the M_READ message. Modules that do not recognize this message must pass it on. All other drivers may or may not take action and then free the message.

This message cannot be generated by a user-level process and should not be generated by a module or driver. It is always discarded if passed to the stream head.

SO_MREADOFF and M_STOP
The SO_MREADOFF and M_STOP messages request devices to start or stop their output. They are used to produce momentary pauses in a device’s output, not to turn devices on or off.
The message format is not defined by STREAMS and its use is developer dependent. These messages may be considered special cases of an M_CTL message. These messages cannot be generated by a user-level process and each is always discarded if passed to the stream head.

**SO_MREADOFFI and M_STOPI**

The SO_MREADOFFI and M_STOPI messages are the same as SO_MREADOFF and M_STOP except that SO_MREADOFFI and M_STOPI are used to start and stop input.

**M_UNHANGUP**

The M_UNHANGUP message reconnects the carrier after it has been dropped.
Kernel Utility Interface Summary

Use the following kernel utilities to develop and maintain drivers.

**TABLE B–1 Kernel Utility Interfaces**

STREAMS-Based Terminal Subsystem

This chapter describes how a terminal subsystem is set up and how interrupts are handled. Different protocols are addressed, as well as canonical processing and line discipline substitution.

- “Overview of Terminal Subsystem” on page 331
- “STREAMS-based Pseudo-Terminal Subsystem” on page 340

Overview of Terminal Subsystem

STREAMS provides a uniform interface for implementing character I/O devices and networking protocols in the kernel. The SunOS 5.6 software implements the terminal subsystem in STREAMS. The STREAMS-based terminal subsystem (Figure C–1) provides many benefits:

- **Reusable line discipline modules.** The same module can be used in many streams where the configuration of these streams may be different.

- **Line-discipline substitution.** Although the Solaris operating environment provides a standard terminal line-discipline module, another one conforming to the interface can be substituted. For example, a remote login feature may use the terminal subsystem line discipline module to provide a terminal interface to the user.

- **Internationalization.** The modularity and flexibility of the STREAMS-based terminal subsystem enables an easy implementation of a system that supports multiple-byte characters for internationalization. This modularity also allows easy addition of new features to the terminal subsystem.

- **Easy customizing.** Users may customize their terminal subsystem environment by adding and removing modules of their choice.

- **The pseudo-terminal subsystem.** The pseudo-terminal subsystem can be easily supported (this is discussed in more detail in the section “STREAMS-based Pseudo-Terminal Subsystem” on page 340).
- **Merge with networking.** By pushing a line discipline module on a network line, you can make the network look like a terminal line.

```
+------------+                  +-----------------+                  +-----------------+
| User process|                  | User space      |                  | Kernel space     |
| Downstream  | Stream head       | Line discipline | TTY driver       | Upstream         |
```

**FIGURE C-1 STREAMS-based Terminal Subsystem**

The initial setup of the STREAMS-based terminal subsystem is handled with the `ttymon(1M)` command within the framework of the Service Access Facility (autopush feature). See “STREAMS Administrative Driver” on page 241 for more information.

The STREAMS-based terminal subsystem supports `termio(7I)`, the `termios(3C)` specification of the POSIX standard, multiple-byte characters for internationalization, the interface to asynchronous hardware flow control and peripheral controllers for asynchronous terminals. XENIX™ and BSD compatibility can also be provided by pushing the `ttcompat` module.

To use `shl` with the STREAMS-based terminal subsystem, the `sxt` driver is implemented as a STREAMS-based driver. The `sxt` feature is being discontinued and might not be available, so try to use the job-control mechanism instead of `sxt`. Note that both `shl` and job control should *not* be run simultaneously.

**Master Driver and Slave Driver Characteristics**

The master driver and slave driver have the following characteristics:

- Each master driver has one-to-one relationship with a slave device based on major/minor device numbers.
- Only one open is allowed on a master device. Multiple opens are allowed on the slave device according to standard file mode and ownership permissions.
- Each slave driver minor device has a node in the file system.
An open on a master device automatically locks out an open on the corresponding slave driver.

A slave cannot be opened unless the corresponding master is open and has unlocked the slave.

To provide a TTY interface to the user, the ldterm and pterm modules are pushed on the slave side.

A close on the master sends a hang up to the slave and renders both streams unusable, after all data have been consumed by the process on the slave side.

The last close on the slave side sends a zero-length message to the master but does not sever the connection between the master and slave drivers.

Line-Discipline Module

A STREAMS line-discipline module called ldterm is a key part of the STREAMS-based terminal subsystem. Throughout this chapter, the terms line discipline and ldterm are used interchangeably and refer to the STREAMS version of the standard line discipline and not the traditional character version. ldterm performs the standard terminal I/O processing traditionally done through the linesw mechanism.

The termio(7I) and termios(3C) specifications describe four flags that are used to control the terminal:

- c_iflag defines input modes
- c_oflag defines output modes
- c_cflag defines hardware control modes
- c_lflag defines terminal functions used by ldterm(7M)

To process these flags elsewhere (for example, in the firmware or in another process), a mechanism is in place to turn the processing of these flags on and off. When ldterm(7M) is pushed, it sends an M_CTL message downstream that asks the driver which flags the driver will process. The driver sends back that message in response if it needs to change the ldterm default processing. By default, ldterm(7M) assumes that it must process all flags except c_cflag unless it receives a message indicating otherwise.

Default Settings

When ldterm is pushed on the stream, the open routine initializes the settings of the termio flags. The default settings are:

- c_iflag = BRKINT|ICRNL|IXON|IMAXBEL
- c_oflag = OPOST|ONLCR|TAB3
- c_cflag = CREAD|CS8|B9600
- c_lflag = ISIG|ICANON|ECHO|ECHOK|IEXTEN|ECHOE|ECHOKE | ECHOCTL
In canonical mode (ICANON flag in c_lflag is turned on), read from the terminal file descriptor is in message non-discard (RMSGN) mode (see streamio(7I)). This implies that in canonical mode, read on the terminal file descriptor always returns at most one line, regardless of how many characters have been requested. In non-canonical mode, read is in byte-stream (RNORM) mode. The flag ECHOCTL has been added for SunOS 4.1 compatibility.

For information on user-configurable settings, see termio(7I).

Module open and close Routines

The open routine of the ldterm(7M) module allocates space for holding the TTY structure (see ldtermstd_state_t in ldterm.h) by allocating a buffer from the STREAMS buffer pool. The number of modules that can be pushed on one stream, as well as the number of TTYs in use, is limited. The number of instances of ldterm that have been pushed is limited only by available memory. The open also sends an M_SETOPTS message upstream to set the stream head high-water and low-water marks to 1024 and 200, respectively. These are the current values.

The ldterm module identifies itself as a TTY to the stream head by sending an M_SETOPTS message upstream with the SO_ISTTY bit of so_flags set. The stream head allocates the controlling TTY on the open, if one is not already allocated.

To maintain compatibility with existing applications that use the O_NDELAY flag, the open routine sets the SO_NDELON flag on in the so_flags field of the stroptions(9S) structure in the M_SETOPTS message.

The open routine fails if there are no buffers available (so it cannot allocate the internal state structure) or when an interrupt occurs while waiting for a buffer to become available.

The close routine frees all the outstanding buffers allocated by this stream. It also sends an M_SETOPTS message to the stream head to undo the changes made by the open routine. The ldterm(7M) module also sends M_START messages downstream to undo the effect of any previous M_STOP messages.

Read-Side Processing

The ldterm(7M) module’s read-side processing has put and service procedures. High-water and low-water marks for the read queue are 1024 and 200, respectively. These are the current values.

ldterm(7M) can send the following messages upstream:

M_DATA, M_BREAK, M_PCSIG, M_SIG, M_FLUSH, M_ERROR, M_IOCACK, M_IOCNAK, M_HANGUP, M_CTL, M_SETOPTS, M_COPYOUT, and M_COPYIN.
The ldterm(7M) module’s read side processes M_BREAK, M_DATA, M_CTL, M_FLUSH, M_HANGUP, M_IOCACK and M_IOCNAK messages. All other messages are sent upstream unchanged.

The put procedure scans the message for flow-control characters (IXON), signal-generating characters, and, after (possible) transformation of the message, queues the message for the service procedure. Echoing is handled completely by the service procedure.

If the ICANON flag is on in c_lflag, canonical processing is performed. If the ICANON flag is off, non-canonical processing is performed (see termio(7I) for more details). Handling of VMIN/VTIME in the STREAMS environment is somewhat complicated, because read needs to activate a timer in the ldterm module in some cases; hence, read notification becomes necessary. When a user issues an ioctl(2) to put ldterm(7M) in non-canonical mode, the module sends an M_SETOPTS message to the stream head to register read notification. Further reads on the terminal file descriptor will cause the stream head to issue an M_READ message downstream and data will be sent upstream in response to the M_READ message. With read notification, buffering of raw data is performed by ldterm(7M). Canonizing the raw data when the user has switched from raw to canonical mode is possible. However, the reverse is not possible.

To summarize, in non-canonical mode, the ldterm(7M) module buffers all data until VMIN or VTIME criteria are met. For example, if VMIN=3 and VTIME=0, and three bytes have been buffered, these characters are sent to the stream head regardless of whether there is a pending M_READ, and no M_READ needs to be sent downstream. If an M_READ message is received, the number of bytes sent upstream is the argument of the M_READ message unless VTIME is satisfied before VMIN (for example, the timer has expired), in which case whatever characters are available will be sent upstream.

The service procedure of ldterm(7M) handles STREAMS-related flow control. Because the read side high-water and low-water marks are 1024 and 200 respectively, placing 1024 characters or more on the read queue causes the QFULL flag be turned on, indicating that the module below should not send more data upstream.

Input flow control is regulated by the line-discipline module which generates M_STARTI and M_STOPI high priority messages. When sent downstream, receiving drivers or modules take appropriate action to regulate the sending of data upstream. Output flow control is activated when ldterm(7M) receives flow control characters in its data stream. The module then sets an internal flag indicating that output processing is to be restarted/stopped and sends an M_START/M_STOP message downstream.

Write-Side Processing

Write-side processing of the ldterm(7M) module is performed by the write-side put and service procedures.

The ldterm module supports the following ioctl(s):

Appendix C • STREAMS-Based Terminal Subsystem  335
TCSETA, TCSETAW, TCSETAF, TCSETS, TCSETSF, TCGETA, TCGETS, TCXONC, TCFLSH, and TCSBRK.

All ioctl is not recognized by the ldterm(7M) module are passed downstream to the neighboring module or driver.

The following messages can be received on the write side:

M_DATA, M_DELAY, M_BREAK, M_FLUSH, M_STOP, M_START, M_READ, M_IOCTL, and M_IOCTL.

On the write side, the ldterm module processes M_FLUSH, M_DATA, M_IOCTL, and M_READ messages, and all other messages are passed downstream unchanged.

An M_CTL message is generated by ldterm(7M) as a query to the driver for an intelligent peripheral and to decide on the functional split for termio(7I) processing. If all or part of termio(7I) processing is done by the intelligent peripheral, ldterm(7M) can turn off this processing to avoid computational overhead. This is done by sending an appropriate response to the M_CTL message, as follows:

- If all of the termio(7I) processing is done by the peripheral hardware, the driver sends an M_CTL message back to ldterm(7M) with ioc_cmd of the structure iocblk(9S) set to MC_NO_CANON. If ldterm(7M) is to handle all termio(7I) processing, the driver sends an M_CTL message with ioc_cmd set to MC_DO_CANON. The default is MC_DO_CANON.

- If the peripheral hardware handles only part of the termio(7I) processing, it informs ldterm(7M) in the following way:
  
The driver for the peripheral device allocates an M_DATA message large enough to hold atermios(3C) structure. The driver then turns on those c_iflag, c_oflag, and c_lflag fields of the termios(3C) structure that are processed on the peripheral device by executing an OR operation on the flag values. The M_DATA message is then attached to the b_cont field of the M_CTL message it received. The message is sent back to ldterm(7M) with ioc_cmd in the data buffer of the M_CTL message set to MC_PART_CANON.

One difference between AT&T STREAMS and SunOS 5 STREAMS is that AT&T's line discipline module does not check whether write-side flow control is in effect before forwarding data downstream. It expects the downstream module or driver to add the messages to its queue until flow control is lifted. This is not true in SunOS 5 STREAMS.

EUC Handling in ldterm

Post-processing (the o_flags) should not be handled by the host processor unless the board software is prepared to deal with international (EUC) character sets properly because that post-processing must take the EUC information into account.

ldterm(7M) allots the appropriate screen width of characters (that is, how many columns are taken by characters from each given code set on the current physical
display) and it takes this width into account when calculating tab expansions. When using multi-byte characters or multi-column characters, ldterm automatically handles tab expansion (when TAB3 is set) and does not leave this handling to a lower module or driver.

By default, multi-byte handling by ldterm is turned off. When ldterm receives an EUC_WSET ioctl(2), it turns multi-byte processing on if it is essential to properly handle the indicated code set. Thus, if you use single byte 8-bit codes and have no special multi-column requirements, the special multi-column processing is not used at all. This means that multi-byte processing does not reduce the processing speed or efficiency of ldterm unless it is actually used.

The following describes how the EUC handling in ldterm works:

First, the multi-byte and multi-column character handling is only enabled when the EUC_WSET ioctl indicates that one of the following conditions is met:

- Code set consists of more than one byte (including the SS2 and/or SS3) of characters
- Code set requires more than one column to display on the current device, as indicated in the EUC_WSET structure

Assuming that one or more of the previous conditions exists, EUC handling is enabled. At this point, a parallel array (see ldterm_mod structure) used for other information is allocated and a pointer to it is stored in t_eucp_mp. The parallel array that it holds is pointed to by t_eucp. The t_codeset field holds the flag that indicates which of the code sets is currently being processed on the read side. When a byte with the high bit arrives, ldterm checks to see if it is SS2 or SS3. If yes, it belongs to code set 2 or 3. Otherwise, it is a byte that comes from code set 1.

Once the extended code set flag has been set, the input processor retrieves the subsequent bytes, as they arrive, to build one multi-byte character. The counter field t_eucleft tells the input processor how many bytes remain to be read for the current character. The parallel array t_eucp holds its display width for each logical character in the canonical buffer. During erase processing, positions in the parallel array are consulted to determine how many backspaces need to be send to erase each logical character. (In canonical mode, one backspace of input erases one logical character, no matter how many bytes or columns that character consumes.) This greatly simplifies erase processing for EUC.

The t_maxeuc field holds the maximum length, in memory bytes, of the EUC character mapping currently in use. The eucwioc field is a substructure that holds information about each extended code set.

The t_eucign field aids in output post-processing (tab expansion). When characters are output, ldterm(7M) keeps a column to indicate what the current cursor column is supposed to be. When it sends the first byte of an extended character, it adds the number of columns required for that character to the output column. It then subtracts one from the total width in memory bytes of that character and stores the result in
The field `t_eucign` tells `ldterm(7M)` how many subsequent bytes to ignore for the purposes of column calculation. (`ldterm(7M)` calculates the appropriate number of columns when it sees the first byte of the character.)

The field `t_eucwarn` is a counter for occurrences of bad extended characters. It is mostly useful for debugging. After receiving a certain number of illegal EUC characters (perhaps because of some problem on the line or with declared values), a warning is given on the system console.

There are two relevant files for handling multi-byte characters: `euc.h` and `eucioctl.h`. `eucioctl.h` contains the structure that is passed with `EUC_WSET` and `EUC_WGET` calls. The normal way to use this structure is to get `CSWIDTH` from the locale using a mechanism such as `getwidth(3C)` or `setlocale(3C)`, copy the values into the structure in `eucioctl.h`, and send the structure using an `I_STR_ioctl(2)`. The `EUC_WSET` call informs the `ldterm(7M)` module about the number of bytes in extended characters and how many columns the extended characters from each set consume on the screen. This enables `ldterm(7M)` to treat multi-byte characters as single units for the purpose of erase processing and to correctly calculate tab expansions for multi-byte characters.

---

**Note** — `LC_CTYPE` (instead of `CSWIDTH`) should be used in SunOS 5 systems.

---

The file `euc.h` has fields for EUC width, screen width, and wide-character width. The functions in Example C-1 are used to set and get EUC widths (these functions assume the environment where the `eucwidth_t` structure is needed and available).

### EXAMPLE C-1 EUC Header File

```c
#include <eucioctl.h> /* need others, like stropts.h*/

struct eucioc eucw; /*for EUC_WSET/WGET to line disc*/
eucwidth_t width; /* ret struct from _getwidth() */
/*
 * set_euc
 */
set_euc(struct eucioc *e)
{
    struct strioctl sb;
    sb.ic_cmd = EUC_WSET;
    sb.ic_timeout = 15;
    sb.ic_len = sizeof(struct eucioc);
    sb.ic_dp = (char *) e;
    if (ioctl(0, I_STR, &sb) < 0)
        fail();
}
/*
 * euclook. Get current EUC code widths from line discipline.
 */
```

338  STREAMS Programming Guide • May 2002
Hardware Emulation Module

If a stream supports a terminal interface, a driver or module that understands all
ioctls is needed to support terminal semantics (specified by termio(71) and
termion(71). If there is no hardware driver that understands all ioctl commands
downstream from the ldterm module, a hardware emulation module must be placed
downstream from the line-discipline module. The function of the hardware emulation
module is to understand and acknowledge the ioctl's that may be sent to the process
at the stream head and to mediate the passage of control information downstream.
Together, the line-discipline module and the hardware emulation module behave as if
there was an actual terminal on that stream.

The hardware emulation module is necessary whenever there is no TTY driver at the
end of the stream. For example, the module is necessary in a pseudo-TTY situation
where there is process-to-process communication on one system (discussed in
"STREAMS-based Pseudo-Terminal Subsystem" on page 340), or in a network
situation where a termio interface is expected (for example, remote login) but there is
no TTY driver on the stream.

Most of the actions taken by the hardware emulation module are the same regardless
of the underlying architecture. However, there are some actions that are different,
depending on whether the communication is local or remote and whether the
underlying transport protocol is used to support the remote connection.

Each hardware emulation module has an open, close, read queue put procedure,
and write queue put procedure.

The hardware emulation module does the following:
Processes, if appropriate, and acknowledges receipt of the following `ioctl` on its write queue by sending an `M_IOCTL` message back upstream: `TCSETA`, `TCSETAW`, `TCSETAF`, `TCSETS`, `TCSETSW`, `TCSETSF`, `TCGETA`, `TCGETS`, and `TCSBRK`.

Acknowledges the Extended UNIX Code (EUC) `ioctl(2)`.

If the environment supports windowing, it acknowledges the windowing `TIOCSWINSZ`, `TIOCGWINSZ`, and `JWINSIZE` `ioctl(2)`s. If the environment does not support windowing, an `M_IOCTL` message is sent upstream.

If another `ioctl(2)` is received on its write queue, it sends an `M_IOCTL` message upstream. It doesn’t pass any unrecognized `ioctl` to the slave driver.

When the hardware emulation module receives an `M_IOCTL` message of type `TCSBRK` on its write queue, it sends an `M_IOCTL` message upstream and the appropriate message downstream. For example, an `M_BREAK` message could be sent downstream.

When the hardware emulation module receives an `M_IOCTL` message on its write queue to set the baud rate to 0 (`TCSETAW` with `CBAUD` set to `B0`), it sends an `M_IOCTL` message upstream and an appropriate message downstream; for networking situations this will probably be an `M_PROTO` message, which is a TPI`DISCON_REQ` message requesting the transport provider to disconnect.

All other messages (`M_DATA`, for instance) not mentioned here are passed to the next module or driver in the stream.

The hardware emulation module processes messages in a way consistent with the driver that exists.

---

STREAMS-based Pseudo-Terminal Subsystem

The STREAMS-based pseudo-terminal subsystem provides the user with an interface that is identical to the STREAMS-based terminal subsystem described earlier in this chapter. The pseudo-terminal subsystem (pseudo-TTY) supports a pair of STREAMS-based devices called the master device and slave device. The slave device provides processes with an interface that is identical to the terminal interface.

However, where devices that provide the terminal interface have some kind of hardware device behind them, the slave device has another process manipulating it through the master half of the pseudo-terminal. Anything written on the master device is given to the slave as an input, and anything written on the slave device is presented as an input on the master side.

Figure C–2 illustrates the architecture of the STREAMS-based pseudo-terminal subsystem. The master driver (called ptm) is accessed through the clone driver and is the controlling part of the system. The slave driver (called pts) works with the line...
discipline module and the hardware emulation module to provide a terminal interface to the user process. An optional packetizing module (called pckt) is also provided. It can be pushed on the master side to support packet mode (this is discussed in “Packet Mode” on page 345).

The number of pseudo-TTY devices that can be installed on a system depends on available memory.

**Line-Discipline Module**

In the pseudo-TTY subsystem, the line discipline module is pushed on the slave side to present the user with the terminal interface.

`ldterm(7M)` can turn off the processing of the `c_iflag`, `c_oflag`, and `c_lflag` fields to allow processing to take place elsewhere. The `ldterm(7M)` module can also turn off all canonical processing when it receives an `M_CTL` message with the `MC_NO_CANON` command to support remote mode. Although `ldterm(7M)` passes through messages without processing them, the appropriate flags are set when an `ioctl(2)`, such as `TCGETA` or `TCGETS`, is issued to indicate that canonical processing is being performed.

![FIGURE C–2 Pseudo-TTY Subsystem Architecture](image-url)
Pseudo-TTY Emulation Module: ptem

Because the pseudo-TTY subsystem has no hardware driver downstream from the ldterm(7M) module to process the terminal ioctl(2) calls, another module that understands the ioctl commands is placed downstream from the ldterm(7M). This module, ptem(7M), processes all of the terminal ioctl(2) calls and mediates the passage of control information downstream.

ldterm(7M) and ptem(7M) together behave like a real terminal. Since there is no real terminal or modem in the pseudo-TTY subsystem, some of the ioctl(2) commands are ignored and cause only an acknowledgment of the command. For example, if a “set” ioctl is called, none of the bits in the c_cflag field of termio(7I) has any effect on the pseudo-terminal unless the baud rate is set to 0. Setting the baud rate to 0 has the effect of hanging up the pseudo-terminal.

The pseudo-terminal does not recognize parity, so none of the flags in the c_iflag that control the processing of parity errors have any effect. The delays specified in the c_oflag field are also not supported.

ptem(7M) does the following:

- Processes, if appropriate, and acknowledges receipt of the following ioctls on its write queue by sending an M_IOCACK message back upstream: TCSETA, TCSETAW, TCSETAF, TCSETS, TCSETSW, TCSETSF, TCGETA, TCGETS, and TCSBRK.
- Keeps track of the window size; information needed for the TIOCSWINSZ, TIOCNOFLD, and JWINSIZE ioctl.
- When it receives an ioctl, other than for TIOCSWINSZ, TIOCNOFLD, or JWINSIZE on its write queue, it sends an M_IOCNAK message upstream.
- It passes downstream the following ioctls after processing them: TCSETA, TCSETAW, TCSETAF, TCSETS, TCSETSW, TCSETSF, TCGETA, TCGETS, and TIOCSWINSZ.
- Frees any M_IOCNAK messages it receives on its read queue in case the pckt module (pckt(7M) (described in the section “Packet Mode” on page 345) is not on the pseudo-terminal subsystem and the TCSETA, TCSETAW, TCSETAF, TCSETS, TCSETSW, TCSETSF, TCGETA, TCGETS, or TIOCSWINSZ ioctl gets to the master’s stream head which then sends an M_IOCNAK message.
- In its open routine, ptem sends an M_SETOPTS message upstream requesting allocation of a controlling TTY.
- When ptem receives an M_IOCTL message of type TCSBRK on its read queue, it sends an M_IOCACK message downstream and an M_BREAK message upstream.
- When ptem receives an ioctl(2) message on its write queue to set the baud rate to 0 (TCSETAW with CBAUD set to B0), it sends an M_IOCACK message upstream and a zero-length message downstream.
When ptem receives an M_IOCTL of type TIOCSIGNAL on its read queue, it sends an M_IOCACK downstream and an M_PCSIG upstream, where the signal number is the same as in the M_IOCTL message.

When ptem receives an M_IOCTL of type TIOCREMOTE on its read queue, it sends an M_IOCACK message downstream and the appropriate M_CTL message upstream to enable or disable canonical processing.

When ptem receives an M_DELAY message on its read or write queue, it discards the message and does not act on it.

When ptem receives an M_IOCTL of type JWINSIZE on its write queue, and if the values in its jwinize structure are not zero, it sends an M_IOCACK message upstream with the jwinize structure. If the values are zero, it sends an M_IOCNAK message upstream.

When ptem receives an M_IOCTL message of type TIOCGWINSZ on its write queue and the values in the winsize structure are not zero, it sends an M_IOCACK message upstream with the winsize structure. If the values are zero, it sends an M_IOCNAK message upstream. It also saves the information passed to it in the winsize structure and sends a STREAMS signal message for signal SIGWINCH upstream to the slave process if the size changed.

When ptem(7M) receives an M_IOCTL message with type TIOCGWINSZ on its read queue and the values in the winsize structure are not zero, it sends an M_IOCACK message downstream with the winsize structure. If the values are zero, it sends an M_IOCNAK message downstream. It also saves the information passed to it in the winsize structure and sends a STREAMS signal message for signal SIGWINCH upstream to the slave process if the size changed.

All other messages are passed to the next module or driver.

ptem Data Structure

Each instantiation of ptem(7M) is associated with a local area. These data are held in a structure called ptem that has the following format:

```c
struct ptem
{
    long cflags;      /* copy of c_flags */
    mblk_t *dack_ptr; /* pointer to preallocated msg blk
                          used to send disconnect */
    queue_t *q_ptr;   /* pointer to ptem's read queue */
    struct winsize wsz; /*struct to hold windowing info*/
    unsigned short state; /* state of ptem entry */
};
```

When ptem(7M) is pushed onto the slave side stream, a search of the ptem structure is made for a free entry (state is not set to INUSE). The c_cflags of the termio(7I) structure and the windowing variables are stored in cflags and wsz respectively. The dack_ptr is a pointer to a message block used to send a zero-length message whenever a hang-up occurs on the slave side.
Note – ptem(7M) internal implementation might change. This structure should be relevant only to people wanting to change the module.

open and close Routines

Caution – The following information is implementation-dependent.

In the open routine of ptem(7M) a STREAMS message block is allocated for a zero-length message for delivering a hangup message. This allocation of a buffer is done before it is needed to ensure that a buffer is available. An M_SETOPTS message is sent upstream to set the read-side stream head queues, to assign high-water and low-water marks (1024 and 256 respectively), and to establish a controlling terminal.

The same default values as for the line-discipline module are assigned to cflags, and INUSE to the state field.

Note – These default values are currently being examined and may change in the future.

The open routine fails if:
- No free entries are found when the ptem(7M) structure is searched
- sflag is not set to MODOPEN
- A zero-length message cannot be allocated (no buffer is available)
- A stroptions(9S) structure cannot be allocated

The close routine is called on the last close of the slave-side stream. Pointers to read and write queues are cleared and the buffer for the zero-length message is freed.

Remote Mode

Remote mode available with the pseudo-TTY subsystem, is used for applications that perform the canonical function normally done by ldtterm(7M) and the TTY driver. The remote mode enables applications on the master side to turn off the canonical processing. An TIOCREMOTE ioctl with a nonzero parameter (ioctl(fd, TIOCREMOTE, 1)) is issued on the master side to enter the remote mode. When this
occurs, an M_CTL message with the command MC_NO_CANON is sent to 1dterm(7M), indicating that data should be passed when received on the read side and that no canonical processing is to take place. The remote mode may be disabled by ioctl(fd, TIOCREMOTE, 0).

Packet Mode

In the STREAMS-based pseudo-terminal subsystem packet mode is used to inform the process on the master side when state changes have occurred in the pseudo-TTY. Packet mode is enabled by pushing the pckt module on the master side. Data written on the master side is processed normally. When data is written on the slave side, or when other messages are encountered by the pckt module, a header is added to the message so it can be subsequently retrieved by the master side with a getmsg operation.

pckt(7M) does the following:

- When a message is passed to this module on its write queue, the module does no processing and passes the message to the next module or driver.
- pckt creates an M_PROTO message when one of the following messages is passed to it: M_DATA, M_IOCTL, M_PROTO/M_PROTO, M_FLUSH, M_READ, M_START/M_STOP, and M_STARTI/M_STOP.

All other messages are passed through. The M_PROTO message is passed upstream and retrieved when the user issues getmsg(2).

- If the message is an M_FLUSH message, pckt(7M) does the following:
  - If the flag is FLUSHW, it is changed to FLUSHR (because FLUSHR was the original flag before the pts(7D) driver changed it), changed into an M_PROTO message, and passed upstream. To prevent the stream head’s read queue from being flushed, the original M_FLUSH message must not be passed upstream.
  - If the flag is FLUSHR, it is changed to FLUSHW, packetized into an M_PROTO message, and passed upstream. To flush both of the write queues properly, an M_FLUSH message with the FLUSHW flag set is also sent upstream.
  - If the flag is FLUSHRW, the message with both flags set is packetized and passed upstream. An M_FLUSH message with the FLUSHW flag set is also sent upstream.

Pseudo-TTY Drivers: ptm and pts

To use the pseudo-TTY subsystem, a node for the master side driver /dev/ptmx and N number of slave drivers must be installed (N is determined at installation). The names of the slave devices are /dev/pts/M where M has the values 0 through N-1. A user accesses a pseudo-TTY device through the master device (called ptm) that in turn is accessed through the clone driver. The master device is set up as a clone device where its major device number is the major for the clone device and its minor device number is the major for the ptm(7D) driver.
The master pseudo driver is opened by calling `open(2)` with `/dev/ptmx` as the device to be opened. The clone open finds the next available minor device for that major device. A master device is available only if it, and its corresponding slave device, are not already open. There are no nodes in the file system for master devices.

When the master device is opened, the corresponding slave device is automatically locked out. No user may open that slave device until it is unlocked. A user may invoke a function `grantpt` to change the owner of the slave device to that of the user who is running this process, change the group ID to TTY, and change the mode of the device to 0620. Once the permissions have been changed, the device may be unlocked by the user. Only the owner or the root user can access the slave device. The user must then invoke the `unlockpt` function to unlock the slave device. Before opening the slave device, the user must call the `ptsname` function to obtain the name of the slave device. The functions `grantpt`, `unlockpt`, and `ptsname` are called with the file descriptor of the master device. The user may then invoke the open system call with the name that was returned by the `ptsname` function to open the slave device.

The following example shows how a user may invoke the pseudo-TTY subsystem:

```c
int fdm fds;
char *slavename;
extern char *ptsname();

fdm = open("/dev/ptmx", O_RDWR); /* open master */
grantpt(fdm); /* change permission of slave */
unlockpt(fdm); /* unlock slave */
slavename = ptsname(fdm); /* get name of slave */
fds = open(slavename, O_RDWR); /* open slave */
ioctl(fds, I_PUSH, "ptem"); /* push ptem */
ioctl(fds, I_PUSH, "ldterm"); /* push ldterm */
```

Unrelated processes may open the pseudo device. The initial user may pass the master file descriptor using a STREAMS-based pipe or a slave name to another process to enable it to open the slave. After the slave device is open, the owner is free to change the permissions.

**Note** – Certain programs such as `write` and `wall` are set group ID (`setgid(2)`) to TTY and are also able to access the slave device.

After both the master and slave have been opened, the user has two file descriptors that provide full-duplex communication using two streams. The two streams are automatically connected. The user may then push modules onto either side of the stream. The user also needs to push the `ptem` and `ldterm` modules onto the slave side of the pseudo-terminal subsystem to get terminal semantics.
The master and slave drivers pass all STREAMS messages to their adjacent queues. Only the M_FLUSH needs some processing. Because the read queue of one side is connected to the write queue of the other, the FLUSHR flag is changed to FLUSHW and vice versa.

When the master device is closed, an M_HANGUP message is sent to the slave device to render the device unusable. The process on the slave side gets the errno ENXIO when attempting to write on that stream, but it will be able to read any data remaining on the stream head read queue. When all the data has been read, read(2) returns 0, indicating that the stream can no longer be used.

On the last close of the slave device, a zero-length message is sent to the master device. When the application on the master side issues a read or getmsg and 0 is returned, the user of the master device decides whether to issue a close that dismantles the pseudo-terminal subsystem. If the master device is not closed, the pseudo-TTY subsystem is available to another user to open the slave device.

Since zero-length messages are used to indicate that the process on the slave side has closed (and should be interpreted that way by the process on the master side), applications on the slave side should not write zero-length messages. If that occurs, the write returns 0, and the zero-length message is discarded by the pterm module.

The standard STREAMS system calls can access the pseudo-TTY devices. The slave devices support the O_NDELAY and O_NONBLOCK flags. Because the master side does not act like the terminal, if O_NONBLOCK or O_NDELAY is set, read on the master side returns -1 with errno set to EAGAIN if no data is available, and write(2) returns -1 with errno set to EAGAIN if there is internal flow control.

The master driver supports the ISPTM and UNLKPT ioctl(2) that are used by the functions grantpt(3C), unlockpt(3C), and ptsname(3C). The ISPTM ioctl(2) determines whether the file descriptor is that of an open master device. On success, it returns the major/minor number (type dev_t) of the master device which can be used to determine the name of the corresponding slave device. The UNLKPT ioctl(2) unlocks the master and slave devices. It returns 0 on success. On failure, the errno is set to EINVAL indicating that the master device is not open.

The format of these commands is:

```c
int ioctl (int fd, int command, int arg)
```

where command is either ISPTM or UNLKPT and arg is 0. On failure, -1 is returned.

When data is written to the master side, the entire block of data written is treated as a single line. The slave-side process reading the terminal receives the entire block of data. Data is not edited by the ldtterm module at input, regardless of the terminal mode. The master-side application is responsible for detecting an interrupt character and sending an interrupt signal SIGINT to the process in the slave side. This can be done as follows:

```c
ioctl (fd, TIOCSIGNAL, SIGINT)
```
where SIGINT is defined in the file signal.h. When a process on the master side issues this ioctl(2), the argument is the number of the signal that should be sent. The specified signal is then sent to the process group on the slave side.

**grantpt**

Grantpt(3C) changes the mode and the ownership of the slave device that is associated with the given master device. Given a file descriptor fd, grantpt(3C) first checks that the file descriptor is that of the master device. If so, it obtains the name of the associated slave device and sets the user ID to that of the user running the process and the group ID to TTY. The mode of the slave device is set to 0620.

If the process is already running as root, the permission of the slave can be changed directly without invoking this function. grantpt(3C) returns 0 on success and -1 on failure. It fails if one or more of the following occurs: fd is not an open file descriptor, fd is not associated with a master device, the corresponding slave could not be accessed, or a system call failed because no more processes could be created.

**unlockpt**

Unlockpt(3C) clears a lock flag associated with a master/slave device pair. unlockpt(3C) returns 0 on success and -1 on failure. It fails if one or more of the following occurs: fd is not an open file descriptor or fd is not associated with a master device.

**ptsname**

Ptsname(3C) returns the name of the slave device that is associated with the given master device. It first checks that the file descriptor is that of the master. If it is, it then determines the name of the corresponding slave device /dev/pts/M and returns a pointer to a string containing the null-terminated path name. The return value points to static data whose content is overwritten by each call. ptsname(3C) returns a non-NULL path name upon success and a NULL pointer upon failure. It fails if one or more of the following occurs: fd is not an open file descriptor or fd is not associated with the master device.

**Pseudo-TTY Streams**

Drivers and modules can make the stream head act as a terminal stream by sending an M_SETOPTS message with the SO_ISTTY flag set upstream. This state may be changed by sending an M_SETOPTS message with the SO_ISNTTY flag set upstream.

Controlling terminals are allocated with the open(2) interface. The device must tell the stream head that it is acting as a terminal.
The TOSTOP flag is set on reception of an M_SETOPTS message with the SO_TOSTOP flag set in the so_flags field. It is cleared on reception of an M_SETOPTS message with the SO_TONSTOP flag set.

Stream head processing is isolated from modules and drivers by using several message types, such as M_ERROR, M_HANGUP and M_SETOPS, which only affect the stream in which they are sent.
STREAMS FAQ

This appendix provides answers to frequently asked questions (FAQs).

With decent code in the kernel (not STREAMS) an in-kernel filter is much faster.

The following discussion provides answers to frequently asked IP interface questions.

What are the rules for naming a Network Interface Card (NIC) device driver?

Naming of the NIC device driver has the following constraints:

- The name can contain alphanumeric and underscore (_) characters only
- The first and last characters of the name cannot be a number
- The name length cannot exceed 16 characters. The recommended length is 3–8 characters

Do Solaris operating environment Ethernet drivers support Data Link Provider Interfaces (DLPI)?

Yes. The Solaris operating environment Ethernet le(7D) drivers support Data Link Provider Interfaces (DLPI).

Is there documentation that describes the interface between IP and network drivers, namely, the Sun-specific requirements not outlined in the DLPI Version 2 specification?

IP is a STREAMS module in the Solaris operating environment. Any module or driver interface with IP should follow the STREAMS mechanism. There are no specific requirements for the interface between IP and network drivers.

When an ifconfig device0 plumb is issued, the driver immediately receives a DL_INFO_REQ. Exactly what is required in the DL_INFO_ACK from a DLPI Style 2 provider?

Look at the dl_info_ack_t struct in /usr/include/sys/dlpi.h.
Can a driver be a clone driver and also a DLPI Style 2 provider? If so, how do I map the minor number selected in the open routine to an instance prior to a DL_ATTACH_REQ? The technique of using the minor number to obtain the instance in the getinfo routine is not valid prior to the DL_ATTACH_REQ. Yes, it is possible for the driver to be a clone driver and also a DLPI Style 2 provider. The DL_ATTACH_REQ request assigns a physical point of attachment (PPA) to a stream. The DL_ATTACH_REQ request can be issued any time after a file or stream being opened. The DL_ATTACH_REQ request does not have anything to do with assigning, retrieving or mapping minor/instance number. Of course, you can issue a DL_ATTACH_REQ request for a file or stream with desired major/minor number. As for the question of mapping minor number to instance, usually the minor number (getminor(9F)) is the instance number.

In the examples, a minor node is created each time the driver’s attach routine is called. How would a clone driver attach to multiple boards; that is, have multiple instances, and still only create one minor node? For the clone driver, this might not be possible. A non-clone driver, it can use the bits information in a particular minor number, for example FF, to map all other minor nodes.

Do Solaris 2.1 Ethernet drivers support LLI 2.0 interfaces? Do you mean DLPI (Data Link Provider interfaces)? The Solaris 2.1 ethernet drivers, le and ie, both support DLPI. See the le(7D) man page.

Does Solaris 2.1 DLPI provide both connection-oriented services and connectionless services? Also, is your DLPI Version 2.0, which includes multicast facilities? Yes and yes. Please see the dlpi(7P) man page. TCP and IP are STREAMS modules in the Solaris operating environment. The command strconf < /dev/tcp lists all the modules. STREAMS is not supported in SunOS 4 system TCP/IP.

Is multicasting supported on SunOS 4? If not, how can the customer obtain this feature?

IP multicast is a standard supported feature in the Solaris operating environment, but it is not supported in the SunOS 4 environment. If customers want to run an unsupported IP multicast on their SunOS 4 machines, it is available via anonymous FTP from gregorio.stanford.edu in the file vmtcp-ip/ipmulti-sunos4lx.tar.Z.
Glossary

anchor  A STREAMS locking mechanism that prevents the removal of STREAMS modules with the I_POP ioctl. Anchors are placed on STREAMS modules by adding the [anchor] flag to autopush configuration files or by directly calling the I_ANCHOR ioctl.

autopush  A STREAMS mechanism that enables a prespecified list of modules to be pushed automatically onto the stream when a STREAMS device is opened. This mechanism is used only for administrative purposes.

back-enable  To enable (by STREAMS) a preceding blocked queue’s service procedure when STREAMS determines that a succeeding queue has reached its low-water mark.

blocked  A queue’s service procedure that cannot be enabled due to flow control.

close routine  A procedure that is called when a module is popped from a stream or when a driver is closed.

controlling stream  A stream above the multiplexing driver used to establish the lower connections. Multiplexed stream configurations are maintained through the controlling stream to a multiplexing driver.

DDI  Device Driver Interface. An interface that facilitates driver portability across different UNIX system versions.

device driver  A stream component whose principle functions are handling an associated physical device and transforming data and information between the external interface and stream.
**DKI**

Driver–Kernel Interface. An interface between the UNIX system kernel and different types of drivers. It consists of a set of driver-defined functions that are called by the kernel. These functions are entry points into a driver.

**downstream**

A direction of data flow going from the stream head toward a driver. Also called write side and output side.

**driver**

A module that forms the stream end. It can be a device driver or a pseudo-device driver. It is a required component in STREAMS (except in STREAMS-based pipe mechanism), and physically identical to a module. It typically handles data transfer between the kernel and a device and does little or no processing of data.

**enable**

A term used to describe scheduling of a queue’s service procedure.

**FIFO**

First in, first out. A term used in STREAMS for named pipes. This term is also used in queue scheduling.

**flow control**

A STREAMS mechanism that regulates the rate of message transfer within a stream and from user space into a stream.

**hardware emulation module**

A module required when the terminal line discipline is on a stream but there is no terminal driver at the end of the stream. This module recognizes all ioctl s necessary to support terminal semantics specified by termio and termios.

**input side**

A direction of data flow going from a driver toward the stream head. Also called read side and upstream.

**line discipline**

A STREAMS module that performs termio canonical and non-canonical processing. It shares some termio processing with a driver in a STREAMS terminal subsystem.

**lower stream**

A stream connected below a multiplexer pseudo-device driver, by means of an I_LINK or I_PLINK ioctl. The far end of a lower stream terminates at a device driver or another multiplexer driver.

**master driver**

A STREAMS-based device supported by the pseudo-terminal subsystem. It is the controlling part of the pseudo-terminal subsystem (also called ptm).

**message**

One or more linked message blocks. A message is referenced by its first message block and its type is defined by the message type of that block.

**message block**

A triplet consisting of a data buffer and associated control structures, an msgb structure and a datab structure. It carries data or information, as identified by its message type, in a stream.

**message queue**

A linked list of zero or more messages connected together.

**message type**

A defined set of values identifying the contents of a message.
module  A defined set of kernel-level routines and data structures used to process data, status, and control information on a stream. It is an optional element, but there can be many modules in one stream. It consists of a pair of queues (read queue and write queue), and it communicates to other components in a stream by passing messages.

multiplexer  A STREAMS mechanism that enables messages to be routed among multiple streams in the kernel. A multiplexing configuration includes at least one multiplexing pseudo-device driver connected to one or more upper streams and one or more lower streams.

named stream  A stream, typically a pipe, with a name associated with it by way of a call to `fattach` (that is, a mount operation). This is different from a named pipe (FIFO) in two ways: a named pipe (FIFO) is unidirectional while a named stream is bidirectional; a named stream need not refer to a pipe but can be another type of a stream.

open routine  A procedure in each STREAMS driver and module called by STREAMS on each `open` system call made on the stream. A module’s `open` procedure is also called when the module is pushed.

packet mode  A feature supported by the STREAMS-based pseudo-terminal subsystem. It is used to inform a process on the master side when state changes occur on the slave side of a pseudo-TTY. It is enabled by pushing a module called `pckt` on the master side.

persistent link  A connection below a multiplexer that can exist without having an open controlling stream associated with it.

pipe  See STREAMS-based pipe.

pop  A term used when a module that is immediately below the stream head is removed.

pseudo-device driver  A software driver, not directly associated with a physical device, that performs functions internal to a stream such as a multiplexer or log driver.

pseudo-terminal subsystem  A user interface identical to a terminal subsystem except that there is a process in place of a hardware device. It consists of at least a master device, slave device, line-discipline module, and hardware emulation module.

push  A term used when a module is inserted in a stream immediately below the stream head.

pushable module  A module put between the stream head and driver. It performs intermediate transformations on messages flowing between the stream head and driver. A driver is a non-pushable module.

put procedure  A routine in a module or driver associated with a queue that receives messages from the preceding queue. It is the single entry point into a queue from a preceding queue. It may perform processing on the
message and will then generally either queue the message for subsequent processing by this queue’s service procedure, or will pass the message to the put procedure of the following queue.

**queue**

A data structure that contains status information, a pointer to routines processing messages, and pointers for administering a stream. It typically contains pointers to a put and service procedure, a message queue, and private data.

**read side**

A direction of data flow going from a driver towards the stream head. Also called upstream and input side.

**read queue**

A message queue in a module or driver containing messages moving upstream. Associated with the read system call and input from a driver.

**remote mode**

A feature available with the pseudo-terminal subsystem. It is used for applications that perform the canonical and echoing functions normally done by the line discipline module and TTY driver. It enables applications on the master side to turn off the canonical processing.

**SAD**

A STREAMS Administrative Driver that provides an interface to the autopush mechanism.

**schedule**

To place a queue on the internal list of queues that will subsequently have their service procedure called by the STREAMS scheduler. STREAMS scheduling is independent of the Solaris operating environment process scheduling.

**service interface**

A set of primitives that define a service at the boundary between a service user and a service provider and the rules (typically represented by a state machine) for allowable sequences of the primitives across the boundary. At a stream/user boundary, the primitives are typically contained in the control part of a message; within a stream, in M_PROTO or M_PCPROTO message blocks.

**service procedure**

A routine module or driver associated with a queue that receives messages queued for it by the put procedure of that queue. The procedure is called by the STREAMS scheduler. It may perform processing on the message and generally passes the message to the put procedure of the following queue.

**service provider**

An entity in a service interface that responds to request primitives from the service user with response and event primitives.

**service user**

An entity in a service interface that generates request primitives for the service provider and consumes response and event primitives.

**slave driver**

A STREAMS-based device supported by the pseudo-terminal subsystem. It is also called pts and works with a line discipline module and hardware emulation module to provide an interface to a user process.
standard pipe  A mechanism for the unidirectional flow of data between two processes where data written by one process becomes data read by the other process.

stream  A kernel aggregate created by connecting STREAMS components, resulting from an application of the STREAMS mechanism. The primary components are the stream head, the driver, and zero or more pushable modules between the stream head and driver.

stream end  A stream component furthest from the user process that contains a driver.

stream head  A stream component closest to the user process. It provides the interface between the stream and the user process.

STREAMS  A kernel mechanism that provides the framework for network services and data communication. It defines interface standards for character input/output within the kernel, and between the kernel and user level. The STREAMS mechanism includes integral functions, utility routines, kernel facilities, and a set of structures.

STREAMS-based pipe  A mechanism used for bidirectional data transfer implemented using STREAMS, and sharing the properties of STREAMS-based devices.

TTY driver  A STREAMS-based device used in a terminal subsystem.

upper stream  A stream that terminates above a multiplexer. The beginning of an upper stream originates at the stream head or another multiplexer driver.

upstream  A direction of data flow going from a driver towards the stream head. Also called read-side and input side.

water mark  A limit value used in flow control. Each queue has a high-water mark and a low-water mark. The high-water mark value indicates the upper limit related to the number of bytes contained on the queue. When the queued character reaches its high-water mark, STREAMS causes another queue that attempts to send a message to this queue to become blocked. When the characters in this queue are reduced to the low-water mark value, the other queue is unblocked by STREAMS.

write queue  A message queue in a module or driver containing messages moving downstream. Associated with the write system call and output from a user process.

write side  A direction of data flow going from the stream head toward a driver. Also called downstream and output side.
