About This Guide

This guide describes how to set up and administer security for the Sun™ Open Network Environment (ONE) Application Server 7 product.

NOTE Not all of the content in this guide is applicable or usable for J2EE applications; some material only applies to HTTP server functionality. For information and instructions on developing secure J2EE applications, refer to the J2EE specifications and the Sun ONE Application Server Developer’s Guide.

This section addresses the following topics:

• Who Should Use This Book
• Using the Documentation
• How This Guide Is Organized
• Documentation Conventions
• Product Support

Who Should Use This Book

This guide is intended for information technology administrators in the corporate enterprise who are familiar with implementing and administering enterprise security mechanisms for servers, including:

• Authentication
• Authorization
Using the Documentation

The Sun ONE Application Server manuals are available as online files in Portable Document Format (PDF) and Hypertext Markup Language (HTML) formats, at:

http://docs.sun.com/

The following table lists tasks and concepts described in the Sun ONE Application Server manuals. The left column lists the tasks and concepts, and the right column lists the corresponding manuals.

Table 1  Sun ONE Application Server Documentation Roadmap

</table>
How This Guide Is Organized

This guide includes the following components:

- “Introducing Sun ONE Application Server Security” on page 17
- “General Security Measures” on page 31
- “Administering Certificates” on page 43
- “Administering SSL/TLS Encryption” on page 61
- “Administering HTTP Server Access Control” on page 81

Documentation Conventions

This section describes the types of conventions used throughout this guide:

- General Conventions
- Conventions Referring to Directories
General Conventions

The following general conventions are used in this guide:

- **File and directory paths** are given in UNIX® format (with forward slashes separating directory names). For Windows versions, the directory paths are the same, except that backslashes are used to separate directories.

- **URLs** are given in the format:
  
  http://server.domain/path/file.html

  In these URLs, server is the server name where applications are run; domain is your Internet domain name; path is the server’s directory structure; and file is an individual filename. Italic items in URLs are placeholders.

- **Font conventions** include:
  
  - The monospace font is used for sample code and code listings, API and language elements (such as function names and class names), file names, pathnames, directory names, and HTML tags.
  
  - *Italic* type is used for code variables.
  
  - *Italic* type is also used for book titles, emphasis, variables and placeholders, and words used in the literal sense.
  
  - **Bold** type is used as either a paragraph lead-in or to indicate words used in the literal sense.

- **Installation root directories** for most platforms are indicated by `install_dir` in this document. Exceptions are noted in “Conventions Referring to Directories” on page 14.

  By default, the location of `install_dir` on most platforms is:

  - Solaris 8 non-package-based Evaluation installations:
    
    `user’s home directory/sun/appserver7`
  
  - Solaris unbundled, non-evaluation installations:
    
    `/opt/SUNWappserver7`
  
  - Windows, all installations:
    
    `C:\Sun\AppServer7`

  For the platforms listed above, `default_config_dir` and `install_config_dir` are identical to `install_dir`. See “Conventions Referring to Directories” on page 14 for exceptions and additional information.
• **Instance root directories** are indicated by `instance_dir` in this document, which is an abbreviation for the following:

```
default_config_dir/domains/domain/instance
```

• **UNIX-specific descriptions** throughout this manual apply to the Linux operating system as well, except where Linux is specifically mentioned.

### Conventions Referring to Directories

By default, when using the Solaris 8 and 9 package-based installation and the Solaris 9 bundled installation, the application server files are spread across several root directories. These directories are described in this section.

• **For Solaris 9 bundled installations**, this guide uses the following document conventions to correspond to the various default installation directories provided:

  o `install_dir` refers to `/usr/appserver/`, which contains the static portion of the installation image. All utilities, executables, and libraries that make up the application server reside in this location.

  o `default_config_dir` refers to `/var/appserver/domains`, which is the default location for any domains that are created.

  o `install_config_dir` refers to `/etc/appserver/config`, which contains installation-wide configuration information such as licenses and the master list of administrative domains configured for this installation.

• **For Solaris 8 and 9 package-based, non-evaluation, unbundled installations**, this guide uses the following document conventions to correspond to the various default installation directories provided:

  o `install_dir` refers to `/opt/SUNWappserver7`, which contains the static portion of the installation image. All utilities, executables, and libraries that make up the application server reside in this location.

  o `default_config_dir` refers to `/var/opt/SUNWappserver7/domains`, which is the default location for any domains that are created.

  o `install_config_dir` refers to `/etc/opt/SUNWappserver7/config`, which contains installation-wide configuration information such as licenses and the master list of administrative domains configured for this installation.
Product Support

If you have problems with your system, contact customer support using one of the following mechanisms:

• The online support web site at:
  http://www.sun.com/supporttraining/

• The telephone dispatch number associated with your maintenance contract

Please have the following information available prior to contacting support. This helps to ensure that our support staff can best assist you in resolving problems:

• Description of the problem, including the situation where the problem occurs and its impact on your operation

• Machine type, operating system version, and product version, including any patches and other software that might be affecting the problem

• Detailed steps on the methods you have used to reproduce the problem

• Any error logs or core dumps
Chapter 1

Introducing Sun ONE Application Server Security

This section discusses fundamental security concepts and provides an overview of security features and functionality as applied in the Sun™ ONE Application Server 7 environment.

**NOTE**
Not all the content in this guide is applicable or usable for J2EE applications; some material only applies to the HTTP server. For information and instructions on developing secure J2EE applications, refer to the J2EE specifications and the Sun ONE Application Server Developer’s Guide.

This section addresses the following topics:

- Application Server Security
- HTTP Server Security Features
- J2EE Application Security Features
- Good Practices
- Files Associated With Server Security
Application Server Security

As the administrator responsible for server security, you are focusing on protecting the Sun ONE Application Server and its data from unauthorized access, damage (both intentional and unintentional), theft, and misrepresentation. This is done by using a combination of good security practices and a set of security tools, which include such mechanisms as digital certificates, encryption, authorization, and auditing.

In the Sun ONE Application Server environment, your general areas of responsibility include:

- Certificate Administration
- SSL/TLS Encryption
- Authentication
- Auditing

Certificate Administration

A certificate consists of digital data that specifies the name of an individual, company, or other entity, and certifies that the public key included in the certificate belongs to that entity. Both clients and servers can have certificates.

Information on how certificates work in the Sun ONE Application Server environment is contained in “Administering Certificates” on page 43.

SSL/TLS Encryption

Encryption is the process of transforming information so it is unintelligible to anyone but the intended recipient; decryption is the process of transforming encrypted information so that it is intelligible again.

A cipher is a cryptographic algorithm (a mathematical function), used for encryption or decryption. The Secure Sockets Layer (SSL) and Transport Layer Security (TLS) protocols supported by the Sun ONE Application Server contain numerous cipher suites. Some ciphers are stronger and more secure than others.

SSL 3.0 and TLS 1.0 encryption protocols are supported. Information on encryption can be found in “Administering SSL/TLS Encryption” on page 61.
Authentication

Authentication is the mechanism by which callers and service providers prove to one another that they are acting on behalf of specific users or systems. When the proof is bidirectional, it is referred to as mutual authentication. For example, the user may enter a user name and password in a web browser, and if those credentials match the permanent profile stored in the active database domain, the user is authenticated. The user is associated with this authenticated security identity for the remainder of the session.

Server authentication refers to the confident identification of a server by a client; that is, identification of the organization assumed to be responsible for the server at a particular network address.

In virtual server authentication, you can have a different certificate database for each virtual server on your system. Each virtual server database can contain multiple certificates. Virtual servers can also have different certificates within each instance.

Auditing

Auditing is the method by which significant events are recorded for subsequent examination, such as errors or security breaches. All authentication events are logged to the Sun ONE Application Server logs. A complete access log provides a sequential trail of Sun ONE Application Server access events.

Information on logging is contained in the Sun ONE Application Server Administrator’s Guide.

HTTP Server Security Features

NOTE The features described as HTTP server features are applicable only to the HTTP server side of the Sun ONE Application Server and not for J2EE applications. In some cases, equivalent functionality is available to J2EE applications as well.

The HTTP server security features include:

- HTTP Server User-Group Authentication
- HTTP Server Host-IP Authentication
HTTP Server Security Features

- HTTP Server SSL Client Authentication
- HTTP Server Access Control
- Netscape API (NSAPI)

HTTP Server User-Group Authentication

User-Group authentication requires that users authenticate themselves before access can be granted. This is done by entering a user name and password, using a client certificate, or using the digest authentication plug-in. Types of User-Group authorization supported by the Sun ONE Application Server include Basic, Default, SSL, Digest, and Custom.

For information on HTTP server User-Group authentication, refer to “HTTP Server User-Group Authentication” on page 83 and “Implementing Host-IP Authentication” on page 91.

For information on user-group authentication for J2EE applications, refer to the Sun ONE Application Server Developer’s Guide.

HTTP Server Host-IP Authentication

Host-IP authentication, also known as Host-IP access control, is a method of limiting access to the Admin Server, or the files and directories on your web site, by making them available only to clients who are using specific computers.

Information on HTTP server Host-IP authentication is contained in “Implementing Host-IP Authentication” on page 91.

HTTP Server SSL Client Authentication

Client authentication refers to authenticating client certificates by cryptographically verifying the certificate signature and the certificate chain leading to the CA on the trust CA list. Clients can have multiple certificates, much like a person might have several different pieces of identification.

Information on HTTP server client authentication is contained in “Setting Up Client Authentication” on page 102.
HTTP Server Access Control

By creating a hierarchy of rules called access control entries (ACEs) you can allow or deny access to individuals, groups, or other entities such as particular servers or applications. Each ACE specifies whether or not the server should check the next ACE in the hierarchy. The collection of ACEs you create is called an access control list (ACL).

There are many options for restricting access to your HTTP server content, among them:

- Restricting Access to the Entire Server
- Restricting Access to a Directory (Path)
- Restricting Access to a URI (Path)
- Restricting Access to a File Type
- Restricting Access Based on Time of Day
- Restricting Access Based on Security

Information on HTTP server access control is contained in “Administering HTTP Server Access Control” on page 81.

Netscape API (NSAPI)

A C language API which provides a number of HTTP-centric utility functions, the NSAPI allows plugins to provide Server Application Function (SAF) functions that participate in request processing and other server activities.

Information can be found in the Sun ONE Application Server Developer’s Guide to NASPI.
J2EE Application Security Features

The J2EE application authentication and authorization requirements are defined by the J2EE specification and are briefly listed here.

NOTE For developing J2EE application security, use the security mechanisms as described in the J2EE specifications and the Sun ONE Application Server Developer’s Guide.

The following J2EE security features are supported in the Sun ONE Application Server environment:

• Declarative Security
• Programmatic Security
• User Authentication
• Realm Administration
• Single Sign-On
• Resource Authentication
• Pluggable Authentication

Declarative Security

In declarative security, authorization is handled by the container. Deployment descriptors are referenced to determine whether the principal associated with the current security context is permitted access to the requested operation.

Web applications may also specify transport guarantee requirements of confidentiality or integrity. This translates to requiring SSL for such resources.

Refer to the Sun ONE Application Server Developer’s Guide for more information.

Programmatic Security

In programmatic security, authorization is handled by the application code directly. This code is written by the developer.

Refer to the Sun ONE Application Server Developer’s Guide for more information.
User Authentication

Three caller authentication paths exist: web client, J2EE application client (running in the application container), and external RMI/IIOP clients that do not use the Sun ONE Application Server container. Form authentication is supported.

Refer to the Sun ONE Application Server Developer’s Guide for more information.

Realm Administration

The Administration interface provides the capability to add/edit/delete supported realms from the server. Realms included in the Sun ONE Application Server are file, ldap, certificate, and solaris.

Refer to the Sun ONE Application Server Developer’s Guide for more information.

Single Sign-On

For single sign-on, a user’s authentication state can be shared across multiple J2EE applications in a single virtual server instance.

Refer to the Sun ONE Application Server Developer’s Guide for more information.

Resource Authentication

The Sun ONE Application Server supports authentication into external resources (which may require separate authentication).

Refer to the Sun ONE Application Server Developer’s Guide for more information.

Pluggable Authentication

Pluggable authentication allows for J2EE applications to use the Java Authentication and Authorization Service (JAAS) feature from the J2SE platform. Developers can plug in their own authentication mechanisms.

Refer to the Sun ONE Application Server Developer’s Guide for more information.
Good Practices

There are many precautions you can take to protect your Sun ONE Application Server resources. Some involve mechanisms (such as authentication or encryption) and many are simply based on security-aware operational practices and common sense.

Some good practices include:

- Limiting physical access to the Sun ONE Application Server
- Setting up firewalls
- Limiting access to administration capabilities
- Managing passwords
- Limiting the presence of other applications on the server
- Configuring for protected and unprotected servers

These topics are discussed in “General Security Measures” on page 31.

Files Associated With Server Security

Many of the Sun ONE Application Server configuration files are used to define security parameters for the server. The main security-related tasks associated with each file are listed briefly in the following sections:

- The init.conf File
- The dbswitch.conf File
- The server.xml File
- The password.conf File
- The certmap.conf File
- ACL Files
- The htaccess Files
- Keyfile
- The server.policy File
Details on the contents of the Sun ONE Application Server configuration files are contained in the *Sun ONE Application Server Administrator’s Configuration File Reference*.

**The init.conf File**

The *init.conf* file contains low-level server configuration information, such as the path the server is installed to, performance tuning options, location of plugin shared objects, and so on. This is the startup file. When the Sun ONE Application Server starts up, it looks in this file to establish a set of global variable settings that affect the server instance’s behavior and configuration. Security-related tasks include:

- To use the *chroot* command to secure an unprotected server, all paths in *init.conf* must be absolute; paths in *obj.conf* must be relative to the *chroot* directory. Refer to “Securing Against an Unprotected Server” on page 41 for guidelines.

- Installing an SSL-enabled server creates SSL directive entries in the *init.conf* file for global security parameters. Refer to “Configuring Security Globally” on page 69 for instructions.

- You can control the ACL user cache by setting directives in the *init.conf* file. Refer to “Configuring the ACL User Cache” on page 115 for further information.

- To manually enable your server to use the *htaccess* file, you need to first modify the server’s *init.conf* file to load, initialize, and activate the plug-in. Refer to “Enabling *htaccess* from *init.conf*” on page 135 for instructions.

**The dbswitch.conf File**

*NOTE*

This section only applies to HTTP server content.

The *dbswitch.conf* file specifies the LDAP directory used by the Sun ONE Application Server. It is only read at server startup.

You can globally define user authentication databases in the *dbswitch.conf* file. Refer to “Accessing Databases from Virtual Servers” on page 130 for further information.
The server.xml File

The server.xml file is the main configuration file for the Sun ONE Application Server. Security-related tasks include:

- Handles configuration of HTTP listeners (including SSL ciphers, certificates, and so on), virtual servers, access control lists, and so on. Handles the relationships between these entities.
- Contains a list of security domains with configuration data for the provider class and realm-specific properties. Refer to the Sun ONE Application Server Developer’s Guide for more information on security domains (realms).
- SSL properties for virtual servers can be found on a per-server basis in the ssl element of the server.xml file. Refer to “Configuring Security Globally” on page 69 for more information.
- By manually editing the server.xml file, you can tell the Sun ONE Application Server to start with an external server certificate. Refer to “Starting the Server with an External Certificate” on page 73 for more information.

Further information on the server.xml file can be found in the Sun ONE Application Server Administrator’s Configuration File Reference.

The obj.conf File

NOTE This section only applies to HTTP server content.

The obj.conf file contains directives that instruct the Sun ONE Application Server on how to handle requests from clients. Security-related tasks include:

- HTTP server authentication uses the default method you specify in the obj.conf file, or Basic if there is no setting in the obj.conf file. For more information, refer to “HTTP Server User-Group Authentication” on page 83.
- If you have named ACLs or created separate ACL files, you can reference them in the obj.conf file. For further information on doing this, refer to “Referencing ACL Files in the obj.conf File” on page 115.
- Handles configuration of the NSAPI request processing path (each virtual server may have its own obj.conf file). Further information is contained in the Sun ONE Application Server Developer’s Guide to NSAPI.
The password.conf File

If you want an SSL/TLS-enabled Sun ONE Application Server to be able to restart unattended when configured for SSL, you can save the trust database password in a password.conf file.

**NOTE** Be sure that your system is adequately protected so that this file and the key databases are not compromised. Such protection is discussed in “Limiting Physical Access” on page 32.

Further information on the password.conf file can be found in “Using the password.conf File” on page 39 and the Sun ONE Application Server Administrator’s Configuration File Reference.

The certmap.conf File

**NOTE** This section only applies to HTTP server content.

The certmap.conf file specifies how a certificate, designated by name, is mapped to an LDAP entry, designated by issuerDN. The certmap.conf file provides the following information:

- Where in the LDAP tree the server should begin its search
- What certificate attributes the Sun ONE Application Server should use as search criteria when searching for the entry in the LDAP directory
- Whether or not the server goes through an additional verification process

Refer to “Working with the certmap.conf File” on page 106 for further information.

ACL Files

Access control list (ACL) files are text files that contain lists identifying who can access the resources stored on your Sun ONE Application Server.
By default, the Sun ONE Application Server uses a single ACL file that contains all the lists for accessing your server. As an alternative to this default, you can create multiple ACL files and reference them in the `obj.conf` file.

Information on working with ACL files is contained “Administering HTTP Server Access Control” on page 81. Additional information can be found in the Sun ONE Application Server Developer’s Guide to NASPI.

The htaccess Files

This section only applies to HTTP server content.

The `htaccess` files are dynamic configuration files that store a subset of configuration options. You can use `htaccess` files in combination with the Sun ONE Application Server standard access controls (standard access controls are always applied before any `htaccess` access controls).

Information on working with `htaccess` files is contained in “Using `htaccess` Files” on page 133.

Keyfile

The keyfile contains the list of users for the file realm (applicable only for J2EE applications). Every server instance has a default keyfile which is empty. Users can be added through the Administration interface or the command-line interface.

By default, the file realm is always set to use this file, with the name `keyfile`. However, the name and location of this file can be changed by editing the file realm properties in the `server.xml` file.

NOTE The access control methods described in this document should not be used for J2EE application development. Using these methods, especially ACLs, could cause your applications to work unpredictably and be inconsistent with the J2EE model. For application development, use the J2EE security mechanisms as described in the J2EE specifications and the Sun ONE Application Server Developer’s Guide.
Refer to the *Sun ONE Application Server Developer’s Guide* for more information.

### The server.policy File

The `server.policy` file contains the J2SE policy configuration which will be in effect for all the Java code running in an instance.

Refer to the *Sun ONE Application Server Developer’s Guide* for more information.
In addition to using security mechanisms such as authentication, encryption, and ACL files, as well as taking advantage of the J2EE authentication and authorization mechanisms, there are a number of manual steps you can take to make your Sun ONE Application Server more secure.

This section contains the following topics:

- About General Security
- Limiting Physical Access
- Using Firewalls
- Limiting Administration Access
- Managing Passwords
- Limiting Other Applications on the Server
- Securing Against an Unprotected Server

**About General Security**

Networks face risks from external and internal attackers, who use a variety of tactics to gain access to your server and the information on it. The Sun ONE Application Server offers secure connections between the server and the client. However, it can’t control the security of information once the client has the information, nor can it control access to the server machine itself and its directories and files.
Being aware of these limitations helps you understand what situations to avoid. For example, you might acquire credit card numbers over an SSL connection, but are those numbers stored in a secure file on the server machine? What happens to those numbers after the SSL connection is terminated? You are responsible for securing any information clients send to you through SSL.

Limiting Physical Access

The simple security measure of physically protecting your server from access is often overlooked. Keep the server machine in a locked room that only authorized people can enter. This prevents anyone from attacking the server machine itself.

- Root password—It is crucial to protect your machine’s administrative (root) password. As with all passwords, but particularly the root password, be sure to select passwords that are difficult to guess.

- Application server configuration—Some of the Sun ONE Application Server configuration files (such as server.xml, various J2EE application descriptor XML files, password.conf) may contain cleartext passwords for a number of external resources (such as JDBC database passwords and SSL databases) that the application server needs to authenticate to during its operation. All such configuration files must be carefully protected.

  By default all the configuration files in the /config directory as well as the /application directory are only readable by the instance owner. To protect the password data, it is important to maintain these directories with these default restricted-access permissions.

- Backup tapes—You must protect your backup tapes as vigilantly as you protect data on the server.

  **NOTE** Because some of configuration files may contain cleartext passwords, when the Sun ONE Application Server file systems are backed up these passwords will, if present, be contained in these backups, and can be retrieved and potentially abused by anyone who has access to the backup media.

- Ports—Disable any ports not used on the machine. Use routers or firewall configurations to prevent incoming connections to anything other than the absolute minimum set of ports. This means that the only way to get a shell is to physically use the server’s machine, which should already be in a restricted area.
Security hardening of the operating system—This is recommended and should be considered a requirement on any production system that is accessible through the Internet.

Operating system hardening is very platform-specific and cannot be covered in any detail in this documentation. Please consult your platform vendor. See, for example, the JASS Toolkit for Solaris

http://wwws.sun.com/software/security/jass/

The Sun ONE Application Server assumes that those who have access to the physical server will not abuse the server channel. It is very important that you take whatever precautions you can to restrict server access only to authorized, well intentioned users.

Using Firewalls

This section examines some common firewall configurations and the parameters to be configured for correct functioning. This is general information that pertains to the Sun ONE Application Server. For details, refer to the documentation from your particular firewall vendor.

The following topics are addressed in this section:

• Single Firewall
• Double Firewall - DMZ Configuration
• Triple Firewall - DMZ With Database Protection

Single Firewall

The simplest and most common firewall configuration places a single firewall between the Sun ONE Application Server server and the Internet browser. The firewall needs to be configured to allow HTTP connections to the HTTP port (default 80) and/or the HTTPS port (default 443) as appropriate for web container access.

NOTE

If direct RMI/IIOP access to EJBs is allowed from the Internet, the IIOP/RMI listener port (default 3700) must be opened as well. However, this practice is strongly discouraged as it creates potential security risks.
The advantage of the single firewall configuration is simplicity. The biggest disadvantage is that there is a single line of defense. If the firewall is breached, the only defense is the security of each of the individual machines within the private network.

The following table summarizes the protocols and ports which need to be configured to the firewall to permit correct functioning. The left column indicates the protocol used, the center column indicates the port, and the right column indicates the type of communication.

<table>
<thead>
<tr>
<th>Protocol</th>
<th>Wall</th>
<th>Port</th>
<th>Reason</th>
</tr>
</thead>
<tbody>
<tr>
<td>TCP/IP</td>
<td>Outer</td>
<td>80 (default)</td>
<td>HTTP requests</td>
</tr>
<tr>
<td>TCP/IP</td>
<td>Outer</td>
<td>443</td>
<td>HTTPS requests</td>
</tr>
</tbody>
</table>

For information on these ports, refer to the Sun ONE Application Server Administrator’s Guide and the Administration interface online help.

Double Firewall - DMZ Configuration

The double firewall, also known as the demilitarized zone (DMZ) configuration, is becoming more common as many organizations allow limited access to their private networks to partners and customers. The double layer of protection combined with active monitoring of activity at each firewall and within the DMZ will detect most attempts to penetrate the internal network. The security provided is much better than the single firewall configuration.

The double firewall configuration provides:

- An outer firewall between the Internet browser and a routing web server/application server located in the DMZ
- An inner firewall between the routing server in the DMZ and the protected Sun ONE Application Server
- A proxy plugin that forwards requests to the Sun ONE Application Server behind the second firewall
In the double firewall configuration, the outer firewall must be configured to allow for HTTP and HTTPS transactions. The inner firewall must be configured to allow the HTTP server plug in to communicate with the Sun ONE Application Server server(s) behind the firewall.

The following table summarizes the protocols and ports which need to be configured to the firewall to permit correct functioning. The left column indicates the protocol used, the second column indicates which firewall the protocol/port applies to, the third column indicates the port, and the right column indicates the type of communication.

<table>
<thead>
<tr>
<th>Protocol</th>
<th>Wall</th>
<th>Default Port</th>
<th>Reason</th>
</tr>
</thead>
<tbody>
<tr>
<td>TCP/IP</td>
<td>Outer</td>
<td>80</td>
<td>HTTP requests to routing server</td>
</tr>
<tr>
<td>TCP/IP</td>
<td>Outer</td>
<td>443</td>
<td>HTTPS requests to routing server</td>
</tr>
<tr>
<td>TCP/IP</td>
<td>Inner</td>
<td>80</td>
<td>HTTP requests to Sun ONE Application Server</td>
</tr>
<tr>
<td>TCP/IP</td>
<td>Inner</td>
<td>443</td>
<td>HTTPS requests to Sun ONE Application Server</td>
</tr>
</tbody>
</table>

For information on these ports, refer to the Sun ONE Application Server Administrator’s Guide and the Administration interface online help.

**Triple Firewall - DMZ With Database Protection**

In some corporate settings, databases reside on their own networks, protected by firewalls. The triple firewall configuration provides maximum security for what may be the most important corporate asset: the data contained within the corporate database. The firewall between the LAN and the database systems provides protection against internal as well as external threats.

The connections to the database use standard access mechanisms such as Open DataBase Connectivity (ODBC), Java DataBase Connectivity (JDBC), and database vendor-supplied connector libraries. The connections to the database are not different from any other application, so the firewall configuration for the database protection layer will conform to the standard settings required for access to the specific database in use.
Limiting Administration Access

If you use remote configuration, be sure to set access control to allow administration access by only a few users and computers.

You should always turn on encryption for the master Admin Server. If you don’t use an SSL connection for administration, you must be very cautious when performing remote server administration over the unsecure network. Anyone can intercept your administrative password and reconfigure your servers.

If you want your Admin Server to provide end-user access to the LDAP server or local directory information, consider maintaining two Admin Servers and using cluster management, so that the SSL-enabled Admin Server acts as the master server, and the other Admin Server is available for end-user access. Refer to “Enabling SSL Communication with LDAP” on page 64 for further information.

Instructions for implementing cluster management can be found in the Sun clustering documentation collection.

Managing Passwords

There are a number of passwords with your server: the administrative password, the private key password, database passwords, and so on. Your administrative password is the most important password of all, since anyone with that password can configure any and all servers on your computer. Your private key password is next most important. If someone gets your private key and your private key password, they can create a fake server that appears to be yours, or intercept and change communications to and from your server.

A good password is one you’ll remember but others won’t guess. For example, you might remember MCi12mo as “My Child is 12 months old!” A bad password is your child’s name or birth date.

The following topics address additional information on passwords:

- Creating Hard-to-Crack Passwords
- Managing the Superuser Password
- Changing Passwords or PINs
- Using the password.conf File
Creating Hard-to-Crack Passwords

There are some simple guidelines that will help you create a stronger password.

It is not necessary to incorporate all the following guidelines in one password, but the more of these guidelines you use, the harder your password will be to crack:

- Passwords should be 6-14 characters long (observing whatever length limitation your system has).
- Do not use the illegal characters: *, " , or spaces
- Do not use dictionary words (any language)
- Do not make common letter substitutions, like replacing E with 3, or L with 1
- Do include characters from as many of these classes as possible:
  - Uppercase letters
  - Lowercase letters
  - Numbers
  - Symbols

Managing the Superuser Password

You can configure superuser access for your Admin Server. In this case, the superuser is the person who has access to change any or all parts of the server configuration (not to be confused with the system’s superuser/root). These settings affect only the superuser account. That is, if your Admin Server uses distributed administration, you need to set up additional access controls for the administrators you enable.

The superuser’s user name and password are kept in a file called `install_dir/domains/domain_dir/admin-server/config/admpw`. If you forget the user name, you can view this file to obtain the actual name; however, the password is encrypted and unreadable. The file has the format `username:password`.

If you forget the password, you can edit the `admpw` file and simply delete the encrypted password.
Managing Passwords

CAUTION  Because you can edit the admpw file, it is very important that you keep the server machine in a secure place and restrict access to its file system:

- On UNIX/Linux systems, consider changing the file ownership so that it is writable only by root or whatever system user runs the Admin Server daemon. By default, the /config directory is readable only by the instance owner which protects the directory and other sensitive files. Be sure these permissions are not altered.

- On Windows systems, restrict the file ownership to the user account the Admin Server uses.

To set up superuser access for the Admin Server, perform the following steps in the Administration interface:

1. Access Admin Server and select Security. The following screen is displayed:

**Figure 2-1**  Superuser Access Control Page
2. Select Access Control.
   The Superuser Access Control page is displayed.
3. Enter the host names that are allowed superuser access to the Admin Server.
4. Enter the IP addresses that are allowed superuser access to the Admin Server.
5. Enter the authentication user name.
6. Enter the authentication password.
   For a list of guidelines to consider when changing a password, see “Creating Hard-to-Crack Passwords” on page 37.
7. Re-enter the authentication password.
8. Click OK.
9. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
10. Stop and start the server for changes to take effect.

Changing Passwords or PINs

It's good practice to change your trust database/key pair file password or PIN periodically. If your Admin Server is SSL-enabled, this password is required when starting the server. You should only change this password on your local machine. Refer to “Changing a Trust Database Password” on page 46 for instructions.

It is important to make sure your key-pair file is protected. The Admin Server stores key-pair files in the /config directory of the instance. By default, the /config directory files are set to be readable only by the instance owner. It is important to monitor these permissions to ensure that the file permissions aren’t inadvertently changed later by backup scripts or other events.

It's also important to know if the file is stored on backup tapes or is otherwise available for someone to intercept. If so, you must protect your backup tapes as carefully as you protect your server data.

Using the password.conf File

By default, the Sun ONE Application Server prompts you for the SSL key database password at startup. If you want to be able to restart an unattended Sun ONE Application Server, you must save the password in a password.conf file.
Managing Passwords

• For UNIX—Normally, you cannot start a UNIX SSL-enabled server with the 
  /etc/rc.local or the /etc/inittab files because the server requires a 
  password before starting. Although you can start an SSL-enabled server 
  automatically if you keep the password in plain text in a file, this is not 
  recommended. The server's password.conf file should be owned by root or 
  the user who installed the server, with only the owner having read and write 
  access.

  **NOTE** Only use the password.conf file if your system is adequately 
  protected so that this file and the key databases cannot be 
  compromised.

• For Windows—If you have a New Technology File System (NTFS) file system, 
  you should protect the directory that contains the password.conf file by 
  restricting its access, even if you do not use the file. The directory should have 
  read/write permissions for the Admin Server user and the Sun ONE 
  Application Server user. Protecting the directory prevents others from creating 
  a false password.conf file.

  **NOTE** Leaving the SSL-enabled server's password in the password.conf 
  file is a large security risk. Anyone who can access the file has access 
  to the SSL-enabled server's password. Consider the security risks 
  before keeping the SSL-enabled server's password in the 
  password.conf file.

• For Windows—If you have a New Technology File System (NTFS) file system, 
  you should protect the directory that contains the password.conf file by 
  restricting its access, even if you do not use the file. The directory should have 
  read/write permissions for the Admin Server user and the Sun ONE 
  Application Server user. Protecting the directory prevents others from creating 
  a false password.conf file.

  **NOTE** On Windows, you cannot protect directories or files on File 
  Allocation Table (FAT) file systems by restricting access to them.

If security risks are not a concern for you, follow these steps to start your 
SSL-enabled server automatically:

1. Make sure SSL is on.

2. Create a new password.conf file in the config subdirectory of the server 
   instance.
   
   o If you are using the internal PKCS11 software encryption module that 
     comes with the server, enter the following information:

     ```
     internal:your_password
     ```
If you are using a different PKCS11 module (for hardware encryption or hardware accelerators), specify the name of the PKCS11 module, followed with the password. For example:

```
nFast:your_password
```

3. Stop and start your server for the new setting to take effect.

Limiting Other Applications on the Server

It is possible to circumvent Sun ONE Application Server security by exploiting weaknesses in other programs running on your server. An obvious prevention step is to disable any unnecessary programs and services running on your server.

- UNIX—Carefully choose the processes that are started from the `inittab` script and the `rc` script.
  - Don’t run `telnet` or `rlogin` from the server machine.
  - Don’t have `rdist` on the server machine. While the purpose of `rdist` is to distribute files, it can also be used by an attacker to update files on the server machine illegally.
- Windows—Be selective about which drives and directories you share with other machines. Also, carefully choose which users have accounts or Guest privileges.

Be careful about what programs you or other people install on your server. Other people’s programs might have security holes that they may or may not be aware of. Worst of all, someone might install a malicious program designed specifically to subvert your security. Always examine programs carefully before you allow them on your server.

Securing Against an Unprotected Server

If you want to have both protected and unprotected servers, you should operate the unprotected server on a different machine from the protected one.

If your resources are limited and you must run an unprotected server on the same machine as your protected server, do the following:
Securing Against an Unprotected Server

- Different port numbers—Make sure that the protected server and the unprotected server are assigned different port numbers. The registered default port numbers are:
  - 443 for the protected server
  - 80 for the unprotected server

- For UNIX—Redirect the document root directory using the `chroot` tool.

  The UNIX `chroot` command allows you to create a second root directory to limit the server to specific directories. Refer to the man page for guidelines on using this command.

In the Administration interface, you can specify the `chroot` directory for a specific virtual server by performing the following steps:

1. Access App Server Instances and select the server instance from the left pane.
2. Select HTTP Server and Virtual Servers.
3. Select the virtual server you want to specify the `chroot` directory for.
   The page for the General tab is displayed.
4. Scroll down the page until you find the Chroot field.
5. Enter the full pathname in the Chroot directory.
6. Click Save.
7. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
8. Stop and start the server for changes to take effect.
This section describes how to set up and administer the trust database, certificates, and certificate-related lists for your Sun ONE Application Server 7 environment.

This section addresses the following topics:

- About Certificates and Authentication
- Implementing the Trust Database
- Implementing a Certificate
- Using the Built-in Root Certificate Module
- Managing Certificates
- Managing CRLs and CKLs

About Certificates and Authentication

*Authentication* is the process of confirming an identity. In the context of network interactions, authentication is the confident identification of one party by another party. Certificates are one way of supporting authentication.

A *certificate* consists of digital data that specifies the name of an individual, company, or other entity, and certifies that the public key, included in the certificate, belongs to that entity. Both clients and servers can have certificates.

A certificate is issued and digitally signed by a *Certificate Authority (CA)*. The CA can be a company that sells certificates over the Internet, or it can be a department responsible for issuing certificates for your company’s intranet or extranet. You decide which CAs you trust enough to serve as verifiers of other people’s identities.
In addition to a public key and the name of the entity identified by the certificate, a certificate also includes an expiration date, the name of the CA that issued the certificate, and the digital signature of the issuing CA. For more information regarding the content and format of a certificate, see *Introduction to SSL* at the following location:

http://docs.sun.com/db/prod/3802#hic

The task sequence for setting up basic security is:

1. Create the trust database.

   Refer to “Creating a Trust Database” on page 45.

2. Request a certificate.

   Refer to “Requesting a Certificate” on page 48.

3. Install the certificate.

   Refer to “Installing a Certificate” on page 51.

4. Activate encryption.

   Refer to “Administering SSL/TLS Encryption” on page 61.

Other administrative tasks associated with certificates are discussed in “Managing Certificates” on page 55 and “Managing CRLs and CKLs” on page 57.

### Implementing the Trust Database

In the Sun ONE Application Server, the Admin Server and each server instance has its own certificate and key-pair file, referred to as a *trust database*.

**NOTE** Before requesting a server certificate, you must create a trust database for identifying your trusted entities.

In the trust database you create and store the public and private keys, referred to as your *key-pair file*. The key-pair file is used for SSL encryption. You will use the key-pair file when you request and install your server certificate, which is stored in the trust database after installation. The key-pair file is stored encrypted in the `/config` directory of the instance.
The Admin Server has only one trust database, while each server instance can have its own trust database. The certificate and key-pair database files are named after the server instance that uses them. Virtual servers are covered by the trust database created for their server instance.

As the administrator, you manage the trust database and its constituent certificates, including the server certificate and all the included CAs.

This section addresses the following:

- Creating a Trust Database
- Changing a Trust Database Password

**Creating a Trust Database**

When you create the trust database, you specify a password that will be used for a key-pair file. You will also need this password to start a server using encrypted communications.

To create a trust database on your local machine, perform the following steps in the Administration interface:

1. Access App Server Instances and select the server instance.
3. Click Manage Database.
4. Click the Create Database link.
   
   The Initialize Trust Database page is displayed.
Implementing the Trust Database

Figure 3-1  Creating a Trust Database Page

5. Enter a password for the database.
6. Repeat the password.
7. Click OK.
8. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
9. Stop and restart the server for changes to take effect.

Changing a Trust Database Password

To change an existing trust database password, perform the following steps in the Administration interface:

1. Access App Server Instances and select the server instance.
3. Click Manage Database.
4. Click the Change Password link.
   The Change the Key Pair File Password page is displayed.
5. Select the cryptographic module from the dropdown list.
6. Enter the old password.
7. Enter the new password.
8. Repeat the new password.
9. Click OK.
10. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
11. Stop and restart the server for changes to take effect.

Implementing a Certificate

After creating a trust database for your server, you can request a certificate and submit it to a CA. If your company has its own internal CA, request your certificate from them. If you plan to purchase your certificate from a commercial CA, choose a CA and ask about the specific format of the information they require.

The Admin Server can have only one server certificate, while a server instance can have its own server certificate. You can select a server instance certificate for each virtual server.

The following topics address implementing certificates:

• **Required CA Information**
• **Requesting a Certificate**
• **Installing a Certificate**

Required CA Information

Before you begin the request process, make sure you know what information your CA requires. Whether you are requesting a server certificate from a commercial CA or an internal CA, you need to provide the following information:

• **Common Name**—The fully qualified hostname used in DNS lookups (for example, www.sun.com). This is the hostname in the URL that a browser uses to connect to your site. If these two names don’t match, a client is notified that the certificate name doesn’t match the site name, creating doubt about the authenticity of your certificate. Some CAs might have different requirements, so it’s important to check with them.
You can also enter wildcard and regular expressions in this field if you are requesting a certificate from an internal CA. However, most vendors will not approve a certificate request with a wildcard or regular expression entered for the common name.

- **email Address**—Your business email address. This is used for correspondence between you and the CA.
- **Organization**—The official, legal name of your company, educational institution, partnership, and so on. Most CAs require that you verify this information with legal documents (such as a copy of your business license).
- **Organizational Unit**—An optional field that describes an organization within your company. This can also be used to specify a less formal company name (without the Inc., Corp., and so on).
- **Locality**—An optional field that usually describes the city, principality, or country for the organization.
- **State or Province**—Usually a required field, but can be optional for some CAs. Most CAs won’t accept abbreviations, but check with them to be sure.
- **Country**—A required field that contains the two-character abbreviation of your country name, in ISO format. The country code for the United States is US.

All this information is combined as a series of attribute-value pairs called the distinguished name (DN), which uniquely identifies the subject of the certificate.

If you are purchasing your certificate from a commercial CA, you must contact the CA to find out what additional information is required before they will issue a certificate. Most CAs require that you prove your identity. For example, they want to verify your company name and who is authorized by the company to administer the server. They might also ask whether you have the legal right to use the information you provide.

Some commercial CAs offer certificates with greater detail and veracity to organizations or individuals who provide more thorough identification. For example, you might be able to purchase a certificate stating that the CA has not only verified that you are the rightful administrator of the `www.your_company.com` computer, but that you are a company that has been in business for three years, and has no outstanding customer litigation.

### Requesting a Certificate

After you have created your trust database, you are ready to request a certificate.
To request a certificate from a CA, perform the following steps in the Administration interface:

1. Access App Server Instances and select the server instance in the left pane.
4. Click the Request link.

The Request a Server Certificate page is displayed.

5. Select if this is a new certificate or a certificate renewal.

Many certificates expire after a set period of time, such as six months or a year. Some CAs will automatically send you a renewal.
6. Perform the following steps to specify how you want to submit the request for the certificate:
   - If the CA expects to receive the request in an email message, check CA Email and enter the email address of the CA. For a list of CAs, click List of available certificate authorities.
   - If you are requesting the certificate from an internal CA that is using the Sun ONE Certificate Server, click CA URL and enter the URL for the Certificate Server. This URL should point to the certificate server’s program that handles certificate requests.

7. Select the cryptographic module for the key-pair file you want to use when requesting the certificate from the drop-down list.

8. Enter the password for your key-pair file.
   - This is the password you specified when you created the trust database, unless you selected a cryptographic module other than the internal module. The server uses the password to get your private key and encrypt a message to the CA. The server then sends both your public key and the encrypted message to the CA. The CA uses the public key to decrypt your message.

9. Enter your identification information.

Figure 3-3  Request a Server Certificate Identification Information

The format of this information varies by CA.

10. Verify your work to ensure accuracy.
   - The more accurate the information, the faster your certificate is likely to be approved. If your request is going to a certificate server, you’ll be prompted to verify the form information before the request is submitted.
11. Click OK.

12. Access App Server Instances and your server instance in the left pane, then click Apply Changes.

13. Stop and restart the server for changes to take effect.

The server generates a certificate request that contains your information. The request has a digital signature created with your private key. The CA uses a digital signature to verify that the request wasn’t tampered with during routing from your server machine to the CA. In the rare event that the request is tampered with, the CA will usually contact you by phone.

If you choose to email the request, the server composes an email message containing the request and sends the message to the CA. Typically, the certificate is then returned to you using email. If instead you specified a URL to a certificate server, your server uses the URL to submit the request to the certificate server. You might get a response using email or other means, depending on the CA.

The CA will notify you if it agrees to issue you a certificate. In most cases, the CA will send your certificate using email. If your organization is using a certificate server, you may be able to search for the certificate by using the certificate server’s forms.

| NOTE | Not everyone who requests a certificate from a commercial CA is given one. Many CAs require you to prove your identity before issuing you a certificate. Also, it can take anywhere from one day to two months to get approval. You are responsible for promptly providing all the necessary information to the CA. |

Once you receive the certificate, you can install it. In the meantime, you can still use your server without encryption.

**Installing a Certificate**

When you receive your certificate back from the CA, it will be encrypted with your public key so that only you can decrypt it. After you enter the correct password for your trust database, you will be able to decrypt and install your certificate.

There are three types of certificates:

- Your own server’s certificate to present to clients
- A CA’s own certificate for use in a certificate chain
A certificate chain is a hierarchical series of certificates signed by successive certificate authorities. A CA certificate identifies a CA and is used to sign certificates issued by that authority. A CA certificate can in turn be signed by the CA certificate of a parent CA, and so on, up to a root CA.

- A trusted CA’s certificate

**NOTE**  
If your CA doesn’t automatically send you their certificate, you should request it. Many CAs include their certificate in the email with your certificate, and your server installs both certificates at the same time.

The server will use the key-pair file password you specify to decrypt the certificate when you install it. You can either save the email somewhere accessible to the server, or copy the text of the email and be ready to paste the text into the Install Certificate form, as described here.

To install a certificate from a CA, perform the following steps in the Administration interface:

1. Access App Server Instances and select the server instance in the left pane.
4. Click the Install link.

The Install a Server Certificate is displayed.
5. Select the type of certificate you are installing:
   - This Server—for a single certificate associated only with your server
   - Server Certificate Chain—for a CA’s certificate to include in a certificate chain
   - Trusted Certificate Authority (CA)—for a certificate of a CA that you want to accept as a trusted CA for client authentication

6. Select the cryptographic module from the drop-down list.

7. Enter the password for your key-pair file.

8. Leave the name for the certificate field blank if it will be the only one used for this server instance, unless:
   - Multiple certificates will be used for virtual servers. In this case, enter a certificate name unique within the server instance.
Cryptographic modules other than internal are used. In this case, enter a certificate name unique across all server instances within a single cryptographic module.

If a name is entered, it will be displayed in the Manage Certificates list, and should be descriptive. For example, “United States Postal Service CA” is the name of a CA, while “VeriSign Class 2 Primary CA” describes both a CA and the type of certificate.

**NOTE** When no certificate name is entered, the default value is applied.

**Figure 3-5** Certificate Installation Message Information

9. Select one:
   - Message is in this file. In this case, enter the full pathname to the saved email
   - Message text (with headers). In this case, paste the email text.
     If you copy and paste the text, be sure to include the headers “Begin Certificate” and “End Certificate,” including the beginning and ending hyphens.

10. Click OK.

11. Select one:
   - Add Certificate—to install a new certificate.
   - Replace Certificate—to install a certificate renewal.
12. Access App Server Instances and your server instance in the left pane, then click Apply Changes.

13. Stop and restart the server for changes to take effect.

The certificate is stored in the server’s certificate database. The file name will be cert7.db.

Using the Built-in Root Certificate Module

The dynamically loadable root certificate module included with the Sun ONE Application Server contains the root certificates for many CAs. The root certificate module simplifies upgrading your root certificates. To install well-known CA certificates, you can update the root certificate module file to a newer version as it becomes available through future versions of the Sun ONE Application Server, or in service packs.

Because the root certificate is implemented as a PKCS11 cryptographic module, you can never delete the root certificates it contains; the option to delete will not be offered when managing these certificates. To remove the root certificates from your server instances, you can disable the root certificate module by deleting the following in the server’s alias file:

- libnssckbi.so (on most UNIX platforms)
- nssckbi.dll (on Windows), located under install_directory/bin/

**NOTE**
You can modify the trust information of the root certificates. The trust information is written to the certificate database for the server instance being edited, not back to the root certificate module itself.

Managing Certificates

You can view or delete the trust settings of the various certificates installed on your server. This includes your own certificate and certificates from CAs. Certificate information includes the owner and who issued it.

Trust settings allow you to set client trust or unset server trust. For LDAP server certificates, the server must be trusted.

To manage certificates, perform the following steps in the Administration interface:
1. Access App Server Instances and select the server instance.

4. Click the Manage link.
   - If you are managing a certificate for a default configuration using the internal cryptographic module, a list of all installed certificates with their type and expiration date is displayed. All certificates are stored in the `instance_dir/config` directory.
   - If you are using an external cryptographic module, such as a hardware accelerator, you will first need to enter your password for each specific module and click OK. The certificate list will be updated to include certificates in the module.

5. Click the Certificate Name you want to manage.
   An Edit Server Certificate page is displayed with management options for that type of certificate.

6. In the Edit Server Certificate window you may select:
   - For certificates obtained internally—Delete Certificate or Quit
   - For CA certificates—Set client trust, Unset server trust, or Quit

 **NOTE** Only CA certificates will allow you to set or unset client trust. Some external cryptographic modules will not allow certificates to be deleted.

   You are prompted to confirm your edits.

7. Select OK or Cancel.

8. Access App Server Instances and your server instance in the left pane, then click Apply Changes.

9. Stop and start the server for changes to take effect.
Managing CRLs and CKLs

A certificate revocation list (CRL) and compromised key list (CKL) publishes any certificates and keys that either client users or server users should no longer trust. Typical situations include:

- If data in a certificate changes, for example, a user changes offices or leaves the organization before the certificate expires, the certificate is revoked, and its data appears in a CRL.
- If a key is tampered with or otherwise compromised, the key and its data appear in a CKL.

Both CRLs and CKLs are produced and periodically updated by a CA. As the administrator, you can install new CRLs or CKLs that you obtain from the CA, or delete existing CRLs or CKLs from your system.

The following topics address managing CRLs and CKLs:

- Installing a CRL or CKL
- Deleting a CRL or CKL

Installing a CRL or CKL

To obtain a CRL or CKL from a CA, perform the following steps in the Administration interface:

1. Obtain the CA’s URL for downloading CRLs or CKLs.
2. Enter the URL in your browser to access the site.
3. Follow the CA’s instructions for downloading the CRL or CKL to a local directory.
4. In the Admin interface, access App Server Instances and select the server instance.
6. Select CRL/CKL.
7. Click the Install link.

The Install a Certificate Revocation List/Compromised Key List page is displayed.
Figure 3-6  Install a Certificate Revocation List/Compromised Key List Page

8. Select one:
   - Certificate Revocation List
   - Compromised Key List

9. Enter the full pathname to the associated file.

10. Click OK.
    - If you selected Certificate Revocation List, the Add Certificate Revocation List page appears listing CRL information.
    - If you selected Compromised Key List, the Add Compromised Key List page appears listing CKL information.

   **NOTE**  If a CRL or CKL list already exists in the database, a Replace Certificate Revocation List or Replace Compromised Key List page appears. In this case, click Replace.

11. Click Add.

12. Click OK.

13. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
14. Stop and start the server for changes to take effect.

**Deleting a CRL or CKL**

To delete a CRL or CKL, perform the following steps in the Administration interface:

1. Access App Server Instances and select the server instance.
3. Select CRL/CKL.
4. Click the Manage link.
   - The Manage a Certificate Revocation List/Compromised Key List page is displayed with all installed Server CRLs and CKLs listed along with their expiration dates.
5. Select a Certificate Name from either the Server CRLs or Server CKLs list.
6. Select one:
   - Delete CRL
   - Delete CKL
7. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
8. Stop and start the server for changes to take effect.
Managing CRLs and CKLs
Before beginning any of the tasks described in this section, you should already have a certificate and be familiar with the basic concepts of public-key cryptography, including encryption and decryption, public and private keys, digital certificates, and encryption protocols.

This section addresses the following topics:

- **About Encryption**
- Enabling SSL Communication with LDAP
- Turning Security On
- Enabling SSL and TLS
- Configuring Security Globally
- Using External Encryption Modules
- Setting Strong Ciphers
- Preventing Clients from Caching SSL Files

For more information on encryption and related topics, see *Introduction to SSL* in the Sun ONE Directory Server document collection.

### About Encryption

*Encryption* is the process of transforming information so it is unintelligible to anyone but the intended recipient; *decryption* is the process of transforming encrypted information so that it is intelligible again. The Sun ONE Application Server 7 supports the Secure Sockets Layer (SSL) and Transport Layer Security (TLS) encryption protocols.
A *cipher* is a cryptographic algorithm (a mathematical function), used for encryption or decryption. A *cipher suite* is a set of ciphers. The SSL and TLS protocols contain numerous cipher suites. Some ciphers are stronger and more secure than others. Generally speaking, the more bits a cipher uses, the harder it is to decrypt the data.

In any two-way encryption process, both parties must use the same ciphers. Because a number of ciphers are available, you need to enable your Sun ONE Application Server for those that are most commonly used in your environment.

**SSL and TLS Protocols**

The Sun ONE Application Server supports the Secure Sockets Layer (SSL) 3.0 and the Transport Layer Security (TLS) 1.0 protocols for encrypted communication. SSL and TLS are application independent, and higher-level protocols can be layered transparently on them.

SSL and TLS protocols support a variety of ciphers used to authenticate the server and client to each other, transmit certificates, and establish session keys. Clients and servers may support different cipher suites, depending on factors such as which protocol they support, company policies on encryption strength, and government restrictions on export of encrypted software. Among other functions, the SSL and TLS handshake protocols determine how the server and client negotiate which cipher suites they will use to communicate.

During a secure connection, the client and the server agree to use the strongest cipher they have both enabled for communication. You can choose ciphers from the SSL2, SSL3, and TLS protocols.

---

**NOTE**  
Improvements to security and performance were made after SSL version 2.0; you should not use SSL 2.0 unless you have clients that are not capable of using SSL 3.0. Client certificates are not guaranteed to work with SSL 2.0 ciphers.
Public and Private Keys

The encryption cipher process alone isn’t enough to secure your server’s confidential information. A key must be used with the encrypting cipher to produce the actual encrypted result, or to decrypt previously encrypted information. The encryption process uses two keys to achieve this result: a public key and a private key. Information encrypted with a public key can be decrypted only with the associated private key. The public key is published as part of a certificate; only the associated private key is safeguarded.

For description of the various cipher suites, and more information about keys and certificates, see Introduction to SSL at the following location:

http://docs.sun.com/db/prod/3802#hic

Task Sequence

The task sequence for setting up basic security is:

1. Install a certificate.
   Refer to “Administering Certificates” on page 43.

2. Enable encryption communication with LDAP.
   Refer to “Enabling SSL Communication with LDAP” on page 64.

3. Turn security on.
   Refer to “Turning Security On” on page 64.

4. Enable encryption protocols.
   Refer to “Enabling SSL and TLS” on page 67.

5. Set global security using SSL directives.
   “Configuring Security Globally” on page 69.

Other administrative tasks associated with encryption are discussed in “Using External Encryption Modules” on page 72, “Setting Strong Ciphers” on page 76, and “Preventing Clients from Caching SSL Files” on page 79.
Enabling SSL Communication with LDAP

After a server certificate has been installed, you are ready to activate encryption on the Sun ONE Application Server. It is important that you immediately configure your Admin Server to communicate with the LDAP database using SSL.

To enable SSL, perform the following steps:

1. Access App Server Instances and select the server instance in the left pane.
4. Click Yes next to Use Secure Sockets Layer (SSL) for connections?
5. Click Save Changes.
   You are asked if you want to switch to the standard port.
6. Click OK to change your port to the standard port for LDAP over SSL.
7. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
8. Stop and start the server for changes to take effect.

Turning Security On

You must turn security on before you can configure any other security settings. The following sections describe the ways of turning security on:

- Turning Security On When Creating an HTTP Listener
- Turning Security On When Editing an HTTP Listener
- Enabling SSL and TLS
Turning Security On When Creating as HTTP Listener

To turn security on when creating a new HTTP listener, perform the following steps:

1. Access App Server Instances and select the server instance in the left pane.
2. Access HTTP Server and HTTP Server Listeners in the left pane.
   The HTTP Listeners page is displayed.
3. Click New.
   The listener settings page is displayed.
4. Check Security Enabled under the SSL/TLS Settings to turn security on.
5. Under Certificate Nickname, select the certificate. For example, Server-Cert.
6. Entering the rest of the information for the new HTTP listener. Additional information on the fields is contained in the online help.
Turning Security On

7. Click OK.
8. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
9. Stop and start the server for changes to take effect.

Turning Security On When Editing an HTTP Listener

To turn security on when editing an existing HTTP listener, perform the following steps:
1. Access App Server Instances and select the server instance in the left pane.
2. Access HTTP Server and HTTP Listeners in the left pane.
3. Select a listener.
   The HTTP Listeners settings page is displayed.

   **NOTE**  If you have an external module installed, the Manage Server Certificates page appears requiring the external module’s password before you can continue.

4. Under the SSL/TLS Settings, check Security Enabled to turn security on.
5. Under Certificate Nickname, select the certificate. For example, Server-Cert.
6. Click Save.
7. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
8. Stop and start the server for changes to take effect.

---

**Enabling SSL and TLS**

To protect the security of your application server, you should enable SSL by enabling the SSL2, SSL3, and TLS encryption protocols and selecting the various cipher suites.

The default settings allow the most commonly-used ciphers. Unless you have a compelling reason for not using a specific cipher suite, you should allow them all. For more information regarding specific ciphers, see *Introduction to SSL* at the following location:

`http://docs.sun.com/db/prod/3802#hic`

---

**CAUTION**  Do not select “No Encryption, only MD5 message authentication”. If no other ciphers are available on the client side, the server will default to this setting and no encryption will occur.

Before enabling SSL and TLS, security must be turned on, and you must have at least one certificate installed.

To enable SSL and TLS, perform the following steps:

1. Access App Server Instances and select the server instance in the left pane.
Enabling SSL and TLS

2. Access HTTP Servers and HTTP Server Listeners in the left pane.

3. Select the HTTP listener you want.
   The HTTP Listeners setting page is displayed.

4. Under the SSL/TLS Settings, check the appropriate boxes associated with SSL and TLS, including all the ciphers.

   **NOTE** If you have an external module installed, the Manage Server Certificates page appears requiring the external module’s password before you can continue.

5. For rollback:
   - TLS must also be enabled on the browser seeking access to your server:
     - For Netscape Navigator 6.0, check both TLS and SSL3.
     - For Microsoft Internet Explorer 5.0 and 5.5, use the TLS Rollback option.
     - For TLS Rollback, check TLS and make sure both SSL3 and SSL2 are disabled.

6. Click Save.

7. Access App Server Instances and your server instance in the left pane, then click Apply Changes.

8. Stop and start the server for changes to take effect.

   The **init.conf** file is automatically modified to show security on, and all virtual servers are automatically assigned the default security parameters.

   After you have enabled SSL on a server, its URLs use **https** instead of **http**. URLs that point to documents on an SSL-enabled server have this format:

   \[https://servername.[domain].[dom]]:[port#]\]

   For example:

   \[https://admin.sun.com:443\]
Configuring Security Globally

Installing an SSL-enabled server creates directive entries in the init.conf file for global security parameters. Security must be enabled for virtual server security settings to work. SSL properties for virtual servers can be found on a per-server basis in the ssl element of the server.xml file.

The Security directive globally enables or disables SSL by making certificates available to the server instance. If enabled, the user is prompted for the administrator password to access certificates, and so on.

NOTE
If you use the default secure HTTP port number (443), you don’t have to enter the port number in the URL.

NOTE
When you create a secure HTTP listener through the Administration interface, security is automatically turned on globally in the init.conf file. When you create a secure HTTP listener manually in the server.xml file, security must be turned on by editing the init.conf file.

The following topics address global security configuration:

• SSL Configuration File Directives
• Setting Values for SSL Directives

SSL Configuration File Directives

To configure security globally, you must set values for the following SSL configuration file directives in the init.conf file:

• SSLCacheEntries
• SSLClientAuthDataLimit
• SSLClientAuthTimeout
• SSLSessionTimeout
• SSLSessionTimeout
SSLCacheEntries
Specifies the number of SSL sessions that can be cached. There is no upper limit.

Syntax
SSLCacheEntries number
If number is 0, the default value, which is 10000, is used.

SSLClientAuthDataLimit
Specifies the maximum amount of application data, in bytes, that is buffered during the client certificate handshake phase. The default value is 1048576 (1 MB).

SSLClientAuthTimeout
Specifies the number of seconds after which the client certificate handshake phase times out. The default value is 60.

SSLSessionTimeout
Controls SSL2 session caching.

Syntax
SSLSessionTimeout seconds
The seconds value is the number of seconds until a cached SSL2 session becomes invalid. If the SSLSessionTimeout directive is specified, the value of seconds is silently constrained to be between 5 and 100 seconds. The default value is 100.

SSL3SessionTimeout
Controls SSL3 session caching.

Syntax
SSL3SessionTimeout seconds
The seconds value is the number of seconds until a cached SSL3 session becomes invalid. The default value is 86400 (24 hours). If the SSL3SessionTimeout directive is specified, the value of seconds is silently constrained to be between 5 and 86400 seconds.
Setting Values for SSL Directives

To set values for your SSL configuration file directives, perform the following steps:

1. Access App Server Instances and select the server instance in the left pane.
2. Access HTTP Server and HTTP Listener in the left pane.
3. Click the HTTP listener you want.
   The HTTP Listener settings page is displayed.
4. In the SSL/TLS Settings section, check the Security Enabled checkbox.
5. Under Certificate Nickname, select the certificate. For example, Server-Cert.
6. Click Save.
7. Select HTTP Server in the left pane.
   The HTTP Server page is displayed.
8. Select the Advanced tab.
   The Advanced settings page is displayed.

Figure 4-3 HTTP Server Advanced Settings Page
Using External Encryption Modules

9. Choose the SSL link.
   The SSL directives table is displayed.

**Figure 4-4** HTTP Server Advanced SSL Settings Page

10. Select the cipher suites and values.

11. Click OK.

12. Access App Server Instances and your server instance in the left pane, then click Apply Changes.

13. Stop and start the server for changes to take effect.

Using External Encryption Modules

The Sun ONE Application Server supports the two methods for using external cryptographic modules (such as smart cards or token rings): Public Key Cryptography Standard (PKCS#11) and Federal Information Processing Standards (FIPS-140).

**NOTE** You will need to add the PKCS #11 module before enabling the FIPS-140 encryption standard.
• Installing the PKCS11Module
• Enabling FIPS-140 Standard
• Starting the Server with an External Certificate

Installing the PKCS11Module

The Sun ONE Application Server supports Public Key Cryptography Standard (PKCS) #11, which defines the interface used for communication between SSL and PKCS11 modules. PKCS11 modules are used for standards-based connectivity to SSL hardware accelerators. Imported certificates and keys for external hardware accelerators are stored in the secmod.db file, which is generated when the PKCS11 module is installed.

Starting the Server with an External Certificate

If you install a certificate for your server into an external PKCS11 module (for example, a hardware accelerator), the server will not be able to start using that certificate until you enable the HTTP listener to use that certificate.

The server always tries to start with the certificate named Server-Cert. However, certificates in external PKCS11 modules include one of the module’s token names in their identifier. For example, a server certificate installed on an external smartcard reader called smartcard0 would be named smartcard0:Server-Cert.

To start a server with a certificate installed in an external module, you’ll need to specify the certificate name. Using the Administration interface, request and install the certificate specifying the hardware cryptographic module to use.

After you install the certificate in the external hardware token, you can see it in the Manage Certificate page, but not in the HTTP Listener page due to the inherent limitation of the Administration interface.

At this point, you must use the command-line interface to edit the HTTP listener to select the certificate for SSL, change the port number, and so on.
Using External Encryption Modules

1. Edit the HTTP listener to select the certificate:

   `/sun/appserver7/bin/asadmin create-ssl
    -user admin
    -password netscape
    -host qa280r-1.red.iplanet.com
    -port 8888
    -type http-listener
    -certname nobody@apprealm:Server-Cert
    -instance server1
    -ssl3enabled=true
    -ssl3tlsciphers +rsa_rc4_128_md5
    http-listener-1`

   To find out the external certificate nickname, go to Manage Certificates page, and enter the key password for external tokens. The certificate name will be displayed, such as `nobody@apprealm:Server-Cert`.

2. Enable security on the HTTP listener:

   `/sun/appserver7/bin/asadmin set
    -user admin
    -password netscape
    -host qa280r-1.red.iplanet.com
    -port 8888
    server1.http-listener.http-listener-1.securityEnabled=true`

3. Change the port number of the HTTP listener:

   `/sun/appserver7/bin/asadmin set
    -user admin
    -password netscape
    -host qa280r-1.red.iplanet.com
    -port 8888
    server1.http-listener.http-listener-1.port=443`

4. Apply the changes thus far:

   `/sun/appserver7/bin/asadmin reconfig
    -u admin
    -w netscape
    -H qa280r-1.red.iplanet.com
    -p 8888
    server1`
5. Stop and start the server to enable the HTTP listener to listen on SSL.

**Enabling FIPS-140 Standard**

PKCS11 APIs enable communication with software or hardware modules that perform cryptographic operations. Once PKCS11 is installed on your Sun ONE Application Server, you can configure the server to be Federal Information Processing Standards (FIPS)-140 compliant.

| NOTE | These libraries are included only in SSL version 3.0. |

To enable FIPS-140, perform the following steps:

1. Install the plug-in following the FIPS-140 instructions.
2. In the Administration interface, access App Server Instances and select the server instance in the left pane.
3. Access HTTP Server and HTTP Listeners in the left pane.
4. Click the link for the HTTP listener you want.
   The HTTP Listeners page is displayed.
5. In the SSL/TLS Settings section of the page, check Security Enabled if it is not already checked.
6. Check SSL3 Enabled, if it is not already checked.
7. Check all the SSL/TLS Ciphers, if they are not already checked.
8. Click Save.
9. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
10. Stop and start the server for changes to take effect.
Setting Strong Ciphers

The Strong Ciphers option presents a choice of 168, 128, or 56-bit secret key size for access or no restriction. You can specify a file to be served when the restriction is not met. If no file is specified, the Sun ONE Application Server returns a Forbidden status.

If you select a key size for access that is not consistent with the current cipher settings, the Sun ONE Application Server warns that you need to enable ciphers with larger secret key sizes.

The implementation of the key size restriction is based on an NSAPI PathCheck directive in the `obj.conf` file, rather than Service `fn=key-toosmall`. This directive is:

```
PathCheck fn="ssl-check" [secret-keysize=nbits]
               [bong-file=filename]
```

where:

- `nbits` is the minimum number of bits required in the secret key.
- `filename` is the name of a file (not a URI) to be served if the restriction is not met.

PathCheck returns REQ_NOACTION if SSL is not enabled, or if the `secret-keysize` parameter is not specified. If the secret key size for the current session is less than the specified `secret-keysize`, the function returns REQ_ABORTED with a status of PROTOCOL_FORBIDDEN if `bong-file` is not specified, or else REQ_PROCEED, and the path variable is set to the `bong-file filename`. Also, when a key size restriction is not met, the SSL session cache entry for the current session is invalidated, so that a full SSL handshake will occur the next time the same client connects to the server.

**NOTE** The Strong Ciphers option removes any Service `fn=key-toosmall` directives that it finds in an object when it adds a PathCheck `fn=ssl-check`.

To use the Strong Ciphers option, perform the following steps:

1. Access App Server Instances and select the server instance in the left pane.
2. Access HTTP Server in the left pane.
3. Select Virtual Servers and click the virtual server you want.
4. Select the HTTP/HTML tab, then click the Strong Ciphers link.

The Enforce Strong Security Requirements page is displayed.
5. Choose to edit:
   - From the drop down list
   - By clicking Browse
   - By clicking Wildcard

6. Select the secret key size restriction:
   - 168 bit or larger
   - 128 bit or larger
   - 56 bit or larger
   - No restrictions

7. Enter the file location of the message that will be used to reject access.

8. Click OK.

9. Access App Server Instances and your server instance in the left pane, then click Apply Changes.

10. Stop and start the server for changes to take effect.
Preventing Clients from Caching SSL Files

You can prevent pre-encrypted files from being cached by a client by adding the following line inside the <HEAD> section of a file in HTML:

<meta http-equiv="pragma" content="no-cache">
Preventing Clients from Caching SSL Files
Chapter 5

Administering HTTP Server Access Control

This section provides information on the mechanisms and procedures used for controlling access to HTTP server resources.

NOTE The content in this chapter cannot be applied to J2EE applications. For J2EE application development, refer to the J2EE security mechanisms as described in the J2EE specifications and the Sun ONE Application Server Developer's Guide.

This section addresses the following topics:

• About HTTP Server Access Control
• Implementing Digest Authentication
• Implementing Host-IP Authentication
• Working With ACL Files
• Setting Up Client Authentication
• ACL/ACE Settings
• Referencing ACL Files in the obj.conf File
• Configuring the ACL User Cache
• Setting Access Control for a Server Instance
• Restricting Access to Areas of Your Server
• Turning Off Access Control
• Responding When Access is Denied
About HTTP Server Access Control

Access control is the means of securing your Sun ONE Application Server by controlling who and what has access to it. For example, you can specify who has full control of all the servers installed on a machine and who has partial control of one or more servers.

**NOTE** Before you can apply access control on the Admin Server set up an administration group. The instructions in this section assume you have already defined users and groups in your directory database.

Access is allowed or denied based on:

- Who is making the request
- Where the request is coming from
- When the request is happening (for example, time of day)
- What type of connection is being used (such as SSL)

The security mechanisms that control access to your HTTP server include various authentication restrictions and ACL files.

This section addresses the following topics:

- HTTP Server User-Group Authentication
- Host-IP Authentication
- Access Control List (ACL) Files
- Client Authentication
HTTP Server User-Group Authentication

*User-Group authentication* requires that users authenticate themselves before access can be granted. This is done by entering a user name and password, using a client certificate, or using the digest authentication plug-in. The Sun ONE Application Server receives this information encrypted or unencrypted, depending on whether encryption is turned on for your server.

**NOTE**  
In J2EE applications, user-group authentication is provided through realms (security domains). For information on developing realms for J2EE application security, refer to the *Sun ONE Application Server Developer’s Guide*.

The default authentication used is the default method you specify in the `obj.conf` file, or Basic authentication if there is no setting in the `obj.conf` file.

If you select Default as your authentication method, the ACL rule doesn’t specify a method in the ACL file. Choosing Default allows you to easily change the methods for all ACLs by editing one line in the `obj.conf` file.

Using the default is the preferred method.

There are three User-Group authentication methods, all of which require a directory server:

- **Basic Authentication**
- **SSL Authentication**
- **Digest Authentication**

**NOTE**  
If you want to require client authentication on your Admin Server, you must manually edit the ACL files in the `obj.conf` file, changing the method to SSL. For further information on client authentication, refer to “Setting Up Client Authentication” on page 102.

Basic Authentication

*Basic authentication* requires a user to enter a user name and password to access your Sun ONE Application Server or web site. You must first create and store a list of users and groups in an LDAP database, such as the Sun ONE Directory Server. The directory server must be installed on a different server root than your Sun ONE Application Server, or on a directory server installed on a remote machine.
Basic authentication is the default setting.

**NOTE** Using Basic authentication without SSL encryption sends the user name and password in unencrypted text across the network. There is a risk that network packets could be intercepted, and the user name and password could be stolen. Basic authentication is most effective when combined with SSL encryption, Host-IP authentication, or both. Using Digest authentication avoids this problem.

### SSL Authentication

*SSL authentication* requires that the Sun ONE Application Server confirm user identities using the users’ security certificates. This can happen in two ways:

- Using the information in the client certificate as proof of identity
- Verifying a client certificate published in an directory (additional)

When you set the server to use certificate information for authenticating the client, the Sun ONE Application Server does the following:

- Verifies that the certificate is from a trusted authority (CA). If not, the authentication fails and the transaction ends.
- If the certificate is from a trusted certificate CA, maps the certificate to a user’s entry using the `certmap.conf` file. To learn how to set up the certificate mapping file see “Working with the certmap.conf File” on page 106.
- If the certificate maps correctly, checks the ACL rules specified for that user.

**NOTE** Even if the certificate maps correctly, ACL rules may deny access to the user.

### User-Group SSL Authentication

If you set the server’s access control to use the User-Group SSL authentication method, the following must be true:

- A valid certificate issued by a trusted CA is presented.
- The certificate is mapped to a valid user in the directory database.
- The access control list (ACL) evaluates properly
Client SSL Authentication to Specific Resources

Requiring client authentication for controlling access to specific resources differs from requiring client authentication for all connections to the server. If you set the server to require client authentication for all connections, the client only needs to present a valid certificate issued by a trusted CA. To learn how to turn on client authentication, see “Setting Up Client Authentication” on page 102.

When you require client SSL authentication, you need to have SSL ciphers enabled for your server. Refer to “Enabling SSL and TLS” on page 67 for further information.

To successfully gain access to an SSL-authenticated resource, the client certificate must be from a CA trusted by the server. The client certificate needs to be published in a directory server if the server's certmap.conf file is configured to compare the client's certificate in the browser with the client certificate in the directory server. However, the certmap.conf file can be configured to compare only selected information from the certificate to the directory server entry. For example, you could configure the certmap.conf file to compare only the user ID and email address in the browser certificate with the directory server entry. To learn more about the certmap.conf file and certificate mapping, see “Working with the certmap.conf File” on page 106.

**NOTE**

Only the User-Group SSL authentication method requires modifying the certmap.conf file (because the certificate is checked against the directory database); requiring client authentication for all connections to the server does not. If you choose to use client certificates, you should increase the value of the AcceptTimeout directive in the init.conf file.

Digest Authentication

*Digest authentication* allows the user to authenticate based on user name and password without sending the user name and password as cleartext. The browser uses the MD5 algorithm to create a digest value using the user's password and some information provided. This digest value is also computed on the server side using the Digest authentication plug-in, and compared against the digest value provided by the client. If the digest values match, the user is authenticated.

For this to work, your directory server needs access to the user's password in cleartext. The Sun ONE Directory Server includes a reversible password plug-in that uses a symmetric encryption algorithm to store data in an encrypted form. Later the data can be decrypted to its original form. Only the Sun ONE Directory Server holds the key to the data.
When processing an ACL with `method=digest`, the server attempts to authenticate using the following process:

- **Checking for authorization request header**—If not found, an error is generated with a Digest challenge, and the process stops.
- **Checking for authorization type**—If Authentication type is Digest, the server does the following:
  - Checks nonce—If this is not a valid, fresh nonce is generated by this server, an error is generated, and the process stops. If stale, an error is generated with `stale=true`, and the process stops.
  - Checks realm—If it does not match, an error is generated, and the process stops.
  - Checks existence of user in LDAP directory—If not found, an error is generated, and the process stops.
  - Gets request-digest value from directory server and checks for match to client's request-digest—If it does not match, an error is generated, and the process stops.
  - Constructs Authorization-Info header and inserts into server headers.

The server tries to authenticate against the directory database based on the ACL method as specified in the following table.

<table>
<thead>
<tr>
<th>ACL Method Configured</th>
<th>Authentication DB Supports Digest Authentication</th>
<th>Authentication DB Does Not Support Digest Authentication</th>
</tr>
</thead>
<tbody>
<tr>
<td>Default None specified</td>
<td>Digest and Basic</td>
<td>Basic</td>
</tr>
<tr>
<td>Basic</td>
<td>Basic</td>
<td>Basic</td>
</tr>
<tr>
<td>Digest</td>
<td>Digest</td>
<td>ERROR</td>
</tr>
</tbody>
</table>

For more information, refer to “Implementing Host-IP Authentication” on page 91.
Host-IP Authentication

*Host-IP access control* is a method of limiting access to the Admin Server, or the files and directories on your web site by making them available only to clients using specific computers. You do this by specifying the hostnames or IP addresses for the computers that you want to allow or deny access to. You can use wildcard patterns to specify multiple computers or entire networks.

Host-IP authentication appears seamless to users, who can access the files and directories immediately without entering a user name or password. Further information can be found in “Implementing Host-IP Authentication” on page 91.

Access Control List (ACL) Files

ACL files are text files that contain lists identifying who can access the resources stored on your Sun ONE Application Server. By creating a hierarchy of rules called *access control entries* (ACEs) you can allow or deny access to individuals, groups, or other entities such as particular servers or applications. Each ACE specifies whether or not the server should check the next ACE in the hierarchy. The collection of ACEs you create is called an *access control list* (ACL).

By default, the Sun ONE Application Server uses a single ACL file that contains all the lists for accessing your server. As an alternative to this default, you can create multiple ACL files and reference them in the obj.conf file.

When the Sun ONE Application Server receives a request for a page, the server uses the rules in the ACL file to determine if it should grant access or not. The rules can reference the hostname or IP address of the computer sending the request. The rules can also reference users and groups stored in an LDAP directory such as the Sun ONE Directory Server.

After determining which virtual server to use for an incoming request, the Sun ONE Application Server determines if any ACLs are configured for that virtual server. If ACLs are found that apply to the current request, the Sun ONE Application Server evaluates their ACEs to determine whether access should be allowed (granted) or denied (refused).

Information on using ACLs is contained in “Working With ACL Files” on page 92.
Client Authentication

When client authentication is enabled, the client’s certificate is required before the server will send a response to a query. The Sun ONE Application Server supports authenticating client certificates by matching the CA in the client certificate with a CA trusted for signing client certificates.

When the Sun ONE Application Server receives a request from a client, it asks for the client’s certificate before proceeding. Some clients send the client certificate to the server along with the request.

1. The Sun ONE Application Server tries to match the CA to the list of trusted CAs in the Admin Server.
   If there isn’t a match, the Sun ONE Application Server ends the connection.
2. If there is a match, the server continues processing the request.
3. After verifying the certificate is from a trusted CA, the server maps the certificate to an LDAP entry by:
   - Mapping the issuer and subject DN from the client certificate to a branch point in the LDAP directory.
   - Searching the LDAP directory for an entry that matches the information about the subject (end-user) of the client certificate.

   The server uses a certificate mapping file called `certmap.conf` to determine how to do the LDAP search. The mapping file tells the server what values to take from the client certificate (such as the user’s name, email address, and so on). The server uses these values to search for a user entry in the LDAP directory, but first the server needs to determine where in the LDAP directory it needs to start its search. The certificate mapping file tells the server where to start.

   (Optional) Verifying the client certificate with one in the LDAP entry that corresponds to the DN.

**NOTE** Before mapping client certificates to LDAP, you need to set up the required ACLs. More information on access control can be found in “Working With ACL Files” on page 92
4. Once the server knows where to start its search and what it needs to search for, it performs the search in the LDAP directory. If it finds no matching entry or more than one matching entry, and the mapping is not set to verify the certificate, the search fails.

You can specify the expected behavior in the ACL. For example, you can specify that Sun ONE Application Server accepts only you if the certificate match fails. For more information regarding how to set the ACL preferences, see “ACL File Syntax” on page 92.

5. After the server finds a matching entry and certificate in the LDAP directory, it can use that information to process the transaction. For example, some servers use certificate-to-LDAP mapping to determine access to a server.

Information on implementation is contained in “Setting Up Client Authentication” on page 102.

Implementing Digest Authentication

If you are unfamiliar with how Digest authentication works, refer to “Digest Authentication” on page 85.

For Digest authentication, you need to enable the reversible password plug-in and the digestauth-specific plug-in included with the Sun ONE Application Server. To configure your server to process Digest authentication, you will need to set the digestauth property of the database definition in the dbswitch.conf file.

The tasks required for implementing User-Group Digest authentication are addressed in the following sections:

• Installing the Digest Authentication Plug-in

• Setting the Sun ONE Directory Server to Use the DES Algorithm

Installing the Digest Authentication Plug-in

The Digest authentication plug-in consists of a shared library found in both libdigest-plugin.lib and libdigest-plugin.ldif.

Digest Authentication on UNIX

To install the Digest authentication plug-in on UNIX, perform the following steps:
1. Make sure this shared library resides on the same server machine that the Sun ONE Directory Server is installed on.

2. Make sure you know the Directory Manager password.

3. Modify the libdigest-plugin.ldif file changing all references to /path/to to the location where you installed the Digest plug-in shared library.

4. To install the plug-in, enter the following command:

   % ldapmodify -D "cn=Directory Manager" -w password -a < libdigest-plugin.ldif

**Digest Authentication on Windows**

To install the Digest authentication plug-in on Windows, perform the following steps:

**NOTE** You will need to copy several .dll files from the Sun ONE Application Server installation to your Sun ONE Directory Server machine in order for the Sun ONE Directory Server to start properly with the Digest plug-in.

1. Access the shared libraries in the Sun ONE Application Server installation in:

   \install_dir\bin

2. Copy the files:
   - nsldap32v50.dll
   - libnspr4.dll
   - libplds4.dll

3. Paste them into either:
   - \Winnt\system32
   - Sun ONE Directory Server installation directory:
     \[server_root]\bin\sldap\server
Implementing Host-IP Authentication

Setting the Sun ONE Directory Server to Use the DES Algorithm

The DES algorithm is needed to encrypt the attribute where the Digest password is stored. To set the Sun ONE Directory Server to use the DES algorithm, perform the following steps:

1. Launch the Sun ONE Directory Server Console.
2. Open your Sun ONE Directory Server instance.
3. Select the Configuration tab.
4. Click the + sign next to plug-ins.
5. Select the DES plug-in.
6. To add a new attribute, choose Add.
7. Enter iplanetReversiblePassword.
8. Click Save.
9. Stop and start the server for changes to take effect.

**NOTE** In order to set a digest authentication password in the iplanetReversiblePassword attribute for a user, your entry must include the iplanetReversiblePasswordObject object.

Implementing Host-IP Authentication

Since more than one person may use a particular computer, Host-IP authentication is more effective when combined with User-Group authentication. If both User-Group and Host-IP authentication are used, a user name and password is required for access.

Host-IP authentication does not require DNS to be configured on your Sun ONE Application Server, but you must have DNS running in your network and your Sun ONE Application Server must be configured to use it.

**NOTE** You can enable DNS on the HTTP Server->Tuning page of the Administration interface.
Enabling DNS degrades the performance of the Sun ONE Application Server because the server is required to do DNS look-ups. To reduce the impact of DNS look-ups on your Sun ONE Application Server performance, resolve IP addresses only for access control and CGI instead of resolving IP addresses for every request. To minimize DNS impact, append `iponly=1` to `AddLog fn="flex-log" name="access"` in your `obj.conf` file:

```
AddLog fn="flex-log" name="access" iponly=1
```

## Working With ACL Files

The main ACL file name is `generated.server-id.acl`; the temporary working file is called `genwork.server-id.acl`. If you use the Admin Server to configure access, these two files will exist. However, if you want more complex restrictions, you can create multiple files, and reference them from the `server.xml` file. There are also a few features available only by editing the files, such as restricting access to the server based on the time of day or day of the week.

Access control files are stored in the directory `instance_dir/config` where `instance_dir` is the name of the instance. For example, the access control files for the initial server instance are stored in the `install_dir/domains/domain1/server1/config` directory.

The following topics are addressed in this section:

- **ACL File Syntax**
- **Type Statement**
- **Authentication Statement**
- **Authorization Statement**
- **Sample ACL File**
- **Writing Customized ACL Expressions**

### ACL File Syntax

ACL files must follow a specific format and syntax. A typical ACL definition in the ACL list is made up of a number of statements about type, the authentication method, and the authorization method.

A snippet from an ACL file might look like this:
version 3.0;
# The "default" rules apply to the entire document
acl "default";

authenticate (user, group) {
  database = "default";
  method = "basic";
}

deny (all)
  user = "anyone";
allow (read, execute, list, info)
  (user = "all");

The components of this snippet include:

• Version Line—All ACL files begin with a line specifying the version number. There can be only one version line in an ACL file. For example:

  version 3.0;

• Type statement—Identifies the type of ACL the definition is for. For example:

  acl "default";

• Authentication statement—Optionally specifies the authentication method. For example:

  authenticate (user, group) {
    database = "default";
    method = "basic";
  }

• Authorization statement—Specifies who is allowed or denied access to a server resource. For example:

  deny (all)
    (user = "anyone");
  allow (read, execute, list, info)
    (user = "all");

Input strings can contain the following characters:

• Letters a through z
• Numbers 0 through 9
• Period and underscore

If you use any other characters, you must use double quotation marks ("") around the characters.
• A single statement is placed on its own line and is terminated with a semicolon.

• Multiple statements are placed within braces.

• In a list of items, the items must be separated from each other with commas, and the list must be enclosed in double quotation (") marks.

Type Statement

Each ACL definition in the file contains a statement that identifies what type of ACL it is. This type can be one of the following:

• Path ACL—Specifies an absolute path to the resource it affects.

• URI (Uniform Resource Indicator) ACL—Specifies a directory or file relative to the server’s document root.

• Named ACL—Specifies a name that is referenced in resources in the obj.conf file. The server comes with a default named resource that allows read access to anyone and write access to users in the LDAP directory. Even though you can create a named ACL from the Sun ONE Application Server, you must manually reference the named ACLs with resources in the obj.conf file.

A type line begins with the letters acl, followed by the type information in double quotation marks, ended by a semicolon. The type information for each ACL must be a unique name—even among different ACL files. The following lines are examples of several different types of ACLs:

```
  acl "path=C:/Sun/Servers/docs/mydocs/";
  acl "default";
  acl "uri=/mydocs/";
```

Path and URI ACLs can include wildcards at the end of the entry. For example: /a/b/*. Wildcards placed anywhere except at the end of the entry will not work.

Authentication Statement

Optionally, ACLs can specify the authentication method the Sun ONE Application Server must use when processing the ACL. There are three general methods:

• Basic authentication—(Default) Requires the user to enter a user name and password before accessing a resource.
By default, the Sun ONE Application Server uses the Basic method for any ACL that doesn’t specify a method.

- SSL authentication—Requires the user to have a client certificate. The Sun ONE Application Server must have encryption turned on, and the user’s certificate issuer must be in the list of trusted CAs.

- Digest authentication—Requires the user to enter a user name and password before accessing a resource.

**NOTE** In this case, your Sun ONE Application Server authentication database must be able to handle Digest authentication sent by a user.

Each authentication statement specifies what attributes (users, groups, or both users and groups) the Sun ONE Application Server must authenticate.

**Examples**

Specifies Basic authentication with users matched to individual users in the database or directory:

```plaintext
authenticate (user) {
    method = "basic";
};
```

Specifies the User-Group SSL authentication method:

```plaintext
authenticate (user, group) {
    method = "ssl";
};
```

Allows access to any user whose user name begins with the letters sales:

```plaintext
authenticate (user) {
    allow (all)
        user = sales*
    }
};
```

If the last line were changed to group=sales, the ACL would fail because the authenticate line specifies user, not group.
Authorization Statement

An authorization statement specifies who is allowed or denied access to a server resource. Each ACL entry can include one or more authorization statements. Use the following syntax when writing authorization statements:

```
allow|deny [absolute] (right[,right...]) attribute expression;
```

Each line starts with the keyword allow or deny.

Because of the hierarchy of rules, it is usually a good idea to deny access to everyone in the top-level rule, then specifically allow access for users, groups, or computers in subsequent rules.

**Scenario**

If you allow full access to a directory called `my_stuff`, then you want a subdirectory called `my_stuff/personal` that will allow access to only a few users, the access control on the subdirectory won’t work—everyone allowed access to the `/my_stuff` directory will also be allowed access to the `/my_stuff/personal` directory. To prevent this, first create a rule for `/my_stuff/personal` that denies access to everyone, then allow access for the few users you specify.

| NOTE | In some cases, if you set the default ACL to deny access to everyone, then your other ACL rules won’t need a deny all rule. |

The following authorization statement denies access to everyone:

```
deny (all)
    user = "anyone";
```

The following sections are association with authorization statements:

- **Hierarchy of Authorization Statements**
- **Attribute Expressions**
- **Operators**

**Hierarchy of Authorization Statements**

ACLs have a hierarchy based on the resource. For example, if the Sun ONE Application Server receives a request for the document (URI) `/my_stuff/web/presentation.html`, the server builds a list of ACLs that apply for this URI.
First the Sun ONE Application Server adds ACLs listed in the check-acl statements of the server’s obj.conf file.

Then the server appends matching URI and PATH ACLs. All statements are evaluated in order, unless absolute ACL statements are present. If an absolute allow or absolute deny statement evaluates to true, the server stops processing and accepts this result.

If there are multiple ACLs that match, the Sun ONE Application Server uses the last statement that matches. However, if you use an absolute statement, the server stops looking for other matches and uses the ACL containing the absolute statement. If you have two absolute statements for the same resource, the Sun ONE Application Server uses the first one in the file and stops looking for other resources that match.

The following example stops searching when it reaches the absolute "joe", even if there might be additional users named joe:

```plaintext
version 3.0;
 acl "default";
 authenticate (user,group) {
   prompt="Sun ONE Application Server";
};
 allow (read,execute,list,info)
   user = "anyone";
 allow (write,delete)
   user = "all";
 acl "uri=/my_stuff/web/presentation.html";
 deny (all)
   user = "anyone";
 allow (all)
   user = "joe";
```

Attribute Expressions
An attribute expression defines who is allowed or denied access based on their user name, group name, host name, or IP address. The following are examples of how access is given to different people or computers:

```plaintext
user = "anyone"
user = "smith*"
group = "sales"
dns = "*.sun.com"
dns = "*.sun.com,*.mozilla.com"
```
You can also restrict access to your server by time of day (based on the local time on the server) using the `timeofday` attribute. Refer to “Restricting Access Based on Time of Day” on page 127 for additional information.

For example, the `timeofday` attribute can restrict access to certain users during specific hours.

**Example**
Restricts access to a group of users called guests between 8:00 a.m. and 4:59 p.m:

```plaintext
allow (read
  (group="guests") and
  (timeofday<0800 or timeofday=1700));
```

You can also restrict access by day of the week using the `dayofweek` attribute with the following three-letter abbreviations to specify days of the week: Sun, Mon, Tue, Wed, Thu, Fri, Sat.

**Example**
Allows access for users in the premium group any day and any time. Users in the discount group get access all day on weekends and on weekdays anytime except 8am-4:59pm.

```plaintext
allow (read
  (group="discount" and dayofweek="Sat,Sun") or
  (group="discount" and (dayofweek="mon,tue,wed,thu,fri" and
    (timeofday<0800 or timeofday=1700)))
  or
  (group="premium");
```
Operators
You can use various operators in attribute expressions. Parentheses delineate the operator order of precedence. With user, group, DNS, and IP, you can use the following operators:
- and
- or
- not
- = (equals)
- != (not equal to)
With the `timeofday` and `dayofweek` attributes, you can use:
- > greater than
- < less than
- >= greater than or equal to
- <= less than or equal to

Sample ACL File
The following sample ACL file contains the two default entries for the Admin Server (`admin-server`), plus an additional entry that allows users in the admin-reduced group to access the Admin Server.

```
version 3.0;
# The following "es-internal" rules protect files such
# as icons and images related to Sun ONE Application Server.
# These "es-internal" rules should not be modified.
acl "es-internal";
  allow (read, list, execute, info) user = "anyone";
  deny (write, delete) user = "anyone";
# The following "default" rules apply to the entire document
# directory of Sun ONE Application Server. In this example, the rules
# are set up so that "all" users in the directory server are
# allowed to read, execute, list, and get information.
# All clients that accesses the document directory of the web
# server will be required to submit a username and password
# since this example is using the "basic" method of
# authentication. A client must be in the directory server
```
# to gain access to this default directory since "anyone" # not in the directory server is denied, and "all" in the # directory server are allowed.

acl "default";
authenticator (user,group) {
  database = "default";
  method = "basic";
};
deny (all)
  (user = "anyone");
allow (read,execute,list,info)
  (user = "all");

# The following rules deny access to the directory "web" # to everyone not in the directory server and deny everyone # in the directory server who is not in GroupB.
# Only the users in GroupB are allowed read, execute, list, # and info permissions. GroupA can not gain access to the # directory "web" even though (in the ACL rule below) they # can access the directory "my_stuff". Furthermore, members # of GroupB can not write or delete files.

acl "path=/export/user/990628.1/docs/my_stuff/web/";
authenticator (user,group) {
  database = "default";
  method = "basic";
};
deny (all)
  (user = "anyone");
allow (read,execute,list,info)
  (group = "GroupB");

# The following rule denies everyone not in the directory # server and denies everyone in the directory server except # user with the ID of "SpecificMemberOfGroupB". The ACL rule # in this setting also has a requirement that the user # connect from a specific IP address. The IP address setting # in the rule is optional; it has been added to for extra # security. Also, this ACL rule has a Customized prompt # of "Presentation Owner". This Customized prompt appears # in the username and password dialog box in the client's # browser.

acl "path=/export/user/990628.1/docs/my_stuff/web/presentation.html";
authenticator (user,group) {
  database = "default";
  method = "basic";
  prompt = "Presentation Owner";
};
deny (all)
  (user = "anyone" or group = "my_group");
allow (all)
  (user = "SpecificMemberOfGroupB") and
  (ip = "208.12.54.76");
Working With ACL Files

Example

If a user requests: http://server_name/my_stuff/web/presentation.html, the Sun ONE Application Server first checks access control for the entire server. If the ACL for the entire server was set to continue, the server would check for an ACL for the directory my_stuff. If an ACL exists, the server checks the ACEs within the ACL, then moves on to the next directory. This process continues until an ACL is found that denies access, or until the final ACL for the requested URL (in this case, the file presentation.html) is reached.

Writing Customized ACL Expressions

You can enter custom expressions for an ACL. There are a few features that are available only by editing the ACL file or by creating custom expressions. For example, you can restrict access to your server depending on the time of day, day of the week, or both.

NOTE

Only select this option if you are familiar with the syntax and structure of ACL files.

The following customized expression shows how you could restrict access by time of day and day of the week. This example assumes you have two groups in your LDAP directory: the regular group is allowed access Monday through Friday, 8:00am to 5:00pm. The critical group is allowed access all the time.
Setting Up Client Authentication

allow (read)
{
    (group=regular and dayofweek="mon,tue,wed,thu,fri");
    (group=regular and (timeofday>=0800 and timeofday<=1700));
    (group=critical)
}

Setting Up Client Authentication

NOTE Certificate expired—If the certificate has expired, the Sun ONE Application Server logs an error, rejects the certificate, and returns a message to the client. You can view which certificates have expired in the Admin Server Manage Certificates page.

You can set up client authentication for the Admin Server or for a server instance. Instructions are contained in the following sections:

• Setting Client Authentication for the Admin Server
• Setting Client Authentication for a Server Instance
• Working with the certmap.conf File

Setting Client Authentication for the Admin Server

To set up client authentication at the Admin Server level:

1. Access the Admin Server and select the HTTP Listener tab in the right pane.
   The Admin Server HTTP Listener page is displayed.
2. Click SSL/TLS Enabled to turn security on (default is off).

3. Click Client Authentication Enabled to turn client authentication on (default is off).

4. Click Save.

5. Select the Control tab on the right pane and click Apply Changes.
6. Stop and start the server for changes to take effect.

   To start the Admin Server, go to
   
   \texttt{install\_dir/domains/domain1/admin-server/bin/startserv}

**Setting Client Authentication for a Server Instance**

To set up client authentication at the Server Instance level:

1. Access the App Server Instance and select the server instance in the left pane.
2. Expand HTTP Server in the left pane and click HTTP Listeners.
   
   The HTTP Listener page is displayed, listing the listener instances.
3. Select the instance you want.
   
   The HTTP Listener page for that instance is displayed.
4. Click the SSL/TLS Enabled checkbox to turn security on (default is off).
5. Click the Client Authentication Enabled checkbox to turn it on (default is off).
6. Click Save.
7. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
8. Stop and start the server for changes to take effect.

**NOTE**  There is a single certificate trust database per Sun ONE Application Server instance. All the secure virtual servers running under that server instance share the same list of trusted client CAs. If two virtual servers require different trusted CAs, these virtual servers should be run in different server instances with separate trust databases.
Working with the certmap.conf File

Certificate mapping is the mechanism by which a server looks up a user entry in the LDAP directory. You can use the certmap.conf file to configure how a certificate, designated by name, is mapped to an LDAP entry. You edit this file and add entries to match the organization of your LDAP directory and to list the certificates you want your users to have. Users can be authenticated based on user ID, email, or any other value used in the subjectDN. Specifically, the mapping file provides the following information:

- Where in the LDAP tree the server should begin its search
- What certificate attributes the server should use as search criteria when searching for the entry in the LDAP directory
- Whether or not the server goes through an additional verification process

The certificate mapping file is located here:

/instance_dir/config/certmap.conf

The file contains one or more named mappings, each applying to a different CA. A mapping has the following syntax:

```certmap <name> <issuerDN>
  <name>:<property> [=<value>]
```

The first line specifies a name for the entry and the attributes that form the DN found in the CA certificate. The name is arbitrary; you can define it to be whatever you want. However, issuerDN must exactly match the issuer DN of the CA who issued the client certificate. For example, the following two issuerDN lines differ only in the spaces separating the attributes, but the server treats these two entries as different:

```certmap iplanet1 ou=Sun Certificate Authority, o=Sun, c=US
certmap iplanet2 ou=Sun Certificate Authority, o=Sun, c=US```

**TIP**

If you are using the Sun ONE Directory Server and experiencing problems in matching the issuerDN, check the Sun ONE Directory Server error logs for useful information.

The following topics address the certmap.conf file:

- Default Properties
- Creating Custom Properties
Sample Mappings

Default Properties

The second and subsequent lines in the named mapping match properties with values. The certmap.conf file has six default properties (you can use the certificate API to customize your own properties):

- **DNComps**—A list of comma-separated attributes used to determine where in the LDAP directory the Sun ONE Application Server should start searching for entries that match the user’s information (that is, the owner of the client certificate). The server gathers values for these attributes from the client certificate and uses the values to form an LDAP DN, which then determines where the server starts its search in the LDAP directory. For example, if you set DNComps to use the o and c attributes of the DN, the server starts the search from the o=<org>, c=<country> entry in the LDAP directory, where <org> and <country> are replaced with values from the DN in the certificate.

  Note the following situations:

  - If there isn’t a DNComps entry in the mapping, the server uses either the CmapLdapAttr setting or the entire subject DN in the client certificate (that is, the user’s information).

  - If the DNComps entry is present but has no value, the server searches the entire LDAP tree for entries matching the filter.

- **FilterComps**—A list of comma-separated attributes used to create a filter by gathering information from the user’s DN in the client certificate. The server uses the values for these attributes to form the search criteria used to match entries in the LDAP directory. If the server finds one or more entries in the LDAP directory that match the user’s information gathered from the certificate, the search is successful and the server optionally performs a verification.

  For example, if FilterComps is set to use the email and user ID attributes (FilterComps=e,uid), the server searches the directory for an entry whose values for email and user ID match the end user’s information gathered from the client certificate. Email addresses and user IDs are good filters because they are usually unique entries in the directory. The filter needs to be specific enough to match one and only one entry in the LDAP database.

The following table contains a list of the x509v3 certificate attributes.
Setting Up Client Authentication

### Table 5-2 Attributes for x509v3 Certificates

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>c</td>
<td>Country</td>
</tr>
<tr>
<td>o</td>
<td>Organization</td>
</tr>
<tr>
<td>cn</td>
<td>Common name</td>
</tr>
<tr>
<td>l</td>
<td>Location</td>
</tr>
<tr>
<td>st</td>
<td>State</td>
</tr>
<tr>
<td>ou</td>
<td>Organizational unit</td>
</tr>
<tr>
<td>uid</td>
<td>UNIX userid</td>
</tr>
<tr>
<td>email</td>
<td>email address</td>
</tr>
</tbody>
</table>

**NOTE** The attribute names for the filters need to be attribute names from the certificate, not from the LDAP directory. For example, some certificates have an \( e \) attribute for the user’s email address; whereas LDAP calls that attribute \( mail \).

- **verifycert**—Tells the server whether it should compare the client’s certificate with the certificate found in the LDAP directory. It takes two values: on, and off. You should only use this property if your LDAP directory contains certificates. This feature is useful to ensure that your users have a valid, unrevoked certificate.

- **CmapLdapAttr**—A name for the attribute in the LDAP directory that contains subject DNs from all certificates belonging to the user. The default for this property is \( \text{certSubjectDN} \). This attribute isn’t a standard LDAP attribute, so to use this property, you have to extend the LDAP schema.

  If this property exists in the \( \text{certmap.conf} \) file, the server searches the entire LDAP directory for an entry whose attribute (named with this property) matches the subject’s full DN (taken from the certificate). If the search doesn’t find any entries, the server retries the search using the \( \text{DNComps} \) and \( \text{FilterComps} \) mappings.

  This approach to matching a certificate to an LDAP entry is useful when it’s difficult to match entries using \( \text{DNComps} \) and \( \text{FilterComps} \).
• **Library**—A property whose value is a pathname to a shared library or DLL. Use this property only if you create your own properties using the certificate API. For more information, see the *Sun ONE Application Server Developer’s Guide to NSAPI*.

• **InitFn**—A property whose value is the name of an init function from a custom library. Use this property only if you create your own properties using the certificate API.

For more information on these properties, refer to the examples described in “Sample Mappings” on page 109.

**Creating Custom Properties**

You can use the client certificate API to create your own properties. For information on programming and using the client certificate API, see the *Sun ONE Application Server Developer’s Guide to NSAPI*.

Once you have a custom mapping, reference the mapping as follows:

```xml
<name>:library <path_to_shared_library>
<name>:InitFn <name_of_init_function>
```

For example:

```xml
certmap default1 o=Netscape Communications, c=US
default1:library /usr/netscape/enterprise/auth-db/plugin.so
default1:InitFn plugin_init_fn
default1:DNComps ou o c
default1:FilterComps l
default1:verifycert on
```

**Sample Mappings**

The certmap.conf file should have at least one entry. The following examples illustrate the different ways you can use the certmap.conf file.

**Example 1**

This example represents a certmap.conf file with only one default mapping:

```xml
certmap default default
default:DNComps ou, o, c
default:FilterComps e, uid
default:verifycert on
```
Using this example, the server starts its search at the LDAP branch point containing the entry `ou=orgunit, o=org, c=country` where the text in <> is replaced with the values from the subject’s DN in the client certificate.

The server then uses the values for the email address and user ID from the certificate to search for a match in the LDAP directory. When it finds an entry, the server verifies the certificate by comparing the one the client sent to the one stored in the directory.

**Example 2**
This example file has two mappings, one for default and another for the US Postal Service:

```plaintext
certmap default default
default:DNComps
default:FilterComps e, uid
certmap usps ou=United States Postal Service, o=usps, c=US
usps:DNComps ou,o,c
usps:FilterComps e
usps:verifycert on
```

When the server gets a certificate from anyone other than the US Postal Service, it uses the default mapping, which starts at the top of the LDAP tree and searches for an entry matching the client’s email and user ID. If the certificate is from the US Postal Service, the server starts its search at the LDAP branch containing the organizational unit and searches for matching email addresses. If the certificate is from the USPS, the server verifies the certificate; other certificates are not verified.

**CAUTION** The issuer DN (that is, the CA’s information) in the certificate must be identical to the issuer DN listed in the first line of the mapping. In the previous example, a certificate from an issuer DN that is `o=United States Postal Service, c=US` won’t match because there isn’t a space between the `o` and the `c` attributes.

**Example 3**
The following example uses the `CmapLdapAttr` property to search the LDAP database for an attribute called `certSubjectDN` whose value exactly matches the entire subject DN taken from the client certificate.
certmap myco ou=My Company Inc, o=myco, c=US
   myco:CmapLdapAttr certSubjectDN
   myco:DNComps o, c
   myco:FilterComps mail, uid
   myco:verifycert on

If the client certificate subject is:

   uid=Walt Whitman, o=LeavesOfGrass Inc, c=US

the server first searches for entries that contain the following information:

   certSubjectDN=uid=Walt Whitman, o=LeavesOfGrass Inc, c=US

If one or more matching entries are found, the server proceeds to verify the entries. If no matching entries are found, the server uses DNComps and FilterComps to search for matching entries.

In this example, the server would search for uid=Walt Whitman in all entries under o=LeavesOfGrass Inc, c=US.

**NOTE** This example assumes the LDAP directory contains entries with the attribute certSubjectDN.

### ACL/ACE Settings

The following topics are addressed in this section:

- Setting to Allow or Deny
- Setting for User-Group Authentication
- Specifying the From Host
- Setting Access Rights

### Setting to Allow or Deny

You can specify the action the server takes when a request matches the access control rule.

- Allow—Users or systems can access the requested resource.
- Deny—Users or systems cannot access the resource.
ACL/ACE Settings

The server goes through the list of ACEs to determine access permission. For example, the first ACE is usually to deny access to everyone. If continue is not checked, everyone is denied access to the resource.

If the first ACE is set to continue, the server checks the second ACE in the list, and if it matches, goes to the next ACE. The server continues down the list until it reaches either an ACE that doesn’t match, or an ACE that matches but is set to not continue. The last matching ACE determines if access is allowed or denied.

Setting for User-Group Authentication

With User-Group authentication, users are prompted to enter a user name and password before they can access the resource specified in the access control rule. The Sun ONE Application Server checks the lists of users and groups stored in your LDAP server.

You can allow or deny access to everyone in the database, you can allow or deny specific people by using wildcard patterns, or you can select who to allow or deny from lists of users and groups.

- **Anyone**—(Default) No authentication is required. Anyone can access the resource without having to enter a user name or password. However, the user might be denied access based on other settings, such as host name or IP address.

- **Authenticated people only**
  - All in the authentication database—Allows a match for any user who has an entry in the database.
  - Only the following people—Allows you to specify which users and groups to match. You can list users or groups of users individually by separating the entries with commas, or with a wildcard pattern, or you can select from the lists of users and groups stored in the database. Group matches all users in the groups you specify. User matches the individual users you specify.

- **Prompt for authentication**—Allows you to enter message text that appears in the authentication dialog box. You can use this text to describe what the user needs to enter. Depending on the operating system, the user will see about the first 40 characters of the prompt. The user name and password are associated with the prompt text. When the user accesses files and directories of the server having the same prompt, the user names and passwords won’t need to be entered again. If you want users to authenticate again for specific files and directories, change the prompt for the ACL on that resource.
• Authentication methods—Specifies the method the server uses for getting authentication information from the client. Uses the default method you specify in the obj.conf file, or Basic if there is no setting in the obj.conf file.
  ○ Basic—(Default) Uses the HTTP method to get authentication information from the client. The user name and password are only encrypted if encryption is turned on for the Sun ONE Application Server. Refer to “Basic Authentication” on page 83 for additional information.

  NOTE  The Admin Server offers only the Basic method of authentication.

  ○ SSL—Uses the client certificate to authenticate the user. To use this method, SSL must be turned on for the Sun ONE Application Server. When encryption is on, you can combine Basic and SSL methods. Refer to “SSL Authentication” on page 84 for additional information.

  ○ Digest—Uses the user name and password without sending the user name and password as cleartext. The browser uses the MD5 algorithm to create a digest value using the user's password and some information provided. Refer to “Digest Authentication” on page 85 and “Implementing Host-IP Authentication” on page 91 for additional information.

• Authentication database—Allows you to select a database the Sun ONE Application Server will use to authenticate users. If you choose Default, the server looks for users and groups in an LDAP directory.

  If you want to configure individual ACLs to use different databases, select Other as the authentication method, and choose the database from the drop-down list. Non-default databases and LDAP directories need to have already been specified in the instance_dir/config/dbswitch.conf file.

Specifying the From Host

You can restrict access to the Admin Server or your web site based on which computer the request comes from.

• Anyplace—Allows access to all users and systems.

• Only from—Allows you to restrict access to specific host names or IP addresses.
If you select the Only from option, enter a wildcard pattern or a comma-separated list in the Host Names or IP Addresses fields. Restricting by hostname is more flexible than by IP address: if a user’s IP address changes, you won’t need to update this list. Restricting by IP address, however, is more reliable: if a DNS lookup fails for a connected client, hostname restriction cannot be used.

You can only use the * wildcard notation for wildcard patterns that match the computers’ host names or IP addresses. For example, to allow or deny all computers in a specific domain, you would enter a wildcard pattern that matches all hosts from that domain, such as *.sun.com. You can set different hostnames and IP addresses for superusers accessing the Admin Server.

For more information, refer to “Implementing Host-IP Authentication” on page 91.

**NOTE**

For hostnames, the * must replace an entire component of the name. For example, *.sun.com is acceptable, but *users.sun.com is not. When the * appears in a hostname, it must be the leftmost character. For example, *.sun.com is acceptable, but users.*.com is not.

For the IP address, the * must replace an entire byte in the address. For example, 198.95.251.* is acceptable, but 198.95.251.3* is not. When the * appears in an IP address, it must be the right-most character. For example, 198.* is acceptable, but not 198.*.251.30.

---

### Setting Access Rights

Access rights restrict access to files and directories on your web site. In addition to allowing or denying all access rights, you can specify a rule that allows or denies partial access rights. For example, you can allow users read-only access to your files, so they can view the information, but deny them write access, so they cannot change the files.

- **All Access Rights**—(Default) Allows or denies all rights.
- **Only the following rights**—Allows you to select a particular combination of rights the following rights to be allowed or denied:
  - **Read**—Allows users to view files, including includes the HTTP methods GET, HEAD, POST, and INDEX.
  - **Write**—Allows users to change or delete files, including the HTTP methods PUT, DELETE, MKDIR, RMDIR, and MOVE. To delete a file, a user must have both write and delete rights.
Referencing ACL Files in the obj.conf File

If you have named ACLs or created separate ACL files, you can reference them in the obj.conf file. Do this in the PathCheck directive using the check-acl function. The line has the following syntax:

```
PathCheck fn="check-acl" acl="aclname"
```

The aclname is the unique name of an ACL as it appears in any ACL file.

For example, you might add the following lines to your obj.conf file if you want to restrict access to a directory using the ACL named testacl:

```
<Object ppath="/usr/ns-home/docs/test/**"
    PathCheck fn="check-acl" acl="testacl"
</Object>
```

In the previous example, the first line is the object that states which server resource you want to restrict access to. The second line is the PathCheck directive that uses the check-acl function to bind the ACL name (testacl) to the object in which the directive appears.

The testacl ACL can appear in any ACL file referenced in the init.conf file.

Configuring the ACL User Cache

By default, the Sun ONE Application Server caches user and group authentication results in the ACL user cache. This section describes the ACL user cache directives that are contained in the init.conf file:

- **ACLCacheLifetime**
• ACLUserCacheSize
• ACLGroupCacheSize

**ACLCacheLifetime**

ACLCacheLifetime determines the number of seconds before cache entries expire. Each time an entry in the cache is referenced, its age is calculated and checked against ACLCacheLifetime. The entry is not used if its age is greater than or equal to the ACLCacheLifetime. If this value is set to 0, the cache is turned off.

If you use a large number for this value, you may need to restart the Sun ONE Application Server when you make changes to the LDAP entries. For example, if this value is set to 120 seconds, the Sun ONE Application Server might be out of sync with the LDAP server for as long as two minutes. If your LDAP is not likely to change often, use a large number. Default value is 120.

**ACLUserCacheSize**

ACLUserCacheSize determines the number of users in the User Cache. New entries are added to the head of the list; entries at the end of this list are recycled to make new entries when the cache reaches its maximum size.

Default value is 200.

**ACLGroupCacheSize**

ACLGroupCacheSize determines how many group IDs can be cached for a single UID/cache entry. Unfortunately non-membership of a user in a group is not cached, and will result in several LDAP directory accesses on every request. Default value is 4.

For more information on ACL file directives, see the *Sun ONE Application Server Administrator’s Configuration File Reference*.

**Setting Access Control for a Server Instance**

You can create, edit, or delete access control for a specific server instance.

| NOTE | If deleting, you should not delete all the ACL rules from the ACL files. At least one ACL file containing a minimum of one ACL rule is required to start the server. Deleting all ACL rules and restarting the server will result in a syntax error. |
To create access control for a server instance, perform the following steps:

2. Select ACLs.
   The ACLs page displays the existing ACLs.
3. Click the ACL File to edit.
   The Edit ACL file page is displayed.
4. Click the Edit ACL File button.
   The Access Control List Management page is displayed.
5. Under the Option column choose one:
   - Add and enter the ACL file location.
   - Edit and select the ACL file from the drop-down menu.
   - Delete from the drop-down menu and select the ACL file.

The Access Control List Management page offers three options.

6. Select one of the following:
   - Pick a resource—To specify a wildcard pattern for files or directories (such as ".html"), choose a directory or a file name to restrict, or browse for a file or directory.
   - Pick an existing ACL—To select from a list of all the ACLs you have enabled. Existing ACLs you have not enabled will not appear in this list.
   - Type in the ACL name—To specify the named ACL.
The following table lists the resource wildcards you can use. The left column lists the resource wildcard and the right column describes its functionality.

<table>
<thead>
<tr>
<th>Resource wildcard</th>
<th>What it means</th>
</tr>
</thead>
<tbody>
<tr>
<td>Default</td>
<td>A named ACL created during installation that restricts write access so only users in the LDAP directory can publish documents.</td>
</tr>
<tr>
<td>Entire server</td>
<td>One set of rules determines the access to your entire web site, including any virtual servers you have running. To restrict access to a virtual server, specify the path of its document root.</td>
</tr>
<tr>
<td>/usr/Sun/server4/docs/cgi-bin/*</td>
<td>Controls access to all files and directories in the cgi-bin directory. You must specify an absolute path. On Windows, the path must include the drive letter.</td>
</tr>
<tr>
<td>uri=&quot;:/sales&quot;</td>
<td>Controls access to the sales directory in the document root. To specify URIs, create a named ACL.</td>
</tr>
</tbody>
</table>

7. Click Edit Access Control.

The Access Control Rules for: (server instance) appears.

![Access Control Rules](image)
8. Verify Access control is on, if not already selected.

9. To create or edit the ACL for this server instance, click Deny in the Action column.

10. Select Allow, if it isn’t already selected as the default, and click Update.

11. Click anyone in the Users/Groups column.

   The User/Group page appears.

**Figure 5-7**  Access Control User/Group Rules

<table>
<thead>
<tr>
<th>User/Group</th>
</tr>
</thead>
<tbody>
<tr>
<td>Anyone (No Authentication)</td>
</tr>
<tr>
<td>Authenticated people only</td>
</tr>
<tr>
<td>All in the authentication database</td>
</tr>
<tr>
<td>Only the following people</td>
</tr>
<tr>
<td>Group:</td>
</tr>
<tr>
<td>User:</td>
</tr>
</tbody>
</table>

Prompt for authentication: Sun ONE Application Server

Authentication Methods:
- Default
- Basic
- SSL
- Digest
- Other

Authentication Database:
- Default
- Other
- Default LDAP

12. Select which users and groups you will allow access to, and click Update.

   Clicking List for Group and User will provide lists for you to choose from.

13. Click anyplace in the From Host column.
14. Enter Host Names and IP Addresses allowed access, and click Update.

15. Click on all in the Rights column.

16. Select one of the following and then click Update:
   - All Access Rights
   - Only the following rights and check all appropriate rights for this user

17. (Optional) Click the x under the Extra column to add a customized ACL expression.

18. Put a check in the Continue column, if it isn’t already selected as the default.

   The server will evaluate the next line before determining if the user is allowed access. When creating multiple lines, work from the most general restrictions to the most specific ones.
19. (Optional) Click Response when denied.
   - Respond with the default file (redirection off)
   - Respond with the following URL or URI: (redirection on)

20. Enter the path to the absolute URL or a relative URI and click update.

21. Click Submit to store the new access control rules in the ACL file.

**NOTE**

Clicking Revert will remove all of the settings you’ve just created.

22. Repeat all steps above for each server instance you want to establish access control for.

23. When finished, click Apply.

24. Click OK.

25. Access App Server Instances and your server instance in the left pane, then click Apply Changes.

26. Stop and start the server for changes to take effect.

ACL settings can also be enabled on a per virtual server basis. To learn how this is done, see “Editing Access Control Lists for Virtual Servers” on page 132.

---

**Restricting Access to Areas of Your Server**

After you have completed the steps described in “Setting Access Control for a Server Instance” on page 116, you can take additional measures to restrict areas of your server as described in the following topics:

- Restricting Access to the Entire Server
- Restricting Access to a Directory (Path)
- Restricting Access to a URI (Path)
- Restricting Access to a File Type
- Restricting Access Based on Time of Day
- Restricting Access Based on Security
Restricting Access to the Entire Server

You may want to allow access to users in a group who access the server from a specific subdomain of your network.

To restrict access to the entire server (using the steps described for setting access control for a server instance), perform the following steps:

2. Select ACLs.
   The ACLs page displays the existing ACLs.
3. Click the ACL File to edit.
4. Click the Edit ACL File button.
   The Access Control List Management page is displayed.
5. Pick the entire server resource, and click Edit Access Control.
6. Add a new rule to deny access to all.
7. Add another new rule to allow access to a specific group.
8. Enter a wildcard pattern for the host names of the computers to be allowed.
   For example, *.employee.sun.com
10. Click OK.
11. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
12. Stop and start the server for changes to take effect.

Restricting Access to a Directory (Path)

You can allow users in a group to read or run applications in directories, and its subdirectories and files, that are controlled by an owner of the group. For example, a project manager might update status information for a project team to review.

To restrict access to a directory on the server (using the steps described for setting access control for a server instance), perform the following steps:

2. Select ACLs.

The ACLs page displays the existing ACLs.

3. Click the ACL file to edit.

4. Click the Edit ACL File button.

The Access Control List Management page is displayed.

5. Browse the Pick a Resource section and select the directory you want to restrict.

The directories in the server’s document root are displayed. Once selected, the Editing drop-down list displays the absolute path to the directory.

6. Click Edit Access Control.

7. Create a new rule and leave the defaults to deny access to everyone from everywhere.

8. Create another new rule allowing users in a specific group to have read and execute rights only.

9. Create a third line to allow a specific user to have all rights.

10. Unselect Continue for the second and third lines and click Update.

11. Click OK.

12. Access App Server Instances and your server instance in the left pane, then click Apply Changes.

13. Stop and start the server for changes to take effect.

An absolute path to the file or directory is created in the docroot directory. An entry similar to the following would appear in the ACL file:

```
 acl "path=d:/Sun/suitespot/docroot1/sales/";
```
Restricting Access to a URI (Path)

You can use a URI to control access to a single user's content on the server. URIs are paths and files relative to the server's document root directory. Using URIs is an easy way to manage your server's content if you frequently rename or move all or part of it (for example, for disk space). It's also a good way to handle access control if you have additional document roots.

To limit access to a URI (using the steps described for setting access control for a server instance), perform the following steps:

2. Select ACLs.
   The ACLs page displays the existing ACLs.
3. Click the ACL file to edit.
4. Click the Edit ACL File button.
   The Access Control List Management page is displayed.
5. Enter the URI you want to restrict in the Type in the ACL name section.
   For example: uri=/my_directory.
6. Click Edit Access Control.
7. Create a new rule to allows all users read access.
8. Create another new rule to allow access for the owner of the directory.
9. Uncheck Continue for both the first and second rules.
10. Click OK.
11. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
12. Stop and start the server for changes to take effect.

A path for the URI is created relative to the document root. The entry in the ACL file would appear as follows: acl "uri=/my_directory";
Restricting Access to Areas of Your Server

Restricting Access to a File Type

You can limit access to file types on your server or web site. For example, you might want to allow only specific users to create programs that run on your server. Anyone would be able to run the programs, but only specified users in the group would be able create or delete them.

To limit access to a file type (using the steps described for setting access control for a server instance), perform the following steps:

2. Select ACLs.
   - The ACLs page displays the existing ACLs.
3. Click the ACL file to edit.
4. Click the Edit ACL File button.
   - The Access Control List Management page is displayed.
5. Click Wildcard in the Pick a resource section and enter a wildcard pattern.
   - For example, *.cgi.
6. Click Edit Access Control.
7. Create a new rule to allow read access to all users.
8. Create another rule that allows write and delete access only to a specified group.
9. Click OK.
10. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
11. Stop and start the server for changes to take effect.

For file type restriction, you would leave both continue boxes checked. If a request for a file comes in, the server will then check the ACL for the file type first.

A Pathcheck function is created in the obj.conf file that may include wildcard patterns for files or directories. The entry in the ACL file would appear as follows:

```
 acl ".*\.cgi"
```
Restricting Access Based on Time of Day

You can restrict write and delete access to the server or during specified hours or on specified days. You might use this to prevent people from publishing documents during working hours when people might be accessing the files.

To limit access based on time of day (using the steps described for setting access control for a server instance), perform the following steps:

2. Select ACLs.
   The ACLs page displays the existing ACLs.
3. Click the ACL file to edit.
4. Click the Edit ACL File button.
   The Access Control List Management page is displayed.
5. Select the entire server from the drop-down list in Pick a Resource and click Edit Access Control.
6. Create a new rule allowing read and execute rights to all.
   This means that if a user wants to add, update, or delete a file or directory, this rule won’t apply and the server will search for another rule that matches.
7. Create another new rule denying write and delete rights to all.
8. Click X link to create a customized expression.
9. Enter the days of the week and the times of day to be allowed. For example:
   
   ```
   user = "anyone" and 
   dayofweek = "sat,sun" or 
   (timeofday >= 1800 and 
   timeofday <= 600)
   ```
   
   The Unrecognized Expressions message will be displayed in the Users/Groups and From Host fields when you create a custom expression.
10. Click OK.
11. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
12. Stop and start the server for changes to take effect.
Any errors in the custom expression will generate an error message. Make corrections and submit again.

Restricting Access Based on Security

You can configure SSL and non-SSL HTTP Listeners for the same server instance. Restricting access based on security allows you to create protection for resources that should only be transmitted over a secure channel.

To limit access based on security (using the steps described for setting access control for a server instance), perform the following steps:

2. Select ACLs.
   The ACLs page displays the existing ACLs.
3. Click the ACL file to edit.
4. Click the Edit ACL File button.
   The Access Control List Management page is displayed.
5. Select the entire server from the drop-down list in Pick a Resource and click Edit Access Control.
6. Create a new rule allowing read and execute rights to all.
   This means that if a user wants to add, update, or delete a file or directory, this rule won’t apply and the server will search for another rule that matches.
7. Create another new rule denying write and delete rights to all.
8. Click X link to create a customized expression.
9. Enter \texttt{ssl="on"}. For example:
   \begin{verbatim}
   user = "anyone" and ssl="on"
   \end{verbatim}
10. Click OK.
11. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
12. Stop and start the server for changes to take effect.
   Any errors in the custom expression will generate an error message. Make corrections and submit again.
Turning Off Access Control

When you uncheck the option labeled Access Control Is On, you’ll receive a prompt asking if you want to erase records in the ACL. When you click OK, the server deletes the ACL entry for that resource from the ACL file.

If you want to deactivate an ACL, you can comment out the ACL lines in the generated-server-id.acl file by putting a # sign at the beginning of each line.

NOTE  This access control is in addition to the user being in the administrators group. The Admin Server first verifies that a user (other than superuser) is in the administrators group, then evaluates the access control rules.

Responding When Access is Denied

The Sun ONE Application Server provides the following default message when access is denied:

FORBIDDEN. Your client is not allowed access to the restricted object.

You can choose a different response, or you can create a different message for each access control object.

To change the message sent for a particular ACL, perform the following steps:

1. In the ACL page, click the Response when denied link
2. In the lower frame, check Respond with the following file.
3. Enter the path to the absolute URL or a relative URI and click update.
   Make sure users have access to the URL or URI they are redirected to.
4. Click Update.
5. Click Submit in the top frame to submit the access control rule.
6. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
7. Stop and start the server for changes to take effect.
Controlling Access for Virtual Servers

Access control information in Sun ONE Application Server can come from a per-virtual server ACL file and .htaccess files in the document directories.

Your server.xml file can contain one or more acl tags which define an ID associated to a particular standard ACL file. For example:

```
<acl id="standard" file="standard.acl">
```

For virtual servers to use access control, you must create a reference to one or more ACL file IDs in their acls attribute. Example:

```
<virtual-server acls="standard">
```

This configuration allows multiple virtual servers to share the same ACL file. If you want to require user-group authentication for a virtual server, you must add one or more auth-db tags to its definition. These auth-db tags create a connection between the database names in your ACL file and the actual databases found in dbswitch.conf.

The following example maps the ACLs with no ‘database’ attribute to the ‘default’ database in dbswitch.conf file.

```
<virtual-server>
    <auth-db id="default" database="default"/>
</virtual-server>
```

The following topics address virtual server access:

- Accessing Databases from Virtual Servers
- Editing Access Control Lists for Virtual Servers

Accessing Databases from Virtual Servers

You can globally define user authentication databases in the dbswitch.conf file, which is only read at server startup. The baseDN of the LDAP URL in the dbswitch.conf file defines the global root of all accesses to the database. This maintains backward compatibility. For most new installations, the baseDN is empty. You can also use the Administration interface to set up authentication databases for your virtual servers.

**NOTE**

When you use the App Server Instance->Security->Configure Directory Service page in Administration interface to configure the directory, the dbswitch.conf file is updated.
The following sections provide instructions:

- Using the dbswitch.conf File
- Creating a New Authentication Database
- Specifying Databases in the User Interface

Using the dbswitch.conf File

The dcsuffix attribute for LDAP databases in dbswitch.conf defines the root of the DC tree according to the Sun ONE Directory Server schema. It is relative to the baseDN in the LDAP URL. When the dcsuffix attribute is present, the LDAP database is Sun ONE Directory Server schema compliant, and the behavior of some operations changes. For more information about the Sun ONE Directory Server schema, and an example, see the Sun ONE Application Server Developer’s Guide to NSAPI.

For every virtual server, you can define one or more auth-db blocks that point to one of the directories, and you can define additional information. The auth-db blocks ID can be referenced in the database parameter of the ACL. If a virtual server has no auth-db blocks, user or group-based ACLs will fail.

auth-db tags define an additional layer of indirection between the database attribute of an ACL and the dbswitch.conf file. This layer of indirection adds the necessary protection for the server administrator to have full control over which databases the virtual server administrators have access to.

For more information on auth-db, see the Sun ONE Application Server Developer’s Guide to NSAPI.

Creating a New Authentication Database

To create a new authentication database in the Administration interface, perform the following steps:

1. Access App Server Instances and HTTP Server in the left pane.
2. Access Virtual Servers and open the virtual server you want (expand the node).
3. Under the virtual server in the left pane, click Authentication Databases. The Authentication Databases page lists the current databases.
4. To create a new authentication database, click New. The Authentication Databases New page is displayed.
Controlling Access for Virtual Servers

5. Enter the information as described in the online help.

6. Click OK.

7. Access App Server Instances and your server instance in the left pane, and click Apply Changes.

8. Stop and start the server for changes to take effect.

Specifying Databases in the User Interface

After you have created one or more user authentication databases in the dbswitch.conf file, or using the Administration interface, you can use the Administration interface to configure which databases each of your virtual servers will use for authentication. You can also use the Administration interface to add a newly-created database definition from the dbswitch.conf file for the virtual server to authenticate against. This is done by associating the newly-created authentication database with an ACL and using the ACL with the virtual server.

<table>
<thead>
<tr>
<th>NOTE</th>
<th>To use ACLs with a virtual server, an authentication database must be associated with the virtual server and the ACL.</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>An instance is always created with a default virtual server and a default ACL. If acl is enabled, the default virtual server is already set up to use the default authentication database.</td>
</tr>
<tr>
<td></td>
<td>For any new virtual servers you want to associate with ACLs, the authentication database association is not done automatically. In this case, you must create a new authentication database entry for the new virtual server. The form of the entry will depend on the ACL being used.</td>
</tr>
</tbody>
</table>

Editing Access Control Lists for Virtual Servers

ACLs for virtual servers are created for the server instance that the virtual server resides in. Virtual server ACL settings default to those created for the server instance. However, you can choose to define a new ACL or edit an existing one.

To edit an existing ACL for a virtual server, perform the following steps:

1. Access App Server Instances and HTTP Server in the left pane.

2. Select ACLs and click the ACL you want to edit.

3. Click Edit ACL File
5. Edit the information as described in the online help.
7. Select Virtual Server and click the server instance.
8. On the edit page, under the section where the ACLs are listed, choose whichever ACL you want to associate with the virtual server.
9. Access App Server Instances and your server instance in the left pane, then click Apply Changes.
10. Stop and start the server for changes to take effect.

---

### Using htaccess Files

Server content is seldom managed entirely by one person. You may need to allow end users to access a subset of configuration options so that they can configure what they need to, without giving them access to the Sun ONE Application Server. The subset of configuration options is stored in dynamic configuration files.

The Sun ONE Application Server supports *htaccess* dynamic configuration files. You can enable *htaccess* files either through the user interface or by manually changing the configuration files. The *htaccess* plug-in is in the `install_dir/lib` directory.

You can use *htaccess* files in combination with the server’s standard access control. The standard access controls are always applied before any *htaccess* access control, regardless of the ordering of PathCheck directives.

**NOTE**

Do not require user authentication with both standard and *htaccess* access control when User-Group authentication is Basic. You could use SSL client authentication using the standard server access control, and also require HTTP Basic authentication using an *htaccess* file.

This section addresses the following topics:

- Enabling *htaccess* from the User Interface
Using htaccess Files

- Enabling htaccess from init.conf
- Using htaccess-register
- Supported htaccess Directives

Enabling htaccess from the User Interface

To configure your Sun ONE Application Server to use htaccess, perform the following steps:

2. Select a virtual server instance.

   The Additional Documentation Directories page is displayed.

4. Click the htaccess Configuration link.

   The htaccess Configuration page is displayed.
5. Select the server to edit by:
   - Choosing the entire server or a specific server from the drop-down list
   - Choosing the directory and files to edit by clicking Browse
   - Choosing a wildcard pattern to edit by clicking Wildcard

6. Select Yes to activate .htaccess.

7. Enter the file name where you want the .htaccess configuration to be added.

8. Click OK.

9. Access App Server Instances and your server instance in the left pane, then click Apply Changes.

10. Stop and start the server for changes to take effect.

**Enabling .htaccess from init.conf**

To manually enable your server to use the .htaccess, you need to first modify the server’s init.conf file to load, initialize, and activate the plug-in.
Using htaccess Files

1. Open init.conf in the instance_dir/config directory.

2. After the other initialization directives, add the following lines:
   a. For UNIX:
      - Init fn="load-modules"
        func="htaccess-init,htaccess-find,htaccess-register"
        shlib="install_dir/lib/htaccess.so" NativeThread="no"
        Init fn="htaccess-init"
   b. For Windows:
      - Init fn="load-modules"
        func="htaccess-init,htaccess-find,htaccess-register"
        NativeThread="no"
        Init fn="htaccess-init"

3. (Optional) Edit the final line to read:
   - Init fn="htaccess-init"[groups-with-users=yes]

4. Click File/Save.

5. Open obj.conf file.

6. Add the PathCheck directive as the last directive in the object.
   a. To activate htaccess file processing for all directories managed by a virtual server, add the PathCheck directive to the default object in the obj.conf file:
      <Object name="default">
      ...
      PathCheck fn="htaccess-find"
      ...
      </Object>

     htaccess processing should be the last PathCheck directive in the object.

   b. To activate htaccess processing for particular server directories, place the PathCheck directive in the corresponding definition in init.conf.

7. To name your htaccess files something other than htaccess, you must specify the file name in the PathCheck directive using the following format:
   - PathCheck fn="htaccess-find" filename="filename"
Subsequent access to the server will be subject to `.htaccess` access control in the specified directories. For example, to restrict write access to `.htaccess` files, create a configuration style for them, and apply access control to that configuration style. For more information, see Applying Configuration Styles.

### Using `.htaccess-register`

The `.htaccess-register` allows you to create your own authentication methods. Like Apache, you can create external authentication modules and plug them into the `.htaccess` module using `.htaccess-register`.

You can use external modules to create one or more new directives. For example, you might specify the user database for authentication. The directives may not appear within `<Limit>` or `<LimitExcept>` tags.

The following example shows an `.htaccess` file:

```plaintext
<Limit> GET POST
order deny,allow
deny from all
allow from all
</Limit>
<Limit> PUT DELETE
order deny,allow
deny from all
</Limit>
AuthName mxyzptlk.kawaii.com
AuthUserFile /server_root/mxyz-docs/service.pwd
AuthGroupFile /server_root/mxyz-docs/service.grp
```

### Supported `.htaccess` Directives

The following topics address the `.htaccess` directives that are supported by the Sun ONE Application Server:

- `allow`
- `deny`
Using htaccess Files

- AuthGroupFile
- AuthName
- AuthType
- <Limit>
- <LimitExcept>
- order
- require

**allow**
Allows access to the specified hosts. Normally appears inside a `<Limit>` range.

**Syntax**

```
allow from_host
```

where:

```
from_host is all, to allow access from all client hosts
from_host is all or the last part of a DNS host name
from_host is a full or partial IP address
```

Does not need to be enclosed within a `<Limit>` or `<LimitExcept>` range but usually is.

**deny**
Denies access to the specified host(s). Normally appears inside a `<Limit>` range.

**Syntax**

```
deny from_host
```

where:

```
deny from_host is all, to deny access from all client hosts
deny from_host is all or the last part of a DNS host name
deny from_host is a full or partial IP address
```

Does not need to be enclosed in a `<Limit>` `<LimitExcept>` range but usually is.
AuthGroupFile
Specifies that the named group file to be used for any group definitions referenced in a require group directive. If the file name specified in an AuthGroupFile directive is the same as the file name in an AuthUserFile directive, the file is assumed to contain users and groups in the format:

username:DES-encrypted-password:comma-separated-list-of-groups

**Syntax**

```plaintext
AuthGroupFile file_name
```

where:

- `file_name` is the name of file containing group definitions in this form:
  ```plaintext
groupname: user user
  
  Must not appear within a `<Limit>` or `<LimitExcept>` range.
  
AuthUserFile
Specifies that the named user file is to be used for any user names referenced in a require user or require valid-user directive.

Note that the use of `groups-with-users=yes` in the Init `fn=htaccess-init` directive in `obj.conf`, or specifying an AuthGroupFile directive with the same file name, causes that file to be assumed to be in the format:

username:DES-encrypted-password:comma-separated-list-of-groups

**Syntax**

```plaintext
AuthUserFile filename
```

where:

- `filename` is the name of file containing user definitions in this form:
  ```plaintext
  username:password
  
  Must not appear within a `<Limit>` or `<LimitExcept>` range.
AuthName
The authentication realm string typically appears in the prompt for user name and password on the client side. It may affect caching of user name and password on the client.

Syntax
AuthName authentication_realm

where

authentication_realm is a string identifying an authorization realm to be associated with any request for user authentication.

Must not appear within a <Limit> or <LimitExcept> range.

AuthType
Specifies the user authentication method as HTTP Basic Authentication, the only method currently supported.

Syntax
AuthType Basic

Must not appear within a <Limit> or <LimitExcept> range.

<Limit>
Applies the enclosed directives only for requests using the specified HTTP methods.

Syntax
<Limit method method ...>

allow, deny, order, or require directives

</Limit>

where

method is an HTTP method such as GET, POST, or PUT. Any method that the web server understands can be used here.

<LimitExcept>
Applies the enclosed directives only for requests types not matching the specified HTTP methods.
Using htaccess Files

Chapter 5 Administering HTTP Server Access Control 141

Syntax

```html
<LimitExcept method method ...>
allow, deny, order, or require directives
</LimitExcept>
```

where

- `method` is an HTTP method such as GET, POST, or PUT. Any method that the web server understands can be used here.

order

- Allows, denies, evaluates allow directives, and then deny directives.
- Denies, allows, evaluates deny directives, and then allow directives.
- Mutual-failure denies access for a host listed in both allow and deny directives, regardless of their ordering.

Syntax

```html
order ordering
```

where

- `ordering` is one of:
  - allow, deny
  - deny, allow
  - mutual-failure

Does not need to be enclosed within a `<Limit>` or `<LimitExcept>` range, but usually is.

require

- Requires group requires the authenticated user to be a member of one of the specified groups.
- Requires user requires the authenticated user to be one of the specified users.
- Requires valid-user requires an authenticated user

Syntax

```html
requires group groupname groupname
requires user username username
```
requires valid-user

Does not need to be enclosed within a `<Limit>` or `<LimitExcept>` range, but usually is.
