Preface

This manual describes the programmatic interfaces to transport services in the Solaris operating system.

In this guide the terms SunOS and Solaris are used interchangeably because the interfaces described in this manual are common to both. Solaris 2.5, SunSoft’s distributed computing operating environment, is a superset of SunOS. It is comprised of SunOS release 5.5 with ONC+, OpenWindows, ToolTalk, DeskSet, OPEN LOOK®, and other utilities. This release of Solaris is fully compatible with System V, Release 4 (SVR4) and conforms to the third edition of the System V Interface Description (SVID). It supports all System V network services.

Who Should Use This Book

The guide assists you in developing a networked, distributed application in the Solaris operating system.

Use of this guide assumes basic competence in programming, a working familiarity with the C programming language, and a working familiarity with the UNIX® operating system. Previous experience in network programming is helpful, but is not required to use this manual.
How This Book Is Organized

Chapter 1, “Introduction to Network Programming Interfaces,” gives a high-level introduction to networking concepts and the topics covered in this book.

Chapter 2, “Programming With Sockets,” describes the socket interface at the transport layer.

Chapter 3, “Programming With the Transport Layer Interface (TLI),” describes the UNIX System V Transport Interface.

Chapter 4, “Transport Selection and Name-to-Address Mapping,” describes the network selection mechanisms used by applications in selecting a network transport and its configuration.

Introduction to Network Programming Interfaces

This chapter is a high-level introduction to this book. It is most helpful to those who are new to network programming and for those who would like a brief overview of network programming in the Solaris environment.

The Client-Server Model

The client-server model is a common method of implementing distributed applications. Figure 1-1 shows a typical networked environment where different services are provided and used by client and server processes.

Figure 1-1  Client-Server Model

A server is a process that provides a service that can be used by other processes. Examples are a file service such as the NFS filesystem, which provides access to files and directories to other processes or systems, and a display service, such as the X Window System™ environment, which provides access to a high resolution display device. A server process normally listens at a known address for service requests. When a request is received, the server is unblocked and serves the client requests.
A client is a process that makes use of a service, or services, provided by other processes. An individual system may be both client and server for different services, or even for the same service. For example, a print server receives print requests, but may need to issue a client request to a file server to access a file.

**Network Services in the Solaris Environment**

The Solaris environment provides a large number of networking services based upon the Internet protocol suite (also loosely referred to as the TCP/IP protocol suite, described on page 7). These services are listed in Table 1-1.

<table>
<thead>
<tr>
<th>Service</th>
<th>Service Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ARP</td>

<td>Trivial File Transfer Protocol. Simpler but less secure version of FTP.</td>
</tr>
<tr>
<td>DNS</td>
<td>Domain Name System. Name service used by the Internet. Uses both TCP and UDP protocols.</td>
</tr>
<tr>
<td>BOOTP</td>
<td>Boot Protocol. Allows diskless systems to boot from a remote server.</td>
</tr>
</tbody>
</table>
In addition to the base protocols and services it also provides some commonly used utility applications (such as \texttt{rcp}, \texttt{rsh}, and \texttt{rlogin}) built on top of the Internet protocol suite.

The Solaris computing environment also provides heterogeneous distributed computing facilities in its ONC+ architecture. The ONC+ architecture is a set of services built on top of Sun’s remote procedure call (RPC) protocol. The programming interfaces available in the ONC+ platform are described fully in the \textit{ONC+ Developer’s Guide}.

**Layered Protocols**

A \textit{protocol} is a set of rules and conventions that describes how information is to be exchanged between two entities. Networking tasks often require more than one protocol in order to perform a task, such as file transfer.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{layered_protocols.png}
\caption{Layered Protocols}
\end{figure}
These protocols can be conceptualized in a model comprising of a series of layers, each of which deals with one functional aspect of the communication. Each layer has a well-defined interface to the layer immediately above and below it. Figure 1-2 on page 4 shows that data is passed through the interface to the layer below. Each layer adds on the necessary information in order for the receiving system to understand and be able to route the data. At the bottom layer, the data is physically transmitted across some medium to the receiving system. It is passed up through the layers, with each layer removing the control information added by the layers on the sending system. A set of protocols layered in this way is called a protocol stack. A layer can have more than one protocol defined for it.

Two well-known reference models are discussed in the following sections: OSI reference model and Internet (TCP/IP) protocol suite.

**Open Systems Interconnection Reference Model**

The open systems interconnection (OSI) reference model is used to conceptualize network service architectures and as a convenient framework for explaining networking concepts. It is not the basis for the Internet protocol suite, but the Internet protocol’s four-layer model can be mapped to the more general OSI reference model. The OSI protocol suite follows the OSI reference model closely.

The OSI reference model divides networking functions into seven layers, as shown in Figure 1-3 on page 6. Each protocol layer performs services for the layer above it. The ISO definition of the protocol layers gives designers considerable freedom in implementation. For example, some applications skip the presentation and session layers to interface directly with the transport layer. In this case, the application performs any needed presentation and session services.

Industry standards have been or are being defined for each layer of the reference model.
Figure 1-3  OSI Reference Model

Layer 1: Physical Layer
The hardware layer of the model. It specifies the physical media connecting hosts and networks, and the procedures used to transfer data between machines using a specified media.

Layer 2: Data-Link Layer
Manages the reliable delivery of data across the physical network. For example, it provides the abstraction of a reliable wire over the potentially unreliable physical layer.

Layer 3: Network Layer
This layer is responsible for routing machine-to machine communications. It determines the path a transmission must take, based upon the destination machine’s address.

Layer 4: Transport Layer
This layer provides end-to-end sequenced delivery of data. It is the lowest layer that provides applications and higher layers with end-to-end service. This layer hides the topology and characteristics of the underlying network from users. It provides reliable end-to-end data delivery if the service characteristics require it.
Layer 5: Session Layer
The session layer manages sessions between cooperating applications.

Layer 6: Presentation Layer
Performs the translation between the data representation local to the computer and the processor-independent format that is sent across the network. It can also negotiate the transfer formats in some protocol suites.

Layer 7: Application Layer
At this top layer are the user-level programs and network services. Some examples are telnet, ftp, and tftp.

Internet Protocol Suite (TCP/IP)
TCP/IP is a widely used protocol suite for internetworking, a term that refers to the connection of various physical networks to form one large virtual network. Any system connected to a TCP/IP internetwork should be able to communicate with any other system within the internetwork, regardless of which physical network the systems actually reside. Networks are linked together by a system that functions as a gateway between systems.

TCP/IP has a closely associated history with UNIX systems, but the protocols themselves are independent of the operating system, the network topology, and the connection medium. TCP/IP operates on Ethernet and Token Ring local area networks (LANs), across wide area links such as X.25, and serial connections. Support for TCP/IP networking has been an integral part of SunOS in all versions of the operating system.

TCP/IP Protocol Stack
The TCP/IP protocol suite can be described using a reference model similar to the OSI seven layer reference model. Figure 1-4 shows the corresponding OSI layers and some example services at each layer. TCP/IP does not delineate the presentation and session layers as the OSI model does; application code provides the necessary presentation or session functionality.
The core protocol is IP, which corresponds to the network layer in the OSI reference model. IP provides a connectionless, “unreliable” packet-forwarding service which routes packets from one system to another.

Built on top of IP are the two transport protocols, TCP, a connection-oriented transport service (COTS), and the user datagram protocol (UDP), a connectionless transport service (CLTS).

The TCP/IP protocols are defined in documents called Requests for Comments (RFCs). RFCs are maintained by the Network Information Center (NIC), the organization that handles address registration for the Internet.

RFCs define a number of applications, the most widely used being telnet, a terminal emulation service on remote hosts, and ftp, which allows files to be transferred between systems.

**Connection Oriented and Connectionless Protocols**

A number of characteristics can be used to describe communications protocols. The most important is the distinction between connection-oriented transport (COTS) and connectionless transport (CLTS).
Connection-Oriented Protocols

TCP is an example of a connection-oriented protocol. It requires a logical connection to be made between two processes before data can be exchanged. The connection must be maintained during the time communication is taking place and then released afterwards. The process is much like a telephone call, where a virtual circuit is established—the caller must know the person’s telephone number and the person must answer the phone before the message can be delivered.

TCP/IP is also a connection-oriented transport with orderly release. With orderly release, any data remaining in the buffer will be sent before the connection is terminated. The release is accomplished in a four-way handshake between client and server processes. The connection-oriented protocols in the OSI protocol suite do not support orderly release. Applications perform any handshake necessary for ensuring orderly release.

Connectionless Protocols

In contrast, connectionless protocols allow data to be exchanged without setting up a link between processes. Each unit of data is transferred independently with all the necessary information to route it to the intended destination. UDP is a connectionless protocol. It is known as a datagram protocol because it is analogous to sending a letter where you don’t acknowledge receipt.
Choosing Between COTS and CLTS

The application developer must decide which type of protocol works best for the particular application. Some questions to ask are:

- How reliable must the connection be?
- Must the data arrive in the same order as it was sent?
- Must it be able to handle duplicate data packets?
- Must it have flow control?
- Must it acknowledge the messages it receives?
- What kind of service can the application live with?
- What level of performance is required?

Broadcasting and tftp are other examples of applications that use CLTS. NFS is one example of an application that uses a connectionless protocol such as UDP. However, recent versions of NFS also operate over TCP.

On the other hand, if reliability is paramount, then COTS is better. telnet, rlogin, and ftp are examples of services that use COTS.
This chapter presents the socket interface and illustrates them with sample programs. The programs demonstrate the Internet domain sockets.

**Sockets are Multithread Safe**

The interface described in this chapter is multithread safe. Applications that contain socket function calls can be used freely in a multithreaded application.

**SunOS Binary Compatibility**

There are two major changes from SunOS 4.x that hold true for Solaris 2.x releases. The binary compatibility package allows SunOS 4.x–based dynamically linked socket applications to run in Solaris 2.x.

1. You must explicitly specify the socket library (-lsocket) on the compilation line.
2. You must recompile all SunOS 4.x socket-based applications with the socket library to run under Solaris 2.x. The differences in the two socket implementations are outlined in “Moving Socket Applications to Solaris 2.x” on page 54.

What Are Sockets

Sockets are the 4.2 Berkeley software distribution (BSD) UNIX interface to network protocols. It has been an integral part of SunOS releases since 1981. They are commonly referred to as Berkeley sockets or BSD sockets. Since the days of early UNIX, applications have used the file system model of input/output to access devices and files. The file system model is sometimes called open-close-read-write after the basic system calls used in this model. However, the interaction between user processes and network protocols are more complex than the interaction between user processes and I/O devices.

A socket is an endpoint of communication to which a name can be bound. A socket has a type and one associated process. Sockets were designed to implement the client-server model for interprocess communication where:

- The interface to network protocols needs to accommodate multiple communication protocols, such as TCP/IP, XNS, and UNIX domain.
- The interface to network protocols need to accommodate server code that waits for connections and client code that initiates connections.
- They also need to operate differently, depending on whether communication is connection-oriented or connectionless.
- Application programs may wish to specify the destination address of the datagrams it delivers instead of binding the address with the open() call.

To address these issues and others, sockets are designed to accommodate network protocols, while still behaving like UNIX files or devices whenever it makes sense to. Applications create sockets when they need to. Sockets work with the open(), close(), read(), and write() system calls, and the operating system can differentiate between the file descriptors for files, and file descriptors for sockets.

UNIX domain sockets are named with UNIX paths. For example, a socket may be named /tmp/foo. UNIX domain sockets communicate only between processes on a single host. Sockets in the UNIX domain are not considered part
of the network protocols because they can only be used to communicate with processes within the same UNIX system. They are rarely used today and are only briefly covered in this manual.

**Socket Libraries**

The socket interface routines are in a library that must be linked with the application. The libraries `libsocket.so` and `libsocket.a` are contained in `/usr/lib` with the rest of the system service libraries. The difference is that `libsocket.so` is used for dynamic linking, whereas `libsocket.a` is used for static linking. Static linking is strongly discouraged.

**Socket Types**

Socket types define the communication properties visible to a user. The Internet domain sockets provide access to the TCP/IP transport protocols. The Internet domain is identified by the value `AF_INET`. Sockets exchange data only with sockets in the same domain.

Three types of sockets are supported:

1. Stream sockets allow processes to communicate using TCP. A stream socket provides bidirectional, reliable, sequenced, and unduplicated flow of data with no record boundaries. Once the connection has been established, data can be read from and written to these sockets as a byte stream. The socket type is `SOCK_STREAM`.

2. Datagram sockets allow processes to use UDP to communicate. A datagram socket supports bidirectional flow of messages. A process on a datagram socket may receive messages in a different order from the sending sequence and may receive duplicate messages. Record boundaries in the data are preserved. The socket type is `SOCK_DGRAM`.

3. Raw sockets provide access to ICMP. These sockets are normally datagram oriented, although their exact characteristics are dependent on the interface provided by the protocol. Raw sockets are not for most applications. They are provided to support developing new communication protocols or for access to more esoteric facilities of an existing protocol. Only superuser processes may use raw sockets. The socket type is `SOCK_RAW`. See “Selecting Specific Protocols” on page 46 for further information.
Socket Tutorial

This section covers the basic methodologies of using sockets.

Socket Creation

The `socket()` call creates a socket,

```c
s = socket(domain, type, protocol);
```

in the specified domain and of the specified type. If the protocol is unspecified (a value of 0), the system selects a protocol that supports the requested socket type. The socket handle (a file descriptor) is returned.

The domain is specified by one of the constants defined in `<sys/socket.h>`. For the UNIX domain the constant is `AF_UNIX`. For the Internet domain it is `AF_INET`. Constants named `AF_<suite>` specify the address format to use in interpreting names.

Socket types are defined in `<sys/socket.h>`, `SOCK_STREAM`, `SOCK_DGRAM`, or `SOCK_RAW` is supported by `AF_INET` and `AF_UNIX`. The following creates a stream socket in the Internet domain:

```c
s = socket(AF_INET, SOCK_STREAM, 0);
```

This call results in a stream socket with the TCP protocol providing the underlying communication. A datagram socket for intramachine use is created by:

```c
s = socket(AF_UNIX, SOCK_DGRAM, 0);
```

Use the default protocol (the `protocol` argument is 0) in most situations. You can specify a protocol other than the default, as described in “Advanced Topics” on page 41.

Binding Local Names

A socket is created with no name. A remote process has no way to refer to a socket until an address is bound to it. Communicating processes are connected through addresses. In the Internet domain, a connection is composed of local and remote addresses, and local and remote ports. In the UNIX domain, a connection is composed of (usually) one or two path names. In most domains, connections must be unique.
In the Internet domain, there may never be duplicate ordered sets, such as:
<protocol, local address, local port, foreign address, foreign port>. UNIX domain sockets need not always be bound to a name, but when
bound there may never be duplicate ordered sets such as: <local pathname,
foreign pathname>. The path names may not refer to existing files.

The bind() call allows a process to specify the local address of the socket. This
forms the set <local address, local port> (or <local pathname>)
while connect() and accept() complete a socket’s association. The bind() system call is used as follows:

bind (s, name, namelen);

s is the socket handle. The bound name is a byte string that is interpreted by
the supporting protocol(s). Internet domain names contain an Internet address
and port number. UNIX domain names contain a path name and a family.

Code Example 2-1 binds the name /tmp/foo to a UNIX domain socket.

Code Example 2-1  Bind Name to Socket

```
#include <sys/un.h>
...

struct sockaddr_un addr;
...

strcpy(addr.sun_path, "/tmp/foo");
addr.sun_family = AF_UNIX;
bind (s, (struct sockaddr *) &addr,
     strlen(addr.sun_path) + sizeof (addr.sun_family));
```

Note that in determining the size of an AF_UNIX socket address, null bytes are
not counted, which is why strlen() use is fine.

The file name referred to in addr.sun_path is created as a socket in the
system file name space. The caller must have write permission in the directory
where addr.sun_path is created. The file should be deleted by the caller
when it is no longer needed. AF_UNIX sockets can be deleted with unlink().

Binding an Internet address is more complicated. The call is similar:

```
#include <sys/types.h>
#include <netinet/in.h>
...

struct sockaddr_in sin;
...

bind (s, (struct sockaddr *) &sin, sizeof sin);
```
The content of the address \texttt{sin} is described in “Address Binding” on page 47, where Internet address bindings are discussed.

\textbf{Connection Establishment}

Connection establishment is usually asymmetric, with one process acting as the client and the other as the server. The server binds a socket to a well-known address associated with the service and blocks on its socket for a connect request. An unrelated process can then connect to the server. The client requests services from the server by initiating a connection to the server’s socket. On the client side, the \texttt{connect()} call initiates a connection. In the UNIX domain, this might appear as:

```c
struct sockaddr_un server;
server.sun.family = AF_UNIX;
...
connect(s, (struct sockaddr *)&server,
       strlen(server.sun_path) + sizeof (server.sun_family));
```

while in the Internet domain it might be:

```c
struct sockaddr_in server;
...
connect(s, (struct sockaddr *)&server, sizeof server);
```

If the client’s socket is unbound at the time of the connect call, the system automatically selects and binds a name to the socket. See “Signals and Process Group ID” on page 45. This is the usual way that local addresses are bound to a socket on the client side.

In the examples that follow, only \texttt{AF_INET} sockets are described.

To receive a client’s connection, a server must perform two steps after binding its socket. The first is to indicate how many connection requests can be queued. The second step is to accept a connection:

```c
struct sockaddr_in from;
...
listen(s, 5); /* Allow queue of 5 connections */
fromlen = sizeof(from);
newsock = accept(s, (struct sockaddr *)&from, &fromlen);
```

\texttt{s} is the socket bound to the address to which the connection request is sent. The second parameter of \texttt{listen()} specifies the maximum number of outstanding connections that may be queued. \texttt{from} is a structure that is filled
with the address of the client. A NULL pointer may be passed. `fromlen` is the length of the structure. (In the UNIX domain, `from` is declared a `struct sockaddr_un`.)

`accept()` normally blocks. `accept()` returns a new socket descriptor that is connected to the requesting client. The value of `fromlen` is changed to the actual size of the address.

There is no way for a server to indicate that it will accept connections only from specific addresses. The server can check the from-address returned by `accept()` and close a connection with an unacceptable client. A server can accept connections on more than one socket, or avoid blocking on the `accept` call. These techniques are presented in “Advanced Topics” on page 41.

Connection Errors

An error is returned if the connection is unsuccessful (however, an address bound by the system remains). Otherwise, the socket is associated with the server and data transfer may begin.

Table 2-2 lists some of the more common errors returned when a connection attempt fails.

<table>
<thead>
<tr>
<th>Socket Errors</th>
<th>Error Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ENOBUFS</td>
<td>Lack of memory available to support the call.</td>
</tr>
<tr>
<td>EPROTONOSUPPORT</td>
<td>Request for an unknown protocol.</td>
</tr>
<tr>
<td>EPROTOTYPE</td>
<td>Request for an unsupported type of socket.</td>
</tr>
<tr>
<td>ETIMEDOUT</td>
<td>No connection established in specified time. This happens when the destination host is down or when problems in the network result in lost transmissions.</td>
</tr>
<tr>
<td>ECONNREFUSED</td>
<td>The host refused service. This happens when a server process is not present at the requested address.</td>
</tr>
<tr>
<td>ENETDOWN or EHOSTDOWN</td>
<td>These errors are caused by status information delivered by the underlying communication interface.</td>
</tr>
</tbody>
</table>
Data Transfer

This section describes the functions to send and receive data. You can send or receive a message with the normal `read()` and `write()` system calls:

```markdown
write(s, buf, sizeof buf);
read(s, buf, sizeof buf);
```

Or the calls `send()` and `recv()` can be used:

```markdown
send(s, buf, sizeof buf, flags);
recv(s, buf, sizeof buf, flags);
```

`send()` and `recv()` are very similar to `read()` and `write()`, but the `flags` argument is important. The `flags`, defined in `<sys/socket.h>`, can be specified as a nonzero value if one or more of the following is required:

- `MSG_OOB`: send and receive out-of-band data
- `MSG_PEEK`: look at data without reading
- `MSG_DONTROUTE`: send data without routing packets

Out-of-band data is specific to stream sockets. When `MSG_PEEK` is specified with a `recv()` call, any data present is returned to the user but treated as still unread. The next `read()` or `recv()` call on the socket returns the same data. The option to send data without routing applied to the outgoing packets is currently used only by the routing table management process and is unlikely to be interesting to most users.

Closing Sockets

A `SOCK_STREAM` socket can be discarded by a `close()` system call. If data is queued to a socket that promises reliable delivery after a `close()`, the protocol continues to try to transfer the data. If the data is still undelivered after an arbitrary period, it is discarded.
shutdown() closes SOCK_STREAM sockets gracefully. Both processes can acknowledge that they are no longer sending. This call has the form:

```
shutdown(s, how);
```

where how is 0 disallows further receives, 1 disallows further sends, and 2 disallows both.

Connecting Stream Sockets

Figure 2-1 and the next two code examples illustrate initiating and accepting an Internet domain stream connection.

To initiate a connection, the client program in Code Example 2-2 creates a stream socket and calls `connect()`, specifying the address of the socket to connect to. If the target socket exists and the request is accepted, the connection is complete and the program can send data. Data are delivered in sequence with no message boundaries. The connection is destroyed when either socket is closed. For more information about data representation routines, such as `ntohl()`, `ntohs()`, `htons()`, and `htonl()`, in this program, see the `byteorder(3N)` man page.

The program in Code Example 2-3 is a server. It creates a socket and binds a name to it, then displays the port number. The program calls `listen()` to mark the socket ready to accept connection requests and initialize a queue for the requests. The rest of the program is an infinite loop. Each pass of the loop accepts a new connection and removes it from the queue, creating a new socket. The server reads and displays the messages from the socket and closes it. The use of `INADDR_ANY` is explained in “Address Binding” on page 47.
**Figure 2-1** Connection-Oriented Communication Using Stream Sockets

**Code Example 2-2**  Internet Domain Stream Connection (Client)

```c
#include <sys/types.h>
#include <sys/socket.h>
#include <netinet/in.h>
#include <netdb.h>
#include <stdio.h>

#define DATA "Half a league, half a league . . ."
```
/*
 * This program creates a socket and initiates a connection with the
 * socket given in the command line. Some data are sent over the
 * connection and then the socket is closed, ending the connection.
 * The form of the command line is: streamwrite hostname portnumber
 * Usage: pgm host port
 */

main(argc, argv)
    int argc;
    char *argv[];
{
    int sock;
    struct sockaddr_in server;
    struct hostent *hp, *gethostbyname();
    char buf[1024];

    /* Create socket. */
    sock = socket( AF_INET, SOCK_STREAM, 0 );
    if (sock == -1) {
        perror("opening stream socket");
        exit(1);
    }

    /* Connect socket using name specified by command line. */
    server.sin_family = AF_INET;
    hp = gethostbyname(argv[1] );

    /* gethostbyname returns a structure including the network address
     * of the specified host. */
    if (hp == (struct hostent *) 0) {
        fprintf(stderr, "%s: unknown host\n", argv[1]);
        exit(2);
    }
    memcpy((char *) &server.sin_addr, (char *) hp->h_addr,
            hp->h_length);
    server.sin_port = htons(atoi( argv[2]));
    if (connect(sock, (struct sockaddr *) &server, sizeof server) == -1) {
        perror("connecting stream socket");
        exit(1);
    }

    if (write( sock, DATA, sizeof DATA ) == -1)
        perror("writing on stream socket");
close(sock);
exit(0);
}

Code Example 2-3  Accepting an Internet Stream Connection (Server)
#include <sys/types.h>
#include <sys/socket.h>
#include <netinet/in.h>
#include <netdb.h>
#include <stdio.h>
#define TRUE 1

/*
 * This program creates a socket and then begins an infinite loop.
 * Each time through the loop it accepts a connection and prints
 * data from it. When the connection breaks, or the client closes
 * the connection, the program accepts a new connection.
 */

main()
{
    int sock, length;
    struct sockaddr_in server;
    int msgsock;
    char buf[1024];
    int rval;

    /* Create socket. */
    sock = socket(AF_INET, SOCK_STREAM, 0);
    if (sock == -1) {
        perror("opening stream socket");
        exit(1);
    }

    /* Bind socket using wildcards.*/
    server.sin_family = AF_INET;
    server.sin_addr.s_addr = INADDR_ANY;
    server.sin_port = 0;
    if (bind(sock, (struct sockaddr *) &server, sizeof server) == -1) {
        perror("binding stream socket");
        exit(1);
    }

    /* Find out assigned port number and print it out. */
    length = sizeof server;
    if (getsockname(sock, (struct sockaddr *) &server, &length)
Datagram Sockets

A datagram socket provides a symmetric data exchange interface. There is no requirement for connection establishment. Each message carries the destination address. Figure 2-2 shows the flow of communication between server and client.

Datagram sockets are created as described in “Socket Creation” on page 14. If a particular local address is needed, the bind() operation must precede the first data transmission. Otherwise, the system sets the local address and/or port when data is first sent. To send data, the sendto() call is used:

sendto(s, buf, buflen, flags, (struct sockaddr *) &to, tolen);
The $s$, buf, buflen, and flags parameters are the same as in connection-oriented sockets. The to and tolen values indicate the address of the intended recipient of the message. A locally detected error condition (such as an unreachable network) causes a return of $-1$ and errno to be set to the error number.

To receive messages on a datagram socket, the recvfrom() call is used:
```
recvfrom(s, buf, buflen, flags, (struct sockaddr *) &from, &fromlen);
```
Before the call, fromlen is set to the size of the from buffer. On return it is set to the size of the address from which the datagram was received.

Datagram sockets can also use the connect() call to associate a socket with a specific destination address. It can then use the send() call. Any data sent on the socket without explicitly specifying a destination address is addressed to the connected peer, and only data received from that peer is delivered. Only one connected address is permitted for one socket at a time. A second connect() call changes the destination address. Connect requests on datagram sockets return immediately. The system simply records the peer’s address. accept(), and listen() are not used with datagram sockets.

While a datagram socket is connected, errors from previous send() calls may be returned asynchronously. These errors can be reported on subsequent operations on the socket, or an option of getsockopt, SO_ERROR, can be used to interrogate the error status.
Figure 2-2  Connectionless Communication Using Datagram Sockets

Code Example 2-4 shows how to read an Internet call, and Code Example 2-5 shows how to send an Internet call.

**Code Example 2-4**  Reading Internet Domain Datagrams

```
#include <sys/types.h>
#include <sys/socket.h>
#include <netinet/in.h>
socket()  
bind()  
recvfrom()  

Server

normally block until a request is received

process the request

sendto()  

normal block waiting for reply

Client

socket()  

sendto()  

recvfrom()
```

data

data
#include <stdio.h>

/*
 * The include file <netinet/in.h> defines sockaddr_in as:
 * struct sockaddr_in {
 *     short sin_family;
 *     u_short sin_port;
 *     struct in_addr sin_addr;
 *     char sin_zero[8];
 * };
 * This program creates a datagram socket, binds a name to it, then
 * reads from the socket.
 */

main()
{
    int sock, length;
    struct sockaddr_in name;
    char buf[1024];

    /* Create socket from which to read. */
    sock = socket(AF_INET, SOCK_DGRAM, 0);
    if (sock == -1) {
        perror("opening datagram socket");
        exit(1);
    }

    /* Create name with wildcards. */
    name.sin_family = AF_INET;
    name.sin_addr.s_addr = INADDR_ANY;
    name.sin_port = 0;
    if (bind(sock, (struct sockaddr *)&name, sizeof name) == -1) {
        perror("binding datagram socket");
        exit(1);
    }

    /* Find assigned port value and print it out. */
    length = sizeof(name);
    if (getsockname(sock, (struct sockaddr *) &name, &length) == -1) {
        perror("getting socket name");
        exit(1);
    }

    printf("Socket port %d\n", ntohs(name.sin_port));

    /* Read from the socket. */
    if (read(sock, buf, 1024) == -1 )
        perror("receiving datagram packet");
    printf("-->%s\n", buf);
close(sock);
exit(0);
}

Code Example 2-5  Sending an Internet Domain Datagram
#include <sys/types.h>
#include <sys/socket.h>
#include <netinet/in.h>
#include <netdb.h>
#include <stdio.h>
#define DATA "The sea is calm, the tide is full . . ."

/*
 * Here I send a datagram to a receiver whose name I get from the
 * command line arguments. The form of the command line is:
 * dgramsend hostname portnumber
 */
main(argc, argv)
  int argc;
  char *argv[];
{
  int sock;
  struct sockaddr_in name;
  struct hostent *hp, *gethostbyname();

  /* Create socket on which to send. */
  sock = socket(AF_INET,SOCK_DGRAM, 0);
  if (sock == -1) {
    perror("opening datagram socket");
    exit(1);
  }

  /* Construct name, with no wildcards, of the socket to ‘send’
   * to. gethostbyname returns a structure including the network
   * address of the specified host. The port number is taken from
   * the command line.
   */
  hp = gethostbyname(argv[1]);
  if (hp == (struct hostent *) 0) {
    fprintf(stderr, "%s: unknown host
", argv[1]);
    exit(2);
  }
  memcpy((char *) &name.sin_addr, (char *) hp->h_addr,
    hp->h_length);
  name.sin_family = AF_INET;
  /*
name.sin_port = htons( atoi( argv[2] ));
/* Send message. */
if (sendto(sock,DATA, sizeof DATA ,0,  
    (struct sockaddr *) &name,sizeof name) == -1)  
    perror("sending datagram message");  
    close(sock);  
    exit(0);  
}

Input/Output Multiplexing

Requests can be multiplexed among multiple sockets or files. The select() call is used to do this:
#include <sys/time.h>
#include <sys/types.h>
#include <sys/select.h>
...
fd_set readmask, writemask, exceptmask;
struct timeval timeout;
...
select(nfds, &readmask, &writemask, &exceptmask, &timeout);

The first argument of select() is the number of file descriptors in the lists pointed to by the next three arguments.

The second, third, and fourth arguments of select() are pointers to three sets of file descriptors: a set of descriptors to read on, a set to write on, and a set on which exception conditions are accepted. Out-of-band data is the only exceptional condition. Any of these pointers can be a properly cast null. Each set is a structure containing an array of long integer bit masks. The size of the array is set by FD_SETSIZE (defined in select.h). The array is long enough to hold one bit for each FD_SETSIZE file descriptor.

The macros FD_SET(fd, &mask) and FD_CLR(fd, &mask) add and delete, respectively, the file descriptor fd in the set mask. The set should be zeroed before use, and the macro FD_ZERO(&mask) clears the set mask.

A time-out value may be specified. If the timeout pointer is NULL, select() blocks until a descriptor is selectable, or until a signal is received. If the fields in timeout are set to 0, select() polls and returns immediately.
select() normally returns the number of file descriptors selected. select() returns 0 if the time-out has expired. select() returns -1 for an error or interrupt with the error number in errno and the file descriptor masks unchanged.

For a successful return, the three sets indicate which file descriptors are ready to be read from, written to, or have exceptional conditions pending.

Test the status of a file descriptor in a select mask with the FD_ISSET(fd, &mask) macro. It returns a nonzero value if fd is in the set mask, and 0 if it is not. Use select() followed by a FD_ISSET(fd, &mask) macro on the read set to check for queued connect requests on a socket.

Code Example 2-6 shows how to select on a “listening” socket for readability to determine when a new connection can be picked up with a call to accept(). The program accepts connection requests, reads data, and disconnects on a single socket.

**Code Example 2-6  Check for Pending Connections With select()**

```c
#include <sys/types.h>
#include <sys/socket.h>
#include <sys/time.h>
#include <netinet/in.h>
#include <netdb.h>
#include <stdio.h>

#define TRUE 1

/*
 * This program uses select to check that someone is
 * trying to connect before calling accept.
 */

main()
{
    int sock, length;
    struct sockaddr_in server;
    int msgsock;
    char buf[1024];
    int rval;
    fd_set ready;
    struct timeval to;

    /* Open a socket and bind it as in previous examples. */
```
/* Start accepting connections. */
listen(sock, 5);
  do {
    FD_ZERO(&ready);
    FD_SET(sock, &ready);
    to.tv_sec = 5;
    to.tv_usec = 0;
    if (select(1, &ready, (fd_set *)0, (fd_set *)0, &to) == -1) {
      perror("select");
      continue;
    }
    if (FD_ISSET(sock, &ready)) {
      msgsock = accept(sock, (struct sockaddr *)0,
                        (int *)0);
      if (msgsock == -1)
        perror("accept");
      else do {
        memset(buf, 0, sizeof buf);
        if ((rval = read(msgsock, buf, 1024)) == -1)
          perror("reading stream message");
        else if (rval == 0)
          printf("Ending connection\n");
        else
          printf("-->%s\n", buf);
      } while (rval > 0);
      close(msgsock);
    } else
      printf("Do something else\n");
  } while (TRUE);
exit(0);
}

In previous versions of the `select()` routine, its arguments were pointers to integers instead of pointers to `fd_sets`. This style of call still works if the number of file descriptors is smaller than the number of bits in an integer.

`select()` provides a synchronous multiplexing scheme. The SIGIO and SIGURG signals described in “Advanced Topics” on page 41 provide asynchronous notification of output completion, input availability, and exceptional conditions.
Standard Routines

You may need to locate and construct network addresses. This section describes the new routines that manipulate network addresses. Unless otherwise stated, functions presented in this section apply only to the Internet domain.

Locating a service on a remote host requires many levels of mapping before client and server communicate. A service has a name for human use. The service and host names must be translated to network addresses. Finally, the address is used to locate and route to the host. The specifics of the mappings may vary between network architectures. Preferably, a network will not require that hosts be named, thus protecting the identity of their physical locations. It is more flexible to discover the location of the host when it is addressed.

Standard routines map host names to network addresses, network names to network numbers, protocol names to protocol numbers, and service names to port numbers, and the appropriate protocol to use in communicating with the server process. The file `<netdb.h>` must be included when using any of these routines.

Host Names

An Internet host name to address mapping is represented by the `hostent` structure:

```c
struct hostent {
    char *h_name;          /* official name of host */
    char **h_aliases;      /* alias list */
    int h_addrtype;       /* hostaddrtype(e.g.,AF_INET) */
    int h_length;         /* length of address */
    char **h_addr_list;    /* list of addrs, null terminated */
};
/*1st addr, net byte order*/
#define h_addr h_addr_list[0]
```

gethostbyname() maps an Internet host name to a hostent structure.
gethostbyaddr() maps an Internet host address to a hostent structure.
inet_ntoa() maps an Internet host address to a displayable string.
The routines return a `hostent` structure containing the name of the host, its aliases, the address type (address family), and a NULL-terminated list of variable length addresses. The list of addresses is required because a host can have many addresses. The `h_addr` definition is for backward compatibility, and is the first address in the list of addresses in the `hostent` structure.

**Network Names**

There are routines to map network names to numbers, and back. These routines return a `netent` structure:

```c
/*
 * Assumes that a network number fits in 32 bits.
 */
struct netent {
    char *n_name;     /* official name of net */
    char **n_aliases; /* alias list */
    int n_addrtype;  /* net address type */
    int n_net;       /* net number, host byte order */
};
```

`getnetbyname()`, `getnetbyaddr()`, and `getnetent()` are the network counterparts to the host routines described above.

**Protocol Names**

The `protoent` structure defines the protocol-name mapping used with `getprotobyname()`, `getprotobynumber()`, and `getprotoent()`:

```c
struct protoent {
    char *p_name;     /* official protocol name */
    char **p_aliases; /* alias list */
    int p_proto;      /* protocol number */
};
```

In the UNIX domain, no protocol database exists.

**Service Names**

An Internet domain service resides at a specific, well-known port and uses a particular protocol. A service name to port number mapping is described by the `servent` structure:
struct servent {
    char  *s_name;  /* official service name */
    char **s_aliases; /* alias list */
    int   s_port;   /* port number, network byte order */
    char  *s_proto; /* protocol to use */
};

getservbyname() maps service names and, optionally, a qualifying protocol to a servent structure. The call
sp = getservbyname("telnet", (char *) 0);
returns the service specification of a telnet server using any protocol. The call
sp = getservbyname("telnet", "tcp");
returns the telnet server that uses the TCP protocol. getservbyport() and getservent() are also provided. getservbyport() has an interface similar to that of getservbyname(); an optional protocol name may be specified to qualify lookups.

Other Routines

In addition to address-related database routines, there are several other routines that simplify manipulating names and addresses. Table 2-3 summarizes the routines for manipulating variable-length byte strings and byte-swapping network addresses and values.

<table>
<thead>
<tr>
<th>Call</th>
<th>Synopsis</th>
</tr>
</thead>
<tbody>
<tr>
<td>memcmp(s1, s2, n)</td>
<td>Compares byte-strings; 0 if same, not 0 otherwise</td>
</tr>
<tr>
<td>memcpy(s1, s2, n)</td>
<td>Copies n bytes from s2 to s1</td>
</tr>
<tr>
<td>memset(base, value, n)</td>
<td>Sets n bytes to value starting at base</td>
</tr>
<tr>
<td>htonl(val)</td>
<td>32-bit quantity from host into network byte order</td>

</tbody>
</table>
The byte-swapping routines are provided because the operating system expects addresses to be supplied in network order. On some architectures the host byte ordering is different from network byte order, so, programs must sometimes byte-swap values. Routines that return network addresses do so in network order. There are byte-swapping problems only when interpreting network addresses. For example, the following code formats a TCP or UDP port:

```c
printf("port number %d\n", ntohs(sp->s_port));
```

On certain machines, where these routines are not needed, they are defined as null macros.

**Client-Server Programs**

The most common form of distributed application is the client/server model. In this scheme, client processes request services from a server process.

An alternate scheme is a service server that can eliminate dormant server processes. An example is `inetd`, the Internet service daemon. `inetd` listens at a variety of ports, determined at start up by reading a configuration file. When a connection is requested on an `inetd` serviced port, `inetd` spawns the appropriate server to serve the client. Clients are unaware that an intermediary has played any part in the connection. `inetd` is described in more detail in “inetd Daemon” on page 53.

**Servers**

Most servers are accessed at well-known Internet port numbers or UNIX domain names. Code Example 2-7 illustrates the main loop of a remote-login server.

**Code Example 2-7  Remote Login Server**

```c
main(argc, argv)
    int argc;
    char *argv[];
{
    int f;
    struct sockaddr_in from;
    struct sockaddr_in sin;
    struct servent *sp;
```
sp = getservbyname("login", "tcp");
if (sp == (struct servent *) NULL) {
    fprintf(stderr, "rlogind: tcp/login: unknown service");
    exit(1);
}
...
 ifndef DEBUG
     /* Disassociate server from controlling terminal. */
     ...
 #endif
    sin.sin_port = sp->s_port; /* Restricted port */
    sin.sin_addr.s_addr = INADDR_ANY;
    ...
    f = socket(AF_INET, SOCK_STREAM, 0);
    ...
    if (bind(f, (struct sockaddr *) &sin, sizeof sin) == -1) {
        ...
    }
    ...
    listen(f, 5);
    while (TRUE) {
        int g, len = sizeof from;
        g = accept(f, (struct sockaddr *) &from, &len);
        if (g == -1) {
            if (errno != EINTR)
                syslog(LOG_ERR, "rlogind: accept: %m");
            continue;
        }
        if (fork() == 0) {
            close(f);
            doit(g, &from);
        }
        close(g);
    }
    exit(0);
}
First, the server gets its service definition, as Code Example 2-8 shows.

Code Example 2-8  Remote Login Server: Step 1
sp = getservbyname("login", "tcp");
if (sp == (struct servent *) NULL) {
    fprintf(stderr, "rlogind: tcp/login: unknown service\n");
    exit(1);
}
The result from `getservbyname()` is used later to define the Internet port at which the program listens for service requests. Some standard port numbers are in `/usr/include/netinet/in.h`.

In the non-DEBUG mode of operation, the server dissociates from the controlling terminal of its invoker, shown in Code Example 2-9.

**Code Example 2-9**  Dissociating from the Controlling Terminal

```
(void) close(0);
(void) close(1);
(void) close(2);
(void) open("/", O_RDONLY);
(void) dup2(0, 1);
(void) dup2(0, 2);
setsid();
```

This prevents the server from receiving signals to the process group of the controlling terminal. Once a server has dissociated itself, it cannot send reports of errors to a terminal and must log errors with `syslog()`.

A server next creates a socket and listens for service requests. `bind()` insures that the server listens at the expected location. (The remote login server listens at a restricted port number, so it runs as super-user.)

Code Example 2-10 illustrates the main body of the loop.

**Code Example 2-10**  Remote Login Server: Main Body

```
while(TRUE) {
    int g, len = sizeof(from);
    if (g = accept(f, (struct sockaddr *) &from, &len) == -1) {
        if (errno != EINTR)
            syslog(LOG_ERR, "rlogind: accept: %m");
        continue;
    }
    if (fork() == 0) { /* Child */
        close(f);
        doit(g, &from);
    }
    close(g); /* Parent */
}
```
accept() blocks until a client requests service. accept() returns a failure indication if it is interrupted by a signal such as SIGCHLD. The return value from accept() is checked and an error is logged with syslog() if an error has occurred.

The server then forks a child process and invokes the main body of the remote login protocol processing. The socket used by the parent to queue connection requests is closed in the child. The socket created by accept() is closed in the parent. The address of the client is passed to doit() for authenticating clients.

**Clients**

This section describes the steps taken by the client remote login process. As in the server, the first step is to locate the service definition for a remote login:

```c
sp = getservbyname("login", "tcp");
if (sp == (struct servent *) NULL) {
    fprintf(stderr,"rlogin: tcp/login: unknown service");
    exit(1);
}
```

Next, the destination host is looked up with a gethostbyname() call:

```c
hp = gethostbyname(argv[1]);
if (hp == (struct hostent *) NULL) {
    fprintf(stderr, "rlogin: %s: unknown host", argv[1]);
    exit(2);
}
```

Then, connect to the server at the requested host and start the remote login protocol. The address buffer is cleared and filled with the Internet address of the foreign host and the port number at which the login server listens:

```c
memset((char *) &server, 0, sizeof server);
memcpy((char*) &server.sin_addr,hp->h_addr,hp->h_length);
server.sin_family = hp->h_addrtype;
server.sin_port = sp->s_port;
```

A socket is created, and a connection initiated. connect() implicitly does a bind(), since s is unbound.

```c
s = socket(hp->h_addrtype, SOCK_STREAM, 0);
if (s < 0) {
    perror("rlogin: socket");
    exit(3);
}
```
if (connect(s, (struct sockaddr *) &server, sizeof server) < 0) {
    perror("rlogin: connect");
    exit(4);
}

Connectionless Servers

Some services use datagram sockets. The rwho service provides status information on hosts connected to a local area network. (Avoid running in.rwho; it causes heavy network traffic.) This service requires the ability to broadcast information to all hosts connected to a particular network. It is an example of datagram socket use.

A user on a host running the rwho server may get the current status of another host with uptime. Typical output is illustrated in Code Example 2-11.

Code Example 2-11  Output of uptime Program
itchy up 9:45, 5 users, load 1.15, 1.39, 1.31
scratchy up 2+12:04, 8 users, load 4.67, 5.13, 4.59
click up 10:10, 0 users, load 0.27, 0.15, 0.14
clack up 2+06:28, 9 users, load 1.04, 1.20, 1.65
ezekiel up 25+09:48, 0 users, load 1.49, 1.43, 1.41
dandy 5+00:05, 0 users, load 1.51, 1.54, 1.56
peninsula down 0:24
wood down 17:04
carpediem down 16:09
chances up 2+15:57, 3 users, load 1.52, 1.81, 1.86

Status information is periodically broadcast by the rwho server processes on each host. The server process also receives the status information and updates a database. This database is interpreted for the status of each host. Servers operate autonomously, coupled only by the local network and its broadcast capabilities.

Use of broadcast is fairly inefficient, since a lot of net traffic is generated. Unless the service is used widely and frequently, the expense of periodic broadcasts outweighs the simplicity.

A simplified version of the rwho server is shown in Code Example 2-12. It does two tasks: receives status information broadcast by other hosts on the network and supplies the status of its host. The first task is done in the main loop of the program: Packets received at the rwho port are checked to be sure they were...
sent by another `rwho` server process, and are stamped with the arrival time. They then update a file with the status of the host. When a host has not been heard from for an extended time, the database routines assume the host is down and logs it. This application is prone to error, as a server may be down while a host is up.

**Code Example 2-12  rwho Server**

```c
main() {
...
sp = getservbyname("who", "udp");
net = getnetbyname("localnet");
sin.sin_addr = inet_makeaddr(net->n_net, INADDR_ANY);
sin.sin_port = sp->s_port;
...
s = socket(AF_INET, SOCK_DGRAM, 0);
...
on = 1;
if (setsockopt(s, SOL_SOCKET, SO_BROADCAST, &on, sizeof on)
== -1) {
    syslog(LOG_ERR, "setsockopt SO_BROADCAST: %m");
    exit(1);
}
binding(s, (struct sockaddr *) &sin, sizeof sin);
...
signal(SIGALRM, onalrm);
onalrm();
while(1) {
    struct whod wd;
    int cc, whod, len = sizeof from;
    cc = recvfrom(s, (char *) &wd, sizeof(struct whod), 0,
    (struct sockaddr *) &from, &len);
    if (cc <= 0) {
        if (cc == -1 && errno != EINTR)
            syslog(LOG_ERR, "rwhod: recvv: %m");
        continue;
    }
    if (from.sin_port != sp->s_port) {
        syslog(LOG_ERR, "rwhod: %d: bad from port",
        ntohs(from.sin_port));
        continue;
    }
    ...
    if (!verify( wd.wd_hostname)) {
```
syslog(LOG_ERR, "rwhod: bad host name from %x",
    ntohl(from.sin_addr.s_addr));
    continue;
}
(void) sprintf(path, "%s/whod.%s", RWHODIR, wd.wd_hostname);
whod = open(path, O_WRONLY|O_CREAT|O_TRUNC, 0666);
...
(void) time(&wd.wd_recvtime);
(void) write(whod, (char *) &wd, cc);
(void) close(whod);
} exit(0);
}

The second server task is to supply the status of its host. This requires periodically acquiring system status information, packaging it in a message, and broadcasting it on the local network for other rwho servers to hear. This task is run by a timer and triggered with a signal. Locating the system status information is involved but uninteresting.

Status information is broadcast on the local network. For networks that do not support broadcast, another scheme must be used.

It is important that software operating in a distributed environment not have any site-dependent information compiled into it. This would require a separate copy of the server at each host and make maintenance a severe problem. The system isolates host-specific data from applications by providing system calls that return the required data. (For example, `uname()` returns the host’s official name.) The `ioctl()` call lets you find the networks to which a host is directly connected. A local network broadcasting mechanism has been implemented at the socket level. Combining these two features lets a process broadcast on any directly connected local network that supports broadcasting in a site-independent manner. This solves the problem of deciding how to propagate status with rwho, or more generally in broadcasting. Such status is broadcast to connected networks at the socket level, where the connected networks have been obtained through the appropriate `ioctl()` calls. “Broadcasting and Determining Network Configuration” on page 49 details the specifics of broadcasting.
Advanced Topics

For most programmers, the mechanisms already described are enough to build distributed applications. Others will need some of the features in this section.

Out-of-Band Data

The stream socket abstraction includes out-of-band data. Out-of-band data is a logically independent transmission channel between a pair of connected stream sockets. Out-of-band data is delivered independently of normal data. The out-of-band data facilities must support the reliable delivery of at least one out-of-band message at a time. This message can contain at least one byte of data, and at least one message may be pending delivery at any time.

For communications protocols that support only in-band signaling (that is, urgent data is delivered in sequence with normal data), the message is extracted from the normal data stream and stored separately. This lets users choose between receiving the urgent data in order and receiving it out of sequence, without having to buffer the intervening data.

You can peek (with MSG_PEEK) at out-of-band data. If the socket has a process group, a SIGURG signal is generated when the protocol is notified of its existence. A process can set the process group or process id to be informed by SIGURG with the appropriate fcntl() call, as described in “Interrupt Driven Socket I/O” on page 44 for SIGIO. If multiple sockets have out-of-band data waiting delivery, a select() call for exceptional conditions can be used to determine the sockets with such data pending.

A logical mark is placed in the data stream at the point at which the out-of-band data was sent. The remote login and remote shell applications use this facility to propagate signals between client and server processes. When a signal is received, all data up to the mark in the data stream is discarded.

To send an out-of-band message, the MSG_OOB flag is applied to send() or sendto(). To receive out-of-band data, specify MSG_OOB to recvfrom() or recv() (unless out-of-band data is taken in line, in which case the MSG_OOB flag is not needed). The SIOCATMARK ioctl ioctl tells whether the read pointer currently points at the mark in the data stream:

ioctl(s, SIOCATMARK, &yes);
If yes is 1 on return, the next read returns data after the mark. Otherwise, assuming out-of-band data has arrived, the next read provides data sent by the client before sending the out-of-band signal. The routine in the remote login process that flushes output on receipt of an interrupt or quit signal is shown in Code Example 2-13. This code reads the normal data up to the mark (to discard it), then reads the out-of-band byte.

Code Example 2-13 Flushing Terminal I/O on Receipt of Out-of-Band Data

```c
#include <sys/ioctl.h>
#include <sys/file.h>
...

oob()
{
    int out = FWRITE;
    char waste[BUFSIZ];
    int mark;

    /* flush local terminal output */
    ioctl(1, TIOCFLUSH, (char *) &out);
    while(1) {
        if (ioctl(rem, SIOCATMARK, &mark) == -1) {
            perror("ioctl");
            break;
        }
        if (mark)
            break;
        (void) read(rem, waste, sizeof waste);
    }
    if (recv(rem, &mark, 1, MSG_OOB) == -1) {
        perror("recv");
        ...
    }
    ...
}
```

A process can also read or peek at the out-of-band data without first reading up to the mark. This is more difficult when the underlying protocol delivers the urgent data in-band with the normal data, and only sends notification of its presence ahead of time (for example, TCP, the protocol used to provide socket streams in the Internet domain). With such protocols, the out-of-band byte may not yet have arrived when a `recv()` is done with the MSG_OOB flag. In that case, the call returns the error of EWOULDBLOCK. Also, there may be enough in-
band data in the input buffer that normal flow control prevents the peer from sending the urgent data until the buffer is cleared. The process must then read enough of the queued data before the urgent data can be delivered.

There is also a facility to retain the position of urgent in-line data in the socket stream. This is available as a socket-level option, SO_OOBINLINE. See the getsockopt(3N) manpage for usage. With this option, the position of urgent data (the mark) is retained, but the urgent data immediately follows the mark in the normal data stream returned without the MSG_OOB flag. Reception of multiple urgent indications causes the mark to move, but no out-of-band data are lost.

### Nonblocking Sockets

Some applications require sockets that do not block. For example, requests that cannot complete immediately and would cause the process to be suspended (awaiting completion) are not executed. An error code would be returned. Once a socket is created and any connection to another socket is made, it may be made nonblocking by `fcntl()` as Code Example 2-14 shows.

#### Code Example 2-14  Set Nonblocking Socket

```c
#include <fcntl.h>
#include <sys/file.h>
...
int fileflags;
int s;
...
s = socket(AF_INET, SOCK_STREAM, 0);
...
if (fileflags = fcntl(s, F_GETFL, 0) == -1)
    perror("fcntl F_GETFL");
    exit(1);
}
if (fcntl(s, F_SETFL, fileflags | FNDELAY) == -1)
    perror("fcntl F_SETFL, FNDELAY");
    exit(1);
}...
```

When doing I/O on a nonblocking socket, check for the error EWOULDBLOCK (in <errno.h>), which occurs when an operation would normally block. `accept()`, `connect()`, `send()`, `recv()`, `read()`, and `write()` can all
return EWOULDBLOCK. If an operation such as a send() cannot be done in its entirety, but partial writes work (such as when using a stream socket), the data that can be sent immediately are processed, and the return value is the amount actually sent.

Asynchronous Sockets

Asynchronous communication between processes is required in real-time applications. Asynchronous sockets must be SOCK_STREAM type. Make a socket asynchronous as shown in Code Example 2-15.

Code Example 2-15  Making a Socket Asynchronous

```c
#include <fcntl.h>
#include <sys/file.h>
...
int fileflags;
int s;
...
s = socket(AF_INET, SOCK_STREAM, 0);
...
if (fileflags = fcntl(s, F_GETFL ) == -1)
    perror("fcntl F_GETFL");
    exit(1);
}
if (fcntl(s, F_SETFL, fileflags | FNDELAY | FASYNC) < 0)
    perror("fcntl F_SETFL, FNDELAY | FASYNC");
    exit(1);
}
...
```

After sockets are initialized, connected, and made asynchronous, communication is similar to reading and writing a file asynchronously. A send(), write(), recv(), or read() initiates a data transfer. A data transfer is completed by a signal-driven I/O routine, described in the next section.

Interrupt Driven Socket I/O

The SIGIO signal notifies a process when a socket (actually any file descriptor) has finished a data transfer. There are three steps in using SIGIO:

- Set up a SIGIO signal handler with the signal() or sigvec() calls.
• Use `fcntl()` to set the process ID or process group ID to receive the signal to its own process ID or process group ID (the default process group of a socket is group 0).

• Convert the socket to asynchronous as shown in “Asynchronous Sockets” on page 44.

Sample code to allow a given process to receive information on pending requests as they occur for a socket is shown in Code Example 2-16. With the addition of a handler for `SIGURG`, this code can also be used to prepare for receipt of `SIGURG` signals.

**Code Example 2-16**  Asyncynchronous Notification of I/O Requests

```c
#include <fcntl.h>
#include <sys/file.h>
...
signal(SIGIO, io_handler);
/* Set the process receiving SIGIO/SIGURG signals to us. */
if (fcntl(s, F_SETOWN, getpid()) < 0) {
    perror("fcntl F_SETOWN");
    exit(1);
}
```

**Signals and Process Group ID**

For `SIGURG` and `SIGIO`, each socket has a process number and a process group ID. These values are initialized to zero, but may be redefined at a later time with the `F_SETOWN` `fcntl()`, as in the previous example. A positive third argument to `fcntl()` sets the socket’s process ID. A negative third argument to `fcntl()` sets the socket’s process group ID. The only allowed recipient of `SIGURG` and `SIGIO` signals is the calling process.

A similar `fcntl()`, `F_GETOWN`, returns the process number of a socket.

Reception of `SIGURG` and `SIGIO` can also be enabled by using `ioctl()` to assign the socket to the user’s process group:

```c
/* oobdata is the out-of-band data handling routine */
sigset(SIGURG, oobdata);
int pid = -getpid();
if (ioctl(client, SIOCSPGRP, (char *) &pid) < 0) {
    perror("ioctl: SIOCSPGRP");
}
```
Another signal that is useful in server processes is **SIGCHLD**. This signal is delivered to a process when any child process changes state. Normally, servers use the signal to “reap” child processes that have exited without explicitly awaiting their termination or periodically polling for exit status. For example, the remote login server loop shown previously can be augmented as shown in Code Example 2-17.

**Code Example 2-17**  **SIGCHLD Signal**

```c
int reaper();
...
siset(SIGCHLD, reaper);
listen(f, 5);
while (1) {
    int g, len = sizeof from;
    g = accept(f, (struct sockaddr *) &from, &len);
    if (g < 0) {
        if (errno != EINTR)
            syslog(LOG_ERR, "rlogind: accept: %m");
        continue;
    }
    ...
}
#include <wait.h>
reaper()
{
    int options;
    int error;
    siginfo_t info;

    options = WNOHANG | WEXITED;
    bzero((char *) &info, sizeof(info));
    error = waitid(P_ALL, 0, &info, options);
}
```

If the parent server process fails to reap its children, zombie processes result.

**Selecting Specific Protocols**

If the third argument of the `socket()` call is 0, `socket()` selects a default protocol to use with the returned socket of the type requested. The default protocol is usually correct, and alternate choices are not usually available.
When using “raw” sockets to communicate directly with lower-level protocols or hardware interfaces, it may be important for the protocol argument to set up de-multiplexing. For example, raw sockets in the Internet domain can be used to implement a new protocol on IP, and the socket will receive packets only for the protocol specified. To obtain a particular protocol, determine the protocol number as defined in the protocol domain. For the Internet domain, use one of the library routines discussed in “Standard Routines” on page 31, such as getprotobynumber():

```
#include <sys/types.h>
#include <sys/socket.h>
#include <netinet/in.h>
#include <netdb.h>
...
pp = getprotobynumber("newtcp");
s = socket(AF_INET, SOCK_STREAM, pp->p_proto) ;
```

This results in a socket \( s \) using a stream-based connection, but with protocol type of newtcp instead of the default tcp.

### Address Binding

In the Internet Protocol family, bindings are composed of local and foreign IP addresses, and of local and foreign port numbers. Port numbers are allocated in separate spaces, one for each system and one for each transport protocol (TCP or UDP). Through bind(), a process specifies the \(<local IP address, local port number>\) half of an association, while connect() and accept() complete a socket’s association by specifying the \(<foreign IP address, foreign port number>\) part. Since the association is created in two steps, the association-uniqueness requirement might be violated, unless care is taken. It is unrealistic to expect user programs to always know proper values to use for the local address and local port, since a host may reside on multiple networks and the set of allocated port numbers is not directly accessible to a user.

The wildcard address simplifies local address binding in the Internet domain. When an address is specified as INADDR_ANY (a constant defined in <netinet/in.h>), the system interprets the address as any valid address. Code Example 2-18 binds a specific port number to a socket, and leaves the local address unspecified.
Code Example 2-18  Bind Port Number to Socket

```c
#include <sys/types.h>
#include <netinet/in.h>
...
struct sockaddr_in sin;
...
s = socket(AF_INET, SOCK_STREAM, 0);
sin.sin_family = AF_INET;
sin.sin_addr.s_addr = htonl(INADDR_ANY);
sin.sin_port = htons(MYPORT);
bind(s, (struct sockaddr *) &sin, sizeof sin);
```

Each network interface on a host typically has a unique IP address. Sockets with wildcard local addresses may receive messages directed to the specified port number and sent to any of the possible addresses assigned to a host. For example, if a host has two interfaces with addresses 128.32.0.4 and 10.0.0.78, and a socket is bound as in Code Example 2-18, the process can accept connection requests addressed to 128.32.0.4 or 10.0.0.78. To allow only hosts on a specific network to connect to it, a server binds the address of the interface on the appropriate network.

Similarly, a local port number can be left unspecified (specified as 0), in which case the system selects a port number. For example, to bind a specific local address to a socket, but to leave the local port number unspecified:

```c
sin.sin_addr.s_addr = inet_addr("127.0.0.1");
sin.sin_family = AF_INET;
sin.sin_port = htons(0);
bind(s, (struct sockaddr *) &sin, sizeof sin);
```

The system uses two criteria to select the local port number:

- The first is that Internet port numbers less than 1024 (IPPORT_RESERVED) are reserved for privileged users (that is, the superuser). Nonprivileged users may use any Internet port number greater than 1024. The largest Internet port number is 65535.
- The second criterion is that the port number is not currently bound to some other socket.

The port number and IP address of the client is found through either accept() (the from result) or getpeername().
In certain cases, the algorithm used by the system to select port numbers is unsuitable for an application. This is because associations are created in a two-step process. For example, the Internet file transfer protocol specifies that data connections must always originate from the same local port. However, duplicate associations are avoided by connecting to different foreign ports. In this situation the system would disallow binding the same local address and port number to a socket if a previous data connection’s socket still existed. To override the default port selection algorithm, an option call must be performed before address binding:

```c
int on = 1;
...
setsockopt(s, SOL_SOCKET, SO_REUSEADDR, &on, sizeof on);
bind(s, (struct sockaddr *) &sin, sizeof sin);
```

With this call, local addresses can be bound that are already in use. This does not violate the uniqueness requirement, because the system still verifies at connect time that any other sockets with the same local address and port do not have the same foreign address and port. If the association already exists, the error EADDRINUSE is returned.

### Broadcasting and Determining Network Configuration

Messages sent by datagram sockets can be broadcast to reach all of the hosts on an attached network. The network must support broadcast; the system provides no simulation of broadcast in software. Broadcast messages can place a high load on a network since they force every host on the network to service them. Broadcasting is usually used for either of two reasons: to find a resource on a local network without having its address, or functions like routing require that information be sent to all accessible neighbors.

To send a broadcast message, create an Internet datagram socket:

```c
s = socket(AF_INET, SOCK_DGRAM, 0);
```

and bind a port number to the socket:

```c
sin.sin_family = AF_INET;
sin.sin_addr.s_addr = htonl(INADDR_ANY);
sin.sin_port = htons(MYPORT);
bind(s, (struct sockaddr *) &sin, sizeof sin);
```
The datagram can be broadcast on only one network by sending to the
network’s broadcast address. A datagram can also be broadcast on all attached
networks by sending to the special address INADDR_BROADCAST, defined in
<netinet/in.h>.

The system provides a mechanism to determine a number of pieces of
information (including the IP address and broadcast address) about the
network interfaces on the system. The SIOCGIFCONF ioctl call returns the
interface configuration of a host in a single ifconf structure. This structure
contains an array of ifreq structures, one for each address domain supported
by each network interface to which the host is connected. Code Example 2-19
shows these structures defined in <net/if.h>.

Code Example 2-19  net/if.h Header File

```c
struct ifreq {
    #define IFNAMSIZ 16
    char ifr_name[IFNAMSIZ]; /* if name, e.g., "en0" */
    union {
        struct sockaddr ifru_addr;
        struct sockaddr ifru_dstaddr;
        char ifru_oname[IFNAMSIZ]; /* other if name */
        struct sockaddr ifru_broadaddr;
        short ifru_flags;
        int ifru_metric;
        char ifru_data[1]; /* interface dependent data */
        char ifru_enaddr[6];
    } ifr_ifru;
    #define ifr_addr ifr_ifru.ifru_addr
    #define ifr_dstaddr ifr_ifru.ifru_dstaddr
    #define ifr_oname ifr_ifru.ifru_oname
    #define ifr_broadaddr ifr_ifru.ifru_broadaddr
    #define ifr_flags ifr_ifru.ifru_flags
    #define ifr_metric ifr_ifru.ifru_metric
    #define ifr_data ifr_ifru.ifru_data
    #define ifr_enaddr ifr_ifru.ifru_enaddr
};
```

The call that obtains the interface configuration is:

```c
struct ifconf ifc;
char buf[BUFSIZ];

ifc.ifc_len = sizeof buf;
ifc.ifc_buf = buf;
```
After this call, buf contains an array of ifreq structures, one for each network to which the host is connected. These structures are ordered first by interface name and then by supported address families. ifc.ifc_len is set to the number of bytes used by the ifreq structures.

Each structure has a set of interface flags that tell whether the corresponding network is up or down, point to point or broadcast, and so on. The SIOCGIFFLAGS ioctl returns these flags for an interface specified by an ifreq structure shown in Code Example 2-20.

Code Example 2-20  Obtaining Interface Flags

```c
struct ifreq *ifr;
ifr = ifc.ifc_req;
for (n = ifc.ifc_len/sizeof (struct ifreq); --n >= 0; ifr++) {
    /*
    * Be careful not to use an interface devoted to an address
    * domain other than those intended.
    */
    if (ifr->ifr_addr.sa_family != AF_INET)
        continue;
    if (ioctl(s, SIOCGIFFLAGS, (char *) ifr) < 0) {
        ...
    }
    /* Skip boring cases */
    if (((ifr->ifr_flags & IFF_UP) == 0 ||
         (ifr->ifr_flags & IFF_LOOPBACK) ||
         (ifr->ifr_flags & (IFF_BROADCAST | IFF_POINTOPOINT)) == 0)
        continue;
}
```

Code Example 2-21 shows the broadcast of an interface can be obtained with the SIOGIFBROADCAST ioctl().

Code Example 2-21  Broadcast Address of an Interface

```c
if (ioctl(s, SIOGIFBROADCAST, (char *) ifr) < 0) {
    ...
}
memcpy((char *) &dst, (char *) &ifr->ifr_broadaddr,
       sizeof ifr->ifr_broadaddr);
```
The `SIOGIFBRDADDR` ioctl can also be used to get the destination address of a point-to-point interface.

After the interface broadcast address is obtained, transmit the broadcast datagram with `sendto()`:

```c
sendto(s, buf, buflen, 0, (struct sockaddr *)&dst, sizeof dst);
```

Use one `sendto()` for each interface to which the host is connected that supports the broadcast or point-to-point addressing.

**Socket Options**

You can set and get several options on sockets through `setsockopt()` and `getsockopt()`; for example changing the send or receive buffer space. The general forms of the calls are:

```c
setsockopt(s, level, optname, optval, optlen);
```

and

```c
getsockopt(s, level, optname, optval, optlen);
```

Table 2-4 shows the arguments of the calls.

<table>
<thead>
<tr>
<th>Arguments</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>s</code></td>
<td>Socket on which the option is to be applied</td>
</tr>
<tr>
<td><code>level</code></td>
<td>Specifies the protocol level, i.e. socket level, indicated by the symbolic constant SOL_SOCKET in <code>&lt;sys/socket.h&gt;</code></td>
</tr>
<tr>
<td><code>optname</code></td>
<td>Symbolic constant defined in <code>&lt;sys/socket.h&gt;</code> that specifies the option</td>
</tr>
<tr>
<td><code>optval</code></td>
<td>Points to the value of the option</td>
</tr>
<tr>
<td><code>optlen</code></td>
<td>Points to the length of the value of the option</td>
</tr>
</tbody>
</table>

For `getsockopt()`, `optlen` is a value-result argument, initially set to the size of the storage area pointed to by `optval` and set on return to the length of storage used.

It is sometimes useful to determine the type (for example, stream or datagram) of an existing socket. Programs invoked by `inetd` may need to do this by using the `SO_TYPE` socket option and the `getsockopt()` call:
#include <sys/types.h>
#include <sys/socket.h>

int type, size;

size = sizeof (int);
if (getsockopt(s, SOL_SOCKET, SO_TYPE, (char *) &type, &size) < 0) {
    ...
}

After getsockopt(), type is set to the value of the socket type, as defined in <sys/socket.h>. For a datagram socket, type would be SOCK_DGRAM.

**inetd Daemon**

One of the daemons provided with the system is inetd. It is invoked at startup time, and gets the services for which it listens from the /etc/inetd.conf file. The daemon creates one socket for each service listed in /etc/inetd.conf, binding the appropriate port number to each socket. See the inetd(1M) man page for details.

inetd does a select() on each socket, waiting for a connection request to the service corresponding to that socket. For SOCK_STREAM type sockets, inetd does an accept() on the listening socket, fork()s, dup()s the new socket to file descriptors 0 and 1 (stdin and stdout), closes other open file descriptors, and exec()s the appropriate server.

The primary benefit of inetd is that services that are not in use are not taking up machine resources. A secondary benefit is that inetd does most of the work to establish a connection. The server started by inetd has the socket connected to its client on file descriptors 0 and 1, and can immediately read(), write(), send(), or recv(). Servers can use buffered I/O as provided by the stdio conventions, as long as they use fflush() when appropriate.

getpeername() returns the address of the peer (process) connected to a socket; it is useful in servers started by inetd. For example, to log the Internet address in decimal dot notation (such as 128.32.0.4, which is conventional for representing an IP address of a client), an inetd server could use the following:
struct sockaddr_in name;
int namelen = sizeof name;
...
if (getpeername(0, (struct sockaddr *) &name, &namelen) < 0) {
    syslog(LOG_ERR, "getpeername: %m");
    exit(1);
} else
    syslog(LOG_INFO, "Connection from %s",
        inet_ntoa(name.sin_addr));
...

Moving Socket Applications to Solaris 2.x

Sockets and the socket implementation are mostly compatible with previous releases of SunOS. But, an application programmer must be aware of some differences that are listed in the tables provided in this section.

Table 2-5  Connection-Mode Primitives (SunOS 4.x/Solaris 2.x)

<table>
<thead>
<tr>
<th>SunOS 4.x (BSD)</th>
<th>Solaris 2.x</th>
</tr>
</thead>
<tbody>
<tr>
<td>connect()</td>
<td></td>
</tr>
</tbody>
</table>

When connect() is called on an unbound socket, the protocol determines whether the endpoint is bound before the connection takes place.

When connect() is called on an unbound socket, that socket is always bound to an address selected by the protocol.

Table 2-6  Data Transfer Primitives (SunOS 4.x/Solaris 2.x)

<table>
<thead>
<tr>
<th>SunOS 4.x (BSD)</th>
<th>Solaris 2.x</th>
</tr>
</thead>
<tbody>
<tr>
<td>write()</td>
<td></td>
</tr>
</tbody>
</table>

write() fails with errno set to ENOTCONN if it is used on an unconnected socket.

A call to write() appears to succeed, but the data are discarded. The socket error option SO_ERROR returns ENOTCONN if this happens.
write() can be used on type SOCK_DGRAM sockets (either AF_UNIX or AF_INET domains) to send zero-length data.

- A call to write() returns -1, with errno set to ERANGE. send(), sendto(), or sendmsg() should be used to send zero-length data.

read() fails with errno set to ENOTCONN if read() is used on an unconnected socket.

- read() returns zero bytes read if the socket is in blocking mode. If the socket is in non-blocking mode, it returns -1 with errno set to EAGAIN.

Table 2-6  Data Transfer Primitives (SunOS 4.x/Solaris 2.x)

<table>

  dumps core. |
| Sockets in Directories |                 |
| If `ls -l` is executed in a directory containing a UNIX domain socket, an `s` is displayed on the left side of the mode field. | If `ls -l` is executed in a directory that contains a UNIX domain socket, a `p` is displayed on the left side of the mode field. |
| An `ls -F` causes an equal sign (=) to be displayed after any file name of a UNIX domain socket. | Nothing is displayed after the file name. |
Programming With the Transport Layer Interface (TLI)

The transport layer interface (TLI) is a set of functions that enable networked applications to be transport independent. TLI and the socket interface are the standard network interfaces in the current release of SunOS. TLI may be more appropriate for some applications than are the socket services.

<table>

TLI Is Multithread Safe

The interface described in this chapter is multithread safe. This means that applications that contain TLI function calls can be used freely in a multithreaded application.
What Is TLI

TLI was introduced with AT&T’s System V, Release 3 in 1986. It provides a non-BSD transport layer interface. TLI is modeled after the ISO Transport Service Definition and provides an API between the OSI transport and session layers.

TLI is referred to as a library of functions, rather than a set of system calls. Whereas system calls are implemented within the kernel, TLI functions are user-callable and hide the actual streams interface to the networking system.

Intrinsic to TLI are the notions of transport endpoints and a transport provider. The transport endpoints are two processes that are communicating, and the transport provider is the set of routines on the computer host that provide communication support for user processes. TLI is the interface to the transport provider, not the provider itself. See Figure 3-1.

Figure 3-1  How TLI Works

TLI code can be written to be independent of transport provider. The Solaris 2.x product includes some transport providers (TCP, for example) as part of the base operating system. A transport provider performs services, and the transport user requests the services. The transport user issues service requests
to the transport provider. An example is a request to transfer data over a connection TCP and UDP are examples of transport providers. A transport user may be a networking application or a session layer protocol.

TLI can also be used for transport-independent programming. TLI has two components to achieve this:

- Library routines that perform the transport services, in particular, transport selection and name-to-address translation. The network services library includes a set of functions that implement TLI for user processes. See Chapter 4, “Transport Selection and Name-to-Address Mapping.”

Programs using TLI should be linked with the network services library, lnsl, as follows:

```
cc prog.c -lnsl
```

- State transition rules that define the sequence in which the transport routines may be invoked. For more information on state transition rules, see section, “State Transitions” on page 100. The state tables define the legal sequence of library calls based on the state and the handling of events. These events include user-generated library calls, as well as provider-generated event indications. TLI programmers should understand all state transitions before using the interface.

TLI provides two modes of service, connection mode and connectionless mode. The next two sections give an overview of these modes.

**Connectionless Mode**

Connectionless mode is message oriented. Data are transferred in self-contained units with no relationship between the units. This service requires only an established association between the peer users that determines the characteristics of the data. All the information required to deliver a message (such as the destination address) is presented to the transport provider, with the data to be transmitted, in one service request. Each message is entirely self-contained. Use connectionless mode service for applications that:

- Have short-term request/response interactions
- Are dynamically reconfigurable
- Do not require sequential delivery of data
Connectionless transports are usually called “unreliable,” since they do not necessarily maintain message sequence, and messages are sometimes lost.

Connectionless Mode Routines

Connectionless-mode transport service has two phases: local management and data transfer. The local management phase defines the same local operations as for the connection mode service.

The data transfer phase lets a user transfer data units (usually called datagrams) to the specified peer user. Each data unit must be accompanied by the transport address of the destination user. \texttt{t_sndudata()} sends and \texttt{t_rcvudata()} receives messages. Table 3-1 summarizes all routines for connectionless mode data transfer.

\begin{table}[h]
\centering
\begin{tabular}{|l|l|}
\hline
\textbf{Command} & \textbf{Description} \\
\hline
\texttt{t_sndudata} & Sends a message to another user of the transport \\
\texttt{t_rcvudata} & Receives a message sent by another user of the transport \\
\texttt{t_rcvuderr} & Retrieves error information associated with a previously sent message \\
\hline
\end{tabular}
\caption{Routines for Connectionless-Mode Data Transfer}
\end{table}

Connectionless Mode Service

Connectionless mode service is appropriate for short-term request/response interactions, such as transaction-processing applications. Data are transferred in self-contained units with no logical relationship required among multiple units.

Endpoint Initiation

Transport users must initiate TLI endpoints before transferring data. They must choose the appropriate connectionless service provider using \texttt{t_open()} and establish its identity using \texttt{t_bind()}. 
Use `t_optmgmt()` to negotiate protocol options. Like connection mode service, each transport provider specifies the options, if any, it supports. Option negotiation is a protocol-specific activity. In Code Example 3-22, the server waits for incoming queries, and processes and responds to each query. The example also shows the definitions and initiation sequence of the server.

**Code Example 3-22  CLTS Server**

```c
#include <stdio.h>
#include <fcntl.h>
#include <tiuser.h>
#define SRV_ADDR 2 /* server's well known address */

main()
{
    int fd;
    int flags;
    struct t_bind *bind;
    struct t_unitdata *ud;
    struct t_uderr *uderr;
    extern int t_errno;

    if ((fd = t_open("/dev/exmp", O_RDWR, (struct t_info *) NULL))
        == -1) {
        t_error("unable to open /dev/exmp");
        exit(1);
    }

    if ((bind = (struct t_bind *)t_alloc(fd, T_BIND, T_ADDR))
        == (struct t_bind *) NULL) {
        t_error("t_alloc of t_bind structure failed");
        exit(2);
    }

    bind->addr.len = sizeof(int);
    *(int *)bind->addr.buf = SRV_ADDR;
    bind->qlen = 0;
    if (t_bind(fd, bind, bind) == -1) {
        t_error("t_bind failed");
        exit(3);
    }

    /*
     * is the bound address correct?
     */
    if (bind->addr.len != sizeof(int) ||
        *(int *)bind->addr.buf != SRV_ADDR) {
```

*Programming With the Transport Layer Interface (TLI)*
fprintf(stderr, "t_bind bound wrong address\n");
exit(4);
}

The server establishes a transport endpoint with the desired transport provider using t_open(). Each provider has an associated service type, so the user may choose a particular service by opening the appropriate transport provider file. This connectionless mode server ignores the characteristics of the provider returned by t_open() by setting the third argument to NULL. The transaction server assumes the transport provider has the following characteristics:

- The transport address is an integer value that uniquely identifies each user.
- The transport provider supports the T_CLTS service type (connectionless transport service, or datagram).
- The transport provider does not require any protocol-specific options.

The connectionless server binds a transport address to the endpoint so that potential clients can access the server. A t_bind structure is allocated using t_alloc() and the buf and len fields of the address are set accordingly.

One difference between a connection mode server and a connectionless mode server is that the qlen field of the t_bind structure is 0 for connectionless mode service. There are no connection requests to queue.

TLI defines an inherent client-server relationship between two users while establishing a transport connection in the connection mode service. No such relationship exists in connectionless mode service. This example, not TLI, defines one user as a server and the other as a client.

Because the address of the server is known by all potential clients, the server checks the bound address returned by t_bind() to ensure it is correct. t_bind() can also bind the endpoint to a separate, free address if the one requested is busy.

**Data Transfer**

Once a user has bound an address to the transport endpoint, datagrams may be sent or received over the endpoint. Each outgoing message carries the address of the destination user. TLI also lets you specify protocol options to the transfer of the data unit (for example, transit delay). Each transport provider defines the set of options on a datagram. When the datagram is passed to the destination user, the associated protocol options may be passed too.
Code Example 3-23 illustrates the data transfer phase of the connectionless mode server.

**Code Example 3-23  Data Transfer Routine**

```c
if ((ud = (struct t_unitdata *) t_alloc(fd, T_UNITDATA, T_ALL))
    == (struct t_unitdata *) NULL) {
    t_error("t_alloc of t_unitdata struct failed");
    exit(5);
}
if ((uderr = (struct t_uderr *) t_alloc(fd, T_UDERROR, T_ALL))
    == (struct t_uderr *) NULL) {
    t_error("t_alloc of t_uderr struct failed");
    exit(6);
}
while(1) {
    if (t_rcvudata(fd, ud, &flags) == -1) {
        if (t_errno == TLOOK) {
            /* Error on previously sent datagram */
            if (t_rcvuderr(fd, uderr) == -1) {
                exit(7);
            }
            fprintf(stderr, "bad datagram, error=%d\n",
                    uderr->error);
            continue;
        }
        t_error("t_rcvudata failed");
        exit(8);
    }
    /* Query() processes the request and places the response in
     * ud->udata.buf, setting ud->udata.len
     */
    query(ud);
    if (t_sndudata(fd, ud) == -1) {
        t_error("t_sndudata failed");
        exit(9);
    }
}
/* ARGS USED */
void
query(ud)
struct t_unitdata *ud;
```

*Programming With the Transport Layer Interface (TLI)*
To buffer datagrams, the server first allocates a `t_unitdata` structure, which has the following format:

```c
struct t_unitdata {
    struct netbuf addr;
    struct netbuf opt;
    struct netbuf udata;
}
```

- `addr` holds the source address of incoming datagrams and the destination address of outgoing datagrams.
- `opt` holds any protocol options on the datagram.
- `udata` holds the data. The `addr`, `opt`, and `udata` fields must all be allocated with buffers large enough to hold any possible incoming values. The `T_ALL` argument of `t_alloc()` ensures this and sets the `maxlen` field of each `netbuf` structure accordingly. The provider does not support protocol options in this example, so `maxlen` is set to 0 in the `opt` `netbuf` structure. The server also allocates a `t_uderr` structure for datagram errors.

The transaction server loops forever, receiving queries, processing the queries, and responding to the clients. It first calls `t_rcvudata()` to receive the next query. `t_rcvudata()` blocks until a datagram arrives, and returns it. The second argument of `t_rcvudata()` identifies the `t_unitdata` structure in which to buffer the datagram. The third argument, `flags`, points to an integer variable and may be set to `T_MORE` on return from `t_rcvudata()` to indicate that the user’s `udata` buffer is too small to store the full datagram. If this happens, the next call to `t_rcvudata()` gets the rest of the datagram. Because `t_alloc()` allocates a `udata` buffer large enough to store the maximum size datagram, this transaction server does not have to check `flags`. This is true only of `t_rcvudata()` and not of any other receive primitives.

When a datagram is received, the transaction server calls its `query` routine to process the request. This routine stores a response in the structure pointed to by `ud`, and sets `ud->udata.len` to the number of bytes in the response. The source address returned by `t_rcvudata()` in `ud->addr` is the destination address for `t_sndudata()`. When the response is ready, `t_sndudata()` is called to send the response to the client.
Datagram Errors

If the transport provider cannot process a datagram sent by `t_sndudata()`, it returns a unit data error event, `T_UDERR`, to the user. This event includes the destination address and options of the datagram, and a protocol-specific error value that identifies the error. Datagram errors are protocol specific.

**Note** – A unit data error event does not always indicate success or failure in delivering the datagram to the specified destination. Remember, connectionless service does not guarantee reliable delivery of data.

The transaction server is notified of an error when it tries to receive another datagram. In this case, `t_rcvudata()` will fail, setting `t_errno` to `TLOOK`. If `TLOOK` is set, the only possible event is `T_UDERR`, so the server calls `t_rcvuderr()` to retrieve the event. The second argument of `t_rcvuderr()` is the `t_uderr` structure that was allocated earlier. This structure is filled in by `t_rcvuderr()` and has the following format:

```c
struct t_uderr {
    struct netbuf addr;
    struct netbuf opt;
    long error;
}
```

where `addr` and `opt` identify the destination address and protocol options specified in the bad datagram, and `error` is a protocol-specific error code. The transaction server prints the error code and then continues.

Connection Mode

Connection mode is circuit oriented. Data are transmitted in sequence over an established connection. The mode also provides an identification procedure that avoids address resolution and transmission in the data transfer phase. Use this service for applications that require data stream-oriented interactions. Connection mode transport service has four phases:

- Local management
- Connection establishment
- Data transfer
- Connection release
The local management phase defines local operations between a transport user and a transport provider. For example, a user must establish a channel of communication with the transport provider. Each channel between a transport user and transport provider is a unique endpoint of communication, and is called the transport endpoint. \texttt{t\_open()} lets a user choose a particular transport provider to supply the connection mode services, and establishes the transport endpoint.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{transport_endpoint.png}
\caption{Transport Endpoint}
\end{figure}

\textit{Connection Mode Routines}

Each user must establish an identity with the transport provider. A transport address is associated with each transport endpoint. One user process may manage several transport endpoints. In connection mode service, one user requests a connection to another user by specifying the other’s address. The structure of a transport address is defined by the transport provider. An address may be as simple as an unstructured character string (for example, \texttt{file\_server}), or as complex as an encoded bit pattern that specifies all information needed to route data through a network. Each transport provider defines its own mechanism for identifying users. Addresses may be assigned to the endpoint of a transport by \texttt{t\_bind()}. 
In addition to `t_open()` and `t_bind()`, several routines support local operations. Many TLI routines have equivalents in the socket service library. The following table summarizes all local management routines of TLI.

<table>
<thead>
<tr>
<th>Command</th>

</table>
Figure 3-3  Transport Connection

The connection phase lets two users create a connection, or virtual circuit, between them, as shown in Figure 3-3.

For example, the connection phase occurs when a server advertises its service to a group of clients, and then blocks on t_listen() to wait for a request. A client tries to connect to the server at the advertised address by a call to t_connect(). The connection request causes t_listen() to return to the server, which can call t_accept() to complete the connection.

Table 3-3 summarizes all routines available for establishing a transport connection. Refer to man pages for the specifications on these routines.

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>t_accept</td>
<td>Accepts a request for a transport connection</td>
</tr>
<tr>
<td>t_connect</td>
<td>Establishes a connection with the transport user at a specified destination</td>
</tr>
<tr>
<td>t_listen</td>
<td>Listens for connect request from another transport user</td>
</tr>
<tr>
<td>t_rcvconnect</td>
<td>Completes connection establishment if t_connect was called in asynchronous mode (see “Advanced Topics” on page 93)</td>
</tr>
</tbody>
</table>
The data transfer phase lets users transfer data in both directions via the connection. \texttt{t snd()} sends and \texttt{t rcv()} receives data through the connection. It is assumed that all data sent by one user is guaranteed to be delivered to the other user in the order in which it was sent. Table 3-4 summarizes the connection mode data transfer routines.

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{t rcv}</td>
<td>Receives data that has arrived over a transport connection</td>
</tr>
<tr>
<td>\texttt{t snd}</td>
<td>Sends data over an established transport connection</td>
</tr>
</tbody>
</table>

TLI has two types of connection release. The abortive release directs the transport provider to release the connection immediately. Any previously sent data that has not yet been transmitted to the other user may be discarded by the transport provider. \texttt{t snddis()} initiates the abortive disconnect. \texttt{t rcvdis()} cleans up after an abortive disconnect. All transport providers must support the abortive release procedure.

Transport providers may also support an orderly release that terminates communication without discarding data. \texttt{t sndrel()} and \texttt{t rcvrel()} perform this function. Table 3-5 summarizes the connection release routines. Refer to man pages for the specifications on these routines.

<table>

</tr>
<tr>
<td>\texttt{t snddis}</td>
<td>Aborts a connection or rejects a connect request</td>
</tr>
<tr>
<td>\texttt{t sndrel}</td>
<td>Requests the orderly release of a connection</td>
</tr>
</tbody>
</table>
Connection Mode Service

The main concepts of connection mode service are illustrated through a client program and its server. The examples are presented in segments.

In the examples, the client establishes a connection to a server process. The server transfers a file to the client. The client receives the file contents and writes them to standard output.

Endpoint Initiation

Before a client and server can connect, each must first open a local connection to the transport provider (the transport endpoint) through `t_open()`, and establish its identity (or address) through `t_bind()`.

Many protocols perform a subset of the services defined in TLI. Each transport provider has characteristics that determine the services it provides and limit the services. Data defining the transport characteristics are returned by `t_open()` in a `t_info` structure. Table 3-6 shows the fields in a `t_info` structure.

Table 3-6  `t_info` Structure

<table>
<thead>

<td>Maximum bytes of user data that may be passed between users during the abortive release of a connection</td>
</tr>
<tr>
<td>servtype</td>
<td>The type of service supported by the transport provider</td>
</tr>
</tbody>
</table>
The three service types defined by TLI are:

- **T_COTS** – The transport provider supports connection mode service but does not provide the orderly release facility. Connection termination is abortive, and any data not already delivered is lost.

- **T_COTS_ORD** – The transport provider supports connection mode service with the orderly release facility.

- **T_CLTS** – The transport provider supports connectionless mode service.

Only one such service can be associated with the transport provider identified by `t_open()`.

- `t_open()` returns the default provider characteristics of a transport endpoint. Some characteristics may change after an endpoint has been opened. This happens with negotiated options (option negotiation is described later in this section). `t_getinfo()` returns the current characteristics of a transport endpoint.

Once a user establishes an endpoint with the chosen transport provider, the client and server must establish their identities. `t_bind()` does this by binding a transport address to the transport endpoint. For servers, this routine informs the transport provider that the endpoint is used to listen for incoming connect requests.

- `t_optmgmt()` can be used during the local management phase. It lets a user negotiate the values of protocol options with the transport provider. Each transport protocol defines its own set of negotiable protocol options, such as quality-of-service parameters. Because the options are protocol-specific, only applications written for a specific protocol use this function.

### Client

The local management requirements of the example client and server are used to discuss details of these facilities. Code Example 3-24 shows the definitions needed by the client program, followed by its necessary local management steps.

**Code Example 3-24**  
Client Implementation of Open and Bind

```c
#include <stdio.h>
#include <tiuser.h>
#include <fcntl.h>
```
```c
#define SRV_ADDR 1                        /* server’s address */

main()
{
    int fd;
    int nbytes;
    int flags = 0;
    char buf[1024];
    struct t_call *sndcall;
    extern int t_errno;

    if ((fd = t_open("/dev/exmp", O_RDWR, (struct t_info *), NULL))
        == -1) {
        t_error("t_open failed");
        exit(1);
    }
    if (t_bind(fd, (struct t_bind *) NULL, (struct t_bind *) NULL)
        == -1) {
        t_error("t_bind failed");
        exit(2);
    }
}
```

The first argument of `t_open()` is the path of a file system object that identifies the transport protocol. `/dev/exmp` is the example name of a special file that identifies a generic, connection-based transport protocol. It must be created on the workstation for this purpose. The second argument, `O_RDWR`, specifies to open for both reading and writing. The third argument points to a `t_info` structure in which to return the service characteristics of the transport. This data is useful to write protocol-independent software (see “Guidelines to Protocol Independence” on page 106). In this example a `NULL` pointer is passed. For Code Example 3-24 on page 73, the transport provider must have the following characteristics:

- The transport address is an integer value that uniquely identifies each user.
- The transport provider supports the `T_COTS_ORD` service type since the example uses orderly release.
- The transport provider does not require protocol-specific options.

If the user needs a service other than `T_COTS_ORD`, another transport provider can be opened. An example of the `T_CLTS` service invocation is shown in the section “A Read/Write Interface” on page 90.
t_open() returns the transport endpoint file handle that is used by all subsequent TLI function calls. The identifier is a file descriptor from opening the transport protocol file. See open(2).

The client then calls t_bind() to assign an address to the endpoint. The first argument of t_bind() is the transport endpoint handle. The second argument points to a t_bind structure that describes the address to bind to the endpoint. The third argument points to a t_bind structure that describes the address that the provider bound.

The address of a client is rarely important, because no other process tries to access it. That is why the second and third arguments to t_bind() are NULL. The second NULL argument directs the transport provider to choose an address for the user.

If t_open() or t_bind() fails, the program calls t_error() to display an appropriate error message via stderr. The global integer t_errno is assigned an error value. A set of error values is defined in <tiuser.h>. t_error() is analogous to perror(). If the transport function error is a system error, t_errno() is set to TSYSERR, and errno is set to the appropriate value.

Server

The server example must also establish a transport endpoint at which to listen for connection requests. Code Example 3-25 shows the definitions and local management steps.

Code Example 3-25 Server Implementation of Open and Bind

```
#include <tiuser.h>
#include <stropts.h>
#include <fcntl.h>
#include <stdio.h>
#include <signal.h>

#define DISCONNECT -1
#define SRV_ADDR 1 /* server’s address */
int conn_fd; /* connection established here */
extern int t_errno;

main()
{
    int listen_fd; /* listening transport endpoint */
    struct t_bind *bind;
```
Like the client, the server first calls `t_open()` to establish a transport endpoint with the desired transport provider. The endpoint, `listen_fd`, is used to listen for connect requests.

Next, the server binds its address to the endpoint. This address is used by each client to access the server. The second argument points to a `t_bind` structure that specifies the address to bind to the endpoint. The `t_bind` structure has the following format:

```c
struct t_bind {
    struct netbuf addr;
    unsigned qlen;
}
```
where \texttt{addr} describes the address to be bound, and \texttt{qlen} specifies the maximum number of outstanding connect requests. All TLI structure and constant definitions are in \texttt{<tiuser.h>}. 

The address is specified in the \texttt{netbuf} structure with the following format:

\begin{verbatim}
struct netbuf {
    unsigned int maxlen;
    unsigned int len;
    char *buf;
}
\end{verbatim}

where \texttt{maxlen} specifies the maximum length of the buffer in bytes, \texttt{len} specifies the bytes of data in the buffer, and \texttt{buf} points to the buffer that contains the data.

In the \texttt{t_bind} structure, the data identifies a transport address. \texttt{qlen} specifies the maximum number of connect requests that can be queued. If the value of \texttt{qlen} is positive, the endpoint can be used to listen for connect requests. \texttt{t_bind()} directs the transport provider to queue connect requests for the bound address immediately. The server must dequeue each connect request and accept or reject it. For a server that fully processes a single connect request and responds to it before receiving the next request, a value of 1 is appropriate for \texttt{qlen}. Servers that dequeue several connect requests before responding to any should specify a longer queue. The server in this example processes connect requests one at a time, so \texttt{qlen} is set to 1.

\texttt{t_alloc()} is called to allocate the \texttt{t_bind} structure. \texttt{t_alloc()} has three arguments: a file descriptor of a transport endpoint; the identifier of the structure to allocate; and a flag that specifies which, if any, \texttt{netbuf} buffers to allocate. \texttt{T_ALL} specifies to allocate all \texttt{netbuf} buffers, and causes the \texttt{addr} buffer to be allocated in this example. Buffer size is determined automatically and stored in the \texttt{maxlen} field.

Each transport provider manages its address space differently. Some transport providers allow a single transport address to be bound to several transport endpoints, while others require a unique address per endpoint. TLI supports both. Based on its rules, a provider determines if it can bind the requested address. If not, it chooses another valid address from its address space and binds it to the transport endpoint. The server must check the bound address to ensure that it is the one previously advertised to clients.

If \texttt{t_bind()} succeeds, the provider begins queuing connect requests, entering the next phase of communication.
Connection Establishment

TLI imposes different procedures in this phase for clients and servers. The client starts connection establishment by requesting a connection to a specified server using `t_connect()`. The server receives a client’s request by calling `t_listen()`. The server must accept or reject the client’s request. It calls `t_accept()` to establish the connection, or `t_snddis()` to reject the request. The client is notified of the result when `t_connect()` returns.

TLI supports two facilities during connection establishment that may not be supported by all transport providers:

- Data transfer between the client and server when establishing the connection – The client may send data to the server when it requests a connection. This data is passed to the server by `t_listen()`. The server can send data to the client when it accepts or rejects the connection. The connect characteristic returned by `t_open()` determines how much data, if any, two users may transfer during connect establishment.

- The negotiation of protocol options – The client may specify preferred protocol options to the transport provider and/or the remote user. TLI supports both local and remote option negotiation. Option negotiation is a protocol-specific capacity.

These facilities produce protocol-dependent software (see “Guidelines to Protocol Independence” on page 106).

Client

The steps for the client to establish a connection are shown in Code Example 3-26.

Code Example 3-26  Client-to-Server Connection

```c
/*
 * Because it assumes it knows the format of the provider’s
 * address, this program is transport-dependent
 */
if ((sndcall = (struct t_call *) t_alloc(fd, T_CALL, T_ADDR))
    == (struct t_call *) NULL) {
    t_error("t_alloc failed");
    exit(3);
}
sndcall->addr.len = sizeof(int);```

*(int *) sndcall->addr.buf = SRV_ADDR;
if (t_connect( fd, sndcall, (struct t_call *) NULL) == -1 ) {
    t_error("t_connect failed for fd");
    exit(4);
}

The t_connect() call connects to the server. The first argument of
the t_connect() identifies the client’s endpoint, and the second argument points
to a t_call structure that identifies the destination server. This structure has
the following format:

```
struct t_call {
    struct netbuf addr;
    struct netbuf opt;
    struct netbuf udata;
    int sequence;
}
```

addr identifies the address of the server, opt specifies protocol-specific
options to the connection, and udata identifies user data that may be sent with
the connect request to the server. The sequence field has no meaning for
t_connect(). In this example, only the server’s address is passed.

t_alloc() allocates the t_call structure dynamically. The third argument of
t_alloc() is T_ADDR to specify to allocate a netbuf buffer. The server’s
address is then copied to buf, and len is set accordingly.

The third argument of t_connect() can be used to return information about
the newly established connection, and can return any user data sent by the
server in its response to the connect request. The third argument here is set to
NULL by the client. The connection is established on successful return of
t_connect(). If the server rejects the connect request, t_connect() sets
t_errno to TLOOK.
Event Handling

The TLOOK error has special significance. TLOOK is set if a TLI routine is interrupted by an unexpected asynchronous transport event on the endpoint. TLOOK does not report an error with a TLI routine, but the normal processing of the routine is not done because of the pending event. The events defined by TLI are listed in Table 3-7.

Table 3-7  Asynchronous Endpoint Events

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>T_LISTEN</td>
<td>Connection request arrived at the transport endpoint</td>
</tr>
<tr>
<td>T_CONNECT</td>
<td>Confirmation of a previous connect request arrived (generated when a server accepts a connect request)</td>
</tr>
<tr>
<td>T_DATA</td>
<td>User data has arrived</td>
</tr>
<tr>
<td>T_EXDATA</td>
<td>Expedited user data arrived</td>
</tr>
<tr>
<td>T_DISCONNECT</td>
<td>Notice of an aborted connection or of a rejected connect request arrived</td>
</tr>
<tr>
<td>T_ORDREL</td>
<td>A request for orderly release of a connection arrived</td>
</tr>
<tr>
<td>T_UDERR</td>
<td>Notice of an error in a previous datagram arrived. (see “A Read/Write Interface” on page 90)</td>
</tr>
</tbody>
</table>

The state table in “State Transitions” on page 100 shows which events can happen in each state. t_look() lets a user determine what event has occurred if a TLOOK error is returned. In the example, if a connect request is rejected, the client exits.

Server

When the client calls t_connect(), a connect request is sent at the server’s transport endpoint. For each client, the server accepts the connect request and spawns a process to service the connection.

```c
if ((call = (struct t_call *) t_alloc(listen_fd, T_CALL, T_ALL))
    == (struct t_call *) NULL) {
    t_error("t_alloc of t_call structure failed");
    exit(5);
}
while(1) {
    if (t_listen( listen_fd, call) == -1) {
```
The server allocates a \texttt{t\_call} structure, then does a closed loop. The loop blocks on \texttt{t\_listen()} for a connect request. When a request arrives, the server calls \texttt{accept\_call()} to accept the connect request. \texttt{accept\_call()} accepts the connection on an alternate transport endpoint (as discussed below) and returns the handle of that endpoint. (\texttt{conn\_fd} is a global variable.) Because the connection is accepted on an alternate endpoint, the server can continue to listen on the original endpoint. If the call is accepted without error, \texttt{run\_server} spawns a process to service the connection.

\textbf{Note} – TLI supports an asynchronous mode for these routines that prevents a process from blocking. See “Advanced Topics” on page 93.

When a connect request arrives, the server calls \texttt{accept\_call()} to accept the client’s request, as Code Example 3-27 shows.

\emph{Code Example 3-27} \texttt{accept\_call} Function

\begin{verbatim}
accept_call(listen_fd, call)
int listen_fd;
struct t\_call *call;
{
  int resfd;

  if ((resfd = t\_open("/dev/exmp", O\_RDWR, (struct t\_info *)
      NULL)) == -1) {
    t\_error("t\_open for responding fd failed");
    exit(7);
  }

  if (t\_bind(resfd,(struct t\_bind *) NULL, (struct t\_bind *NULL))
      == -1) {
    t\_error("t\_bind for responding fd failed");
    exit(8);
  }

  if (t\_accept(listen_fd, resfd, call) == -1) {
    if (t\_errno == TLOOK) { /* must be a disconnect */
      if (t\_rcvdis(listen_fd,(struct t\_discon *) NULL) == -1) {
        t\_error("t\_listen failed for listen_fd");
        exit(6);
      }
    }
  }

  if ((conn\_fd = accept\_call(listen_fd, call)) != DISCONNECT)
    run\_server(listen_fd);
}
\end{verbatim}
t_error("t_rcvdis failed for listen_fd");
exit(9);
}

if (t_close(resfd) == -1) {
    t_error("t_close failed for responding fd");
    exit(10);
}

/* go back up and listen for other calls */
return(DISCONNECT);
}

t_error("t_accept failed");
exit(11);
}
return(resfd);
}

accept_call() has two arguments:

1. listen_fd is the file handle of the transport endpoint where the connect request arrived.

2. call points to a t_call structure that contains all information associated with the connect request.

The server first opens another transport endpoint by opening the clone device special file of the transport provider and binding an address. A NULL specifies not to return the address bound by the provider. The new transport endpoint, resfd, accepts the client’s connect request.

The first two arguments of t_accept() specify the listening transport endpoint and the endpoint where the connection is accepted respectively. Accepting a connection on the listening endpoint prevents other clients from accessing the server for the duration of the connection.

The third argument of t_accept() points to the t_call structure containing the connect request. This structure should contain the address of the calling user and the sequence number returned by t_listen(). The sequence number is significant if the server queues multiple connect requests. The “Advanced Topics” on page 93 shows an example of this. The t_call structure also identifies protocol options and user data to pass to the client. Because this transport provider does not support protocol options or the transfer of user data during connection, the t_call structure returned by t_listen() is passed without change to t_accept().
The example is simplified. The server exits if either the `t_open()` or `t_bind()` call fails. `exit()` closes the transport endpoint of `listen_fd`, causing a disconnect request to be sent to the client. The client’s `t_connect()` call fails, setting `t_errno` to `TLOOK`.

`t_accept()` can fail if an asynchronous event occurs on the listening endpoint before the connection is accepted, and `t_errno` will be set to `TLOOK`. Table 6-8 on page 207 shows that only a disconnect request can be sent in this state with only one queued connect request. This event can happen if the client undoes a previous connect request. If a disconnect request arrives, the server must respond by calling `t_rcvdis()`. This routine argument is a pointer to a `t_discon` structure, which is used to retrieve the data of the disconnect request. In this example, the server passes a `NULL`.

After receiving a disconnect request, `accept_call()` closes the responding transport endpoint and returns `DISCONNECT`, which informs the server that the connection was disconnected by the client. The server then listens for further connect requests.

The figure illustrates how the server establishes connections:

![Diagram](image)

Figure 3-4  Listening and Responding Transport Endpoints

The transport connection is established on the new responding endpoint, and the listening endpoint is freed to retrieve further connect requests.
Data Transfer

Once the connection is established, both the client and the server can transfer data through the connection using `t_snd()` and `t_rcv()`. TLI does not differentiate the client from the server from this point on. Either user may send data, receive data, or release the connection.

There are two classes of data on a transport connection:

1. Normal data
2. Expedited data

Expedited mode is for urgent data. The exact semantics of expedited data vary between transport providers. Not all transport protocols support expedited data (see `t_open(3N)`).

All connection oriented mode protocols must transfer data in byte streams. “Byte stream” implies no message boundaries in data sent over a connection. Some transport protocols preserve message boundaries over a transport connection. This service is supported by TLI, but protocol-independent software must not rely on it.

The message boundaries are invoked by the `T_MORE` flag of `t_snd()` and `t_rcv()`. The messages, called transport service data units (TSDU), may be transferred between two transport users as distinct units. The maximum message size is defined by the underlying transport protocol. Get the message size through `t_open()` or `t_getinfo()`. You can send a message in multiple units.

Set the `T_MORE` flag on every `t_snd()` call except the last to send a message in multiple units. The flag specifies that the data in the current and the next `t_snd()` calls are a logical unit. Send the last message unit with `T_MORE` turned off to specify the end of the logical unit.

Similarly, a logical unit may be sent in multiple units. If `t_rcv()` returns with the `T_MORE` flag set, the user must call `t_rcv()` again to receive the rest of the message. The last unit in the message is identified by a call to `t_rcv()` that does not set `T_MORE`.

The `T_MORE` flag implies nothing about how the data is packaged below TLI or how the data is delivered to the remote user. Each transport protocol, and each implementation of a protocol, may package and deliver the data differently.
For example, if a user sends a complete message in a single call to `t_snd()`, there is no guarantee that the transport provider delivers the data in a single unit to the receiving user. Similarly, a message transmitted in two units may be delivered in a single unit to the remote transport user. The message boundaries are preserved only by setting the value of `T_MORE` for `t_snd()` and testing it after `t_rcv()`. This guarantees that the receiver sees a message with the same contents and message boundaries as was sent.

**Client**

The example server transfers a log file to the client over the transport connection. The client receives the data and writes it to its standard output file. A byte stream interface is used by the client and server, with no message boundaries. The client receives data by the following:

```c
while ((nbytes = t_rcv(fd, buf, nbytes, &flags))!= -1){
    if (fwrite(buf, 1, nbytes, stdout) == -1) {
        fprintf(stderr, "fwrite failed\n");
        exit(5);
    }
}
```

The client repeatedly calls `t_rcv()` to receive incoming data. `t_rcv()` blocks until data arrives. `t_rcv()` writes up to `nbytes` of the data available into `buf` and returns the number of bytes buffered. The client writes the data to standard output and continues. The data transfer loop ends when `t_rcv()` fails. `t_rcv()` fails when an orderly release or disconnect request arrives. If `fwrite()` fails for any reason, the client exits, which closes the transport endpoint. If the transport endpoint is closed (either by `exit()` or `t_close()`) during data transfer, the connection is aborted and the remote user receives a disconnect request.

**Server**

The server manages its data transfer by spawning a child process to send the data to the client. The parent process continues the loop to listen for more connect requests. `run_server()` is called by the server to spawn this child process, as shown in Code Example 3-28.
Code Example 3-28  Spawning Child Process to Loopback and Listen

connrelease()
{
    /* conn_fd is global because needed here */
    if (t_look(conn_fd) == T_DISCONNECT) {
        fprintf(stderr, "connection aborted\n");
        exit(12);
    }
    /* else orderly release request - normal exit */
    exit(0);
}

run_server(listen_fd)
int listen_fd;
{
    int nbytes;
    FILE *logfp;                    /* file pointer to log file */
    char buf[1024];

    switch(fork()) {
    case -1:
        perror("fork failed");
        exit(20);
    default:                                          /* parent */
        /* close conn_fd and then go up and listen again*/
        if (t_close(conn_fd) == -1) {
            t_error("t_close failed for conn_fd");
            exit(21);
        }
        return;
    case 0:                                            /* child */
        /* close listen_fd and do service */
        if (t_close(listen_fd) == -1) {
            t_error("t_close failed for listen_fd");
            exit(22);
        }
        if ((logfp = fopen("logfile", "r")) == (FILE *) NULL) {
            perror("cannot open logfile");
            exit(23);
        }
        signal(SIGPOLL, connrelease);
        if (ioctl(conn_fd, I_SETSIG, S_INPUT) == -1) {
            perror("ioctl I_SETSIG failed");
            exit(24);
        }
        if (t_look(conn_fd) != 0) /* disconnect there?*/
```c
fprintf(stderr, "t_look: unexpected event\n");
exit(25);
}
while ((nbytes = fread(buf, 1, 1024, logfp)) > 0)
  if (t_snd(conn_fd, buf, nbytes, 0) == -1) {
    t_error("t_snd failed");
    exit(26);
  }
```

After the fork, the parent process returns to the main listening loop. The child process manages the newly established transport connection. If the fork fails, `exit()` closes both transport endpoints, sending a disconnect request to the client, and the client’s `t_connect()` call fails.

The server process reads 1024 bytes of the log file at a time and sends the data to the client using `t_snd()`. `buf` points to the start of the data buffer, and `nbytes` specifies the number of bytes to transmit. The fourth argument can be zero or one of the two optional flags below:

- **T_EXPEDITED** specifies that the data is expedited.
- **T_MORE** specifies that the next block will continue the message in this block.

Neither flag is set by the server in this example.

If the user floods the transport provider with data, `t_snd()` blocks until enough data is removed from the transport.

`t_snd()` does not look for a disconnect request (showing that the connection was broken). If the connection is aborted, the server should be notified since data may be lost. One solution is to call `t_look()` to check for incoming events before each `t_snd()` call or after a `t_snd()` failure. The example has a cleaner solution. The `I_SETSIG` ioctl lets a user request a signal when a specified event occurs. See the `streamio(7I)` manpage. `S_INPUT` causes a signal to the user when any input arrives at the endpoint `conn_fd`. If a disconnect request arrives, the signal-catching routine (`connrelease()`) prints an error message and exits.

If the server alternates `t_snd()` and `t_rcv()` calls, it can use `t_rcv()` to recognize an incoming disconnect request.
Connection Release

At any time during data transfer, either user can release the transport connection and end the conversation. There are two forms of connection release. The first way, abortive release, breaks the connection immediately and discards any data that has not been delivered to the destination user.

Either user can call `t_snddis()` to perform an abortive release. The transport provider can abort a connection if a problem occurs below TLI. `t_snddis()` lets a user send data to the remote user when aborting a connection. The abortive release is supported by all transport providers, the ability to send data when aborting a connection is not.

When the remote user is notified of the aborted connection, call `t_rcvdis()` to receive the disconnect request. The call returns a code that identifies why the connection was aborted, and returns any data that may have accompanied the disconnect request (if the abort was initiated by the remote user). The reason code is specific to the underlying transport protocol, and should not be interpreted by protocol-independent software.

The second way, orderly release, ends a connection so that no data is lost. All transport providers must support the abortive release procedure, but orderly release is an option not supported by all connection-oriented protocols.

Server

This example assumes that the transport provider supports orderly release. When all the data has been sent by the server, the connection is released as follows:

```c
if (t_sndrel(conn_fd) == -1) {
    t_error("t_sndrel failed");
    exit(27);
}
pause(); /* until orderly release request arrives */
```

Orderly release requires two steps by each user. The server can call `t_sndrel()`. This routine sends a disconnect request. When the client receives the request, it can continue sending data back to the server. When all data have been sent, the client calls `t_sndrel()` to send a disconnect request back. The connection is released only after both users have received a disconnect request.
In this example, data is transferred only from the server to the client. So there is no provision to receive data from the client after the server initiates release. The server calls `pause()` after initiating the release.

The client responds with its orderly release request, which generates a signal caught by `connrelease()`. (In Code Example 3-28 on page 86, the server issued an `I_SETSIG` ioctl call to generate a signal on any incoming event.) The only TLI event possible in this state is a disconnect request or an orderly release request, so `connrelease()` exits normally when the orderly release request arrives. `exit()` from `connrelease()` closes the transport endpoint and frees the bound address. To close a transport endpoint without exiting, call `t_close()`.

**Client**

The client releases the connection similarly to the server. The client processes incoming data until `t_rcv()` fails. When the server releases the connection (using either `t_snddis()` or `t_sndrel()`), `t_rcv()` fails and sets `t_errno` to `TLOOK`. The client then processes the connection release as follows:

```c
if ((t_errno == TLOOK) && (t_look(fd) == T_ORDREL)) {
    if (t_rcvrel(fd) == -1) {
        t_error("t_rcvrel failed");
        exit(6);
    }
    if (t_sndrel(fd) == -1) {
        t_error("t_sndrel failed");
        exit(7);
    }
    exit(0);
}
```

Each event on the client’s transport endpoint is checked for an orderly release request. When one is received, the client calls `t_rcvrel()` to process the request and `t_sndrel()` to send the response release request. The client then exits, closing its transport endpoint.

If a transport provider does not support the orderly release, use abortive release with `t_snddis()` and `t_rcvdis()`. Each user must take steps to prevent data loss. For example, use a special byte pattern in the data stream to indicate the end of a conversation.
A Read/Write Interface

A user may want to establish a transport connection using `exec()` on an existing program (such as `/usr/bin/cat`) to process the data as it arrives over the connection. Existing programs use `read()` and `write()`. TLI does not directly support a read/write interface to a transport provider, but one is available. The interface lets you issue `read()` and `write()` calls over a transport connection in the data transfer phase. This section describes the read/write interface to the connection mode service of TLI. This interface is not available with the connectionless mode service.

The read/write interface is presented using the client example of “Connection Mode Service” on page 72 with modifications. The clients are identical until the data transfer phase. Then the client uses the read/write interface and `cat` to process incoming data. `cat` is run without change over the transport connection. Only the differences between this client and that of the client in Code Example 3-24 on page 73 are shown in Code Example 3-29.

Code Example 3-29  Read/Write Interface

```c
#include <stropts.h>
.
/*
   Same local management and connection establishment steps.
   */
.
if (ioctl(fd, I_PUSH, "tirdwr") == -1) {
    perror("I_PUSH of tirdwr failed");
    exit(5);
}
close(0);
dup(fd);
execl("/usr/bin/cat", "/usr/bin/cat", (char *) 0);
perror("exec of /usr/bin/cat failed");
exit(6);
}
```

The client invokes the read/write interface by pushing `tirdwr` onto the stream associated with the transport endpoint. See `I_PUSH` in `streamio(7I)`. `tirdwr` converts TLI above the transport provider into a pure read/write interface. With the module in place, the client calls `close()` and `dup()` to establish the transport endpoint as its standard input file, and uses `/usr/bin/cat` to process the input.
By pushing `tirdwr` onto the transport provider, TLI is changed. The semantics of `read()` and `write()` must be used, and message boundaries are not preserved. `tirdwr` can be popped from the transport provider to restore TLI semantics (see `I_POP` in `streamio(7I)`.

**Caution** – The `tirdwr` module may only be pushed onto a stream when the transport endpoint is in the data transfer phase. Once the module is pushed, the user may not call any TLI routines. If a TLI routine is invoked, `tirdwr` generates a fatal protocol error, `EPROTO`, on the stream, rendering it unusable. If you then pop the `tirdwr` module off the stream, the transport connection is aborted. See `I_POP` in `streamio(7I)`.

**write**

Send data over the transport connection with `write()`. `tirdwr` passes data through to the transport provider. If you send a zero-length data packet, which the mechanism allows, `tirdwr` discards the message. If the transport connection is aborted (for example, because the remote user aborts the connection using `t_snddis()`), a hang-up condition is generated on the stream, further `write()` calls fail, and `errno` is set to `ENXIO`. You can still retrieve any available data after a hang-up.

**read**

Receive data that arrives at the transport connection with `read()`. `tirdwr` which passes data from the transport provider. Any other event or request passed to the user from the provider is processed by `tirdwr` as follows:

- `read()` cannot identify expedited data to the user. If an expedited data request is received, `tirdwr` generates a fatal protocol error, `EPROTO`, on the stream. The error causes further system calls to fail. Do not use `read()` to receive expedited data.

- `tirdwr` discards an abortive disconnect request and generates a hang-up condition on the stream. Subsequent `read()` calls will retrieve any remaining data, then return zero for all further calls (indicating end of file).

- `tirdwr` discards an orderly release request and delivers a zero-length message to the user. As described in `read()`, this notifies the user of end of file by returning 0.
If any other TLI request is received, \texttt{tirdwr} generates a fatal protocol error, \texttt{EPROTO}, on the stream. This causes further system calls to fail. If a user pushes \texttt{tirdwr} onto a stream after the connection has been established, no request is generated.

**close**

With \texttt{tirdwr} on a stream, you can send and receive data over a transport connection for the duration of the connection. Either user can terminate the connection by closing the file descriptor associated with the transport endpoint or by popping the \texttt{tirdwr} module off the stream. In either case, \texttt{tirdwr} does the following:

- If an orderly release request was previously received by \texttt{tirdwr}, it is passed to the transport provider to complete the orderly release of the connection. The remote user who initiated the orderly release procedure receives the expected request when data transfer completes.

- If a disconnect request was previously received by \texttt{tirdwr}, no special action is taken.

- If neither an orderly release nor a disconnect request was previously received by \texttt{tirdwr}, a disconnect request is passed to the transport provider to abort the connection.

- If an error previously occurred on the stream and a disconnect request has not been received by \texttt{tirdwr}, a disconnect request is passed to the transport provider.

A process cannot initiate an orderly release after \texttt{tirdwr} is pushed onto a stream. \texttt{tirdwr} handles an orderly release if it is initiated by the user on the other side of a transport connection. If the client in this section is communicating with the server program in “Connection Mode Service” on page 72, the server will terminate the transfer of data with an orderly release request. The server then waits for the corresponding request from the client. At that point, the client exits and the transport endpoint is closed. When the file descriptor is closed, \texttt{tirdwr} initiates the orderly release request from the client’s side of the connection. This generates the request that the server is blocked on.

Some protocols, like TCP, require this orderly release to ensure that the data is delivered intact.
Advanced Topics

This section presents additional TLI concepts:

• An optional nonblocking (asynchronous) mode for some library calls
• How to set and get TCP and UDP options under TLI
• A program example of a server supporting multiple outstanding connect requests and operating in an event-driven manner

Asynchronous Execution Mode

Many TLI library routines block to wait for an incoming event. However, some time-critical applications should not block for any reason. An application may do local processing while waiting for some asynchronous TLI event.

Asynchronous processing of TLI events is available to applications through the combination of asynchronous features and the non-blocking mode of TLI library routines. Use of the poll() system call and the I_SETSIG ioctl command to process events asynchronously is described in ONC+ Developer’s Guide.

Each TLI routine that blocks for an event can be run in a special non-blocking mode. For example, t_listen() normally blocks for a connect request. A server can periodically poll a transport endpoint for queued connect requests by calling t_listen() in the non-blocking (or asynchronous) mode. The asynchronous mode is enabled by setting O_NDELAY or O_NONBLOCK in the file descriptor. These modes can be set as a flag through t_open(), or by calling fcntl() before calling the TLI routine. fcntl() enables or disables this mode at any time. All program examples in this chapter use the default synchronous processing mode.

O_NDELAY or O_NONBLOCK affect each TLI routine differently. You will need to determine the exact semantics of O_NDELAY or O_NONBLOCK for a particular routine.

Advanced Programming Example

The following example demonstrates two important concepts. The first is a server’s ability to manage multiple outstanding connect requests. The second is event-driven use of TLI and the system call interface.
The server example in Code Example 3-25 on page 75 supports only one outstanding connect request, but TLI lets a server manage multiple outstanding connect requests. One reason to receive several simultaneous connect requests is to prioritize the clients. A server can receive several connect requests, and accept them in an order based on the priority of each client. The second reason for handling several outstanding connect requests is the limits of single-threaded processing. Depending on the transport provider, while a server processes one connect request, other clients find it busy. If multiple connect requests are processed simultaneously, the server will be found busy only if more than the maximum number of clients try to call the server simultaneously.

The server example is event-driven: the process polls a transport endpoint for incoming TLI events, and takes the appropriate actions for the event received. The example demonstrates the ability to poll multiple transport endpoints for incoming events.

The definitions and endpoint establishment functions of Code Example 3-30 are similar to those of the server example in Code Example 3-25 on page 75.

**Code Example 3-30  Endpoint Establishment (Convertible to Multiple Connections)**

```c
#include <tiuser.h>
#include <fcntl.h>
#include <stdio.h>
#include <poll.h>
#include <stropts.h>
#include <signal.h>

#define NUM_FDS 1
#define MAX_CONN_IND 4
#define SRV_ADDR 1                  /* server’s well known address */

int conn_fd;                        /* server connection here */
extern int t_errno;                 /* holds connect requests */
struct t_call *calls[NUM_FDS][MAX_CONN_IND];

main()
{
    struct pollfd pollfds[NUM_FDS];
    struct t_bind *bind;
    int i;
```
The file descriptor returned by `t_open()` is stored in a `pollfd` structure that controls polling the transport endpoints for incoming data. See `poll(2)`. Only one transport endpoint is established in this example. However, the remainder of the example is written to manage multiple transport endpoints. Several endpoints could be supported with minor changes to Code Example 3-30.

This server sets `qilen` to a value greater than 1 for `t_bind()`. This specifies that the server queues multiple outstanding connect requests. The server accepts the current connect request before accepting additional connect requests. This example can queue up to `MAX_CONN_IND` connect requests. The transport provider may negotiate the value of `qilen` smaller if it cannot support `MAX_CONN_IND` outstanding connect requests.
Once the server has bound its address and is ready to process connect requests, it behaves as shown in Code Example 3-31.

**Code Example 3-31  Processing Connection Requests**

```c
pollfds[0].events = POLLIN;

while (TRUE) {
    if (poll(pollfds, NUM_FDS, -1) == -1) {
        perror("poll failed");
        exit(5);
    }
    for (i = 0; i < NUM_FDS; i++) {
        switch (pollfds[i].revents) {
            default:
                perror("poll returned error event");
                exit(6);
            case 0:
                continue;
            case POLLIN:
                do_event(i, pollfds[i].fd);
                service_conn_ind(i, pollfds[i].fd);
        }
    }
}
```

The `events` field of the `pollfd` structure is set to `POLLIN`, which notifies the server of any incoming TLI events. The server then enters an infinite loop in which it polls the transport endpoint(s) for events, and processes events as they occur.

The `poll()` call blocks indefinitely for an incoming event. On return, each entry (one per transport endpoint) is checked for a new event. If `revents` is 0, no event has occurred on the endpoint and the server continues to the next endpoint. If `revents` is `POLLIN`, there is an event on the endpoint. `do_event()` is called to process the event. Any other value in `revents` indicates an error on the endpoint, and the server exits. With multiple endpoints, it is better for the server to close this descriptor and continue.

For each iteration of the loop, `service_conn_ind()` is called to process any outstanding connect requests. If another connect request is pending, `service_conn_ind()` saves the new connect request and responds to it later. `do_event()` in Code Example 3-32 is called to process an incoming event.
Code Example 3-32  Event Processing Routine

do_event(slot, fd)
int slot;
int fd;
{
    struct t_discon *discon;
    int i;

    switch (t_look(fd)) {
    default:
        fprintf(stderr, "t_look: unexpected event\n");
        exit(7);
    case T_ERROR:
        fprintf(stderr, "t_look returned T_ERROR event\n");
        exit(8);
    case -1:
        t_error("t_look failed");
        exit(9);
    case 0:
        /* since POLLIN returned, this should not happen */
        fprintf(stderr,"t_look returned no event\n");
        exit(10);
    case T_LISTEN:
        /* find free element in calls array */
        for (i = 0; i < MAX_CONN_IND; i++) {
            if (calls[slot][i] == (struct t_call *) NULL)
                break;
        }
    if ((calls[slot][i] = (struct t_call *) t_alloc(fd, T_CALL,
            T_ALL)) == (struct t_call *) NULL) {
            t_error("t_alloc of t_call structure failed");
            exit(11);
        }
    if (t_listen(fd, calls[slot][i] ) == -1) {
            t_error("t_listen failed");
            exit(12);
        }
    break;
    case T_DISCONNECT:
        discon = (struct t_discon *) t_alloc(fd, T_DIS, T_ALL);
        if(t_rcvdis(fd, discon) == -1) {
            t_error("t_rcvdis failed");
            exit(13);
        }
    /* find call ind in array and delete it */
for (i = 0; i < MAX_CONN_IND; i++) {
    if (discon->sequence == calls[slot][i]->sequence) {
        t_free(calls[slot][i], T_CALL);
        calls[slot][i] = (struct t_call *) NULL;
    }
}
t_free(discon, T_DIS);
break;
}

The arguments are a number (slot) and a file descriptor (fd). slot is the index into the global array calls. calls has an entry for each transport endpoint. Each entry is an array of t_call structures that hold incoming connect requests for the endpoint.

do_event() calls t_look() to identify the TLI event on the endpoint specified by fd. If the event is a connect request (T_LISTEN event) or disconnect request (T_DISCONNECT event), the event is processed. Otherwise, the server prints an error message and exits.

For connect requests, do_event() scans the array of outstanding connect requests for the first free entry. A t_call structure is allocated for the entry, and the connect request is received by t_listen(). The array is large enough to hold the maximum number of outstanding connect requests. The processing of the connect request is deferred.

A disconnect request must correspond to an earlier connect request. do_event() allocates a t_discon structure to receive the request. This structure has the following fields:

```
struct t_discon {
    struct netbuf udata;
    int reason;
    int sequence;
}
```

udata contains any user data sent with the disconnect request. reason contains a protocol-specific disconnect reason code. sequence identifies the connect request that matches the disconnect request.

t_rcvdis() is called to receive the disconnect request. The array of connect requests is scanned for one that contains the sequence number that matches the sequence number in the disconnect request. When the connect request is found, its structure is freed and the entry is set to NULL.
When an event is found on a transport endpoint, `service_conn_ind()` is called to process all queued connect requests on the endpoint as Code Example 3-33 shows.

**Code Example 3-33  Process All Connect Requests**

```c
service_conn_ind(slot, fd)
{
    int i;

    for (i = 0; i < MAX_CONN_IND; i++) {
        if (calls[slot][i] == (struct t_call *) NULL)
            continue;
        if((conn_fd = t_open( "/dev/tivc", O_RDWR,
            (struct t_info *) NULL)) == -1) {
            t_error("open failed");
            exit(14);
        }
        if (t_bind(conn_fd, (struct t_bind *) NULL,
            (struct t_bind *) NULL) == -1) {
            t_error("t_bind failed");
            exit(15);
        }
        if (t_accept(fd, conn_fd, calls[slot][i]) == -1) {
            if (t_errno == TLOOK) {
                t_close(conn_fd);
                return;
            }
            t_error("t_accept failed");
            exit(16);
        }
        t_free(calls[slot][i], T_CALL);
        calls[slot][i] = (struct t_call *) NULL;
        run_server(fd);
    }
}
```

For each transport endpoint, the array of outstanding connect requests is scanned. For each request, the server opens a responding transport endpoint, binds an address to the endpoint, and accepts the connection on the endpoint. If another event (connect request or disconnect request) arrives before the current request is accepted, `t_accept()` fails and sets `t_errno` to `TLOOK`. (You cannot accept an outstanding connect request if any pending connect request events or disconnect request events exist on the transport endpoint.)
If this error occurs, the responding transport endpoint is closed and `service_conn_ind()` will return immediately (saving the current connect request for later processing). This causes the server’s main processing loop to be entered, and the new event will be discovered by the next call to `poll()`. In this way, multiple connect requests may be queued by the user.

Eventually, all events will be processed, and `service_conn_ind()` will be able to accept each connect request in turn. Once the connection has been established, the `run_server()` routine used by the server in the Code Example 3-26 on page 78 is called to manage the data transfer.

### State Transitions

These tables describe all state transitions associated with TLI. First, however, the states and events are described.

#### TLI States

Table 3-8 defines the states used in TLI state transitions, along with the service types.

<table>
<thead>
<tr>
<th>State</th>
<th>Description</th>
<th>Service Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>T_UNIT</td>
<td>Uninitialized – initial and final state of interface</td>
<td>T_COTS, COTS_ORD, T_CLTS</td>

<td>No connection established</td>
<td>T_COTS, T_COTS_ORD, T_CLTS</td>
</tr>
<tr>
<td>T_OUTCON</td>
<td>Outgoing connection pending for client</td>
<td>T_COTS, T_COTS_ORD</td>
</tr>
<tr>
<td>T_INCON</td>
<td>Incoming connection pending for server</td>
<td>COTS, T_COTS_ORD</td>
</tr>
</tbody>
</table>
Outgoing Events

The outgoing events described in Table 3-9 correspond to the status returned from the specified transport routines, where these routines send a request or response to the transport provider. In the table, some events (such as accept() are distinguished by the context in which they occur. The context is based on the values of the following variables:

- `ocnt` – count of outstanding connect requests
- `fd` – file descriptor of the current transport endpoint
- `resfd` – file descriptor of the transport endpoint where a connection is accepted

Table 3-9  Outgoing Events

</tbody>
</table>
Incoming Events

The incoming events correspond to the successful return of the specified routines. These routines return data or event information from the transport provider. The only incoming event not associated directly with the return of a routine is pass_conn, which occurs when a connection is transferred to another endpoint. The event occurs on the endpoint that is being passed the connection, although no TLI routine is called on the endpoint.

In Table 3-10, the rcvdis events are distinguished by the value of ocnt, the count of outstanding connect requests on the endpoint.

Table 3-9 Outgoing Events (Continued)

### Transport User Actions

Some state transitions (below) have a list of actions the transport user must take. Each action is represented by a digit from the list below:

- Set the count of outstanding connect requests to zero
- Increment the count of outstanding connect requests
- Decrement the count of outstanding connect requests
- Pass a connection to another transport endpoint as indicated in `t_accept()`

### State Tables

The tables describe the TLI state transitions. Each box contains the next state, given the current state (column) and the current event (row). An empty box is an invalid state/event combination. Each box may also have an action list. Actions must be done in the order specified in the box.

The following should be understood when studying the state tables:

---

</tbody>
</table>
• t_close() will cause an established connection to be terminated for a
collection-oriented transport provider. The connection termination will be
orderly or abortive depending on the service type supported by the
transport provider. See t_getinfo(3N).

• If a transport user issues a function out of sequence, the function fails and
t_errno is set to TOUTSTATE. The state does not change.

• The error codes TLOOK or TNODATA after t_connect() can result in state
changes described in “Event Handling” on page 80. The state tables assume
correct use of TLI.

• Any other transport error does not change the state unless the manual page
for the function says otherwise.

• The support functions t_getinfo(), t_getstate(), t_alloc(),
t_free(), t_sync(), t_look(), and t_error() are excluded from the
state tables because they do not affect the state.

Table 3-11, Table 3-12, and Table 3-13 show endpoint establishment, data
transfer in connectionless mode, and connection establishment/connection
release/data transfer in connection mode.

Guidelines to Protocol Independence

TLI’s set of services, common to many transport protocols, offers protocol independence to applications. Not all transport protocols support all TLI services. If software must run in a variety of protocol environments, use only the common services. The following is a list of services that may not be common to all transport protocols.

1. In connection mode service, a transport service data unit (TSDU) may not be supported by all transport providers. Make no assumptions about the preserving logical data boundaries across a connection.

2. Protocol and implementation specific service limits are returned by the t_open() and t_getinfo() routines. Use these limits to allocate buffers to store protocol-specific transport addresses and options.

3. Do not send user data with connect requests or disconnect requests, such as t_connect() and t_snddis(). Not all transport protocols work this way.

4. The buffers in the t_call structure used for t_listen() must be large enough to hold any data sent by the client during connection establishment. Use the T_ALL argument to t_alloc() to set maximum buffer sizes to store the address, options, and user data for the current transport provider.

5. Do not test or change options of any TLI routine. These options are specific to the underlying transport protocol. Do not pass options with t_connect() or t_sndudata(). In such cases, the transport provider will use default values. Also, a server should use the options returned by t_listen() to accept a connection.

6. Do not specify a protocol address on t_bind(). Let the transport provider assign an appropriate address to the transport endpoint. A server should retrieve its address for t_bind() in such a way that it does not require knowledge of the transport provider’s name space.

7. Do not make assumptions about formats of transport addresses. Transport addresses should not be constants in a program. Chapter 4, “Transport Selection and Name-to-Address Mapping,” contains detailed information.

8. The reason codes associated with t_rcvdis() are protocol-dependent. Do not interpret this information if protocol-independence is important.

9. The t_rcvuderr() error codes are protocol dependent. Do not interpret this information if protocol independence is a concern.
10. Do not code the names of devices into programs. The device node identifies a particular transport provider and is not protocol independent. See Chapter 4, “Transport Selection and Name-to-Address Mapping,” for details.

11. Do not use the optional orderly release facility of the connection mode service (provided by `t_sndrel()` and `t_rcvrel()`) in programs targeted for multiple protocol environments. This facility is not supported by all connection-based transport protocols. Its use can prevent programs from successfully communicating with open systems.

**TLI Versus Socket Interfaces**

TLI and sockets are different ways of doing the same tasks. Mostly, they provide mechanisms and services that are functionally similar. They do not provide one-to-one compatibility of routines or low-level services. Observe the similarities and differences between the TLI and socket-based interfaces before you decide to port an application.

The following issues are related to transport independence, and may have some bearing on RPC applications:

- **Privileged ports** – Privileged ports are an artifact of the Berkeley Software Distribution (BSD) implementation of the TCP/IP Internet Protocols. They are not portable. The notion of privileged ports is not supported in the transport-independent environment.

- **Opaque addresses** – There is no transport-independent way of separating the portion of an address that names a host from the portion of an address that names the service at that host. Code that assumes it can discern the host address of a network service must be changed.

- **Broadcast** – There is no transport independent form of broadcast address.
## Socket-to-TLI Equivalents

Table 3-14 shows approximate equivalents between TLI functions and socket functions. The comment field describes the differences. If there is no comment either the functions are similar, or there is no equivalent function in either interface.

<table>

connect() can be done without first binding the local endpoint. The endpoint must be bound before calling t_connect(). A connect() can be done on a connectionless endpoint to set the default destination address for datagrams. Data may be sent on a connect().

Transport Selection and Name-to-Address Mapping

This chapter covers selecting transports and resolving network addresses. It describes interfaces that enable you to specify the available communication protocols for an application. The chapter also describes additional functions that provide direct mapping of names to network addresses.

<table>
<thead>
<tr>
<th>How Transport Selection Works</th>
<th>page 112</th>
</tr>
</thead>
<tbody>
<tr>
<td>Name-to-Address Mapping</td>
<td>page 120</td>
</tr>
<tr>
<td>Using the Name-to-Address Mapping Routines</td>
<td>page 122</td>
</tr>
</tbody>
</table>

**Note** – In this chapter the terms *network* and *transport* are used interchangeably to refer to the programmatic interface that conforms to the transport layer of the OSI Reference Mode. The term network is also used to refer to the physical collection of computers connected through some electronic medium.

Transport Selection Is Multithread Safe

The interface described in this chapter is multithread safe. This means that applications that contain transport selection function calls can be used freely in a multithreaded application.
Transport Selection

A distributed application must use a standard interface to the transport services if it is to be portable to different protocols. Transport selection services provide an interface that allows an application to select which protocols to use. This makes an application “protocol” and “medium independent.”

Transport selection makes it easy for a client application to try each available transport until it establishes communication with a server. Transport selection lets server applications accept requests on multiple transports, and in doing so, communicate over a number of protocols. Transports may be tried in either the order specified by the local default sequence or in an order specified by the user.

Choosing from the available transports is the responsibility of the application. The transport selection mechanism makes that selection uniform and simple.

How Transport Selection Works

The transport selection component is built around:

- A network configuration database (the /etc/netconfig file), which contains an entry for each network on the system
- Optional use of the NETPATH environment variable

The NETPATH variable is set by the user; it contains an ordered list of transport identifiers. The transport identifiers match the netconfig network ID field and are links to records in the netconfig file. The netconfig file is described in “/etc/netconfig File” on page 113. The network selection interface is a set of access routines for the network-configuration database.

One set of library routines accesses only the /etc/netconfig entries identified by the NETPATH environment variable:

```c
setnetpath()
getnetpath()
endnetpath()
```

They are described in “NETPATH Access to netconfig Data” on page 116 and in getnetpath(3N). These routines let the user influence the selection of transports used by the application.
To avoid user influence on transport selection, use the routines that access the netconfig database directly. These routines are described in “Accessing netconfig” on page 118 and in getnetconfig(3N).

setnetconfig()
getnetconfig()
endnetconfig()

The following two routines manipulate netconfig entries and the data structures they represent.

getnetconfigent()
freenetconfigent()

/etc/netconfig File

The netconfig file describes all transport protocols on a host. The entries in the netconfig file are explained briefly in Table 4-1 and in more detail in netconfig(4).

Table 4-1 The netconfig File

<table>
<thead>
<tr>
<th>Entries</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>network ID</td>
<td>A local representation of a transport name (such as tcp). Do not assume that this field contains a well-known name (such as tcp or udp) or that two systems use the same name for the same transport.</td>
</tr>
<tr>
<td>semantics</td>
<td>The semantics of the particular transport protocol. Valid semantics are: tpi_clts = connectionless tpi_cots = connection oriented tpi_cots_ord = connection oriented with orderly release</td>
</tr>
<tr>
<td>flags</td>
<td>May take only the values, v, or hyphen (-). Only the visible flag (-v) is defined.</td>
</tr>
<tr>
<td>protocol family</td>
<td>The protocol family name of the transport provider (for example, inet or loopback).</td>
</tr>
</tbody>
</table>
Code Example 4-1 shows a sample netconfig file. Use of the netconfig file has been changed for the inet transports, as described in the commented section in the sample file. This change is also described in “Name-to-Address Mapping” on page 120.

Code Example 4-1 Sample netconfig File

```bash
# The “Network Configuration” File.
#
# Each entry is of the form:
#<net <semantics> <flags> <proto <proto <proto <device> <nametoaddr_libs>
# id>                       family>   name>
#
# The "-" in <nametoaddr_libs> for inet family transports indicates redirection
# to the name service switch policies for "hosts" and "services. The "-" may be
# replaced by nametoaddr libraries that comply with the SVR4 specs, in which
# case the name service switch will be used for netdir_getbyname, netdir_
# getbyaddr, gethostbyname, gethostbyaddr, getservbyname, and getservbyport.
# There are no nametoaddr libs for the inet family in Solaris anymore.
#
udp  tpi_clts     v       inet     udp      /dev/udp      -
# tcp  tpi_cots_ord v       inet     tcp      /dev/tcp      -
# icmp tpi_raw      -       inet     icmp     /dev/icmp     -
# rawip tpi_raw     -       inet     -        /dev/rawip    -
```
Network selection library routines return pointers to netconfig entries. The netconfig structure is shown in Code Example 4-2.

**Code Example 4-2  The netconfig Structure**

```c
struct netconfig {
    char *nc_netid;     /* network identifier */
    unsigned long nc_semantics; /* semantics of protocol */
    unsigned long nc_flag;            /* flags for the protocol */
    unsigned long nc_protofmly;  /* family name */
    unsigned long nc_proto;          /* proto specific */
    char *nc_device;      /* device name for network id */
    unsigned long nc_nlookups;   /* # entries in nc_lookups */
    char **nc_lookups;  /* list of lookup libraries */
    unsigned long nc_unused[8];
};
```

Valid network IDs are defined by the system administrator, who must ensure that network IDs are locally unique. If they are not, some network selection routines can fail. For example, it is not possible to know which network getnetconfigent("udp") will use if there are two netconfig entries with the network ID udp.

The system administrator also sets the order of the entries in the netconfig database. The routines that find entries in /etc/netconfig return them in order, from the beginning of the file. The order of transports in the netconfig file is the default transport search sequence of the routines. Loopback entries should be at the end of the file.

The netconfig file and the netconfig structure are described in greater detail in netconfig(4).
The NETPATH Environment Variable

An application usually uses the default transport search path set by the system administrator to locate an available transport. However, when a user wants to influence the choices made by an application, the application can modify the interface by using the environment variable NETPATH and the routines described in the section, “NETPATH Access to netconfig Data.” These routines access only the transports specified in the NETPATH variable.

NETPATH is similar to the PATH variable. It is a colon-separated list of transport IDs. Each transport ID in the NETPATH variable corresponds to the network ID field of a record in the netconfig file. NETPATH is described in environ(5).

The default transport set is different for the routines that access netconfig through the NETPATH environment variable (described in the next section) and the routines that access netconfig directly. The default transport set for routines that access netconfig via NETPATH consists of the visible transports in the netconfig file. For routines that access netconfig directly, the default transport set is the entire netconfig file. A transport is visible if the system administrator has included a v flag in the flags field of that transport’s netconfig entry.

NETPATH Access to netconfig Data

Three routines access the network configuration database indirectly through the NETPATH environment variable. The variable specifies the transport or transports an application is to use and the order to try them. NETPATH components are read from left to right. The functions have the following interfaces:

```c
#include <netconfig.h>

void *setnetpath(void);
struct netconfig *getnetpath(void *);
int endnetpath(void *);
```

A call to setnetpath() initializes the search of NETPATH. It returns a pointer to a database that contains the entries specified in a NETPATH variable. The pointer, called a handle, is used to traverse this database with getnetpath(). setnetpath() must be called before the first call to getnetpath().
When first called, `getnetpath()` returns a pointer to the `netconfig` file entry that corresponds to the first component of the `NETPATH` variable. On each subsequent call, `getnetpath()` returns a pointer to the `netconfig` entry that corresponds to the next component of the `NETPATH` variable; `getnetpath()` returns NULL if there are no more components in `NETPATH`. A call to `getnetpath()` without an initial call to `setnetpath()` causes an error; `getnetpath()` requires the pointer returned by `setnetpath()` as an argument.

`getnetpath()` silently ignores invalid `NETPATH` components. A `NETPATH` component is invalid if there is no corresponding entry in the `netconfig` database.

If the `NETPATH` variable is unset, `getnetpath()` behaves as if `NETPATH` were set to the sequence of default or visible transports in the `netconfig` database, in the order in which they are listed.

`endnetpath()` is called to release the database pointer to elements in the `NETPATH` variable when processing is complete. `endnetpath()` fails if `setnetpath()` was not called previously. Code Example 4-3 shows the `setnetpath()`, `getnetpath()`, and `endnetpath()` routines.

```c
#include <netconfig.h>

void *handlep;
struct netconfig *nconf;

if ((handlep = setnetpath()) == (void *)NULL) {
    nc_perror(argv[0]);
    exit(1);
}

while ((nconf = getnetpath(handlep)) != (struct netconfig *)NULL) {
    /*
     * nconf now describes a transport provider.
     */
    endnetpath(handlep);
}
```

The `netconfig` structures obtained through `getnetpath()` become invalid after the execution of `endnetpath()`. To preserve the data in the structure, use `getnetconfigent(nconf->nc_netid)` to copy them into a new data structure.
Accessing netconfig

Three functions access /etc/netconfig and locate netconfig entries. The routines setnetconfig(), getnetconfig(), and endnetconfig() have the following interfaces:

```c
#include <netconfig.h>

void *setnetconfig(void);
struct netconfig *getnetconfig(void *);
int endnetconfig(void *);
```

A call to setnetconfig() initializes the record pointer to the first index in the database; setnetconfig() must be used before the first use of getnetconfig(). setnetconfig() returns a unique handle (a pointer into the database) to be used by the getnetconfig() routine. Each call to getnetconfig() returns the pointer to the current record in the netconfig database and increments its pointer to the next record. It can be used to search the entire netconfig database. getnetconfig() returns a NULL at the end of file.

You must use endnetconfig() to release the database pointer when processing is complete. endnetconfig() must not be called before setnetconfig().

**Code Example 4-4** setnetconfig(), getnetconfig(), and endnetconfig()
void *handlep;
struct netconfig *nconf;

```c
if ((handlep = setnetconfig()) == (void *)NULL){
    nc_perror(argv[0]);
    exit(1);
}
/*
 * transport provider information is described in nconf.
 * process_transport is a user-supplied routine that
 * tries to connect to a server over transport nconf.
 */
while ((nconf = getnetconfig(handlep)) != (struct netconfig*)NULL){
    if (process_transport(nconf) == SUCCESS){
        break;
    }
}
endnetconfig(handlep);
```
The last two functions have the following interface:

```c
#include <netconfig.h>
struct netconfig *getnetconfigent(char *);
int freenetconfigent(struct netconfig *);
```

`getnetconfigent()` returns a pointer to the `struct netconfig` structure corresponding to `netid`. It returns `NULL` if `netid` is invalid.

`freenetconfigent()` frees the structure returned by `getnetconfigent()`.

Code Example 4-5 shows the `getnetconfigent()` and `freenetconfigent()` routines.

```c
/* assume udp is a netid on this host */
struct netconfig *nconf;
if ((nconf = getnetconfigent("udp")) == (struct netconfig *)NULL){
    nc_perror("no information about udp");
    exit(1);
}
process_transport(nconf);
freenetconfigent(nconf);
```

### Loop Through All Visible netconfig Entries

The `setnetconfig()` call is used to step through all the transports marked `visible` (by a `v` flag in the `flags` field) in the `netconfig` database. The transport selection routine returns a `netconfig` pointer.

```c
void *handlep;
struct netconfig *nconf;
if ((handlep = setnetconfig() == (void *) NULL) { 
    nc_perror("setnetconfig");
    exit(1);
}
while (nconf = getnetconfig(handlep))
    if (nconf->nc_flag & NC_VISIBLE)
        doit(nconf);
(void) endnetconfig(handlep);
```
Loopy Through User-Defined netconfig Entries

Users can control the loop by setting the NETPATH environment variable to a colon-separated list of transport names. If NETPATH is set as follows:

```
NETPATH(tcp:udp)
```

The loop first returns the tcp entry, and then the udp entry. If NETPATH is not defined, the loop returns all visible entries in the netconfig file in the order in which they are stored. The NETPATH environment variable lets users define the order in which client-side applications try to connect to a service. It also lets the server administrator limit transports on which a service can listen.

Use getnetpath() and setnetpath() to obtain or modify the network path variable. Code Example 4-6 shows the form and use, which are similar to the getnetconfig() and setnetconfig() routines.

Name-to-Address Mapping

Name-to-address mapping lets an application obtain the address of a service on a specified host, independent of the transport used. Name-to-address mapping consists of the following functions:

```
netdir_getbyname()
netdir_getbyaddr()
netdir_free()
taddr2uaddr()
uaddr2taddr()
netdir_options()
```

The first argument of each routine points to a netconfig structure that describes a transport. The routine uses the array of directory-lookup library paths in the netconfig structure to call each path until the translation succeeds.

The libraries are described in Table 4-2 on page 121. The routines described in the section, “Using the Name-to-Address Mapping Routines,” are defined in netdir(3N).
Note – The following libraries no longer exist in the Solaris 2.x environment: tcpip.so, switch.so, and nis.so. For more information on this change, see nsswitch.conf(4) and the NOTES section of gethostbyname(3N).

Table 4-2 Name-to-Address Libraries

<table>
<thead>
<tr>
<th>Library</th>
<th>Transport Family</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>-</td>
<td>inet</td>
<td>For networks of the protocol family inet, its name-to-address mapping is provided by the name service switch based on the entries for hosts and services in the file nsswitch.conf. For networks of other families, the &quot;-&quot; indicates a non-functional name-to-address mapping.</td>
</tr>
<tr>
<td>straddr.so</td>
<td>loopback</td>
<td>Contains the name-to-address mapping routines of any protocol that accepts strings as addresses, such as the loopback transports.</td>
</tr>
</tbody>
</table>

straddr.so Library

Files for the library are created and maintained by the system administrator. The straddr.so files are /etc/net/transport-name/hosts and /etc/net/transport-name/services. transport-name is the local name of the transport that accepts string addresses (specified in the network ID field of the /etc/netconfig file). For example, the host file for ticlts would be /etc/net/ticlts/hosts, and the service file for ticlts would be /etc/net/ticlts/services.

Even though most string addresses do not distinguish between host and service, separating the string into a host part and a service part is consistent with other transports. The /etc/net/transport-name/hosts file contains a text string that is assumed to be the host address, followed by the host name. For example:

```
joyluckaddr joyluck
carpediemaddr carpediem
thehopaddr thehop
pongoaddr pongo
```

For loopback transports, it makes no sense to list other hosts because the service cannot go outside the containing host.
The /etc/net/transport-name/services file contains service names followed by strings identifying the service address. For example:

```
  rpcbind       rpc
  listen        serve
```

The routines create the full string address by concatenating the host address, a period (.), and the service address. For example, the address of the listen service on pongo is pongoaddr.serve.

When an application requests the address of a service on a particular host on a transport that uses this library, the host name must be in /etc/net/transport/hosts, and the service name must be in /etc/net/transport/services. If either is missing, the name-to-address translation fails.

### Using the Name-to-Address Mapping Routines

This section provides an overview of what routines are available to use. The routines return or convert the network names to their respective network addresses. Note that netdir_getbyname(), netdir_getbyaddr(), and taddr2uaddr() return pointers to data that must be freed by calls to netdir_free().

```c
int netdir_getbyname(struct netconfig *ncnf,
                    struct nd_hostserv *service,
                    struct nd_addrlist **addrs);
```

netdir_getbyname() maps the host and service name specified in service to a set of addresses consistent with the transport identified in ncnf. The nd_hostserv and nd_addrlist structures are defined in netdir(3N). A pointer to the addresses is returned in addrs.

To find all addresses of a host and service (on all available transports), call netdir_getbyname() with each netconfig structure returned by either getnetpath() or getnetconfig().

```c
int netdir_getbyaddr(struct netconfig *ncnf,
                     struct nd_hostservlist **service,
                     struct netbuf *netaddr);
```

netdir_getbyaddr() maps addresses into host and service names. The function is called with an address in netaddr and returns a list of host-name and service-name pairs in service. The nd_hostservlist structure is defined in netdir(3N).
The `netdir_free()` routine frees structures allocated by the name-to-address translation routines. The parameters can take the values shown in Table 4-3.

**Table 4-3  netdir_free() Routines**

<table>
<thead>
<tr>
<th><code>struct_type</code></th>
<th><code>ptr</code></th>
</tr>
</thead>
<tbody>
<tr>
<td>ND_HOSTSERV</td>
<td>pointer to an nd_hostserv structure</td>
</tr>
<tr>
<td>ND_HOSTSERVLIST</td>
<td>pointer to an nd_hostservlist structure</td>
</tr>
<tr>
<td>ND_ADDR</td>
<td>pointer to a netbuf structure</td>
</tr>
<tr>
<td>ND_ADDRLIST</td>
<td>pointer to an nd_addrlist structure</td>
</tr>
</tbody>
</table>

`char *taddr2uaddr(struct netconfig *nconf, struct netbuf *addr);`

`taddr2uaddr()` translates the address pointed to by `addr` and returns a transport-independent character representation of the address ("universal address"). `nconf` specifies the transport for which the address is valid. The universal address can be freed by `free()`.

`struct netbuf *uaddr2taddr(struct netconfig *nconf, char *uaddr);`

The "universal address" pointed to by `uaddr` is translated into a `netbuf` structure; `nconf` specifies the transport for which the address is valid.

`int netdir_options(struct netconfig *nconf, int option, int fd, char *point_to_args);`

`netdir_options()` interfaces to transport-specific capabilities (such as the broadcast address and reserved port facilities of TCP and UDP). `nconf` specifies a transport. `option` specifies the transport-specific action to take. `fd` may or may not be used depending upon the value of `option`. The fourth argument points to operation-specific data.
Table 4-4 shows the values used for option:

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ND_SET_BROADCAST</td>
<td>Sets the transport for broadcast (if the transport supports broadcast).</td>
</tr>
<tr>
<td>ND_SET_RESERVEDPORT</td>
<td>Lets the application bind to a reserved port (if allowed by the transport).</td>
</tr>
<tr>
<td>ND_CHECK_RESERVEDPORT</td>
<td>Verifies that an address corresponds to a reserved port (if the transport supports reserved ports).</td>
</tr>
<tr>
<td>ND_MERGEADDR</td>
<td>Transforms a locally meaningful address into an address to which client hosts can connect.</td>
</tr>
</tbody>
</table>

```c
void netdir_perror(char *s);
```

`netdir_perror()` displays the message stating why one of the name-to-address mapping routines failed on stderr.

```c
char *netdir_sperror(void);
```

`netdir_sperror()` returns a string containing the error message stating why one of the name-to-address mapping routines failed.

Code Example 4-7 shows network selection and name-to-address mapping.

```c
Code Example 4-7    Network Selection and Name-To-Address Mapping
#include <netconfig.h>
#include <netdir.h>
#include <sys/tiuser.h>

struct nd_hostserv nd_hostserv; /* host and service information */
struct nd_addrlist *nd_addrlistp; /* addresses for the service */
struct netbuf *netbufp; /* the address of the service */
struct netconfig *nconf; /* transport information*/
int i; /* the number of addresses */
char *uaddr; /* service universal address */
void *handlep; /* a handle into network selection */
/*
 * Set the host structure to reference the "date"
 * service on host "gandalf"
 */
nd_hostserv.h_host = "gandalf";
```
**Transport Selection and Name-to-Address Mapping**

```c
nd_hostserv.h_serv = "date";
/*
 * Initialize the network selection mechanism.
 */
if ((handlep = setnetpath()) == (void *)NULL) {
    nc_perror(argv[0]);
    exit(1);
}
/*
 * Loop through the transport providers.
 */
while ((nconf = getnetpath(handlep)) != (struct netconfig *)NULL) {
    /*
    * Print out the information associated with the
    * transport provider described in the "netconfig"
    * structure.
    */
    printf("Transport provider name: %s\n", nconf->nc_netid);
    printf("Transport protocol family: %s\n", nconf->nc_protofmly);
    printf("The transport device file: %s\n", nconf->nc_device);
    printf("Transport provider semantics: ");
    switch (nconf->nc_semantics) {
    case NC_TPI_COTS:
        printf("virtual circuit\n");
        break;
    case NC_TPI_COTS_ORD:
        printf("virtual circuit with orderly release\n");
        break;
    case NC_TPI_CLTS:
        printf("datagram\n");
        break;
    }
    printf("<%d> address of date service on gandalf:
",
        nd_addrlistp->n_cnt);
    if (netdir_getbyname(nconf, &nd_hostserv, &nd_addrlistp)
        != ND_OK) {
        printf("Cannot determine address for service\n");
        netdir_perror(argv[0]);
        continue;
    }
    printf("<%d> address of date service on gandalf:\n",
        nd_addrlistp->n_cnt);
```
/ *
 * Print out all addresses for service "date" on
 * host "gandalf" on current transport provider.
 */
netbufp = nd_addrlistp->n_addrs;
for (i = 0; i < nd_addrlistp->n_cnt; i++, netbufp++) {
    uaddr = taddr2uaddr(nconf,netbufp);
    printf("%s\n",uaddr);
    free(uaddr);
}
netdir_free( nd_addrlistp, ND_ADDRLIST );
}
endnetconfig(handlep);

Portability From Previous Releases

The list that follows contains the names of the functions with functionality unchanged from earlier releases.

gethostbyname()
gethostbyaddr()
gethostent()
getrpcbyname()
getrpcbyname()
getservbyname()
getservbyaddr()
netdir_free()
netdir_getbyname()
netdir_getbyaddr()
netdir_options()
netdir_perror()
netdir_sbyname() taddr2uaddr()
uaddr2taddr()

Other porting issues are described in ONC+ Developer's Guide.
**Glossary**

**CLTS**
Connectionless transport service. Data may be exchanged without a prior link between processes. Also known as a datagram protocol because the operation is like sending a letter.

**client**
A process that makes use of a service or services provided by other processes. A client process initiates requests for services.

**concurrent server**
A multithreaded server that creates a new process to handle each request, leaving the main server process to listen for more requests. With a multithreaded OS, such as Solaris, it is possible to implement concurrent servers without creating a complete process to handle requests; each request can be dealt with in a single thread.

**COTS**
Connection-oriented transport service. Requires a logical connection to be established between two processes before data can be exchanged. Conceptually analogous to a telephone call.

**ephemeral port numbers**
Short-lived port numbers. TCP or UDP can assign an unused port to a process.

**ICMP**
Internet Control Message Protocol. A network layer protocol dealing with routing, reliability, flow control and sequencing of data.
internetwork
The connection of different physical networks into a large, virtual network. The Internet refers to the TCP/IP-based Internet that connects many commercial sites, government agencies, and universities.

IP
Internet protocol. Core protocol of TCP/IP at the network layer. A connectionless service, it handles packet delivery for TCP, UDP, and ICMP protocols.

ISO/OSI
The International Standards Organization (ISO) model for Open Systems Interconnection (OSI) is a seven layer model for describing networked systems.

iterative server
A single-threaded server that can handle only one request at a time. Requests are received and processed within a single process. It is possible for client processes to be blocked for some time while waiting for requests to be finished.

protocol
A set of rules and conventions that describes how information is to be exchanged between two entities.

protocol stack
A set of layered protocols where each layer has a well-defined interface to the layer immediately above and immediately below.

protocol peers
A pair of protocols that reside in the same layer. They communicate with each other.

RFC
Request for Comments. Formal specifications of the Internet protocols.

server
A process that provides some facility that can be used by other processes. A server process waits for requests.

TCP
Transmission Control Protocol. Built on top of IP at the transport layer, TCP provides a reliable connection-oriented byte stream service between two hosts on an internetwork.
UDP

User Datagram Protocol. Built on top of IP at the transport layer, UDP provides an unreliable datagram-based service between two hosts on an internetwork.

well-known port numbers

16-bit port numbers that identify individual processes on a host. Well-known services are provided at well-known port numbers.
