which enforces execution whenever the binding is accessed the first time. If no `refreshCondition` value exists, the executable is invoked. If a value for `refreshCondition` exists, then that value is evaluated as an EL expression, and if the return value of the evaluation is `true`, then the executable is invoked. If the value evaluates to `false`, the executable is not invoked. For details about the `refresh` attribute, see [Section A.8.1, "PageDef.xml Syntax."](#)

For most cases in a Fusion web application, you should not need to change the `refresh` or `refreshCondition` values on an iterator binding. These values are set to ensure that the correct data is displayed. You should not need to change these values for an `invokeAction` either. Normally, you use a method activity in a task flow to call an action binding (or any backing bean method) to perform some application behavior before the page is rendered. For example, for a page used to create an object, you might have a task flow that begins with a method activity that calls the `CreateInsert` operation. The task flow then proceeds to the view activity for the page where the user inputs data. Modeling this behavior as discrete method call activities provides a much cleaner separation of application logic and data bindings, making applications both self-documenting and easier to maintain. For more information, see [Section 22.6, "Creating an Input Form."](#)

However, for completeness' sake, in case you encounter situations where you decide to change the `refresh` attribute for iterator bindings or for `invokeAction` (for example, if you have programmatic code that runs after the Prepare Model phase and needs to access the iterator programmatically), you should do so, informed of the following information regarding the valid values:

- `deferred` (the default): On demand

**Tip:** Any `invokeAction` executable in a page definition file must have a value other than the default (`deferred`) for its `refresh` attribute, or it will not be refreshed and invoked.

- `prepareModel`: During the Prepare Model phase.
- `renderModel`: During the Prepare Render phase.

**Tip:** Notice in [Figure 21–2](#) that the key distinction between the Prepare Model phase and the Prepare Render phase is that one comes before JSF's Invoke Application phase, and one after. Since JSF's Invoke Application phase is when action listeners fire, if you need your iterator refreshed or the method or operation associated with the `invokeAction` to execute after these action listeners have performed their processing, you'll want to set the `refresh` attribute to `renderModel`.

- `ifNeeded`: During the Prepare Model and Prepare Render phases, only if needed. For iterators, the refresh is considered needed if the binding has not yet been refreshed. To determine if the execution is needed for an `invokeAction`, the framework compares the current set of evaluated parameter values with the set that was used to invoke the method action binding previously, and also compares the results of the invoked method with the cached results. If the parameter values and/or the returned values for the current invocation are exactly the same as those used previously, the `invokeAction` does not invoke its bound method action binding. Use this setting if the `invokeAction` executable binds to a method action binding that accepts parameters.

**Tip:** For `invokeAction` executables bound to methods that do not take parameters, the `invokeAction` executable will be called twice. To use the `invokeAction` executable with parameterless methods, you should use `ensure` that the condition associated with the `refreshCondition` attribute evaluates to `true` to invoke the method only if the value has changed. This will prevent multiple invocations.

- `prepareModelIfNeeded` and `renderModelIfNeeded`: Same as `ifNeeded`, except that it is executed during the named phase.
- `never`: Not valid for `invokeAction` executables. For iterators, the iterator will never be refreshed. Use when your own code calls `getRowSetIterator()` on the iterator binding.
- `always`: Not valid for `invokeAction` executables. For iterators, the iterator will always be refreshed (potentially multiple times) during both the Prepare Model and Prepare Render phases, as well as during the Update Model phase.
- `refreshAfter`: Use to handle dependencies between executables. For example, you can set the condition so that this executable refreshes after another executable.

**Tip:** You can determine the order of executable invocation using the `refreshAfter` attribute. For example, suppose you have two `invokeAction` elements—one with an ID of `myAction` and another with an ID of `anotherAction`—and you want `myAction` to fire after `anotherAction`. You would set the `refreshAfter` condition on `myAction` to `anotherAction`.

## 21.2.2 What You May Need to Know About Task Flows and the Lifecycle

Task flows are initially refreshed when the parent binding container (the one associated with the page) is refreshed. This happens in the Prepare Model phase. On a subsequent request, the task flow will be refreshed during the Prepare Render phase, depending on its `refresh` and `refreshCondition` attributes and its parameter value.

---

**Note:** Any child page fragment's page definition still handles the refresh of the bindings of the child page fragments.

---

**Tip:** If you have a region on a page that is not initially disclosed (for example, a popup dialog), the parameters still need to be available when the parent page is rendered, even though the region might not be displayed. If a region requires parameters, but those parameter values will not be available when the parent page is rendered, then you should use dynamic regions. If the parameters are null, an empty task flow can be used until the parameters for the region are ready and that region can display. To swap in an empty task flow, you set the dynamic region's `taskFlowId` attribute to an empty string.

If you set an EL expression as the value of the `refreshCondition` attribute, it will be evaluated during the Prepare Render phase of the lifecycle. When the expression evaluates to `true`, the task flow will be refreshed again. When `refreshCondition` evaluates to `false`, the behavior is the same as if the `refreshCondition` had not been specified.

---

---

**Note:** If the variable `bindings` is used within the EL expression, the context refers to the binding container of the parent page, not the page fragment displayed within the region.

---

---

The valid values for the `refresh` property of a task flow executable are as follows:

- `default`: The region will be refreshed only once, when the parent page is first displayed.
- `ifNeeded`: Refreshes the region only if there has been a change to `taskFlow` binding parameter values. If the `taskFlow` binding does not have parameters, then `ifNeeded` is equivalent to the default. When `ifNeeded` is used, the `refreshCondition` attribute is not considered.

---

---

**Note:** Setting the `refresh` attribute to `ifNeeded` takes precedence over any value for the `refreshCondition` attribute. Also note that `ifNeeded` is not supported when you pass parameters to the `taskFlow` binding using a dynamic parameter Map. Instead, use `refreshCondition="{EL.Expression}"`.

---

---

Because the only job of the `taskFlow` binding is to refresh its parameters, setting `Refresh` to `always` does not make sense. If the `taskFlow` binding's parameters don't change, there is no reason to refresh the ADF region.

Note that the child page fragment's page definition still handles the refresh of the bindings of the child page fragments.

## 21.3 Object Scope Lifecycles

At runtime, ADF objects such as the binding container and managed beans are instantiated. Each of these objects has a defined lifespan set by its scope attribute. You can access a scope as a `java.util.Map` from the `RequestContext` API. For example, to access an object named `foo` in the request scope, you would use the expression `{requestScope.foo}`.

There are six types of scopes in a Fusion web application:

- **Application scope:** The object is available for the duration of the application.
- **Session scope:** The object is available for the duration of the session.

---

---

**Note:** There's no window uniqueness for session scope, all windows in the session share the same session scope instance. If you are concerned about multiple windows being able to access the same object (for example to ensure that managed beans do not conflict across windows), you should use a scope that is window-specific, such as page flow or view scope.

---

---

- **Page flow scope:** The object is available for the duration of a bounded task flow.

---

---

**Note:** Because this is not a standard JSF scope, EL expressions must explicitly include the scope to reference bean. For example, to reference the `MyBean` managed bean from the `pageFlowScope` scope, your expression would be `#{pageFlowScope.MyBean}`.

---

---

- Request scope: The object is available from the time an HTTP request is made until a response is sent back to the client.
- Backing bean scope: Used for managed beans for page fragments and declarative components only, the object is available from the time an HTTP request is made until a response is sent back to the client. This scope is needed for fragments and declarative components because there may be more than one page fragment or declarative component on a page, and to prevent collisions, any values must be kept in separate scope instances. Therefore, any managed bean for a page fragment or declarative component must use backing bean scope.

---

---

**Note:** Because this is not a standard JSF scope, EL expressions must explicitly include the scope to reference bean. For example, to reference the `MyBean` managed bean from the backing bean scope, your expression would be `#{backingBeanScope.MyBean}`.

---

---

- View scope: The object is available until the view ID for the current view activity changes. This scope can be used to hold values for a given page. However, unlike request scope, which can be used to store a value needed from one page to the next, anything stored in view scope will be lost once the view ID changes.

---

---

**Note:** Because this is not a standard JSF scope, EL expressions must explicitly include the scope to reference bean. For example, to reference the `MyBean` managed bean from the view scope, your expression would be `#{viewScope.MyBean}`.

---

---

---

---

**Note:** When you create objects (such as a managed bean) that require you to define a scope, you can set the scope to `none`, meaning that it will not live within any particular scope, but will instead be instantiated each time it is referenced.

---

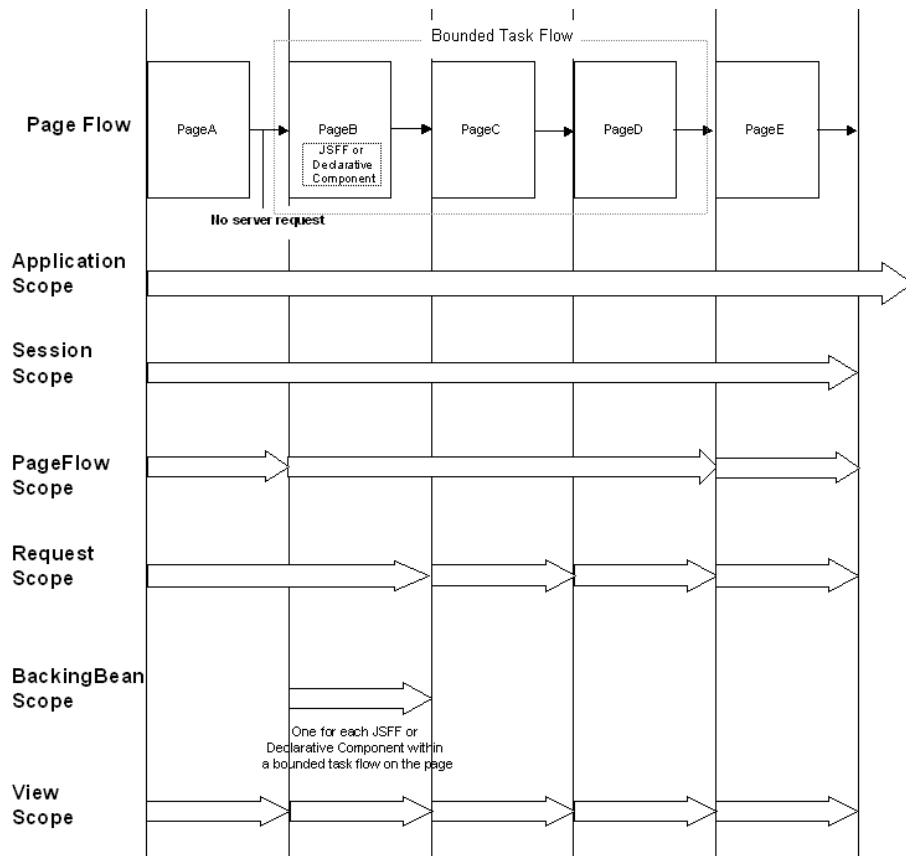

---

Object scopes are analogous to global and local variable scopes in programming languages. The wider the scope, the higher availability of an object. During their life, these objects may expose certain interfaces, hold information, or pass variables and parameters to other objects. For example, a managed bean defined in session scope will be available for use during multiple page requests. However, a managed bean defined in request scope will only be available for the duration of one page request.

By default, the binding container and the binding objects it contains are defined in session scope. However, the *values* referenced by value bindings and iterator bindings are undefined between requests and for scalability reasons do not remain in session scope. Therefore, the values that binding objects refer to are valid only during a request in which that binding container has been prepared by the ADF lifecycle. What stays in session scope are only the binding container and binding objects themselves.

Figure 21–3 shows the time period during which each type of scope is valid.

**Figure 21–3 Relationship Between Scopes and Page Flow**

When determining what scope to register a managed bean with, always try to use the narrowest scope possible. Only use the session scope for information that is relevant to the whole session, such as user or context information. Avoid using session scope to pass values from one task flow to another. When creating a managed bean for a page fragment or a declarative component, you must use backing bean scope.

Managed beans can be registered in either the `adfc-config.xml` or the configuration file for a specific task flow. For more information about using managed beans in a Fusion application, see [Section 20.4, "Using a Managed Bean in a Fusion Web Application."](#)

---

**Note:** Registering managed beans within the `faces-config.xml` file is not recommended in a Fusion web application.

---

### 21.3.1 What You May Need to Know About Object Scopes and Task Flows

When determining what scope to use for variables within a task flow, you should use any of the scope options other than application or session scope. These two scopes will persist objects in memory beyond the life of the task flow and therefore compromise the encapsulation and reusable aspects of a task flow. In addition, application and session scopes may keep objects in memory longer than needed, causing unneeded overhead.

When you need to pass data values between activities within a task flow, you should use page flow scope. View scope is recommended for variables that are needed only within the current view activity, not across view activities. Request scope should be

used when the scope does not need to persist longer than the current request. It is the only scope that should be used to store UI component information. Lastly, backing bean scope must be used for backing beans in your task flow if there is a possibility that your task flow will appear in two region components or declarative components on the same page and you would like to achieve region instance isolations.

## 21.4 Customizing the ADF Page Lifecycle

The ADF lifecycle contains clearly defined phases that notify ADF lifecycle listeners before and after the corresponding JSF phase is executed. You can customize this lifecycle by creating a custom phase listener that invokes your needed code, and then registering it with the lifecycle to execute during one of these phases.

For example, you can create a custom listener that executes custom code and then register it with the JSF Apply Request Values phase so that it can be invoked either before or after the Apply Request Values phase.

---

---

**Note:** An application cannot have multiple phase listener instances. An initial `ADFPhaseListener` instance is by default, registered in the `META-INF/faces-config.xml` configuration file. Registering, for example, a customized subclass of the `ADFPhaseListener` creates a second instance. In this scenario, only the instance that was most recently registered is used.

The following warning message indicates when an instance has been replaced by a newer one: "ADFC: Replacing the ADF Page Lifecycle implementation with *class name of the new listener*."

---

---

### 21.4.1 How to Create a Custom Phase Listener

To create a custom phase listener, you must create a listener class that implements the `PagePhaseListener` interface. You then add methods that execute code either before or after the phase that the code needs to execute.

[Example 21–1](#) contains a template that you can modify to create a custom phase listener. See [Section 4.13.1, "How to Generate Custom Classes,"](#) for more information about creating a class in JDeveloper.

#### **Example 21–1 Example Custom Phase Listener**

```
public class MyPagePhaseListener implements PagePhaseListener
{
    public void afterPhase(PagePhaseEvent event)
    {
        System.out.println("In afterPhase " + event.getPhaseId());
    }

    public void beforePhase(PagePhaseEvent event)
    {
        System.out.println("In beforePhase " + event.getPhaseId());
    }
}
```

Once you create the custom listener class, you need to register it with the phase in which the class needs to be invoked. You can either register it globally (so that the whole application can use it), or you can register it only for a single page.

## 21.4.2 How to Register a Listener Globally

To customize the ADF lifecycle globally, register your custom phase listener by editing the `adf-settings.xml` configuration file. The `adf-settings.xml` file is shared by several ADF components, including ADF Controller, to store configuration information. If the `adf-settings.xml` file does not yet exist, you need to create it. For information, see the "Configuration in `adf-settings.xml`" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### To register the listener in `adf-settings.xml`:

1. In the **META-INF** directory, double-click the **adf-settings.xml** file to open it.
2. Click the **Source** tab, and scroll down to  

```
<adfc-controller-config xmlns=
"http://xmlns.oracle.com/adf/controller/config">
```

If this entry does not exist, add it to the file.
3. Enter the remaining elements shown in italics in [Example 21-2](#).

#### **Example 21-2** *adf-settings.xml Configuration File with Listener Registration*

```
<?xml version="1.0" encoding="US-ASCII" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config">
.
.
.
  <adfc-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
    <lifecycle>
      <phase-listener>
        <listener-id>MyPagePhaseListener</listener-id>
        <class>mypackage.MyPagePhaseListener</class>
      </phase-listener>
    </lifecycle>
  </adfc-controller-config>
.
.
.
</adf-config>
```

4. Add values for the following elements:
  - `<listener-id>` A unique identifier for the listener (you can use the fully qualified class name)
  - `<class>` The class name of the listener

## 21.4.3 What You May Need to Know About Listener Order

You can specify multiple phase listeners in the `adf-settings.xml` and, optionally, the relative order in which they are called. When registering a new listener in the file, you determine the position in the list of listeners using two parameters:

- `beforeIdSet`: The listener is called before any of the listeners specified in `beforeIdSet`
- `afterIdSet`: The listener is called after any of the listeners specified in `afterIdSet`

[Example 21–3](#) contains an example configuration file in which multiple listeners have been registered for an application.

**Example 21–3 *adf-settings.xml* Configuration File with Multiple Listener Registration**

```
<lifecycle>
  <phase-listener>
    <listener-id>MyPhaseListener</listener-id>
    <class>view.myPhaseListener</class>
    <after-id-set>
      <listener-id>ListenerA</listener-id>
      <listener-id>ListenerC</listener-id>
    </after-id-set>
    <before-id-set>
      <listener-id>ListenerB</listener-id>
      <listener-id>ListenerM</listener-id>
      <listener-id>ListenerY</listener-id>
    </before-id-set>
  </phase-listener>
</lifecycle>
```

In the example, `MyPhaseListener` is a registered listener that executes after listeners A and C but before listeners B, M, and Y. To execute `MyPhaseListener` after listener B, move the `<listener-id>` element for listener B under the `<after-id-set>` element.

## 21.4.4 How to Register a Lifecycle Listener for a Single Page

To customize the lifecycle of a single page, you set the `ControllerClass` attribute on the page definition file. This listener will be valid only for the lifecycle of the particular page described by the page definition. For more information about the page definition file and its role in a Fusion web application, see [Section 12.6, "Working with Page Definition Files."](#)

You specify a different controller class depending on whether it is for a standard JSF page or a page fragment:

**To customize the ADF Lifecycle for a single page or page fragment:**

1. In the Application Navigator, right-click the page or page fragment and choose **Go To Page Definition**.
2. In the Structure window, select the page definition node.
3. In the Property Inspector, click the dropdown menu next to the **ControllerClass** field and choose **Edit**.
4. Click **Hierarchy** and navigate to the appropriate controller class for the page or page fragment. Following are the controller classes to use for different types of pages:
  - Standard JSF page - specify  
`oracle.adf.controller.v2.lifecycle.PageController`  
If you need to receive `afterPhase`/`beforePhase` events, specify  
`oracle.adf.controller.v2.lifecycle.PagePhaseListener`
  - Page fragment - specify  
`oracle.adf.model.RegionController`

**Tip:** You can specify the value of the page definition's `ControllerClass` attribute as a fully qualified class name or you can enter an EL expression that resolves to a class directly in the **ControllerClass** field.

When using an EL expression for the value of the `ControllerClass` attribute, the Structure window may show a warning indicating that `"#{YourExpression}"` is not a valid class. You can safely ignore this warning.

---

---

## Creating a Basic Databound Page

This chapter describes how to use the Data Controls panel to create databound forms using ADF Faces components and ADF data binding.

This chapter includes the following sections:

- [Section 22.1, "Introduction to Creating a Basic Databound Page"](#)
- [Section 22.2, "Using Attributes to Create Text Fields"](#)
- [Section 22.3, "Creating a Basic Form"](#)
- [Section 22.4, "Incorporating Range Navigation into Forms"](#)
- [Section 22.5, "Creating a Form to Edit an Existing Record"](#)
- [Section 22.6, "Creating an Input Form"](#)
- [Section 22.7, "Using a Dynamic Form to Determine Data to Display at Runtime"](#)
- [Section 22.8, "Modifying the UI Components and Bindings on a Form"](#)

### 22.1 Introduction to Creating a Basic Databound Page

You can create UI pages that allow you to display and collect information using data controls created for your business services. For example, using the Data Controls panel, you can drag an attribute for an item, and then choose to display the value either as read-only text or as an input text field with a label. JDeveloper creates all the necessary JSF tag and binding code needed to display and update the associated data. For more information about the Data Controls panel and the declarative binding experience, see [Chapter 12, "Using ADF Model in a Fusion Web Application."](#)

Instead of having to drop individual attributes, JDeveloper allows you to drop all attributes for an object at once as a form. The actual UI components that make up the form depend on the type of form dropped. You can create forms that display values, forms that allow users to edit values, and forms that collect values (input forms).

For example, the StoreFront module contains a page that allows users to register information about themselves, as shown in [Figure 22-1](#). This form was created by dragging and dropping the `CustomerRegistration` collection from the Data Controls panel.

**Figure 22–1 Register Customer Form in the StoreFront Module**

Once you drop the UI components, you can then drop built-in operations as command UI components that allow you to navigate through the records in a collection or that allow users to operate on the data, such as committing, deleting, or creating a record. For example, you can create a button that allows users to delete data objects displayed in the form. You can also modify the default components to suit your needs.

## 22.2 Using Attributes to Create Text Fields

JDeveloper allows you to create text fields declaratively in a WYSIWYG development environment for your JSF pages, meaning you can design most aspects of your pages without needing to look at the code. When you drag and drop items from the Data Controls panel, JDeveloper declaratively binds ADF Faces text UI components to attributes on a data control using an attribute binding.

### 22.2.1 How to Create a Text Field

To create a text field that can display or update an attribute, you drag and drop an attribute of a collection from the Data Controls panel.

#### To create a bound text field:

1. From the Data Controls panel, select an attribute for a collection. For a description of the icons that represent attributes and other objects in the Data Controls panel, see [Section 12.3, "Using the Data Controls Panel."](#)

For example, [Figure 22–2](#) shows the `FirstName` attribute under the `CustomerRegistration` collection of the `StoreServiceAMDataControl` data control in the StoreFront module. This is the attribute to drop to display or enter the customer's first name.

**Figure 22–2 Attributes Associated with a Collection in the Data Controls Panel**

2. Drag the attribute onto the page, and from the context menu choose the type of widget to display or collect the attribute value. For an attribute, you are given the following choices:

- **Text:**

- **ADF Input Text w/ Label:** Creates an ADF Faces `inputText` component with a nested `validator` component. The `label` attribute is populated.

**Tip:** For more information about validators and other attributes of the `inputText` component, see the "Using Input Components and Defining Forms" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

- **ADF Input Text:** Creates an ADF Faces `inputText` component with a nested `validator` component. The `label` attribute is not populated.
- **ADF Output Text w/ Label:** Creates a `panelLabelAndMessage` component that holds an ADF Faces `outputText` component. The `label` attribute on the `panelLabelAndMessage` component is populated.
- **ADF Output Text:** Creates an ADF Faces `outputText` component. No label is created.
- **ADF Output Formatted w/Label:** Same as ADF Output Text w/Label, but uses an `outputFormatted` component instead of an `outputText` component. The `outputFormatted` component allows you to add a limited amount of HTML formatting. For more information, see the "Displaying Output Text and Formatted Output Text" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*
- **ADF Output Formatted:** Same as ADF Output Formatted w/Label, but without the label.
- **ADF Label:** An ADF Faces `outputLabel` component.
- **List of Values:** Creates ADF LOV lists. For more information about how these lists work, see [Section 5.13, "Working with List of Values \(LOV\) in View Object Attributes."](#) For more information about using the lists on a JSF page, see [Section 25.3, "Creating a Selection List."](#)
- **Single selections:** Creates single selection lists. For more information about creating lists on a JSF page, see [Section 25.3, "Creating a Selection List."](#)

---

---

**Note:** These selections are your choices by default. However, the list of components available to use for an attribute can be configured as a control hint on the associated entity or view object. For more information, see [Section 4.6, "Defining Attribute Control Hints for Entity Objects"](#) and [Section 5.14, "Defining Control Hints for View Objects."](#)

---

---

For the purposes of this chapter, only the text components (and not the lists) will be discussed.

## 22.2.2 What Happens When You Create a Text Field

When you drag an attribute onto a JSF page and drop it as a UI component, among other things, a page definition file is created for the page (if one does not already exist). For a complete account of what happens when you drag an attribute onto a page, see [Section 12.3.2, "What Happens When You Use the Data Controls Panel."](#) Bindings for the iterator and attributes are created and added to the page definition file. Additionally, the necessary JSPX page code for the UI component is added to the JSF page.

### 22.2.2.1 Creating and Using Iterator Bindings

Whenever you create UI components on a page by dropping an item that is part of a collection from the Data Controls panel (or you drop the whole collection as a form or table), JDeveloper creates an iterator binding if it does not already exist. An iterator binding references an iterator for the data collection, which facilitates iterating over its data objects. It also manages currency and state for the data objects in the collection. An iterator binding does not actually access the data. Instead, it simply exposes the object that can access the data and it specifies the current data object in the collection. Other bindings then refer to the iterator binding in order to return data for the current object or to perform an action on the object's data. Note that the iterator binding is not an iterator. It is a binding to an iterator. In the case of ADF Business Components, the actual iterator is the default row set iterator for the default row set of the view object instance in the application module's data model.

For example, if you drop the `FirstName` attribute under the `CustomerRegistration` collection, JDeveloper creates an iterator binding for the `CustomerRegistration` collection.

**Tip:** There is one iterator binding created for each collection. This means that when you drop two attributes from the same collection (or drop the collection twice), they use the same binding. This is fine, unless you need the binding to behave differently for the different components. In that case, you will need to manually create separate iterator bindings.

The iterator binding's `rangeSize` attribute determines how many rows of data are fetched from a data control each time the iterator binding is accessed. This attribute gives you a relative set of 1-*n* rows positioned at some absolute starting location in the overall row set. When you create the iterator binding by dragging an attribute or collection on to a page, the attribute is initially set to 25. For more information about using this attribute, see [Section 22.4.2.2, "Iterator RangeSize Attribute."](#) [Example 22-1](#) shows the iterator binding created when you drop an attribute from the `CustomerRegistration` collection.

**Example 22–1 Page Definition Code for an Iterator Binding for an Attribute Dropped from a Collection**

```
<executables>
  <iterator Binds="CustomerRegistration" RangeSize="25"
           DataControl="StoreServiceAMDataControl"
           id="CustomerRegistrationIterator" />
</executables>
```

For information regarding the iterator binding element attributes, see [Appendix B, "Oracle ADF Binding Properties."](#)

This metadata allows the ADF binding container to access the attribute values. Because the iterator binding is an executable, by default, it is invoked when the page is loaded, thereby allowing the iterator to access and iterate over the `CustomerRegistration` collection. This means that the iterator will manage all the `CustomerRegistration` objects in the collection, including determining the current `CustomerRegistration` or range of `CustomerRegistration` objects.

**22.2.2.2 Creating and Using Value Bindings**

When you drop an attribute from the Data Controls panel, JDeveloper creates an attribute binding that is used to bind the UI component to the attribute's value. This type of binding presents the value of an attribute for a single object in the current row in the collection. Value bindings can be used both to display and to collect attribute values.

For example, if you drop the `PrincipalName` attribute under the `CustomerRegistration` collection as an ADF Output Text w/Label widget onto a page, JDeveloper creates an attribute binding for the `PrincipalName` attribute. This allows the binding to access the attribute value of the current record. [Example 22–2](#) shows the attribute binding for `PrincipalName` created when you drop the attribute from the `CustomerRegistration` collection. Note that the attribute value references the iterator named `CustomerRegistrationIterator`.

**Example 22–2 Page Definition Code for an Attribute Binding**

```
<bindings>
  ...
  <attributeValues IterBinding="CustomerRegistrationIterator"
                  id="PrincipalName">
    <AttrNames>
      <Item Value="PrincipalName" />
    </AttrNames>
  </attributeValues>
</bindings>
```

For information regarding the attribute binding element properties, see [Appendix B, "Oracle ADF Binding Properties."](#)

**22.2.2.3 Using EL Expressions to Bind UI Components**

When you create a text field by dropping an attribute from the Data Controls panel, JDeveloper creates the UI component associated with the widget dropped by writing the corresponding tag to the JSF page.

For example, when you drop the `PrincipalName` attribute as an Output Text w/Label widget, JDeveloper inserts the tags for a `panelLabelAndMessage` component and an `outputText` component. It creates an EL expression that binds the `label` attribute of the `panelLabelAndMessage` component to the `label` property

of hints created for the `PrincipalName`'s binding. This expression evaluates to the label hint set on the view object (for more information about hints, see [Section 5.14, "Defining Control Hints for View Objects"](#)). It creates another expression that binds the `outputText` component's value attribute to the `inputValue` property of the `PrincipalName` binding, which evaluates to the value of the `PrincipalName` attribute for the current row. An ID is also automatically generated for both components.

**Tip:** JDeveloper automatically generates IDs for all ADF Faces components. You can override these values as needed.

[Example 22-3](#) shows the code generated on the JSF page when you drop the `PrincipalName` attribute as an Output Text w/Label widget.

**Example 22-3 JSF Page Code for an Attribute Dropped as an Output Text w/Label**

```
<af:panelLabelAndMessage label="#{bindings.PrincipalName.hints.label}" id="plam1">
  <af:outputText value="#{bindings.PrincipalName.inputValue}" id="ot1"/>
</af:panelLabelAndMessage>
```

If instead you drop the `PrincipalName` attribute as an Input Text w/Label widget, JDeveloper creates an `inputText` component. As [Example 22-4](#) shows similar to the output text component, the value is bound to the `inputValue` property of the `PrincipalName` binding. Additionally, the following properties are also set:

- `label`: Bound to the `label` property of the control hint set on the object.
- `required`: Bound to the `mandatory` property of the control hint.
- `columns`: Bound to the `displayWidth` property of the control hint, which determines how wide the text box will be.
- `maxLength`: Bound to the `precision` property of the control hint. This control hint property determines the maximum number of characters per line that can be entered into the field.

In addition, JDeveloper adds a validator component.

**Example 22-4 JSF Page Code for an Attribute Dropped as an Input Text w/Label**

```
<af:inputText value="#{bindings.PrincipalName.inputValue}"
  label="#{bindings.PrincipalName.hints.label}"
  required="#{bindings.PrincipalName.hints.mandatory}"
  columns="#{bindings.PrincipalName.hints.displayWidth}"
  maxLength="#{bindings.PrincipalName.hints.precision}">
  <f:validator binding="#{bindings.PrincipalName.validator}" id="it1">
    <f:validator binding="#{bindings.PrincipalName.validator}"/>
  </f:validator>
</af:inputText>
```

You can change any of these values to suit your needs. For example, the `mandatory` control hint on the view object is set to `false` by default, which means that the `required` attribute on the component will evaluate to `false` as well. You can override this value by setting the `required` attribute on the component to `true`. If you decide that all instances of the attribute should be mandatory, then you can change the control hint on the view object, and all instances will then be required. For more information about these properties, see [Appendix B, "Oracle ADF Binding Properties."](#)

## 22.3 Creating a Basic Form

Instead of dropping each of the individual attributes of a collection to create a form, you can create a complete form that displays or collects data for all the attributes on an object.

For example, you could create a page that displays basic information about registered users in the StoreFront module by dragging and dropping the `CustomerInfoVO1` collection.

You can also create forms that provide more functionality than simply displaying data from a collection. For information about creating a form that allows a user to update data, see [Section 22.5, "Creating a Form to Edit an Existing Record."](#) For information about creating forms that allow users to create a new object for the collection, see [Section 22.6, "Creating an Input Form."](#) You can also create search forms. For more information, see [Chapter 27, "Creating ADF Databound Search Forms."](#)

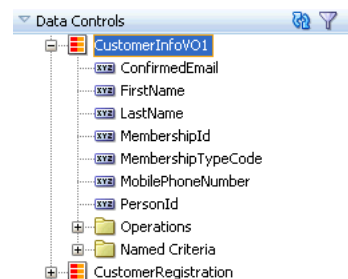

### 22.3.1 How to Create a Form

To create a form using a data control, you bind the UI components to the attributes on the corresponding object in the data control. JDeveloper allows you to do this declaratively by dragging and dropping a collection or a structured attribute from the Data Controls panel.

#### To create a basic form:

1. From the Data Controls panel, select the collection that represents the data you wish to display. [Figure 22–3](#) shows the `CustomerInfoVO1` collection for the `StoreServiceAMDDataControl` data control.

**Figure 22–3** *CustomerInfo View Object in the Data Controls Panel*

2. Drag the collection onto the page, and from the context menu choose the type of form that will be used to display or collect data for the object. For a form, you are given the following choices:
  - **ADF Form:** Launches the Edit Form Fields dialog that allows you to select individual attributes instead of having JDeveloper create a field for every attribute by default. It also allows you to select the label and UI component used for each attribute. By default, ADF `inputText` components are used for most attributes. Each `inputText` component has the `label` attribute populated.

Attributes that are dates use the `InputDate` component. Additionally, if a control type control hint has been created for an attribute, or if the attribute has been configured to be a list, then the component set by the hint is used instead. `InputText` components contain a `validator` tag that allows you to set up validation for the attribute, and if the attribute is a number or a date, a converter is also included.

**Tip:** For more information about validators, converters, and other attributes of the `inputText` component, see the "Using Input Components and Defining Forms" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

- **ADF Read-Only Form:** Same as the ADF Form, but only read-only `outputText` components are used. Since the form is meant to display data, no `validator` tags are added (converters are included). Attributes of type `Date` use the `outputText` component when in a read-only form. All components are placed inside `panelLabelAndMessage` components, which have the `label` attribute populated, and are placed inside a `panelFormLayout` component.
  - **ADF Search Form:** Creates a form that can be used to execute a Query-by-Example (QBE) search. For more information, see [Chapter 27, "Creating ADF Databound Search Forms."](#)
3. In the Edit Form Fields dialog, configure your form.  
 You can elect to include navigational controls that allow users to navigate through all the data objects in the collection. For more information, see [Section 22.4, "Incorporating Range Navigation into Forms."](#) You can also include a **Submit** button used to submit the form. This button submits the HTML form and applies the data in the form to the bindings as part of the JSF/ADF page lifecycle. For additional help in using the dialog, click **Help**. All UI components are placed inside a `panelFormLayout` component.
  4. If you are building a form that allows users to update data, you now need to drag and drop an operation that will perform the update. For more information, see [Section 22.5, "Creating a Form to Edit an Existing Record."](#)

### 22.3.2 What Happens When You Create a Form

Dropping an object as a form from the Data Controls panel has the same effect as dropping a single attribute, except that multiple attribute bindings and associated UI components are created. The attributes on the UI components (such as `value`) are bound to properties on that attribute's binding object (such as `inputValue`) or to the values of control hints set on the corresponding business object. [Example 22–5](#) shows some of the code generated on the JSF page when you drop the `CustomerInfoVO1` collection as a default ADF Form.

---

**Note:** If an attribute is marked as hidden on the associated view or entity object, then no corresponding UI is created for it.

---

#### **Example 22–5 Code on a JSF Page for an Input Form**

```
<af:panelFormLayout id="pf11">
  <af:inputText value="#{bindings.PersonId.inputValue}"
    label="#{bindings.PersonId.hints.label}"
    required="#{bindings.PersonId.hints.mandatory}"
    columns="#{bindings.PersonId.hints.displayWidth}"
    maximumLength="#{bindings.PersonId.hints.precision}"
    shortDesc="#{bindings.PersonId.hints.tooltip}" id="it2">
    <f:validator binding="#{bindings.PersonId.validator}"/>
  </af:inputText>
  <af:inputText value="#{bindings.FirstName.inputValue}"
```

```

        label="#{bindings.FirstName.hints.label}"
        required="#{bindings.FirstName.hints.mandatory}"
        columns="#{bindings.FirstName.hints.displayWidth}"
        maxLength="#{bindings.FirstName.hints.precision}"
        shortDesc="#{bindings.FirstName.hints.tooltip}"
        id="it1">
    <f:validator binding="#{bindings.FirstName.validator}"/>
</af:inputText>
<af:inputText value="#{bindings.LastName.inputValue}"
    label="#{bindings.LastName.hints.label}"
    required="#{bindings.LastName.hints.mandatory}"
    columns="#{bindings.LastName.hints.displayWidth}"
    maxLength="#{bindings.LastName.hints.precision}"
    shortDesc="#{bindings.LastName.hints.tooltip}" id="it7">
    <f:validator binding="#{bindings.LastName.validator}"/>
</af:inputText>
. . .
</af:panelFormLayout>

```

---

**Note:** For information regarding the validator and converter tags, see the "Validating and Converting Input" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

---

When you choose to create an input form using an object that contains a defined list of values (LOV), then a `selectOneChoice` component is created instead of an `inputText` component. For example, the `PersonsVO` view object contains a defined LOVs for the `Title`, `Gender`, `MaritalStatusCode`, and `PersonTypeCode` attributes. When you drop the `Persons` data control object as an ADF Form, instead of as an empty input text field, a dropdown list showing all values is created. For more information about how these lists work, see [Section 5.13, "Working with List of Values \(LOV\) in View Object Attributes."](#) For more information about using the lists on a JSF page, see [Section 25.3, "Creating a Selection List."](#)

---

**Note:** If the object contains a structured attribute (an attribute that is neither a Java primitive type nor a collection), that attribute will not appear in the dialog, and it will not have a corresponding component in the form. You will need to create those fields manually.

---

## 22.4 Incorporating Range Navigation into Forms

When you create an ADF Form, if you elect to include navigational controls, JDeveloper includes ADF Faces command components bound to existing navigational logic on the data control. This built-in logic allows the user to navigate through all the data objects in the collection. For example, [Figure 22-4](#) shows a form that would be created if you drag the `CustomerInfoVO1` collection and drop it as an ADF Form that uses navigation.

**Figure 22–4 Navigation in a Form**

### 22.4.1 How to Insert Navigation Controls into a Form

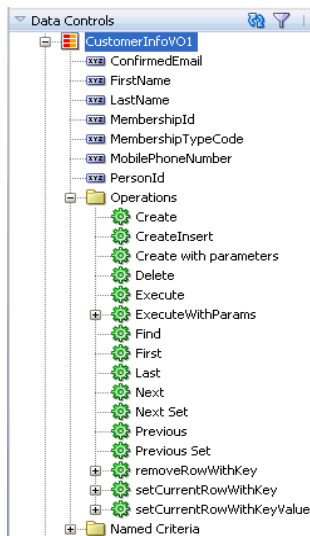

By default, when you choose to include navigation when creating a form using the Data Controls panel, JDeveloper creates **First**, **Last**, **Previous**, and **Next** buttons that allow the user to navigate within the collection.

You can also add navigation buttons to an existing form manually.

#### To manually add navigation buttons:

1. From the Data Controls panel, select the operation associated with the collection of objects on which you wish the operation to execute, and drag it onto the JSF page.

For example, if you want to navigate through a collection of persons, you would drag the **Next** operation associated with the `Persons` collection. [Figure 22–5](#) shows the operations associated with the `CustomerInfoVO1` collection.

**Figure 22–5 Operations Associated with a Collection**

2. From the ensuing context menu, choose either **ADF Button** or **ADF Link**.

**Tip:** You can also drop the **First**, **Previous**, **Next**, and **Last** buttons at once. To do so, drag the corresponding collection, and from the context menu, choose **Navigation > ADF Navigation Buttons**.

### 22.4.2 What Happens When You Create Command Buttons

When you drop any operation as a command component, JDeveloper:

- Defines an action binding in the page definition file for the associated operations
- Configures the iterator binding to use partial page rendering for the collection

- Inserts code in the JSF page for the command components

### 22.4.2.1 Action Bindings for Built-in Navigation Operations

Action bindings execute business logic. For example, they can invoke built-in methods on the action binding object. These built-in methods operate on the iterator or on the data control itself, and are represented as operations in the Data Controls panel. JDeveloper provides navigation operations that allow users to navigate forward, backwards, to the last object in the collection, and to the first object.

Like value bindings, action bindings for operations contain a reference to the iterator binding when the action binding is bound to one of the iterator-level actions, such as `Next` or `Previous`. These types of actions are performed by the iterator, which determines the current object and can therefore determine the correct object to display when a navigation button is clicked. Action bindings to other than iterator-level actions, for example for a custom method on an application module, or for the commit or rollback operations, will not contain this reference.

Action bindings use the `RequiresUpdateModel` property, which determines whether or not the model needs to be updated before the action is executed. In the case of navigation operations, by default this property is set to `true`, which means that any changes made at the view layer must be moved to the model before navigation can occur. [Example 22–6](#) shows the action bindings for the navigation operations.

#### **Example 22–6 Page Definition Code for an Operation Action Binding**

```
<action IterBinding="CustomerInfoVO1Iterator" id="First"
    RequiresUpdateModel="true" Action="first" />
<action IterBinding="CustomerInfoVO1Iterator" id="Previous"
    RequiresUpdateModel="true" Action="previous" />
<action IterBinding="CustomerInfoVO1Iterator" id="Next"
    RequiresUpdateModel="true" Action="next" />
<action IterBinding="CustomerInfoVO1Iterator" id="Last"
    RequiresUpdateModel="true" Action="last" />
```

### 22.4.2.2 Iterator RangeSize Attribute

Iterator bindings have a `rangeSize` attribute that the binding uses to determine the number of data objects to make available for the page for each iteration. This attribute helps in situations when the number of objects in the data source is quite large. Instead of returning all objects, the iterator binding returns only a set number, which then become accessible to the other bindings. Once the iterator reaches the end of the range, it accesses the next set. [Example 22–7](#) shows the default range size for the `CustomerInfoVO` iterator.

#### **Example 22–7 RangeSize Attribute for an Iterator**

```
<iterator Binds="CustomerInfoVO" RangeSize="25"
    DataControl="StoreServiceAMDataControl"
    id="CustomerInfoVO1Iterator"
    ChangeEventPolicy="ppr" />
```

---

**Note:** This `rangeSize` attribute is not the same as the `rows` attribute on a table component. For more information, see [Table 23–1, "ADF Faces Table Attributes and Populated Values"](#).

---

When the iterator binding is initially generated, the `RangeSize` attribute is set to 25. This means that a user can view 25 objects, navigating back and forth between them, without needing to access the data source. The iterator keeps track of the current object. Once a user clicks a button that requires a new range (for example, clicking the **Next** button on object number 25), the binding object executes its associated method against the iterator, and the iterator retrieves another set of 25 records. The bindings then work with that set. You can change this setting as needed. You can set it to -1 to have the full record set returned. If the `RangeSize` attribute is not specified, the full record set is returned.

---

---

**Note:** When you create a navigatable form using the Data Controls panel, the `CacheResults` property on the associated iterator is set to `true`. This ensures that the iterator's state, including currency information, is cached between requests, allowing it to determine the current object. If this property is set to `false`, navigation will not work.

---

---

Table 22-1 shows the built-in navigation operations provided on data controls and the result of invoking the operation or executing an event bound to the operation. For more information about action events, see [Section 22.4.4, "What Happens at Runtime: How Action Events and Action Listeners Work."](#)

**Table 22-1 Built-in Navigation Operations**

Operation	When invoked, the associated iterator binding will...
First	Move its current pointer to the beginning of the result set.
Last	Move its current pointer to the end of the result set.
Previous	Move its current pointer to the preceding object in the result set. If this object is outside the current range, the range is scrolled backward a number of objects equal to the range size.
Next	Move its current pointer to the next object in the result set. If this object is outside the current range, the range is scrolled forward a number of objects equal to the range size.
Previous Set	Move the range backward a number of objects equal to the range size attribute.
Next Set	Move the range forward a number of objects equal to the range size attribute.

### 22.4.2.3 EL Expressions Used to Bind to Navigation Operations

When you create command components using navigation operations, the command components are placed in a `panelGroupLayout` component. JDeveloper creates an EL expression that binds a navigational command button's `actionListener` attribute to the `execute` property of the action binding for the given operation.

At runtime an action binding will be an instance of the `FacesCtrlActionBinding` class, which extends the core `JUCtrlActionBinding` implementation class. The `FacesCtrlActionBinding` class adds the following methods:

- public void execute(ActionEvent event):** This is the method that is referenced in the `actionListener` property, for example `{bindings.First.execute}`.

This expression causes the binding's operation to be invoked on the iterator when a user clicks the button. For example, the **First** command button's

`actionListener` attribute is bound to the `execute` method on the `First` action binding.

- `public String outcome():` This can be referenced in an Action property, for example `#{bindings.Next.outcome}`.

This can be used for the result of a method action binding (once converted to a `String`) as a JSF navigation outcome to determine the next page to navigate to.

---

**Note:** Using the `outcome` method on the action binding implies tying the view-controller layer too tightly to the model, so it should be rarely used.

---

Every action binding for an operation has an `enabled` boolean property that Oracle ADF sets to `false` when the operation should not be invoked. By default, JDeveloper binds the UI component's `disabled` attribute to this value to determine whether or not the component should be enabled. For example, the UI component for the **First** button has the following as the value for its `disabled` attribute:

```
#{!bindings.First.enabled}
```

This expression evaluates to `true` whenever the binding is not enabled, that is, when operation should not be invoked, thereby disabling the button. In this example, because the framework will set the `enabled` property on the binding to `false` whenever the first record is being shown, the **First** button will automatically be disabled because its `disabled` attribute is set to be `true` whenever `enabled` is `False`. For more information about the `enabled` property, see [Appendix B, "Oracle ADF Binding Properties."](#)

[Example 22-8](#) shows the code generated on the JSF page for navigation operation buttons. For more information about the `partialSubmit` attribute on the button, see [Section 22.4.3, "What You May Need to Know About Automatic Partial Page Rendering."](#)

#### **Example 22-8 JSF Code for Navigation Buttons Bound to ADF Operations**

```
<f:facet name="footer">
  <af:panelGroupLayout>
    <af:commandButton actionListener="#{bindings.First.execute}"
      text="First"
      disabled="#{!bindings.First.enabled}"
      partialSubmit="true" id="cb1"/>
    <af:commandButton actionListener="#{bindings.Previous.execute}"
      text="Previous"
      disabled="#{!bindings.Previous.enabled}"
      partialSubmit="true" id="cb2"/>
    <af:commandButton actionListener="#{bindings.Next.execute}"
      text="Next"
      disabled="#{!bindings.Next.enabled}"
      partialSubmit="true" id="cb3"/>
    <af:commandButton actionListener="#{bindings.Last.execute}"
      text="Last"
      disabled="#{!bindings.Last.enabled}"
      partialSubmit="true" id="cb4"/>
  </af:panelGroupLayout>
</f:facet>
```

### 22.4.3 What You May Need to Know About Automatic Partial Page Rendering

When you create a form with navigational controls, JDeveloper configures the iterator binding to automatically use partial page rendering (PPR). PPR allows only certain components on a page to be rerendered without the need to refresh the entire page. For example, a command link or button can cause another component on the page to be rerendered, without the whole page refreshing. You can configure components to use PPR by setting one component as a target for another component's event, for example a value change or action event. For more information about partial page rendering, see the "Rerendering Partial Page Content" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

When you create a form, setting up PPR to work for all the components in the form can be time consuming and error prone. To alleviate this, you can set the `changeEventPolicy` attribute to `ppr` on value bindings. Doing so means that anytime the associated component's value changes as a result of backend business logic, the component will be automatically rerendered. You can also set an iterator binding's `changeEventPolicy` to `ppr`. When you do this, any action or value binding associated with the iterator will act as though its `changeEventPolicy` is set to PPR. This allows entire forms to use PPR without your having to configure each component separately.

When you drop a form and elect to include navigation controls, JDeveloper automatically sets the `changeEventPolicy` attribute on the associated iterator to `ppr`. JDeveloper also sets each of the navigation buttons' `partialSubmit` attribute to `true`. This is how command components notify the framework that PPR should occur. When you set the navigation command components' `partialSubmit` attribute to `true` and you set the iterator's `changeEventPolicy` to `ppr`, each time a navigation button is clicked, all the components in the form that use the iterator binding are rerendered. [Example 22–9](#) shows the page definition code for the iterator created when dropping the `CustomerInfoVO` collection from the Data Controls Panel as a form with navigation.

#### **Example 22–9 ChangeEventPolicy Attribute for an Iterator**

```
<iterator Binds="CustomerInfoVO1" RangeSize="25"
  DataControl="StoreServiceAMDataControl"
  id="CustomerInfoVOIterator"
  ChangeEventPolicy="ppr"/>
```

### 22.4.4 What Happens at Runtime: How Action Events and Action Listeners Work

An action event occurs when a command component is activated. For example, when a user clicks a **Submit** button, the form is submitted, and subsequently, an action event is fired. Action events might affect only the user interface (for example, a link to change the locale, causing different field prompts to display), or they might involve some logic processing in the back end (for example, a button to navigate to the next record).

An action listener is a class that wants to be notified when a command component fires an action event. An action listener contains an action listener method that processes the action event object passed to it by the command component.

In the case of the navigation operations, when a user clicks, for example, the **Next** button, an action event is fired. This event object stores currency information about the current data object, taken from the iterator. Because the component's `actionListener` attribute is bound to the `execute` method of the `Next` action

binding, the `Next` operation is invoked when the event fires. This method takes the currency information passed in the event object to determine what the next data object should be.

In addition, when a user clicks a navigation button, only those components associated with the same iterator as the button's action binding are processed through the lifecycle. This is because a navigation command button's `partialSubmit` attribute is set to `true`, and the associated iterator is configured to use PPR.

### 22.4.5 What You May Need to Know About the Browser Back Button and Navigating Through Records

You must use the navigation buttons to navigate through the records displayed in a form; you cannot use the browser's back or forward buttons. Because navigation forms automatically use PPR, only part of the page goes through the lifecycle, meaning that when you click a navigation button, the components displaying the data are refreshed and display new data, and you actually remain on the same page. Therefore, when you click the browser's back button, you will be returned to the page that was rendered before the page with the form, instead of to the previous record displayed in the form.

For example, say you are on a page that contains a link to view all current orders. When you click the link, you navigate to a page with a form and the first order, Order #101, is displayed. You then click **Next** and Order #102 is displayed. You click **Next** again, and Order #103 is displayed. If you click the browser's back button, you will not be shown Order #102. Instead, you will be returned to the page that contained the link to view all current orders.

## 22.5 Creating a Form to Edit an Existing Record

You can create a form that allows a user to edit the current data, and then commit those changes to the data source. To do this, you use operations that can modify data records associated with the collection or the data control itself to create command buttons. For example, you can use the `Delete` operation to create a button that allows a user to delete a record from the current range. Or you can use the built-in **Submit** button to submit changes.

**Tip:** While you can use the `Create` operation on a form to create a new object, using the ADF Creation Form instead provides additional built-in functionality. See [Section 22.6, "Creating an Input Form"](#) for more information.

If instead of using one of the ADF built-in operations, you want to use a custom method to operate on the data in a form, see [Section 28.2, "Creating Command Components to Execute Methods."](#)

It is important to note that these operations are executed only against objects in the ADF cache. You need to use the `Commit` operation on the root data control to actually commit any changes to the data source. You use the data control's `Rollback` operation to roll back any changes made to the cached object. If the page is part of a transaction within a bounded task flow, you would most likely use these operations to resolve the transaction in a task flow return activity. For more information, see [Section 18.4, "Managing Transactions."](#)

## 22.5.1 How to Create Edit Forms

To use the operations on a form, you follow the same procedures as with the navigation operations.

### To create an edit form:

1. From the Data Controls panel, drag the collection for which you wish to create the form, and select **ADF Form** from the context menu.

This creates a form using `inputText` components, which will allow the user to edit the data in the fields.

2. In the Edit Form Fields dialog, select **Include Submit Button** and click **OK**.
3. You can either create new buttons for the operations you want to include, or you can rebind the **Submit** button so that it invokes another operation. To keep the **Submit** button as is and create new buttons for the operations, continue with this step. To rebind the **Submit** button, see Step 5.

From the Data Controls panel, select the operation associated with the collection of objects on which you wish the operation to execute, and drag it onto the JSF page. If you simply want to be able to edit the data, then the **Submit** button is all that is required.

For example, if you want to be able to delete a customer record, you would drag the `Delete` operation associated with the `CustomerInfoVO1` collection.

Figure 22–6 shows the operations associated with a collection.

**Figure 22–6 Operations Associated with a Collection**

4. From the ensuing context menu, choose either **ADF Button** or **ADF Link**.
5. To rebind the Submit button, right-click the button in the Structure window, and choose **Bind to ADF Control**. In the Bind to ADF Control dialog, select the operation to which you want the button bound. Ensure that the operation you select is associated with the collection on which the form is based.

For example, if you want to be able to delete a customer record, you would select the Delete operation associated with the `CustomerInfoVO1` collection. [Figure 22–6](#) shows the operations associated with a collection.

6. If the page is not part of a transaction within a bounded task flow, then you need to create buttons that allow the user either to commit or roll back the changes. From the Data Controls panel, drag the **Commit** and **Rollback** operations associated with the root-level data control, and drop them as either a command button or a command link. [Figure 22–7](#) shows the commit and rollback operations for the `StoreServiceAMDataControl` data control (note that for viewing simplicity, the figure omits details in the tree that appear for each view object).

**Figure 22–7 Commit and Rollback Operations for a Data Control**

If the page is part of a transaction within a bounded task flow, then you can simply enter `Commit` and `Rollback` as the values for the transaction resolution when creating the task flow return activity. For more information, see [Section 18.4, "Managing Transactions."](#)

## 22.5.2 What Happens When You Use Built-in Operations to Change Data

Dropping any data control operation as a command button causes the same events as does dropping navigation operations. For more information, see [Section 22.4.2, "What Happens When You Create Command Buttons."](#)

The only difference is that the action bindings for the `Commit` and `Rollback` operations do not require a reference to the iterator, because they execute a method on the application module (the data control itself), as opposed to the iterator. Note that the `Rollback` action has the `RequiresUpdateModel` property set to `false`. This is because the model should not be updated before the operation is executed, since all changes need to be discarded. [Example 22–10](#) shows the action bindings generated in the page definition file for these operations.

**Example 22–10 Action Bindings for Commit and Rollback Operations**

```
<action id="Commit" RequiresUpdateModel="true" Action="commitTransaction"
  DataControl="StoreServiceAMDataControl" />
<action id="Rollback" RequiresUpdateModel="false"
  Action="rollbackTransaction"
  DataControl="StoreServiceAMDataControl" />
```

[Table 22–2](#) shows the built-in non-navigation operations provided on data controls and data control objects, along with the result of invoking the operation or executing an event bound to the operation. For more information about action events, see [Section 22.4.4, "What Happens at Runtime: How Action Events and Action Listeners Work."](#)

**Table 22–2 More Built-in Operations**

Operation	When invoked, the associated iterator binding will...
CreateInsert	Creates a row directly before the current row, inserts the new record into the row set, then moves the current row pointer to the new row. Note that the range does not move, meaning that the last row in the range may now be excluded from the range. For more information about using the CreateInsert operation to create objects, see <a href="#">Section 22.6, "Creating an Input Form."</a>
Create	Creates a row directly before the current row, then moves the current row pointer to the new row. Note that the range does not move, meaning that the last row in the range may now be excluded from the range. Also note that the record will not be inserted into the row set, preventing a blank row should the user navigate away without actually creating data. The new row will be created when the user submits the data. For more information, see <a href="#">Section 23.4.5, "What You May Need to Know About Create and CreateInsert."</a>
CreateWithParameters	Same as the CreateInsert operation (the new record is inserted into the row set), however uses named parameters to create the object.
CreateWithParameters (temporary)	Same as the CreateWithParameters operation, however the newly created record will not be inserted into the row set, preventing a blank row should the user navigate away without actually creating data. The new row will be created when the user submits the data. This difference is the same as the difference between CreateInsert and Create. For more information, see <a href="#">Section 23.4.5, "What You May Need to Know About Create and CreateInsert."</a>
Delete	Deletes the current row from the cache and moves the current row pointer to the next row in the result set. Note that the range does not move, meaning that a row may be added to the end of the range. If the last row is deleted, the current row pointer moves to the preceding row. If there are no more rows in the collection, the enabled attribute is set to disabled.
RemoveRowWithKey	Uses the row key as a String converted from the value specified by the input field to remove the data object in the bound data collection.
SetCurrentRowWithKey	Sets the row key as a String converted from the value specified by the input field. The row key is used to set the currency of the data object in the bound data collection. For an example of when this is used, see <a href="#">Section 23.2.3, "What You May Need to Know About Setting the Current Row in a Table."</a>
SetCurrentRowWithKeyValue	Sets the current object on the iterator, given a key's value. For more information, see <a href="#">Section 23.2.3, "What You May Need to Know About Setting the Current Row in a Table."</a>
ExecuteWithParams	<p>Refreshes the data collection by first assigning new values to the named bind variables passed as parameters, then (re)executing the view object's query. You would use this operation in the same manner as you would use the CreateInsert operation to create an input form. For more information, see <a href="#">Section 22.6, "Creating an Input Form."</a></p> <p>This operation appears only for view objects that have defined one or more named bind variables at design time. For more information, see <a href="#">Section 5.10, "Working with Bind Variables."</a> For more information about how the page definition works with bind variables and the executeWithParams operation, see <a href="#">Section 28.2.2.2, "Using Parameters in a Method."</a></p>
Commit	Causes all items currently in the cache to be committed to the database.
Rollback	Clears the cache and returns the transaction and iterator to the initial state. Resets the ActionListener method.

**Table 22–2 (Cont.) More Built-in Operations**

Operation	When invoked, the associated iterator binding will...
Execute and Find	These operations are used only in search forms. See <a href="#">Chapter 27, "Creating ADF Databound Search Forms"</a> for more information.

## 22.6 Creating an Input Form

You can create a form that allows a user to enter information for a new record and then commit that record to the data source. You need to use a task flow that contains a method activity that will call the `CreateInsert` operation before the page with the input form is displayed. This method activity causes a blank row to be inserted into the row set which the user can then populate using a form.

For example, in the `StoreFront` module, the `customer-registration-task-flow` task flow contains the `createAddress` method activity, which calls the `CreateInsert` operation on the `CustomerAddress` view object. Control is then passed to the `addressDetails` view activity, which displays a form where the user can enter a new address, as shown in [Figure 22–8](#).

**Figure 22–8 Address Creation Form**

---

**Note:** If your application does not use task flows, then the calling page should invoke the `createInsert` operation similar to the way in which a task flow's method activity would. For example, you could provide application logic within an event handler associated with a command button on the calling page. For more information about invoking logic with a command button, see [Section 28.2, "Creating Command Components to Execute Methods."](#)

---

### 22.6.1 How to Create an Input Form Using a Task Flow

Before you create the input form, you need to create a bounded task flow that will contain both the form and the method activity that will execute the `CreateInsert` operation.

#### To create an input form:

1. To the bounded task flow, add a method activity. Have this activity execute the `CreateInsert` operation associated with the collection for which you are creating the form. For procedures on using method activities, see [Section 15.5, "Using Method Call Activities."](#)

2. In the Property Inspector, enter a string for the **fixed-outcome** property. For example, the `createAddress` method activity in the `customer-registration-task-flow` task flow has `editAddress` as the `fixed-outcome` value.
3. Add a view activity that represents the page for the input form. For information on adding view activities, see [Section 15.2, "Using View Activities."](#)
4. Add a control flow case from the method activity to the view activity. In the Property Inspector, enter the value of the **fixed-outcome** property of the method activity set in Step 2 as the value of the `from-outcome` of the control flow case.
5. Open the page for the view activity in the design editor, and from the Data Controls panel, drag the collection for which the form will be used to create a new record, and choose **ADF Form** from the context menu.

**Tip:** If you want the user to be able to create multiple entries before committing to the database, do the following:

1. In the task flow, add another control flow case from the view activity back to the method activity, and enter a value for the `from-outcome` method. For example, you might enter `createAnother`.
  2. Drag and drop a command component from the Component Palette onto the page, and set the `action` attribute to the `from-outcome` just created. This will cause the task flow to return to the method activity and reinvoke the `CreateInsert` operation.
6. Because you need to commit the new data, the application needs to execute the `commit` operation of the data control. To do this, you can add a button that navigates to a return activity that calls the `commit` operation. For procedures for using a return activity, see [Section 15.7, "Using Task Flow Return Activities."](#)

**Best Practice:** Use the return activity unless the task flow contains data managed by more than one data control, or you need to commit the data before the end of the flow. In those cases, you can add a button to the page bound to the `commit` button.

If you need to add a `commit` button to the page, do the following:

1. In the Data Controls panel, drag the `commit` operation associated with the data control that contains the collection associated with the input form, and drop it as a command button.
2. In the Structure window, select the command button for the `commit` operation.
3. In the Property Inspector, set the action to the outcome String that will navigate back to the method activity. You then need to add a control flow case from the page back to the activity, using the same outcome value.
4. Set the command button's `disabled` property to `false`.

By default, JDeveloper binds the `disabled` attribute of the button to the `enabled` property of the binding, causing the button to be disabled when the `enabled` property is set to `false`. For this binding, the `enabled` property is `false` until an update has been posted. For the purposes of an input form, the button should always be enabled, since there will be no changes posted before the user needs to create the new object.

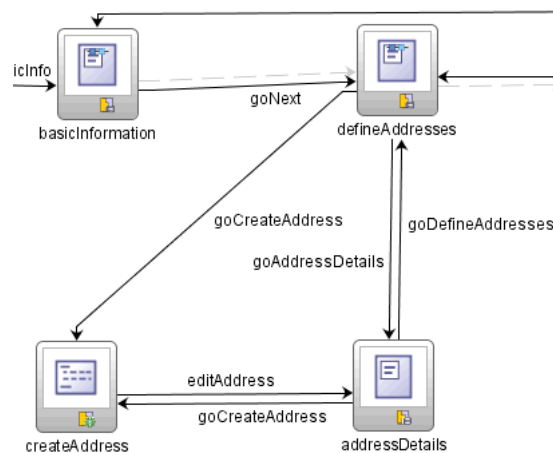

## 22.6.2 What Happens When You Create an Input Form Using a Task Flow

When you use an ADF Form to create an input form, JDeveloper:

- Creates an iterator binding for the collection and an action binding for the `CreateInsert` operation in the page definition for the method activity. The `CreateInsert` operation is responsible for creating a row in the row set and populating the data source with the entered data. In the page definition for the page, JDeveloper creates an iterator binding for the collection and attribute bindings for each of the attributes of the object in the collection, as for any other form. If you created command buttons or links using the `Commit` and `Rollback` operations, JDeveloper also creates an action bindings for those operations.
- Inserts code in the JSF page for the form using ADF Faces `inputText` components, and in the case of the operations, `commandButton` components.

For example, the `StoreFront` module contains a page that displays all the addresses for a customer in a table. The table includes an **Add** button that navigates to a form where you can input data for a new address. Once the address is created, you return to the page with the table and the new address is displayed. [Figure 22-9](#) shows the `customer-registration-task-flow` task flow with the `createAddress` method activity.

**Figure 22-9 Task Flow for an Input Form**

[Example 22-11](#) shows the page definition file for the method activity.

**Example 22-11 Page Definition Code for a Creation Method Activity**

```
<executables>
  <iterator id="CustomerAddressIterator" RangeSize="25"
    Binds="CustomerAddress" DataControl="StoreServiceAMDataControl" />
</executables>
<bindings>
  <action id="CreateInsert" IterBinding="CustomerAddressIterator"
    InstanceName="StoreServiceAMDataControl.CustomerAddress"
    DataControl="StoreServiceAMDataControl" RequiresUpdateModel="true"
    Action="createInsertRow" />
</bindings>
```

### 22.6.3 What Happens at Runtime: CreateInsert Action from the Method Activity

When the `createMethodCall` activity is accessed, the `CreateInsert` action binding is invoked, which executes the `CreateInsertRow` operation, and a new blank instance for the collection is created. Note that during routing from the method

activity to the view activity, the method activity's binding container skips validation for required attributes, allowing the blank instance to be displayed in the form on the page.

## 22.6.4 What You May Need to Know About Displaying Sequence Numbers

Because the `Create` action is executed before the page is displayed, if you are populating the primary key using sequences, the next number in the sequence will appear in the input text field, unlike the rest of the fields, which are blank. The sequence number is displayed because the associated entity class contains a method that uses an eager fetch to generate a sequence of numbers for the primary key attribute. The eager fetch populates the value as the row is created. Therefore, using sequences works as expected with input forms.

However, if instead you've configured the attribute's type to `DBSequence` (which uses a database trigger to generate the sequence), the number would not be populated until the object is committed to the database. In this case, the user would see a negative number as a placeholder. To avoid this, you can use the following EL expression for the `Rendered` attribute of the input text field:

```
{bindings.EmployeeId.inputValue.value > 0}
```

This expression will display the component only when the value is greater than zero, which will not be the case before it is committed. Similarly, you can simply set the `Rendered` attribute to `false`. However, then the page will never display the input text field component for the primary key.

## 22.7 Using a Dynamic Form to Determine Data to Display at Runtime

ADF Faces offers a library of dynamic components that includes dynamic form and dynamic table widgets that you can drop from the Data Controls panel. Dynamic components differ from standard components in that all the binding metadata is created at runtime. This dynamic building of the bindings allows you set display information using control hints on a view object instead of configuring the information in the Edit Form Fields dialog as you drop the control onto the page. Then if you want to change how the data displays, you need only change it on the view object, and all dynamic components bound to that view object will change their display accordingly. With standard components, if you want to change any display attributes (such as the order or grouping of the attributes) you would need to change each page on which the data is displayed.

For example, in the `StoreFront` module, you could set the `Category` and `Field Order` attribute hints on the `CustomerInfoVO` view object that groups the `FirstName` and `LastName` attributes together and at the top of a form (or at the leftmost columns of a table), the `ConfirmedEmail` and `MobilePhoneNumber` together and at the bottom of a form (or the rightmost columns of a table), and the `MembershipID` and `MembershipType` together and at the middle of a form or table. You could make it so that the `PersonId` does not display at all. For more information about control hints on view objects, see [Section 5.14, "Defining Control Hints for View Objects."](#)

[Figure 22–10](#) shows a dynamic form at runtime created by dragging and dropping the `CustomerInfoVO` view object with control hints set as described previously, as a dynamic form. Note that the input fields are grayed out because the view object is nonupdateable.

**Figure 22–10 Dynamic Form Displays Based on Hints Set on the View Object**

First Name	<input type="text" value="John"/>
Last Name	<input type="text" value="Chen"/>
Membership Type	<input type="text" value="PERS"/>
Membership ID	<input type="text" value="1"/>
Phone	<input type="text"/>
Email	<input type="text" value="JCHEN"/>

## 22.7.1 How to Use Dynamic Forms

To use dynamic forms you first need to set control hints (especially the order and grouping hints) on any corresponding view objects. Next you import the libraries for the dynamic components. You can then drop the dynamic form or table widgets onto your page.

### To use dynamic components:

1. Set UI hints on the corresponding view objects. For the Category hint, enter a string that can be used to group attributes together. For example, in the CustomerInfoVO hints, the `FirstName` and `LastName` attributes both have name as the value for the Category UI hint. The Field Order hint determines the order the attributes are displayed within a category. For example, in the CustomerInfoVO hints, the `FirstName` attribute has a Field Order value of 1 and the `LastName` attribute has a Field Order value of 2.

For procedures on creating UI hints, see [Section 5.14, "Defining Control Hints for View Objects."](#)

2. If not already included, import the dynamic component library.
  1. In the Application Navigator, right-click the view project in which the dynamic components will be used, and from the context menu, choose **Project Properties**.
  2. In the tree, select **JSP Tag Libraries**.
  3. On the JSP Tag Libraries page, click **Add**.
  4. In the Choose Tag Libraries dialog, select **ADF Dynamic Components**, and click **OK**.
  5. On the JSP Tag Libraries page, click **OK**.
3. From the Data Controls panel, select the collection that represents the view object.
4. Drag the collection onto the page, and from the context menu, choose **Forms > ADF Dynamic Form**.

**Tip:** If dynamic components are not listed, then the library was not imported into the project. Repeat Step 2.

5. In the Property Inspector, enter the following: for the **Category** field,.
  - **Category:** Enter the string used as the value for the Category UI hint for the first group you'd like to display in your form. For example, in [Figure 22–10](#), the Category value would be name.
  - **Editable:** Enter `true` if you want the data to be editable (the default). Enter `false` if the data should be read-only.

6. Repeat Steps 4 and 5 for each group that you want to display on the form. For example, the form in [Figure 22–10](#) is actually made up of three different forms: one for the category name, one for the category membership, and one for the category contact.

## 22.7.2 What Happens When You Use Dynamic Components

When you drop a dynamic form, only a binding to the iterator is created.

[Example 22–12](#) shows the page definition for a page that contains one dynamic form component created by dropping the `CustomerInfoVO` collection. Note that no attribute bindings are created.

### **Example 22–12 Page Definition Code for a Dynamic Form**

```
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uiModel"
    version="11.1.1.53.2" id="DynamicFormPageDef"
    Package="package.pageDefs">
  <parameters/>
  <executables>
    <iterator Binds="CustomerInfoVO1" RangeSize="25"
      DataControl="StoreServiceAMDataControl"
      id="CustomerInfoVO1Iterator" />
  </executables>
  <bindings/>
</pageDefinition>
```

JDeveloper inserts a `form` tag which contains a dynamic form tag for each of the forms dropped. The form tag's value is bound to the iterator binding, as shown in [Example 22–13](#). This binding means the entire form is bound to the data returned by the iterator. You cannot set display properties for each attribute individually, nor can you rearrange attributes directly on the JSF page.

### **Example 22–13 JSF Page Code for a Dynamic Form**

```
<af:document>
  <af:messages/>
  <af:form>
    <dynamic:form value="#{bindings.CustomerInfoVO1Iterator}"
      category="name" />
    <dynamic:form value="#{bindings.CustomerInfoVO1Iterator}"
      category="member" />
    <dynamic:form value="#{bindings.CustomerInfoVO1Iterator}"
      category="contact" />
  </af:form>
</af:document>
```

**Tip:** You can set certain properties that affect the functionality of the form. For example, you can make a form available for upload, set the rendered property, or set a partial trigger. To do this, select the `af:form` tag in the Structure window, and set the needed properties using the Property Inspector.

## 22.7.3 What Happens at Runtime: How Attribute Values Are Dynamically Determined

When a page with dynamic components is rendered, the bindings are created just as they are when items are dropped from the Data Controls panel at design time, except

that they are created at runtime. For more information, see [Section 22.3.2, "What Happens When You Create a Form."](#)

**Tip:** While there is a slight performance hit because the bindings need to be created at runtime, there is also a performance gain because the JSF pages do not need to be regenerated and recompiled when the structure of the view object changes.

## 22.7.4 What You May Need to Know About Converters for Dynamic Forms

By default, when you create a dynamic form, any necessary converters are created dynamically and the converter's pattern string is set to the format hint on the attribute definition in the view object.

If you want to use an alternate format string for a converter for attributes of a given Java type, you can do so by creating a custom converter and registering it in the `faces-config.xml` file to be used on attributes of that type. [Example 22-14](#) shows a `faces-config.xml` entry for a converter for `java.sql.Date` attributes.

### **Example 22-14** *faces-config.xml* Entry for a Custom Converter

```
<converter>
  <display-name>Date Time Converter</display-name>
  <converter-for-class>java.sql.Date</converter-for-class>
  <converter-class>sample.apps.view.DateTimeConverter</converter-class>
</converter>
```

The custom converter that you create must extend an ADF Faces or Trinidad converter class (such as `org.apache.myfaces.trinidadinternal.convert.DateTimeConverter` and implement the `getPattern()` method. For more information on creating a custom converter, see "Creating Custom JSF Converters" in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

The dynamic form looks up the converter based on the Java type specified in the `faces-config.xml` entry. If the attribute definition in the view object has a format hint specified, then that hint is used as a pattern on the converter. Otherwise, the pattern is untouched and the default pattern from the return of the converter's `getPattern()` method is used.

## 22.8 Modifying the UI Components and Bindings on a Form

Once you use the Data Controls panel to create any type of form (except a dynamic form), you can then delete attributes, change the order in which they are displayed, change the component used to display data, and change the attribute to which the components are bound.

---

**Note:** You cannot change how a dynamic form displays using the following procedures. You must change display information on the view object or entity object instead.

---

### 22.8.1 How to Modify the UI Components and Bindings

You can modify certain aspects of the default components dropped from the Data Controls panel. You can use the Structure window to change the order in which

components are displayed, to add new components or change existing components, or to delete components. You can use the Property Inspector to change or delete bindings, or to change the label displayed for a component.

**To modify default components and bindings:**

1. Use the Structure window to do the following:
  - Change the order of the UI components by dragging them up or down the tree. A black line with an arrowhead denotes where the UI component will be placed.
  - Add a UI component. Right-click an existing UI component in the Structure window and choose to place the new component before, after, or inside the selected component. You then choose from a list of UI components.
  - Bind a UI component. Right-click an existing UI component in the Structure window and choose **Bind to ADF Control**. You can then select the object to which you want your component bound.
  - Rebind a UI component. Right-click an existing UI component in the Structure window and choose **Rebind to another ADF Control**. You can then select the new control object to which you want your component bound.
  - Delete a UI component. Right-click the component and choose **Delete**. If you wish to keep the component, but delete the binding, you need to use the Property Inspector. See the second bullet point in Step 2.
2. With the UI component selected in the Structure window, you can then do the following in the Property Inspector:
  - Add a non-ADF binding for the UI component. Enter an EL expression in the **Value** field, or use the dropdown menu and choose **Edit**.
  - Delete a binding for the UI component by deleting the EL expression.
  - Change the label for the UI component. By default, the label is bound to the binding's `label` property of its hint. This property allows your page to use the UI control hints for labels that you have defined for your entity object attributes or view object attributes. The UI hints allow you to change the value once and have it appear the same on all pages that display the label.

You can change the label just for the current page. To do so, select the `label` attribute. You can enter text or an EL expression to bind the label value to something else, for example, a key in a properties or resource file.

For example, the `inputText` component used to display the name of a product might have the following for its `Label` attribute:

```
{bindings.ProductName.hints.label}
```

However, you could change the expression to instead bind to a key in a properties file, for example:

```
{properties['productName']}
```

In this example, `properties` is a variable defined in the JSF page used to load a properties file.

## 22.8.2 What Happens When You Modify Attributes and Bindings

When you modify how an attribute is displayed by moving or changing the UI component, JDeveloper changes the corresponding code on the JSF page. When you

use the binding editors to add or change a binding, JDeveloper adds the code to the JSF page, and also adds the appropriate elements to the page definition file.

## Creating ADF Databound Tables

This chapter describes how to use the Data Controls panel to create databound tables using ADF Faces components and ADF data binding.

This chapter includes the following sections:

- [Section 23.1, "Introduction to Adding Tables"](#)
- [Section 23.2, "Creating a Basic Table"](#)
- [Section 23.3, "Creating an Editable Table"](#)
- [Section 23.4, "Creating an Input Table"](#)
- [Section 23.5, "Creating a List View of a Collection"](#)
- [Section 23.6, "Providing Multiselect Capabilities"](#)
- [Section 23.7, "Modifying the Attributes Displayed in the Table"](#)

### 23.1 Introduction to Adding Tables

Unlike forms, tables allow you to display more than one data object from a collection at a time. [Figure 23–1](#) shows the Items Ordered tab of the My Orders page in the StoreFront module application, which uses a browse table to display the items for a given order.

**Figure 23–1** The Orders Table

Item(s) Summary

You can create tables that simply display data, or you can create tables that allow you to edit or create data. You can also display a collection of objects in a list that uses a grid to display each object's attributes, similar to a simple table. Once you drop a collection as a table, you can add command buttons bound to actions that execute

some logic on a selected row. You can also modify the default components to suit your needs.

## 23.2 Creating a Basic Table

Unlike with forms where you bind the individual UI components that make up a form to the individual attributes on the collection, with a table you bind the ADF Faces `table` component to the complete collection or to a range of  $n$  data objects at a time from the collection. The individual components used to display the data in the columns are then bound to the attributes. The iterator binding handles displaying the correct data for each object, while the `table` component handles displaying each object in a row. JDeveloper allows you to do this declaratively, so that you don't need to write any code.

### 23.2.1 How to Create a Basic Table

To create a table using a data control, you bind the `table` component to a collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

**Tip:** You can also create a table by dragging a table component from the Component Palette and completing the Create ADF Faces Table wizard.

#### To create a databound table:

1. From the Data Controls panel, select a collection.

For example, to create a simple table in the StoreFront module that displays products in the system, you would select the `Products` collection.

2. Drag the collection onto a JSF page, and from the context menu, choose the appropriate table from the **Table/List View** submenu.

When you drag the collection, you can choose from the following types of tables:

- **ADF Table:** Allows you to select the specific attributes you wish your editable table columns to display, and what UI components to use to display the data. By default, ADF `inputText` components are used for most attributes, thus enabling the table to be editable. Attributes that are dates use the `inputDate` component. Additionally, if a control type control hint has been created for an attribute, or if the attribute has been configured to be a list, then the component set by the hint is used instead.
- **ADF Read-Only Table:** Same as the **ADF Table**; however, each attribute is displayed in an `outputText` component.
- **ADF Read-Only Dynamic Table:** Allows you to create a table when the attributes returned and displayed are determined dynamically at runtime. This component is helpful when the attributes for the corresponding object are not known until runtime, or you do not wish to hardcode the column names in the JSF page.

You can also create a `listView` component, which is a simple table that consists of a single column and uses layout components to group data and other components within that column. For more information, see [Section 23.5, "Creating a List View of a Collection."](#)

3. The ensuing Edit Table Columns dialog shows each attribute in the collection, and allows you to determine how these attributes will behave and appear as columns in your table.

---

**Note:** If the collection contains a structured attribute (an attribute that is neither a Java primitive type nor a collection), the attributes of the structured attributes will also appear in the dialog.

---

Using this dialog, you can do the following:

- Allow the ADF Model layer to handle selection by selecting the **Row Selection** checkbox. Selecting this option means that the iterator binding will access the iterator to determine the selected row. Select this option unless you do not want the table to allow selection.
- Allow the ADF Model layer to handle column sorting by selecting the **Sorting** checkbox. Selecting this option means that the iterator binding will access the iterator, which will perform an order-by query to determine the order. Select this option unless you do not want to allow column sorting.
- Allow the columns in the table to be filtered using entered criteria by selecting the **Filtering** checkbox. Selecting this option allows the user to enter criteria in text fields above each column. That criteria is then used to build a Query-by-Example (QBE) search on the collection, so that the table will display only the results returned by the query. For more information, see [Section 27.5, "Creating Standalone Filtered Search Tables from Named View Criteria."](#)
- Group columns for selected attributes together under a parent column, by selecting the desired attributes (shown as rows in the dialog), and clicking the **Group** button. [Figure 23–2](#) shows how three grouped columns appear in the visual editor after the table is created.

**Figure 23–2 Grouped Columns in an ADF Faces Table**

Group			Name
Product Id	Supplier Id	Category Id	
{...ProductId}	{...SupplierId}	{...CategoryId}	{...ProductName}
{...ProductId}	{...SupplierId}	{...CategoryId}	{...ProductName}
{...ProductId}	{...SupplierId}	{...CategoryId}	{...ProductName}

- Change the display label for a column. By default, the label is bound to the `labels` property for any control hint defined for the attribute on the table binding. This binding allows you to change the value of a label text once on the view object, and have the change appear the same on all pages that display the label.

Instead of using this default, you can enter text or an EL expression to bind the label value to something else, for example, a key in a resource file.

- Change the value binding for a column. You can change the column to be bound to a different attribute. If you simply want to rearrange the columns, you should use the order buttons. If you do change the attribute binding for a column, the label for the column also changes.
- Change the UI component used to display an attribute. The UI components are set based on the table you selected when you dropped the collection onto

the page, on the type of the corresponding attribute (for example, `inputDate` components are used for attributes that are dates), and on whether or not default components were set as control hints on the corresponding view object. You can change to another component using the dropdown menu.

**Tip:** If one of the attributes for your table is also a primary key, you may want to choose a UI component that will not allow a user to change the value.

**Tip:** If you want to use a component that is not listed in the dropdown menu, use this dialog to select the `outputText` component, and then manually add the other tag to the page.

- Change the order of the columns using the order buttons.
  - Add a column using the **Add** icon. There's no limit to the number of columns you can add. When you first click the icon, JDeveloper adds a new column line at the bottom of the dialog and populates it with the values from the first attribute in the bound collection; subsequent new columns are populated with values from the next attribute in the sequence, and so on.
  - Delete a column using the **Delete** icon.
4. Once the table is dropped on the page, you can use the Property Inspector to set other display properties of the table. For example, you may want to set the width of the table to a certain percentage or size. For more information about display properties, see the "Using Tables, Trees, and Other Collection-Based Components" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

**Tip:** When you set the table width to 100%, the table will not include borders, so the actual width of the table will be larger. To have the table set to 100% of the container width, expand the **Style** section of the Property Inspector, select the **Box** tab, and set the `Border Width` attribute to 0 pixels.

5. If you want the user to be able to edit information in the table and save any changes, you need to provide a way to submit and persist those changes. For more information, see [Section 23.3, "Creating an Editable Table."](#) For procedures on creating tables that allow users to input data, see [Section 23.4, "Creating an Input Table."](#)

## 23.2.2 What Happens When You Create a Table

Dropping a table from the Data Controls panel has the same effect as dropping a text field or form. Briefly, JDeveloper does the following:

- Creates the bindings for the table and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

For more information, see [Section 22.2.2, "What Happens When You Create a Text Field."](#)

### 23.2.2.1 Iterator and Value Bindings for Tables

When you drop a table from the Data Controls panel, a tree value binding is created. A tree consists of a hierarchy of nodes, where each subnode is a branch off a higher level

node. In the case of a table, it is a flattened hierarchy, where each attribute (column) is a subnode off the table. Like an attribute binding used in forms, the tree value binding references the iterator binding, while the iterator binding references an iterator for the data collection, which facilitates iterating over the data objects in the collection. Instead of creating a separate binding for each attribute, only the tree binding to the table node is created. In the tree binding, the `AttrNames` element within the `nodeDefinition` element contains a child element for each attribute that you want to be available for display or reference in each row of the table.

The tree value binding is an instance of the `FacesCtrlHierBinding` class that extends the core `JUCtrlHierBinding` class to add two JSF specific properties: `collectionModel`.

- `collectionModel`: Returns the data wrapped by an object that extends the `javax.faces.model.DataModel` object that JSF and ADF Faces use for collection-valued components like tables.
- `treeModel`: Extends `collectionModel` to return data that is hierarchical in nature. For more information, see [Chapter 24, "Displaying Master-Detail Data."](#)

[Example 23–1](#) shows the value binding for the table created when you drop the `Products` collection.

#### **Example 23–1 Value Binding Entries for a Table in the Page Definition File**

```
<bindings>
  <tree IterBinding="ProductsIterator" id="Products">
    <nodeDefinition DefName="oracle.fodemo.storefront.store.queries.ProductsVO">
      <AttrNames>
        <Item Value="ProductId"/>
        <Item Value="SupplierId"/>
        <Item Value="CategoryId"/>
        <Item Value="ProductName"/>
        <Item Value="CostPrice"/>
        <Item Value="ListPrice"/>
        .
        .
        .
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

Only the table component needs to be bound to the model (as opposed to the columns or the text components within the individual cells), because only the table needs access to the data. The tree binding for the table drills down to the individual structure attributes in the table, and the table columns can then derive their information from the table component.

#### **23.2.2.2 Code on the JSF Page for an ADF Faces Table**

When you use the Data Controls panel to drop a table onto a JSF page, JDeveloper inserts an ADF Faces `table` component, which contains an ADF Faces `column` component for each attribute named in the table binding. Each column then contains another component (such as an `inputText` or `outputText` component) bound to the attribute's value. Each column's heading is bound to the `labels` property for the control hint of the attribute.

**Tip:** If an attribute is marked as hidden on the associated view or entity object, no corresponding UI is created for it.

[Example 23–2](#) shows a simplified code excerpt from a table created by dropping the `Products` collection as a read only table.

**Example 23–2 Simplified JSF Code for an ADF Faces Table**

```
<af:table value="#{bindings.Products.collectionModel}" var="row"
  rows="#{bindings.Products.rangeSize}"
  emptyText="#{bindings.Products.viewable ? 'No data to display.':
    'Access Denied.'}"
  fetchSize="#{bindings.Products.rangeSize}"
  selectedRowKeys="#{bindings.Products.collectionModel.selectedRow}"
  selectionListener="#{bindings.Products.collectionModel.makeCurrent}"
  rowSelection="single" id="t1">
  <af:column sortProperty="ProductId" sortable="true"
    headerText="#{bindings.Products.hints.ProductId.label}" id="c1">
    <af:outputText value="#{row.ProductId}" id="ot1"/>
  </af:column>
  <af:column sortProperty="SupplierId" sortable="true"
    headerText="#{bindings.Products.hints.SupplierId.label}" id="c2">
    <af:outputText value="#{row.SupplierId}" id="ot2">
      <af:convertNumber groupingUsed="false"
        pattern="#{bindings.Products.hints.SupplierId.format}"/>
    </af:outputText>
  </af:column>
  <af:column sortProperty="CostPrice" sortable="true"
    headerText="#{bindings.Products.hints.CostPrice.label}" id="c3">
    <af:outputText value="#{row.CostPrice}" id="ot3">
      <af:convertNumber groupingUsed="false"
        pattern="#{bindings.Products.hints.CostPrice.format}"/>
    </af:outputText>
  </af:column>
  .
  .
  .
</af:table>
```

The tree binding iterates over the data exposed by the iterator binding. Note that the table's value is bound to the `collectionModel` property, which accesses the `collectionModel` object. The table wraps the result set from the iterator binding in a `collectionModel` object. The `collectionModel` allows each item in the collection to be available within the table component using the `var` attribute.

In the example, the table iterates over the rows in the current range of the `Products` iterator binding. The iterator binding binds to a row set iterator that keeps track of the current row. When you set the `var` attribute on the table to `row`, each column then accesses the current data object for the current row presented to the table tag using the `row` variable, as shown for the value of the `af:outputText` tag:

```
<af:outputText value="#{row.ProductId}"/>
```

When you drop an ADF Table (as opposed to an ADF Read Only Table), instead of being bound to the row variable, the value of the input component is implicitly bound to a specific row in the binding container through the `bindings` property, as shown in [Example 23–3](#). Additionally, JDeveloper adds validator and converter components for each input component. By using the `bindings` property, any raised exception can be linked to the corresponding binding object or objects. The controller iterates through all exceptions in the binding container and retrieves the binding object to get the client ID when creating `FacesMessage` objects. This retrieval allows the table to display

errors for specific cells. This strategy is used for all input components, including selection components such as lists.

### Example 23–3 Using Input Components Adds Validators and Converters

```
<af:table value="#{bindings.Products.collectionModel}" var="row"
  rows="#{bindings.Products.rangeSize}"
  first="#{bindings.Products.rangeStart}"
  emptyText="#{bindings.Products.viewable ? 'No data to display.':
    'Access Denied.'}"
  fetchSize="#{bindings.Products.rangeSize}"
  selectedRowKeys="#{bindings.Products.collectionModel.selectedRow}"
  selectionListener="#{bindings.Products.collectionModel.makeCurrent}"
  rowSelection="single" id="t1">
  <af:column sortProperty="ProductId" sortable="true"
    headerText="#{bindings.Products.hints.ProductId.label}" id="c1">
    <af:inputText value="#{row.bindings.ProductId.inputValue}" id="it1"
      <f:validator binding="#{row.bindings.ProductId.validator}"/>
      <af:convertNumber groupingUsed="false"
        pattern="#{bindings.Products.hints.ProductId.format}"/>
    </af:inputText>
  </af:column>
```

For more information about using ADF Faces validators and converters, see the "Validating and Converting Input" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

Table 23–1 shows the other attributes defined by default for ADF Faces tables created using the Data Controls panel.

**Table 23–1 ADF Faces Table Attributes and Populated Values**

Attribute	Description	Default Value
rows	Determines how many rows to display at one time.	An EL expression that, by default, evaluates to the <code>rangeSize</code> property of the associated iterator binding, which determines how many rows of data are fetched from a data control at one time. Note that the value of the <code>rows</code> attribute must be equal to or less than the corresponding iterator's <code>rangeSize</code> value, as the table cannot display more rows than are returned.
first	Index of the first row in a range (based on 0).	An EL expression that evaluates to the <code>rangeStart</code> property of the associated iterator binding.
emptyText	Text to display when there are no rows to return.	An EL expression that evaluates to the <code>viewable</code> property on the iterator. If the table is viewable, the attribute displays <b>No data to display</b> when no objects are returned. If the table is not viewable (for example, if there are authorization restrictions set against the table), it displays <b>Access Denied</b> .

**Table 23–1 (Cont.) ADF Faces Table Attributes and Populated Values**

Attribute	Description	Default Value
fetchSize	Number of rows of data fetched from the data source.	An EL expression that, by default, evaluates to the rangeSize property of the associated iterator binding. For more information about the rangeSize property, see <a href="#">Section 22.4.2.2, "Iterator RangeSize Attribute."</a> This attribute can be set to a larger number than the rows attribute.  Note that to improve scrolling behavior in a table, when the table's iterator binding is expected to manage a data set consisting of over 200 items, and the view object is configured to use range paging, the iterator actually returns a set of ranges instead of just one range. For more information about using range paging, see <a href="#">Section 39.1.5, "Efficiently Scrolling Through Large Result Sets Using Range Paging."</a>
selectedRowKeys	The selection state for the table.	An EL expression that by default, evaluates to the selected row on the collection model.
selectionListener	Reference to a method that listens for a selection event.	An EL expression that by default, evaluates to the makeCurrent method on the collection model.
rowSelection	Determines whether rows are selectable.	Set to single to allow one row to be selected at a time. For information about allowing more than one row to be selected at a time, see <a href="#">Section 23.6, "Providing Multiselect Capabilities."</a>
<b>Column Attributes</b>		
sortProperty	Determines the property on which to sort the column.	Set to the columns corresponding attribute binding value.
sortable	Determines whether a column can be sorted.	Set to false. When set to true, the iterator binding will access the iterator to determine the order.
headerText	Determines the text displayed at the top of the column.	An EL expression that, by default, evaluates to the label control hint set on the corresponding attribute.

### 23.2.3 What You May Need to Know About Setting the Current Row in a Table

When you use tables in an application and you allow the ADF Model layer to manage row selection, the current row is determined by the iterator. When a user selects a row in an ADF Faces table, the row in the table is shaded, and the component notifies the iterator of the selected row. To do this, the selectedRowKeys attribute of the table is bound to the collection model's selected row, as shown in [Example 23–4](#).

**Example 23–4 Selection Attributes on a Table**

```
<af:table value="#{bindings.Products1.collectionModel}" var="row"
.
.
.
      selectedRowKeys="#{bindings.Products.collectionModel.selectedRow}"
      selectionListener="#{bindings.Products.collectionModel.
                                                makeCurrent}"
```

```
rowSelection="single">
```

This binding binds the selected keys in the table to the selected row of the collection model. The `selectionListener` attribute is then bound to the collection model's `makeCurrent` property. This binding makes the selected row of the collection the current row of the iterator.

---

**Note:** If you create a custom selection listener, you must create a method binding to the `makeCurrent` property on the collection model (for example `#{binding.Products.collectionModel.makeCurrent}`) and invoke this method binding in the custom selection listener before any custom logic.

---

Although a table can handle selection automatically, there may be cases where you need to programmatically set the current row for an object on an iterator.

You can call the `getKey()` method on any view row to get a `Key` object that encapsulates the one or more key attributes that identify the row. You can also use a `Key` object to find a view row in a row set using the `findByKey()`. At runtime, when either the `setCurrentRowWithKey` or the `setCurrentRowWithKeyValue` built-in operation is invoked by name by the data binding layer, the `findByKey()` method is used to find the row based on the value passed in as a parameter before the found row is set as the current row.

The `setCurrentRowWithKey` and `setCurrentRowWithKeyValue` operations both expect a parameter named `rowKey`, but they differ precisely by what each expects that `rowKey` parameter value to be at runtime:

#### **setCurrentRowWithKey**

`setCurrentRowWithKey` expects the `rowKey` parameter value to be the *serialized string representation* of a view row key. This is a hexadecimal-encoded string that looks like this:

```
000200000002C20200000002C102000000010000010A5AB7DAD9
```

The serialized string representation of a key encodes all of the key attributes that might comprise a view row's key in a way that can be conveniently passed as a single value in a browser URL string or form parameter. At runtime, if you inadvertently pass a parameter value that is not a legal serialized string key, you may receive exceptions like `oracle.jbo.InvalidParamException` or `java.io.EOFException` as a result. In your web page, you can access the value of the serialized string key of a row by referencing the `rowKeyStr` property of an ADF control binding (for example `#{bindings.SomeAttrName.rowKeyStr}`) or the row variable of an ADF Faces table (e.g. `#{row.rowKeyStr}`).

#### **setCurrentRowWithKeyValue**

The `setCurrentRowWithKeyValue` operation expects the `rowKey` parameter value to be the literal value representing the key of the view row. For example, its value would be simply "201" to find product number 201.

**Note:** If you write custom code in an application module class and need to find a row based on a serialized string key passed from the client, you can use the `getRowFromKey()` method in the `JboUtil` class in the `oracle.jbo.client` package:

```
static public Row getRowFromKey(RowSetIterator rsi, String sKey)
```

The first parameter is the view object instance in which you'd like to find the row. The second parameter is the serialized string format of the key.

### 23.3 Creating an Editable Table

You can create a table that allows the user to edit information within the table, and then commit those changes to the data source. To do this, you use operations that can modify data records associated with the collection (or the data control itself) to create command buttons, and place those buttons in a toolbar in the table. For example, you might use the `Delete` operation to create a button that allows a user to delete a record from the current range. Or you can use the built-in **Submit** button to submit changes.

**Tip:** To create a table that allows you to insert a new record into the data store, see [Section 23.4, "Creating an Input Table."](#)

It is important to note that these operations are executed only against objects in the ADF cache. You need to use the `Commit` operation on the root data control to actually commit any changes to the data source. You use the data control's `Rollback` operation to roll back any changes made to the cached object. If the page is part of a transaction within a bounded task flow, you would most likely use these operations to resolve the transaction in a task flow return activity. For more information, see [Section 18.4, "Managing Transactions."](#)

When you decide to use editable components to display your data, you have the option of the table displaying all rows as editable at once, or displaying all rows as read-only until the user double-clicks within the row. [Figure 23-3](#) shows a table whose rows all have editable fields. The page renders using the components that were added to the page (for example, `inputText`, `inputDate`, and `inputNumberSpinbox` components).

**Figure 23-3 Table with Editable Fields**

ShippingOptionId	CountryCode	CostPerClass1Item	LastUpdatedBy	LastUpdateDate
<input type="text" value="1"/>	<input type="text" value="EN"/>	<input type="text" value="3.15"/>	<input type="text" value="0"/>	<input type="text" value="9/15/2012"/>
<input type="text" value="2"/>	<input type="text" value="EN"/>	<input type="text" value="4.5"/>	<input type="text" value="0"/>	<input type="text" value="9/15/2012"/>
<input type="text" value="3"/>	<input type="text" value="EN"/>	<input type="text" value="4.25"/>	<input type="text" value="0"/>	<input type="text" value="9/15/2012"/>
<input type="text" value="4"/>	<input type="text" value="EN"/>	<input type="text" value="0"/>	<input type="text" value="0"/>	<input type="text" value="9/15/2012"/>

[Figure 23-4](#) shows the same table, but configured so that the user must double-click (or single-click if the row is already selected) a row in order to edit or enter data. Note that `outputText` components are used to display the data in the non-selected rows, even though the same input components as in [Figure 23-3](#) were used to build the page. The only row that actually renders those components is the row selected for editing.

**Figure 23–4 Click to Edit a Row**

ShippingOptionId	CountryCode	CostPerClass1Item	LastUpdatedBy	LastUpdateDate
1	EN	3.15	0	9/15/2012
2	EN	4.5	0	9/15/2012 
3	EN	4.25	0	9/15/2012
4	EN	0	0	9/15/2012

For more information about how ADF Faces table components handle editing, see the "Editing Data in Tables, Trees, and Tree Tables" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 23.3.1 How to Create an Editable Table

To create an editable table, you follow similar procedures to creating a basic table, then you add command buttons bound to operations. However, in order for the table to contain a toolbar, you need to add an ADF Faces component that associates the toolbar with the items in the collection used to build the table.

#### To create an editable table:

1. From the Data Controls panel, select a collection.

For example, to create a simple table in the StoreFront module that will allow you to edit products in the system, you would select the `Products` collection.

2. Drag the collection onto a JSF page, and from the context menu, choose **ADF Table**.

This creates an editable table using input components.

3. Use the ensuing Edit Table Columns dialog to determine how the attributes should behave and appear as columns in your table. Be sure to select the **Row Selection** checkbox, which will allow the user to select the row to edit.

For more information about using this dialog to configure the table, see [Section 23.2.1, "How to Create a Basic Table."](#)

4. With the table selected in the Structure window, expand the **Behavior** section of the Property Inspector and set the **EditingMode** attribute. If you want all the rows to be editable select **editAll**. If you want the user to click into a row to make it editable, select **clickToEdit**.

5. From the Structure window, right-click the table component and select **Surround With** from the context menu.

6. In the Surround With dialog, ensure that **ADF Faces** is selected in the dropdown list, select the **Panel Collection** component, and click **OK**.

The `panelCollection` component's toolbar facet will hold the toolbar which, in turn, will hold the command components used to update the data.

7. In the Structure window, right-click the `panelCollection`'s **toolbar** facet folder and from the context menu, choose **Insert inside toolbar > Toolbar**.

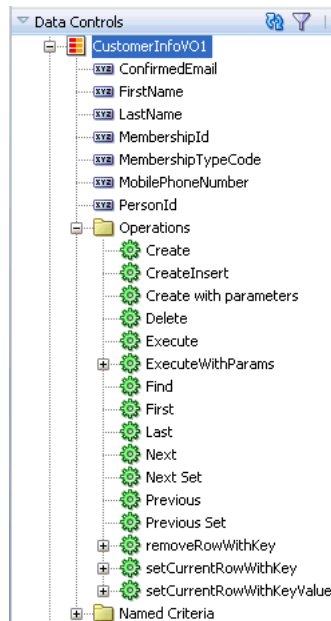

This creates a toolbar that already contains a default menu that allows users to change how the table is displayed and a **Detach** link that detaches the entire table and displays it such that it occupies the majority of the space in the browser window. For more information about the `panelCollection` component, see the "Displaying Table Menus, Toolbars, and Status Bars" section of the *Oracle Fusion*

*Middleware Web User Interface Developer's Guide for Oracle Application Development Framework.*

8. From the Data Controls panel, select the operation associated with the collection of objects on which you wish the operation to execute, and drag it onto the `toolbar` component in the Structure window. This will place the databound command component inside the toolbar.

For example, if you want to be able to delete a product record, you would drag the `Delete` operation associated with the `Products` collection. [Figure 23–5](#) shows the operations associated with a collection.

**Figure 23–5 Operations Associated with a Collection**

9. Choose **Operations > ADF Toolbar Button** from the context menu.
10. To create a **Submit** button that submits changes to the cache, right-click the **toolbar** component in the Structure window and choose **Insert inside af:toolbar > Toolbar Button**.
11. If the page is not part of a transaction within a bounded task flow, then you need to create buttons that allow the user to either commit or rollback the changes. From the Data Controls panel, drag the `Commit` and `Rollback` operations associated with the root-level data control, and drop them as either a command button or command link into the toolbar.

[Figure 23–6](#) shows the commit and roll back operations for the `StoreServiceAMDDataControl` data control.

**Figure 23–6 Commit and Rollback Operations for a Data Control**

If the page is part of a transaction within a bounded task flow, then you can simply enter `Commit` and `Rollback` as the values for the transaction resolution when creating the task flow return activity. For more information, see [Section 18.4, "Managing Transactions."](#)

### 23.3.2 What Happens When You Create an Editable Table

Creating an editable table is similar to creating a form used to edit records. Action bindings are created for the operations dropped from the Data Controls panel. For details on what happens when you create an editable table, see [Section 22.4.2, "What Happens When You Create Command Buttons."](#)

## 23.4 Creating an Input Table

You can create a table that allows users to insert a new blank row into a table and then add values for each column (any default values set on the corresponding entity or view object will be automatically populated).

### 23.4.1 How to Create an Input Table

When you create an input table, you want the user to see the new blank row in the context of the other rows within the current row set. To allow this insertion, you need to use the `CreateInsert` operation instead of the `Create` operation (as you would use with forms). The `CreateInsert` operation actually creates the new row within the row set instead of only in the cache.

ADF Faces components can be set so that one component refreshes based on an interaction with another component, without the whole page needing to be refreshed. This is known as *partial page rendering*. When the user clicks a button to create the new row, you want the table to refresh to display that new row. To have that happen, you need to configure the table to respond to that user action.

#### Before you begin:

1. Create an editable table, as described in [Section 23.3, "Creating an Editable Table."](#)
2. If your table is not part of a bounded task flow, be sure to include buttons bound to the `Commit` and `Rollback` operations.

#### To create an input table:

1. From the Data Controls panel, drag the `CreateInsert` operation associated with the dropped collection and drop it as a toolbar button into the toolbar. You may want to change the ID to something more recognizable, such as `CreateInsert`. This will make it easier to identify when you need to select it as the partial trigger.
2. In the Structure window, select the table component. In the Property Inspector, expand the **Behavior** section.
3. In the Property Inspector, click the dropdown menu for the **PartialTriggers** attribute, and select **Edit**.
4. In the Edit Property dialog, expand the toolbar facet for the `panelCollection` component and then expand the toolbar that contains the `CreateInsert` command component. Select that component and shuttle it to the **Selected** panel. Click **OK**. This sets that component to be the trigger that will cause the table to refresh.

## 23.4.2 What Happens When You Create an Input Table

When you use the `CreateInsert` operation to create an input table, JDeveloper:

- Creates an iterator binding for the collection, an action binding for the `CreateInsert` operation, and attribute bindings for the table. The `CreateInsert` operation is responsible for creating the new row in the row set. If you created command buttons or links using the `Commit` and `Rollback` operations, JDeveloper also creates an action bindings for those operations.
- Inserts code in the JSF page for the table using ADF Faces `table`, `column`, and `inputText` components, and in the case of the operations, `commandButton` components.

[Example 23–5](#) shows the page definition file for an input table created from the `Products` collection (some attributes were deleted in the `Edit Columns` dialog when the collection was dropped).

### Example 23–5 Page Definition Code for an Input Table

```
<executables>
  <iterator Binds="Products" RangeSize="25"
    DataControl="StoreServiceAMDataControl" id="ProductsIterator" />
</executables>
<bindings>
  <tree IterBinding="ProductsIterator" id="Products">
    <nodeDefinition DefName="oracle.fodemo.storefront.store.queries.ProductsVO">
      <AttrNames>
        <Item Value="ProductId" />
        <Item Value="ProductName" />
        <Item Value="CostPrice" />
        <Item Value="ListPrice" />
        <Item Value="Description" />
        <Item Value="CategoryName" />
        <Item Value="CategoryDescription" />
        <Item Value="ProductImageId" />
      </AttrNames>
    </nodeDefinition>
  </tree>
  <action IterBinding="ProductsIterator" id="CreateInsert"
    RequiresUpdateModel="true" Action="createInsertRow" />
  <action id="Commit" RequiresUpdateModel="true" Action="commitTransaction"
    DataControl="StoreServiceAMDataControl" />
  <action id="Rollback" RequiresUpdateModel="false"
    Action="rollbackTransaction"
    DataControl="StoreServiceAMDataControl" />
</bindings>
```

[Example 23–6](#) shows the code added to the JSF page that provides partial page rendering, using the `CreateInsert` command toolbar button as the trigger to refresh the table.

### Example 23–6 Partial Page Trigger Set on a Command Button for a Table

```
<af:form>
  <af:panelCollection id="pcl">
    <f:facet name="menus" />
    <f:facet name="toolbar">
      <af:toolbar id="tbl">
        <af:commandToolbarButton actionListener="#{bindings.CreateInsert.execute}"
          text="CreateInsert" />
      </af:toolbar>
    </f:facet>
  </af:panelCollection>
</af:form>
```

```

                disabled="#{!bindings.CreateInsert.enabled}"
                id="CreateInsert"/>
<af:commandToolbarButton actionListener="#{bindings.Commit.execute}"
    text="Commit"
    disabled="false" id="ctb2"/>
<af:commandToolbarButton actionListener="#{bindings.Rollback.execute}"
    text="Rollback"
    disabled="#{!bindings.Rollback.enabled}"
    immediate="true" id="ctb3">
    <af:resetActionListener/>
</af:commandToolbarButton>
</af:toolbar>
</f:facet>
<f:facet name="statusbar"/>
<af:table value="#{bindings.Products.collectionModel}" var="row"
    rows="#{bindings.Products.rangeSize}"
    emptyText="#{bindings.Products.viewable ? \'No data to display.\' :
        \'Access Denied.\'}"
    fetchSize="#{bindings.Products.rangeSize}"
    rowSelection="single" partialTriggers="CreateInsert" id="t1">
<af:column sortProperty="ProductId" sortable="false"
    headerText="#{bindings.Products.hints.ProductId.label}" id="c1">
<af:inputText value="#{row.ProductId}" simple="true"
    required="#{bindings.Products.hints.ProductId.mandatory}"
    columns="#{bindings.Products.hints.ProductId.displayWidth}"
    maximumLength="#{bindings.Products.hints.
        productId.precision}" id="it1"/>
</af:column>
.
.
.
</af:table>
</af:panelCollection>
</af:form>

```

### 23.4.3 What Happens at Runtime: How CreateInsert and Partial Page Refresh Work

When the button bound to the `CreateInsert` operation is invoked, the action executes, and a new instance for the collection is created and inserted as the page is rerendered. Because the button was configured to be a trigger that causes the table to refresh, the table redraws with the new empty row shown at the top. When the user clicks the button bound to the `Commit` action, the newly created rows in the row set are inserted into the database. For more information about partial page refresh, see the "Rerendering Partial Page Content" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 23.4.4 What You May Need to Know About Creating a Row and Sorting Columns

If your table columns allow sorting, and the user has sorted on a column before inserting a new row, then that new row will not be sorted. To have the column sort with the new row, the user must first sort the column opposite to the desired sort, and then resort. This is because the table assumes the column is already sorted, so clicking on the desired sort order first will have no effect on the column.

For example, say a user had sorted a column in ascending order, and then added a new row. Initially, that row appears at the top. If the user first clicks to sort the column again in ascending order, the table will not resort, as it assumes the column is already in ascending order. The user must first sort on descending order and then ascending order.

If you want the data to automatically sort on a specific column in a specific order after inserting a row, then programmatically queue a `SortEvent` after the commit, and implement a handler to execute the sort. For more information about adding functionality to a declarative operation (such as the `Commit` operation), see [Section 28.4, "Overriding Declarative Methods."](#)

### 23.4.5 What You May Need to Know About Create and CreateInsert

When you use the `Create` or `CreateInsert` operation to declaratively create a new row, it performs the following lines of code:

```
// create a new row for the view object
Row newRow = yourViewObject.createRow();
// mark the row as being "initialized", but not yet new
newRow.setNewRowState(Row.STATUS_INITIALIZED);
```

However, if you are using the `CreateInsert` operation, it performs the additional line of code to insert the row into the row set:

```
// insert the new row into the view object's default rowset
yourViewObject.insertRow(newRow);
```

When you create a row in an entity-based view object, the `Transaction` object associated with the current application module immediately takes note of the fact. The new entity row that gets created behind the view row is already part of the `Transaction`'s list of pending changes. When a newly created row is marked as having the *initialized* state, it is removed from the `Transaction`'s pending changes list and is considered a blank row in which the end user has not yet entered any data values. The term *initialized* is appropriate since the end user will see the new row initialized with any default values that the underlying entity object has defined. If the user never enters any data into any attribute of that initialized row, then it is as if the row never existed. At transaction commit time, since that row is not part of the `Transaction`'s pending changes list, no `INSERT` statement will be attempted for it.

As soon as at least one attribute in an initialized row is set, it automatically transitions from the initialized status to the new status (`Row.STATUS_NEW`). At that time, the underlying entity row is enrolled in the `Transaction`'s list of pending changes, and the new row will be permanently saved the next time you commit the transaction.

---

---

**Note:** If the end user performs steps that result in creating many initialized rows but never populating them, it might seem like a recipe for a slow memory leak. However, the memory used by an initialized row that never transitions to the new state will eventually be reclaimed by the Java virtual machine's garbage collector.

---

---

## 23.5 Creating a List View of a Collection

You can use the `Listview` component when you need to display a collection of objects in a list. The attributes of each object are displayed in a group or grid within a single row and single column. [Figure 23–7](#) shows a collection of orders displayed using a `listview` component.

**Figure 23–7 A Collection Displayed in a List in a Single Column**

In this `listView`, a child `listItem` component contains a `panelGridLayout` component that in turn contains `outputText` components that display the data and a `button` component that allows users to delete the item. The `listView` component is bound to the collection, in the same way that a table is bound to a collection, using the `value` attribute. The `listItem` component is a direct child to the `listView` component and is the container for the components that display the data, in the same way that the `column` component holds the data components for a table.

If your collection has a master-detail relationship with another collection, you can group the child collection under the parent collection using grouping functionality in the `listView` component. For more information, see [Section 24.6, "Using List Views to Display Master-Detail Objects."](#)

For complete information about the `listView` and `listItem` components, see the "Displaying a Collection in a List" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. For complete information about using the `panelGridLayout` component to group items in grid within the list (as shown in [Figure 23–7](#)), see the "Arranging Content in a Grid" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. You can also use a `panelGroupLayout` component to group components when you don't need a grid layout. For more information, see the "Grouping Related Items" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 23.5.1 How to Create a Databound List View

You use the Create List View wizard to create your list. This wizard allows you to choose between a `panelGroupLayout` or a `panelGridLayout` component to arrange the components for your list item. If you are creating the list for a child of a master-detail relationship, you can also use the wizard to configure the headers for the list.

#### To create a list view:

1. From the Data Controls panel, drag a collection onto the page and choose **Table/List View > ADF List View**. If you want to create a list with headers from a parent collection, drag a collection that is a child to another collection.
2. Use the Create List View wizard to select your layout component to organize your display of the data, and to select the attributes and components to display. If you are creating a group, on the first page of the wizard, select **Include header using parent collection**.

For more information about using the wizard, press the F1 key or click **Help**.

- Use the Property Inspector to further configure the layout components.

For complete information about using the `panelGridLayout` component, see the "Arranging Content in a Grid" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. For more information about the `panelGroupLayout` component, see the "Grouping Related Items" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

## 23.5.2 What Happens When You Create a Databound List View

When you use the wizard to create a `listView` component, JDeveloper creates and configures the `listView`, `listItem`, and layout components. The bindings are the same as for a table—the `listView` component is bound to the collection dropped from the Data Controls panel. The value of the `var` attribute on this component is used by the `outputFormatted` components to access the data, in the same way as in a table. For more information about the page definition code and the JSP code for collections, see [Section 23.2.2, "What Happens When You Create a Table."](#)

[Example 23–7](#) shows the page code for the simple table shown in [Figure 23–7](#).

### Example 23–7

```
<af:.listView value="#{bindings.OrdersView1.collectionModel}" var="item"
    emptyText="#{bindings.OrdersView1.viewable ?
        'No data to display.' : 'Access Denied.'}"
    fetchSize="#{bindings.OrdersView1.rangeSize}" id="lv1">
  <af:listItem id="li1">
    <af:panelGridLayout id="pgl1">
      <af:gridRow marginTop="5px" height="auto" id="gr3">
        <af:gridCell marginStart="5px" width="50%" id="gc1">
          <af:outputFormatted value="<b>Order ID:</b>&nbsp;" id="of4"
            <af:outputFormatted value="#{item.bindings.OrderId.inputValue}"
              id="of2" styleUsage="inContextBranding">
          <af:convertNumber groupingUsed="false"
            pattern="#{bindings.OrdersView1.hints.OrderId.format}"/>
          </af:outputFormatted>
        </af:gridCell>
        <af:gridCell marginStart="5px" width="50%" marginEnd="5px"
          id="gc4"/>
      </af:gridRow>
      <af:gridRow marginTop="5px" height="auto" id="gr1">
        <af:gridCell marginStart="5px" width="50%" id="gc6">
          <af:outputFormatted value="<b>Order Status:</b>&nbsp;" id="of5"/>
          <af:outputFormatted value="#{item.bindings.OrderStatusCode.inputValue}"
            id="of3"/>
        </af:gridCell>
        <af:gridCell marginStart="5px" width="50%" marginEnd="5px"
          id="gc2">
          <af:commandButton actionListener="#{bindings.Delete.execute}"
            text="Delete Order"
            disabled="#{!bindings.Delete.enabled}"
            id="cb1"/>
        </af:gridCell>
      </af:gridRow>
      <af:gridRow marginTop="5px" height="auto" marginBottom="5px"
        id="gr2">
        <af:gridCell marginStart="5px" width="50%" id="gc5">
```

```

<af:outputFormatted value="<b>Ship Date:</b>&nbsp;" id="of6"/>
<af:outputFormatted value="#{item.bindings.OrderShippedDate.inputValue}"
    id="of1">
    <af:convertDateTime
        pattern="#{bindings.OrdersView1.hints.OrderShippedDate.format}"/>
</af:outputFormatted>
</af:gridCell>
<af:gridCell marginStart="5px" width="50%" marginEnd="5px"
    id="gc3"/>
</af:gridRow>
</af:panelGridLayout>
</af:listItem>
</af:listView>

```

## 23.6 Providing Multiselect Capabilities

By default, when you drop a table component and set it to use row selection, it is set to allow a user to select a single row. You can change the table so that using the CTRL key or the SHIFT key, the user can select multiple rows, allowing the application to work on multiple rows at the same time.

For example, [Figure 23–8](#) shows the Addresses tab of the `UpdateUserInfo` page, which shows the current addresses for the logged-in user in a table. The user can select multiple addresses and then click the **Remove** toolbar button. This action removes the addresses from the data store.test

**Figure 23–8 Address Table Allowing Multiple Selection**

Address Label	Address Usage Type
100 N Peach St, Philadelphia, PA, 19139 - UNITED S1IN	
100 N Peach St, Philadelphia, PA, 19139 - UNITED S1SH	
2100 S Casino Dr, Laughlin, NV, 89029 - UNITED STA' SH	
2549 Yonge Street, Toronto, ON, M4P 2H9 - CANADA' SH	
5415 W 11th St, Greeley, CO, 80634 - UNITED STATE SH	

In order to allow the user to select and operate on more than one row, among other things, you need to change the `rowSelection` attribute to `multiple`. In Fusion web applications, operations (such as methods) work on the current data object, which the iterator keeps track of. When the `rowSelection` attribute is set to `single` (as it is by default when you select the **Row Selection** checkbox in the Edit Table Columns dialog when creating the table), the table is able to show the current data object as being selected, and it is also able to set any newly selected row to the current object on the iterator. If the same iterator is used on a subsequent page (for example, if the user selects a row and then clicks the command button to navigate to a page where the object can be edited), the selected object will be displayed. This selection and navigation works because the iterator and the component are working with a single object: the notion of the current row is the same because the different iterator bindings in different binding containers are bound to the same row set iterator.

However, when you set the `rowSelection` attribute to `multiple`, there potentially could be multiple selected objects. The ADF Model layer has no notion of "selected" as opposed to "current." You must add logic to the model layer that takes the component instance, reads the selected rows, and translates the selection state to the binding. The method can then perform some action on the selected rows.

## 23.6.1 How to Add Multiselect Capabilities

To add multiselect capabilities, you first modify certain table component attributes. Then you use a managed bean to handle setting the selected rows as the current rows.

**Tip:** You can follow the same procedures for adding multiselect capabilities to a tree or tree table.

### Before you begin:

Create a table as described in [Section 23.2, "Creating a Basic Table,"](#) being sure to *not* select the **Row Selection** checkbox.

---

---

**Note:** You should *not* select the **Row Selection** checkbox, because when you do, JDeveloper automatically binds the `selectionListener` attribute to the `makeCurrent` method on the `CollectionModel` class and the `selectedRowKeys` attribute to the `selectedRow` property on that class. Both are designed to work only for single selection tables. Make sure that for any table for which you need multiple selection, that neither of these attributes are populated.

---

---

### To add multiselect capabilities:

1. In the Structure window, select the table component and set the following attributes in the Property Inspector:
  - **Row Selection:** `multiple`
  - **ID:** an ID of your choice for the table
2. Create and register a managed bean for the page, if one does not already exist. You'll use the managed bean to handle the row selection and execute logic against the selection (for example, deleting the selected rows), so that it executes against all selected rows. For procedures for creating a managed bean, see [Section 20.4, "Using a Managed Bean in a Fusion Web Application."](#)
3. Add a property to the managed bean that represents the table component. Set the value of the property to the table ID value as set in Step 1, and the property class to be the ADF Faces table component class, as shown in [Example 23–8.](#)

#### **Example 23–8 Property on a Managed Bean That Represents a Table**

```
<managed-property>
  <property-name>table1</property-name>
  <property-class>
    oracle.adf.view.rich.component.rich.data.RichTable
  </property-class>
  <value>#{table1}</value>
</managed-property>
```

4. Add getter and setter methods for the table to the managed bean, as shown in [Example 23–9.](#)

#### **Example 23–9 Getter and Setter Methods for the Table Component**

```
private RichTable _table1;

public void setTable1(RichTable table1) {
    this.table1 = table1;
}
```

```
public RichTable getTable1() {
    return table1;
}
```

**Tip:** You'll need to import the ADF Faces table class into the managed bean. JDeveloper can do this for you declaratively when you press CTRL+ENTER after adding the code in [Example 23–9](#).

5. Back in the JSP page, in the Structure window select the table component and set the binding attribute to be bound to the managed property you created in Step 3. For example:

```
binding="#{myBean.table1}"
```

This binding is what allows the application to work with the entire table component. For more information about the `binding` attribute and how it allows you access objects programmatically, refer to the Java EE 5 tutorial on Sun's web site (<http://www.oracle.com/technetwork/java/index.html>).

**Tip:** If you elected to use automatic component binding when creating the JSF page, then most of Steps 2 through 5 will have been done for you. You need only create the set method on the managed bean, as shown in Step 6. It is important, however, to understand the behavior of the page when using automatic component binding. For more information, see the "What You May Need to Know About Automatic Component Binding" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

6. Add logic to allow the declarative operation or method to operate against the set of selected rows.

[Example 23–10](#) shows the method named `deleteOnTable()` that removes the selected rows from the address table on the `updateUserInfo` page.

#### **Example 23–10 Deleting Multiple Rows on an Iterator**

```
public void deleteOnTable(RichTable myTable) {
    RowKeySet rowKeySet = (RowKeySet) myTable.getSelectedRowKeys();
    CollectionModel cm = (CollectionModel) myTable.getValue();
    for (Object facesTreeRowKey : rowKeySet) {
        cm.setRowKey(facesTreeRowKey);
        JUCtrlHierNodeBinding rowData = (JUCtrlHierNodeBinding)
            cm.getRowData()
            rowData.getRow().remove();
    }
}
```

---

---

**Note:** `CollectionModel` supports a version of the `getRowData` method that takes a row key parameter and thus allows you to get row data without changing currency. This is particularly useful when your view object uses range paging.

In the above example, you can thus replace this code:

```
cm.setRowKey(facesTreeRowKey);
JUCtrlHierNodeBinding rowData = (JUCtrlHierNodeBinding)
    cm.getRowData();
```

with this code:

```
JUCtrlHierNodeBinding rowData = (JUCtrlHierNodeBinding)
    cm.getRowData(facesTreeRowKey);
```

---

---

## 23.6.2 What Happens at Runtime: How an Operation Executes Against Multiple Rows

When the user selects multiple rows and then clicks the command button, the application uses different contexts to access the expression factory to build an expression that resolves to the binding container. It then retrieves the iterator and the selected row keys on the component, and sets the selected rows on the binding. Next, it uses the collection model of the binding to remove the row and then reaccesses the component to display the collection with the now removed rows.

## 23.7 Modifying the Attributes Displayed in the Table

Once you use the Data Controls panel to create a table, you can then delete attributes, change the order in which they are displayed, change the component used to display them, and change the attribute binding for the component. You can also add new attributes, or rebind the table to a new data control.

### 23.7.1 How to Modify the Displayed Attributes

You can modify the following aspects of a table that was created using the Data Controls panel:

- Change the binding for the label of a column
- Change the attribute to which a UI component is bound
- Change the UI component bound to an attribute
- Reorder the columns in the table
- Delete a column in the table
- Add a column to the table
- Enable selection and sorting

**To change the attributes for a table:**

1. In the Structure window, select the table component.
2. In the Property Inspector, expand the different sections to change the attributes for the table.

## 23.7.2 How to Change the Binding for a Table

Instead of modifying a binding, you can completely change the object to which the table is bound.

### To rebind a table:

1. Right-click the table in the Structure window and choose **Rebind to Another ADF Control**.
2. In the Bind to ADF Control dialog, select the new collection to which you want to bind the table. Note that changing the binding for the table will also change the binding for all the columns. You can then use the procedures in [Section 23.7.1, "How to Modify the Displayed Attributes"](#) to modify those bindings.

**Tip:** You can also rebind a table by dragging a different view object on top of the existing table.

## 23.7.3 What Happens When You Modify Bindings or Displayed Attributes

When you simply modify how an attribute is displayed by moving the UI component or changing the UI component, JDeveloper changes the corresponding code on the JSF page. When you use the binding editors to add or change a binding, JDeveloper adds the code to the JSF page, and also adds the appropriate elements to the page definition file.

---

---

## Displaying Master-Detail Data

This chapter describes how to create various types of pages that display master-detail related data using ADF data binding.

This chapter includes the following sections:

- [Section 24.1, "Introduction to Displaying Master-Detail Data"](#)
- [Section 24.2, "Identifying Master-Detail Objects on the Data Controls Panel"](#)
- [Section 24.3, "Using Tables and Forms to Display Master-Detail Objects"](#)
- [Section 24.4, "Using Trees to Display Master-Detail Objects"](#)
- [Section 24.5, "Using Tree Tables to Display Master-Detail Objects"](#)
- [Section 24.7, "Using Selection Events with Trees and Tables"](#)

For information about using a selection list to populate a collection with a key value from a related master or detail collection, see [Chapter 25, "Creating Databound Selection Lists and Shuttles"](#).

### 24.1 Introduction to Displaying Master-Detail Data

In ADF Business Components, a master-detail relationship refers to two view object instances that are related by a view link. As described in [Section 5.1, "Introduction to View Objects"](#), a view link represents the relationship between two view objects, which is usually, but not necessarily, based on a foreign-key relationship between the underlying data tables. The view link associates a row of one view object instance (the master object) with one or more rows of another view object instance (the detail object).

To display master-detail data on a page using ADF data binding, you exclusively use data model view link instances, which support master-detail coordination. When using ADF Business Components in combination with the ADF Model layer and ADF Faces UI components, the data model automatically updates to reflect any changes to the row sets of these business objects.

To enable master-detail coordination, you must add both the master view object and the detail view object instances to the application module data model. For example, in the Fusion Order Demo application, there is a view link from the `ProductsVO` view object to the `WarehouseStockLevelsVO` view object based on the `ProductId` attribute, both contained in the application module data model, as shown in [Figure 24-1](#). A change in the current row of the master view object instance causes the row set of the detail view object instance to refresh to include the details for the current master.

**Figure 24–1 View Link between Products and WarehouseStockLevels View Objects**

When objects have a master-detail relationship, you can declaratively create pages that display the data from both objects simultaneously. For example, the page shown in [Figure 24–2](#) displays a country code in a form at the top of the page and its related states and provinces in a table at the bottom of the page. This is possible because the objects have a master-detail relationship. In this example, the `Country Code` is the master object and `States` is the detail object. ADF iterators automatically manage the synchronization of the detail data objects displayed for a selected master data object. Iterator bindings simplify building user interfaces that allow scrolling and paging through collections of data and drilling-down from summary to detail information.

**Figure 24–2 Detail Table**

**Order**

Creation Date 9/15/2012  
 Last Updated 9/15/2012  
 Order Date 9/11/2012  
 Order ID 1002  
 Ship Date  
 Status Code PICK  
 Total 1249.91

First Previous Next Last

**Order Items**

Quantity	Unit Price
1	199.95
3	49.99
1	899.99

You display master and detail objects in forms and tables. The master-detail form can display these objects on separate pages. For example, you can display the master object in a table on one page and detail objects in a read-only form on another page.

---

**Note:** There are some cases when the master-detail UI components that JDeveloper provides cannot provide the functionality you require. For example, you may need to bind components programmatically instead of using the master-detail UI components.

A master object can have many detail objects, and each detail object can in turn have its own detail objects, down to many levels of depth. If one of the detail objects in this hierarchy is dropped from the Application Navigator as a master-detail form on a page, only its immediate parent master object displays on the page. The hierarchy will not display all the way up to the topmost parent object.

If you display the detail object as a tree or tree table object, it is possible to display the entire hierarchy with multiple levels of depth, starting with the topmost master object, and traversing detail children objects at each node.

---

## 24.2 Identifying Master-Detail Objects on the Data Controls Panel

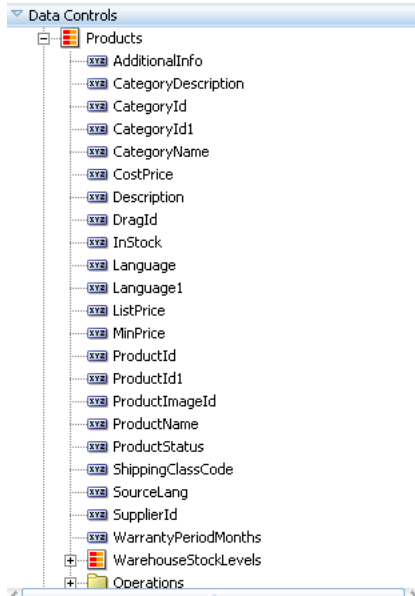

You can declaratively create pages that display master-detail data using the Data Controls panel. The Data Controls panel displays master-detail related objects in a hierarchy that mirrors the one you defined in the application module data model, where the detail objects are children of the master objects. For information about adding master-detail objects to the data model, see [Section 5.6.4, "How to Enable Active Master-Detail Coordination in the Data Model."](#)

To display master-detail objects as form or table objects, drag the detail object from the Data Controls panel and drop it on the page. Its master object is automatically created on the page.

[Figure 24–3](#) shows two master-detail related collections in the Data Controls panel of the Fusion Order Demo application. The `Products` collection is an instance of the `ProductsVO` view object, and the `WarehouseStockLevels` collection, which appears as a child of the `Products` collection, is an instance of the `WarehouseStockLevelsVO` view object.

**Note:** The master-detail hierarchy displayed in the Data Controls panel does not reflect the cardinality of the relationship (that is, one-to-many, one-to-one, many-to-many). The hierarchy simply shows which collection (the master) is being used to retrieve one or more objects from another collection (the detail).

**Figure 24–3 Master-Detail Objects in the Data Controls Panel**

The master-detail hierarchy on the Data Controls panel reflects the hierarchy defined in the application module data model, as shown in Figure 24–4. The hierarchy was established by creating a view link from the ProductsVO view object to the WarehouseStockLevelsVO view object. Next, an instance of the resulting detail view object, WarehouseStockLevelsVO via ProductsToWarehouseStockLevels, was added to the application module data model shown in Figure 24–4.

**Figure 24–4 Master-Detail Hierarchy Defined in the Application Module Data Model**

In the Fusion Order Demo application, the view link between the `ProductsVO` view object and `WarehouseStockLevelsVO` view object is a one-way relationship. If the view link were bidirectional and both sets of master and detail view objects were added to the application module data model, then the Data Controls panel would also display the `WarehouseStockLevelsVO` collection at the same node level as the `Products` collection, and the detail instance of the `Products` collection as a child of the `WarehouseStockLevelsVO` collection.

**Tip:** By default, when you define a view link using the Create View Link wizard, the source view object is the master and the destination view object is the detail. However, if you choose to generate accessors in both the source and the destination view objects, then the master-detail relationship is bidirectional. If both sets of master-detail view objects resulting from a bidirectional view link are added to the application module data model, then instances of both sets of view objects will appear independently on the Data Controls panel.

For more information about the icons displayed on the Data Controls panel, see ["Section 12.3.1, "How to Use the Data Controls Panel."](#)

## 24.3 Using Tables and Forms to Display Master-Detail Objects

You can create a master-detail browse page in a single declarative action using the Data Controls panel. All you have to do is drop the detail collection on the page and choose the type of widget you want to use.

The prebuilt master-detail widgets available from the Data Controls panel include range navigation that enables the end user to scroll through the data objects in collections. You can delete unwanted attributes by removing the text field or column from the page.

[Figure 24-5](#) shows an example of prebuilt master-detail widget, which displays products information in a form at the top of the page and stock levels in a table at the bottom of the page. When the user clicks the **Next** button to scroll through the records in the master data at the top of the page, the page automatically displays the related detail data.

**Figure 24–5 Prebuilt Data Controls Panel Master-Detail Widget**

### 24.3.1 How to Display Master-Detail Objects in Tables and Forms

If you do not want to use the prebuilt master-detail widgets, you can drag and drop the master and detail objects individually from the Data Controls panel as tables and forms on a single page or on separate pages.

The Data Controls panel enables you to create both the master and detail widgets on one page with a single declarative action using prebuilt master-detail forms and tables. For information about displaying master and detail data on separate pages, see [Section 24.3.4, "What You May Need to Know About Displaying Master-Detail Widgets on Separate Pages."](#)

#### To create a master-detail page using the prebuilt ADF master-detail forms and tables:

1. From the Data Controls panel, locate the detail object, as described in [Section 24.2, "Identifying Master-Detail Objects on the Data Controls Panel."](#)
2. Drag and drop the detail object onto the JSF page.

---

**Note:** If you want to create an editable master-detail form, drop the master object and the detail object separately on the page.

---

3. In the context menu, choose one of the following **master-detailsUI** components:
  - **ADF Master Table, Detail Form:** Displays the master objects in a table and the detail objects in a read-only form under the table.

When a specific data object is selected in the master table, the first related detail data object is displayed in the form below it. The user must use the form navigation to scroll through each subsequent detail data object.

- **ADF Master Form, Detail Table:** Displays the master objects in a read-only form and the detail objects in a read-only table under the form.

When a specific master data object is displayed in the form, the related detail data objects are displayed in a table below it.

- **ADF Master Form, Detail Form:** Displays the master and detail objects in separate forms.

When a specific master data object is displayed in the top form, the first related detail data object is displayed in the form below it. The user must use the form navigation to scroll through each subsequent detail data object.

- **ADF Master Table, Detail Table:** Displays the master and detail objects in separate tables.

When a specific master data object is selected in the top table, the first set of related detail data objects is displayed in the table below it.

If you want to modify the default forms or tables, see [Section 22.3, "Creating a Basic Form"](#) or [Section 23.2, "Creating a Basic Table."](#)

## 24.3.2 What Happens When You Create Master-Detail Tables and Forms

When you drag and drop a collection from the Data Controls panel, JDeveloper does many things for you, including adding code to the JSF page and the corresponding entries in the page definition file. For a full description of what happens and what is created when you use the Data Controls panel, see [Section 12.3.1, "How to Use the Data Controls Panel."](#)

### 24.3.2.1 Code Generated in the JSF Page

The JSF code generated for a prebuilt master-detail widget is similar to the JSF code generated when you use the Data Controls panel to create a read-only form or table. If you are building your own master-detail widgets, you might want to consider including similar components that are automatically included in the prebuilt master-detail tables and forms.

The tables and forms in the prebuilt master-detail widgets include a `panelHeader` tag that contains the fully qualified name of the data object populating the form or table. You can change this label as needed using a string or an EL expression that binds to a resource bundle.

If there is more than one data object in a collection, a form in a prebuilt master-detail widget includes four `commandButton` tags for range navigation: `First`, `Previous`, `Next`, and `Last`. These range navigation buttons enable the user to scroll through the data objects in the collection. The `actionListener` attribute of each button is bound to a data control operation, which performs the navigation. The `execute` property used in the `actionListener` binding, invokes the operation when the button is clicked. (If the form displays a single data object, JDeveloper automatically omits the range navigation components.) For more information about range navigation, see [Section 22.4, "Incorporating Range Navigation into Forms."](#)

**Tip:** If you drop an **ADF Master Table, Detail Form** or **ADF Master Table, Detail Table** widget on the page, the parent tag of the detail component (for example, `panelHeader` tag or `table` tag) automatically has the `partialTriggers` attribute set to the `id` of the master component (see [Section 23.4.1, "How to Create an Input Table"](#) for more information about partial triggers). At runtime, the `partialTriggers` attribute causes only the detail component to be rerendered when the user makes a selection in the master component, which is called *partial rendering*. When the master component is a table, ADF uses partial rendering, because the table does not need to be rerendered when the user simply makes a selection in the facet. Only the detail component needs to be rerendered to display the new data.

### 24.3.2.2 Binding Objects Defined in the Page Definition File

[Example 24–1](#) shows the page definition file created for a master-detail page that was created by dropping the `WarehouseStockLevels` collection, which is a detail object under the `Products` object, on the page as an **ADF Master Form, Detail Table**.

The `executables` element defines two iterators: one for the product (the master object) and one for the `WarehouseStockLevels` (the detail object). The underlying view link from the master view object to the detail view object establishes the relationship between the two iterators. At runtime, the UI-aware data model and the row set iterator for the detail view object instance keep the row set of the detail view object refreshed to the correct set of rows for the current master row as that current row changes (for more information, see [Section 24.3.3, "What Happens at Runtime: ADF Iterator for Master-Detail Tables and Forms"](#)).

The `bindings` element defines the value bindings for the form and the table. The attribute bindings that populate the text fields in the form are defined in the `attributeValues` elements. The `id` attribute of the `attributeValues` element contains the name of each data attribute, and the `IterBinding` attribute references an iterator binding to display data from the master object in the text fields.

The attribute bindings that populate the text fields in the form are defined in the `attributeValues` elements. The `id` attribute of the `attributeValues` element contains the name of each data attribute, and the `IterBinding` attribute references an iterator binding to display data from the master object in the text fields.

The range navigation buttons in the form are bound to the action bindings defined in the `action` elements. As in the attribute bindings, the `IterBinding` attribute of the action binding references the iterator binding for the master object.

The table, which displays the detail data, is bound to the table binding object defined in the `table` element. The `IterBinding` attribute references the iterator binding for the detail object.

For more information about the elements and attributes of the page definition file, see [Section A.8, "pageNamePageDef.xml."](#)

#### **Example 24–1 Binding Objects Defined in the Page Definition for a Master-Detail Page**

```
<executables>
  <iterator Binds="Products" RangeSize="25"
    DataControl="StoreServiceAMDataControl" id="ProductsIterator"/>
  <iterator Binds="WarehouseStockLevels" RangeSize="25"
    DataControl="StoreServiceAMDataControl"
    id="WarehouseStockLevelsIterator"/>
</executables>
```

```

<bindings>
  <methodAction id="findHelpTextById" RequiresUpdateModel="true"
    Action="invokeMethod" MethodName="findHelpTextById"
    IsViewObjectMethod="false"
    DataControl="LookupServiceAMDataControl"
    InstanceName="LookupServiceAMDataControl.dataProvider"
    ReturnName="LookupServiceAMDataControl.methodResults.
      findHelpTextById_LookupServiceAMDataControl_
      dataProvider_findHelpTextById_result">
    <NamedData NDName="helpId" NDType="java.lang.Long"
      NDOption="2"/>
  </methodAction>
  <tree IterBinding="ProductsIterator" id="Products">
    <nodeDefinition DefName="oracle.fodemo.storefront.store.queries.ProductsVO">
      <AttrNames>
        <Item Value="ProductId"/>
        <Item Value="SupplierId"/>
        <Item Value="CategoryId"/>
        <Item Value="ProductName"/>
        ...
        <Item Value="CostPrice"/>
        <Item Value="DragId"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
  <tree IterBinding="WarehouseStockLevelsIterator" id="WarehouseStockLevels">
    <nodeDefinition DefName="oracle.fodemo.storefront.store.
      queries.WarehouseStockLevelsVO">
      <AttrNames>
        <Item Value="ProductId"/>
        <Item Value="WarehouseId"/>
        ...
        <Item Value="ShippingClassCode"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>

```

### 24.3.3 What Happens at Runtime: ADF Iterator for Master-Detail Tables and Forms

At runtime, an ADF iterator determines which row from the master table object to display in the master-detail form. When the form first displays, the first master table object row appears highlighted in the master section of the form. Detail table rows that are associated with the master row display in the detail section of the form.

As described in [Section 24.3.2.2, "Binding Objects Defined in the Page Definition File,"](#) ADF iterators are associated with underlying `row setIterator` objects. These iterators manage which data objects, or rows, currently display on a page. At runtime, the row set iterators manage the data displayed in the master and detail components.

Both the master and detail row set iterators listen to row set navigation events, such as the user clicking the range navigation buttons, and display the appropriate row in the UI. In the case of the default master-detail components, the row set navigation events are the command buttons on a form (**First, Previous, Next, Last**).

The row set iterator for the detail collection manages the synchronization of the detail data with the master data. Because of the underlying view link from the master view

object to the detail view object, the detail row set iterator listens for row navigation events in both the master and detail collections. If a row set navigation event occurs in the master collection, the detail row set iterator automatically executes and returns the detail rows related to the current master row.

#### 24.3.4 What You May Need to Know About Displaying Master-Detail Widgets on Separate Pages

The default master-detail components display the master-detail data on a single page. However, using the master and detail objects on the Data Controls panel, you can also display the collections on separate pages, and still have the binding iterators manage the synchronization of the master and detail objects.

For example, in the Fusion Order Demo application, a product table and product details are displayed on the home page. However, the page could display the product table only. It could provide a button called **Details**. If the user clicked the **Details** button, the application would navigate to a new page that displays all the related details in a list. A button on the list's page would enable the user to return to the service request page.

To display master-detail objects on separate pages, create two pages, one for the master object and one for the detail object, using the individual tables or forms available from the Data Controls panel. Remember that the detail object iterator manages the synchronization of the master and detail data. Be sure to drag the appropriate detail object from the Data Controls panel when you create the page to display the detail data. For more information, see [Section 24.2, "Identifying Master-Detail Objects on the Data Controls Panel."](#)

To handle the page navigation, create an ADF task flow, and then add two view activities to it, one for the master page and one for the detail page. (See [Section 14.2, "Creating a Task Flow"](#) for information about associating a View activity with an existing JSF page). Add command buttons or links to each page, or use the default **Submit** button available when you create a form or table using the Data Controls panel. Each button must specify a navigation rule outcome value in the `action` attribute. In the `task-flow-definition.xml` file, add a navigation rule from the master data page to the detail data page, and another rule to return from the detail data page to the master data page. The `from-outcome` value in the navigation rules must match the outcome value specified in the action attribute of the buttons. For information about adding navigation between pages, see [Section 14.2, "Creating a Task Flow."](#)

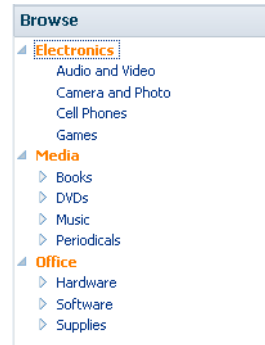

## 24.4 Using Trees to Display Master-Detail Objects

In addition to tables and forms, you can also display master-detail data in hierarchical trees. The ADF Faces `tree` component is used to display hierarchical data. It can display multiple root nodes that are populated by a binding on a master object. Each root node in the tree may have any number of branches, which are populated by bindings on detail objects. A tree can have multiple levels of nodes, each representing a detail object of the parent node. Each node in the tree is indented to show its level in the hierarchy.

The `tree` component includes mechanisms for expanding and collapsing the tree nodes; however, it does not have focusing capability. If you need to use focusing, consider using the ADF Faces `treeTable` component (for more information, see [Section 24.5, "Using Tree Tables to Display Master-Detail Objects"](#)). By default, the icon for each node in the tree is a folder; however, you can use your own icons for each level of nodes in the hierarchy.

Figure 24–6 shows an example of a tree located on the home .jspx page of the Fusion Order Demo application. The tree displays two levels of nodes: root and branch. The root node displays parent product categories such as Media, Office, and Electronics. The branch nodes display and subcategories under each parent category, such as Hardware, Supplies, and Software under the Office parent category.

**Figure 24–6 Databound ADF Faces Tree**

### 24.4.1 How to Display Master-Detail Objects in Trees

A *tree* consists of a hierarchy of nodes, where each subnode is a branch off a higher level node. Each node level in a databound ADF Faces `tree` component is populated by a different data collection. In JDeveloper, you define a databound tree using the Edit Tree Binding dialog, which enables you to define the rules for populating each node level in the tree. There must be one rule for each node level in the hierarchy. Each rule defines the following node-level properties:

- The data collection that populates that node level
- The attributes from the data collection that are displayed at that node level
- A view link accessor attribute that returns a detail object to be displayed as a branch of the current node level (for information about view link accessors, see [Section 5.6.6.2, "Programmatically Accessing a Detail Collection Using the View Link Accessor"](#))

To create the Browse tree on the Fusion Order Demo home page shown in [Figure 24–6](#), a view object, `ParentProductCategories` was created to return a list of parent categories. Another view object, `ProductCategories` was created to return subcategories of products. A view link was created from the `ParentProductCategories` view object to the `ProductCategories` view object, thus establishing a master-detail relationship.

To add a third-level node, for example, a list of products under each subcategory, a view link would need to exist from the `ProductCategories` object to the `Products` view object. For more information about creating view links, see [Section 5.6.6, "How to Access the Detail Collection Using the View Link Accessor."](#)

In the case where a branch of the tree is recursive, a single view object accompanied by a self-referential view link must be defined in the data model project. For example, in a collection defined by `EmployeesView`, the root node of each branch is specified by the `ManagerId` attribute and the child nodes of the same branch are the employees (also known as "direct reports") who are related to the `ManagerId`. The source and destination view object named by the self-referential view link are both defined as `EmployeesView` with the destination renamed to `DirectReports` for clarify. For

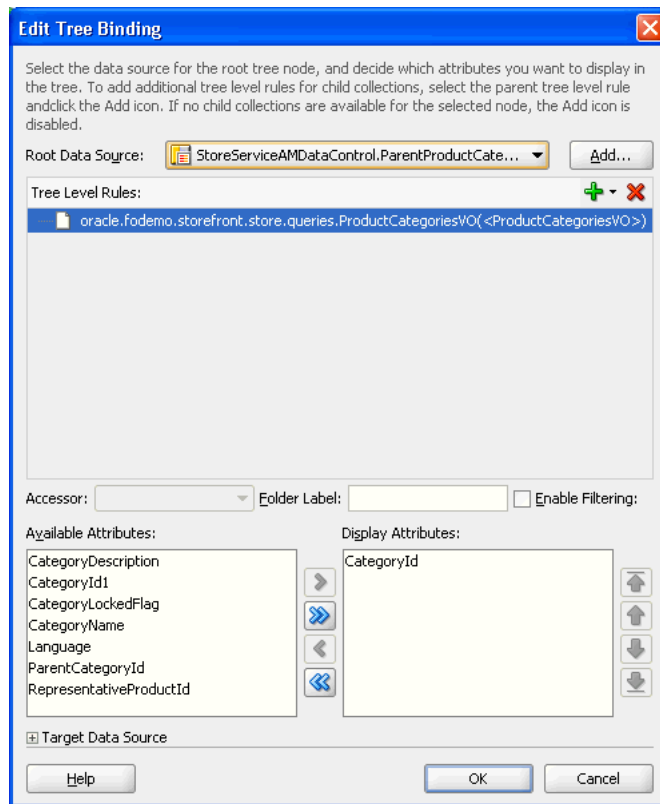

more information about creating self-referential view links, see [Section 5.7.1, "How to Create a Recursive Master-Detail Hierarchy for an Entity-Based View Object."](#)

**To display master-detail objects in a tree:**

1. Drag the master object from the Data Controls panel, and drop it onto the page. This should be the master data that will represent the root level of the tree.
2. In the context menu, choose **Trees > ADF Tree**.

JDeveloper displays the Edit Tree Binding dialog, as shown in [Figure 24-7](#). You use the binding editor to define a rule for each level that you want to appear in the tree.

**Figure 24-7** Edit Tree Binding Dialog

3. In the **Root Data Source** dropdown list, select the data collection that will populate the root node level. This will be the master data collection. By default, this is the same collection that you dragged from the Data Controls panel to create the tree, which was a master collection.

**Tip:** If you don't see the data collection you want in the **Root Data Source** list, click the **Add** button. In the Add Data Source dialog, select a data control and an iterator name to create a new data source.

4. Click the + icon to add the root data source you selected to the **Tree Level Rules** list.
5. In the **Tree Level Rules** list, select the data source you just added.
6. In the **Accessor** dropdown list, select a view link accessor attribute.

The list displays only the accessor attributes that return the detail collections for the master collection you selected. For example, if you are defining the `ParentProductCategories` node level and you want to add a detail level that displays all subcategories under each parent category, you would select the accessor attribute that returns the `ProductCategories` collection.

If you select `<none>`, the node will not expand to display any detail collections, thus ending the branch.

View link accessor attributes, which return data collections, are generated when you create a view link. The **Accessor** field displays all accessor attributes that return detail collections for the master collection selected in the **Tree Level Rules** list. For more information about view objects, view links, and view link accessors, see [Section 5.6.6, "How to Access the Detail Collection Using the View Link Accessor."](#)

7. Select an attribute in the **Available Attributes** list and move it to the **Display Attributes** list.

The attribute will be used to display nodes at the master level. For example, for the `Parent Product Categories` level, you might select the `Categories` attribute.

When you are finished, the Tree Binding Editor should contain values similar to those in [Figure 24–7](#).

After defining a rule for the master level, you must next define a second rule for the detail level that will appear under the master level in the tree.

For example, in the sample tree shown in [Figure 24–6](#), the first rule added to the tree binding editor populates the parent category nodes (`Media`, `Office`, and `Electronics`). The detail level rule populates the product category nodes (for example, `Hardware`, `Supplies`, and `Software` under the `Media` parent category).

8. To add a second rule, click the **Add** icon above the **Tree Level Rules** list.

A detail data source should appear automatically under the master data source, as shown in [Figure 24–8](#).

**Figure 24–8 Master-Detail Tree Level Rules**

For example, if you specified `Products` as the master Root Data Source, `WarehouseStockLevels` will automatically appear underneath in the **Tree Level Rules** list, because the two data sources share a master-detail relationship.

If you are creating a tree with a recursive master-detail hierarchy, then you only need to define a rule that specifies a data source with a self accessor. A recursive tree displays root nodes based on a single collection and displays the child nodes from the attributes of a self accessor that recursively fetches data from that collection. The recursive tree differs from a typical master-detail tree because it requires only a single rule to define the branches of the tree. A recursive data source should display the data source followed by the name of the self accessor in brackets, as shown in [Figure 24–9](#).

**Figure 24–9 Recursive Tree Level Rule**

For example, in a collection defined by `EmployeesView`, the root node of each branch could be specified by the `ManagerId` for the employee and the child nodes of the same branch are the employees who are related to the `ManagerId`, as specified by the self accessor `DirectReports`.

9. Click **OK**.
10. You can add data sources to the **Tree Level Rules** list to increase the number of nodes that display in the tree. The order of the remaining data sources should follow the hierarchy of the nodes you want to display in the tree.

## 24.4.2 What Happens When You Create an ADF Databound Tree

When you drag and drop from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see [Section 12.3.1, "How to Use the Data Controls Panel."](#)

When you create a databound tree using the Data Controls panel, JDeveloper adds binding objects to the page definition file, and it also adds the tree tag to the JSF Page. The resulting UI component is fully functional and does not require any further modification.

### 24.4.2.1 Code Generated in the JSF Page

[Example 24–2](#) shows the code generated in a JSF page when you use the Data Controls panel to create a tree. This sample tree displays two levels of nodes: parent product categories and product categories. The `ParentProductCategories` collection was used to populate the root node.

#### **Example 24–2 Code Generated in the JSF Page for a Databound Tree**

```
<af:tree id="productCategoriesTree" contentDelivery="immediate"
  selectionListener="#{homePageBean.
    productCategoriesTreeSelectionListener}"
  rowSelection="single"
  value="#{bindings.ParentProductCategories.treeModel}"
  var="node" initiallyExpanded="true">
  <f:facet name="nodeStamp">
    <af:panelGroupLayout>
      <af:outputText rendered="#{node.ParentCategoryId eq null}"
        value="#{node.CategoryName}"
        inlineStyle="color:#FF8000;font-weight:bold;" />
      <af:outputText rendered="#{node.ParentCategoryId ne null}"
        value="#{node.CategoryName}" />
    </af:panelGroupLayout>
  </f:facet>
</af:tree>
```

By default, the `af:tree` tag is created inside a form. The `value` attribute of the `tree` tag contains an EL expression that binds the `tree` component to the

ParentProductCategories tree binding object in the page definition file. The treeModel property in the binding expression refers to an ADF class that defines how the tree hierarchy is displayed, based on the underlying data model. The var attribute provides access to the current node.

In the f:facet tag, the nodeStamp facet is used to display the data for each node. Instead of having a component for each node, the tree repeatedly renders the nodeStamp facet, similar to the way rows are rendered for the ADF Faces table component.

The ADF Faces tree component uses an instance of the oracle.adf.view.faces.model.PathSet class to display expanded nodes. This instance is stored as the treeState attribute on the component. You may use this instance to programmatically control the expanded or collapsed state of an element in the hierarchy. Any element contained by the PathSet instance is deemed expanded. All other elements are collapsed.

### 24.4.2.2 Binding Objects Defined in the Page Definition File

Example 24-3 shows the binding objects defined in the page definition file for the ADF databound tree.

#### **Example 24-3 Binding Objects Defined in the Page Definition File for a Databound Tree**

```
<executables>
  <iterator Binds="ParentProductCategories" RangeSize="25"
    DataControl="StoreServiceAMDataControl"
    id="ParentProductCategoriesIterator"/>
</executables>
<bindings>
  <tree IterBinding="ParentProductCategoriesIterator"
    id="ParentProductCategories">
    <nodeDefinition
      DefName="oracle.fodemo.storefront.store.queries.ProductCategoriesVO">
      <AttrNames>
        <Item Value="CategoryId"/>
      </AttrNames>
      <Accessors>
        <Item Value="ProductCategoriesVO"/>
        <Item Value="ParentCategoryIdProductCategoriesVO"/>
      </Accessors>
    </nodeDefinition>
  </tree>
</bindings>
```

The page definition file contains the rule information defined in the Tree Binding Editor. In the executables element, notice that although the tree displays two levels of nodes, only one iterator binding object is needed. This iterator iterates over the master collection, which populates the root nodes of the tree. The accessor you specified in the node rules returns the detail data for each branch node.

The tree element is the value binding for all the attributes displayed in the tree. The iterBinding attribute of the tree element references the iterator binding that populates the data in the tree. The AttrNames element within the tree element defines binding objects for all the attributes in the master collection. However, the attributes that you select to appear in the tree are defined in the AttrNames elements within the nodeDefinition elements.

The `nodeDefinition` elements define the rules for populating the nodes of the tree. There is one `nodeDefinition` element for each node, and each one contains the following attributes and subelements:

- `DefName`: An attribute that contains the fully qualified name of the data collection that will be used to populate the node.
- `id`: An attribute that defines the name of the node.
- `AttrNames`: A subelement that defines the attributes that will be displayed in the node at runtime.
- `Accessors`: A subelement that defines the accessor attribute that returns the next branch of the tree.

The order of the `nodeDefinition` elements within the page definition file defines the order or level of the nodes in the tree, where the first `nodeDefinition` element defines the root node. Each subsequent `nodeDefinition` element defines a sub-node of the one before it.

For more information about the elements and attributes of the page definition file, see [Appendix A.8, "pageNamePageDef.xml."](#)

### 24.4.3 What Happens at Runtime: Displaying an ADF Databound Tree

Tree components use `org.apache.myfaces.trinidad.model.TreeModel` to access data. This class extends `CollectionModel`, which is used by the ADF Faces table component to access data. For more information about the `TreeModel` class, refer to the ADF Faces Javadoc.

When a page with a `tree` is displayed, the iterator binding on the tree populates the root nodes. When a user collapses or expands a node to display or hide its branches, a `DisclosureEvent` event is sent. The `isExpanded` method on this event determines whether the user is expanding or collapsing the node. The `DisclosureEvent` event has an associated listener.

The `DisclosureListener` attribute on the `tree` is bound to the accessor attribute specified in the node rule defined in the page definition file. This accessor attribute is invoked in response to the `DisclosureEvent` event; in other words, whenever a user expands the node the accessor attribute populates the branch nodes.

## 24.5 Using Tree Tables to Display Master-Detail Objects

Use the ADF Faces `treeTable` component to display a hierarchy of master-detail collections in a table. The advantage of using a `treeTable` component rather than a `tree` component is that the `treeTable` component provides a mechanism that enables users to focus the view on a particular node in the tree.

For example, you can create a tree table that displays three levels of nodes: countries, states or provinces, and cities. Each root node represents an individual country. The branches off the root nodes display the state or provinces in the country. Each state or province node branches to display the cities contained in it.

As with trees, to create a tree table with multiple nodes, it is necessary to create view links between the view objects. The view links establish the master-detail relationships. For example, to create a tree table with three levels of country, state, and city, it was necessary to create view links from the `CountryCodes` object to the `StatesandProvinces` view object, and another view link from the `StatesandProvinces` view object to the `Cities` view object. For more information

about creating view links, see [Section 5.6, "Working with Multiple Tables in a Master-Detail Hierarchy."](#)

A databound ADF Faces `treeTable` displays one root node at a time, but provides navigation for scrolling through the different root nodes. Each root node can display any number of branch nodes. Every node is displayed in a separate row of the table, and each row provides a focusing mechanism in the leftmost column.

You can edit the following `treeTable` component properties in the Property Inspector:

- Range navigation: The user can click the **Previous** and **Next** navigation buttons to scroll through the root nodes.
- List navigation: The list navigation, which is located between the **Previous** and **Next** buttons, enables the user to navigate to a specific root node in the data collection using a selection list.
- Node expanding and collapsing mechanism: The user can open or close each node individually or use the **Expand All** or **Collapse All** command links. By default, the icon for opening and closing the individual nodes is an arrowhead with a plus or minus sign. You can also use a custom icon of your choosing.
- Focusing mechanism: When the user clicks on the focusing icon (which is displayed in the leftmost column) next to a node, the page is redisplayed showing only that node and its branches. A navigation link is provided to enable the user to return to the parent node.

### 24.5.1 How to Display Master-Detail Objects in Tree Tables

The steps for creating an ADF Faces databound tree table are exactly the same as those for creating an ADF Faces databound tree, except that you drop the data collection as an **ADF Tree Table** instead of an **ADF Tree**.

### 24.5.2 What Happens When You Create a Databound Tree Table

When you drag and drop from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see [Section 12.3.1, "How to Use the Data Controls Panel."](#)

When you create a databound tree table using the Data Controls panel, JDeveloper adds binding objects to the page definition file, and it also adds the `treeTable` tag to the JSF Page. The resulting UI component is fully functional and does not require any further modification.

#### 24.5.2.1 Code Generated in the JSF Page

[Example 24-4](#) shows the code generated in a JSF page when you use the Data Controls panel to create a tree table. This sample tree table displays two levels of nodes: products and stock levels.

By default, the `treeTable` tag is created inside a form. The `value` attribute of the tree table tag contains an EL expression that binds the tree component to the binding object that will populate it with data. The `treeModel` property refers to an ADF class that defines how the tree hierarchy is displayed, based on the underlying data model. The `var` attribute provides access to the current node.

**Example 24–4 Code Generated in the JSF Page for a Databound ADF Faces Tree Table**

```

<af:form>
  <af:treeTable value="#{bindings.Products.treeModel}" var="node"
    selectionListener="#{bindings.Products.treeModel.makeCurrent}"
    rowSelection="single">
    <f:facet name="nodeStamp">
      <af:column customizationId="column1">
        <af:outputText value="#{node}"/>
      </af:column>
    </f:facet>
    <f:facet name="pathStamp">
      <af:outputText value="#{node}"/>
    </f:facet>
  </af:treeTable>
</af:form>

```

In the facet tag, the `nodeStamp` facet is used to display the data for each node. Instead of having a component for each node, the tree repeatedly renders the `nodeStamp` facet, similar to the way rows are rendered for the ADF Faces table component. The `pathStamp` facet renders the column and the path links above the table that enable the user to return to the parent node after focusing on a detail node.

**24.5.2.2 Binding Objects Defined in the Page Definition File**

The binding objects created in the page definition file for a tree table are exactly the same as those created for a tree.

**24.5.3 What Happens at Runtime: Events**

Tree components use `oracle.adf.view.faces.model.TreeModel` to access data. This class extends `CollectionModel`, which is used by the ADF Faces table component to access data. For more information about the `TreeModel` class, refer to the ADF Faces Javadoc.

When a page with a tree table is displayed, the iterator binding on the `treeTable` component populates the root node and listens for a row navigation event (such as the user clicking the **Next** or **Previous** buttons or selecting a row from the range navigator). When the user initiates a row navigation event, the iterator displays the appropriate row.

If the user changes the view focus (by clicking on the component's focus icon), the `treeTable` component generates a focus event (`FocusEvent`). The node to which the user wants to change focus is made the current node before the event is delivered. The `treeTable` component then modifies the `focusPath` property accordingly. You can bind the `FocusListener` attribute on the tree to a method on a managed bean. This method will then be invoked in response to the focus event.

When a user collapses or expands a node, a disclosure event (`DisclosureEvent`) is sent. The `isExpanded` method on the disclosure event determines whether the user is expanding or collapsing the node. The disclosure event has an associated listener, `DisclosureListener`. The `DisclosureListener` attribute on the tree table is bound to the accessor attribute specified in the node rule defined in the page definition file. This accessor attribute is invoked in response to a disclosure event (for example, the user expands a node) and returns the collection that populates that node.

The `treeTable` component includes **Expand All** and **Collapse All** links. When a user clicks one of these links, the `treeTable` sends a `DisclosureAllEvent` event. The `isExpandAll` method on this event determines whether the user is expanding or

collapsing all the nodes. The table then expands or collapses the nodes that are children of the root node currently in focus. In large trees, the expand all command will not expand nodes beyond the immediate children. The ADF Faces `treeTable` component uses an instance of the `oracle.adf.view.faces.model.PathSet` class to determine expanded nodes. This instance is stored as the `treeState` attribute on the component. You can use this instance to programmatically control the expanded or collapsed state of a node in the hierarchy. Any node contained by the `PathSet` instance is deemed expanded. All other nodes are collapsed. This class also supports operations like `addAll()` and `removeAll()`.

For more information about the ADF Faces `treeTable` component, refer to the `oracle.adf.view.faces.component.core.data.CoreTreeTable` class in the ADF Faces Javadoc.

#### 24.5.4 Using the `TargetIterator` Property

You can expand a node binding in the page definition editor to view the page's `nodeDefinition` elements. These are the same tree binding rules that you can configure in the tree binding dialog.

For each node definition (rule), you can specify an optional `TargetIterator` property. Its value is an EL expression that is evaluated at runtime when the user selects a row in the tree. The EL expression evaluates an iterator binding in the current binding container. The iterator binding's view row key attributes match (in order, number, and data type) the view row key of the iterator from which the `nodeDefinition` type's rows are retrieved for the tree.

At runtime, when the tree control receives a `selectionChanged` event, it passes in the list of keys for each level of the tree. These keys uniquely identify the selected node.

The tree binding starts at the top of the tree. For each tree level whose key is present in the `Currently Selected Tree Node Keys` list, if there is a `TargetIterator` property configured for that `nodeDefinition`, the tree binding performs a `setCurrentRowWithKey()` operation on the selected target iterator. It uses the key from the appropriate level of the `Currently Selected Tree Node Keys` list.

For example, you may have created `DeptEO` and `EmpEO` entity objects, and created view links based on these entity objects. The view link accessor in the `DeptVO` object that returns the linked collection of employees in that department is named `EmployeesInDepartment`. The application module will have a `DepartmentsTree` view object instance of type `DeptVO`. It will also have an `EditDepartment` view object instance of type `DeptVO`, and a view link for the `EditEmployees` view object instance of type `EmpVO`.

##### To use the property:

1. Drag the **DepartmentsTree** data collection from the Data Controls panel onto the page and choose **Create > Trees > ADF Tree**.
2. Configure tree binding rules to navigate the `EmployeesInDepartment` view link accessor attribute.

This will access the children employee rows of the current department row.

3. Drag the **EditEmployees** detail view object instance to the page, and choose **Create > Master-Detail > ADF Master Form, Detail Form**.

This creates a form to edit a department and a form to edit an employee in that department.

4. For the `DeptVO` node definition of the tree binding, configure the `TargetIterator` property to be `#{bindings.EditDepartmentIterator}`.
5. For the `EmpVO` node definition of the tree binding, configure the `TargetIterator` property to be `#{bindings.EditEmployeesIterator}`.

When you run the master-detail form, clicking on an employee in any department in the tree will first set the current department row in the target iterator for the department of that selected employee. Then it will set the current employee row in the target iterator for the selected employee.

## 24.6 Using List Views to Display Master-Detail Objects

Use the ADF Faces `listView` component to display a hierarchy of master-detail collections in a simple tree table. The attributes of each object are displayed in a group or grid within a single row and single column.

For example, as shown in [Figure 24–10](#), you can create a `listView` that displays orders and groups them by customer.

**Figure 24–10** Master-Detail with the a `listView` Component

<b>Nexus</b>
<b>Bluetooth Adaptor</b> AVAILABLE
<b>20-Inch iMac</b> AVAILABLE
<b>Oracle Database EE (Processor Perpetual)</b> AVAILABLE
<b>Multi-purpose Scissors</b> AVAILABLE
<b>Sky King:Vol 1 TV Series (1958)</b> AVAILABLE
<b>Gifts-N-More</b>
<b>Treo 650 Phone/PDA</b> AVAILABLE
<b>15-Inch MacBook Pro</b> AVAILABLE
<b>Oracle Application Server (Processor Perpetual)</b> AVAILABLE
<b>Colt .45 / Tall Man Riding / Fort Worth (1950)</b> AVAILABLE
<b>Emporium</b>
<b>17-Inch iMac</b> AVAILABLE

For more information on using databound list views, see [Section 23.5, "Creating a List View of a Collection."](#)

## 24.6.1 How to Display Master-Detail Objects in List Views

You use the Create List View wizard to create your list. This wizard allows you to choose between a `panelGroupLayout` or a `panelGridLayout` component to arrange the components for your list item.

### To create a list view:

1. In the Data Controls panel, locate the detail object, as described in [Section 24.2, "Identifying Master-Detail Objects on the Data Controls Panel."](#)
2. Drag the detail object onto the page and choose **Table/List View > ADF List View**.
3. On the first page of the create List View wizard, select a layout component and select **Include header using parent collection**.
4. If you have selected the **Panel Grid Layout** option on the first page the wizard, use the next two pages of the wizard to organize the size and arrangement of the grid cells.

For more information about using these wizard pages, press the F1 key or click **Help**.

5. On the List Item Data page, determine which fields to display for the detail data by setting the bindings and set the corresponding components to use for each.
6. In the same page, click the **Group Header Data** tab, and set the bindings and components for the master data.
7. Click **Finish**.
8. Use the Property Inspector to further configure the layout components.

For complete information about the `listView` and `listItem` components, see the "Displaying a Collection in a List" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. For complete information about using the `panelGridLayout` component to group items in grid within the list, see the "Arranging Content in a Grid" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. You can also use a `panelGroupLayout` component to group components when you don't need a grid layout. For more information, see the "Grouping Related Items" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

## 24.6.2 What Happens When You Create a Master-Detail List View

When you use the wizard to create a `listView` component with group headers, JDeveloper creates and configures the `listView`, `listItem`, and layout components. The `listView` contains a `listItem` for the detail items and a `facet` for the group header stamp, which in turn contains a `listItem` for the master items.

The bindings are the same as for a table—the `listView` component is bound to the parent of the collection dropped from the Data Controls panel. The value of the `var` attribute on this component is used by the `outputFormatted` components to access the data, in the same way as a table. For more information about the page definition code and the JSP code for collections, see [Section 23.2.2, "What Happens When You Create a Table."](#)

[Example 24–5](#) shows the page code for the simple table shown in [Figure 24–10](#).

**Example 24–5 Page Code for a List View with Group Headers**

```

<f:view>
  <af:document id="d1">
    <af:messages id="m1"/>
    <af:form id="f1">
      <af:listView value="#{bindings.SuppliersView1.treeModel}" var="item"
        emptyText="#{bindings.SuppliersView1.viewable ? 'No data
          to display.' : 'Access Denied.'}"
        fetchSize="#{bindings.SuppliersView1.rangeSize}" id="lv1">
        <af:listItem id="li2">
          <af:panelGroupLayout id="pgl2">
            <af:outputFormatted
              value="<b>#{item.bindings.ProductName.inputValue}</b>"
              id="of2"/>
            <af:outputFormatted value="#{item.bindings.ProductStatus.inputValue}"
              id="of1"/>
          </af:panelGroupLayout>
        </af:listItem>
        <f:facet name="groupHeaderStamp">
          <af:listItem id="li1">
            <af:panelGroupLayout id="pgl1">
              <af:outputFormatted
                value="<b>#{item.bindings.SupplierName.inputValue}</b>"
                id="of3"/
                inlineStyle="font-size:medium; color:Black;"/>
            </af:panelGroupLayout>
          </af:listItem>
        </f:facet>
      </af:listView>
    </af:form>
  </af:document>
</f:view>

```

## 24.7 Using Selection Events with Trees and Tables

There may be cases when you need to determine which node in a tree or tree table has been selected in order to handle some processing in your application. For example, on the home page of the StoreFront module, when a user selects a category node in the **Browse** tree, a selection event is fired. The listener associated with this event needs to determine the product category of the node selected, and then to return all products whose category attribute matches that value.

### 24.7.1 How to Use Selection Events with Trees and Tables

To programmatically use selection events, you need to create a listener in a managed bean that will handle the selection event and perform the needed logic. You then need to bind the `selectionListener` attribute of the tree or table to that listener.

**To use selection events with trees and tables:**

1. If one does not already exist, create a managed bean to contain the needed listener. For more information about creating and using managed beans, see [Section 20.4, "Using a Managed Bean in a Fusion Web Application."](#)
2. Create a listener method on the managed bean. For more information about creating listener methods, see the "Using ADF Faces Server Events" section of the

*Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework.* Your listener should do the following:

- a. Access the component using the event source. [Example 24–6](#) shows how the `productCategoriesTreeSelectionListener` method on the `HomeBean` managed bean accesses the tree that launched the selection event.

**Example 24–6 Getting the Source of an Event**

```
public void productCategoriesTreeSelectionListener(SelectionEvent evt) {
    RichTree tree = (RichTree)evt.getSource();
```

For more information about finding the event source component, see the "How to Return the Original Source of the Event" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

- b. Access the tree model to get the value of the model, use the `RowKeySet` object to get the currently selected node, and then set that as the current row on the model, as shown in [Example 24–7](#). For more information about `RowKeySet` objects, see [Section 24.7.2, "What Happens at Runtime: RowKeySet Objects and SelectionEvent Events."](#)

**Example 24–7 Setting the Current Row on a Tree Model**

```
TreeModel model = (TreeModel)tree.getValue();
RowKeySet rowKeySet = evt.getAddedSet();
Object key = rowKeySet.iterator().next();
model.setRowKey(key);
```

- c. You can now add logic to execute against the currently selected row. For example, the `productCategoriesTreeSelectionListener` method uses the value binding of the selected row to determine the category ID, and then uses that value as the parameter for another method that when executed, returns all products with that category ID, as shown in [Example 24–8](#).

**Example 24–8 Returning Objects that Match a Given Attribute Value**

```
JUCtrlValueBinding nodeBinding =
    (JUCtrlValueBinding)model.getRowData();
Number catId = (Number)nodeBinding.getAttribute("CategoryId");
_selectedCategory = (String)nodeBinding.getAttribute("CategoryName");

OperationBinding ob =
    ADFUtils.findOperation("ProductsByCategoriesExecuteWithParams");
ob.getParamsMap().put("category", catId);
ob.execute();
```

3. On the associated JSF page, select the tree or table component. In the Property Inspector, expand the **Behavior** section and set the value of the `SelectionListener` attribute to the listener method just created. You can use the **Edit** option from the dropdown method to declaratively select the bean and the method.

---

**Note:** `CollectionModel` (and thus also `TreeModel`) supports a version of the `getRowData` method that takes a row key parameter and thus allows you to get row data without changing currency. This is particularly useful when your view object uses range paging.

In the above example, you can thus replace this code:

```
model.setRowKey(key);
JUCtrlValueBinding nodeBinding =
    (JUCtrlValueBinding)model.getRowData();
```

with this code:

```
JUCtrlValueBinding nodeBinding =
    (JUCtrlValueBinding)model.getRowData(key);
```

---

## 24.7.2 What Happens at Runtime: RowKeySet Objects and SelectionEvent Events

Whenever a user selects a node in a tree (or a row in a table), the component triggers selection events. A `selectionEvent` event reports which rows were just deselected and which rows were just selected. The current selection, that is, the selected row or rows, is managed by the `RowKeySet` object, which keeps track of all currently selected nodes by adding and deleting the associated key for the row into or out of the key set. When a user selects a new node, and the tree or table is configured for single selection, then the previously selected key is discarded and the newly selected key is added. If the tree or table is configured for multiple selection, then the newly selected keys are added to the set, and the previously selected keys may or may not be discarded, based on how the nodes were selected. For example, if the user pressed the `CTRL` key, then the newly selected nodes would be added to the current set.

---

# Creating Databound Selection Lists and Shuttles

This chapter describes how to add databound selection lists and shuttle components to pages using ADF data binding. It describes how to create the List of Value (LOV) components that utilize a query to populate the selection list. It includes instructions for creating standard selection components that use a model-driven, fixed-value, or dynamically generated list. It describes how to add navigation list bindings to let users navigate through a list of objects in a collection. It also describes how to use the shuttle component to allow the user to quickly move items between two lists.

This chapter includes the following sections:

- [Section 25.1, "Introduction to Selection Lists and Shuttles"](#)
- [Section 25.2, "Creating List of Values \(LOV\)"](#)
- [Section 25.3, "Creating a Selection List"](#)
- [Section 25.4, "Creating a List with Navigation List Binding"](#)
- [Section 25.5, "Creating a Databound Shuttle"](#)

## 25.1 Introduction to Selection Lists and Shuttles

Selection lists and shuttles work the same way as do standard JSF list components. ADF Faces list components, however, provide extra functionality such as support for label and message display, automatic form submission, and partial page rendering.

List of values (LOV) are UI components that allow the user to enter values by picking from a list that is generated by a query. The LOV displays inside a modal popup dialog that typically includes search capabilities. The `af:inputListOfValues` and `af:inputComboboxListOfValues` components, for example, offer additional features that are not available in selection lists, such as search fields inside the LOV modal dialog and queries based on multiple table columns. For more information, see [Section G.2.6, "How to Create a Popup List of Values"](#) and the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

When the user selects an item from a navigation list, a corresponding component bound to the list also changes its value in response to the selection. For example, when the user selects a product from a shopping list, the table that is bound to the products list updates to display the details of the selected product.

A shuttle allows the user to easily see the available items on an available list and the selected items in the selected list and to quickly move those items back and forth between the lists.

## 25.2 Creating List of Values (LOV)

List of values (LOV) components are input components that allow the user to enter values by picking from a list that is generated by a query. ADF Faces provides the `af:inputListOfValues` and `af:inputComboboxListOfValues` components.

If you are using dependent LOVs as part of your search form, you must use them with the `af:query` component. For more information about using LOV components with search forms, see [Section 27.1.6, "List of Values \(LOV\) Input Fields."](#)

The `af:inputListOfValues` component has a search icon next to the search criteria field, as shown in [Figure 25–1](#).

**Figure 25–1 Search Criteria Input Field Defined as an `inputListOfValues`**

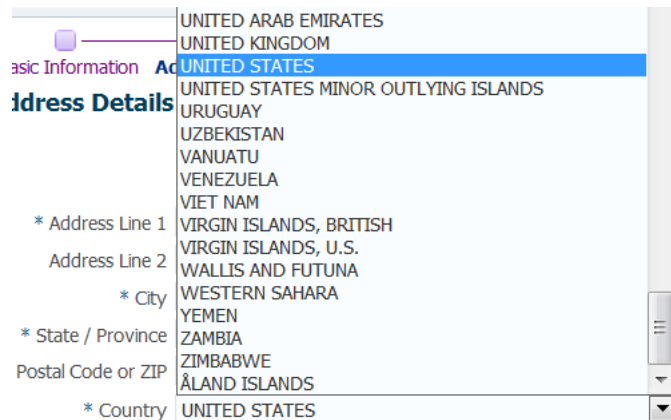

The `af:inputComboboxListOfValues` component has a dropdown icon next to the field, as shown in [Figure 25–2](#) for the `PaymentOptionId` attribute.

**Figure 25–2 Search Criteria Input Field Defined as an `inputComboboxListOfValues`**

For `af:inputComboboxListOfValues`, clicking the dropdown icon displays the LOV dropdown list and either a **More** or a **Search** command link, as shown in [Figure 25–3](#). A **Search** link appears when the LOV Search and Select popup dialog contains a search panel to refine the search. A **More** link appears when the popup dialog contains only the list-of-values table.

**Figure 25–3 LOV Dropdown List with Search Link for `inputComboboxListOfValues`**

The user can select any of the items in the dropdown list to populate the input field. The dropdown list includes a filtered list of values and an optional list of most recently used items. The width of each attribute in the dropdown list can be configured using the `DisplayWidth` UI hint for that attribute in the view object definition. The width of the dropdown list will be the sum of the widths of all the attributes in the dropdown list.

You can create custom content to be rendered in the Search and Select dialog using the `searchContent` facet. You will need to define the `returnPopupDataValue` attribute and implement a `returnPopupListener`. For more information about

adding custom content, see the "Using List-of-Values Components" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

If the component's `readOnly` attribute is set to `true`, then the input field is disabled and the value cannot be changed. By default, the `readOnly` attribute is set to `false`, which also enables the `editMode` attribute to determine whether the user is permitted only to select a value from the list (`editMode` set to `select`) or whether the user can also enter a value into the input field (`editMode` set to `input`).

When the user clicks the **Search** or **More** link (or for `af:inputListOfValues`, the search icon), the LOV Search and Select dialog displays with the full list of values in a table format. The LOV Search and Select dialog is shown in [Figure 25-4](#).

**Figure 25-4 LOV Search and Select Dialog**

EMPNO	ENAME	JOB	DEPTNO
99	Goodon99	Analyst	60
918	Goodon918	Analyst	60
957	Goodon957	Analyst	60
996	Goodon996	Analyst	60

The Search and Select popup dialog also presents a create function that allows the user to add a new row. Be aware that if you are creating a new record using the LOV Search and Select dialog, the new row will appear as an empty row in the table if the LOV has the **Query Automatically** control hint set to `false`. The content of the row will appear when you perform a query using the **Search** button.

If the LOV is part of a task flow that is using an isolated data control, and you use the create function to add a new record, the newly added record will not be displayed in the parent page. This is because the search region is also using isolated data control scope, so the underlying view object updates are not displayed.

To programmatically refresh the LOV and to display the view object updates, add a `returnListener` to the **Create** link with code similar to that shown in [Example 25-1](#).

**Example 25-1 Code to Refresh the LOV**

```
public void refreshLOV() {
    BindingContainer bindings = this.getBindings();
    oracle.jbo.uicli.binding.JUCtrlListBinding lovBinding =
        (oracle.jbo.uicli.binding.JUCtrlListBinding)
        bindings.get("Description1");
    JUIteratorBinding lovIter = lovBinding.getIteratorBinding();
    RowSet rs = lovIter.getRowSetIterator().getRowSet();
    rs.executeQuery();

    //Add LOV as the partialTrigger
```

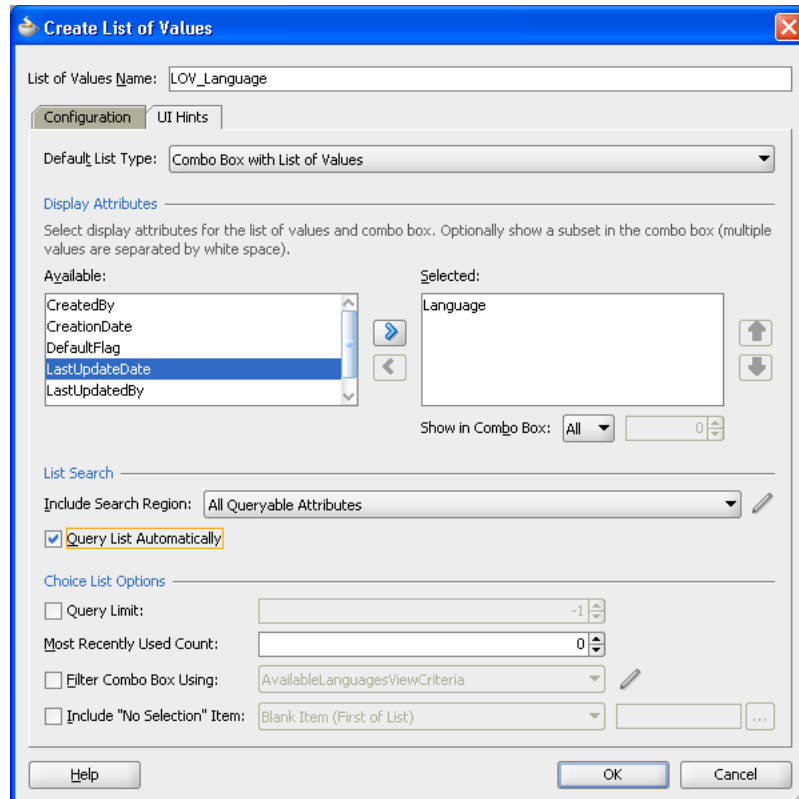

```
AdfFacesContext.getCurrentInstance().addPartialTarget(this.getPlatformDesc());
```

An LOV is associated with a data source via the view accessor. You can apply one or more view criteria to the view accessor associated with the LOV. The view accessor provides permanent filtering to the LOV data source. In addition to this permanent filtering, you may be able to apply other filters.

The LOV dialog may include a query panel to allow the user to enter criteria to search for the list of values, or it may contain only a table of results. When you define the LOV in the view object, you can use the UI hints to specify whether a search region should be displayed, which view criteria should be used as the search to populate the list of values, and which LOV component to use. [Figure 25–5](#) shows the Create List of Values dialog and some of its options. In this example, the search region will be made available with the `AvailableLanguages1ViewCriteria` view criteria used for the query, and `af:inputComboboxListOfValues` as the component. Another useful option for the `af:inputComboboxListOfValues` is the **Show in Combo Box** option, which allows you to select the number of attributes to display in the dropdown list and in the Search and Select dialog. For more information on LOV UI hints, see [Section 5.13.4, "How to Set User Interface Hints on a View Object LOV-Enabled Attribute."](#)

For both `af:inputListOfValues` and `af:inputComboboxListOfValues`, if the user enters a partial match in the input search field and presses the Tab or Enter key, the LOV automatically launches the LOV Search and Select dialog and executes the query after applying an auto-generated view criteria with a single item representing the partial match value entered by the user. If there are matches, the Search and Select dialog displays all the entries matching the partially entered criteria. If there are no entries that match the entered partial match, then the dialog displays all the entries.

Figure 25–5 List of Values Dialog UI Hints Tab

Instead of showing the base attribute as the input field, you can specify a display attribute to be shown in its place. For instance, it may be easier for users to see department name displayed rather than the department number even though the LOV was defined on the department number attribute. You enable this function by defining a custom property for the base attribute with a name/value pair of **displayMode/displayAttribute**, then the first attribute in the display attribute list defined for the LOV will be used for display. Be sure that any converter that is attached to the component is of the proper type. For instance, if the base attribute is a NUMBER datatype, it will have an `af:convertNumber` attached, but if the display attribute is a String datatype, then you need to remove the `af:convertNumber`.

You can also set up the LOV component to display a list of selectable suggested items when the user types in a partial value. For example, when the user types in `Ca`, then a suggested list which partially matches `Ca` is displayed as a suggested items list. The user can select an item from the list to be entered into the input field. You add this *auto suggest behavior* feature by including an `af:autoSuggestBehavior` tag from the Component Palette into the LOV and set the `selectedItem` attribute to the `suggestedItems` method implemented in ADF Model.

If the LOV is an `af:inputComboboxListOfValues`, you can apply an additional view criteria to further filter the values in the dropdown list to create a *smart list*. If the **Filter Combo Box Using** UI hint is not applied, the dropdown list is filtered by the view criteria applied to the view accessor. Note that this smart list filter applies only to the dropdown list. The full list is still used for validation and for searching from the LOV Search and Select popup dialog.

If both the auto suggest behavior and smart list filter are enabled for an LOV, auto suggest will search from the smart list first. If the user waits for two seconds without a gesture, then auto suggest will also search from the full list and append the results.

You can also specify the number of suggested items returned by setting the `maxSuggestedItems` attribute (-1 indicates a complete list). If `maxSuggestedItems > 0`, a **More** link is rendered for the user to click on to launch the LOV's Search and Select dialog. [Example 25–2](#) shows the code from an LOV with both auto suggest behavior and smart list.

**Example 25–2 Auto Suggest Behavior and Smart List**

```
af:autoSuggestBehavior
  suggestItems="#{bindings.CountryName.suggestItems}"
  smartList="#{bindings.CountryName.smartList}"
  maxSuggestedItems="5"
/>
```

You can define an attribute in the view object to be one or more LOVs. If multiple LOVs are defined on an attribute, each LOV has its own name, view accessor, data mappings, validator, and UI hints (except for the **Default List Type** hint, which is defined once for the attribute). To switch between which LOV will be used at runtime, an LOV switcher is used with the multiple LOVs. The LOV switcher can be based on an existing attribute of type `String`, or created as a new `String` attribute solely for switching between LOVs. The LOV switcher returns the name of the LOV to use at runtime. For instance, you can create three LOVs for the price attribute, and designate the `CountryCode` attribute as the LOV switcher. At runtime, the value of `CountryCode` will switch the price attribute to use the LOV that reflects the country's price and currency.

If an attribute is defined as an LOV, you can set the **Support Multiple Value Selection** control hint in its view criteria to enable users to make multiple selections in the search criteria field. If multiple selection is enabled on an LOV attribute, and the `Equal to` or `Not equal to` operator is chosen, a `selectManyChoice` component will render in the query panel. The user can select multiple items as the search criteria.

If the value of an LOV depends on the value of another LOV, then the two LOVs are called *cascading* LOVs. For instance, the list of values for the City LOV depends on the value of the Country LOV that was selected. If the LOV is defined as a named bind variable, or if validation is enabled, the LOV query may behave differently depending on such conditions as whether null values for the named bind variable are acceptable. If the bind variable is null, you may want the LOV query to return an empty list. The view criteria's **Ignore Null Values** and **Validation** options can be used to define LOV query behavior.

If the view object has an LOV with a bind variable, you should set that view object bind variable's control hint to **Hide**. Otherwise, the bind variable will be displayed in the LOV Search and Select popup dialog. In the view object overview editor's **Query** tab, double-click the bind variable, click the **Control Hints** tab and select **Hide** from the **Display Hint** dropdown list.

---

**Note:** List of values are designed to return valid values only. As a result, validation rules defined on data source view object attributes will be suppressed. You should ensure that the list of values returned only contains valid values. For more information, see [Section 7.3.5, "What You May Need to Know About List of Values and Attribute Validation Rules."](#)

---

**Best Practice:** An attribute that has been enabled as an LOV should not be used as search criteria in a manually created search form using the "Find Mode" iterator. Creating a search form in this way could result in SQL exception: `java.sql.SQLException: Attempt to set a parameter name that does not occur in the SQL.` It is best practice to use the query and quick query components for creating search forms. For more information, see [Chapter 27, "Creating ADF Databound Search Forms."](#)

For more information about different usage scenarios and other view criteria options, see [Section 5.11.1, "How to Create Named View Criteria Declaratively,"](#) and [Section 5.11.3, "What You May Need to Know About Bind Variable Options."](#)

## 25.2.1 How to Create an LOV

You can create the LOV using either the `af:inputListOfValues` or the `af:inputComboboxListOfValues` component. You can add auto suggest behavior to the component to display a list of possible matches from user input.

### Before you begin:

Define the attribute to be an LOV in the view object by following the procedure described in [Section 5.13, "Working with List of Values \(LOV\) in View Object Attributes."](#)

### To create an LOV:

1. From the Data Controls panel, drag and drop the attribute onto the JSF page and choose **Create > List of Values > ADF LOV Input** or **Create > List of Values > ADF LOV Choice List**.
2. In the Operations page of the Component Palette, from the ADF Faces panel, drag and drop **Auto Suggest Behavior** as a child to the LOV component.
3. In the Property Inspector, for each of the auto suggest attributes, enter the:
  - EL expression that resolves to the `suggestItems` method.
  - EL expression that resolves to the `smartList` method.
  - number of items to be displayed in the auto suggest list. Enter -1 to display the complete list.

[Example 25-3](#) shows an `inputListOfValues` component with the auto suggest behavior and smart list features.

### Example 25-3 LOV Component with Auto Suggest Behavior

```
<af:inputListOfValues id="ProductsId"
    popupTitle="Search and Select: #{bindings.Products.hints.label}"
    value="#{bindings.Products.inputValue}"
    label="#{bindings.Products.hints.label}"
    model="#{bindings.Products.listOfValuesModel}"
    required="#{bindings.Products.hints.mandatory}"
    columns="#{bindings.Products.hints.displayWidth}"
    shortDesc="#{bindings.Products.hints.tooltip}" />
<f:validator binding="#{bindings.Products.validator}" />
<af:autoSuggestBehavior suggestItems="#{bindings.Products.suggestedItems}"
    smartList="#{bindings.Products.smartList}"
    maxSuggestedItems="5" />
</af:inputListOfValues>
```

4. If you added the auto suggest behavior, you must set the component's `autoSubmit` property to `true`.

## 25.2.2 What Happens When You Create an LOV

When you drag and drop an attribute from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see [Section 22.2.2, "What Happens When You Create a Text Field."](#)

When you drag and drop an attribute defined as an LOV from the Data Controls panel onto a JSF page as an `inputListOfValues` or `inputComboboxListOfValues` component, JDeveloper adds code to the page similar to that shown in [Example 25-4](#). The language attribute in the `CountryCodes` view object has been defined as an LOV and its default component is set to be an `inputComboboxListOfValues`. The component gets its properties from the control hints defined declaratively in the view object. If you want to include the auto suggest behavior, you must manually add that tag from the Component Palette.

### **Example 25-4** *inputComboboxListOfValues Component Code in a JSF Page*

```
<af:inputComboboxListOfValues id="languageId"
    popupTitle="Search and Select: #{bindings.Language.hints.label}"
    value="#{bindings.Language.inputValue}"
    label="#{bindings.Language.hints.label}"
    model="#{bindings.Language.listOfValuesModel}"
    required="#{bindings.Language.hints.mandatory}"
    columns="#{bindings.Language.hints.displayWidth}"
    shortDesc="#{bindings.Language.hints.tooltip}"
    readOnly="false">
    <f:validator binding="#{bindings.Language.validator}" />
</af:inputComboboxListOfValues>
```

In the page definition file, JDeveloper adds code as shown in [Example 25-5](#). The bindings section of the page definition specifies that the LOV is for the language attribute and the name of the LOV is `LOV_language`. JDeveloper adds the definitions for the iterator binding objects into the `executables` element, and the list of values binding object into the `bindings` element,

### **Example 25-5** *inputComboboxListOfValues Component Code in Page Definition*

```
<executables>
    <variableIterator id="variables" />
    <iterator Binds="CountryCodesView1" RangeSize="25"
        DataControl="AppModuleDataControl"
        id="CountryCodesView1Iterator" />
</executables>
<bindings>
    <listOfValues StaticList="false" IterBinding="CountryCodesView1Iterator"
        Uses="LOV_Language" id="Language" />
</bindings>
```

For more information about the page definition file and ADF data binding expressions, see [Section 12.6, "Working with Page Definition Files,"](#) and [Section 12.7, "Creating ADF Data Binding EL Expressions."](#)

## 25.3 Creating a Selection List

ADF Faces Core includes components for selecting a single value and multiple values from a list. Single selection lists are described in [Table 25-1](#).

**Table 25-1 ADF Faces Single and Multiple List Components**

ADF Faces component	Description	Example
SelectOneChoice	Select a single value from a list of items.	
SelectOneRadio	Select a single value from a set of radio buttons.	
SelectOneListbox	Select a single value from a scrollable list of items.	
SelectManyChoice	Select multiple values from a scrollable list of checkboxes. Each selection displays at the top of the list.	
SelectManyCheckbox	Select multiple values from a group of checkboxes.	
SelectManyListbox	Select multiple values from a scrollable list of checkboxes,	

**Table 25–1 (Cont.) ADF Faces Single and Multiple List Components**

ADF Faces component	Description	Example
SelectBooleanRadio	Select a radio button in a group of radio buttons. The buttons can be placed anywhere on the page.	Age <input checked="" type="radio"/> 10-18 Parent's Name Parent's E-Mail Parent's Phone <input type="radio"/> 19-100 Id Password
SelectBooleanCheckbox	Select a checkbox that toggles between selected and unselected states.	Non Smoking room <input type="checkbox"/> Extra Keys <input checked="" type="checkbox"/>  Extra Pillows <input checked="" type="checkbox"/>  Crib <input checked="" type="checkbox"/>

### 25.3.1 How to Create a Single Selection List

You can create selection lists using the `SelectOneChoice` ADF Faces component. The steps are similar for creating other single-value selection lists, such as `SelectOneRadio` and `SelectOneListbox`.

A databound selection list displays values from a data control collection or a static list and updates an attribute in another collection or a method parameter based on the user's selection. When adding a binding to a list, you use an attribute from the data control that will be populated by the selected value in the list.

---

**Note:** By default, ADF Model list binding passes the index to the component. If you set `valuePassThru=true`, then you should set the list binding entry in the corresponding page definition file `Mode` attribute to `Object`. When `Mode=Object`, the list binding will pass an object instead of an index to the component. For more information, see [Section 25.3.6, "What Happens When You Create a Fixed Selection List."](#)

---

To create a selection list, you choose a base data source and a list data source in the Edit List Binding dialog:

- Base data source: Select the data collection that you want to bind to your control and that contains the attributes to be updated from user selections.
- List data source: Select the data collection that contains the attributes to display.

The data collection is based on the view object. For more information about creating a view object, see [Section 5.2.1, "How to Create an Entity-Based View Object."](#)

### 25.3.2 How to Create a Model-Driven List

You can create three types of selection lists in the Edit List Binding dialog:

- **Model-driven list:** List selections are based on a list of values bound to a data collection. This type of selection list offers significant advantages over the other two, as described in [Section 25.3.2, "How to Create a Model-Driven List."](#)
- **Static list:** List selections are based on a fixed list that you create manually by entering values one at a time into the editor. For more information, see [Section 25.3.3, "How to Create a Selection List Containing Fixed Values."](#)
- **Dynamic list:** List selections are generated dynamically based on one or more databound attribute values. For more information, see [Section 25.3.4, "How to Create a Selection List Containing Dynamically Generated Values."](#)

A model-driven list is based on a list of values that is bound to a view data object. Lists of Values are typically used in forms to enable an end user to select an attribute value from a dropdown list instead of having to enter it manually. When the user submits the form with the selected values, ADF data bindings in the ADF Model layer update the value on the view object attributes corresponding to the databound fields.

---

---

**Note:** One way to create a model-driven list is to drag a collection from the Data Controls panel onto a JSF page, choose one of the ADF Forms in the popup menu, and accept the defaults. The advantage is that if there are LOVs defined on the underlying view object attributes, all the LOVs on the entire form will be configured automatically. For more information, see [Section 5.13.1, "How to Define a Single LOV-Enabled View Object Attribute."](#)

---

---

You can also use the list of values as the basis for creating a selection list. The advantages of creating a model-driven list based on a list of values are:

- **Reuse:** The list of values is bound to a view data collection. Any selection list that you create based on the data collection can use the same list of values. Because you define the LOV on the individual attributes of view objects in a data model project with ADF Business Components, you can customize the LOV usage for an attribute once and expect to see the changes anywhere that the business component is used in the user interface.
- **Translation:** Values in the list of values can be included in resource bundles used for translation.

The procedure for creating a list of values is:

1. Create a view object.
2. Create a view accessor on the object.
3. Create a list of values on an attribute of the view object.

This procedure is described in detail in [Section 5.13.1, "How to Define a Single LOV-Enabled View Object Attribute."](#)

**Before you begin:**

Create a list of values that is bound to an attribute on the base data source for the selection list. For example, you can create a list of values bound to the `CountryId` attribute of the `Addresses` view data object. For more information, see [Section 5.13.1, "How to Define a Single LOV-Enabled View Object Attribute."](#)

**To create a model-driven selection list:**

1. From the Data Controls panel, drag and drop the attribute onto the JSF page and choose **Create > Single Selections > ADF Select One Choice**.

The Edit List Binding dialog displays. The view object collection containing the attribute you dropped on the JSF page is selected by default in the **Base Data Source** list.

To select a different view data collection, click the **Add** icon next to the list.

2. Select the **Model Driven List** radio button.
3. In the **Base Data Source Attribute** list, select an attribute on which you based a list of values, for example, `CountryId`.

The list contains all the attributes for the view data collection selected in the **Base Data Source** list.

4. If a list of values was created for the attribute you selected, it will be listed in the **Server List Binding Name** list.

For example, you could select `LOV_CountryId` in the **Server List Binding Name** list because a list of values was created for the `CountryId` attribute.

5. Click **OK**.

### 25.3.3 How to Create a Selection List Containing Fixed Values

You can create a selection list containing selections that you code yourself, rather than retrieving the values from another data source. See [Section 25.3.4, "How to Create a Selection List Containing Dynamically Generated Values,"](#) for information about populating selection lists with values that are dynamically generated from another data source.

**Figure 25–6 Selection List Bound to a Fixed List of Values**

**Before you begin:**

Prepare a list of values that you will enter into the component as a fixed list.

**To create a list bound to a fixed list of values:**

1. From the Data Controls panel, drag and drop the attribute onto the JSF page and choose **Create > Single Selections > ADF Select One Choice**.

The Edit List Binding dialog displays. The view object collection containing the attribute you dropped on the JSF page is selected by default in the **Base Data Source** list.

To select a different view data collection, click the **Add** icon next to the list.

2. Select the **Fixed List** radio button.

The **Fixed List** option lets end users choose a value from a static list that you define.

3. In the **Base Data Source Attribute** list, choose an attribute.

The **Base Data Source Attribute** list contains all of the attributes in the view data collection you selected in the **Base Data Source** list. For example, if you selected `CountryCodes` as the Base Data Source, you can choose `CountryName` in the list.

4. In the **Set of Values** box, enter each value you want to appear in the list. Press the `'Enter` key to set a value before typing the next value. For example, you could add the country codes `India`, `Japan`, and `Russia`.

The order in which you enter the values is the order in which the list items are displayed in the `SelectOneRadio` control at runtime.

The `SelectOneRadio` component supports a `null` value. If the user has not selected an item, the label of the item is shown as blank, and the value of the component defaults to an empty string. Instead of using blank or an empty string, you can specify a string to represent the `null` value. By default, the new string appears at the top of the list.

5. Click **OK**.

### 25.3.4 How to Create a Selection List Containing Dynamically Generated Values

You can populate a selection list component with values dynamically at runtime.

**Tip:** Another option is to create a static view object or a database view object within a shared application module. Then use a model-driven LOV to create the list. This provides caching and translatability.

#### Before you begin:

Define two data sources: one for the list data source that provides the dynamic list of values, and the other for the base data source that is to be updated based on the user's selection.

#### To create a selection list bound containing dynamically generated values:

1. From the Data Controls panel, drag and drop the attribute onto the JSF page and choose **Create > Single Selections > ADF Select One Choice**.

The Edit List Binding dialog displays. The view object collection containing the attribute you dropped on the JSF page is selected by default in the **Base Data Source** list.

To select a different view data collection, click the **Add** icon next to the list.

2. Select the **Dynamic List** radio button.

The **Dynamic List** option lets you specify one or more base data source attributes that will be updated from another set of bound values.

3. Click the **Add** button next to **List Data Source**.
4. In the Add Data Source dialog, select the view data collection that will populate the values in the selection list.

In the Fusion Order Demo application, for example, you could select `ProductQuantities`.

---

---

**Note:** The list and base collections do not have to form a master-detail relationship, but the attribute in the list collection must have the same type as the base collection attributes.

---

---

5. Accept the default iterator name and click **OK**.

The **Data Mapping** section of the Edit List Binding dialog updates with a default data value and list attribute. The **Data Value** control contains the attribute on the data collection that is updated when the user selects an item in the selection list. The **List Attribute Control** contains the attribute that populates the values in the selection list.

6. You can accept the default mapping or select different attributes items from the **Data Value** and **List Attribute** lists to update the mapping.

To add a second mapping, click **Add**.

7. Click **OK**.

### 25.3.5 What Happens When You Create a Model-Driven Selection List

When you drag and drop an attribute from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see [Section 22.2.2, "What Happens When You Create a Text Field."](#)

[Example 25–6](#) shows the page source code after you add a model-driven `SelectOneChoice` component to it.

#### **Example 25–6 Model-Driven SelectOneChoice List in JSF Page Source Code**

```
<af:selectOneChoice value="#{bindings.CountryId1.inputValue}"
                    label="#{bindings.CountryId1.label}">
    <f:selectItems value="#{bindings.CountryId1.items}" />
</af:selectOneChoice>
```

The `f:selectItems` tag, which provides the list of items for selection, is bound to the `items` property on the `CountryId1` list binding object in the binding container. For more information about ADF data binding expressions, see [Section 12.5, "Configuring the ADF Binding Filter."](#)

In the page definition file, JDeveloper adds the list binding object definitions in the `bindings` element, as shown in [Example 25–7](#).

#### **Example 25–7 List Binding Object for the Model-Driven List in the Page Definition File**

```
<bindings>
  <list IterBinding="AddressesView1Iterator" id="CountryId"
        Uses="LOV_AddressId" StaticList="false" ListOperMode="0">
    <AttrNames>
      <Item Value="AddressId" />
    </AttrNames>
  </list>
  <list IterBinding="AddressesView1Iterator" id="CountryId1"
        Uses="LOV_CountryId" StaticList="false" ListOperMode="0">
    <AttrNames>
      <Item Value="CountryId" />
    </AttrNames>
  </list>
```

```
</bindings>
```

In the `list` element, the `id` attribute specifies the name of the list binding object. The `IterBinding` attribute references the variable iterator, whose current row is a row of attributes representing each variable in the binding container. The variable iterator exposes the variable values to the bindings in the same way as do other collections of data. The `AttrNames` element specifies the attribute value returned by the iterator.

For more information about the page definition file and ADF data binding expressions, see [Section 12.6, "Working with Page Definition Files,"](#) and [Section 12.7, "Creating ADF Data Binding EL Expressions."](#)

### 25.3.6 What Happens When You Create a Fixed Selection List

When you add a fixed selection list, JDeveloper adds source code to the JSF page and list and iterator binding objects to the page definition file.

[Example 25-8](#) shows the page source code after you add a fixed `SelectOneChoice` component to it.

#### **Example 25-8 Fixed SelectOneChoice List in JSF Page Source Code**

```
<af:selectOneChoice value="#{bindings.CountryId.inputValue}"
    label="#{bindings.CountryId.label}">
    <f:selectItems value="#{bindings.CountryId.items}" />
</af:selectOneChoice>
```

The `f:selectItems` tag, which provides the list of items for selection, is bound to the `items` property on the `CountryId` list binding object in the binding container. For more information about ADF data binding expressions, see [Section 12.7, "Creating ADF Data Binding EL Expressions."](#)

In the page definition file, JDeveloper adds the definitions for the iterator binding objects into the `executables` element, and the list binding object into the `bindings` element, as shown in [Example 25-9](#).

#### **Example 25-9 List Binding Object for the Fixed Selection List in the Page Definition File**

```
<executables>
    <iterator Binds="Addresses1" RangeSize="10"
        DataControl="StoreFrontModuleDataControl"
        id="Addresses1Iterator" />
</executables>
<bindings>
    <list IterBinding="Addresses1Iterator" id="CountryId" ListOperMode="0"
        StaticList="true">
        <AttrNames>
            <Item Value="CountryId" />
        </AttrNames>
        <ValueList>
            <Item Value="India" />
            <Item Value="Japan" />
            <Item Value="Russia" />
        </ValueList>
    </list>
</bindings>
```

For complete information about page definition files, see [Section 12.6, "Working with Page Definition Files."](#)

### 25.3.7 What You May Need to Know About Values in a Selection List

Once you have created a list binding, you may want to access a value in the list. If you attempt to get the value of the list binding directly using an EL expression, for example, `#{bindings.deptList.inputValue}`, the expression returns an index number that specifies the position of the selected item in the list, not the value of the selected item.

### 25.3.8 What Happens When You Create a Dynamic Selection List

When you add a dynamic selection list to a page, JDeveloper adds source code to the JSF page and list and iterator binding objects to the page definition file.

[Example 25–10](#) shows the page source code after you add a dynamic `SelectOneChoice` component to it.

#### **Example 25–10 Dynamic SelectOneChoice List in JSF Page Source Code**

```
<af:selectOneChoice value="#{bindings.Quantity.inputValue}"
                    label="#{bindings.Quantity.label}">
    <f:selectItems value="#{bindings.Quantity.items}" />
</af:selectOneChoice>
```

The `f:selectItems` tag, which provides the list of items for selection, is bound to the `items` property on the `Quantity` list binding object in the binding container. For more information about ADF data binding expressions, see [Section 12.7, "Creating ADF Data Binding EL Expressions."](#)

In the page definition file, JDeveloper adds the definitions for the iterator binding objects into the `executables` element, and the list binding object into the `bindings` element, as shown in [Figure 25–11](#).

#### **Example 25–11 List Binding Object for the Dynamic Selection List in the Page Definition File**

```
<executables>
  <iterator Binds="OrderItems" RangeSize="-1"
            DataControl="StoreFrontModuleDataControl1"
            id="OrderItemsIterator" />
  <iterator Binds="ProductQuantities" RangeSize="10"
            DataControl="StoreFrontModuleDataControl1"
            id="ProductQuantitiesIterator" />
</executables>
<bindings>
  <list IterBinding="AddressesView1Iterator" id="CountryId"
        Uses="LOV_AddressId" StaticList="false" ListOperMode="0">
    <AttrNames>
      <Item Value="AddressId" />
    </AttrNames>
  </list>
  <list IterBinding="ProductQuantities1Iterator" id="Quantity"
        StaticList="false" ListOperMode="0" ListIter="OrderItems1Iterator">
    <AttrNames>
      <Item Value="Quantity" />
    </AttrNames>
    <ListAttrNames>
      <Item Value="Quantity" />
    </ListAttrNames>
    <ListDisplayAttrNames>
```

```

        <Item Value="OrderId" />
    </ListDisplayAttrNames>
</list>
</bindings>

```

By default, JDeveloper sets the `RangeSize` attribute on the `iterator` element for the `OrderItems` iterator binding to a value of `-1` thus allowing the iterator to furnish the full list of valid products for selection. In the `list` element, the `id` attribute specifies the name of the list binding object. The `IterBinding` attribute references the iterator that iterates over the `ProductQuantities` collection. The `ListIter` attribute references the iterator that iterates over the `ProductList` collection. The `AttrNames` element specifies the base data source attributes returned by the base iterator. The `ListAttrNames` element defines the list data source attributes that are mapped to the base data source attributes. The `ListDisplayAttrNames` element specifies the list data source attribute that populates the values users see in the list at runtime.

For complete information about page definition files, see [Section 12.6, "Working with Page Definition Files."](#)

## 25.4 Creating a List with Navigation List Binding

Navigation list binding lets users navigate through the objects in a collection. As the user changes the current object selection using the navigation list component, any other component that is also bound to the same collection through its attributes will display from the newly selected object. In addition, if the collection whose current row you change is the master view object instance in a data model master-detail relationship, the row set in the detail view object instance is automatically updated to show the appropriate data for the new current master row.

### Before you begin:

Define a data collection.

### To create a list that uses navigation list binding:

1. From the Data Controls panel, drag and drop a collection to the page and choose **Create > Navigation > ADF Navigation Lists**.
2. In the Edit List Binding dialog, from the **Base Data Source** dropdown list, select the collection whose members will be used to create the list.

This should be the collection you dragged from the Data Controls panel. If the collection does not appear in the dropdown menu, click the **Add** button to select the collection you want.

3. From the **Display Attribute** dropdown list, select the attribute that will display in the list. You can choose the selection that includes all the attributes, and you can choose **Select Multiple** to launch a selection dialog.

In the Select Multiple Display Attributes dialog, shuttle the attributes you want to display from the **Available Attributes** pane to the **Attributes to Display** pane. Click **OK** to close the dialog.

4. Click **OK**.

## 25.5 Creating a Databound Shuttle

The `selectManyShuttle` and `selectOrderShuttle` components render two list boxes, and buttons that allow the user to select multiple items from the leading (or

available) list box and to move or shuttle items over to the trailing (or selected) list box, and vice versa. [Figure 25–7](#) shows an example of a rendered `selectManyShuttle` component. You can specify any text you want for the headers that display above the list boxes.

**Figure 25–7** *SelectManyShuttle Component*

The only difference between `selectManyShuttle` and `selectOrderShuttle` is that in the `selectOrderShuttle` component, the user can reorder the items in the trailing list box by using the up and down arrow buttons on the side.

The Fusion Order Demo application uses a `selectManyShuttle` component to select customer interest categories from a **Categories of Interest** list box to an **I am interested in** list box. The leading list box on the left displays all the categories. The trailing list box on the right displays the categories the customer has selected.

Like other ADF Faces selection list components, the `selectManyShuttle` component can use the `f:selectItems` tag to provide the list of items available for display and selection in the leading list.

Before you can bind the `f:selectItems` tag, create a generic class that can be used by any page that requires a shuttle. In the class, declare and include getter and setter methods for the properties that describe the view object instance names that should be used for the list of all available choices (leading list or available product categories) and the list of selected choices (trailing list or assigned product categories).

[Example 25–12](#) shows the `CustRegBasicInformationBean` class that is created to manage the population and selection state of the shuttle component on the `basicInformation.jsff` page.

**Example 25–12** *CustRegBasicInformationBean Class*

```
package oracle.fodemo.storefront.account.view.managed;
import java.io.Serializable;
import java.util.List;
import javax.faces.application.FacesMessage;
import javax.faces.context.FacesContext;
import oracle.binding.OperationBinding;
import oracle.binding.BindingContainer;
import oracle.fodemo.storefront.adf.util.ADFUtils;
import javax.faces.event.ValueChangeEvent;
import oracle.fodemo.storefront.jsf.util.JSFUtils;
public class CustRegBasicInformationBean implements Serializable {
    String allItemsIteratorName;
    String allItemsValueAttrName;
```

```

String allItemsDisplayAttrName;
String allItemsDescriptionAttrName;
String selectedValuesIteratorName;
String selectedValuesValueAttrName;
List selectedValues;
List allItems;
private boolean refreshSelectedList = false;
public CustRegBasicInformationBean() {
}

public void setAllItemsIteratorName(String allItemsIteratorName) {
    this.allItemsIteratorName = allItemsIteratorName;
}
public String getAllItemsIteratorName() {
    return allItemsIteratorName;
}

// other getter and setter methods are omitted
public void setSelectedValues(List selectedValues) {
    this.selectedValues = selectedValues;
}
public void refreshSelectedList(ValueChangeEvent event) {
    refreshSelectedList = true;
}
public List getSelectedValues() {
    if (selectedValues == null || refreshSelectedList) {
        selectedValues =
            ADFUtils.attributeListForIterator(selectedValuesIteratorName,
                selectedValuesValueAttrName);
    }
    return selectedValues;
}
public void setAllItems(List allItems) {
    this.allItems = allItems;
}

public List getAllItems() {
    if (allItems == null) {
        allItems =
            ADFUtils.selectItemsForIterator(allItemsIteratorName,
                allItemsValueAttrName,
                allItemsDisplayAttrName,
                allItemsDescriptionAttrName);
    }
    return allItems;
}
}

```

The `getAllItems()` method populates the shuttle's leading list. The `getSelectedValues()` method also returns a `List`, but the list defines the items in the shuttle's trailing list. Note that the `CustRegBasicInformationBean` class calls several utility methods in the `ADFUtils` class. Also note that this class uses values for several properties of the base bean. [Example 25-13](#) shows the managed bean and managed properties configured in `customer-registration-task-flow.xml` for working with the shuttle component.

**Example 25-13 Managed Bean for the Shuttle Component in the customer-registration-task-flow File**

```
<managed-bean>
```

```

    <managed-bean-name>
      custRegBasicInformationBean</managed-bean-name>
    <managed-bean-class>
      oracle.fodemo.storefront.account.view.managed.CustRegBasicInformationBean
    </managed-bean-class>
    <managed-bean-scope>view</managed-bean-scope>
    <managed-property>
      <property-name>allItemsIteratorName</property-name>
      <value>AvailableCategoriesShuttleListIterator</value>
    </managed-property>
    <managed-property>
      <property-name>allItemsValueAttrName</property-name>
      <value>CategoryId</value>
    </managed-property>
    <managed-property>
      <property-name>allItemsDisplayAttrName</property-name>
      <value>CategoryName</value>
    </managed-property>
    <managed-property>
      <property-name>allItemsDescriptionAttrName</property-name>
      <value>CategoryDescription</value>
    </managed-property>
    <managed-property>
      <property-name>selectedValuesIteratorName</property-name>
      <value>SelectedCategoriesShuttleListIterator</value>
    </managed-property>
    <managed-property>
      <property-name>selectedValuesValueAttrName</property-name>
      <value>CategoryId</value>
    </managed-property>
  </managed-bean>

```

The `basicInformation.jsff` page uses the following iterator objects:

- `CustomerRegistrationIterator`: Iterates over the `CustomerRegistration` collection, which provides the context for the form above the shuttle.
- `SelectedCategoriesShuttleListIterator`: Iterates over the `SelectedCategoriesShuttleList` collection, which provides the list of categories assigned to the current customer.
- `AvailableCategoriesShuttleListIterator`: Iterates over the `AvailableCategoriesShuttleList` collection, which provides the list of product categories.

All the bindings of the `basicInformation.jsff` page are defined in the file `account_basicInformationPageDef.xml`. [Example 25–14](#) shows part of the page definition file for the `basicInformation.jsff` page.

**Example 25–14 Page Definition File for the `basicInformation` Page**

```

<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
  version="11.1.1.48.68" id="account_basicInformationPageDef"
  Package="oracle.fodemo.storefront.pageDefs">
  <parameters/>
  <executables>
    <page path="oracle.fodemo.storefront.pageDefs.
      templates_StoreFrontTemplatePageDef"

```

```

        id="pageTemplateBinding"/>
<iterator Binds="CustomerRegistration" RangeSize="25"
        DataControl="StoreServiceAMDataControl"
        id="CustomerRegistrationIterator" Refresh="ifNeeded"/>
<iterator id="SelectedCategoriesShuttleListIterator"
        Binds="SelectedCategoriesShuttleList" RangeSize="-1"
        DataControl="StoreServiceAMDataControl"/>
<iterator id="AvailableCategoriesShuttleListIterator"
        Binds="AvailableCategoriesShuttleList" RangeSize="-1"
        DataControl="StoreServiceAMDataControl"/>
<invokeAction Binds="setHelpId" id="invokeSetHelpId" Refresh="ifNeeded"/>
</executables>

```

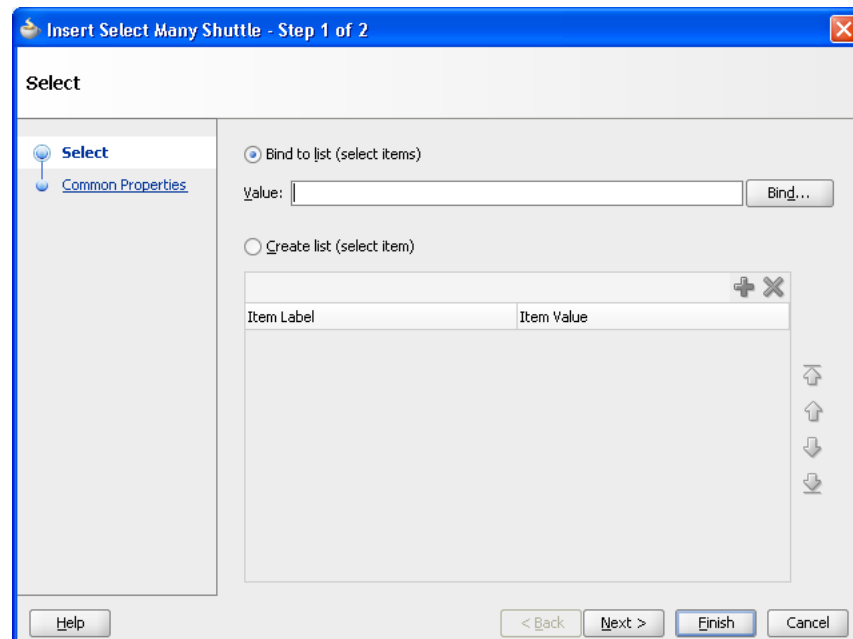

### Before you begin:

- Create the relevant iterator bindings in the page definition file. Use [Example 25–14](#) as a guide.
- Create a class similar to the `CustRegBasicInformationBean` class. Use [Example 25–12](#) as a guide.
- Configure the required managed bean and managed properties in the task flow definition or in the case of an unbounded task flow, the `adf-c-config.xml` file. Use [Example 25–13](#) as a guide.

### To create a shuttle component:

1. In the Common Components page of the Component Palette, from the Common panel, drag and drop **SelectManyShuttle** onto the page. JDeveloper displays the Insert SelectManyShuttle wizard, as illustrated in [Figure 25–8](#).

**Figure 25–8** Insert SelectManyShuttle Wizard

2. Select **Bind to list (select items)** and click **Bind** to open the Expression Builder.

3. In the Expression Builder, expand **ADF Managed Beans > pageFlowScope > CustRegBasicInformationBean > allItems** to build the expression `#{pageFlowScope.custRegBasicInformationBean.allItems}` and click **Next**.

This binds the `f:selectItems` tag to the `getAllItems()` method that populates the shuttle's leading list.

4. In the Common Properties page, click **Bind** next to the **Value** field to open the Expression Builder again.
5. In the Expression Builder, expand **ADF Managed Beans > pageFlowScope > CustRegBasicInformationBean > selectedValues** to build the expression `#{pageFlowScope.custRegBasicInformationBean.selectedValues}` and click **Finish**.

This binds the `value` attribute of the `selectManyShuttle` component to the `getSelectedValues()` method that populates the shuttle's trailing list.

[Example 25–15](#) shows the code for the `selectManyShuttle` component after you complete the Insert `SelectManyShuttle` dialog.

**Example 25–15 *SelectManyShuttle* Component in *basicInformation.jsff* File**

```
<af:selectManyShuttle
    value="#{pageFlowScope.custRegBasicInformationBean.selectedValues}"
    leadingHeader="#{res['basicinfo.leadingHeader']}"
    trailingHeader="#{res['basicinfo.trailingHeader']}"
    leadingDescShown="true" size="8"
    trailingDescShown="true"
    inlineStyle="background-color:transparent;"
    id="sms1">
    <f:selectItems
        value="#{pageFlowScope.custRegBasicInformationBean.allItems}"/>
</af:selectManyShuttle>
```

---

---

## Creating Databound ADF Data Visualization Components

This chapter describes how to use the Data Controls panel and ADF data binding to create databound ADF Data Visualization components. These components allow you to display and analyze data through a wide variety of graphs, several kinds of gauges, a pivot table, geographic maps with multiple layers of information, several kinds of Gantt charts, timelines, a hierarchy viewer, treemaps, and sunbursts.

This chapter includes the following sections:

- [Section 26.1, "Introduction to Creating ADF Data Visualization Components"](#)
- [Section 26.2, "Creating Databound Graphs"](#)
- [Section 26.3, "Creating Databound Gauges"](#)
- [Section 26.4, "Creating Databound Pivot Tables"](#)
- [Section 26.5, "Creating Databound Geographic Maps"](#)
- [Section 26.6, "Creating Databound Thematic Maps"](#)
- [Section 26.7, "Creating Databound Gantt Charts"](#)
- [Section 26.8, "Creating Databound Timelines"](#)
- [Section 26.9, "Creating Databound Hierarchy Viewers"](#)
- [Section 26.10, "Creating Databound Treemaps and Sunbursts"](#)

### 26.1 Introduction to Creating ADF Data Visualization Components

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing data.

Both ADF graph and gauge components render graphical representations of data. However, graphs (which produce more than 50 types of charts) allow you to evaluate multiple data points on multiple axes in a variety of ways. Many graph types assist in the comparison of results from one group with the results from another group. In contrast, gauges focus on a single data point and examine that point relative to minimum, maximum, and threshold indicators to identify problems.

The ADF pivot table component produces a grid that supports multiple layers of data labels on the row edge or the column edge of the grid. An optional pivot filter bar uses a page edge to filter the pivot table data not in view. This component also provides the option of automatically generating subtotals and totals for grid data. Pivot tables let you pivot data layers from one edge to another to obtain different views of your data. For example, a pivot table might initially display total sales data for products within

regions on the row edge, broken out by years on the column edge. If you pivot region and year at runtime, then you end up with total sales data for products within years, broken out by region. At runtime, end users can click buttons that appear in the inner column labels to sort rows in ascending or descending order.

The ADF geographic map component represents business data spatially, enabling you to superimpose multiple layers (also referred to as *themes*) of information on a single map. For example, a map of the United States might use a color theme that provides varying color intensity to indicate the popularity of a product within each state, a pie chart theme that shows sales within product category, and a point theme that identifies the exact location of each warehouse. When all three themes are superimposed on the United States map, you can easily evaluate whether there is sufficient inventory to support the popularity level of a product in specific locations.

Thematic map components represents business data as patterns in stylized areas or associated markers and does not require a connection to an Oracle MapViewer service. Thematic maps focus on data without the geographic details in a geographic map. The thematic map is packaged with prebuilt base maps including a USA base map, a world base map, and base maps for continents and regions of the world including EMEA and APAC. Each base map includes several sets of regions and one fixed set of cities. A set of regions or cities is referred to as a layer. Each layer can be bound to a data collection and stylized to represent the data with color and pattern fills, or a data marker, or both. At runtime, only one map layer and its associated data can be displayed at a time, unless the thematic map has been enabled for drilling.

There are three types of ADF Gantt chart components: the project Gantt chart (which focuses on project management), the scheduling Gantt chart, and the resource utilization Gantt chart (both of which focus on resource management). Each Gantt chart shows the following regions combined with a splitter:

- List region content: The left side of the splitter provides a list of tasks (for the project Gantt chart) and a list of resources (for the resource utilization and scheduling Gantt charts). This region can display any number of additional columns of related information.
- Chart region content: The right side of the splitter consists of an area in which task progress, resource utilization, or resource progress is graphed over time. The ability of the Gantt chart to zoom in or out on its time axis lets you view management information across the desired time period.

An ADF timeline component is an interactive data visualization tool that allows users to view date-based events in chronological order and easily navigate forwards and backwards within a defined time range. A dual timeline can be used for a side-by-side comparison of events.

A timeline is composed of the display of events as timeline items along a time axis, a movable overview window that corresponds to the period of viewable time in the timeline, and an overview time axis that displays the total time increment for the timeline. A horizontal zoom control is available to change the viewable time range. Timeline items corresponding to events display associated information or actions and are connected to the date of the event in the time axis. Timelines items are represented by a marker in the overview panel. No more than two series of events are supported by the timeline component.

The ADF hierarchy viewer component produces a graphic that displays hierarchical data as a set of linked shapes. The shapes and links correspond to the elements and relationships in the data. For example, a hierarchy viewer component might be used to generate an organizational chart based on employee data. At runtime, end users can

pan and zoom the graphic and expand, select, and navigate the management hierarchy that the graphic displays.

The ADF treemap and sunburst components display quantitative hierarchical data across two dimensions, represented visually by size and color. For example, you can use a treemap or sunburst to display quarterly regional sales and to identify sales trends, using the size of the node to indicate each region's sales volume and the node's color to indicate whether that region's sales increased or decreased over the quarter.

Each ADF Data Visualization component needs to be bound to data before it can be rendered because the appearance of the components is dictated by the data that is displayed. This chapter describes how to bind each component to a data source.

Figure 26–1 shows a number of the ADF Data Visualization components at runtime, including a bar graph, a pie chart graph, a status meter gauge, and a dial gauge.

**Figure 26–1 Dashboard with ADF Data Visualization Components**

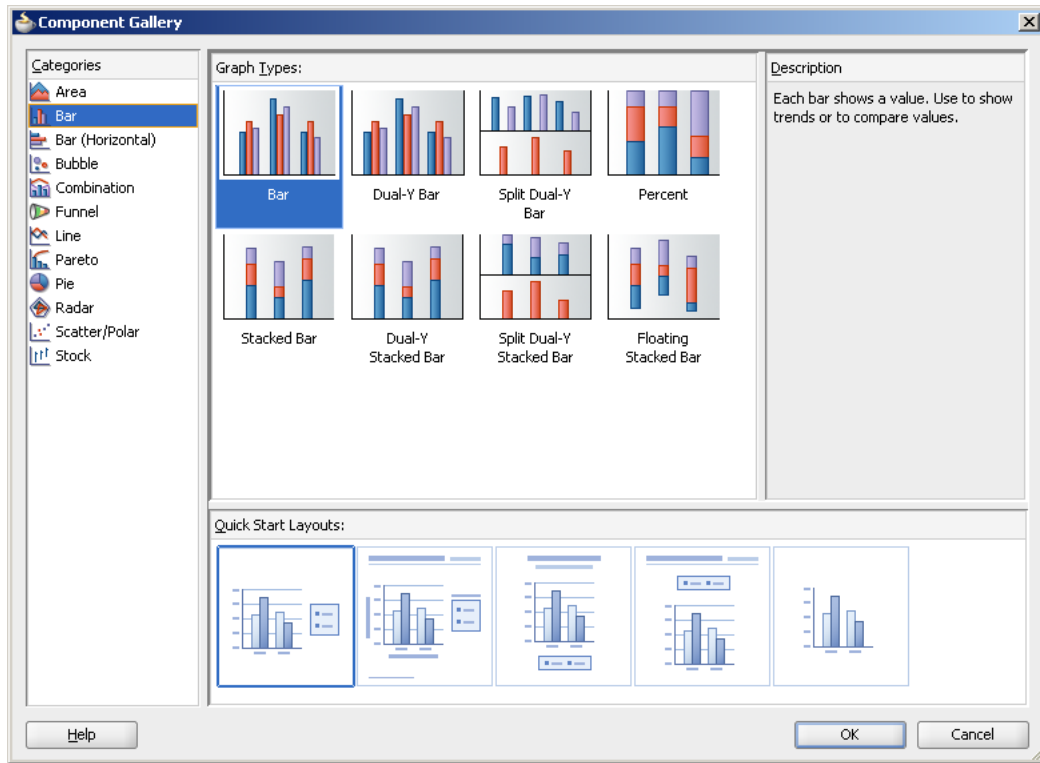

## 26.2 Creating Databound Graphs

When you create a graph using a data collection inserted from the Data Controls panel, a Component Gallery allows you to choose from a wide number of graph categories, graph types, and layout options. Graph categories group together one or more types of graph. For example, the Scatter/Polar category includes the following types of graph:

- Scatter
- Dual-Y Scatter
- Polar

Explore the Component Gallery that appears when you create a graph to view available graph categories, types, and descriptions for each one. Figure 26–2 shows the Component Gallery that appears for ADF graphs when you use the Data Controls panel.

**Figure 26–2 ADF Graphs Component Gallery from Data Controls Panel**

**Note:** Some graph types require very specific kinds of data. If you bind a graph to a data collection that does not contain sufficient data to display the graph type requested, then the graph is not displayed and a message about insufficient data appears.

You can also create a graph by dragging a graph component from the Component Palette. This approach allows you the option of designing the graph user interface before binding the component to data. A Component Gallery appears to view graph types, descriptions, and quick layout options.

**Note:** The ADF sparkchart can only be inserted from the Component Palette and bound to data afterwards. For more information, see [Section 26.2.4, "How to Create a Databound Sparkchart."](#)

Table 26–1 lists the categories that appear in the Component Gallery for graphs. Each category has one or more graph types associated with it.

**Table 26–1 ADF Graph Categories in the Component Gallery**

Category	Description
Area	Creates a graph in which data is represented as a filled-in area. Use area graphs to show trends over time, such as sales for the last 12 months. Area graphs require at least two groups of data along an axis. The axis is often labeled with time periods such as months.

**Table 26–1 (Cont.) ADF Graph Categories in the Component Gallery**

Category	Description
Bar	Creates a graph in which data is represented as a series of vertical bars. Use to examine trends over time or to compare items at the same time, such as sales for different product divisions in several regions.
Bar (Horizontal)	Creates a graph that displays bars horizontally along the y-axis. Use to provide an orientation that allows you to show trends or compare values.
Bubble	Creates a graph in which data is represented by the location and size of round data markers (bubbles). Use to show correlations among three types of values, especially when you have a number of data items and you want to see the general relationships. For example, use a bubble graph to plot salaries (x-axis), years of experience (y-axis), and productivity (size of bubble) for your work force. Such a graph allows you to examine productivity relative to salary and experience.
Combination	Creates a graph that uses different types of data markers (bars, lines, or areas) to display different kinds of data items. Use to compare bars and lines, bars and areas, lines and areas, or all three.
Funnel	Creates a graph that is a visual representation of data related to steps in a process. The steps appear as vertical slices across a horizontal cylinder. As the actual value for a given step or slice approaches the quota for that slice, the slice fills. Typically a funnel graph requires actual values and target values against a stage value, which might be time. For example, use this component to watch a process (such as a sales pipe line) move towards a target across the stage of the quarters of a fiscal year.
Line	Creates a graph in which data is represented as a line, as a series of data points, or as data points that are connected by a line. Line graphs require data for at least two points for each member in a group. For example, a line graph over months requires at least two months. Typically a line of a specific color is associated with each group of data such as the Americas, Europe, or Asia. Use to compare items over the same time.
Pareto	Creates a graph in which data is represented by bars and a percentage line that indicates the cumulative percentage of bars. Each set of bars identifies different sources of defects, such as the cause of a traffic fatality. The bars are arranged by value, from the largest number to the lowest number of incidents. A pareto graph is always a dual-y graph in which the first y-axis corresponds to values that the bars represent and the second y-axis runs from 0 to 100% and corresponds to the cumulative percentage values. Use the pareto graph to identify and compare the sources of defects.
Pie	Creates a graph in which one group of data is represented as sections of a circle causing the circle to look like a sliced pie. Use to show relationship of parts to a whole such as how much revenue comes from each product line.
Radar	Creates a graph that appears as a circular line graph. Use to show patterns that occur in cycles, such as monthly sales for the last three years.
Scatter/Polar	Creates a graph in which data is represented by the location of data markers. Use to show correlation between two different kinds of data values such as sales and costs for top products. Scatter graphs are especially useful when you want to see general relationships among a number of items.
Sparkchart	Creates a simple, condensed graph that displays trends or variations, often in the column of a table, or inline with text. Sparkcharts are only available in the Component Gallery when inserted using the Component Palette and bound to data afterwards.
Stock	Creates a graph in which data shows the high, low, and closing prices of a stock. Each stock marker displays three separate values.

Figure 26–3 shows the horizontal bar graph that appears in the Hot Items Statistics page of the `StoreFrontModule` application. This graph displays the quantity of

orders for each product so that you can easily identify the items that have been ordered most frequently.

**Figure 26–3 Hot Items Statistics Graph**

For information about customizing graphs after the data binding is completed, see the "Using ADF Graph Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 26.2.1 How to Create a Graph

Graphs are based on data collections. Using data controls in Oracle ADF, Oracle JDeveloper makes this a declarative task. You drag and drop a collection from the Data Controls panel.

**To create a databound graph:**

1. From the Data Controls panel, select a collection.

For example, to create the bar graph that displays the order count for each product in the Hot Items Statistics page of the `StoreFrontModule` application, select the `ProductOrdersCount` collection. [Figure 26–4](#) shows the `ProductOrdersCount` collection in the Data Controls panel.

**Figure 26–4 Data Collection for Counting Product Orders**

2. Drag the collection onto a JSF page and, from the context menu, choose **Graphs** to display the Component Gallery.
3. Select a graph category and a graph type from the Component Gallery and click **OK**.

For information about the graph categories and graph types that appear in the Component Gallery, see [Table 26-1](#).

The name of the dialog and the input field labels that appears depends on the category and type of graph that you select. For example, if you select **Bar (Horizontal)** as the category and **Bar** as the type, then the name of the dialog that appears is Create Horizontal Bar Graph and the input field is labeled **Bars**.

4. Do the following in the dialog to configure the graph to display data:
  - Drag attributes from the **Available** list to the **Bars** or **X Axis** input fields, depending on where you want the values for the attributes to appear at runtime.
  - In the **Attribute Labels** field, enter a value or select a value from the dropdown list in the **Label** column to specify the label that appears at runtime.
  - If you want to change the display of the data represented in the bars to the Y-Axis, click the **Swap Bars with Y-Axis** button. This action switches the hidden data layer between the graph series and groups and is not a simple manual swap of the bars and y-axis attributes.
  - If you want to change from the default selection of **Typed Attributes** to **Name-Value Pairs** to configure how data points are stored in a collection, then click the **Change Data Shape** button. A dialog appears that presents you with the following options:
    - Typed Attributes
 

Each kind of data point in the collection is represented by a different attribute. This option is also valid when there is only a single kind of data point in the graph.

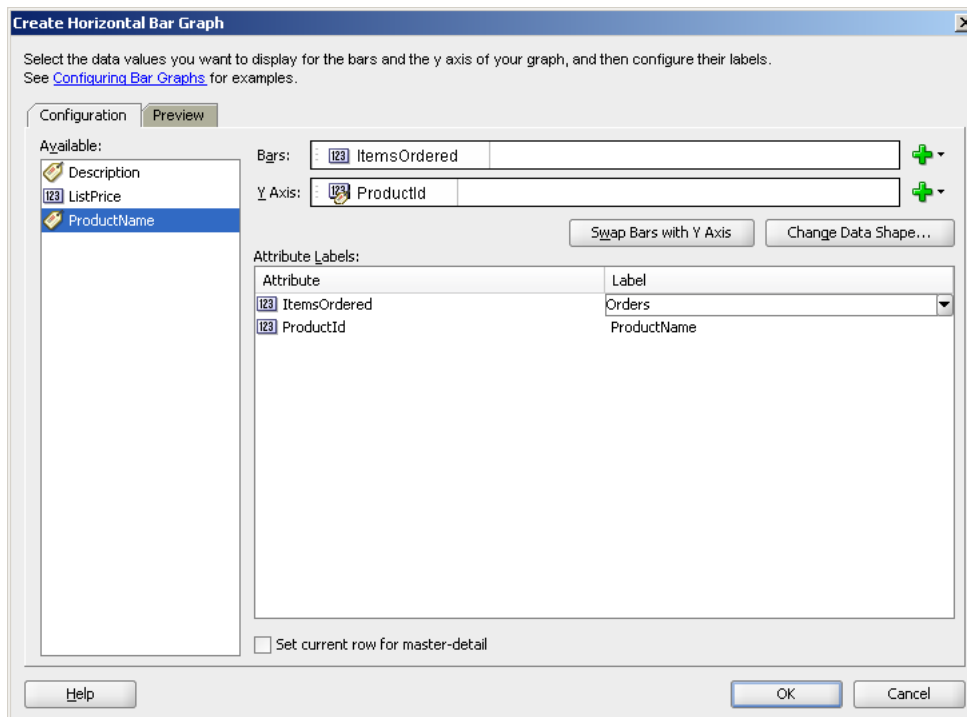

For example, if you have data points for **Estimated Value** and **Actual Value**, then select **Typed Attributes** only if you have one attribute for the estimated value and a second attribute for the actual value.
    - Name-Value Pairs
 

Indicates that there are multiple kinds of data points, but only a single attribute to designate these points. In this case, the single attribute has values that identify each kind of data point.

For example, the attribute might have the value **EST** for a data point that represents an estimated value and **ACT** for a data point that represents an actual value.
  - Select **Set the current row for master-detail** to use the graph's row selection listener to enable clicks on a bar, slice, or other graph data element to update the data in another ADF component. For more information see [Section 26.2.3, "What You May Need to Know About Using a Graph's Row Selection Listener for Master-Detail Processing."](#)

[Figure 26-5](#) shows the Create Horizontal Bar Graph dialog that generates a graph using data from the `ItemsOrdered` attribute in the `ProductOrdersCount` data collection. The `ProductName` attribute provides labels for the displayed data.

**Figure 26–5 Create Horizontal Bar Graph Dialog for ProductsOrderCount**

5. Optionally, click the **Preview** tab to display a live preview of the bar graph and its data. If necessary, go back to the **Configuration** tab so that you can adjust the bar graph specifications.
6. Click **OK**.

After completing the data binding dialog, you can use the Property Inspector to specify settings for the graph attributes and you can also use the child tags associated with the graph tag to customize the graph further.

---

**Note:** Use the `emptyText` attribute to specify the text to display when there is no data to return in the graph. The default message is **No data to display**. The attribute accepts HTML for formatting the message and an EL expression that evaluates to the viewable property of the data. If the graph is not viewable (for example, if there are authorization restrictions set against the graph), it displays **Access Denied**.

---

## 26.2.2 What Happens When You Use the Data Controls Panel to Create a Graph

Dropping a graph from the Data Controls panel has the following effect:

- Creates the bindings for the graph and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

The data binding XML that JDeveloper generates varies depending on the type of graph you select. The XML represents the physical model of the specific graph type you create. [Example 26–1](#) shows the bindings that JDeveloper generated in the page definition file where a horizontal bar graph was created using data from the `ItemsOrdered` attribute in the `ProductOrdersCount` data collection.

**Example 26–1 Binding XML for an ADF Bar (Horizontal) Graph**

```

<graph IterBinding="ProductOrdersCountIterator" id="ProductOrdersCount"
  xmlns="http://xmlns.oracle.com/adfm/dvt" type="BAR_HORIZ_CLUST">
  <graphDataMap leafOnly="true">
    <series>
      <data>
        <item value="ItemsOrdered" label="Orders" />
      </data>
    </series>
    <groups>
      <item value="ProductName" label="ProductName" />
    </groups>
  </graphDataMap>
</graph>

```

Example 26–2 shows the code generated for a horizontal bar graph when you drag the `ProductOrdersCount` data collection onto a JSF page.

**Example 26–2 JSF Code for an ADF Bar (Horizontal) Graph**

```

<dvt:horizontalBarGraph id="horizontalBarGraph1"
  value="#{bindings.ProductOrdersCount.graphModel}"
  subType="BAR_HORIZ_CLUST">
  <dvt:background>
    <dvt:specialEffects/>
  </dvt:background>
  <dvt:graphPlotArea/>
  <dvt:seriesSet>
    <dvt:series/>
  </dvt:seriesSet>
  <dvt:o1Axis/>
  <dvt:y1Axis/>
  <dvt:legendArea automaticPlacement="AP_NEVER" />
</dvt:horizontalBarGraph>

```

### 26.2.3 What You May Need to Know About Using a Graph's Row Selection Listener for Master-Detail Processing

You can use the row selection listener of a graph (which serves as a master view) to enable clicks on a bar, slice, or other graph data element to update the data in another ADF component (which serves as a detail view). For example, a click on a bar that represents sales for a given product in a graph might cause the display of the detailed sales data related to the product in a pivot table.

The following requirements must be met to achieve this master-detail processing declaratively:

1. You must use the same data control to provide data for both views as follows:
  - a. Bind the graph as a row set to the parent collection in the data control, for example, `DepartmentsView`.
  - b. Bind the other ADF view (such as a table or pivot table) to the dependent detail collection in the data control, for example `EmployeesView`.
2. Select **Set the current row for master-detail** in the Create <type> Graph dialog to automatically set a value for the `clickListener` attribute of the graph tag and use the `processClick` method that is already part of the graph binding.

For example, if the value attribute of the graph tag is `value="{bindings.myGraph.graphModel}"`, then the `clickListener` attribute is set to `clickListener="{bindings.myGraph.graphModel.processClick}"`.

3. Ensure that the `partialTriggers` attribute on the parent tag for the detail component is set correctly. It should be set to the ID of the graph component.

You do not have to write Java code for handling clicks on data elements in the graph. The `processClick` event on the graph binding recognizes click events on data component in a graph and performs the necessary processing.

### 26.2.4 How to Create a Databound Sparkchart

Sparkcharts are simple, condensed graphs that display trends or variations, often in the column of a table, or inline with text. Line, bar, and area sparkcharts require a single series of data values. [Figure 26-6](#) shows an example of a line sparkchart in a table column.

**Figure 26-6 Line Sparkchart**

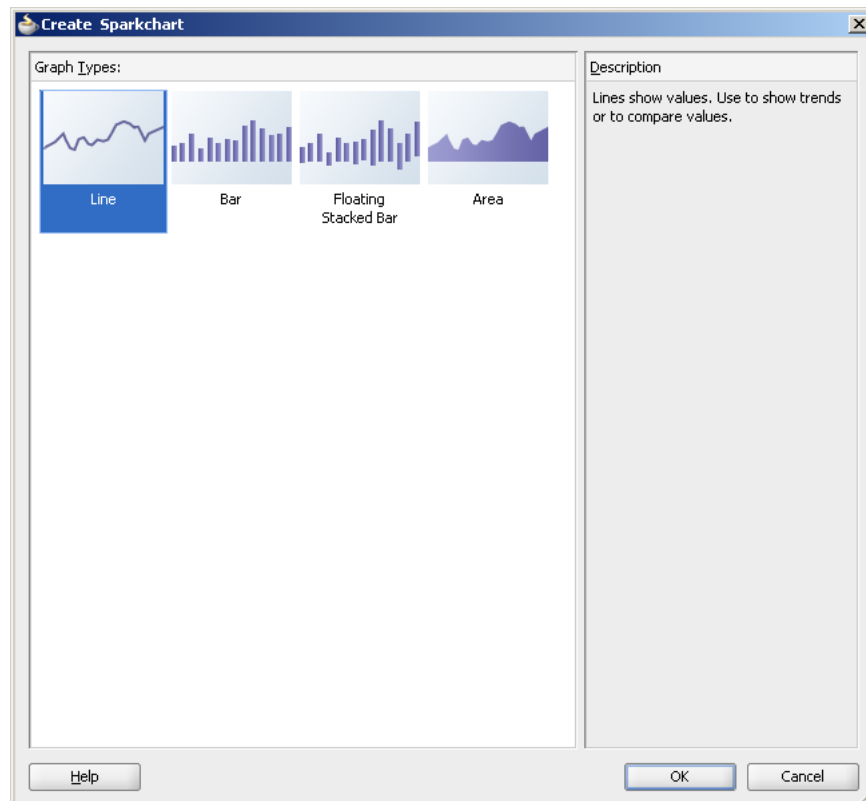

Stock Symbol	Prices for 2008
AAPL	
CSCO	
GOOG	
HPQ	
IBM	
INTC	
MSFT	
ORCL	

Floating bar sparkcharts require two series of data values, one for the float offset, and one for the bar value. [Figure 26-7](#) shows an example of a floating bar sparkchart.

**Figure 26-7 Floating Bar Sparkchart**

You create a sparkchart by inserting the component from the Component Palette and binding the sparkchart to data afterwards. Inserting a sparkchart from the Data Controls panel is not supported. [Figure 26-8](#) shows the Component Gallery that displays when you drag a sparkchart component onto your page from the Component Palette.

**Figure 26–8 Create Sparkchart Component Gallery**

You can provide data to sparkcharts in any of the following ways:

- Specify data statically in child `dvt:sparkItem` tags. [Example 26–3](#) shows an example of providing static data to a sparkchart.

#### **Example 26–3 Static Data in Sparkchart**

```
<dvt:sparkChart>
  <dvt:sparkItem value="20"/>
  <dvt:sparkItem value="15"/>
  <dvt:sparkItem value="30"/>
</dvt:sparkChart>
```

- Specify data using EL Expression in child `dvt:sparkItem` tags. [Example 26–4](#) shows an example of providing data using EL Expressions.

#### **Example 26–4 EL Expression Data in Sparkchart**

```
<af:table value="#{sample.tableModel}" var="row">
  <af:column>
    <dvt:sparkChart>
      <dvt:sparkItem value="#{row.col1}"/>
      <dvt:sparkItem value="#{row.col2}"/>
      <dvt:sparkItem value="#{row.col3}"/>
    </dvt:sparkChart>
  </af:column>
</af:table>
```

- Specify data using a child accessor in a table. [Example 26–5](#) shows an example of using `af:iterator` to provide sparkchart data from the data collection model, `row.stockValues`.

**Example 26–5 Sparkchart Data in Table Child Accessor**

```
<af:table value="#{sample.tableModel}" var="row">
  <af:column>
    <dvt:sparkChart>
      <af:iterator value="#{row.stockValues}" var="data">
        <dvt:sparkItem value="#{data.closeValue}"/>
      </af:iterator>
    </dvt:sparkChart>
  </af:column>
</af:table>
```

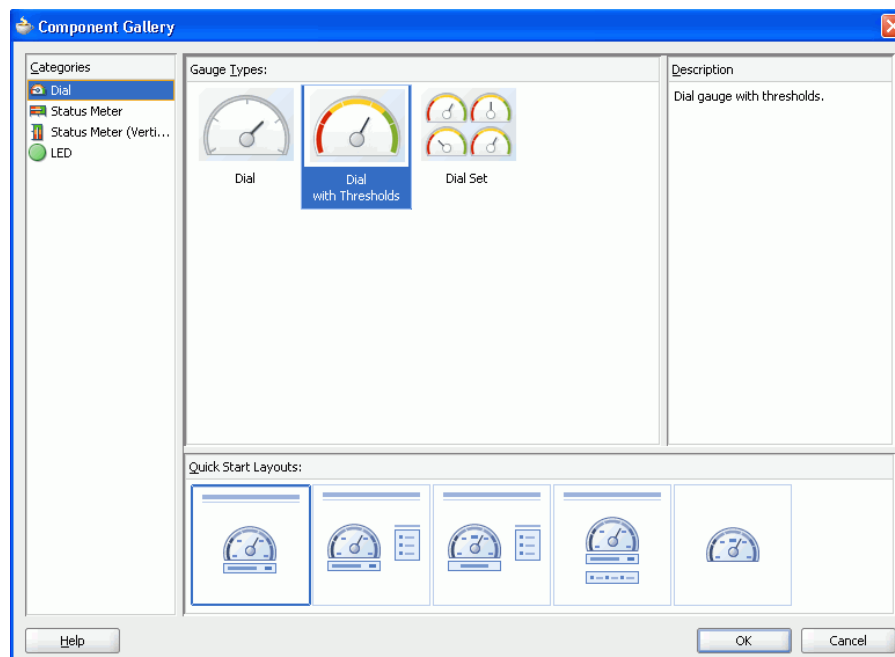

## 26.3 Creating Databound Gauges

A gauge plots one data point with indication of whether the data point falls in an acceptable or unacceptable range. One databound gauge component can create a single gauge or an entire set of gauges, depending on the number of rows in the data collection used. In a collection, each row contains the values for a single gauge.

The Component Gallery for gauges allows you to choose from the following categories of gauges:

- **Dial:** Indicates the metric value of a task along a 180 degree arc.
- **Status Meter:** Indicates the progress of a task or the level of some measurement along a rectangular bar.
- **Status Meter (Vertical):** Indicates the progress of a task or the level of some measurement along a rectangular bar.
- **LED:** Depicts graphically a measurement such as a key performance indicator (KPI). Several styles of graphics are available for LED gauges such as arrows that indicate good (up arrow), fair (left- or right-pointing arrow), and poor (down arrow).

Each of these categories contains a number of different types of gauge. Explore the Component Gallery that appears when you create a gauge to view all available gauge and category types, and descriptions for each one. [Figure 26–9](#) shows the Component Gallery that appears for ADF gauges.

**Figure 26–9 ADF Gauges Component Gallery**

The data binding process is essentially the same regardless of which type of gauge you create. Only the metric value (that is, the measurement that the gauge is to indicate) is required. However, if a row in a data collection contains range information such as maximum, minimum, and thresholds, then these values can be bound to the gauge to provide dynamic settings. If information that you want to use in a gauge's upper or lower labels is available in the data collection, then you can bind these values to the gauge also.

For information about customizing a gauge after the data binding is completed, see the "Using ADF Gauge Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 26.3.1 How to Create a Databound Dial Gauge

You can use the ADF gauge component to create a dial gauge against a background that specifies ranges of values (also called *thresholds*) that vary from poor to excellent. The gauge indicator specifies the current value of the metric while the graphic allows you to evaluate the status of that value easily.

Figure 26–10 shows a single dial gauge that appears if you create a gauge from the collection that stores `WarrantyPeriodMonths` data. Because only one gauge appears, this data collection must contain only a single row of data. The value of the metric (which is 6) appears in a label below the gauge. The range of values in the gauge is displayed as 0 to 24. Threshold ranges are identified at 8, 16, and 24 and are filled with the colors red for poor (below 8), yellow for adequate (from 8 to 16), and green for superior (above 16).

**Figure 26–10 The Warranty in Months Dial Gauge**

To create a dial gauge using a data control, you bind the gauge component to a collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

**To create a databound dial gauge:**

1. From the Data Controls panel, select a collection.

For example, to create a dial gauge in the `StoreFrontModule` application to display the current warranty period in months for a product in a particular warehouse, you would select the `WarehouseStockLevels` collection.

[Figure 26–11](#) shows the `WarehouseStockLevels` collection in the Data Controls panel.

**Figure 26–11 Data Collection with Warranty Period for a Product**

2. Drag the collection onto a JSF page and, from the context menu, choose **Gauges**.
3. In the Component Gallery dialog, choose the category, type of gauge, and quick start layout, and then click **OK**.
4. In the Configuration tab of the dialog, do the following:
  - In the **Metric** box, select the column in your data collection that contains the actual value that the gauge is to plot. This is the only required value in the dialog.
  - In the **Minimum** box, if your data collection stores a minimum value for the gauge range, select the column that contains this value.

- In the **Maximum** box, if your data collection stores a maximum value for the gauge range, select the column that contains this value.
  - In the **Top Label** box, if your data collection stores a value that you want to display in the top label of the gauge, select the column that contains this value.
  - In the **Bottom Label** box, if your data collection stores a value that you want to display in the bottom label of the gauge, then select the column that contains this value.
  - In the **Threshold Attributes** list, if you want to specify threshold values, click the Add icon to insert a row for each threshold and specify the value in that row. Do not create a threshold equal to the maximum value for the gauge because the gauge automatically treats the maximum value as a threshold setting.
5. Optionally, click the **Preview** tab to display a live preview of the gauge and its data. If necessary, go back to the **Configuration** tab so that you can adjust the gauge specifications.
  6. Click **OK**.

Figure 26–12 shows the completed Create Dial Gauge dialog that generates a dial gauge using the WarehouseStockLevels data collection.

---

**Note:** Only the metric data value is required. Other data values in the dialog are optional and can be specified in the gauge tag through the Property Inspector.

---

**Figure 26–12** Create Dial Gauge Dialog

In the Property Inspector, after you complete the binding of the gauge, you can set values for additional attributes in the gauge tag and its child tags to customize the component.

## 26.3.2 What Happens When You Create a Dial Gauge from a Data Control

Dropping a gauge from the Data Controls panel has the following effect:

- Creates the bindings for the gauge and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

[Example 26–6](#) shows the bindings that JDeveloper generated for the dial gauge that displays warranty in months for a product in a warehouse. This code example shows that the gauge metric receives its value dynamically from the `WarrantyPeriodMonths` column in the data collection and that the remaining data values have static settings.

### **Example 26–6 Bindings for a Dial Gauge**

```
<gauge IterBinding="WarehouseStockLevelsIterator" id="WarehouseStockLevels"
  xmlns="http://xmlns.oracle.com/adfm/dvt"
  type="DIAL">
  <gaugeDataMap>
    <thresholds>
      <item value="8" valueType="literal"/>
      <item value="16" valueType="literal"/>
    </thresholds>
    <item type="metric" value="WarrantyPeriodMonths"/>
    <item type="minimum" value="0" valueType="literal"/>
    <item type="maximum" value="24" valueType="literal"/>
    <item type="topLabel" value="Warranty" valueType="literal"/>
    <item type="bottomLabel" value="Months" valueType="literal"/>
  </gaugeDataMap>
</gauge>
```

[Example 26–7](#) shows the code that JDeveloper generated in the JSF page for a dial gauge. The `<dvt:thresholdSet>` element specifies one `<dvt:threshold>` element for each threshold. Colors for the threshold ranges default to red, yellow, and green as specified by the values for the `fillColor` attributes. The `<dvt:indicator>` element specifies `IT_NEEDLE` as the indicator to use. This renders a needle at runtime. The default value for `<dvt:indicator>` renders a line (`IT_LINE`).

### **Example 26–7 Code on the JSF Page for an ADF Dial Gauge**

```
<dvt:gauge id="gauge1"
  value="#{bindings.WarehouseStockLevels.gaugeModel}"
  gaugeType="DIAL">
  <dvt:gaugeBackground>
    <dvt:specialEffects/>
  </dvt:gaugeBackground>
  <dvt:thresholdSet>
    <dvt:threshold text="Low" fillColor="#d62800"/>
    <dvt:threshold text="Medium" fillColor="#ffc221"/>
    <dvt:threshold text="High" fillColor="#84ae31"/>
  </dvt:thresholdSet>
  <dvt:gaugeFrame/>
  <dvt:indicator type="IT_NEEDLE"/>
  <dvt:indicatorBase/>
  <dvt:gaugePlotArea/>
  <dvt:tickLabel/>
  <dvt:tickMark/>
  <dvt:topLabel/>
```

```

<dvt:bottomLabel text="Months" />
<dvt:metricLabel position="LP_WITH_BOTTOM_LABEL" />
</dvt:gauge>

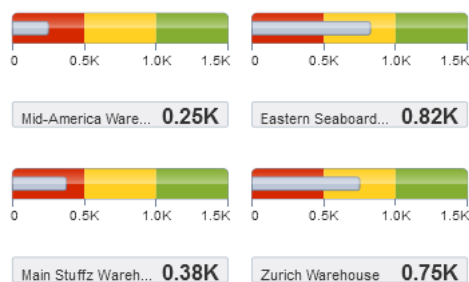

```

### 26.3.3 How to Create a Databound Status Meter Gauge Set

You can use the ADF gauge component to create a status meter gauge where the inner rectangle shows the current level of a measurement against the ranges marked in the outer rectangle. The graphic of the status meter gauge allows you to evaluate the condition or progress of a measurement easily.

Figure 26–13 shows a set of status meter gauges that represent the inventory levels in a number of warehouses. This set of gauges results from binding one gauge component to a data collection (`WarehouseStockLevels`). This data collection contains a row of data for each warehouse. Each row produces one gauge in the set. Notice that all gauges in the set share the same range values of minimum (0) and maximum (1500) with thresholds set at 500 and 1000 and 1500. Each gauge in the set displays the name of the warehouse that it represents and the stock metric for that warehouse in its bottom label.

**Figure 26–13** *The Warehouse Inventory Status Meter Gauge Set*

To create a status meter gauge set using a data control, you bind the gauge component to a data collection that contains multiple rows of data. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

#### To create a databound status meter gauge:

- From the Data Controls panel, select a collection.  
For example, to create a status meter gauge in the `StoreFrontModule` application that displays the quantity of stock on hand in a warehouse, you select the `WarehouseStockLevels` collection.
- Drag the collection onto a JSF page and, from the context menu, choose **Gauges**.
- In the Component Gallery, choose the following:
  - Status Meter** or **Status Meter (Vertical)** in the **Categories** list
  - The type of gauge that you want to create
  - The quick start layout for the gauge at runtime
- Click **OK**.
- In the Create Gauge dialog that appears, select values as described in the following list:
  - Select an attribute binding from the **Metric** dropdown list. This attribute binding contains the actual value that the gauge is to plot.

- Input a minimum value in the **Minimum** field if your data collection stores a minimum value for the gauge range.
- Input a maximum value in the **Maximum** field if your data collection stores a maximum value for the gauge range.
- Write or select a value in the **Top Label** field if you want to display a label on top of the gauge at runtime.
- Write or select a value in the **Bottom Label** field if you want to display a label below the gauge at runtime.
- Click the **Add** icon to insert a row for each threshold and specify the value for that threshold if you want to specify threshold values in the **Threshold Attributes** list. Do not create a threshold equal to the maximum value for the gauge because the gauge automatically treats the maximum value as a threshold setting.

---

**Note:** If you selected a quick start layout that includes thresholds, the dialog includes the threshold attributes, and you do not need to insert the threshold rows unless you want to add an additional row to the threshold list.

---

6. Optionally, click the **Preview** tab to display a live preview of the gauge and its data. If necessary, click the **Configuration** tab so that you can adjust the gauge specifications.

Figure 26–14 shows the settings for the set of status meter gauges that appears in Figure 26–13. In addition to setting values for the required metric value, this dialog sets values for thresholds and for the name of the warehouse to appear in the gauge’s bottom label.

**Figure 26–14 Create Gauge Dialog for Warehouse Inventory Gauge Set**

## 7. Click OK.

In the Property Inspector, after you complete the binding of the gauge, you can set values for additional attributes in the gauge tag and its child tags to customize the component as needed.

### 26.3.4 What Happens When You Create a Status Meter Gauge from a Data Control

Dropping a gauge from the Data Controls panel has the following effect:

- Creates the bindings for the gauge and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

[Example 26–8](#) shows the row set bindings that were generated for the status meter gauge set that displays inventory levels for each warehouse as illustrated in [Figure 26–14](#). This example shows the value binding created between the gauge metric attribute and the `QuantityOnHand` value in the data collection. It also shows the value binding between the `Bottom Label` attribute and the `WarehouseName` value in the data collection.

#### **Example 26–8 Bindings Code for the ADF Status Meter Gauge Set**

```
<gauge IterBinding="WarehouseStockLevelsIterator" id="WarehouseStockLevels"
  xmlns="http://xmlns.oracle.com/adfm/dvt">
  <gaugeDataMap>
    <thresholds>
      <item value="500" valueType="literal"/>
      <item value="1000" valueType="literal"/>
    </thresholds>
    <item type="metric" value="QuantityOnHand"/>
    <item type="minimum" value="0" valueType="literal"/>
    <item type="maximum" value="1500" valueType="literal"/>
    <item type="bottomLabel" value="WarehouseName"/>
  </gaugeDataMap>
</gauge>
```

[Example 26–9](#) shows the code generated on the JSF page for the status meter gauge set that shows inventory levels for warehouses. The `gaugeSetColumnCount` attribute specifies that gauges should be displayed in two columns. The code also specifies three thresholds: Low, Medium, and High. For brevity, the value of the `inlineStyle` attribute has been omitted.

#### **Example 26–9 Code on the JSF Page for the ADF Status Meter Gauge Set**

```
<dvt:gauge id="gauge1"
  value="{bindings.WarehouseStockLevels.gaugeModel}"
  gaugeType="STATUSMETER" gaugeSetDirection="GSD_DOWN"
  gaugeSetColumnCount="2">
  <dvt:gaugeBackground>
    <dvt:specialEffects/>
  </dvt:gaugeBackground>
  <dvt:thresholdSet>
    <dvt:threshold text="Low" fillColor="#d62800"/>
    <dvt:threshold text="Medium" fillColor="#ffcf21"/>
    <dvt:threshold text="High" fillColor="#84ae31"/>
  </dvt:thresholdSet>
  <dvt:indicatorBar/>
  <dvt:gaugePlotArea/>
```

```

<dvt:tickLabel/>
<dvt:tickMark/>
<dvt:topLabel position="LP_NONE"/>
<dvt:bottomLabel/>
<dvt:metricLabel position="LP_WITH_BOTTOM_LABEL"/>
</dvt:gauge>

```

## 26.4 Creating Databound Pivot Tables

The ADF pivot table displays a grid of data with rows and columns and optionally, a pivot filter bar to filter data not displayed in the rows or columns. The pivot table has the following structure:

- Column edge: The horizontal axis above the pivot table containing one or more layers of information in the pivot table.
- Row edge: The vertical axis to the left of the pivot table containing one or more layers of information in the pivot table.
- Page edge: The optional pivot filter bar containing zero or more layers of information for filtering the display of data in the pivot table.
- Data body: One or more measures, or data values, displayed in the cells of the pivot table.

Figure 26–15 shows a Sales pivot table that displays data values for sales and units in the data body, a geography data layer on the column edge, and year and product data layers on the row edge. A pivot filter bar displays a channel filter on the page edge.

**Figure 26–15 Sales Pivot Table**

		World		Boston		Total Geography	
		Sales	Units	Sales	Units	Sales	Units
>	2005	8750	35	500	9	9250	44
∇	2006	17500	70	1000	15	18500	85
	Tents	10000	100	250	25	10250	125
	Canoes	7500	40	750	4	8250	44
∇	2007	15000	28	900	11	15900	39
	Canoes	10000	50	500	2	10500	52
	Tents	5000	5	400	20	5400	25
<b>Total Across Years</b>		<b>41250</b>	<b>265</b>	<b>2400</b>	<b>68</b>	<b>43650</b>	<b>333</b>

The pivot table aggregates data based on a CSV file of data shown in Figure 26–16.

**Figure 26–16 Pivot Table CSV Data**

Year	Product	Channel	Geography	Sales	Units
2007	Tents	Direct	World	5000	5
2007	Tents	Indirect	World	20000	200
2007	Tents	Direct	Boston	400	20
2007	Tents	Indirect	Boston	100	50
2007	Canoes	Direct	World	10000	50
2007	Canoes	Direct	Boston	500	2
2007	Canoes	Indirect	World	15000	75
2007	Canoes	Indirect	Boston	1500	8
2006	Tents	Direct	World	10000	100
2006	Tents	Direct	Boston	250	25
2006	Tents	Indirect	World	20000	200
2006	Tents	Indirect	Boston	500	50
2006	Canoes	Direct	World	7500	40
2006	Canoes	Direct	Boston	750	4
2006	Canoes	Indirect	World	15000	80
2006	Canoes	Indirect	Boston	150	8
2005	Tents	Direct	World	5000	50

A Create Pivot Table wizard provides declarative support for data-binding and configuring the pivot table. In the wizard pages you can:

- Specify the initial layout of the pivot table
- Associate and configure a pivot filter bar
- Specify alternative labels for the data layers
- Configure insert or filter drilling
- Define aggregation of data values
- Configure category and data sorting
- View a live data preview of the pivot table

As you lay out the pivot table in the first page of the wizard, corresponding entries are initialized in the following wizard pages. You can use the **Back** and **Next** buttons to adjust the pivot table as you go through the wizard pages. You can also skip configuration options in later wizard pages by clicking **Finish**.

For information about customizing a pivot table after data binding is completed, see the "Using ADF Pivot Table Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 26.4.1 How to Create a Pivot Table

To create a pivot table using a data control, you bind the pivot table component to a collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

**Tip:** You can also create a pivot table by dragging a pivot table component from the Component Palette. This approach allows you the option of designing the pivot table user interface before binding the component to data.

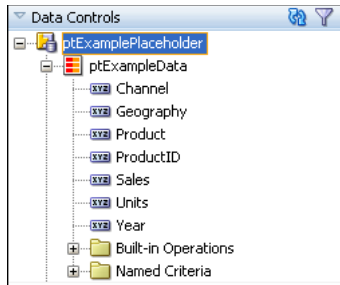

To demonstrate the creation of the sample Sales pivot table shown in [Figure 26–15](#), a placeholder data control was created and data types defined for the CSV file shown in [Figure 26–16](#). For more information, see [Section 29.4, "Using Placeholder Data Controls."](#)

#### To create a databound pivot table:

1. From the Data Controls panel, select a collection.

For example, to create a pivot table that displays sales and units sold by year for each product, you could select the `ptExampleData` defined for the `ptExamplePlaceholder` collection in the Data Controls panel, as shown in [Figure 26–17](#).

**Figure 26–17 Data Collection for Product Sales by Year**

2. Drag the data collection onto a JSF page and, from the context menu, choose **Tables > ADF Pivot Table**.
3. In the Select Display Attributes page of the Create Pivot Table wizard, specify the initial layout of the pivot table by doing the following:
  - a. If you want to associate a pivot filter bar with your pivot table, select **Create Pivot Filter Bar**. Optionally, you can drag attributes from the **Available Attributes** list to the page edge to configure the initial display of filters; otherwise, an empty pivot filter bar is created. If you add a pivot filter bar to a pivot table after data binding, you must edit the page source directly to bind the data model to the pivot filter bar.

---

**Note:** You can add attributes to the page edge without creating a pivot filter bar. The attributes are then available for access programmatically in the data model.

---

- b. For the initial layout, select the attributes for the pivot table’s columns, rows, and data body by dragging the attributes from the **Available Attributes** list to the pivot table layout.

In the pivot table layout, **Data Labels** refers to a layer of the pivot table that identifies the data in the cells (data values), and that appears as header labels in the row, column, or page edge. Labels for attributes that you drag to the data body of the pivot table appear in the data labels layer.

You can drag data labels to any location on the row, column, or page edge. You can also drag attributes to different locations on the same edge or on another edge.

As an alternative to using a drag operation to place or move attributes in the layout, you can right-click the attribute or use **Shift+F10** to display a context menu of options. [Figure 26–18](#) shows the context menu options for the Geography attribute.

**Figure 26–18 Display Attributes Context Menu**

---

**Note:** Potential drill paths between attributes are defined as you lay out multiple attributes on the row, column, and page edges. These drill paths can later be enabled to support pivot table drilling at runtime.

---

- c. If you want to change from the default selection of **Typed Attributes** to **Name-Value Pairs** to configure how data points are stored in a collection, then click the **Change Data Shape** button. A dialog appears that presents you with the following options:

– **Typed Attributes**

Each kind of data point in the collection is represented by a different attribute. This option is also valid when there is only a single kind of data point in the pivot table.

For example, if you have data points for **Estimated Value** and **Actual Value**, then select **Typed Attributes** only if you have one attribute for the estimated value and a second attribute for the actual value.

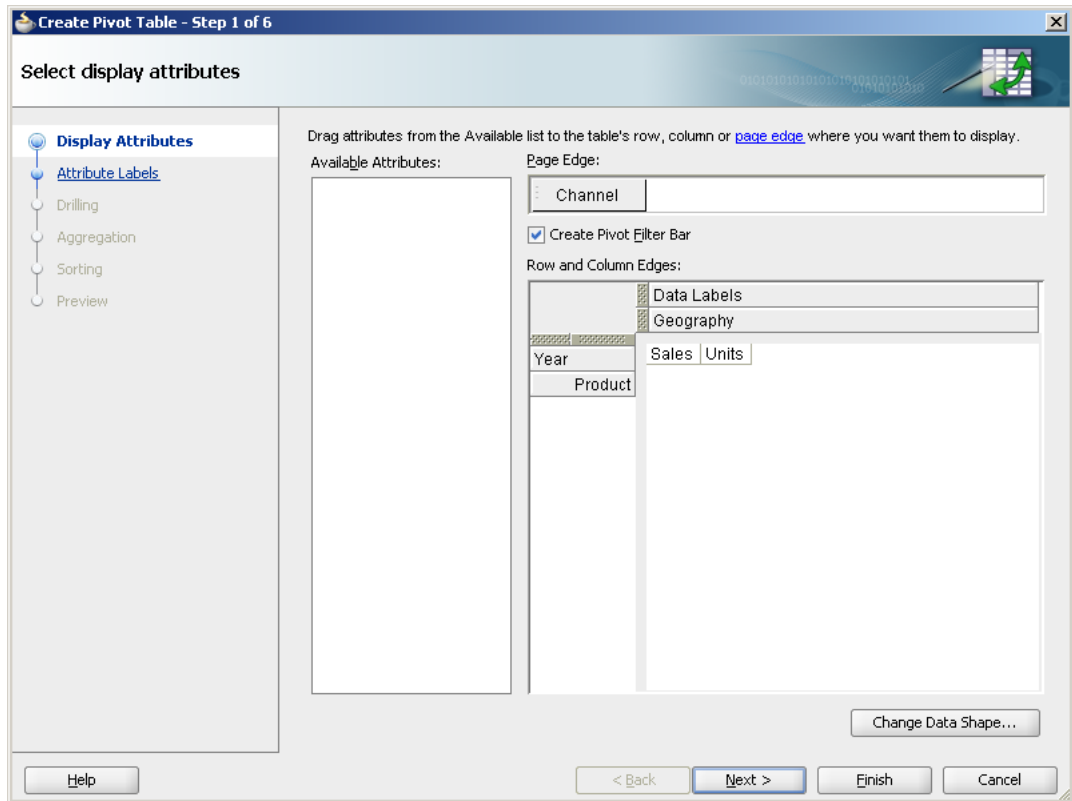

– **Name-Value Pairs**

Indicates that there are multiple kinds of data points, but only a single attribute to designate these types. In this case, the single attribute has values that identify each kind of data type.

For example, the attribute might have the value `EST` for a data point that represents an estimated value and `ACT` for a data point that represents an actual value.

For example, to specify the initial layout of the Sales pivot table shown in [Figure 26–15](#), you would drag the Channel attribute to the page edge, Year and Product attributes to the row edge, Sales and Units attributes to the data body (Data Labels), Geography to the column edge, and select **Create Pivot Filter Bar**, as shown in [Figure 26–19](#).

**Figure 26–19** Select Display Attributes Page of Create Pivot Table Wizard

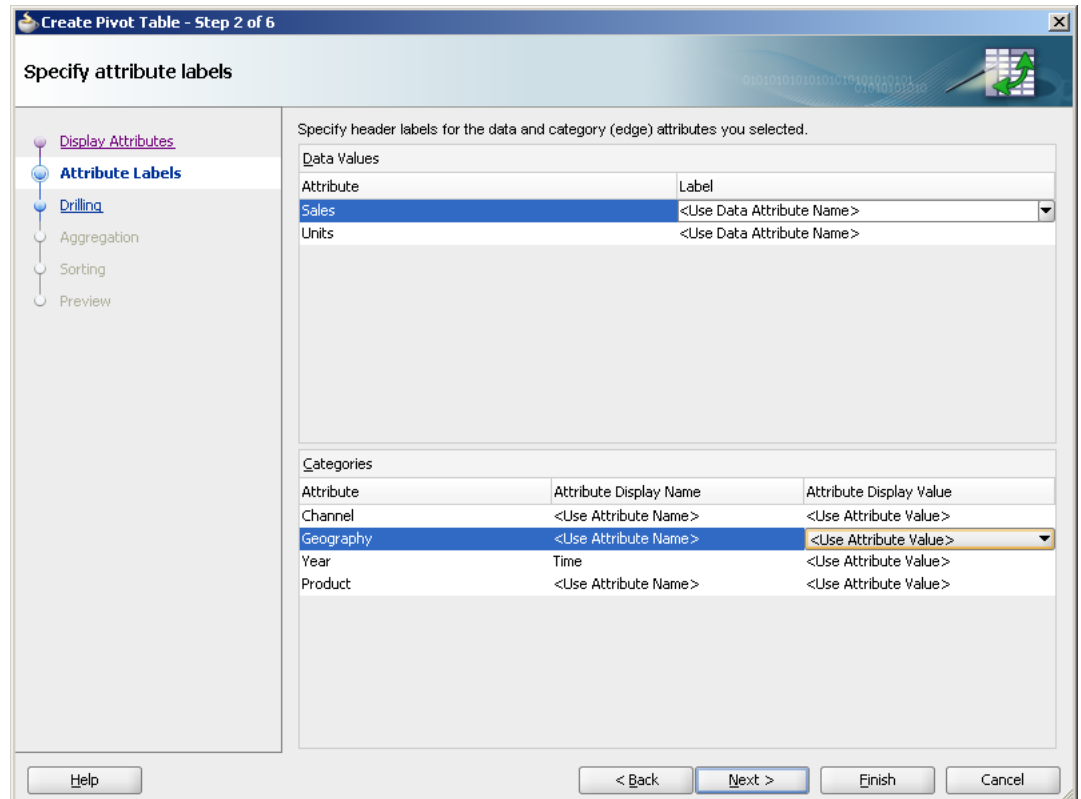

4. If you want to specify alternative labels or values for the attributes laid out in the Select Display Attributes page of the wizard, use the Specify Attribute Labels page to do the following:
  - a. To specify alternative labels for data values in the **Data Values** area, change the default `<Use Data Attribute Name>` text label stamped in the header cell for the attribute at runtime. You can enter the text directly or select `<No Label>` to suppress the header cell, for example, in the case of using a single data value for the pivot table.
  - b. To specify alternative labels for attribute categories in the **Categories** area, change the default `<Use Data Attribute Name>` text label stamped in the header cell for the attribute at runtime by entering the text directly in the **Attribute Display Name** column. The label displays in the pivot handle at runtime.

You can also specify an alternative value for an attribute category by selecting a different attribute in the **Attribute Display Value** column. For example, you might use a `ProductId` attribute in the data collection to lay out the pivot table, but you want the `ProductName` attribute value to improve human readability in the pivot table.

For example, to specify an alternate label for the Year attribute of the Sales pivot table shown in Figure 26–15, you would enter text (Time) in the **Attribute Display Name** field, as shown in Figure 26–20.

**Figure 26–20 Specify Attribute Labels Page of Create Pivot Table Wizard**

5. If you want to expose drill operations in the pivot table at runtime, use the Configure Drilling page of the Create Pivot Table wizard to enable one of the following options:
  - Select **Insert Drilling** to provide a collapsed or expanded view of the relationship between two attributes while preserving the aggregate value of the details in the data layer. At runtime, a drill icon is displayed in the parent attribute display label.

Use **Insert Parent Row** to specify whether the aggregate total for the parent attribute will be displayed before or after the child attributes in the expanded view.

To enable insert drilling you must also:

- Select the drill paths to enable. Drill paths are configured based upon the layout of the attributes in the Select Display Attributes page of the wizard.
- Configure aggregation in the Configure Aggregation page of the wizard.

For example, [Figure 26–21](#) shows a pivot table using insert drilling to expand the view for the Year data layer. The aggregated value of Sales (52,500 in 2007, 544,150 in 2006) and Units (410 in 2007, 507 in 2006) for each year is displayed in the row above the products.

**Figure 26–21 Pivot Table with Insert Drilling Enabled**

	Sales	Units		Sales	Units
TOTAL	128,172	1,135			
▶ 2007	52,500	410			
▶ 2006	54,150				
▶ 2005	21,522				
			TOTAL	128,172	1,135
			▼ 2007	52,500	410
			Tents	25,500	275
			Canoes	27,000	135
			▼ 2006	54,150	507
			Tents	30,750	375
			Canoes	23,400	132
			▶ 2005	21,522	218

- Select **Filter Drilling** to provide a collapsed or expanded view of the relationships between attributes without preserving the aggregate value of the details in the data layer in the collapsed view. At runtime, a drill icon is enabled in the parent attribute display label.

Filter drilling focuses the view on the details of the data layer attribute. For example, [Figure 26–22](#) shows a pivot table using filter drilling to expand the view of the Year (2007) data layer, displaying the total Sales (52,500) and Units (410).

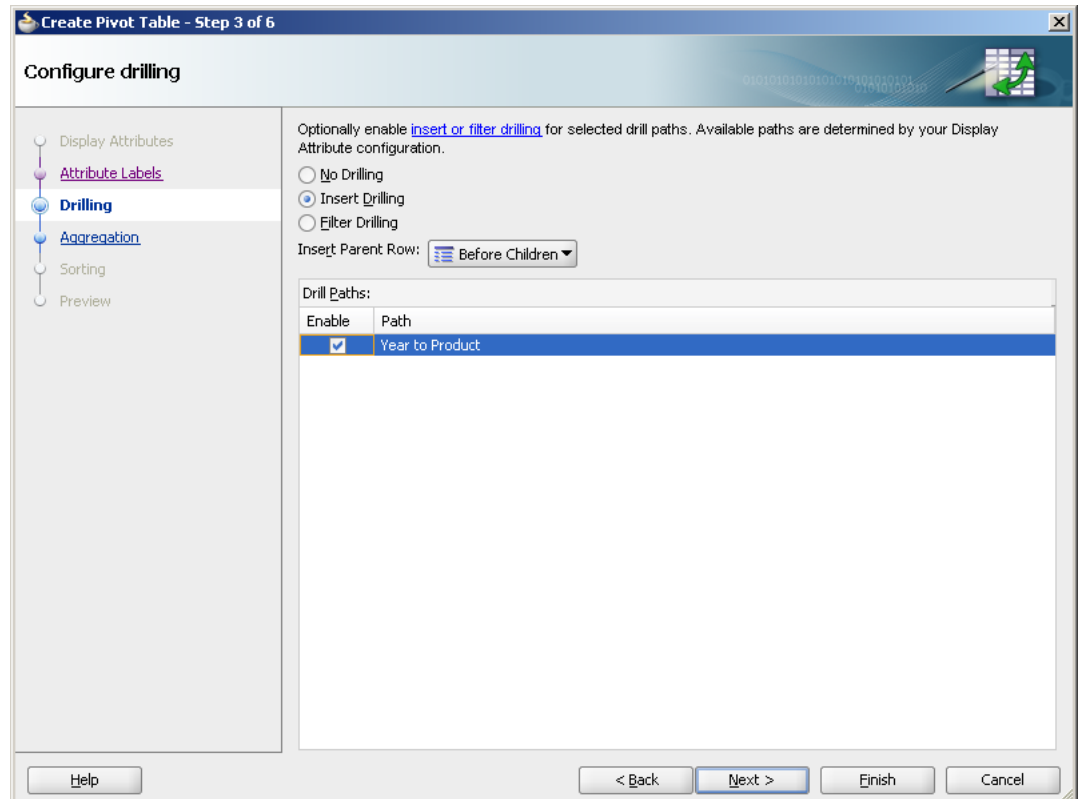

**Figure 26–22 Pivot Table with Filter Drilling Enabled**

	Sales	Units		Sales	Units
TOTAL	128,172	1,135			
▶ 2007	52,500	410			
▶ 2006	54,150				
▶ 2005	21,522				
			TOTAL	52,500	410
			▼ 2007	25,500	275
			Canoes	27,000	135

To enable filter drilling you must select the drill paths to enable. Drill paths are configured based upon the layout of the attributes in the Select Display Attributes page of the wizard.

For example, to enable the insert drilling for the Sales pivot table shown in [Figure 26–15](#), complete the Configure Drilling page of the wizard, as shown in [Figure 26–23](#).

Figure 26–23 Configure Drilling Page of Create Pivot Table Wizard

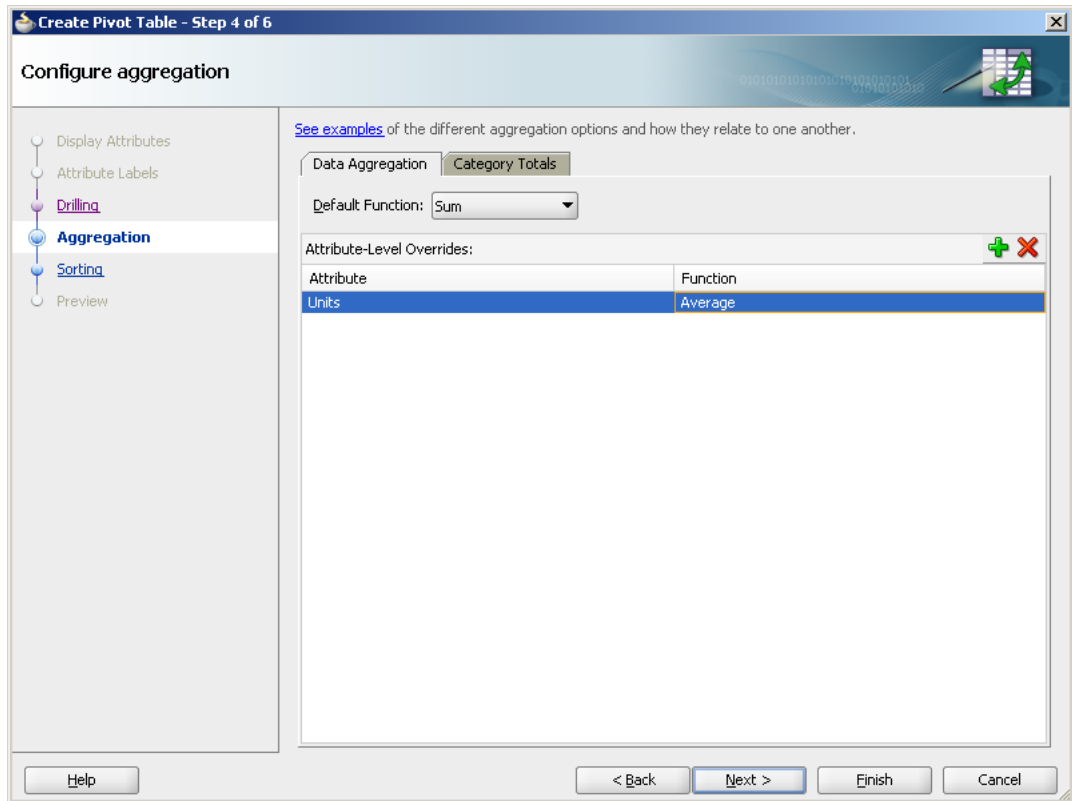

6. If you want to define how data is aggregated in totals and subtotals for the pivot table, use one or both of the Configure Aggregation pages of the Create Pivot Table wizard.

By default, if the attributes displayed in the pivot table do not uniquely identify each row in the data collection, the data from duplicate rows is aggregated to collapse that data into a single pivot table cell. You can also override the default aggregate type for a particular data item.

- If you want to specify how data is aggregated in the pivot table, in the Data Aggregation page, do the following:
  - If you want to change the default aggregation method for handling duplicate rows, use the **Default Function** dropdown list to specify the value. Valid values are Sum, Average, Count, Maximum, Minimum, Standard Deviation, and Variance.
  - If you want to override the default aggregate type for a specific data value, click the **Add** icon to insert a row for the available attributes. Then, in the **Function** column for each attribute, select the mathematical operation that you want to use for the aggregation. Available options are Sum, Average, Count, Maximum, Minimum, Standard Deviation, and Variance. This attribute is useful only when you have multiple data values (such as Sales and Units) bound to your pivot table.

For example, to override the default aggregation type for the Units data value in the Sales pivot table shown in [Figure 26–15](#), use the **Add** icon to add the Units attribute and select Average in the **Function** column in the Data Aggregation page, as shown in [Figure 26–24](#).

**Figure 26–24 Data Aggregation Page of Create Pivot Table Wizard**

- You can also define totals and subtotals for attribute categories added to the column, row, or page edges in the pivot table. In the Categories Totals page, use the **Add** icon to insert each attribute or select **Aggregate All** to add all available attributes, and do the following:
  - In the **Attribute** column, select the attribute that you want to total.
  - In the **Function** column, select the mathematical operation that you want to use for the aggregation. Available options are Sum, Average, Count, Maximum, Minimum, Standard Deviation, and Variance.
  - In the **Insert Total** column, select the value that indicates where you want the aggregate display to appear relative to the item referenced in the **Attribute** column. Valid values are: Before, After, or Replace.
  - In the **Total Label** column, enter the text that you want to use as a label for the aggregation.

---

**Note:** The read-only **Insert Drill Totals** table displays the category totals automatically defined as a consequence of enabling insert drilling on the pivot table.

---

For example, to define totals for the Geography and Year data layers in the Sales pivot table shown in Figure 26–15, select Sum in the **Function** column and After in the **Insert Total** column, and enter text (Total Geography and Total Year) in the **Total Labels** column respectively for each attribute in the Categories Totals page, as shown in Figure 26–25.

In the resulting pivot table at runtime, expanding a particular Year value will automatically preserve the aggregate total computed from its child value based on the layout and configuration of the insert drill option in the previous wizard page.

**Figure 26–25 Categories Totals Page of the Create Pivot Table Wizard**

7. If you want to configure sorting in the pivot table, use one or both of the Configure Sorting pages in the Create Pivot Table wizard.

By default, a pivot table initially sorts data based on values in the outer row data layer. You can specify sort order on the data layer of any row, column, or page edge, called a *category sort*. At runtime, when the data layer is pivoted to a different edge, the specified category sort order is honored.

You cannot specify a category sort of data labels (data values), although you can order the attributes mapped to the data body in the Select Display Attributes page of the wizard. For example, [Figure 26–19](#) shows a pivot table layout with data values for Sales and Units. While you cannot specify a category sort of these measures, you can specify the order in which the values will appear in the data body of the pivot table at runtime, shown in [Figure 26–15](#).

You can also specify an initial sort order of the data values in the data body when the pivot table is rendered, called a *data sort*.

- To configure sorting by category, in the Category Sort page, use the **Add** icon to add the attribute for each row, column, or page edge you wish to configure, and do the following:
  - In the **Sort Attribute** column, accept the default <Use Attribute Value> to specify an alphabetical sort based on the actual values in the pivot table header, or customize the sort order by specifying a data label

value from the dropdown list. For example, if the underlying query included a rank calculation for ranking products by profitability, you could choose to see products ordered by (ProductRank, Descending).

- In the **Initial Sort Order** select the initial direction of the sort. Valid values are ASCENDING or DESCENDING.

For example, [Figure 26–26](#) shows the Category Sort page of the wizard configured to display the Channel data layer descending on the column edge and the Year data layer ascending on the row edge.

**Figure 26–26** Category Sort Page of Create Pivot Table Wizard

At runtime, the pivot table displays as shown in [Figure 26–27](#).

**Figure 26–27** Category Sort Example

	Sales		Units	
	Indirect	Direct	Indirect	Direct
2005	12272	9250	131	87
2006	35650	18500	338	169
2007	36600	15900	333	77

- To configure data sorting, in the Data Sort page, do the following:
  - Select **Sort by Columns** to specify an initial sort order of the data when the pivot table is rendered.
  - In the **Initial Sort Order** dropdown list select the initial direction of the sort. Valid values are ASCENDING and DESCENDING.

- In the **Sequence Nulls** dropdown list, select **First** if you want the null values to appear at the beginning of a sort and select **Last** if you want the null values to appear at the end of the sort.
- In the **Initial Sort Column** table, specify a data value in the **Value** column for the data layer displayed in the **Layer Attribute** column.

For example, [Figure 26–28](#) shows the Data Sort page configured to sort the Channel data layer grouped by Year, based upon Units/World/Canoes data values.

**Figure 26–28 Data Sort Page of the Create Pivot Table Wizard**

At runtime, the pivot table initially renders as shown in [Figure 26–29](#).

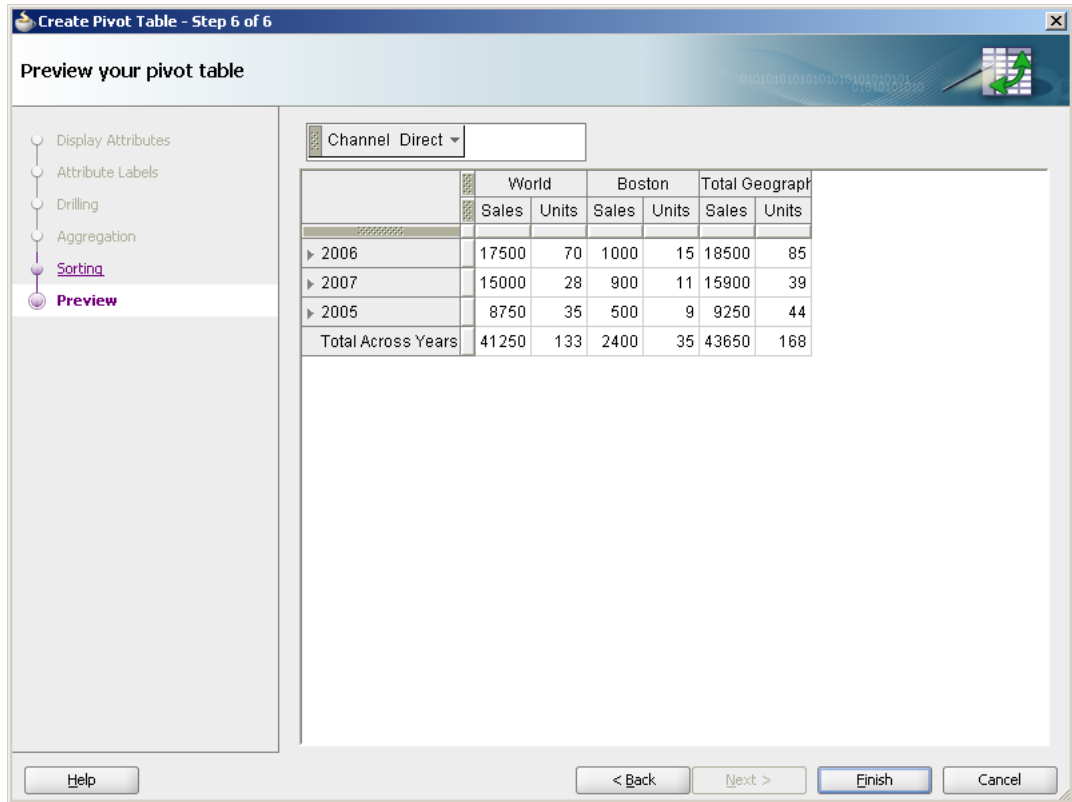

**Figure 26–29 Data Sort Example**

		Units			
		World		Boston	
		Tents	Canoes	Tents	Canoes
2007	Indirect	200	75	50	8
	Direct	5	50	20	2
2006	Indirect	200	80	50	8
	Direct	100	40	25	4
2005	Direct	50	20	15	2
	Indirect	100	10	20	1

8. In the Preview Your Pivot Table page of the Create Pivot Table wizard, see a live preview of the data that will be displayed in the pivot table. The preview does not require that you compile and run code. If you are not satisfied with the preview, alter the settings in the binding wizard pages and return again to the preview page to verify that your data looks as desired.

Figure 26–30 shows the Preview Your Pivot Table page of the wizard for the Sales pivot table shown in Figure 26–15.

**Figure 26–30 Live Data Preview of Pivot Table**

## 26.4.2 What Happens When You Use the Data Controls Panel to Create a Pivot Table

Dropping a pivot table from the Data Controls panel has the following effect:

- Creates the bindings for the pivot table and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

### 26.4.2.1 Bindings for Pivot Tables

When you create a pivot table from the Data Controls panel, the page definition file is updated with the bindings. Example 26–10 shows the row set bindings that were generated for the pivot table that displays product sales and units sold within geography by year. The pivot table data map contains the following elements:

- `<columns>`: Defines each column item
- `<rows>`: Defines each row item in the appropriate sequence
- `<pages>`: Defines the items to be included in the pivot filter bar
- `<aggregatedItems>`: Defines the totals and subtotals of items
- `<hierarchies>`: Defines the potential drill paths between two items
- `<sorts>`: Defines category sorts and the initial sort order of pivot table data

The default data aggregation method for duplicate rows is specified in the <data> element. For more information about aggregating duplicates, see [Section 26.4.3, "What You May Need to Know About Aggregating Attributes in the Pivot Table."](#)

For more information about sorting operations, see [Section 26.4.4, "What You May Need to Know About Specifying an Initial Sort for a Pivot Table."](#)

#### **Example 26–10 Binding XML for the ADF Pivot Table**

```
<pivotTable IterBinding="ptExampleDataIterator" id="ptExampleData"
    xmlns="http://xmlns.oracle.com/adfm/dvt"
    ChangeEventPolicy="ppr">
  <pivotTableDataMap>
    <columns>
      <item value="Geography" itemLabel="Location"/>
      <data aggregateDuplicates="true" defaultAggregateType="SUM">
        <item value="Sales"/>
        <item value="Units" aggregateType="AVERAGE"/>
      </data>
    </columns>
    <rows>
      <item value="Year"/>
    </rows>
    <pages>
      <item value="Channel"/>
    </pages>
    <aggregatedItems>
      <item aggregateLocation="AFTER" aggregateType="SUM" value="Geography"
        aggregateLabel="Total Geography"/>
      <item aggregateLocation="AFTER" aggregateType="SUM" value="Year"
        aggregateLabel="Total Across Years"/>
    </aggregatedItems>
    <drills type="INSERT"/>
    <hierarchies>
      <item value="Year" location="BEFORE">
        <child value="Product" label="Product"/>
      </item>
    </hierarchies>
    <sorts>
      <categorySort item="Channel" direction="DESCENDING"/>
      <categorySort item="Year" direction="ASCENDING"/>
      <qdrSliceSort direction="DESCENDING" edge="rows" grouped="true"
        nullsFirst="true">
        <item name="Geography" value="World"/>
      </qdrSliceSort>
    </sorts>
  </pivotTableDataMap>
</pivotTable>
```

#### **26.4.2.2 Code on the JSF Page for a Pivot Table and Pivot Filter Bar**

When the pivot table is created using the Data Controls panel, the necessary code is added to the page. [Example 26–11](#) shows the code generated on the JSF page for the sales pivot table and associated pivot filter bar.

#### **Example 26–11 XML Code on a JSF Page for the Pivot Table and Pivot Filter Bar**

```
<dvt:pivotFilterBar id="pivotTable1pivotFilterBar"
    value="#{bindings.ptExampleData.pivotFilterBarModel}"
    modelName="pivotTable1Model"/>
<dvt:pivotTable id="pivotTable1"
```

```
value="#{bindings.ptExampleData.pivotTableModel}"
modelName="pivotTable1Model"/>
```

### 26.4.3 What You May Need to Know About Aggregating Attributes in the Pivot Table

If the attributes that you choose to display in your pivot table do not uniquely identify each row in your data collection, then you can aggregate the data from duplicate rows to collapse that data into a single pivot table cell.

For example, if the rows in the data collection shown in [Figure 26–15](#) also contained a store identification, then the data rows from all stores in a given combination of Product, Channel, and Geography would have to be collapsed into a single cell in the pivot table.

The pivot table has the following optional data binding attributes available for controlling the calculation of duplicate data rows:

- `aggregateDuplicates`: Boolean property of the `<data>` element that determines whether special processing is enabled at binding runtime to aggregate data values in duplicate rows. If this attribute is not specified, then `false` is assumed.
- `defaultAggregateType`: String property of the `<data>` element that specifies a default aggregation method for handling duplicates. Valid values are `SUM`, `AVERAGE`, `COUNT`, `MIN`, `MAX`, `STDDEV`, `VARIANCE`. If `aggregateDuplicates` is `true` and `defaultAggregateType` is unspecified, then `SUM` is assumed.
- `aggregateType`: String property of an `<item>` element that enables you to override the default aggregate type for a particular data item. This attribute is useful only when you have multiple data values (such as Sales and Units) bound to your pivot table.

#### 26.4.3.1 Default Aggregation of Duplicate Data Rows

By default, the pivot table uses the `SUM` operation to aggregate the data values of duplicate data rows in a data collection to produce a single cell value in the pivot table. This means that the `aggregateDuplicates` attribute is set to `true` and the `defaultAggregateType` is assumed to be `SUM`.

The `<data>` element shown in [Example 26–10](#) is an example of such default aggregation.

#### 26.4.3.2 Custom Aggregation of Duplicate Rows

If you want the pivot table to use a different mathematical operation to aggregate the data values of duplicate rows, then you set the `defaultAggregateType` to the desired operation.

[Example 26–12](#) shows a data element with the `defaultAggregateType` set to `SUM`. This operation would be appropriate if you want to see the total of sales from all stores for each unique combination of Product, Channel, and State.

#### **Example 26–12** Binding XML for Custom Aggregation of Duplicate Rows

```
<pivotTable IterBinding="SalesPivotTable1Iterator" id="SalesPivotTable11"
  xmlns="http://xmlns.oracle.com/adfm/dvt">
  <pivotTableDataMap>
    <columns>
      <data aggregateDuplicates="true" defaultAggregateType="SUM">
        <item value="Sales"/>
      </data>
    </columns>
  </pivotTableDataMap>
</pivotTable>
```

```

        <item value="Geography" />
    </columns>
    <rows>
        <item value="Channel" />
        <item value="Product" />
    </rows>
    <aggregatedItems>
        <item aggregateLocation="After" aggregateType="AVERAGE"
            value="Product" aggregateLabel="Average" />
    </aggregatedItems>
</pivotTableDataMap>
</pivotTable>

```

If you have a pivot table with multiple data values (such as sales and the average size of a store in square feet) and you want to sum the sales data values in duplicate rows, but you want to average the square feet data values, then do the following:

- On the `<data>` element, set the `defaultAggregateType` to `SUM`.
- On the `<item>` element for the square feet attribute, set the `aggregateType` to `AVERAGE`.

[Example 26–13](#) shows the `<columns>` elements wrapped by a `PivotTableDataMap` element. The `<data>` element contains the default attributes for aggregation. These apply to all data items that do not have a specific custom `aggregateType` attribute specified.

#### **Example 26–13 Data and Item Elements for Multiple Custom Aggregations**

```

<columns>
    <data aggregateDuplicates="true" defaultAggregateType="SUM">
        <item value="Sales" label="Total Sales" />
        <item value="StoreSqFeet" label="Avg Sq Feet" aggregateType="AVERAGE" />
    </data>
    <item value="State" />
</columns>

```

### 26.4.4 What You May Need to Know About Specifying an Initial Sort for a Pivot Table

By default, a pivot table initially sorts data based on values in the outer row data layer. You can specify sort order on the data layer of any row, column, or page item, called a *category sort*. At runtime, when the data layer is pivoted to a different edge, the specified category sort order is honored. Insert a `categorySort` element inside the `sorts` element and set values for the attributes as described in [Table 26–2](#).

**Table 26–2 Attribute Values for categorySort Element**

Attribute	Description
item	Specify the column, row, or page item for which you are setting the category sort. A value for this attribute is required.
direction	Specify the initial direction of the sort. Valid values are <code>ASCENDING</code> and <code>DESCENDING</code> . A value for this attribute is required.

You can also specify the initial sort order of the data values in the data body when the pivot table is rendered, called a *data sort*. You can change the default behavior by inserting a `sorts` element inside the `pivotTableDataMap` element of a pivot table binding in the page definition file. Insert a `qdrSliceSort` element inside the `sorts` element and set values for the attributes as described in [Table 26–3](#).

**Table 26–3 Attribute Values for `qdrSliceSort` Element**

Attribute	Description
<code>direction</code>	Specify the initial direction of the sort. Valid values are <code>ASCENDING</code> and <code>DESCENDING</code> . A value for this attribute is required.
<code>edge</code>	Specify <code>columns</code> or <code>rows</code> to determine which edge sorts data. A value for this attribute is required.
<code>grouped</code>	Specify <code>true</code> if you want to sort slices within their parent or <code>false</code> if you want to sort across the entire edge. A value for this attribute is optional. The default value is <code>false</code> .
<code>nullsFirst</code>	Specify <code>true</code> if you want null values to appear at the beginning of a sort and <code>false</code> if you want null values to appear at the end of a sort. A value for this attribute is optional.

Insert one or more `item` tags inside the `qdrSliceSort` tag. An `item` tag specifies the slice on the opposite edge from which the values to be sorted should be obtained. Set values for the attributes as described in [Table 26–4](#).

**Table 26–4 Attribute Values for `item` Tag**

Attribute	Description
<code>name</code>	Specify the name of the layer to sort on. Typically, this is the column name in the row set. Specify <code>DataLayer</code> if you want to specify the layer that contains the data columns in a row set (for example, <code>Sales</code> , <code>Costs</code> , and so on).
<code>value</code>	Specify the value of the specified layer on the desired slice.

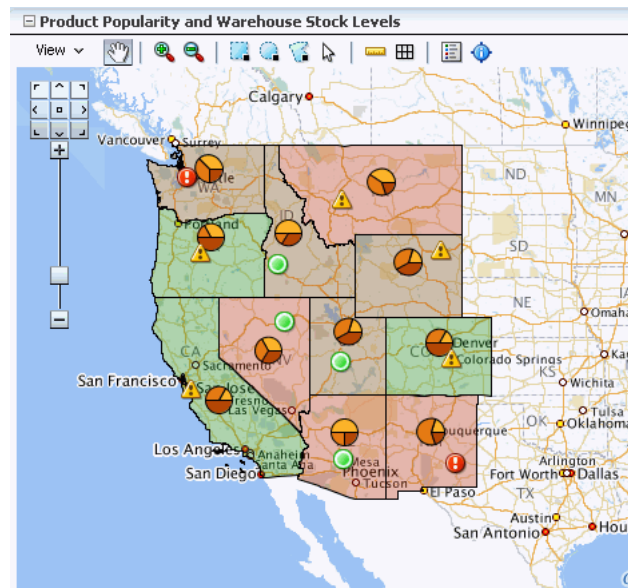

## 26.5 Creating Databound Geographic Maps

An ADF geographic map is an ADF Data Visualization component that provides the functionality of Oracle Spatial within Oracle ADF. This component allows users to represent business data on a geographic map and to superimpose multiple layers of information (known as *themes*) on a single map. These layers can be represented as any of the following themes: bar graph, pie graph, color, point, and predefined theme.

[Figure 26–31](#) shows a geographic map component that uses a base map for a region in the United States with the following themes:

- **Color theme:** For the selected product, this theme colors states based on product popularity. The colors range from green (which represents the highest popularity for that product) to red (which represents the lowest popularity for that product).
- **Pie graph theme:** This theme displays a pie graph in each state to indicate the popular product categories in that state. In this example, the pie graph shows the following product categories as pie slices: Media, Office, and Electronics.
- **Point theme:** This theme identifies warehouses as points. For each point, it displays an icon to indicate the inventory level at that warehouse for the selected product. A separate icon is displayed for each of the following ranges of inventory: low inventory, medium inventory, and high inventory.

**Figure 26–31 Geographic Map with Color Theme, Pie Graph Theme, and Point Theme for a Product**

A geographic map component differs from other ADF Data Visualization components as you do not need to put multiple maps on a page to display multiple sets of data. This contrasts to components such as graphs where you can put multiple graphs on a page. Instead, you show how multiple sets of data relate to each other spatially or, for a specific point, you display different attributes layered in separate themes.

The geographic map component itself is not bound to data. However, each map *theme* has its own data bindings.

A base map forms the background on which the ADF geographic map component layers the themes that developers create.

In Oracle Spatial, administrators create base maps that consist of one or more themes. The administrator controls the visibility of the base map themes. When you zoom in and out on a base map, various base map themes are hidden or displayed. At the ADF geographic map component level, you cannot use zoom factor to control the display of the themes created by the administrator on the base map.

When you overlay themes on the ADF geographic map, you can control the visibility of your themes by setting the `maxZoom` and `minZoom` attributes of the tags related to these themes. At runtime, you can also hide or display your custom themes by using the View menu of the Map toolbar or by using other ADF components that you create on the page.

For information about customizing a geographic map after data-binding is completed, see the "Using ADF Map Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 26.5.1 How to Create a Geographic Map with a Point Theme

To create a geographic map, you first configure the map (that is, select a base map and provide URLs for processing) and then bind a theme of the map to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel for the theme that you want to create.

When you create a map point theme, you have the option of customizing the style of the points that appear in the map. For each different point style, you can use a `mapPointStyleItem` tag.

**To create a geographic map with a databound point theme:**

1. From the Data Controls panel, select a collection.

Figure 26–32 shows an example where you could select the `WarehouseStockLevelsByProduct1` collection in the Data Controls panel to create a geographic map with a point theme that displays an image to represent the quantity on hand for each warehouse point.

**Figure 26–32 Data Collection for Warehouse Stock Levels**

2. Drag the collection onto a JSF page and, from the context menu, choose **Geographic Map > Map and Point Theme**.
3. If you have not yet configured a map on the page, then in the ensuing Create Geographic Map dialog, click the **New** icon to display the Create Geographic Map Configuration dialog and do the following:
  - a. In the **Id** field enter the unique identifier for the map configuration.
  - b. In the **MapViewer URL** field enter the URL for the Oracle Application Server MapViewer Service.
  - c. In the **Geocoder URL** field select the URL for the Geocoder Web service that converts street addresses into latitude and longitude coordinates for mapping.

---

**Note:** The Geocoder URL is needed only if you do *not* already have longitude and latitude information for addresses.

---

- d. Click **OK** to dismiss the dialog and return to the Create Geographic Map dialog.
4. In the Maps page, you select the base map for the geographic map component and provide other settings to use with the map by doing the following:
  - a. From the **Data Source** list select the collection of maps from which you will choose a base map.
  - b. From the **Base Map** list select the map that will serve as the background for the geographic map component.
  - c. To specify values for the **StartingX** field and the **StartingY** field click on the image of the map to center it within the Preview window.  
 You can use the arrows in the map navigator in the upper left-hand corner to move the map in the appropriate direction.
  - d. Optionally use the sliding arrow in the Preview window to adjust the zoom factor of the map.
  - e. Click **OK** to dismiss the dialog and to display the Create Point Map Theme dialog.
5. In the **Theme Id** field enter the unique identifier for the point map theme.
6. In the **Location** section, specify whether the point location is to be specified by a pair of  $x$  and  $y$  coordinates (longitude and latitude) or as an address.

The choice you select for location will determine which controls appear in the Location section.

**Tip:** Using  $x$  and  $y$  coordinates is a more efficient way to present data on the map rather than using the Address controls, which must be converted by a Geocoder to  $x$  and  $y$  coordinates. If the data collection has more than 100 rows, then to ensure adequate performance, use  $x$  and  $y$  coordinates.

7. For the  $x$  and  $y$  point location, you select the data that corresponds to the following items:
  - X (Longitude): The horizontal location of the point on the map.
  - Y (Latitude): The vertical location of the point on the map.
  - Label: The labels for the points in the top section of the information window, which is displayed when you click a point.
8. In the Point Data section, provide the following information that identifies the data associated with the point, its label, and optionally the style for the point:
  - In the **Data** field, select the data column that is associated with the point, such as `QuantityOnHand`.
  - In the **Label** field, enter the text that will appear in the information window before the data value when you click a point.
  - Optionally, in the **Category** field, select a data column to use for finding the appropriate style for a point. If you select a value for Category, that value is stored in the binding for this point theme and then matched against the `itemValue` attribute of the `mapPointStyleItem` tags that you create for this point theme.

---

---

**Note:** If your data does not have a column that you want to use as a category for finding the style of a point, you can also use `mapPointStyleItem` tags to define styles related to data ranges (such as high, medium, and low) that are matched to the values in the column that you select in the Data field. For more information, see [Section 26.5.2, "How to Create Point Style Items for a Point Theme"](#).

---

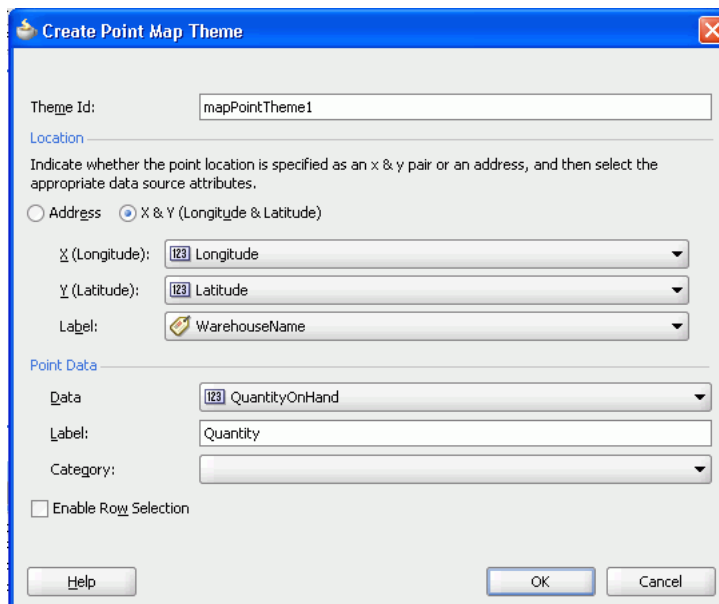

---

9. Select the **Enable Row Selection** field only if you want to enable the selection of rows in a related component. You select this option when the page contains a component that is linked to a data collection which is related to the geographic map that you are creating.
10. Click **OK**.

Figure 26–33 shows the Create Point Map Theme dialog for a geographic map with a point theme that displays an image representing quantity on hand for each warehouse point.

**Figure 26–33 Create Point Map Theme Dialog for Warehouse Inventory Levels**

## 26.5.2 How to Create Point Style Items for a Point Theme

There are a variety of options available for creating point style items for use in a given map point theme. These are:

- A single image for all data points
- Separate images for each data point category
- Images that represent low, medium, and high data value ranges

After you create the data binding for a map point theme, you have the option of selecting a single built-in image that should be used for all points in that map theme. In the Property Inspector, you can make this selection in the `builtInImage` attribute of the `mapPointTheme` tag. The default value for this attribute is `OrangeBall`.

Alternatively, if you specify a value for `Category` in the Create Point Map Theme dialog, then you should also create a set of point style items to determine a separate image that represents data points in each category. In this case, you do not use the minimum and maximum values in the point style item tags. Instead, you set the `itemValue` attribute of point style item tags to a value that matches entries in the data column that you specified for `Category`.

In a point theme for a geographic map, if you do not specify a value for `Category`, you can still use the `mapPointStyleItem` child tags of the `mapPointTheme` tag to specify ranges of values (such as low, medium, and high) and the images that are to represent these ranges. If you do this, then each point will be represented by an image that identifies the range in which the data value for that point falls.

The following procedure assumes that you have already created a geographic map with a point theme.

**To add point style items to a map point theme to represent low, medium, and high data value ranges:**

1. In the Structure window, right-click the `dvt:mapPointTheme` tag and choose **Insert inside the dvt:mapPointTheme > Point Style Item**.
2. In the Point Style Item Property Inspector, set values as described [Table 26–5, "Properties for Point Style Item"](#).

**Table 26–5 Properties for Point Style Item**

For this property	Set this value
<code>Id</code>	Specify a unique ID for the point style item.
<code>MinValue</code>	Specify the minimum value in a data range that you define.
<code>MaxValue</code>	Specify the maximum value in a data range that you define.
<code>ShortLabel</code>	Specify text to appear when a user hovers over the point item. For example, if you define a point item for low inventory, then enter <code>Low Inventory</code> as the value for this property.
<code>ImageUrl</code>	Specify the URL to the image file or select it from the dropdown list. At runtime, the image you specify appears on the map to represent the data range identified by the <b>MinValue</b> and <b>MaxValue</b> properties.  Alternatively, you can select one of a number of predefined images referenced by the <b>BuiltInImage</b> dropdown list that appears in the <b>Other</b> section.
<code>HoverImageUrl</code>	Specify the URL to the image file or select it from the dropdown list. At runtime, the image you specify appears when a user hovers over the point item.
<code>SelectedImageUrl</code>	Specify the URL to the image file or select it from the dropdown list. At runtime, the image you specify appears when a user selects the point item.

3. If you defined a data value range for a low data value range in Steps 1 and 2, then repeat Steps 1 and 2 to define medium and high data value ranges with appropriate values.

---

---

**Note:** The use of `mapPointStyleItem` child tags to customize the style of points is a declarative approach that lets you provide custom point images. For information about using a callback to provide not only custom images but also custom HTML, see [Section 26.5.4, "What You May Need to Know About Adding Custom Point Style Items to a Map Point Theme"](#).

---

---

### 26.5.3 What Happens When You Create a Geographic Map with a Point Theme

Dropping a geographic map and a point theme (which in this case would be the initial theme added to the map) from the Data Controls panel has the following effect:

- Creates the bindings for the point theme and adds the bindings to the page definition file
- Adds the necessary tags to the JSF page for the geographic map component
- Adds the necessary point theme tags to the JSF page within the map XML

#### 26.5.3.1 Binding XML for a Point Theme

[Example 26–14](#) shows the row set bindings that were generated for the point theme of the geographic map.

##### **Example 26–14 Point Theme Binding XML**

```
<mapTheme iterBinding="WarehouseStockLevelsByProduct1Iterator"
  id="WarehouseStockLevelsByProduct1"
  xmlns="http://xmlns.oracle.com/adfm/dvt">
  <mapThemeDataMap mapThemeType="point">
    <item type="data" value="QuantityOnHand" label="Product Quantity"/>
    <item type="lat_long" latitude="Latitude"
      longitude="Longitude" label="WarehouseName"/>
  </mapThemeDataMap>
</mapTheme>
```

#### 26.5.3.2 XML Code on the JSF Page for a Geographic Map and Point Theme

[Example 26–15](#) shows the XML code generated on the JSF page for the geographic map and its point theme. Notice the code for the three kinds of point style settings based on data value.

The initial point style setting (`ps0`) applies to values that do not exceed 500. This point style displays an image for very low inventory and provides corresponding tooltip information.

The second point style setting (`ps1`) applies to values between 500 and 1000. This point style displays an image for low inventory and provides corresponding tooltip information.

The final point style setting (`ps2`) applies to values between 1000 and 1600. This point style displays an image for high inventory and provides corresponding tooltip information.

##### **Example 26–15 Geographic Map and Point Theme XML Code on the JSF Page**

```
<dvt:map id="map1"
  mapServerConfigId="mapConfig1"
  inlineStyle="width:850px;height:490px"
  startingX="-96.0"
```

```

baseMapName="ELOCATION_MERCATOR.WORLD_MAP"
startingY="37.0" zoomBarPosition="WEST"
showScaleBar="false"
partialTriggers="go pointTheme pieTheme colorTheme" mapZoom="3">
  <dvt:mapPointTheme id="mapPointTheme1"
    shortLabel="Warehouse Stock Levels"
    selectionListener="#{MapBean.processSelection}"
    value="#{bindings.WarehouseStockLevelsByProduct1.geoMapModel}"
    rendered="#{AppState.showPointTheme}">
    <dvt:mapPointStyleItem id="ps0"
      minValue="0"
      maxValue="500"
      imageURL="/images/low.png"
      selectedImageURL="/images/lowSelected.png"
      shortLabel="Very Low Inventory"/>
    <dvt:mapPointStyleItem id="ps1"
      minValue="500"
      maxValue="1000"
      imageURL="/images/medium.png"
      selectedImageURL="/images/mediumSelected.png"
      shortLabel="Low Inventory"/>
    <dvt:mapPointStyleItem id="ps2"
      minValue="1000"
      maxValue="1600"
      imageURL="/images/regularGreen.png"
      selectedImageURL="/images/regularGreenSelected.png"
      shortLabel="High Inventory"/>
  </dvt:mapPointTheme>
</dvt:map>

```

## 26.5.4 What You May Need to Know About Adding Custom Point Style Items to a Map Point Theme

If you want to provide custom HTML as well as custom images for map points, then you can use the `customPointCallback` attribute of the `dvt:mapPointTheme` tag to accomplish this customization.

---

---

**Important:** If you set the `customPointCallback` attribute for a map point theme, the map ignores any `dvt:mapPointStyleItem` child tags because the callback overrides these tags.

---

---

### To use a callback to customize the style of map points:

1. Write a method in Java to perform the desired point customization.
2. Store this method in a managed bean for the map.

For more information about managed beans, see the "Creating and Using Managed Beans" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

3. After you finish data-binding the map point theme, use the Property Inspector to specify a reference to the managed bean method in the `customPointCallback` attribute of the `dvt:mapPointTheme` tag.

For example, if the managed bean is named `MapSampleBean` and the method is named `setCustomPointStyle`, then the reference becomes

```
#{mapSampleBean.setCustomPointStyle}
```

## 26.5.5 How to Add a Databound Color Theme to a Geographic Map

When you create a geographic map, you can choose to create themes (point, color, and graph) in any sequence that you wish.

The following procedure assumes that a geographic map has already been configured and, therefore, the map component does not display the dialog for configuring the map. Instead, only the dialog for creating the color theme appears.

### To add a databound color theme to a geographic map:

1. From the Data Controls panel, select a collection.

Figure 26–34 shows an example where you could select the `ProductPopularity1` collection in the Data Controls panel to create a color map theme that shows product popularity by the color of regions (for example, states).

**Figure 26–34** Data Collection for Product Popularity by State

2. Drag the collection onto a JSF page which already contains a geographic map component and, from the context menu, choose **Geographic Map > Color Theme**.
3. In the ensuing Create Color Map Theme dialog, enter a unique identifier for the map theme in the **Id** field.
4. In the **Base Map Theme** section, identify the base map color theme to use for the geographic map by doing the following:
  - a. In the **Name** field, select the name of the base map theme.
  - b. For **Location**, select the location column in the data collection that should be matched to the location column in the base map theme that you selected.
  - c. Optionally, click **View Sample Theme Data** to display the Sample Theme Data dialog, in which you can examine the first several rows of the actual data so that you can identify the appropriate location column.

For example, if you want to view the data for a region that consists of states in the United States map, you might select `MAP_STATES_NAME` as shown in Figure 26–35.

---

**Note:** It is possible for an administrator of Oracle Spatial to disable the display of sample data. If this button is not available, then consult the administrator for guidance.

---

**Figure 26–35 Sample Theme Data for Regions or States**

POLYGON_ID	AREA_ID	POLYGON_NAME	NAME_LANGUAGE	FEATURE_TYPE	GEOMETRY	PARTITION	COLOR
42927269	21559026	Queensland	ENG	STATE		2	AUS
42927271	21559026	Queensland	ENG	STATE		2	AUS
42927274	21559026	Queensland	ENG	STATE		2	AUS
42927278	21559026	Queensland	ENG	STATE		2	AUS
43194367	21555335	New South ...	ENG	STATE		1	AUS

Only the first 5 rows are displayed.

5. In the **Appearance** section, specify the look of the color theme as follows:
  - a. In **Data Bucket Count**, enter the number of groups for the data in this geographic map. Each group is coded with a color. After specifying this number, you can provide colors for the minimum value and the maximum value. The colors for the other values are chosen automatically using an RGB algorithm.
  - b. In **Minimum Value Color**, select the color for the minimum value.
  - c. In **Maximum Value Color**, select the color for the maximum value.

---

**Note:** If you want to specify an exact color for each data bucket, see [Section 26.5.7, "What You May Need to Know About Customizing Colors in a Map Color Theme"](#).

---

6. In the **Data** section, provide the following information about the data in the collection:
  - a. For **Location**, select the column in the data collection that should match the values in the location column that you selected from the base map theme.
  - b. For **Location Label**, select the column in the data collection that contains the labels associated with the values in the location column. These labels are shown in the information window that is displayed when you click or hover over a color.
  - c. For **Data Label**, enter the label to use for describing the data in the information window and the tooltip that is displayed when you click or hover over a color. For example, the information window might include a label before the data value, such as **Product Popularity**.
7. Use **Enable Row Selection** only if you want to enable master-detail relationships. This is useful when the data collection for the map theme is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page.

Figure 26–36 shows the Create Color Map Theme dialog for the product popularity by state color theme.

**Figure 26–36 Create Color Map Theme for Product Popularity By State**

## 26.5.6 What Happens When You Add a Color Theme to a Geographic Map

Dropping a color theme from the Data Controls panel to an existing geographic map has the following effect:

- Creates the bindings for the color theme and adds the bindings to the page definition file
- Adds the necessary color theme tags to the JSF page within the map XML

### 26.5.6.1 Binding XML for a Color Theme

[Example 26–16](#) shows the row set bindings that were generated for the color theme of the geographic map.

**Example 26–16 Color Theme Binding XML**

```
<mapTheme iterBinding="ProductPopularity1Iterator" id="ProductPopularity1"
  xmlns="http://xmlns.oracle.com/adfm/dvt">
  <mapThemeDataMap mapThemeType="color">
    <item type="location" value="StateProvince" label="StateProvince"/>
    <item type="data" value="CountAddressesStateProvince"
      label="Popularity"/>
  </mapThemeDataMap>
</mapTheme>
```

### 26.5.6.2 XML Code on the JSF Page for a Color Theme

[Example 26–17](#) shows the XML code generated on the JSF page for a color theme that represents product popularity in different states on the United States map.

**Example 26–17 Color Theme XML Code on the JSF Page**

```
<dvt:mapColorTheme id="mapColorTheme1"
  themeName="MAP_STATES_NAME"
  shortLabel="Product Popularity"
  value="{bindings.ProductPopularity1.geoMapModel}"
  locationColumn="POLYGON_NAME"
```

```
minColor="#ff0000"
maxColor="#008200"
bucketCount="5"/>
```

## 26.5.7 What You May Need to Know About Customizing Colors in a Map Color Theme

While you are data-binding a map color theme, you can specify only a minimum color and a maximum color for the data buckets. The map uses an algorithm to determine the colors of the buckets between the minimum and maximum. However, after the data-binding is finished, you have the option of specifying the exact color to be used for each data bucket.

In the Object Inspector, for the `dvt:mapColorTheme` tag you can use the `colorList` attribute to specify the color for each bucket. You can either bind a color array to this attribute or you can specify a string of colors using a semicolon separator.

For example, if the value of this attributes is set to: `#ff0000;#00ff00;#0000ff`, then the color of the first bucket is red, the second bucket is green, and the third bucket is blue.

## 26.5.8 How to Add a Databound Pie Graph Theme to a Geographic Map

When you create a geographic map, you can choose to create themes (point, color, and graph) in any sequence that you wish. However, only one graph theme (pie or bar) can be visible at a time on the ADF geographic map component.

The following procedure assumes that a geographic map has already been configured and, therefore, the map component does not display the dialog for configuring the map. Instead, only the dialog for creating the pie graph theme appears.

### To add a databound pie graph theme to a geographic map:

1. From the Data Controls panel, select a collection.

[Figure 26–37](#) shows an example where you could select the `PopularCategories1` collection to create a pie bar theme in an existing geographic map component to represent the popular product categories within a state.

**Figure 26–37** Data Collection for Popular Product Categories by State

2. Drag the collection onto a JSF page and, from the context menu, choose **Create > Pie Graph Theme**.

3. In the ensuing Create Pie Graph Theme Binding dialog, do the following to identify the new theme and the base map theme elements that you want to work with:
  - a. For **Theme Id**, enter a unique identifier for the pie graph theme that you are creating.
  - b. In the **Base Map Theme** section, select the name of the base map and the region in which you want to place the pie graphs.
4. In the **Appearance** section, under **Data**, do the following:
  - a. For **Location**, select the location column in the data collection that should be matched to the location column in the base map theme that you selected.  
 If needed, click **View Sample Theme Data** to examine the first several rows of the actual data so that you can identify the appropriate location column.
  - b. For **Location Label**, select the column in the data collection that contains labels for the locations in the data collection.
  - c. In the grid for **Series Attributes**, enter each attribute that contains values that you want represented in the pie graph that you are creating.
  - d. Beside each series attribute, enter text that should be used as a label for the data values in the series attribute.
5. Select **Enable Row Selection** only if you want to enable the selection of rows in a related component. You select this component when the page contains a component that is linked to a data collection that is related to the geographic map that you are creating.
6. Click **OK**.

Figure 26–38 shows the completed Create Pie Graph Map Theme dialog for the product popularity by state pie graph theme.

**Figure 26–38 Create Pie Graph Map Theme for Product Popularity by State**

## 26.5.9 What Happens When You Add a Pie Graph Theme to a Geographic Map

Dropping a pie graph theme from the Data Controls panel to an existing geographic map has the following effect:

- Creates the bindings for the pie graph theme and adds the bindings to the page definition file
- Adds the necessary pie graph theme code to the JSF page within the map XML

### 26.5.9.1 Binding XML for a Pie Graph Theme

[Example 26–18](#) shows the row set bindings that were generated for the pie graph theme of the geographic map.

#### **Example 26–18 Pie Graph Theme Binding XML**

```
<mapTheme iterBinding="PopularCategoriesByState1Iterator"
  id="PopularCategoriesByState1"
  xmlns="http://xmlns.oracle.com/adfm/dvt">
  <mapThemeDataMap mapThemeType="pieChart">
    <item type="location" value="StateProvince" label="StateProvince"/>
    <item type="data" value="AudioVideo" label="Audio Video"/>
    <item type="data" value="CellPhones" label="Cell Phones"/>
    <item type="data" value="Games" label="Games"/>
  </mapThemeDataMap>
</mapTheme>
```

### 26.5.9.2 Code on the JSF Page for a Pie Graph Theme

[Example 26–19](#) shows the XML code generated on the JSF page for the pie graph theme of the geographic map.

#### **Example 26–19 Pie Graph Theme Code on the JSF Page**

```
<dvt:mapPieGraphTheme id="mapPieGraphTheme1"
  themeName="MAP_STATES_NAME"
  shortLabel="Popular Categories"
  pieRadius="10"
  styleName="comet"
  value="#{bindings.PopularCategoriesByState1.geoMapModel}"
  locationColumn="POLYGON_ID"/>
```

## 26.6 Creating Databound Thematic Maps

A thematic map represents business data as patterns in stylized areas or associated markers and does not require a connection to a remote Oracle MapViewer service. Thematic maps focus on data without the geographic details in a geographic map.

The thematic map is packaged with prebuilt base maps including a USA base map, a world base map, and base maps for continents and regions of the world including EMEA and APAC. Each base map includes several sets of regions and one fixed set of cities. A set of regions or cities is referred to as a layer. Each layer can be bound to a data collection and stylized to represent the data with color and pattern fills, or a data marker, or both. At runtime, only one map layer and its associated data can be displayed at a time, unless the thematic map has been enabled for drilling.

The data displayed in a thematic map is based on data collections. Using ADF data controls, JDeveloper makes data binding a declarative task. You drag and drop a collection from the Data Controls panel onto the JSF page and use a Component

Gallery to select the base map and map layers on which to display the data. You can then use a Layer Browser and binding dialogs to bind data collection attributes to the data layers in the thematic map.

Stamping is used to associate map layers with a row of data in a data collection. Using stamping, each row of data in the data model can be identified by a style, for example a color or pattern; a marker, for example a circle or square; or an image. When you use stamping, child components are not created for every area, marker, or image in a thematic map. Rather, the content of the component is repeatedly rendered, or stamped, once per data attribute, such as the rows in a data collection.

Figure 26–39 shows a thematic map using a USA base map with a states map layer to display customer and warehouse locations, and the product inventory levels for states with warehouses. The example illustrates thematic map default features including a data bound legend and labels associated with the styled points and areas when you use the Data Controls panel and thematic map binding dialogs.

**Figure 26–39 Thematic Map Displaying Customer and Warehouse Locations**

For detailed information about thematic map end user and presentation features, use cases, tag structure, and adding special features to thematic maps, see the "Using Thematic Map Components" section in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 26.6.1 How to Create a Thematic Map Using ADF Data Controls

The `thematicMap` component uses a model to access the data in the underlying list. The specific model class is `oracle.adf.view.rich.model.CollectionModel`. You can also use other model instances, for example, `java.util.List`, `java.util.Array`, and `javax.faces.model.DataModel`. The data layer will automatically convert the instance into a `CollectionModel`.

**Before you begin:**

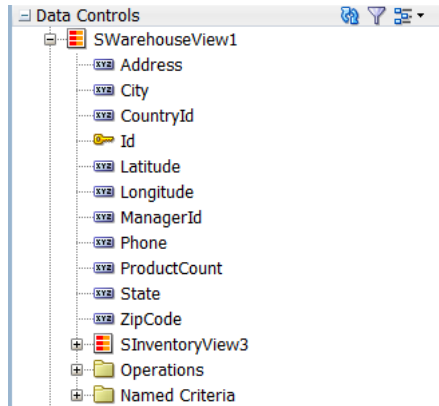

It may be helpful to have an understanding of databound thematic maps. For more information, see [Section 26.6, "Creating Databound Thematic Maps."](#)

**To create a thematic map using the Data Controls panel:**

1. From the Data Controls panel, select a data collection.

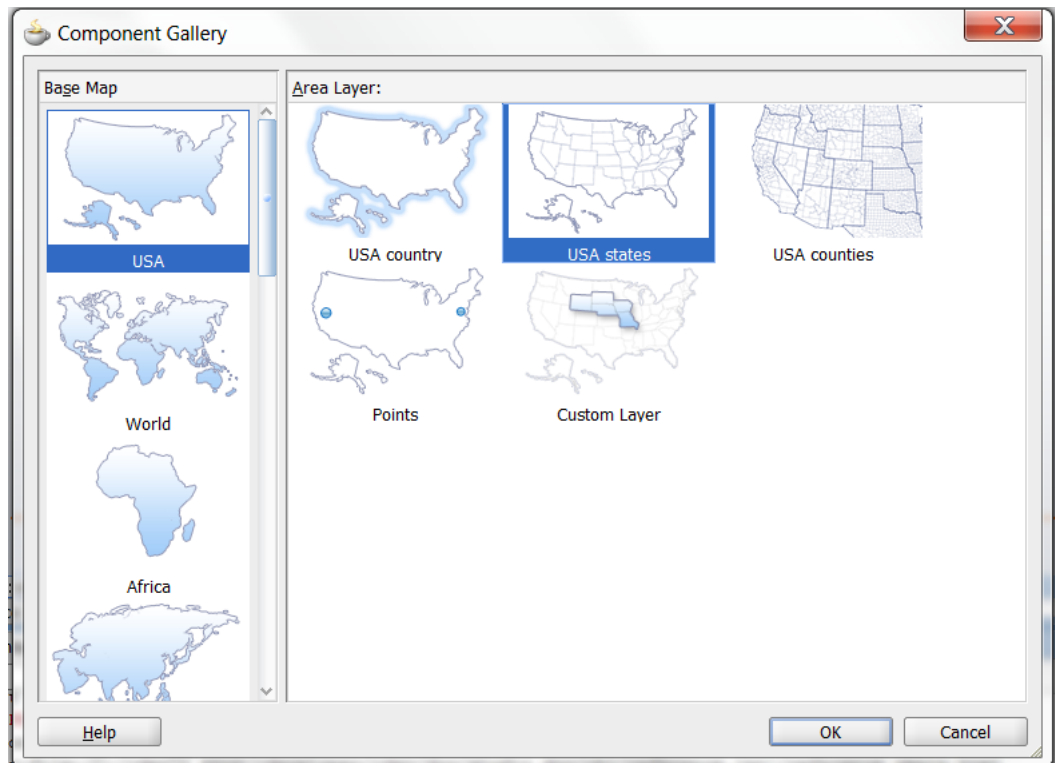

Figure 26–40 shows the data collection for warehouse locations and product inventory levels.

**Figure 26–40 Data Collection for Warehouse Location and Inventory**

2. Drag the collection onto a JSF page and, from the context menu, choose **Thematic Map**.
3. In the Component Gallery, select the map layer associated with the base map you want to configure for displaying data. In the example, a states map layer in the US base map is selected. Figure 26–41 shows the Component Gallery with the USA states map layer selected.

**Figure 26–41 Thematic Map Component Gallery**

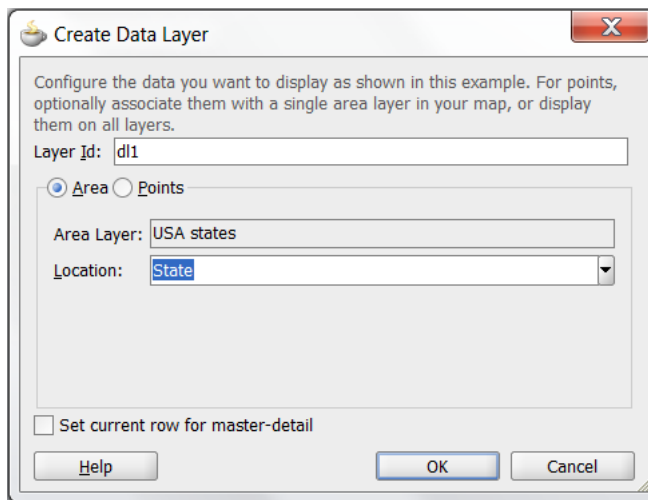

By default, the Create Data Layer dialog opens for adding an area or point data layer to the selected map layer. In the thematic map displayed in [Figure 26-39](#), an area data layer is configured style USA states by warehouse product levels.

4. In the Create Data Layer dialog, enter the following:
  - **Layer Id:** Enter a unique name for the data layer you are defining. By default, a unique, consecutively numbered id is entered, d11, d12, and so on.
  - **Area:** Select to add an area data layer to the map layer.
  - **AreaLayer:** References the map layer to which you are adding a data layer. In the example, a **USA States** map layer.
  - **Location:** Select the attribute that represents the column in the data model that determines the location of the data for the areas in the data layer. The locations are Ids of the regions from the base map for which the data is being displayed. For more information, see [Section 26.6.5, "What You May Need to Know About Base Map Location Ids."](#)
  - **Set current row for master-detail:** Select if you want to enable master-detail relationships. This is useful when the data collection for the thematic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. For more information, see [Section 26.6.6, "What You May Need to Know About Configuring Master-Detail Relationships."](#)

[Figure 26-42](#) shows the completed Create Data Layer dialog.

**Figure 26-42 Create Area Data Layer Dialog**

An area data layer representing the `areaDataLayer` component, and an area, representing the `area` component is added in the Layer Browser hierarchy. [Figure 26-43](#) shows the expanded Layer Browser after adding an area data layer and area to the map layer.

Figure 26-43 Thematic Map Layer Browser

5. In the Layer Browser, expand the area data layer, select the area to be stylized, and click the **Edit** icon.

---

**Note:** You configure an area with a default stamp across all areas in the thematic map layer, or you can use a child `attributeGroups` tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the area tag, and by an `attributeGroups` tag, the `attributeGroups` style type will take precedence. For more information, see [Section 26.6.4, "Styling Areas, Markers, and Images to Display Data."](#)

---

6. In the Configure Area dialog, Attribute Groups page, enter the following:
  - **Grouping Rules:** Use this table to specify the styling of categorical groups of data in a data collection. Use the **Add** icon to add a row to the table for configuring rules for a categorical group and use the **Delete** icon to remove any row selected in the table. Each grouping rule is represented as a `attributeGroups` component, and assigned a unique, consecutively numbered Id, `ag1`, `ag2`, and so on.

For each row added to the table, enter the following:

- **Group by Value:** Enter or use the dropdown list to select the attribute representing the column in the data set by which you wish to group the data values. For example, `ProductCount` represents the warehouse product inventory levels by state.

---

**Note:** The selected attribute should consist of discrete values that can be categorized. For example, a range of numeric values between 40 and 45, are not automatically grouped.

---

- **Area Properties:** Use the dropdown list to select the property to use for styling that area. Areas can be styled using **color**, **pattern**, **opacity**, or any combination of these valid values. Choose **Select multiple attributes** from the dropdown list for a dialog to specify any combination of values.

The default style values that are generated for each property are defined using CSS style properties in the ADF skin. Each `attributeGroups` type has a default ramp defined in the skin, and these can be customized by setting the index-based properties to the desired values. For more information, see [Section 26.6.4.4, "What You May Need to Know About Default Style Values for Attribute Groups."](#)

- **Legend Label:** Enter text or use the dropdown list to select the attribute representing the text to use for the categorical group in the thematic map legend. You can also select **Expression Builder** from the dropdown list to

create an EL expression to specify the legend text. For more information, see [Section 26.6.9, "Creating Databound Legends."](#)

- **Value-Specific Rules:** Click to open the **Match Rules** and **Exception Rules** tables used to specify a finer detail for one or more data values in categorical groups in a data set. For example, use a match rule to style every state with a warehouse with a low product inventory level with a #DD1E2F color, instead of a predefined range of colors.

---

**Note:** Any match or exception rule specified in these tables will override the settings defined in the **Grouping Rules** table.

---

- **Match Rules:** Use to specify the style rule matched to one or more data values in a group of data in a data collection. Use the **Add** icon to add a row to the table for configuring a match rule for a categorical group and use the **Delete** icon to remove any row selected in the table. Each match rule is represented as a `attributeMatchRule` component, and assigned a unique, consecutively numbered Id, `amr1`, `amr2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

```
<dvt:attributeMatchRule id="amr1" group="Mountain Dew">
  <f:attribute name="color" value="#ffff00"/>
</dvt:attributeMatchRule>
```

For each row added to the table, enter the following:

- **Group Value:** Enter the exact value for a **Group By Value** attribute that will trigger this Match Rule to execute. In the example, warehouse product inventory level data collection attribute, values include `low`, `med`, and `high`.
- **Property:** Use the dropdown list to select the property to use for styling that data value. Areas can be styled using **color**, **pattern**, or **opacity** values. The property selected here must match one of the property types listed in the **Area Properties** for the attribute **Grouping Rules**.
- **Property Value:** Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp.

Valid values for **color** are RGB hexadecimal colors.

Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **large-Crosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

Valid values for **opacity** range from **0.0** for transparent to **1.0** for opaque.

- **Exception Rules:** Use to specify one or more exception to the style rules for categorical groups in the data set. Use the **Add** icon to add a row to the table for configuring an exception rule and use the **Delete** icon to remove any row selected in the table. Each exception rule is represented as an `attributeExceptionRule` component, and assigned a unique, consecutively numbered Id, `aer1`, `aer2`, and so on. The property and property value is defined in a child `f:attribute` tag.

For each row added to the table, enter the following:

- **Condition:** Enter an EL expression, or use the dropdown list to open an Expression Builder dialog to create an EL expression that replaces the style property value with another when certain conditions are met. For example:

```
#{row.Sales gt 100000}
```

- **Property:** Use the dropdown list to select the property to use for styling that data value. Areas can be styled using **color**, **pattern**, or **opacity** values. The property selected here must match one of the property types listed in the **Area Properties** for the attribute **Grouping Rules**.
- **Property Value:** Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp.

Valid values for **color** are RGB hexadecimal colors.

Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **large-Crosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

Valid values for **opacity** range from **0.0** for transparent to **1.0** for opaque.

- **Legend Label:** Enter a text resource to use for the legend label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click **Help**.

---

**Note:** the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

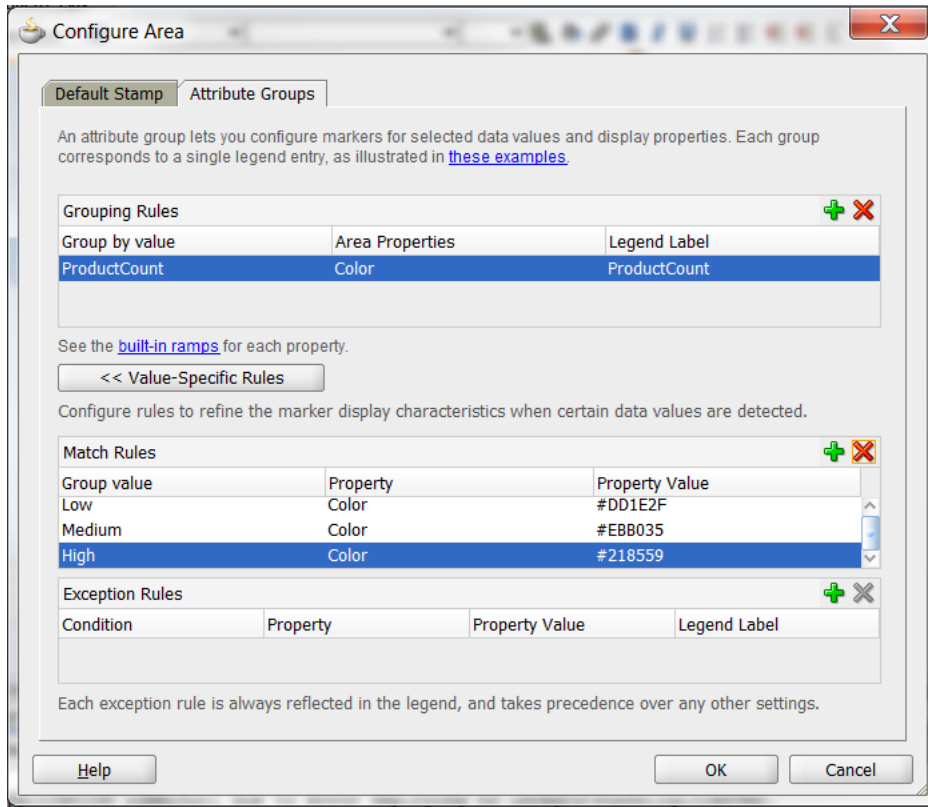

```
#{viewController.ResourceBundle[row.label]}
```

---

- **Messages:** Review and clear as necessary any alerts related to the configuration of the area.

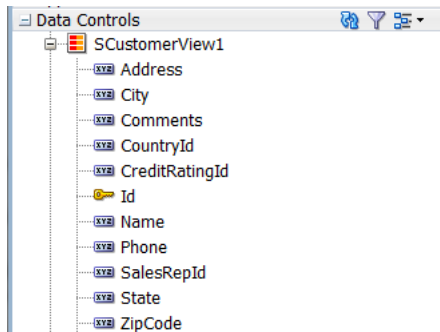

Figure 26–44 shows the completed Configure Area dialog. The warning in the message pane alerts the user that the default area color specified in the Default Stamp page of the dialog will be overwritten by the color specified in the Grouping Rules and any value-specific overrides specified in the Attribute Groups page.

**Figure 26–44 Configure Area Dialog Attribute Groups Page**

7. Use the Layer Browser to add a global point data layer representing warehouse locations using the same data collection you used to create the thematic map. For detailed instructions, see [Section 26.6.3, "How to Add Data Layers to Thematic Maps."](#)
8. Use the Layer Browser to add a global point data layer representing customer addresses using a different data collection than the one you used to create the thematic map. For detailed instructions, see [Section 26.6.3, "How to Add Data Layers to Thematic Maps."](#) [Figure 26–45](#) shows the data collection for customer locations.

**Figure 26–45 Data Collection for Customer Addresses**

9. Use the Layer Browser to add and style a marker representing the customer locations in the global point data layer. For detail instructions, see [Section 26.6.4, "Styling Areas, Markers, and Images to Display Data."](#)

Figure 26–46 shows the expanded Layer Browser for the thematic map in Figure 26–39.

**Figure 26–46 Thematic Map Layer Browser**

10. Add and configure a data bound legend and labels associated with the styled points and areas. For detailed instructions, see [Section 26.6.9, "Creating Databound Legends."](#)

## 26.6.2 What Happens When You Use Data Controls to Create a Thematic Map

When you use ADF data controls to create a thematic map, JDeveloper:

- Defines the bindings for the thematic map in the page definition file of the JSF page, and
- Inserts code in the JSF page for the DVT thematic map components.

[Example 26–20](#) shows the bindings defined in the page definition file of the JSF page for the example thematic map in [Figure 26–39](#).

**Example 26–20 XML Bindings for a Thematic Map**

```
<bindings>
  <tree IterBinding="WorldProductInventory1Iterator"
id="WorldProductInventory1">
    <nodeDefinition DefName="model.WorldProductInventory"
Name="WorldProductInventory10">
      <AttrNames>
        <Item Value="Address" />
        <Item Value="AmountInStock" />
        <Item Value="Category" />
        <Item Value="CategoryId" />
        <Item Value="City" />
        <Item Value="Country" />
        <Item Value="CountryCode" />
        <Item Value="CountryId" />
        <Item Value="Id" />
        <Item Value="Id1" />
        <Item Value="Id2" />
        <Item Value="Id3" />

        <dvt:legendSection source="dpl1:m2" id="ls2" />
        <dvt:legendSection source="dpl2:img1" id="ls1" />
    </dvt:showLegendGroup>
    <dvt:showLegendGroup id="slg2" label="Warehouse Product Levels">
        <dvt:legendSection source="all:dal1:ag1" id="ls3" />
    </dvt:showLegendGroup>
</dvt:legend>
</dvt:thematicMap>

```

Once you have created a data bound thematic map you can add additional map layers representing available regions in the geographical hierarchy of the base map, and associate area or point data layers using the same data collection you used to create the thematic map. The Layer Browser represents the logical structure of the map layers, area and point data layers, and stylized areas and markers. Use the Layer Browser to:

- Add additional map layers in the base map geographical hierarchy to the thematic map.

- Define a custom map layer in the geographical hierarchy of the base map, using lower level regions to aggregate the regions in the custom layer. For more information, see [Section 26.6.7, "How to Define a Custom Map Layer."](#)
- Add, edit, or delete area or point (global or map layer specific) data layers. For more information, see [Section 26.6.3, "How to Add Data Layers to Thematic Maps."](#)
- Add, edit, or delete stylized areas or markers. For more information, see [Section 26.6.4, "Styling Areas, Markers, and Images to Display Data."](#)

After creating a thematic map using data controls, you can customize the default map labels, legend display, and add interactivity and animation effects. For more information, see the "Using Thematic Map Components" section in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 26.6.3 How to Add Data Layers to Thematic Maps

You use data layers to associate map layers with a data collection. Using stamping, each row of data in the data model can be identified by a style, for example a color or pattern; a marker, for example a circle or square; or an image. When a map layer is displayed at runtime, the data appears as stylized areas, markers, or images.

Map layers can display data using an area data layer and/or one or more point data layers. Area data layers can be styled using areas, markers, or images. Point data layers can be styled using markers or images.

When a point data layer is associated with the base map as a direct child of `thematicMap` instead of as a child of a specific map layer, the data displays at all times and is called a *global point layer*.

#### **Before you begin:**

It may be helpful to have an understanding of databound thematic maps. For more information, see [Section 26.6, "Creating Databound Thematic Maps."](#)

#### **To add an area data layer to a map layer:**

1. Select the thematic map in the Visual Editor.
2. In the Layer Browser, select the map layer to which you wish to bind a row in the data collection. If the Layer Browser is not open in the Visual Editor, right-click inside the map and choose **Open Layer Browser**.
3. From the **Add** icon dropdown list, choose **Add Data Layer**.
4. In the Create Data Layer dialog, enter the following:
  - **Layer Id:** Enter a unique name for the data layer you are defining. By default, a unique, consecutively numbered id is entered, `d11`, `d12`, and so on.
  - **Bind Data Now:** Select and click **Browse** to open the Picker dialog > Data Controls Definitions page. Select the data collection in the ADF data controls you are using to data bind your data layer.

---

---

**Note:** Alternatively, you can use the Expression Builder page to select an ADF managed bean you are using to data bind your area data layer and areas. You can also use the Expression Builder dialog in each remaining field.

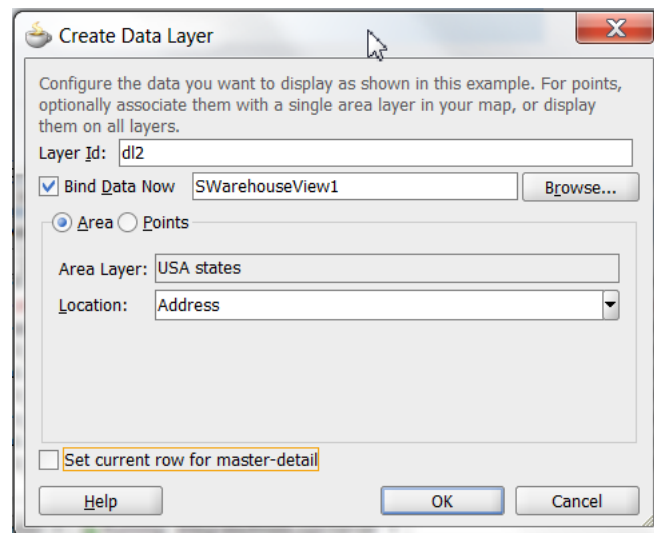

---

---

- **Area:** Select to add an area data layer to the map layer.
- **AreaLayer:** References the map layer to which you are adding a data layer.
- **Location:** Select attribute that represents the column in the data model that determines the location of the data for the areas in the data layer. The locations are Ids of the regions from the base map for which the data is being displayed. For more information, see [Section 26.6.5, "What You May Need to Know About Base Map Location Ids."](#)
- **Set current row for master-detail:** Select if you want to enable master-detail relationships. This is useful when the data collection for the thematic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. For more information, see [Section 26.6.6, "What You May Need to Know About Configuring Master-Detail Relationships."](#)

Figure 26–47 shows the completed Create Area Data Layer dialog.

**Figure 26–47 Create Area Data Layer Dialog**

By default, an area data layer representing the `areaDataLayer` component, and an area, representing the `area` component is added in the Layer Browser hierarchy. [Example 26–22](#) shows the code added to the JSF page when you add an area data layer to a map layer.

**Example 26–22 Area Data Layer Code in JSF Page**

```
<dvt:thematicMap id="tm1" basemap="usa">
  <dvt:areaLayer layer="counties" id="a1">
    <dvt:areaDataLayer id="dl2"
      value="#{bindings.TmapStatesView1.collectionModel}"
      var="row">
      <dvt:areaLocation name="#{row.Name}" id="a12">
        <dvt:area id="a1"/>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  ...
</dvt:thematicMap>
```

**To add a point data layer to a map layer:**

1. Select the thematic map in the Visual Editor.
2. In the Layer Browser, select the map layer to which you wish to bind a data layer. If the Layer Browser is not open in the Visual Editor, right-click inside the map and choose **Open Layer Browser**.
3. From the **Add** icon dropdown list, choose **Add Data Layer**.

---

---

**Note:** If you wish to create a global point layer that displays at all times on the thematic map, choose **Create Global Point Layer**.

---

---

4. In the Create Data Layer dialog, enter the following:
  - **Layer Id:** Enter a unique ID for the data layer you are defining. By default, a unique, consecutively numbered id is entered, d11, d12, and so on.
  - **Bind Data Now:** Select and click **Browse** to open the Picker dialog > Data Controls Definitions page. Select the data collection in the ADF data controls you are using to data bind your data layer.

---

---

**Note:** Alternatively, you can use the Expression Builder page to select an ADF managed bean you are using to data bind your point data layer and markers. You can also use the Expression Builder dialog in each remaining field.

---

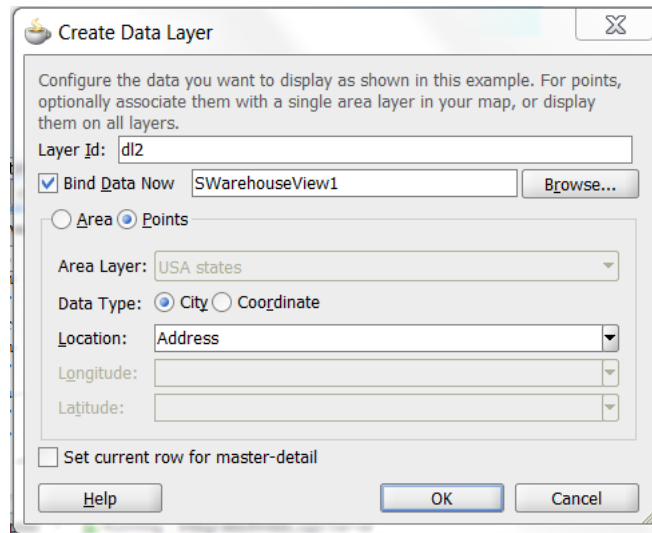

---

- **Points:** Select to add a point data layer to the map layer.
- **AreaLayer:** Use the dropdown list to select the map layer to which you are associating a data layer. If you select **All**, the point data layer will be configured as a global point layer and display at all times. If you select an available map layer, the point data layer will only display with that map layer is displayed.
- **Data Type:** Choose one of the following:
  - **City:** Select to use a `pointName` data type representing the named points, such as cities, in the data collection that map to named points in the base map.
  - **Coordinates:** Select to use a `pointXY` data type representing the columns in the data collection that join `pointX` and `pointY` to define the point locations.
- **Location:** Available if a City Data Type is specified. Use the dropdown list to select the attribute that represents the column in the data model that determines the location of the data for the points in the data layer. The locations are IDs of the points from the base map for which the data is being displayed. For more information, see [Section 26.6.5, "What You May Need to Know About Base Map Location Ids."](#)
- **Longitude:** Available if a Coordinates Data Type is specified. Use the dropdown list to select the attribute in the data collection that represents the longitude, or `pointX` of the marker.
- **Latitude:** Available if a Coordinates Data Type is specified. Use the dropdown list to select the attribute in the data collection that represents the latitude, or `pointY` of the markers.

- Set current row for master-detail:** Select if you want to enable master-detail relationships. This is useful when the data collection for the thematic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. For more information, see [Section 26.6.6, "What You May Need to Know About Configuring Master-Detail Relationships."](#)

Figure 26–48 shows the completed Create Point Data Layer dialog for a `pointName` data type.

**Figure 26–48 Create Point Data Layer Dialog**

By default, a point data layer representing the `pointDataLayer` component, and a marker, representing the `marker` component is added in the Layer Browser hierarchy. [Example 26–23](#) shows the code added to the JSF page when you add a point data layer to a map layer.

**Example 26–23 Point Data Layer Code in JSF Page**

```
<dvt:thematicMap id="tm1" basemap="usa">
  <dvt:areaLayer layer="states" id="all">
    <dvt:pointDataLayer id="dl1"
      value="#{bindings.TmapCitiesView1.collectionModel}"
      var="row">
      <dvt:pointLocation type="pointName" pointName="#{row.City}" id="pl1">
        <dvt:marker id="m2"/>
      </dvt:pointLocation>
    </dvt:pointDataLayer>
  </dvt:areaLayer>
  ...
</dvt:thematicMap>
```

[Example 26–24](#) shows the code added to the JSF page when you add a global point data layer to a thematic map.

**Example 26–24 Global Point Data Layer Code in JSF Page**

```
<dvt:thematicMap>
  <areaLayer layer="states" id="all"/>
  <dvt:pointDataLayer id="dl2">
```

```

        value="{bindings.TmapCitiesView12.collectionModel}"
        var="row">
        <dvt:pointLocation type="pointXY" pointX="{row.Longitude}"
            pointY="{row.Latitude}" id="pl2">
            <dvt:marker id="m3"/>
        </dvt:pointLocation>
    </dvt:pointDataLayer>
    ...
</dvt:thematicMap>

```

After adding the area or point data layer to the thematic map, you style the data using areas, markers, or images. For more information, see [Section 26.6.4, "Styling Areas, Markers, and Images to Display Data."](#)

## 26.6.4 Styling Areas, Markers, and Images to Display Data

An area data layer is used to associate map layers with a data collection. Using stamping, each row of data in the data model can be identified by a style, for example a color or pattern; a marker, for example a circle or square; or an image.

A point data layer is used to associate a set of points on a map with a data collection. The data point can be specified by a named point in a map layer, for example, cities in the US map, or by longitude and latitude. Using stamping, each row of data in the data model can be identified by a marker, for example a circle or square, or an image.

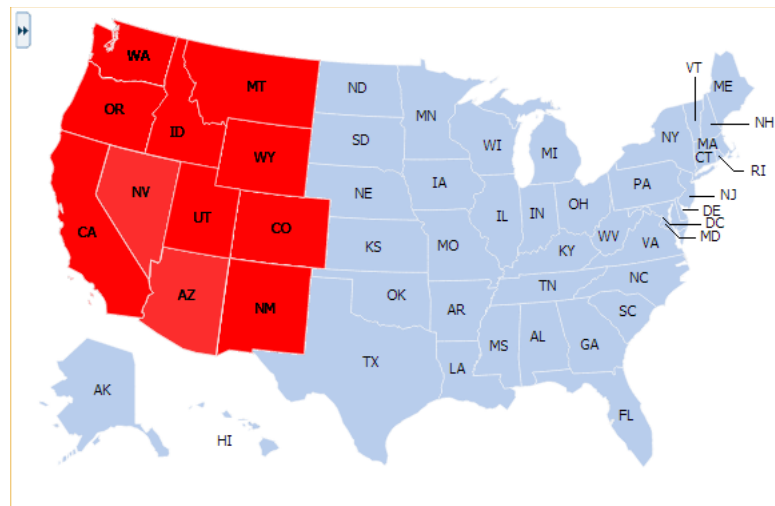

### 26.6.4.1 How to Style Areas to Display Data

You configure an area with a default stamp across all areas in the thematic map `areaLayer`, or you can use a child `attributeGroups` tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the area tag, and by an `attributeGroups` tag, the `attributeGroups` style type will take precedence.

By default, when you add an area data layer, a configurable area is added to the Layer Browser. You can use the Layer Browser to add additional areas or markers to an area data layer, or markers to a point data layer. The Layer Browser reflects the logical structure of the map layers, area or point data layers, and areas or markers configured in the thematic map.

For example, you can style the states in the `states` layer of the `usa` base map with an attribute group to display states with warehouses using the color red as illustrated in [Figure 26–49](#).

**Figure 26–49 Thematic Map with Area Stamp Configured****Before you begin:**

It may be helpful to have an understanding of databound thematic maps. For more information, see [Section 26.6, "Creating Databound Thematic Maps."](#)

**To style areas using a default stamp:**

1. In the Layer Browser, select the area at the area location inside the map layer you are configuring.
2. Click the **Edit** icon.
3. In the Configure Area dialog, Default Stamp page, enter the following:
  - **Location:** By default, the attribute that represents the column in the data model that determines the location of the data for the areas in the data layer. The locations are Ids of the regions from the base map for which the data is being displayed. This read-only field displays the EL expression that maps the stamped area to a region in the base map. For more information, see [Section 26.6.5, "What You May Need to Know About Base Map Location Ids."](#)
  - **Color:** Optionally, from the dropdown list select the fill color for the area. Valid values are RGB hexadecimal. Choose **Custom Color** from the dropdown list to open a Color Picker dialog
  - **Pattern:** Optionally, from the dropdown list select one of twelve prebuilt patterns to style the area, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **largeCrosshatch**. If fill color is specified, the pattern displays in that color on the default white background.
  - **Opacity:** Optionally, specify the opacity of the fill color of the area. Valid values range from **0.0** for transparent to **1.0** for opaque.
  - **Include in Legend:** Select and use the search icon to open a Select Text Resource dialog to select or create an application text resource to use for the legend text. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. If you need help, press F1 or click **Help**.

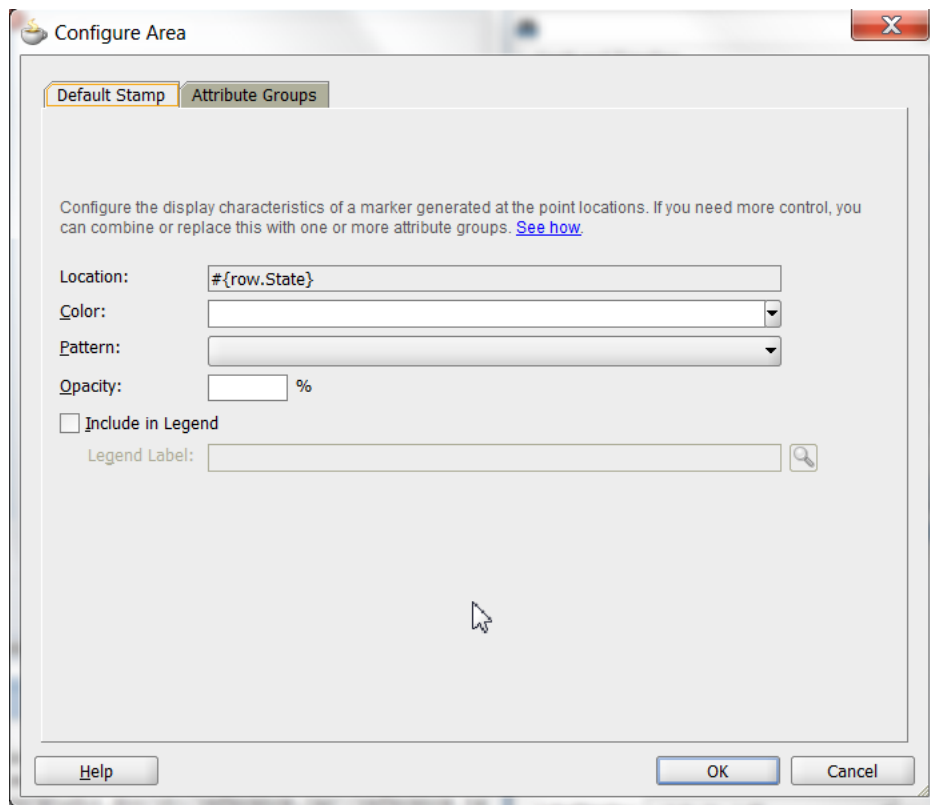

**Note:** the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

```
#{viewController.ResourceBundle[row.label]}
```

- **Messages:** Review and clear as necessary any alerts related to the configuration of the area.

Figure 26–50 shows the Configure Area dialog for the Default Stamp page.

**Figure 26–50 Configure Area Dialog Default Stamp Page**

Example 26–25 shows the code inserted in the JSF page for the configured area.

**Example 26–25 Sample Code for Area Default Stamp Configuration**

```
<dvt:thematicMap id="tm1" basemap="usa">
  <dvt:areaLayer layer="states" id="a1">
    <dvt:areaDataLayer id="dl1"
      value="#{bindings.TmapStatesView1.collectionModel}"
      var="row">
      <dvt:areaLocation name="#{row.Name}" id="a12">
        <dvt:area id="a1" fillColor="#ff0000">
          <f:attribute name="legendLabel"
            value="#{Bundle.US_STATES}"/>
        </dvt:area>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
```

```
</dvt:thematicMap>
```

If you wish to style areas using categorical groups of data in the data collection, use the Attribute Groups page of the Configure Area dialog. For details about using the Attribute Groups page including sample code, see the use case described in [Section 26.6.1, "How to Create a Thematic Map Using ADF Data Controls."](#)

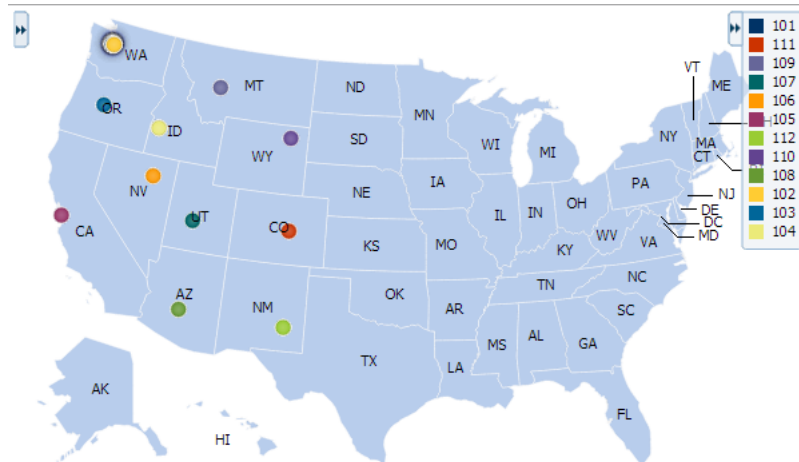

#### 26.6.4.2 How to Style Markers to Display Data

You configure a marker with a default stamp across all markers in the thematic map layer, or you can use a child `attributeGroups` tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the marker tag, and by an `attributeGroups` tag, the `attributeGroups` style type will take precedence.

By default, when you add a point data layer, a configurable marker element is added to the Layer Browser. You can use the Layer Browser to add additional areas or markers to an area data layer, or markers to a point data layer. The Layer Browser reflects the logical structure of the map layers, area or point data layers, and areas or markers configured in the thematic map.

For example, using the default stamp, you can identify all the predefined cities in the states layer of the USA base map with a circle as illustrated in [Figure 26–51](#). In the example, markers are styled on a point data layer. Styling markers on an area data layer is similar.

**Figure 26–51** Thematic Map with Marker Default Stamp Configured

#### Before you begin:

It may be helpful to have an understanding of databound thematic maps. For more information, see [Section 26.6, "Creating Databound Thematic Maps."](#)

#### To style markers using a default stamp:

1. In the Layer Browser, select the marker at the point location inside the map layer you are configuring.
2. Click the **Edit** icon.
3. In the Configure Marker dialog, Default Stamp page, enter the following:

- **Location:** By default, the attribute that represents the column in the data model that determines the location of the data for the markers in the data layer. The locations are Ids of the points from the base map for which the data is being displayed. This read-only field displays the EL expression that maps the stamped marker to a point in the base map. For more information, see [Section 26.6.5, "What You May Need to Know About Base Map Location Ids."](#)
- **Color:** Optionally, from the dropdown list select the fill color for the marker. Valid values are RGB hexadecimal. Choose **Custom Color** from the dropdown list to open a Color Picker dialog.
- **Pattern:** Optionally, from the dropdown list select one of twelve prebuilt patterns to style the marker, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **largeCrosshatch**. If fill color is specified, the pattern displays in that color on the default white background.
- **Opacity:** Optionally, specify the opacity of the fill color of the marker. Valid values range from **0.0** for transparent to **1.0** for opaque.
- **Shape:** Optionally, select the shape of the marker. Valid values are **circle** (default), **square**, **plus**, **diamond**, **triangleUp**, **triangleDown**, and **human**.

Optionally, use the **Custom Shape** field to specify the `shapePath` value to a Scalable Vector Graphics (SVG) file to use for the marker. Enter the path or use the **Search** icon to open the Select SVG File dialog and navigate to the file location. This option is only available if the default shape is selected in the **Shape** field.

Shapes can also be specified using CSS style properties. Predefined marker shapes can be overwritten, and the paths to SVG files for custom markers can also be defined without using the `shapePath` attribute. For more information, see [Section 26.6.4.3, "What You May Need to Know About Styling Markers."](#)

- **Size:** Optionally, enter a percentage by which to scale the marker from its default size for **ScaleX** (horizontal), and **ScaleY** (vertical). The percentages are then scaled to a float. For example, you can double the marker width by setting **ScaleX** to 200, written to the tag as `2.0`, and halve the height by setting **ScaleY** to 50, written to the tag as `0.5`.

You can also use an EL expression to evaluate the size of the marker based on the data, for example:

```
scaleX="#{(5 + row.categories[0]/25)}"
scaleY="#{(5 + row.categories[0]/25)}"
```

---

**Note:** To maintain the size of scaled markers relative to the thematic map when it is zoomed in or out, set the `dvt:thematicMap` component `markerZoomBehavior` property to `zoom`.

---

- **Include in Legend:** Enter a text resource to use for the legend label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click **Help**.

---

**Note:** the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

```
#{viewController.ResourceBundle[row.label]}
```

---

- **Messages:** Review and clear any messages related to the configuration of the marker.

Figure 26–52 shows the Configure Marker dialog, Default Stamp page.

**Figure 26–52** Configure Marker Dialog Default Stamp Page

Example 26–26 shows the code inserted in the JSF page for the configured marker.

**Example 26–26** Sample Code for Marker Default Stamp Configuration

```
<dvt:thematicMap id="tm1" basemap="usa">
  <dvt:areaLayer layer="states" id="all">
    <dvt:pointDataLayer id="dl2"
      value="#{bindings.TmapCitiesView1.collectionModel}"
      var="row">
      <<dvt:pointLocation type="pointName" pointName="#{row.City}" id="pl1">
        <dvt:marker id="m2" fillColor="#ff0000">
          <f:attribute name="legendLabel"
            value="#{Bundle.US_CITIES}"/>
        </dvt:marker>
      </dvt:pointLocation>
    </dvt:pointDataLayer>
  </dvt:areaLayer>
</dvt:thematicMap>
```

```

        </dvt:marker>
    </dvt:pointLocation>
</dvt:pointDataLayer>
</dvt:areaLayer>
</dvt:thematicMap>

```

If you wish to style markers using categorical groups of data in the data collection, use the Attribute Groups page of the Configure Marker dialog. You can configure markers for a point data layer or an area data layer.

**To style markers using categorical groups of data:**

1. In the Layer Browser, select the marker at the marker location inside the map layer you are configuring.
2. Click the **Edit** icon.
3. In the Configure Marker dialog, Attribute Groups page, enter the following:
  - **Grouping Rules:** Use this table to specify the styling of categorical groups of data in a data collection. Use the **Add** icon to add a row to the table for configuring rules for a categorical group and use the **Delete** icon to remove any row selected in the table. Each grouping rule is represented as a `attributeGroups` component, and assigned a unique, consecutively numbered `Id`, `ag1`, `ag2`, and so on.

For each row added to the table, enter the following:

- **Group by Value:** Enter or use the dropdown list to select the attribute representing the column in the data set by which you wish to group the data values.

---

**Note:** The selected attribute should consist of discrete values that can be categorized. For example, a range of numeric values between 40 and 45, are not automatically grouped.

---

- **Marker Properties:** Use the dropdown list to select the property to use for styling that marker. Markers can be styled using **color**, **pattern**, **opacity**, **scaleX**, **scaleY**, or any combination of these valid values. Choose **Select multiple attributes** from the dropdown list for a dialog to specify any combination of values.

The default style values that are generated for each property are defined using CSS style properties in the ADF skin. Each `attributeGroups` type has a default ramp defined in the skin, and these can be customized by setting the index-based properties to the desired values. For more information, see [Section 26.6.4.4, "What You May Need to Know About Default Style Values for Attribute Groups."](#)

- **Legend Label:** Enter text or use the dropdown list to select the attribute representing the text to use for the categorical group in the thematic map legend. You can also select **Expression Builder** from the dropdown list to create an EL expression to specify the legend text. For more information, see [Section 26.6.9, "Creating Databound Legends."](#)
- **Value-Specific Rules:** Click to open the **Match Rules** and **Exception Rules** tables used to specify a finer detail for one or more data values for categorical groups in a data set.

---

---

**Note:** Any match or exception rule specified in these tables will override the settings defined in the **Grouping Rules** table.

---

---

- Match Rules:** Use to specify the style rule matched to one or more data values in a group of data in a data collection. Use the **Add** icon to add a row to the table for configuring a match rule for a categorical group and use the **Delete** icon to remove any row selected in the table. Each match rule is represented as a `attributeMatchRule` component, and assigned a unique, consecutively numbered Id, `amr1`, `amr2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

```
<dvt:attributeMatchRule id="amr1" group="Mountain Dew">
  <f:attribute name="color" value="#ffff00"/>
</dvt:attributeMatchRule>
```

For each row added to the table, enter the following:

- Group Value:** Enter the exact value for the **Group by Value** attribute that will trigger the Match Rule to execute.
- Property:** Use the dropdown list to select the property to use for styling that data value. Markers can be styled using **color**, **pattern**, **opacity**, **scaleX**, **scaleY**, or any combination of these valid values. The property selected here must match one of the property types listed in the **Marker Properties** for the attribute **Grouping Rules**.
- Property Value:** Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp.

Valid values for **color** are RGB hexadecimal colors.

Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **large-Crosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

Valid values for **opacity** range from **0.0** for transparent to **1.0** for opaque.

Valid values for **scaleX** and **scaleY** are percentages that are then scaled to a float.

- Exception Rules:** Use to specify one or more exceptions to the style rules for categorical groups in the data set. Use the **Add** icon to add a row to the table for configuring an exception rule and use the **Delete** icon to remove any row selected in the table. Each exception rule is represented as an `attributeExceptionRule` component, and assigned a unique, consecutively numbered Id, `aer1`, `aer2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

```
<dvt:attributeExceptionRule id="aer1" condition="#{row.name=='TX'}"
  label="Texas">
  <f:attribute name="color" value="#ff00ff"/>
</dvt:attributeExceptionRule>
```

For each row added to the table, enter the following:

- Condition:** Enter an EL expression, or use the dropdown list to open an Expression Builder dialog to create an EL expression that replaces the

style property value with another when certain conditions are met. For example:

```
#{row.Sales gt 100000}
```

- **Property:** Use the dropdown list to select the property to use for styling that data value. Markers can be styled using **color**, **pattern**, **opacity**, **scaleX**, or **scaleY**. The property selected here must match one of the property types listed in the **Marker Properties** for the attribute **Grouping Rules**.

- **Property Value:** Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp

Valid values for **color** are RGB hexadecimal colors.

Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **large-Crosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

Valid values for **opacity** range from **0.0** for transparent to **1.0** for opaque.

Valid values for **scaleX** and **scaleY** are percentages that are then scaled to a float.

- **Legend Label:** Enter a text resource to use for the legend label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click **Help**.

---

---

**Note:** the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

```
#{viewController.ResourceBundle[row.label]}
```

---

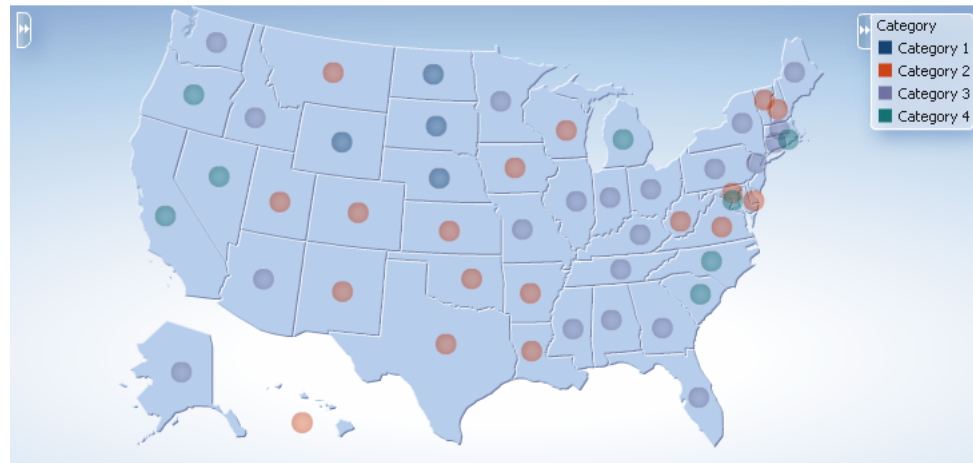

---

- **Messages:** Review and clear as necessary any alerts related to the configuration of the marker.

For example, you can use markers in an area data layer to display categorical groups of data using colors as illustrated in [Figure 26–53](#).

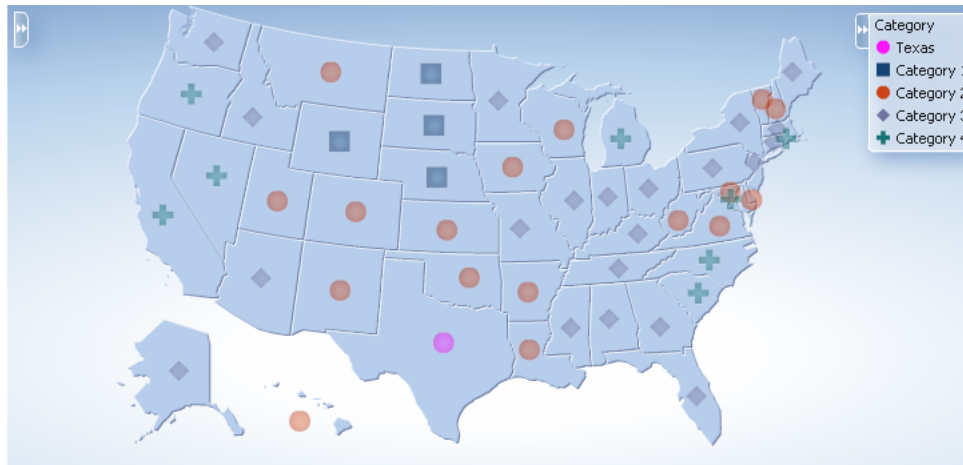

**Figure 26–53 Marker Attribute Groups by Color**

[Example 26–27](#) shows the sample code for marker attribute groups by color.

**Example 26–27 Sample Code for Marker Attribute Groups by Color**

```
<dvt:thematicMap basemap="usa" id="tm1"
  <dvt:areaLayer layer="states" id="all" labelDisplay="off">
    <dvt:areaDataLayer id="dl1" var="row" value="#{stateData.colorModel}">
      <dvt:areaLocation id="al2" name="#{row.name}">
        <dvt:marker id="m1"
          scaleX="3.0"
          scaleY="3.0"
          shape="circle">
          <dvt:attributeGroups id="ag1" type="color" value="#{row.category}"
            label="#{row.category}"/>
        </dvt:marker>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  <dvt:legend id="l1">
    <f:facet name="separator"/>
    <dvt:legendSection id="ls1" label="Category" source="ag1"/>
  </dvt:legend>
</dvt:thematicMap>
```

You can also use markers to display categorical groups of data using multiple attributes such as color and shape, and display an exception to the grouping rules when certain conditions are met. [Figure 26–54](#) shows a thematic map with categorical groups using color and shape with an exception for the state of Texas.

**Figure 26–54 Multiple Marker Attribute Groups with Exception Rule**

**Example 26–28** shows sample code for multiple marker attribute groups with exception rule.

**Example 26–28 Sample Code for Multiple Marker Attribute Groups with Exception Rule**

```
<dvt:thematicMap basemap="usa" id="tm2"
  <dvt:areaLayer layer="states" id="al1" labelDisplay="off">
    <dvt:areaDataLayer id="dl1" var="row" value="#{stateData.colorModel}">
      <dvt:areaLocation id="al2" name="#{row.name}">
        <dvt:marker id="m1"
          scaleX="3.0"
          scaleY="3.0"
          shape="circle">
          <dvt:attributeGroups id="ag1" type="shape color" value="#{row.category}"
            label="#{row.category}">
            <dvt:attributeExceptionRule id="aer1" condition="#{row.name=='TX'}"
              label="Texas">
              <f:attribute name="color" value="#ff00ff"/>
            </dvt:exceptionRule>
          </dvt:attributeGroups>
        </dvt:marker>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  <dvt:legend id="l1">
    <f:facet name="separator"/>
    <dvt:legendSection id="ls1" label="Category" source="ag1"/>
  </dvt:legend>
</dvt:thematicMap>
```

### 26.6.4.3 What You May Need to Know About Styling Markers

Thematic maps support a predefined set of seven shapes (`circle`, `square`, and so on) that can be specified using the `shape` attribute in the marker component. For custom markers, the `shapePath` attribute can be used to specify the path of an SVG file that will get displayed in place of a predefined shape.

Marker shapes can be also specified through CSS style properties in an ADF skin. Using thematic map style properties, predefined marker shapes can be overwritten, and the paths to SVG files for custom markers can be defined without using the

shapePath attribute. When using style properties, the shape attribute in the marker component is used for defining both predefined and custom shapes.

A predefined shape will be overwritten if a global or component-specific style property for that shape is specified in the ADF skin. For example, you can overwrite the predefined circle shape by specifying the newCircle.svg file in the thematic map component style property as follows:

```
af|dvt-thematicMap::shape-circle{
  -tr-path: url(/resources/path/newCircle.svg);
}
```

In the JSF page, the marker component shape attribute is set as follows:

```
<dvt:marker id="m1" shape="circle"/>
```

To specify a custom shape in the marker component shape attribute, you must use a prefix of custom in the shape style property name. For example, if the custom shape is named customName, then the ADF skin file should define either a global .AFDVTShapeCustomName:alias style property, or the thematic map specific af|dvt-thematicMap::shape-customName with the -tr-path property pointing to the SVG file as follows:

```
af|dvt-thematicMap::shape-customName{
  -tr-path: url(/resource/path/newCShape.svg);
}
```

In the JSF page, the marker component shape attribute is set as follows:

```
<dvt:marker id="m1" shape="customName"/>
```

For information about using ADF skins and style properties, see the "Customizing the Appearance Using Styles and Skins" chapter in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

#### 26.6.4.4 What You May Need to Know About Default Style Values for Attribute Groups

The attributeGroups component is used to generate stylistic property values such as colors or shapes based on categorical grouping of the data in a data collection. Based on the attribute representing the column in the data model to group by, the attributeGroups component can generate style values for each unique value, or group, in the data.

The type of stylistic properties to generate values for is specified by the type attribute of the attributeGroups component. Supported types for area components are color, pattern, and opacity. Supported types for marker components are color, shape, pattern, opacity, scaleX, and scaleY. These types can be combined in a space-delimited list to generate multiple stylistic properties for each unique data value.

The default style values that are generated are defined using CSS style properties in the ADF skin. Each attributeGroups type has a default ramp defined in the ADF skin that can be customized by setting the index-based selectors to the desired values. [Example 26–29](#) show sample code for using CSS style properties to specify attribute groups using CSS style properties.

##### **Example 26–29 Attribute Groups CSS Style Properties**

```
af|dvt-attributeGroups::shape1{
  -tr-shape: square;
```

```

}
af|dvt-attributeGroups::shape2{
  -tr-shape: square;
}
...
af|dvt-attributeGroups::color1{
  -tr-fill-color: #003366;
}

```

The default ramps for each attribute groups type are displayed in [Table 26–6](#).

**Table 26–6 Default Ramps for Thematic Map Attribute Groups**

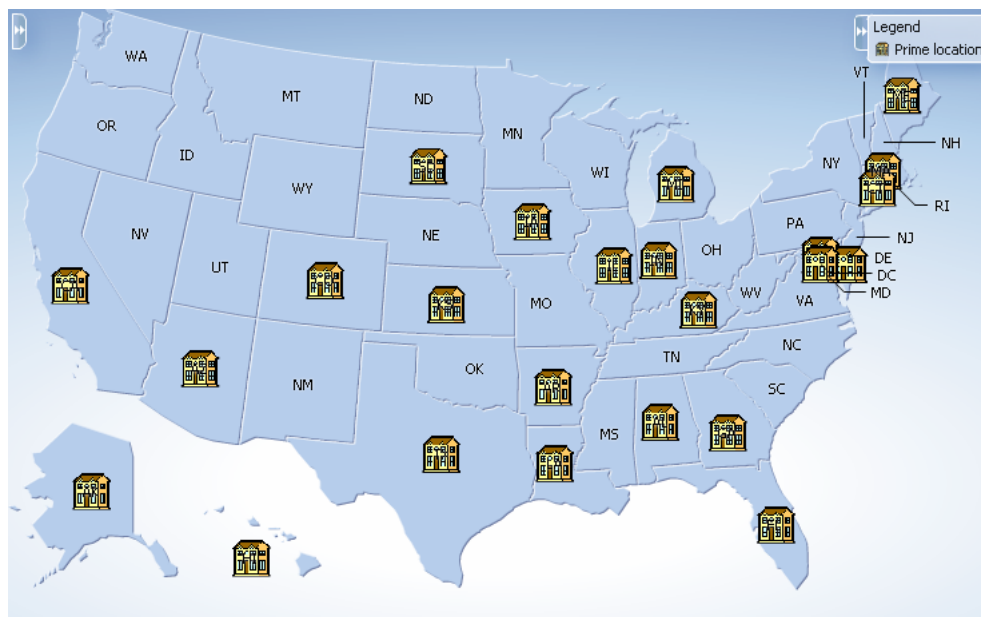

Type	Default Ramps
color	j#003366 (blue), #CC3300 (red), #666699 (lavender), #00066666 (emerald), #FF9900 (orange yellow), #993366 (purple), #99CC33 (lime green), #624390 (violet), #669933 (green), #FFCC33 (yellow), #006699 (turquoise blue), and #EBEA79 (pale yellow).
shape	square, circle, diamond, plus, triangleDown, triangleUp, and human
pattern	smallDiagonalLeft, smallDiagonalRight, smallTriangle, smallChecker, smallChecker, smallCrosshatch, smallDiamond, largeDiagonalLeft, largeDiagonalRight, largeTriangle, largeChecker, largeCrosshatch, largeDiamond
opacity	0.25, 0.50, 0.75, 1.0
scaleX and scaleY	1.0, 2.0, 3.0, 4.0, 5.0

For information about using ADF skins and style properties, see the "Customizing the Appearance Using Styles and Skins" chapter in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 26.6.4.5 How to Use Images to Display Data

You can use images to represent data displayed in a thematic map. Using stamping, each row of data in the data model can be identified by an image. Images can be associated with either an area or point data layer. You can associate an image file with the data layer directly or with a marker to represent the data.

For example, you can use a house image to identify prime locations on the states map layer of a US base map as illustrated in [Figure 26–55](#).

**Figure 26–55 Thematic Map Using Images to Display Data****Before you begin:**

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see [Section 26.6.1, "How to Create a Thematic Map Using ADF Data Controls."](#)

**To use an image to display data:**

1. In the Layer Browser, select the area or point data layer where you are configuring an image to display data.
2. In the Structure window, right-click the area or point data layer child `areaLocation` or `pointLocation` component and select **insert inside dvt:areaLocation** or **insert inside dvt:pointLocation > Image**.
3. In the Insert Image dialog, enter the following:
  - **Source:** Enter the URI specifying the location of the image source. You can use the dropdown menu to choose **Edit** and open an Edit Property: Source dialog or the Expression Builder to specify the location of the image source.
  - **ShortDesc:** Enter the short description of the image used as the `alt` text for screen reader users.

[Example 26–30](#) shows a code sample for the thematic map using images to display data in [Figure 26–55](#).

**Example 26–30 Code Sample for Thematic Map Using Images**

```
<dvt:thematicMap id="thematicMap" imageFormat="flash" basemap="usa"
  summary="Thematic map showing the important real estate markets">
  <dvt:legend label="Legend">
    <dvt:legendSection source="areaLayer:dataLayer:img1" />
  </dvt:legend>
</dvt:thematicMap>
```

```

</dvt:legend>
<dvt:areaLayer id="areaLayer" layer="states">
  <dvt:areaDataLayer id="dataLayer" contentDelivery="immediate"
    value="{tmapBean.colorModel}"
    var="row"varStatus="rowStatus">
    <dvt:areaLocation id="dataLoc" name="{row.name}">
      <af:image id="img1" source="/resources/images/geoMap/mansion.gif"
        rendered="{row.category == 'category1'}"
        shortDesc="House image">
        <f:attribute name="legendLabel" value="Prime location"/>
      </af:image>
    </dvt:areaLocation>
  </dvt:areaDataLayer>
</dvt:areaLayer>
</dvt:thematicMap>

```

You can also configure a marker to use an image file to display data. Separate images can be specified to display user selected and hover states. Support for the rotation of images is also supported when using the `dvt:marker` component. For example, the thematic map in [Figure 26–56](#) represents the locations and tracks of airplane flights, rotating the image as it moves along the track.

**Figure 26–56 Thematic Map Flight Tracker**

**To use an marker image source to display data:**

1. In the Layer Browser, select the area or point data layer where you are configuring an image to display data.
2. In the Structure window, right-click the area or point data layer child `areaLocation` or `pointLocation` component and select **insert inside dvt:areaLocation** or **insert inside dvt:pointLocation > Marker**.
3. In the Structure window, right-click the `dvt:marker` component and choose **Go to Properties**.
4. In the Property Inspector, expand the **Appearance** section and set the following attributes:
  - **Source:** Enter the URI specifying the location of the image source. You can use the dropdown menu to choose **Edit** and open an Edit Property: Source dialog or the Expression Builder to specify the location of the image resource.
  - **SourceHover:** Optionally enter the URI specifying the location of the image resource on hover.

- **SourceHoverSelected:** Optionally enter the URI specifying the location of the selected image resource on hover.
  - **SourceSelected:** Optionally enter the URI specifying the location of the image resource on selection.
  - **ShortDesc:** Enter the short description of the image used as the alt text for screen reader users.
5. Optionally, expand the **Other** section and use the **Rotation** attribute to specify the marker rotation in clockwise degrees around the center of the image.

[Example 26–31](#) shows the code sample for the thematic map flight tracker in [Figure 26–56](#).

**Example 26–31 Code Sample for Flight Tracker Marker Image**

```
<dvt:thematicMap id="thematicMap" basemap="world" animationOnDisplay="none"
  tooltipDisplay="auto"
  summary="flight tracker demo">
<dvt:areaLayer id="all" layer="countries">
  <dvt:pointDataLayer id="pd11" contentDelivery="immediate"
    value="#{flightTrackerBean.flights}"
    selectionListener="#{flightTrackerBean.processSelection}"
    var="row"
    varStatus="rowStatus"
    selectionMode="multiple" partialTriggers=":::sbcbl"
    selectedRowKeys="#{flightTrackerBean.selectedKeys}">
  <dvt:pointLocation id="pl1" type="pointXY" pointX="#{row.currentLongLat.x}"
    pointY="#{row.currentLongLat.y}">
    <dvt:marker id="m1" labelPosition="bottom" scaleX="3" scaleY="3"
      rotation="#{row.rotation}"
      shortDesc="OracleAir#{row.flightNumber}"#{row.flightNumber}"
      sourceHover="/resources/images/thematicMap/planeHover.png"
      source="/resources/images/thematicMap/plane.png"
      sourceSelected="/resources/images/thematicMap/planeSel.png"
      sourceHoverSelected="/resources/images/thematicMap/
        planeHoverSel.png"
      labelDisplay="#{flightTrackerBean.showFlightNo ? 'on' : 'off'}"
      value="Flight #{row.flightNumber}"/>
    </dvt:pointLocation>
  </dvt:pointDataLayer>
</dvt:areaLayer>
</dvt:thematicMap>
```

#### 26.6.4.6 What You May Need to Know About SVG Files

Scalable Vector Graphics (SVG) is the supported file format for creating custom shapes for thematic map markers.

SVG features that are not supported by custom shapes include:

- Image tags within the SVG file. Everything must be declared using SVG's vector shapes.
- Pattern fills
- Gradients on strokes

## 26.6.5 What You May Need to Know About Base Map Location Ids

Each base map provided for the thematic map component has two or more prebuilt map layers that represent a set of regions. For example, the `world` base map includes a map layer for `continents` and another layer for `countries`. The regions in the lower level map layers are aggregated to make up the next level in the geographical hierarchy. The map layer is specified in the `layer` attribute of the `areaLayer` component.

When you are binding your data collection to a thematic map, you must provide a column in the data model that specifies the location of the area or point data using the map location Ids of the regions from the base map for which the data is being displayed. Area locations are specified in the `name` attribute of the `areaLocation` component, and point locations are specified in the `pointName` attribute for the `pointLocation` component when its `type` attribute is set to `pointName`.

For the United States base map, the locations Ids are determined by the following naming rules:

- `country` layer: USA
- `states` layer: Use the two-letter postal abbreviation. For example, the location Id for Massachusetts is `MA`, and the location Id for Texas is `TX`.
- `counties` layer: Use the `states` layer location Id, followed by an underscore, and then the name of the county, all in capital letters with underscores replacing characters that are not letters. For example, the location Id for Middlesex county in Massachusetts is `MA_MIDDLESEX`, and the location Id for Red River county in Texas is `TX_RED_RIVER`.
- `cities` layer: Use the `states` layer location Id, followed by an underscore, and then the name of the city, all in capital letters with underscores replacing characters that are not letters. For example, the location Id for the id for Boston, Massachusetts is `MA_BOSTON`, and the location Id for San Antonio, Texas is `TX_SAN_ANTONIO`.

For all other base maps, location Ids are determined by the following naming rules:

- `continents` layer: `AF` (Africa), `AS` (Asia), `AU` (Australia), `EU` (Europe), `NA` (North America), and `SA` (South America) for the `world`, `africa`, `asia`, `australia`, `europa`, `northAmerica`, and `southAmerica` base maps.
- `worldRegions` layers: `APAC` (Asia-Pacific), `EMEA` (Europe and the Middle East), `LAT` (Latin America), `NA` (United States and Canada) for the `worldRegions`, `apac`, `emea`, `latinAmerica`, and `usaAndCanada` base maps.
- `countries` layer: Use the ISO 3166-1 alpha-3 country codes. For example, the location Id for Canada is `CAN`, and the location Id for China is `CHN`.
- `cities` layer: Use the three-letter `countries` location ID, followed by an underscore, and then the name of the city, all in capital letters with underscores replacing characters that are not letters. For example, the location Id for Toronto, Canada is `CAN_TORONTO`, and the location Id for Los Angeles, United States is `USA_LOS_ANGELES`.

You can download a comma-separated value (CSV) file for each of the prebuilt map layers with a complete listing of all the thematic map base map location Ids. Find these links in the tag documentation for the `areaLocation` component, `name` attribute. To access tag documentation for the data visualization components, select the component in the Structure window and click the help button in the Property Inspector.

## 26.6.6 What You May Need to Know About Configuring Master-Detail Relationships

You can configure a thematic map to display its associated data in another UI component on the page such as a table. In this configuration the data collection for the thematic map is a master in a master-detail relationship with a detail view in another UI component. [Figure 26–57](#) shows a thematic map displaying unemployment rates by state. Users can select one or multiple states to display the data detail view in the table.

**Figure 26–57** Thematic Map Master and Detail Table View

The following requirements must be met to achieve this master-detail processing declaratively:

- You must use the same data collection to provide data for both views as follows:
  - Bind the thematic map `areaDataLayer` or `pointDataLayer` to the data collection whose attributes represent the data to be styled by areas or markers in the thematic map layer.
  - Bind the other ADF component (such as a table) to same data collection.
- Select **Set the current row for master-detail** in the Create Data Layer dialog to automatically set a value for the `selectionListener` attribute of the thematic map `areaLayer` component and use the `processSelection` method that is already part of the thematic map binding.

For example, if the `value` attribute of the thematic map area data layer component is `value="#{stateData.employmentData}"`, then the `selectionListener` attribute is set to:

```
selectionListener="#{stateData.employmentData.processSelection}";
```

- Ensure that the `selectionMode` attribute on the `areaDataLayer` or `pointDataLayer` component is set to `single` or `multiple`, depending on the requirements for the thematic map.

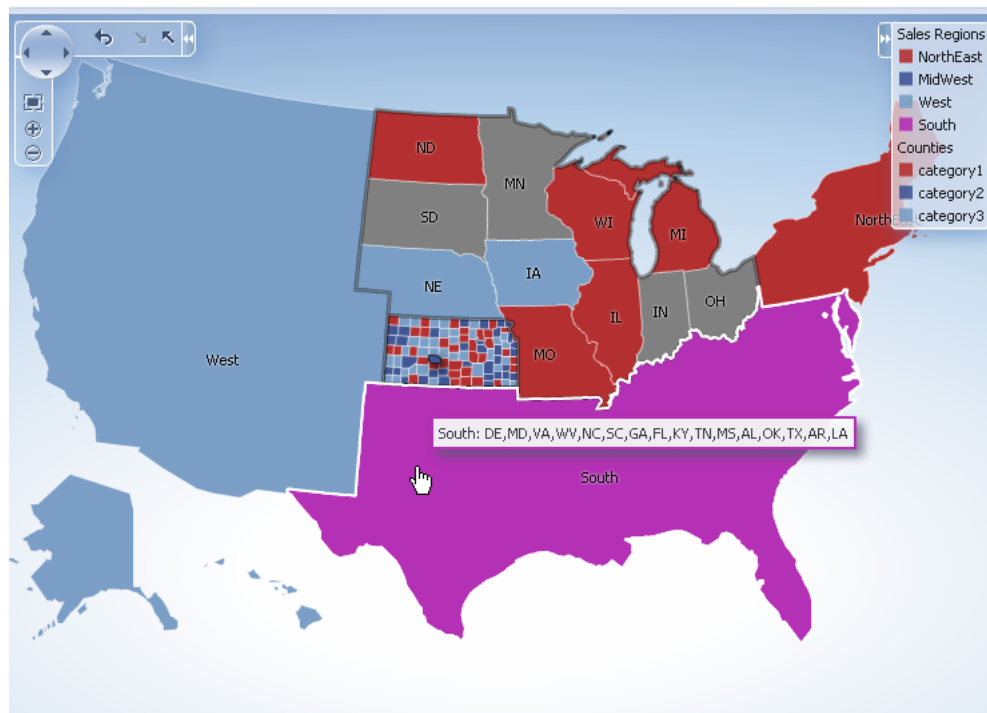

## 26.6.7 How to Define a Custom Map Layer

You can define a custom map layer from your own regional data and insert it into the natural geographical hierarchy of a thematic map. The custom layer is created by

extending a predefined map layer and aggregating the lower level regions to form the new regions in the custom layer. After defining a custom map layer, it is used in the same way as any other map layer.

For example, you could define geographical regions for the NorthEast, Midwest, West and South in the United States in a US Regions custom map layer as illustrated in Figure 26–58. In the figure, the US Regions custom layer is extended from the states layer in the US base map. The new areas in the layer are aggregated from the states in the states layer. The label for the South US Region lists the states in that region. The MidWest US Region is drilled down to display the sales categories in the lower level counties region. For more information about drilling, see Section 26.6.8, "How to Configure Drilling in Thematic Maps."

**Figure 26–58 US Regions Custom Map Layer**

The `customAreaLayer` component uses a model to access the data in the underlying list. The specific model class is `oracle.adf.view.rich.model.CollectionModel`. You can also use other model instances, for example, `java.util.List`, `java.util.Array`, and `javax.faces.model.DataModel`. The `customAreaLayer` will automatically convert the instance into a `CollectionModel`.

**Before you begin:**

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

You should already have an ADF data control or ADF managed bean that defines the aggregated areas in the predefined base map you are extending.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see [Section 26.6.1, "How to Create a Thematic Map Using ADF Data Controls."](#)

### How to add and configure a custom map layer:

1. Select the thematic map in the Visual Editor.
2. In the Layer Browser, from the **Add** icon dropdown list, choose **Add Custom Layer**. If the Layer Browser is not open in the Visual Editor, right-click in the map and choose **Open Layer Browser**.
3. In the Create Custom Layer dialog, enter the following:
  - **Bind Data Now:** Select and click **Browse** to open the Picker dialog > Data Controls Definitions page. Select the data collection in the ADF data controls you are using to data bind your custom layer and areas.

---

**Note:** Alternatively, you can use the Expression Builder page to select an ADF managed bean you are using to data bind your custom layer and areas. You can also use the Expression Builder dialog in each remaining field.

---

- **Layer Id:** Enter a unique identifier for the `customAreaLayer` component. For example, if you divide the US into aggregate regions (Northeast, Midwest, West, and South), then you might define them with corresponding Ids (NE, MW, W, and S).
- **Extends:** Use the search icon to display the built-in map layers that can be used to aggregate areas for the custom layer. Select the map layer that the custom layer will extend.
- **Area List:** Use the dropdown list to select the data collection attribute representing the list of lower level map regions that are used to aggregate the areas in the custom map layer. The comma separated list of values aggregate the regions in the may layer defined in the in the **Extends** attribute.
- **Area Id:** Use the dropdown list to select the data collection attribute representing the unique identifier of lower level map regions that are used to aggregate the areas in the custom map layer. By default, a unique identifier, `ca1`, `ca2`, and so on, is used in the for the `customArea` component.
- **Area Label:** Use the dropdown list to select the data collection attribute representing the names of lower level map regions that are used to aggregate the areas in the custom map layer. At runtime the label will display the comma separated list of the aggregated regions.

[Figure 26–59](#) shows the completed Create Custom Layer dialog.

**Figure 26–59 Create Custom Layer Dialog**

Figure 26–60 shows the Layer Browser after defining a custom layer. In the layer structure, the custom layer `cal1` is referenced in the map layer `a11`, where you add area or point data layers to display data. For more information, see [Section 26.6.3, "How to Add Data Layers to Thematic Maps."](#)

**Figure 26–60 Custom Map Layer in Layer Browser**

Example 26–32 shows the code inserted in the JSF page

**Example 26–32 Custom Map Layer Code**

```
<dvt:thematicMap>
...
  <dvt:areaLayer layer="states" id="al1"/>
  <dvt:areaLayer layer="cal1" id="al3"/>
  <dvt:customAreaLayer id="cal1"
    value="#{bindings.TmapStatesView.collectionModel}"
    var="row"
    extendsLayer="states">
    <dvt:customArea areaId="#{row.RowID}" areaList="#{row.RowID}"
      label="#{row.RowID}" id="cal1"/>
  </dvt:customAreaLayer>
...
</dvt:thematicMap>
```

After configuring and adding a custom layer to the map layer hierarchy, you can then use the map layer in the same way as any other map layer. For example, to create the thematic map illustrated in [Figure 26–58](#), you will need to do the following:

- Configure the thematic map to support drilling. For more information, see [Section 26.6.8, "How to Configure Drilling in Thematic Maps."](#)

---

---

**Note:** If drilling is enabled for the thematic map, drilling between a custom layer and the map layer used to aggregate the custom layer is available without configuring data display for either layer.

---

---

- Add and configure an area data layer for the county data view. For more information, see [Section 26.6.3, "How to Add Data Layers to Thematic Maps."](#)
- Add and style area components to display the related data for each map layer. For more information, see [Section 26.6.4, "Styling Areas, Markers, and Images to Display Data."](#)
- Configure the thematic map legend. For more information, see [Section 26.6.9, "Creating Databound Legends."](#)

[Example 26–33](#) shows sample code for using a custom layer in a thematic map.

**Example 26–33 Sample Code for Thematic Map with Custom Layer**

```
<dvt:thematicMap id="thematicMap" imageFormat="flash" basemap="usa" drilling="on"
    maintainDrill="true"
    controlPanelBehavior="initExpanded" summary="US Custom Regions">
  <dvt:customAreaLayer id="crl1" value="#{tmapRegions.collectionModel}" var="row"
    varStatus="rowStatus"
    extendsLayer="states">
    <dvt:customArea areaId="#{row.name}" label="#{row.name}"
      areaList="#{row.regions}" id="ca1"/>
  </dvt:customAreaLayer>
  <dvt:areaLayer id="custom" layer="crl1">
    <dvt:areaDataLayer contentDelivery="immediate"
      value="#{tmapRegions.collectionModel}"
      selectionMode="single"
      var="row" varStatus="rowStatus" id="ad1">
      <dvt:areaLocation name="#{row.name}" id="al1">
        <dvt:area fillColor="#{row.color}" shortDesc="#{row.regions}"
          id="a1" value="#{row.name}"/>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  <dvt:areaLayer id="areaLayerS" layer="states">
    <dvt:areaDataLayer id="dataLayerS" selectionMode="multiple"
      contentDelivery="immediate"
      value="#{tmapStates.collectionModel}" var="row"
      varStatus="rowStatus">
      <dvt:areaLocation id="areaLocS" name="#{row.name}">
        <dvt:area id="area1S" fillColor="#{row.color}"></dvt:area>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  <dvt:areaLayer id="areaLayer" layer="counties">
    <dvt:areaDataLayer id="dataLayer" selectionMode="single"
      contentDelivery="immediate"
      value="#{tmapCounty.collectionModel}" var="row"
      varStatus="rowStatus">
      <dvt:areaLocation id="areaLoc" name="#{row.name}">
        <dvt:area id="area1" fillColor="#{row.color}"
          value="#{row.category}"></dvt:area>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
```

```

<dvt:legend label="Sales Regions" id="l1">
  <dvt:legendSection source="custom:adl1:a1" id="ls1"/>
  <dvt:legendSection label="Counties" source="areaLayer:dataLayer:areaLoc"
    id="ls3"/>
</dvt:legend>
</dvt:thematicMap>

```

## 26.6.8 How to Configure Drilling in Thematic Maps

A thematic map with related data views in different map layers can be configured for drilling between the higher and lower level data views. For example, a thematic map can display data for sales category by USA state drilled down to USA county data as illustrated in [Figure 26–58](#). When a state or county is selected, drilling up or down is initiated through a context menu choice or the Control Panel.

The following requirements must be met to achieve thematic map area drilling declaratively:

- For each map layer (`areaLayer`) in the drilling hierarchy, you must bind its child `areaDataLayer` with a data control that defines the related data for that map layer.
- Each `areaDataLayer` in the map layer drill hierarchy must have its `selectionMode` attribute set to `single` or `multiple`.
- You must configure the `area` in the lower level map layer drill hierarchy to display data using the same default stamp or categorical attribute style used in the higher level map layer area component.
- The `thematicMap` component `drilling` attribute must be set to `on`.

---

---

**Note:** If drilling is enabled for the thematic map, drilling between a custom layer and the map layer used to aggregate the custom layer is available.

---

---

### Before you begin:

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see [Section 26.6.1, "How to Create a Thematic Map Using ADF Data Controls."](#)

You should already have data controls that define the data model for each of the map layers in the drill hierarchy.

### To configure a thematic map area for drilling:

1. In the Structure window, select the `dvt:thematicMap` component.
2. In the Property Inspector, expand the **Behavior** section. Use this section to set the following attributes:
  - **Drilling:** Use to enable drilling the area data view between thematic map layers. From the dropdown list select **on** to enable drilling. The default value is **off**.

- **MaintainDrill:** Optionally, use to specify an optional **true** value for maintaining the drilled state of a previously drilled area when a new area is drilled. The default value is **false**.
  - **DrillBehavior:** Optionally, use to specify an optional **zoomToFit** effect on the area being drilled. The default value is **none**.
3. In the Layer Browser, select each **Area Layer** component in the desired drilling hierarchy and do the following:
    - Click the **Add icon** and choose **Add Data Layer** to open the Create Data Layer dialog. Complete the dialog to add an area data layer and bind the data layer to the data control for that map layer. If you need help, press F1 or click **Help**.

---

**Note:** If the **Area Data Layer** is already present, click the **Edit icon** to confirm binding to the data control.

---

- In the Property Inspector, expand the **Behavior** section and set the **SelectionMode** attribute to **single** or **multiple**.
4. In the Layer Browser, select each **Area Data Layer** component in the desired drilling hierarchy and do the following:
    - Click the **Add icon** and choose **Add Area** to open the Configure Area dialog. Complete the dialog to define a default stamp or use attribute groups to style the area for that map layer. If you need help, press F1 or click **Help**.

---

**Note:** If the **Area** is already present, click the **Edit icon** to confirm the styling of the area.

---

Figure 26–34 shows sample code for drilling enabled for USA states and counties map layers with an area styled to display data about sales categories.

#### **Example 26–34 Sample Code for Configuring Drilling**

```
<dvt:thematicMap id="thematicMap"
  basemap="usa"
  drilling="on"
  maintainDrill="true"
  drillBehavior="zoomToFit"
  animationOnDisplay="none"
<dvt:areaLayer id="a1" layer="states">
  <dvt:areaDataLayer id="ad1"
    selectionMode="single"
    contentDeliver="immediate"
    value="#{row.state}"
    var="row"
    var="rowStatus">
    <dvt:areaLocation id="areaLocS" name="#{row.stname}">
      <dvt:area id="a1" fillColor="#{row.state}"/>
    </dvt:areaLocation>
  </dvt:areaDataLayer>
</dvt:areaLayer>
<dvt:areaLayer id="a2" layer="counties">
  <dvt:areaDataLayer id="ad2"
    selectionMode="single"
    contentDelivery="immediate"
    value="#{row.county}"
```

```

        var="row"
        varStatus="rowStatus">
        <dvt:areaLocation id="areaLocC" name="{row.coname}">
            <dvt:area id="a2" fillColor="{row.county}" />
        </dvt:areaLocation>
    </dvt:areaDataLayer>
</dvt:areaLayer>
...
</dvt:thematicMap>

```

### 26.6.9 Creating Databound Legends

Legends provide an explanatory table of the thematic map’s styled data in symbol and label pairs. Thematic map legend components (`legend`) support symbols for color, shape, custom shape, fill pattern, opacity, images and size. One or more child legend item components (`legendSection`) are sourced from thematic map `area`, `marker`, `attributeGroups`, or `af:image` components stamped to style the data displayed in the map. The legend section structure supports control over content ordering and appearance. You can wrap legend items into a disclosable section using a `showLegendSection` component. [Figure 26–61](#) shows a legend with a disclosable section for map areas and a marker.

**Figure 26–61 Legend with Disclosable Section and Marker**

Legend items sourced from the `attributeGroups` component automatically split area or marker attribute types into different sections. You can specify a separator facet to draw separators between legend sections. [Figure 26–62](#) shows a legend with attribute groups for color, shape, fill pattern, opacity, and size with separators between each section.

**Figure 26–62 Legend with Attribute Groups**

Legends can be displayed in both Flash (default) and PNG image formats and both formats support locales with right-to-left display. When rendered in a PNG format, for example when printing the thematic map, disclosable sections in the legend are not supported, and legend items display as disclosed.

When you create a thematic map using the Data Controls panel and the thematic map binding dialogs, the legend data bindings are created for you. If you configure an area or marker as a default stamp across all areas in the thematic map, you can assign a static text resource to a fixed area or marker for the legend.

For default stamps displaying row-varying data, you can use an EL expression to assign the legend text and optionally, a managed bean to retrieve a row-varying key to look up the text resource in a resource bundle. [Example 26–35](#) shows a code sample to generate legend entries for area and marker stamps. The code illustrates a disclosable section for a row-varying area and a fixed marker with an assigned text resource.

#### **Example 26–35 Code Sample for Legend Area and Marker Stamps**

```
<dvt:thematicMap id="tm1" basemap="usa" ...>
  <dvt:legend label="Legend">
    <dvt:showLegendGroupLabel label="Voting Majority">
      <dvt:legendSection id="ls1" source="all:adl1:areaStamp"/>
    </dvt:showLegendGroupLabel>
    <dvt:legendSection id="ls2" source="all:adl1:fixedMarker">
    </dvt:legendSection>
  </dvt:legend>
  <dvt:areaLayer id="all" layer="states">
    <dvt:areaDataLayer id="adl1"...>
      <dvt:areaLocation id="aloc1" , , ,>
        <dvt:area id="areaStamp">
          fillColor="#{row.value > 50 ? tmapLegendBean,color1 :
            tmapLegendBean.color2}"
          <f:attribute name="legendLabel" value="#{row.value > 50 ?
            'Candidate 2' : 'Candidate 1'}" />
        </dvt:area>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
</dvt:thematicMap>
```

```

        <dvt:marker id="fixedMarker" shape="human" fillColor="#FF9900"
                scaleX="3" scaleY="3">
            <f:attribute name="legendLabel"
                value="#{Bundle.Office_Locations}"/>
        </dvt:marker>
    </dvt:areaLocation>
</dvt:areaDataLayer>
</dvt:area>
</dvt:thematicMap>

```

If you configure an area or marker to use an attributes group to specify the styling of categorical groups of data in a data collection, you can use an EL expression to assign the legend text and optionally, a managed bean to retrieve a row-varying key to look up the text resource in a resource bundle.

If you specify a match rule for the attributes group, the legend text is specified in the group attribute. If you specify an exception rule, you can specify a text resource from the application resource bundle. [Example 26–36](#) shows sample code for a legend with attribute groups, including both a match rule and an exception rule, and specifying a separator between legend sections.

#### **Example 26–36 Sample Code for Legend with Attribute Groups**

```

<dvt:thematicMap id="tm1" basemap="usa" ...>
  <dvt:legend id="l1" label="Legend">
    <f:facet name="separator"
        <af:separator/>
    <dvt:legendSection id="ls1" source="all:adl1:attributeGroupColor" />
    <dvt:legendSection id="ls2" source="all:adl1:attributeGroupShape" />
    <dvt:legendSection id="ls3" source="all:adl1:attributeGroupPattern" />
    <dvt:legendSection id="ls4" source="all:adl1:attributeGroupOpacity" />
  </dvt:legend>
  <dvt:areaLayer id="all" layer="states">
    <dvt:areaDataLayer id="adl1" value=" " var=" " ...>
      <dvt:areaLocation id="dataLoc" name="#{row.name}">
        <dvt:marker id="m1"... >
          <dvt:attributeGroups id="attributeGroupColor" type="color"
              label="#{row.category1}" value="#{row.category1}" />
          <dvt:attributeMatchRule id="amr1" group="Mountain Dew">
            <f:attribute name="color" value="#ffff00"/>
          </dvt:attributeMatchRule>
          <dvt:attributeGroups id="attributeGroupShape" type="shape"
              label="#{row.category2}" value="#{row.category2}" />
          <dvt:attributeExceptionRule id="aer1" condition="#{row.name=='TX'}"
              label="#{viewController.Texas}">
            <f:attribute name="shape" value="human"/>
          </dvt:exceptionRule>
          <dvt:attributeGroups id="attributeGroupShape" type="pattern"
              label="#{row.category3}" ... />
          <dvt:attributeGroups id="attributeGroupShape" type="opacity"
              label="#{row.category4}" ... />
        </dvt:marker>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
</dvt:thematicMap>

```

You configure thematic map legend areas or markers in a custom region in the same way as any other map layer. [Example 26–37](#) shows sample code for a custom map layer legend.

**Example 26–37 Sample Code for Legend for Custom Map Layer**

```

<dvt:thematicMap>
  <dvt:legend>
    <dvt:legendSection label="Sales Regions" source="customAreaStamp" />
  </dvt:legend>
  ...
  <dvt:customAreaLayer id="cr11">
    ...
  </dvt:customAreaLayer>
  <dvt:areaLayer layer="cr11">
    <dvt:areaDataLayer var="row">
      <dvt:areaLocation name="{row.name}" id="a11">
        <dvt:area id="customAreaStamp" fillColor="{row.color}">
          <f:attribute name="legendLabel" value="{row.name}" />
        </dvt:area>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
</dvt:thematicMap>

```

You can customize the appearance of thematic map legends using ADF skins. For more information, see the "Customizing the Appearance Using Styles and Skins" chapter in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*

## 26.7 Creating Databound Gantt Charts

A Gantt chart is a type of bar graph (with time on the horizontal axis). It is used in planning and tracking projects to show tasks or resources in a time frame with a distinct beginning and end.

When you create a Gantt chart, you can choose from the following types:

- **Project**  
A project Gantt chart lists tasks vertically and shows the duration of each task as a bar on a horizontal time line.
- **Resource Utilization**  
A resource utilization Gantt chart shows graphically whether resources are over or under allocated. It shows resources vertically while showing their allocation and, optionally, capacity on the horizontal time axis.
- **Scheduling**  
A scheduling Gantt chart is based on manual scheduling boards and shows resources vertically with corresponding activities on the horizontal time axis. Examples of resources include people, machines, or rooms.

For information about customizing Gantt chart charts after data-binding is completed, see the "Using ADF Gantt Chart Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

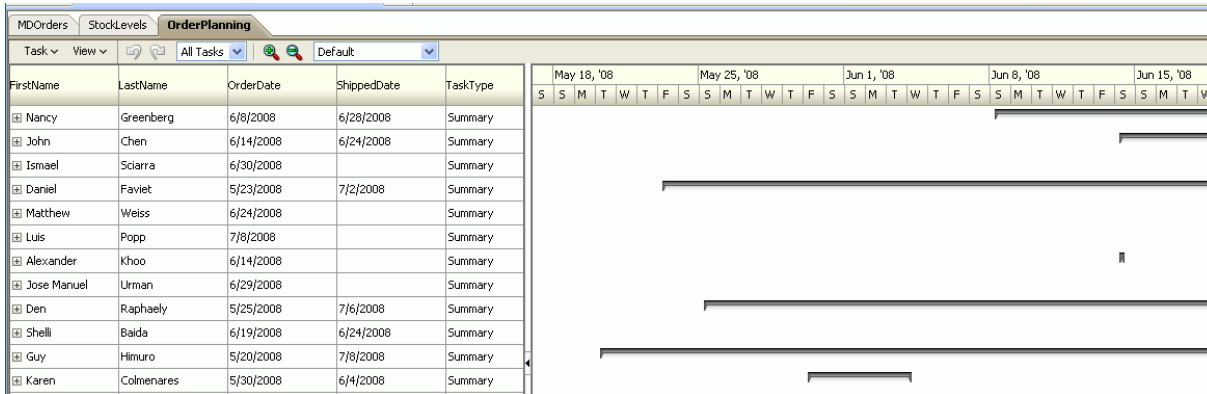

### 26.7.1 How to Create a Databound Project Gantt Chart

For a project Gantt chart, you must specify values for tasks. Optionally, you can specify values for split tasks, subtasks, recurring tasks, and dependencies between tasks, if your data collection has accessors for this additional information.

The project Gantt chart is displayed with default values for overall start time and end time and for the major and minor time axis values. In a project Gantt chart, the setting for the major time axis defaults to weeks and the setting for the minor time axis defaults to days.

Figure 26–63 shows a project Gantt chart in which each task is an order to be filled. The list region on the left side of the splitter shows columns with the name of the person who is responsible for the order and columns for the order date and shipped date. In the chart region on the right side of the splitter, the Gantt chart displays a horizontal bar from the order date to the ship date for each order.

**Figure 26–63 The Order Shipping Project Gantt Chart**

To create a project Gantt chart using a data control, you bind the project Gantt chart component to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

**Tip:** You can also create a project Gantt chart by dragging a project Gantt chart component from the Component Palette and completing the Create Project Gantt dialog. This approach allows you to design the Gantt chart user interface before binding the component to data.

**To create a databound project Gantt chart:**

1. From the Data Controls panel, select a data collection. For a Gantt chart, you can select a row set collection (which produces a flat list of tasks) or a basic tree collection (which produces a hierarchical list of tasks).

Figure 26–64 shows an example where you could select the OrderShippingSummary1 collection in the Data Controls panel to create a project Gantt chart that displays the progress of order shipping.

**Figure 26–64 Data Collection for Shipping Orders**

2. Drag the collection onto a JSF page and, from the context menu, choose **Gantt > Project**.
3. In the ensuing Create Project Gantt dialog, you do the following to connect task-related controls in the pages at the top of the dialog with corresponding columns in the data collection:

- a. In the Tasks page at the top of the dialog, you select the columns in the data collection that correspond to each of the following controls: **Task Id**, **Start Time**, and **End Time**. By clicking **Show More** in the dialog, you can select additional columns in the data collection that correspond to the following controls: **Actual Start**, **Actual End**, **% Complete**, **Completed Through**, **Critical**, and **Is Container**.

Optionally, you can select a column in the data collection to map to the task type. If you do not bind **Task Type** to a column in your data collection, then all tasks default to **Normal**. The task type controls the appearance of the task bar when it is rendered in the Gantt chart.

A project Gantt chart component supports the following task types that you configure the data collection to return: Summary, Normal, and Milestone.

- b. If the data collection has an accessor for subtasks, you have the option of using the Subtasks page in the dialog to select the subtasks accessor and to select the columns in the data collection that correspond to each of the following controls: **SubTask Id**, **Start Time**, and **End Time**. Optionally, you can select a column in the data collection to map to the subtask type. If you do not bind **SubTask Type** to data, then all subtasks default to **Normal**.

A project Gantt chart component supports the following task types that you configure the data collection to return: Summary, Normal, and Milestone.

If you do not bind subtasks, then the Gantt chart cannot render a hierarchy view of tasks. If you bind subtasks, then you can drill from tasks to subtasks in the hierarchy view of the Gantt chart.

- c. If the data collection has an accessor for dependent tasks, you have the option of using the **Dependent Tasks** page in the dialog to select the dependent task accessor and to select the columns in the data collection that correspond to the following controls: **Dependency Type**, **From Task Id**, and **To Task Id**.

Dependent tasks are linked by their dependency between their finish and start times.

A project Gantt chart component supports the following dependency types that you configure the data collection to return: **fs** (for finish to start), **ss** (for start to start), **ff** (for finish to finish), and **sf** (for start to finish).

- d. If the data collection has an accessor for split tasks, you have the option of using the Split Tasks page in the dialog to select **Split Tasks** accessor and to select the columns in that data collection that correspond to each of the following controls: **SplitTask Id**, **Start Time**, and **End Time**.
  - e. If the data collection has an accessor for recurring tasks, you have the option of using the **Recurring Tasks** page in the dialog to select the recurring tasks accessor and to select the columns in that data collection that correspond to each of the following controls: **Recurring Task Id**, **Type**, **Start Time**, and **End Time**.
  - f. You can use the **Appearance** page in the dialog to specify the attributes that correspond to the **Label** of the task bar, and up to three icons to associate with the task bar.
4. In the **Table Columns** section, you specify the columns to appear in the list region of the Gantt chart. Specify one row of information for each column that is to appear. Use the **New** icon to add new rows. Use the arrow icons to arrange the rows in the exact sequence that you want the columns to appear in the Gantt chart list.

---

---

**Note:** The first row that you specify in the **Table Columns** section designates the nodestamp column for the list region. The nodestamp column is the one that you can expand or collapse when you have a subtask collection.

---

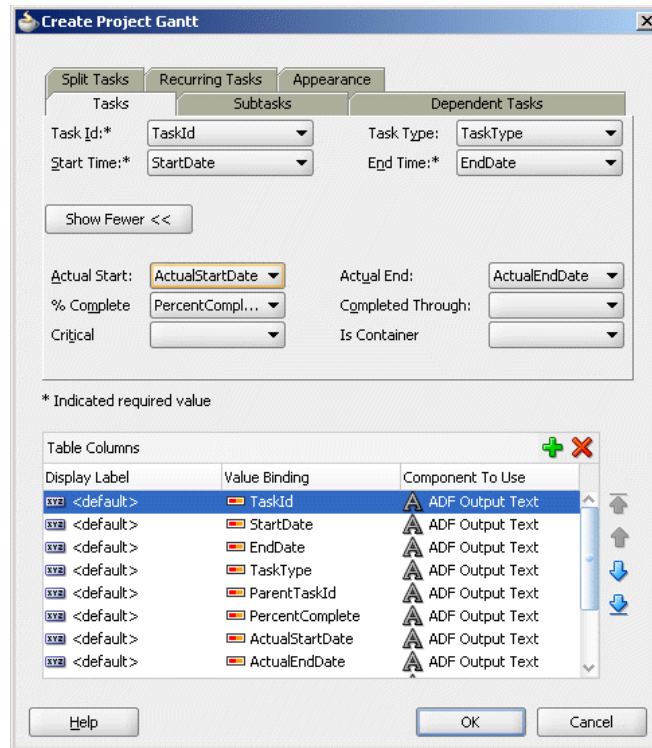

---

For each row, you provide the following specifications:

- **Display Label:** Select the values for the headers of the columns in the Gantt chart list. If you select **<default>**, then the text for the header is automatically retrieved from the data binding.
  - **Value Binding:** Select the columns in the data collection to use for the columns in the Gantt chart list. The available values are the same as those for the tasks group.
  - **Component to Use:** Select the type of component to display in the cell of the Gantt chart list. The default is the ADF Output Text component.
5. Click **OK**.
6. If you want to include a legend in the Gantt chart, right-click the project Gantt chart node in the Structure window and choose **Insert inside dvt:projectGantt > Legend**.

The legend shows information about each symbol and color coded bar that is used to represent different task types. It also shows detailed information about the task that is selected in the Gantt chart.

Figure 26–65 shows the dialog used to create the project Gantt dialog from the data collection for shipping orders.

**Figure 26–65 Create Project Gantt Dialog for Orders Shipped**

After completing the data binding dialog, you can use the Property Inspector to specify values for additional attributes for the project Gantt chart.

## 26.7.2 What Happens When You Create a Project Gantt Chart from a Data Control

Dropping a project Gantt chart from the Data Controls panel has the following effect:

- Creates the bindings for the Gantt chart and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

[Example 26–38](#) displays the row set bindings that were generated for the project Gantt chart that displays orders shipped. This code example shows that there are nodes defined for tasks and subtasks, along with attributes. There are also nodes defined for dependent tasks, split tasks, and recurring tasks but no attributes.

### **Example 26–38 Bindings for a Project Gantt Chart**

```
<gantt IterBinding="OrderShippingSummary2Iterator"
      id="OrderShippingSummary2" xmlns="http://xmlns.oracle.com/adfm/dvt">
  <ganttdatamap>
    <nodeDefinition DefName="oracle.fod.model.OrderShippingSummary"
      type="Tasks">
      <AttrNames>
        <Item Value="PersonId" type="taskId"/>
        <Item Value="OrderDate" type="startTime"/>
        <Item Value="TaskType" type="taskType"/>
        <Item Value="ShippedDate" type="endTime"/>
      </AttrNames>
      <Accessors>
        <Item Value="OrderShippingDetails" type="subTasks"/>
      </Accessors>
    </nodeDefinition>
  </ganttdatamap>
</gantt>
```

```

        </Accessors>
    </nodeDefinition>
    <nodeDefinition type="SubTasks"
        DefName="oracle.fod.model.OrderShippingDetails">
        <AttrNames>
            <Item Value="OrderId" type="taskId"/>
            <Item Value="OrderDate" type="startTime"/>
            <Item Value="TaskType" type="subTaskType"/>
            <Item Value="ShippedDate" type="endTime"/>
        </AttrNames>
    </nodeDefinition>
    <nodeDefinition type="Dependents">
        <AttrNames/>
    </nodeDefinition>
    <nodeDefinition type="SplitTasks">
        <AttrNames/>
    </nodeDefinition>
    <nodeDefinition type="RecurringTasks">
        <AttrNames/>
    </nodeDefinition>
</ganttDataMap>
</gantt>

```

**Example 26–39** shows the code generated on the JSF page for the ADF project Gantt chart. This tag code contains settings for the overall start and end time for the project Gantt chart. It also shows the default time axis settings for the major axis (in weeks) and the minor axis (in days). Finally, it lists the specifications for each column that appears in the list region of the Gantt chart. For brevity, the code in the `af:column` elements for `OrderStatusCode` and `ShippedDate` has been omitted.

**Example 26–39 Code on the JSF Page for a Project Gantt Chart**

```

<projectGantt id="projectGantt1"
    value="#{bindings.OrderShippingSummary2.projectGanttModel}"
    var="row" startTime="2008-05-17" endTime="2008-07-07"
    inlineStyle="width:100%; height:100%;">
    <f:facet name="major">
        <timeAxis scale="weeks"/>
    </f:facet>
    <f:facet name="minor">
        <timeAxis scale="days"/>
    </f:facet>
    <f:facet name="nodeStamp">
        <af:column sortProperty="FirstName" sortable="false"
            headerText="#{bindings.OrderShippingSummary2.hints.FirstName.label}">
            <af:outputText value="#{row.FirstName}"/>
        </af:column>
    </f:facet>
        <af:column sortProperty="LastName" sortable="false"
            headerText="#{bindings.OrderShippingSummary2.hints.LastName.label}">
            <af:outputText value="#{row.LastName}"/>
        </af:column>
        <af:column sortProperty="OrderDate" sortable="false"
            headerText="#{bindings.OrderShippingSummary2.hints.OrderDate.label}">
            <af:outputText value="#{row.OrderDate}">
                <af:convertDateTime
                    pattern="#{bindings.OrderShippingSummary2.hints.OrderDate.format}"/>
            </af:outputText>
        </af:column>
        <af:column sortProperty="ShippedDate" sortable="false"

```

```

        headerText="#{bindings.OrderShippingSummary2.hints.ShippedDate.label}">
<af:outputText value="#{row.ShippedDate}">
<af:convertDateTime
    pattern="#{bindings.OrderShippingSummary2.hints.ShippedDate.format}"/>
</af:outputText>
</af:column>
<af:column sortProperty="TaskType" sortable="false"
    headerText="#{bindings.OrderShippingSummary2.hints.TaskType.label}">
<af:outputText value="#{row.TaskType}"/>
</af:column>
</projectGantt>

```

### 26.7.3 What You May Need to Know About Summary Tasks in a Project Gantt Chart

A summary task shows start time and end time for a group of tasks (which are usually subtasks). A summary task cannot be moved or extended. However, your application should recalculate the summary task times when the dates of any subtask changes.

To detect a change in task duration, register an event handler by specifying a method binding expression on the `DataChangeListener` attribute of the Gantt chart component. When an action occurs that potentially changes data in the Gantt chart, the event fired is of type

`oracle.adf.view.faces.bi.event.DataChangeEvent`. This event contains information about the data changes and is fired to the registered event listener. The listener is responsible for validating the new values and updating the underlying data model.

When the update is completed, the Gantt chart is refreshed with either the old data (if the update failed) or with the new data. The Gantt chart uses partial page rendering so that only the Gantt chart and not the entire page is refreshed.

### 26.7.4 What You May Need to Know About Percent Complete in a Project Gantt Chart

Percent complete can be represented as an inner bar that indicates what percentage of a task is complete. The length of the inner bar is calculated based on percent complete returned by the data object.

The data binding dialog for the project Gantt chart does not provide a control in which you can enter the percentage complete value, but this value is required to render a percent complete. However, the Gantt chart data object does contain a `percentComplete` attribute.

To provide the percent complete integer, you must add a new attribute mapping in the `nodeDefinition` for type `Tasks`. For example, if your data collection has a column named `PercentDone`, then the attribute mapping would appear as follows: `<Item Value="PercentDone" type="percentComplete"/>`.

[Example 26–40](#) shows the percent complete attribute mapping added to the data binding code for the `nodeDefinition` of type `Tasks` in the project Gantt chart binding displayed in [Example 26–38](#).

#### **Example 26–40 Bindings for Project Gantt Chart with Percent Complete**

```

<nodeDefinition DefName="oracle.fod.model.OrderShippingSummary"
    type="Tasks">
    <AttrNames>
        <Item Value="PersonId" type="taskId"/>
        <Item Value="OrderDate" type="startTime"/>
        <Item Value="TaskType" type="taskType"/>
        <Item Value="ShippedDate" type="endTime"/>
    </AttrNames>

```

```

    <Item Value="PercentDone" type="percentComplete"/>
  </AttrNames>
</nodeDefinition>

```

Another attribute (`completedThrough`) exists that allows you to specify a date rather than a percentage. The Gantt chart data object calculates the percentage complete based on the date that the `completedThrough` attribute references. For example, if your data collection has a column named `PercentDone`, then the attribute mapping would appear as follows: `<Item Value="PercentDone" type="completedThrough"/>`.

## 26.7.5 What You May Need to Know About Variance in a Project Gantt Chart

Variance can be rendered within two horizontal bars. One bar represents the base (or original) start and end time for the task. The second bar represents the actual start and end time for the task. You enter the binding information for the base start time and end time in the data binding dialog for a project Gantt chart.

The data binding dialog for Gantt chart does not provide controls in which you can enter the actual start time and actual end time for the Gantt chart, but these values are required to render variance. However, the Gantt chart data object does contain the following attributes: `actualStart` and `actualEnd`.

To provide the actual start and actual end time, you must add two new attribute mappings in the `nodeDefinition` for type `Tasks`. For example, if your data collection has columns named `ActualStartDate` and `ActualEndDate`, then the attribute mappings would appear as shown in [Example 26–41](#).

### **Example 26–41** Attribute Mappings for Actual Start and Actual End

```

<Item Value="ActualStartDate" type="actualStart"/>
<Item Value="ActualEndDate" type="actualEnd"/>

```

[Example 26–42](#) shows the actual start and actual end attribute mappings added to the data binding code for the `nodeDefinition` of type `Tasks` for a project Gantt chart.

### **Example 26–42** Bindings for Project Gantt Chart with Actual Start and Actual End

```

<nodeDefinition DefName="oracle.fod.model.OrderShippingSummary"
  type="Tasks">
  <AttrNames>
    <Item Value="PersonId" type="taskId"/>
    <Item Value="OrderDate" type="startTime"/>
    <Item Value="TaskType" type="taskType"/>
    <Item Value="ShippedDate" type="endTime"/>
    <Item Value="ActualStartDate" type="actualStart"/>
    <Item Value="ActualEndDate" type="actualEnd"/>
  </AttrNames>
</nodeDefinition>

```

## 26.7.6 How to Create a Databound Resource Utilization Gantt Chart

For a resource utilization Gantt chart, you must supply identification for resources, identification for time, and start and end times for resource usage. Optionally, you can provide data values for subresources.

The resource utilization Gantt chart is displayed with default values for the major and minor time axis values. In a resource utilization Gantt chart, the setting for the major time axis defaults to weeks and the setting for the minor time axis defaults to days.

Figure 26–66 shows a resource utilization Gantt chart that lists each resource and an associated calendar that can display when the resource is in use.

**Figure 26–66 Resource Utilization Gantt Chart**

To create a resource utilization Gantt chart using a data control, you bind the resource utilization component to a data collection. JDeveloper allows you to do this declaratively by dragging a collection from the Data Controls panel and dropping it on a JSF page.

**Tip:** You can also create a resource utilization Gantt chart by dragging a resource utilization Gantt chart component from the Component Palette and completing the Create Resource Utilization Gantt dialog. This approach gives you the option of designing the Gantt chart user interface before binding the component to data.

#### To create a resource utilization Gantt chart:

1. From the Data Controls panel, select a data collection. For a Gantt chart, you can select a row set collection or a basic tree collection.

Figure 26–67 shows an example where you could select the `GanttRugResourcesView1` collection in the Data Controls panel to create a resource utilization Gantt chart to display the usage of a resource.

**Figure 26–67 Data Collection for Resource Utilization**

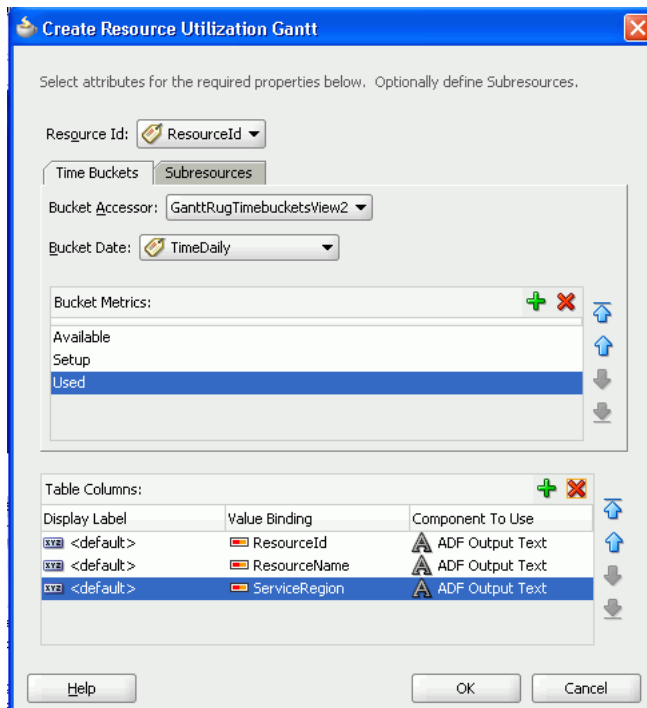

2. Drag the collection onto a JSF page and, from the context menu, choose **Gantt > Resource Utilization**.
3. In the Create Resource Utilization Gantt dialog, connect resource- and time-related controls with corresponding columns in the data collection.
  - a. For **Resource Id**, select the column in the data collection that corresponds to the unique identifier of the resource.
  - b. In the **Time Buckets** page, select a value from the **Bucket Accessor** dropdown list that contains the time buckets assigned to the resource and select a value from the **Bucket Date** dropdown list that corresponds to a unit of time.
  - c. In the **Bucket Metrics** list, you can optionally specify attributes that appear as bars within the time bucket. Each attribute that you specify in the **Bucket**

**Metrics** list must be of type Number as the value of the attribute is used to calculate the height of the bar.

- d. In the **Table Columns** list, specify the column(s) to appear in the list region of the Gantt chart resource utilization on the left side of the splitter. Specify one row of information for each column that is to appear. Use the New icon to add new rows. Use the arrow icon to arrange the rows in the exact sequence that you want the columns to appear in the resource utilization list. For each row, provide values for **Display Label**, **Value Binding**, and **Component to Use**.
  - e. If the data collection has an accessor for subresources, you can use the **Subresources** page to select a subresources accessor and a resource ID.
4. Click **OK**.

Figure 26–68 shows the dialog used to create a resource utilization Gantt chart from the data collection for resources available for a project.

**Figure 26–68 Create Resource Utilization Gantt Chart**

### 26.7.7 What Happens When You Create a Resource Utilization Gantt Chart

Dropping a resource utilization Gantt chart from the Data Controls panel onto a JSF page has the following effects:

- Creates bindings for the resource utilization Gantt chart and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

Example 26–43 shows the row set bindings that were generated for the resource utilization Gantt chart illustrated in Figure 26–68.

**Example 26–43 Binding XML for a Resource Utilization Gantt Chart**

```
<gantt IterBinding="GanttRugResourcesView2Iterator"
```

```

        id="GanttRugResourcesView2"
        xmlns="http://xmlns.oracle.com/adfm/dvt">
<ganttDataMap>
  <nodeDefinition DefName="model.GanttRugResourcesView" type="Resources">
    <AttrNames>
      <Item Value="ResourceId" type="resourceId"/>
    </AttrNames>
    <Accessors>
      <Item Value="GanttRugTimebucketsView2" type="timeBuckets"/>
    </Accessors>
  </nodeDefinition>
  <nodeDefinition type="TimeBuckets"
    DefName="model.GanttRugTimebucketsView">
    <AttrNames>
      <Item Value="TimeDaily" type="time"/>
      <Item type="metric" Value="Available"/>
      <Item type="metric" Value="Setup"/>
      <Item type="metric" Value="Used"/>
    </AttrNames>
  </nodeDefinition>
  <nodeDefinition type="Subresources">
    <AttrNames/>
  </nodeDefinition>
</ganttDataMap>
</gantt>

```

**Example 26–44** shows the code generated on the JSF page for the resource utilization Gantt chart. This tag code contains settings for the overall start and end time for the resource utilization Gantt chart. These settings have to be edited manually. The code also shows the time axis settings for the major time axis (in weeks) and the minor time axis (in days). Finally, it lists the specifications for each column to appear in the list region of the resource utilization Gantt chart.

**Example 26–44 Code on the JSF Page for a Resource Utilization Gantt Chart**

```

<dvt:resourceUtilizationGantt id="resourceUtilizationGantt1"
  value="#{bindings.GanttRugResourcesView2.resourceUtilizationGanttModel}"
  var="row"
  metrics="#{bindings.GanttRugResourcesView2.metrics}"
  taskbarFormatManager="#{bindings.GanttRugResourcesView2.
    resourceUtilizationGanttTaskbarFormatManager}"
  startTime="2008-07-03"
  endTime="2008-07-29">
  <f:facet name="major">
    <dvt:timeAxis scale="weeks"/>
  </f:facet>
  <f:facet name="minor">
    <dvt:timeAxis scale="days"/>
  </f:facet>
  <f:facet name="nodeStamp">
    <af:column sortProperty="ResourceId" sortable="false"
      headerText="#{bindings.GanttRugResourcesView2.hints.ResourceId.label}">
      <af:outputText value="#{row.ResourceId}"/>
    </af:column>
  </f:facet>
  <af:column sortProperty="ResourceName" sortable="false"
    headerText="#{bindings.GanttRugResourcesView2.hints.ResourceName.label}">
    <af:outputText value="#{row.ResourceName}"/>
  </af:column>
  <af:column sortProperty="ServiceRegion" sortable="false"

```

```

        headerText="{bindings.GanttRugResourcesView2.hints.ServiceRegion.label}">
        <af:outputText value="{row.ServiceRegion}" />
    </af:column>
</dvt:resourceUtilizationGantt>

```

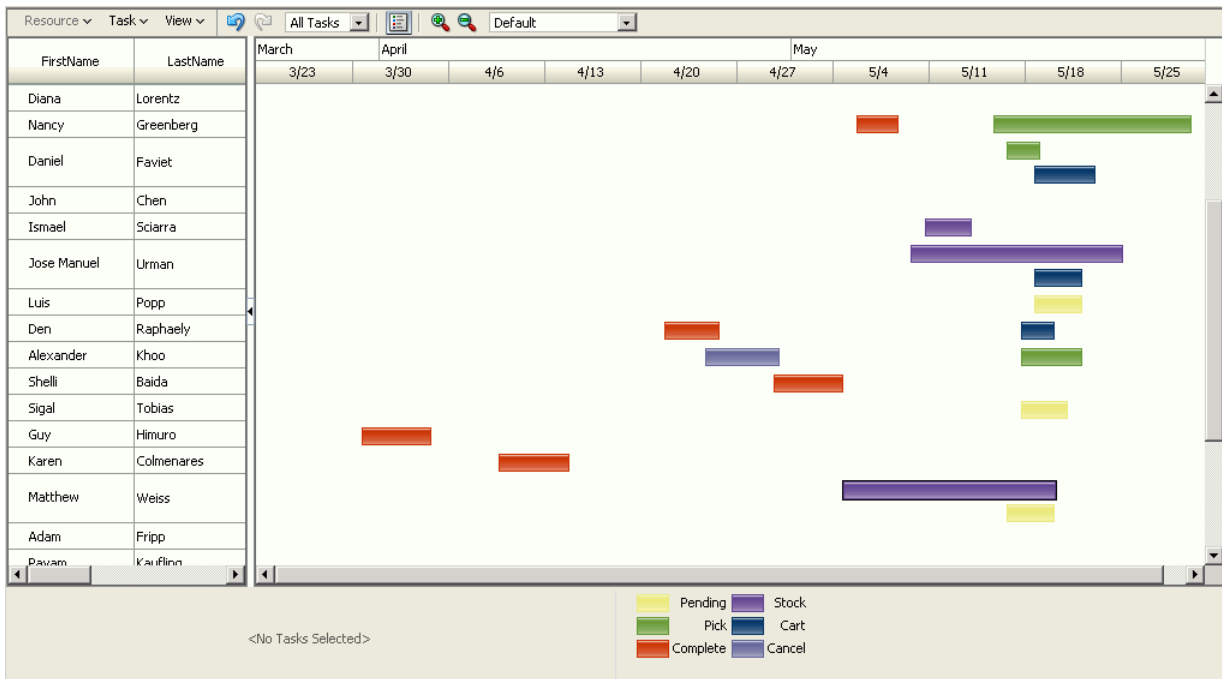

### 26.7.8 How to Create a Databound Scheduling Gantt Chart

For a scheduling Gantt chart, you must supply identification for resources, identification for tasks, and start and end times for tasks. Optionally, you can provide data values for subresources, recurring tasks, split tasks, and dependencies between tasks.

The scheduling Gantt chart is displayed with default values for overall start and end time and for the major and minor time axis values. In a scheduling Gantt chart, the setting for the major time axis defaults to weeks and the setting for the minor time axis defaults to days.

Figure 26–69 shows a scheduling Gantt chart that lists each resource and all the orders for which that resource is responsible. In contrast to a project Gantt chart, the scheduling Gantt chart shows all the tasks for a given resource on the same line, while the project Gantt chart lists each task on a separate line.

**Figure 26–69** The Scheduling Gantt Chart for Order Shipping

To create a scheduling Gantt chart using a data control, you bind the `schedulingGantt` tag to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

**To create a databound scheduling Gantt chart:**

1. From the Data Controls panel, select a data collection. For a Gantt chart, you can select a row set collection or a basic tree collection.

Figure 26–70 shows an example where you could select the `Persons` data collection to create a scheduling Gantt chart that displays the orders that each resource is responsible for.

**Figure 26–70** Data Collection for Resources

2. Drag the collection onto a JSF page and, from the context menu, choose **Gantt**, then **Scheduling**.
3. In the ensuing Create Scheduling Gantt dialog, you do the following to connect resource- and task-related controls at the top of the dialog with corresponding columns in the data collection:
  - a. For **Resource Id**, select the column in the data collection that corresponds to the unique identifier of the resource.
  - b. In the Tasks page select a value from the **Task Accessor** dropdown list that contains the tasks assigned to the resource. Select the columns in the data collection that correspond to each of the following controls: **Task Id**, **Start Time**, and **End Time**. You can optionally specify a data column to map to task type. If you do not bind task type to data, then all task types default to **Normal**.
  - c. If the data collection has an accessor that holds dependent tasks, you have the option of using the Dependent Tasks page in the dialog to select the dependent tasks accessor and to select the columns in that data collection that correspond to each of the following controls: **Dependency Type**, **From Task Id**, and **To Task Id**.
  - d. If the data collection has an accessor for split tasks, you have the option of using the Split Tasks page in the dialog to select the split tasks accessor and to select the columns in that data collection that correspond to each of the following controls: **Split Task Id**, **Start Time**, and **End Time**.
  - e. If the data collection has an accessor for recurring tasks, you have the option of using the Recurring Tasks page in the dialog to select the Recurring Tasks accessor and to select the columns in that data collection that correspond to

each of the following controls: **Recurring Task Id**, **Type**, **Start Time**, and **End Time**.

- f. If the data collection has an accessor for subresources (lower-level resources), you have the option of using the Subresources page to specify the appropriate accessor and to select the data column that contains the unique identifier of the subresource.

For example, a manager might be a resource and his direct reports might be subresources. If data contains subresources, then you can drill in a resource to locate subresources.

4. In the **Table Columns** section, you specify the columns that will appear in the list region of the Gantt chart on the left side of the splitter. Specify one row of information for each column that is to appear. Use the **New** icon to add new rows. Use the arrow icon to arrange the rows in the exact sequence that you want the columns to appear in the Gantt chart list. For each row, you provide the following specifications:
  - **Display Label:** Select the values for the headers of the columns in the Gantt chart list. If you select `<default>`, then the text for the header is automatically retrieved from the data binding.
  - **Value Binding:** Select the columns in the data collection to use for the column in the Gantt chart list. The available values are the same as those for the tasks group.
  - **Component to Use:** Select the type of component to display in the cell of the Gantt chart list. The default is the **ADF Output Text** component.
5. Click **OK** to dismiss the Create Scheduling Gantt dialog.
6. Select the `dvt:schedulingGantt` element in the Structure window of the JSF page and set dates for the following attributes of the `dvt:schedulingGantt` element in the Property Inspector:
  - `StartTime`
  - `EndTime`

The dates that you specify determine the initial view that appears in the scheduling Gantt chart at runtime.

[Figure 26-71](#) shows the dialog used to create the scheduling Gantt chart from the data collection for resources responsible for shipping orders.

**Figure 26–71 Create Scheduling Gantt Dialog**

## 26.7.9 What Happens When You Create a Scheduling Gantt Chart

Dropping a scheduling Gantt chart from the Data Controls panel has the following effect:

- Creates the bindings for the Gantt chart and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

[Example 26–45](#) shows the row set bindings that were generated for the scheduling Gantt chart that displays resources and orders shipped.

### **Example 26–45 Binding XML for a Scheduling Gantt Chart**

```
<gantt IterBinding="PersonsIterator" id="Persons"
  xmlns="http://xmlns.oracle.com/adfm/dvt">
  <ganttDataMap>
    <nodeDefinition DefName="oracle.fodemo.storefront.store.queries.PersonsVO"
      type="Resources">
      <AttrNames>
        <Item Value="PersonId" type="resourceId"/>
      </AttrNames>
      <Accessors>
        <Item Value="OrdersVO" type="tasks"/>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition type="Tasks"
      DefName="oracle.fodemo.storefront.store.queries.OrdersVO">
      <AttrNames>
        <Item Value="OrderId" type="taskId"/>
        <Item Value="OrderDate" type="startTime"/>
        <Item Value="OrderStatusCode" type="taskType"/>
        <Item Value="OrderShippedDate" type="endTime"/>
      </AttrNames>
    </nodeDefinition>
    <nodeDefinition type="Dependents">
```

```

        <AttrNames/>
    </nodeDefinition>
    <nodeDefinition type="SplitTasks">
        <AttrNames/>
    </nodeDefinition>
    <nodeDefinition type="RecurringTasks">
        <AttrNames/>
    </nodeDefinition>
    <nodeDefinition type="Subresources">
        <AttrNames/>
    </nodeDefinition>
</ganttDataMap>
</gantt>

```

**Example 26–46** shows the code generated on the JSF page for the scheduling Gantt chart. This tag code contains settings for the overall start and end time for the scheduling Gantt chart. It also shows the time axis settings for the major time axis (in months) and the minor time axis (in weeks). Finally, it lists the specifications for each column that appears in the list region of the Gantt chart. For brevity, the code in the `af:column` elements for `MembershipId`, `Email`, and `PhoneNumber` has been omitted.

**Example 26–46 Code on the JSF Page for a Scheduling Gantt Chart**

```

<dvt:schedulingGantt id="schedulingGantt1"
    value="#{bindings.Persons.schedulingGanttModel}"
    var="row" startTime="2008-03-29"
    endTime="2008-05-30"
    taskbarFormatManager="#{GanttBean.taskbarFormatManager}">
    <f:facet name="major">
        <dvt:timeAxis scale="months"/>
    </f:facet>
    <f:facet name="minor">
        <dvt:timeAxis scale="weeks"/>
    </f:facet>
    <f:facet name="nodeStamp">
        <af:column sortProperty="FirstName" sortable="false"
            headerText="#{bindings.Persons.hints.FirstName.label}">
            <af:outputText value="#{row.FirstName}"/>
        </af:column>
    </f:facet>
    <af:column sortProperty="LastName" sortable="false"
        headerText="#{bindings.Persons.hints.LastName.label}">
        <af:outputText value="#{row.LastName}"/>
    </af:column>
    ...
    <dvt:ganttLegend>
</dvt:schedulingGantt>

```

## 26.8 Creating Databound Timelines

A timeline is an interactive data visualization tool that allows users to view date-based events in chronological order and easily navigate forwards and backwards within a defined time range. A dual timeline can be used for a side-by-side comparison of events. For example, you can use a timeline to display the hire dates of employees, or use a dual timeline to compare multiple human resource events between two employees.

A timeline is composed of the display of events as timeline items along a time axis, a movable overview window that corresponds to the period of viewable time in the timeline, and an overview time axis that displays the total time increment for the timeline. A horizontal zoom control is available to change the viewable time range. Timeline items corresponding to events display associated information or actions and are connected to the date of the event in the time axis. Timelines items are represented by a marker in the overview panel. No more that two series of events are supported by the timeline component.

Figure 26–72 shows a timeline displaying the chronological order of the hire dates of employees. In this example, timeline items representing each event display information about the employee using an image and text with labels. When selection is configured, the timeline item, line feeler, and the event marker in the overview panel are highlighted.

**Figure 26–72 Timeline of Employee Hire Dates**

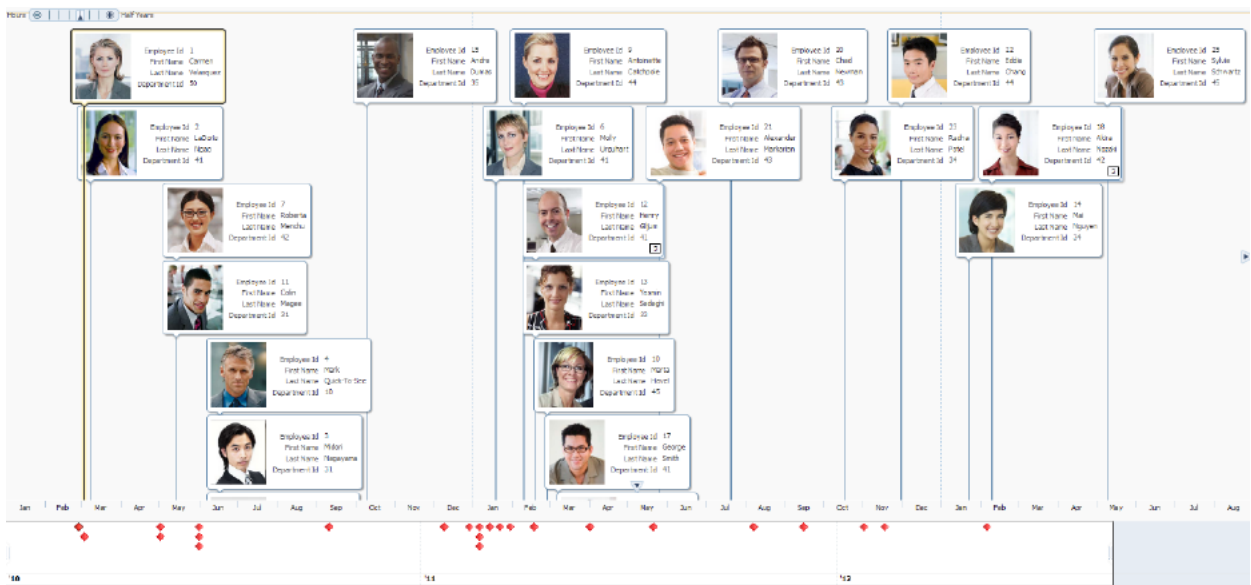

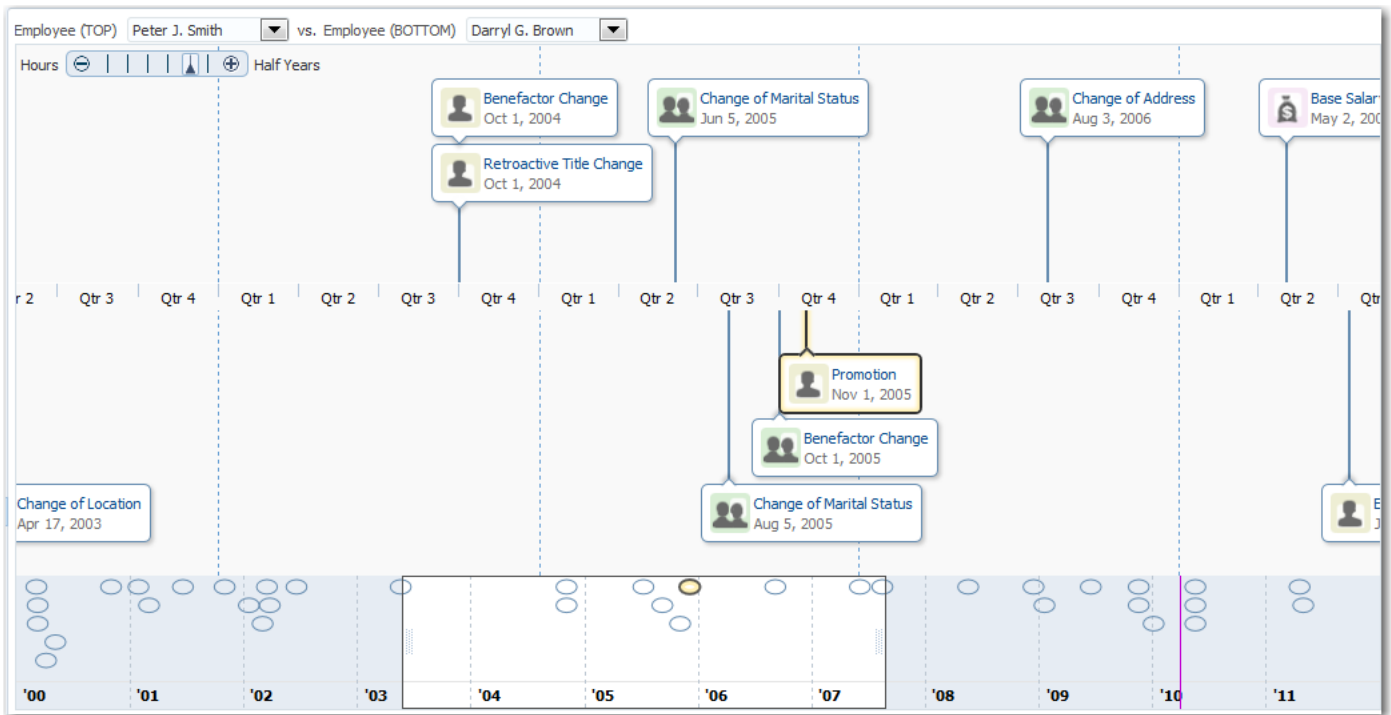

Figure 26–73 shows a dual timeline comparing multiple human resource events between two employees. The time axis is positioned between the two series of events and the overview panel displays at the bottom of the timeline.

**Figure 26–73 Dual Timeline Events Between Employees**

The content of timeline items, marker display, and time axis are configurable. For detailed information about timeline use cases, end user and presentation features, tag structure, and adding special features to timelines, see the "Using ADF Timeline Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 26.8.1 How to Create a Timeline Using ADF Data Controls

The data displayed in a timeline is based on data collections. The `timeline` component uses a model to access the data in the underlying list. The specific model class is `oracle.adf.view.rich.model.CollectionModel`. You can also use other model instances, for example, `java.util.List`, `java.util.Array`, and `javax.faces.model.DataModel`. The data layer will automatically convert the instance into a `CollectionModel`.

Stamping is used to associate information about a timeline event with a row of data in a data collection. Using stamping, each row of data in the data model can be displayed for an event. When you use stamping, child components are not created for every item in the timeline. Rather, the content of the component is repeatedly rendered, or stamped, once per data attribute.

Using data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop a data collection from the Data Controls panel that generates one (up to two) series of events onto the JSF page.

**Before you begin:**

It may be helpful to have an understanding of databound timelines. For more information, see [Section 26.8, "Creating Databound Timelines."](#)

You will need to complete these tasks:

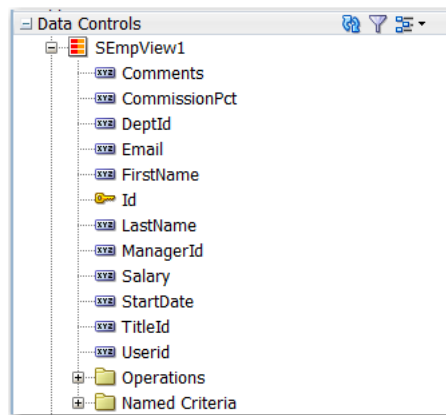

- Create an application module that contains instances of the view objects that you want in your data model, as described in [Section 9.2, "Creating and Modifying an Application Module."](#)
- Create a JSF page as described in the "How to Create JSF JSP Pages" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### To create a timeline using the Data Controls panel:

1. From the Data Controls panel, select a collection.

[Figure 26–74](#) shows the data collection for the timeline in [Figure 26–74](#). In this example the application uses the `SEmpView1` data collection to create the timeline.

**Figure 26–74 Sample Data Collection for Timeline**

2. Drag the collection onto the JSF page, and from the context menu choose **Timeline**.
3. In the Configure Timeline Series Data page of the Create Timeline wizard, configure the timeline data model for at least one (at most two for a dual timeline), by setting the following values:

- Series Value:** Use the dropdown list to select the data collection to use in the timeline. By default, the data collection you inserted from the Data Controls panel is displayed. JDeveloper automatically lists any data collection from the application module that includes at least one qualifying date-based attribute from which to choose.
- Item Date Value:** Use the dropdown list to select the date-based attribute to use for the timeline items stamped in the timeline. JDeveloper automatically lists all qualifying attributes in the data collection referenced in the **Series Value** from which to choose.
- Group:** Optionally use the dropdown list to select the attribute to use to group timeline items when the item date values are identical. JDeveloper automatically lists all data collection attributes from which to choose.

You can also choose **Expression Builder** and create an EL Expression to specify grouping of attributes at runtime. If you need help press **F1** or click **Help**.

4. For each timeline series that you configured as a data model, select the series, and set the following values for the timeline item display attributes:

- a. **Image:** Optionally, enter the relative path to the image file to stamp in the timeline item, or use the **Search** icon to open the Select Image File dialog to navigate to the image source.

You can also choose **Expression Builder** to configure an EL Expression that evaluates at runtime to locate the image file.

---

---

**Note:** if you need to change the size of the image in the timeline item, specify the **InlineStyle** attribute of the `af:image` component in source code or declaratively in the Property Inspector. For example, in the sample, specify

```
inlineStyle="width:85px;height:100px;".
```

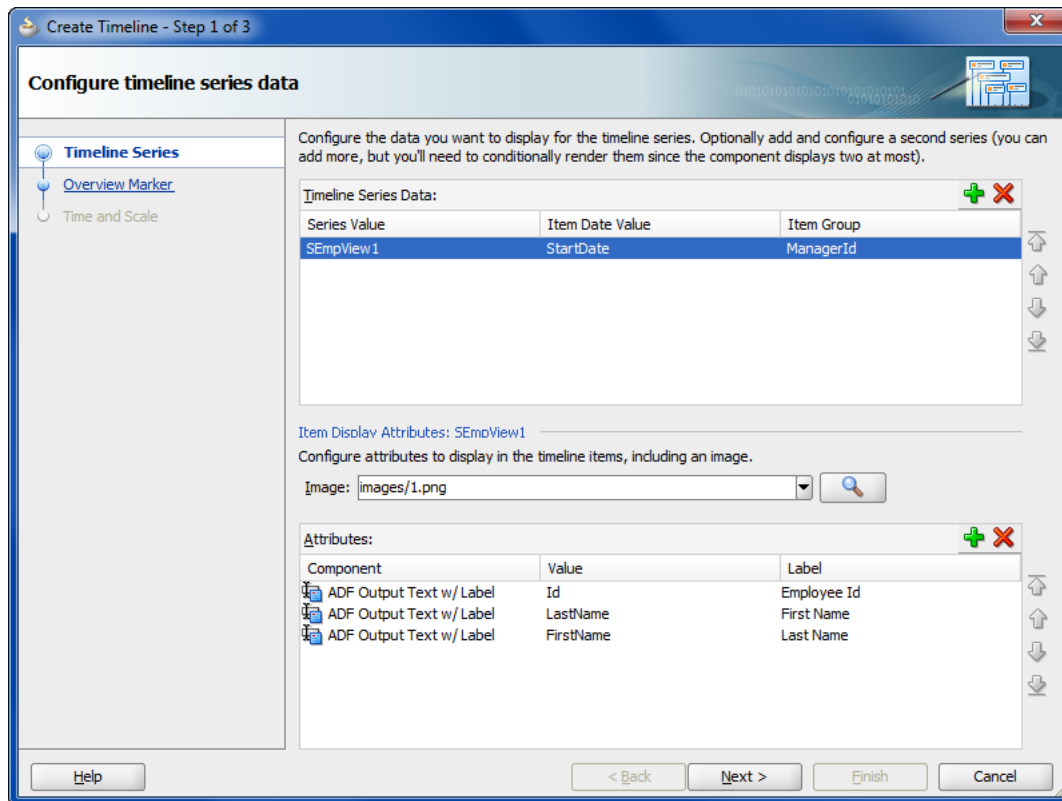

---

---

- b. **Component:** From the dropdown list, select the ADF Faces component to use to display the attribute text in the timeline item. You can choose from `outputText`, which displays unformatted text, and `outputFormatted`, which displays text and can include a limited range of formatting options. You can also choose to associate a label with either output text option in the **Label** value.
- c. **Value:** From the dropdown list select the attribute value to display in the timeline item. JDeveloper automatically lists all attributes in the data collection for the selected timeline series.
- d. **Label:** This option is available if you specify an ADF Faces component with a label in the **Component** value for the display attribute. You can use the default `Use Attribute Name` text, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime. The label displays in the timeline item at runtime.

For example, to specify the timeline series and display attributes for the timeline in [Figure 26-72](#), complete the Configure Timeline Series Data page of the Create Timeline wizard as shown in [Figure 26-75](#).

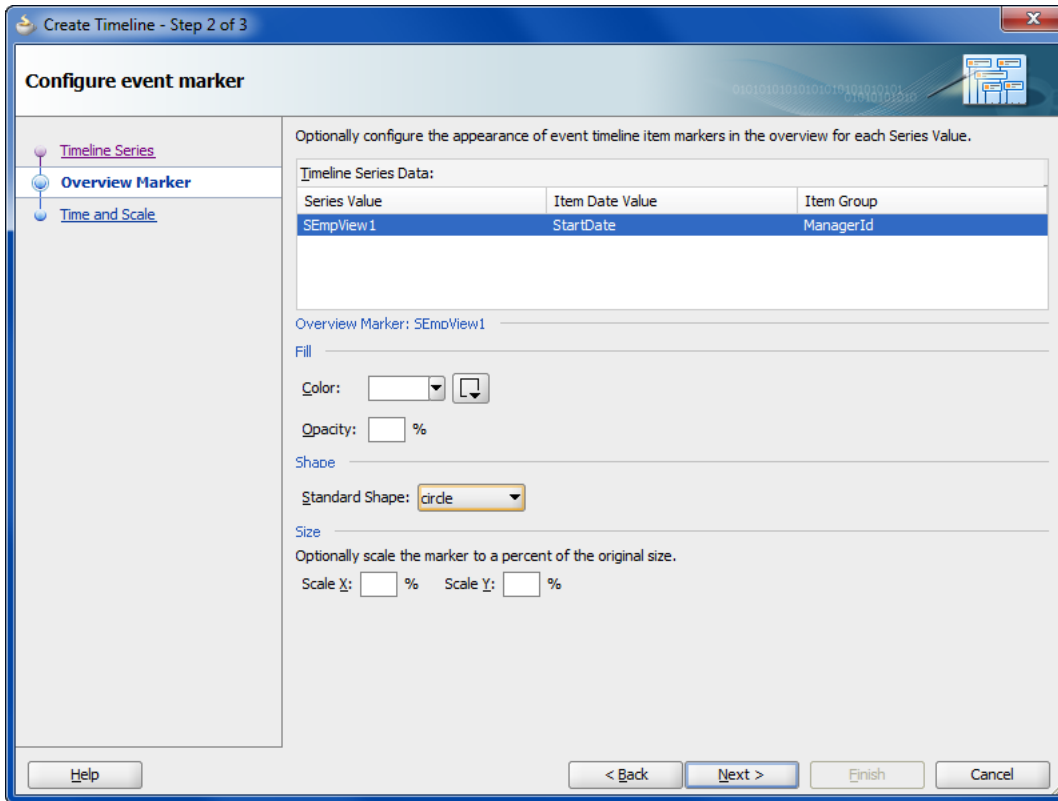

Figure 26–75 Configure Timeline Series Data Page of Create Timeline Wizard

5. Select **Next** to advance to the next page of the wizard, **Finish** to complete the definition of the data binding, or **Cancel** to end the creation of the timeline.
6. In the Configure Event Marker page of the Create Timeline Wizard, for each timeline series that you configured as a data model, select the series, and set the following optional values for the event marker:
  - a. **Color:** Specify the fill color for the event marker. You can use the dropdown list to select available colors, or click the icon to display a color picker dialog. By default, no color is specified.
  - b. **Opacity:** Specify the opacity of the fill color of the marker. Valid values range from 0 percent for transparent, to 100 percent for opaque.
  - c. **Standard Shape:** Specify the shape of the overview marker for each selected timeline series value. From the dropdown list, select one of seven prebuilt shapes to style the overview marker shape. Valid values are `circle` (default), `diamond`, `human`, `plus`, `square`, `triangleDown`, and `triangleUp`.
  - d. **ScaleX/ScaleY:** Enter the horizontal (`scaleX`) and vertical (`scaleY`) scale factor to modify the overview marker from its default size. Valid values are numerical percentages from 0 to 100 percent. JDeveloper will automatically resize a marker to fit within the timeline overview area if the marker is too large.

For example, to specify the timeline overview series markers for the timeline in Figure 26–72, complete the Configure Event Marker page of the Create Timeline wizard as shown in Figure 26–76.

**Figure 26–76 Configure Event Marker Page of Create Timeline Wizard**

7. Select **Back** to return to the last page of the wizard, **Next** to advance to the next page of the wizard, **Finish** to complete the definition of the data binding, or **Cancel** to end the creation of the timeline.
8. In the Configure Time Range and Scale of the Create Timeline Wizard, configure the time axis and overview axis by setting the following values:
  - a. **Start Time:** Enter the starting date to use for the time range of the timeline using the format `yyyy-mm-dd`. Select a start date that will include events in the data collection you wish to display on the timeline. From the dropdown list you can select `Current Date`. You can also click the Calendar icon to display a date picker dialog. The current date is the default value.
  - b. **End Time:** Enter the ending date to use for the timeline time range using the format `yyyy-mm-dd`. Select an end date that will include events in the data collection you wish to display on the timeline. From the dropdown list you can select `Current Date`. You can also click the Calendar icon to display a date picker dialog. The current date is the default value.
  - c. **Axis Scale:** Use the dropdown list to select the time scale to use for the timeline time axis. The time axis shows the user the current time increment for the timeline.

You must use a smaller time scale than the **Overview Scale**. For example, you cannot set the axis scale to `years` if the overview scale is set to `months`. You can also specify a custom axis scale.

Valid values are `twoyears`, `years`, `halfyears`, `quarters` (default), `twomonths`, `months`, `twoweeks`, `weeks`, `days`, `sixhours`, `threehours`, `hours`, `halfhours`, and `quarterhours`. You can also specify a custom axis

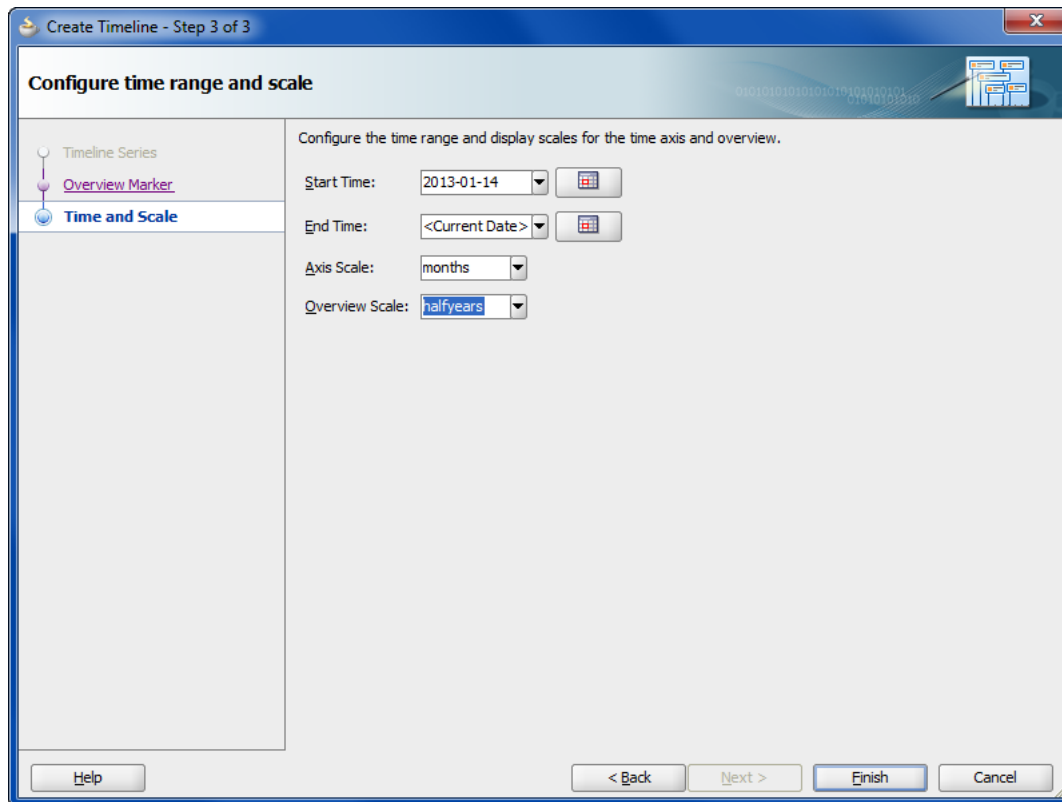

scale. For more information, see "Customizing Timeline Display Elements" in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

- d. **Overview Scale:** Use the dropdown list to select the time scale to use for the timeline overview axis. The overview axis shows the user the total time increment covered by the timeline.

Valid values are *twoyears*, *years* (default), *halfyears*, *quarters*, *twomonths*, *months*, *twoweeks*, *weeks*, *days*, *sixhours*, *threehours*, *hours*, *halfhours*, and *quarterhours*. You can also specify a custom axis scale. For more information, see "Customizing Timeline Display Elements" in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

For example, to specify the timeline axis and overview time range for the timeline in [Figure 26-72](#), complete the Configure Time Range and Scale page in the Create Timeline wizard as shown in [Figure 26-77](#).

**Figure 26-77** Configure Time Range and Scale Page of Create Timeline Wizard

9. Select **Back** to return to the last page of the wizard, **Finish** to complete the definition of the data binding, or **Cancel** to end the creation of the timeline.

## 26.8.2 What Happens When You Use Data Controls to Create a Timeline

When you use ADF data controls to create a timeline, JDeveloper:

- Defines the bindings for the timeline in the page definition file of the JSF page, and
- Inserts code in the JSF page for the DVT timeline components.

[Example 26–47](#) shows the bindings defined in the page definition file of the JSF page for the timeline in [Figure 26–72](#).

**Example 26–47 XML Bindings in Page Definition File**

```
<bindings>
  <tree IterBinding="SEmpView1Iterator" id="SEmpView1" ChangeEventPolicy="ppr">
    <nodeDefinition DefName="model.SEmpView" Name="SEmpView1">
      <AttrNames>
        <Item Value="DeptId"/>
        <Item Value="FirstName"/>
        <Item Value="Id"/>
        <Item Value="LastName"/>
        <Item Value="StartDate"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

[Example 26–48](#) shows the code inserted in the JSF page for the example timeline in [Figure 26–72](#).

**Example 26–48 Sample Code for Timeline Component**

```
<dvt:timeline id="tl1" startTime="2010-01-01" endTime="2012-12-31"
  itemSelection="multiple">
  <dvt:timelineSeries id="ts1" var="evt"
    value="#{bindings.SEmpView1.collectionModel}">
  <dvt:timelineItem value="#{evt.StartDate}" id="ti1" group="#{evt.DeptId}">
    <af:panelGroupLayout id="pg1" layout="horizontal">
      <af:image id="img1" source="images/#{evt.Id}.png"
        inlineStyle="width:85px;height:100px;"/>
      <af:spacer width="3" id="s1"/>
      <af:panelGroupLayout id="pg2" layout="vertical">
        <af:panelLabelAndMessage id="plam1"
          label="#{viewControllerBundle.EMPLOYEE_ID}">
          <af:outputText id="ot1" value="#{evt.Id}" noWrap="true">
            <af:convertNumber groupingUsed="false" pattern=
              "#{bindings.SEmpView1.hints.Id.format}"/>
          </af:outputText>
        </af:panelLabelAndMessage>
        <af:panelLabelAndMessage id="plam2"
          label="#{viewControllerBundle.FIRST_NAME}">
          <af:outputText id="ot2" value="#{evt.FirstName}" noWrap="true"/>
        </af:panelLabelAndMessage>
        <af:panelLabelAndMessage id="plam3"
          label="#{viewControllerBundle.LAST_NAME}">
          <af:outputText id="ot3" value="#{evt.LastName}" noWrap="true"/>
        </af:panelLabelAndMessage>
        <af:panelLabelAndMessage id="plam4"
          label="#{viewControllerBundle.DEPARTMENT_ID}">
          <af:outputText id="ot4" value="#{evt.DeptId}" noWrap="true">
            <af:convertNumber groupingUsed="false" pattern=
              "#{bindings.SEmpView1.hints.DeptId.format}"/>
          </af:outputText>
        </af:panelLabelAndMessage>
      </af:panelGroupLayout>
    </af:panelGroupLayout>
  </dvt:timelineItem>
</dvt:timelineSeries>
</dvt:timeline>
```

```

        </f:facet>
    </dvt:timelineItem>
</dvt:timelineSeries>
<dvt:timeAxis id="ta1" scale="months"/>
<dvt:timelineOverview id="ov1">
    <dvt:timeAxis id="ta2" scale="halfyears"/>
</dvt:timelineOverview>
</dvt:timeline>

```

### 26.8.3 What You May Need to Know About Using Data Controls to Create a Dual Timeline

When you use the Data Controls panel to create a dual timeline, you can configure the same or different data collections to configure the two timeline series and specify the timeline item display attributes and overview marker for each one. JDeveloper automatically lists any data collection from the application module that includes at least one qualifying date-based attribute from which to choose in the Create Timeline wizard.

[Example 26–49](#) show the sample code for the dual timeline displayed in [Figure 26–73](#).

#### **Example 26–49 Sample Code for a Dual Timeline**

```

<dvt:timeline id="tl1" startTime="2000-01-01" endTime="2011-12-31"
    inlineStyle="width:1024px;height:500px" itemSelection="single"
    currentTime="2010-04-01">
    <dvt:timelineSeries id="ts1" var="evt" value="#{timeline.firstModel}"
        contentDelivery="lazy">
        <dvt:timelineItem id="ti1" value="#{evt.date}" group="#{evt.group}">
        <af:panelGroupLayout id="pg1" layout="horizontal">
            <af:image id="img1" inlineStyle="width:30px;height:30px"
                source="/resources/images/timeline/#{evt.type}.png"/>
            <af:spacer width="3"/>
            <af:panelGroupLayout id="pg2" layout="vertical">
                <af:outputText id="ot1" inlineStyle="color:#084B8A"
                    value="#{evt.description}" noWrap="true"/>
                <af:outputText id="ot2" value="#{evt.date}"
                    inlineStyle="color:#6e6e6e" noWrap="true">
                <af:convertDateTime dateStyle="medium"/>
            </af:outputText>
            </af:panelGroupLayout>
        </af:panelGroupLayout>
        <f:facet name="overviewItem">
            <dvt:marker id="m1" shape="circle" fillColor="#ff0000"/>
        </f:facet>
    </dvt:timelineItem>
</dvt:timelineSeries>
    <dvt:timelineSeries id="ts2" var="evt" value="#{timeline.secondModel}"
        contentDelivery="lazy">
        <dvt:timelineItem id="ti2" value="#{evt.date}">
        <af:panelGroupLayout id="pg2" layout="horizontal">
            <af:image id="img2" inlineStyle="width:30px;height:30px"
                source="/resources/images/timeline/#{evt.type}.png"/>
            <af:spacer width="3"/>
            <af:panelGroupLayout id="pg3" layout="vertical">
                <af:outputText id="ot3" inlineStyle="color:#084B8A"
                    value="#{evt.description}" noWrap="true"/>
                <af:outputText id="ot4" value="#{evt.date}"
                    inlineStyle="color:#6e6e6e" noWrap="true">
                <af:convertDateTime dateStyle="medium"/>
            </af:panelGroupLayout>
        </dvt:timelineItem>
    </dvt:timelineSeries>
</dvt:timeline>

```

```

        </af:outputText>
    </af:panelGroupLayout>
</af:panelGroupLayout>
<f:facet name="overviewItem">
    <dvt:marker id="m2" shape="circle" fillColor="#0000ff"/>
</f:facet>
</dvt:timelineItem>
</dvt:timelineSeries>
<dvt:timeAxis id="ta1" scale="quarters"/>
    <dvt:timelineOverview id="ov1">
        <dvt:timeAxis id="ta2" scale="years"/>
    </dvt:timelineOverview>
</dvt:timeline>

```

For information about the data requirements, tag structure, and options for customizing the look and behavior of the component, see the "Using ADF Timeline Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

## 26.9 Creating Databound Hierarchy Viewers

A hierarchy viewer is an ADF Data Visualization component that visually displays data where parent-child relationships exist within the data. This component is useful where you want to display organization charts, network diagrams, or social networks, for example.

Hierarchy viewers use a shape called a *node* to reference the data in a hierarchy. The shape and content of the nodes are configurable, as well as the visual layout of the nodes. Nodes can display multiple views in a panel card.

Figure 26–78 shows a runtime view of a hierarchy viewer component that renders an organization chart.

**Figure 26–78 Hierarchy Viewer Component Rendering an Organization Chart**

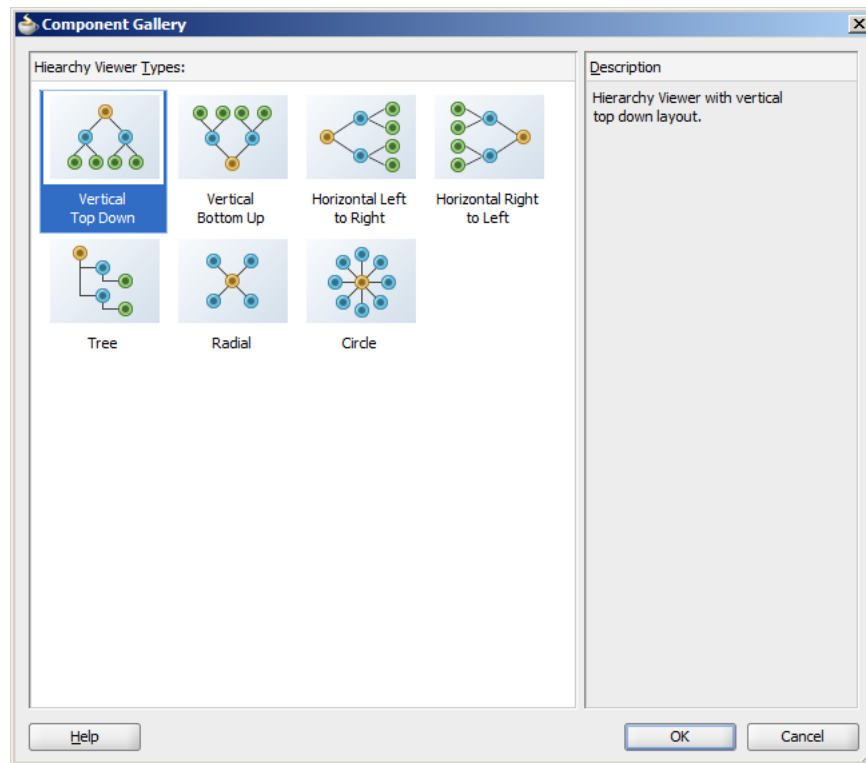

Figure 26–79 shows the Component Gallery displaying the types of hierarchy viewers that you can use to create a hierarchy viewer.

**Figure 26–79 Component Gallery for Hierarchy Viewer Types**

Each hierarchy viewer component (`dvt:hierarchyViewer`) that you create can include:

- One or more node elements (`dvt:node`)
- One or more link elements (`dvt:link`)

The optional panel card element (`dvt:panelCard`) can be used in conjunction with the hierarchy viewer component. The panel card provides a method to switch dynamically between multiple sets of content referenced by a node element using animation by, for example, horizontally sliding the content or flipping a node over.

For information about customizing a hierarchy viewer after the databinding is complete, see the "Using ADF Hierarchy Viewer Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 26.9.1 How to Create a Databound Hierarchy Viewer

Hierarchy viewers are based on data collections where a master-detail relationship exists between one or more detail collections and a master data collection. Using data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop a data collection from the Data Controls panel that generates one or more root nodes onto a JSF page.

#### Before you begin:

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in [Section 9.2, "Creating and Modifying an Application Module."](#)

For example, the data for the hierarchy viewer in [Figure 26–78](#) comes from a single table containing employee data in a fictitious organization. [Figure 26–80](#) shows the SEmp table structure in the Database Navigator. In this example, each employee’s manager is identified by the value in the MANAGER\_ID column.

**Figure 26–80 SEmp Table Showing Employee Information**

COLUMN_NAME	DATA_TYPE	NULLABLE	DATA_DEFAULT	COLUMN_ID	COMMENTS
ID	NUMBER (7, 0)	No	(null)	1 (null)	
LAST_NAME	VARCHAR2 (25 BYTE)	No	(null)	2 (null)	
FIRST_NAME	VARCHAR2 (25 BYTE)	Yes	(null)	3 (null)	
USERID	VARCHAR2 (8 BYTE)	Yes	(null)	4 (null)	
EMAIL	VARCHAR2 (100 BYTE)	Yes	(null)	5 (null)	
START_DATE	DATE	Yes	(null)	6 (null)	
COMMENTS	VARCHAR2 (255 BYTE)	Yes	(null)	7 (null)	
MANAGER_ID	NUMBER (7, 0)	Yes	(null)	8 (null)	
TITLE_ID	NUMBER	Yes	(null)	9 (null)	
DEPT_ID	NUMBER (7, 0)	Yes	(null)	10 (null)	
SALARY	NUMBER (11, 2)	Yes	(null)	11 (null)	
COMMISSION_PCT	NUMBER (4, 2)	Yes	(null)	12 (null)	

To set up a hierarchical relationship between the managers and employees using the SEmp table and to establish the highest level employee as the root of the hierarchy, do the following:

1. Create an entity object based on the SEmp table.

[Figure 26–81](#) shows the SEmp entity object based on the SEmp table. The attributes in the entity object correspond to the columns in the SEmp table. For help with creating entity objects, see [Chapter 4, "Creating a Business Domain Layer Using Entity Objects."](#)

**Figure 26–81 SEmp Entity Object**

2. Create an association between `SEmp.Id` and `SEmp.ManagerID` to establish the relationship between the employee and manager.

Figure 26–82 shows the `SEmpManagerIdFkAssoc`. For additional information about associations, see Section 4.2, "Creating Entity Objects and Associations."

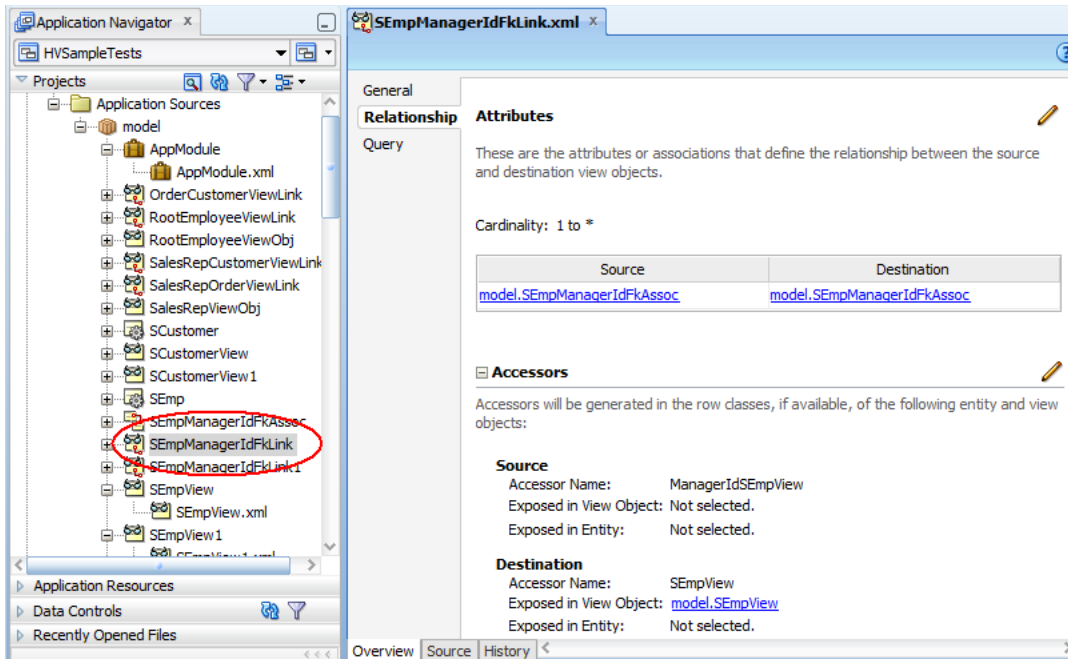

**Figure 26–82 Association Between Manager and Employees**

3. To establish the hierarchy between the managers and employees, create a view link between the managers and employees based on the `SEmpManagerIdFkAssoc` association.

Figure 26–83 shows the `SEmpManagerIdFkLink` view link. For additional information about establishing the master-detail relationship using view links, see Section 5.7, "Working with a Single Table in a Recursive Master-Detail Hierarchy."

**Figure 26–83 View Link Between Managers and Employees**

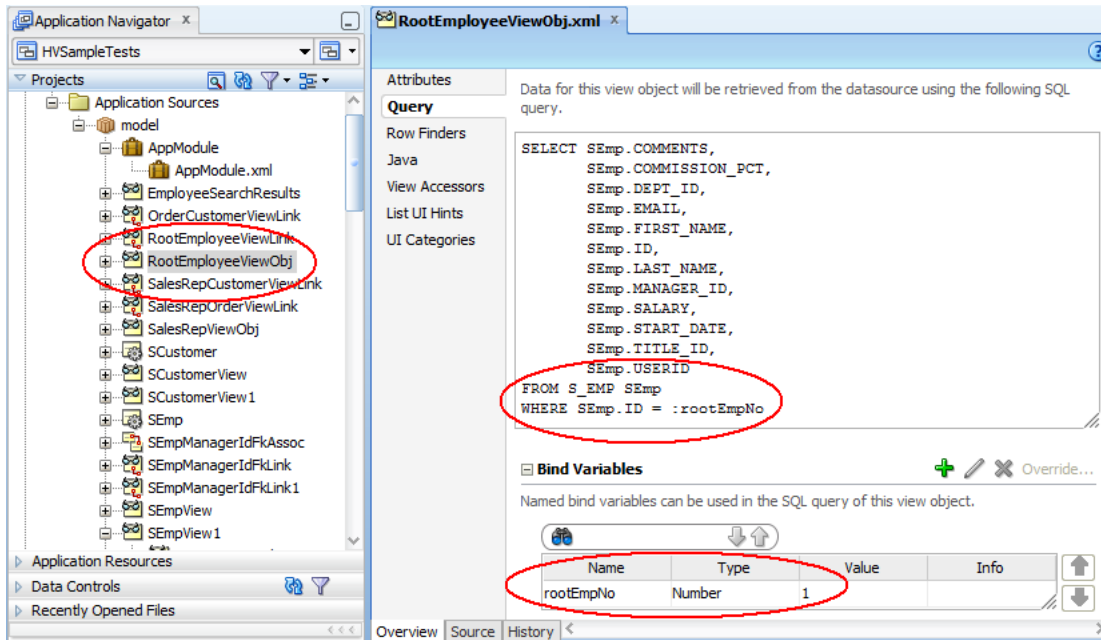

4. Create a view object that retrieves the root value from the data collection.

For example, in the hierarchy viewer displayed in [Figure 26–78](#), Carmen Velasquez is the highest level manager and has a employee ID of 1. To duplicate this example, create a view object that retrieves the employee whose ID is 1.

[Figure 26–84](#) shows the `RootEmployeeViewObject` for a view object based on the `SEmp` table example. The query retrieves the employee whose ID is 1 and stores it in the `rootEmpNo` bind variable. For more information about working with view objects and bind variables, see [Section 5.10, "Working with Bind Variables."](#)

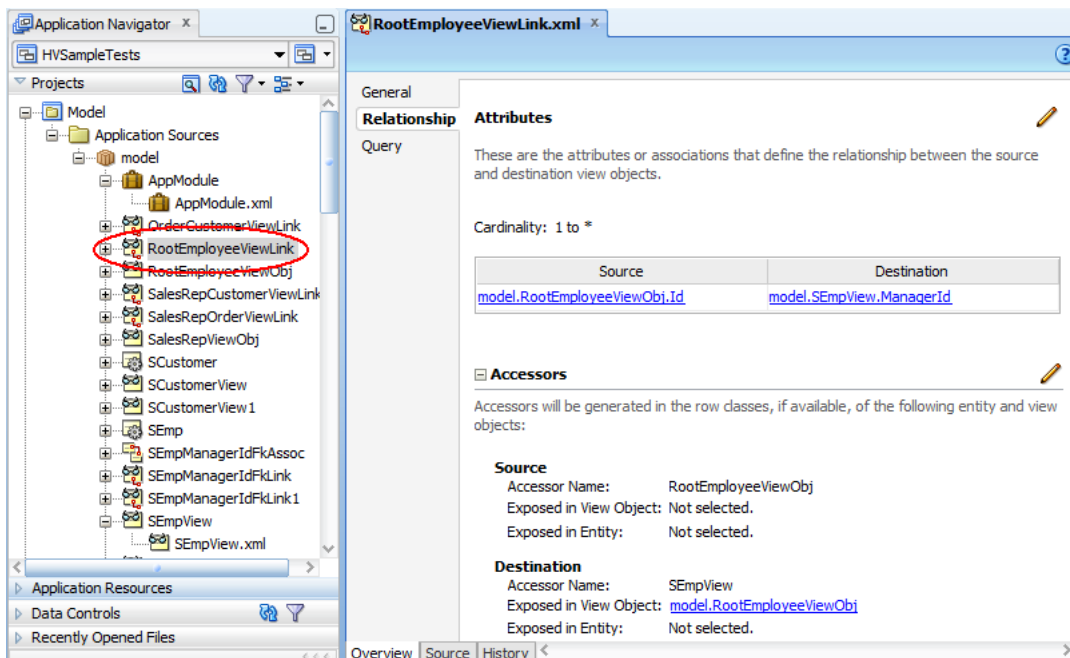

Figure 26–84 RootEmployeeViewObject Showing Query to Retrieve Top Level Employee

5. To establish the hierarchy between the root employee and the lower-level managers and employees, add a view link between the RootEmployeeViewObj and the managers-employees view object created in Step 3.

Figure 26–85 RootEmployeesViewLink Linking Top Level Manager to Employees

6. In the Data Controls panel, click **Refresh** to update the data controls. For additional information about master-detail relationships, see [Chapter 24, "Displaying Master-Detail Data."](#)

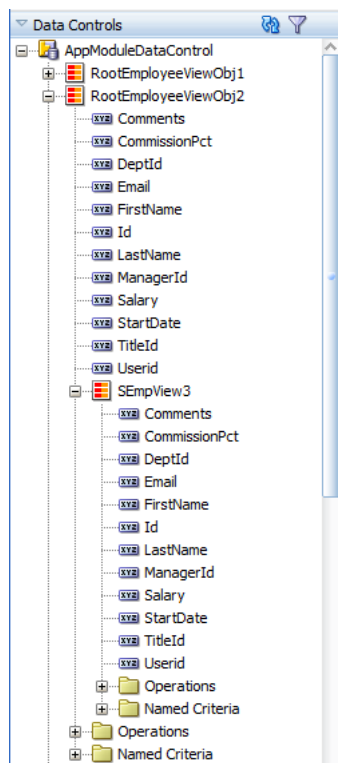

- Create a JSF page as described in the "Creating a View Page" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

**To create a databound hierarchy viewer:**

1. From the Data Controls panel, select a collection.

Figure 26–86 shows an example where you could select the `RootEmployeeViewObject2` collection in the Data Controls panel to create a hierarchy viewer representing the personnel data in an organizational chart.

**Figure 26–86 Data Collection for Personnel Organizational Chart**

2. Drag the collection onto a JSF page and, from the context menu, choose **Hierarchy Viewer**.
3. From the Component Gallery, select the layout of the hierarchy viewer you want to create. Figure 26–79 shows the Component Gallery with the vertical top down layout selected.
4. In the Create Hierarchy Viewer dialog, enter the following:
  - **Hierarchy:** Select the collections you want to include as nodes in the runtime diagram. By default, the root collection is selected. You can also choose to configure ancestors or descendants in the hierarchy.
  - **Node:** For each collection that you select in the Hierarchy list, configure the attributes in the Title Area, and the title and attributes in each panel card, using one or more of the zoom levels available to you. By default, the node for the 100% zoom level follows an algorithm that:
    - Assigns the first three attributes in the data collection to the **Title Area**.
    - Assigns the next two attributes to the first panel card.

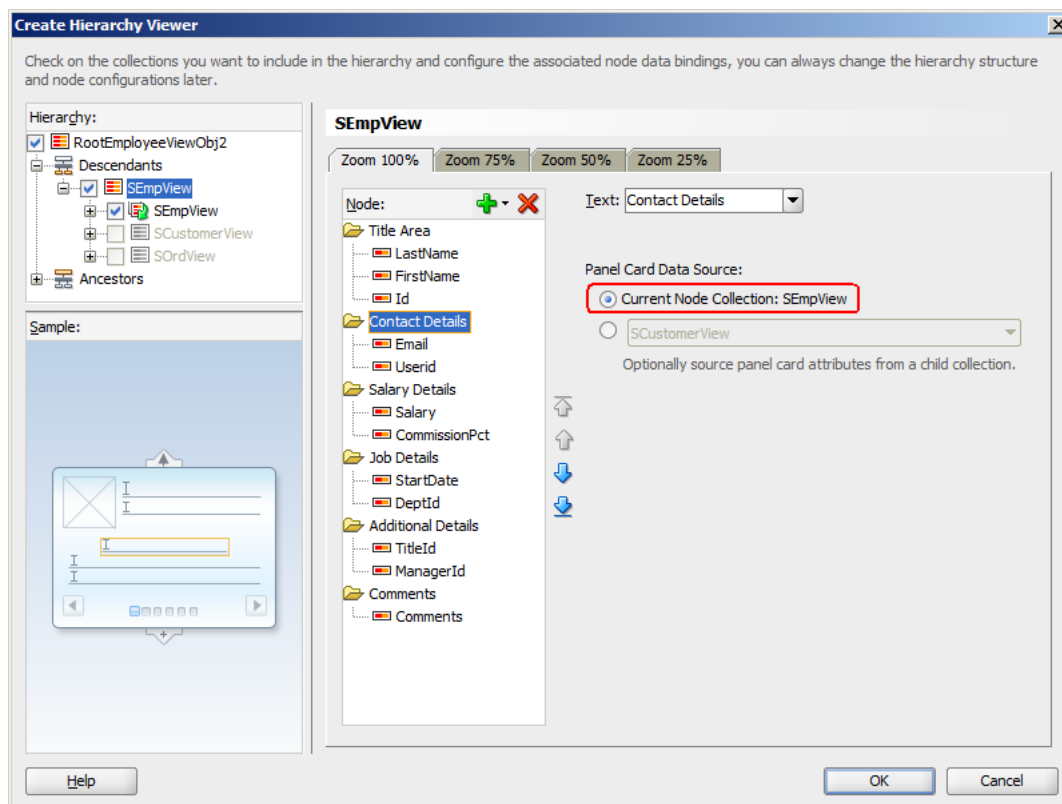

- Assigns the following two attributes to the second panel card, and so on until all attributes are assigned to a panel card.

Select the panel card title or node attributes to configure one or more of the following for that element:

- **Text:** Available for panel card titles. Not available for the **Title Area** element. Enter text for the panel card title in the hierarchy, or choose **Select Text Resource** from the dropdown list to open a dialog to select or add a text resource to use for the title. The text resource is a translatable string from an application resource bundle. If you need help, press F1 or click **Help**.
- **Panel Card Data Source:** Available for panel cards. The data source indicates which data collection will be used for the panel card attributes. By default, the collection associated with the current hierarchy level will be used for attribute selection.

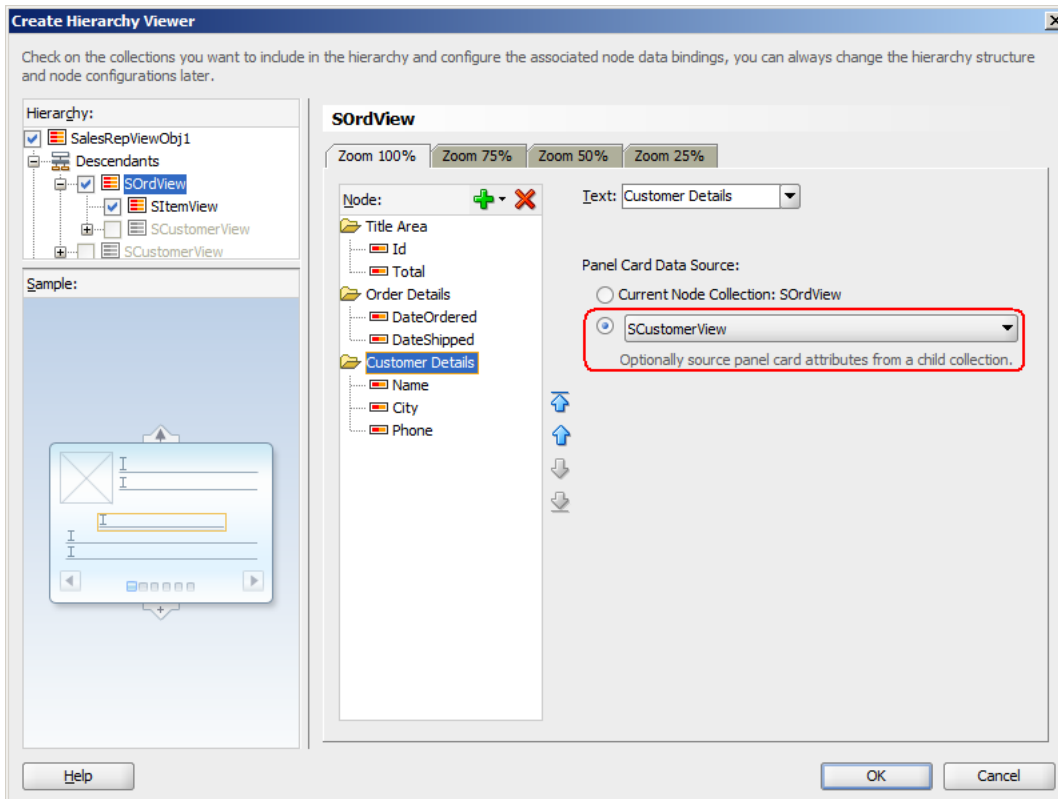

Figure 26–87 shows a Create Hierarchy Viewer dialog for a hierarchy viewer using the `Root.EmployeeViewObj2` data control. In this example, the **Panel Card Data Source** is the default `SEmpView` collection.

**Figure 26–87 Hierarchy Viewer Configured With Default Panel Card Data Source**

To use an alternative child accessor for the panel card attributes, select an alternative child accessor from the dropdown list as shown in Figure 26–88. For additional information, see Section 26.9.3, "How to Configure an Alternate View Object for a Databound Panel Card."

**Figure 26–88 Create Hierarchy Viewer Dialog Showing Alternate Panel Card Data Source**

- **Attribute:** Available for attribute and image elements. From the dropdown list, select the attribute in the data collection that represents the value you wish to display in the hierarchy viewer node.
- **Label:** Available for attributes. From the dropdown list, select the attribute in the data collection that represents the label you wish to display for that element in the hierarchy viewer node. You can use the default **Use Attribute Name** to render the value as a string using the label from the UIHints for that attribute in the underlying `ViewObject`, select **No Label** to render no label for the attribute, or choose **Select Text Resource** to open a Select Text Resource dialog to select or add a text resource to use for the label. The text resource is a translatable string from an application resource bundle.
- **Component:** Available for attributes. Select the type of component to use to display the data in the node. Valid values are: **ADF Output Text w/ Label**, **ADF Output Text**, **ADF Output Formatted Text w/ Label**, and **ADF Output Formatted Text**. For more information about using these components, see the "Using Output Components" chapter in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

Click the **New** icon to add a new panel card, attribute, or image to the node, relative to your selection in the node. After selecting an existing element, use the arrow icons (**Up**, **Down**, **Top**, **Bottom**) to reorder the element, or use the **Delete** icon to delete the selected element.

Use the 75%, 50%, and 25% pages to specify the expanded display of the hierarchy at each page level. Select **Add Zoom Level** to enable the zoom level

for a page level. By default, the algorithms to assign node attributes and panel cards in the node are similar to the 100% zoom level.

---

**Note:** The hierarchy viewer component defines four zoom levels. You cannot modify these zoom levels or create new zoom levels. The default zoom level is 100%.

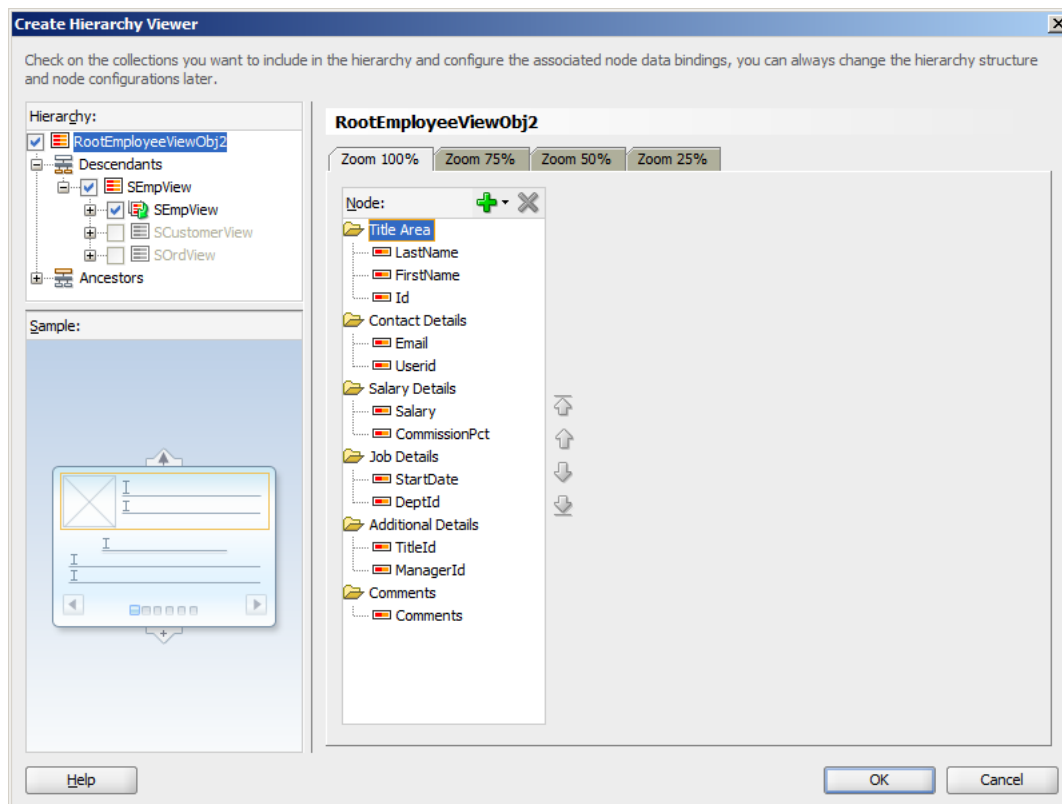

---

- **Sample:** A nonconfigurable display of the sample outline of the hierarchy viewer node. Areas such as Title Area and attributes are highlighted in the sample when selected in the node area.

5. Click OK.

Figure 26–89 shows the Create Hierarchy Viewer dialog that appears if you create a hierarchy viewer using data from a data collection named `RootEmployeeViewObject2`. In this example, the hierarchy viewer is configured to display the title area and a panel card with five sets of employee information.

**Figure 26–89 Create Hierarchy Viewer Dialog for Employees**

After completing the Create Hierarchy Viewer dialog, you can use the Property Inspector to specify settings for the hierarchy viewer attributes, and you can also use the child tags associated with the hierarchy viewer tag to customize the hierarchy viewer further. For detailed information about hierarchy viewer end user and presentation features, use cases, tag structure, and adding special features to hierarchy viewers, see the "Using ADF Hierarchy Viewer Components" chapter in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

When editing the hierarchy viewer in the visual editor, the display approximates the runtime display and functionality. You can move between the panel cards and work with stamped elements within the panel cards and title area to rearrange attributes or bind new attributes imported from the Data Controls panel.

## 26.9.2 What Happens When You Create a Databound Hierarchy Viewer

Creating a hierarchy viewer from Data Controls panel has the following effect:

- Creates the bindings for the hierarchy viewer in the page definition file of the JSF page
- Adds the necessary tags to the JSF page for the hierarchy viewer component

[Example 26–50](#) displays bindings that JDeveloper generated for a hierarchy viewer component. The rules for populating the nodes of the master-detail tree are defined as a node definition. The example shows that two node definitions were generated. Each of these node definitions references a view object and associated attributes. The code example also references an accessor `SEmpView`.

### **Example 26–50 Bindings for a Hierarchy Viewer**

```
<bindings>
  <tree IterBinding="RootEmployeeViewObj2Iterator" id="RootEmployeeViewObj2">
    <nodeDefinition DefName="model.RootEmployeeViewObj"
      Name="RootEmployeeViewObj20">
      <AttrNames>
        <Item Value="ManagerId"/>
        <Item Value="TitleId"/>
        <Item Value="Userid"/>
        <Item Value="Comments"/>
        <Item Value="DeptId"/>
        <Item Value="StartDate"/>
        <Item Value="Email"/>
        <Item Value="Salary"/>
        <Item Value="FirstName"/>
        <Item Value="Id"/>
        <Item Value="CommissionPct"/>
        <Item Value="LastName"/>
      </AttrNames>
      <Accessors>
        <Item Value="SEmpView">
          <Properties>
            <CustomProperties>
              <Property Name="hierarchyType" Value="children"/>
            </CustomProperties>
          </Properties>
        </Item>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.SEmpView" Name="RootEmployeeViewObj21">
      <AttrNames>
        <Item Value="ManagerId"/>
        <Item Value="TitleId"/>
        <Item Value="Userid"/>
        <Item Value="Comments"/>
        <Item Value="DeptId"/>
        <Item Value="StartDate"/>
        <Item Value="Email"/>
        <Item Value="Salary"/>
      </AttrNames>
```

```

        <Item Value="FirstName"/>
        <Item Value="Id"/>
        <Item Value="CommissionPct"/>
        <Item Value="LastName"/>
    </AttrNames>
    <Accessors>
        <Item Value="SEmpView">
            <Properties>
                <CustomProperties>
                    <Property Name="hierarchyType" Value="children"/>
                </CustomProperties>
            </Properties>
        </Item>
    </Accessors>
</nodeDefinition>
</tree>
</bindings>

```

**Example 26–51** shows the code generated on the JSF page that is associated with the page definition file in **Example 26–50**. For brevity, the details in the facet elements named `zoom75`, `zoom50`, and `zoom25` and panel card `showDetailItem` components have been omitted. In addition, the details for the second node in the hierarchy viewer have also been omitted.

The example shows a hierarchy viewer component that references the `RootEmployeeViewObj2` tree binding. It includes two node (`dvt:node`) components that in turn include a panel card component (`dvt:panelCard`). The panel card component defines `slide_horz` as the effect to use when changing the display of content referenced by the node.

Once you create your hierarchy viewer, you can modify the layout of the component or add additional components using the Create Hierarchy dialog illustrated in **Figure 26–89**. To open the dialog, use the **Edit** icon in the Property Inspector for the `hierarchyViewer` component. You can also customize the layout of a hierarchy viewer component directly in the code, in the visual editor, or by setting values in the Property Inspector. You can add additional components, such as panel card attributes, using the Component Palette.

#### **Example 26–51 Code on the JSF Page for a Hierarchy Viewer**

```

<dvt:hierarchyViewer id="hv1" var="node"
    value="#{bindings.RootEmployeeViewObj2.treeModel}"
    selectionListener="#{bindings.RootEmployeeViewObj2.treeModel.makeCurrent}"
    detailWindow="none" layout="hier_vert_top"
    levelFetchSize="#{bindings.RootEmployeeViewObj2.rangeSize}"
    styleClass="AFStretchWidth">
    <dvt:link linkType="orthogonalRounded" id="l1"/>
    <dvt:node type="model.RootEmployeeViewObj" width="233" height="233" id="n1">
        <f:facet name="zoom100">
            <af:panelGroupLayout styleClass="AFStretchWidth AFHVNodeStretchHeight
                AFHVNodePadding"
                layout="vertical" id="pg11">
                <af:panelGroupLayout layout="horizontal" id="pg12">
                    <af:panelGroupLayout layout="vertical" id="pg16">
                        <af:outputText value="#{node.LastName}"
                            styleClass="AFHVNodeTitleTextStyle"
                            id="ot2"/>
                        <af:outputText value="#{node.FirstName}"
                            styleClass="AFHVNodeSubtitleTextStyle"
                            id="ot13"/>
                    </af:panelGroupLayout>
                </af:panelGroupLayout>
            </f:facet>
        </dvt:node>
    </dvt:hierarchyViewer>

```

```

        <af:panelLabelAndMessage label="#{node.hints.Id.label}"
            id="plam5">
            <af:outputText value="#{node.Id}"
                styleClass="AFHVNodeTextStyle" id="ot16">
                <af:convertNumber groupingUsed="false"
                    pattern="#{node.hints.Id.format}"/>
            </af:outputText>
        </af:panelLabelAndMessage>
    </af:panelGroupLayout>
</af:panelGroupLayout>
<af:spacer height="5" id="s7"/>
<dvt:panelCard effect="slide_horz" styleClass="AFHVNodePadding" id="pc2">
    <af:showDetailItem text="Contact Details" id="sdi1">
        <af:spacer height="2" id="s6"/>
        <af:panelFormLayout styleClass="AFStretchWidth AFHVNodeStretchHeight
            AFHVNodePadding"
            id="pfl2">
            <af:panelLabelAndMessage label="#{node.hints.Email.label}"
                id="plam3">
                <af:outputText value="#{node.Email}"
                    styleClass="AFHVPanelCardTextStyle"
                    id="ot12"/>
            </af:panelLabelAndMessage>
            <af:panelLabelAndMessage label="#{node.hints.Userid.label}"
                id="plam15">
                <af:outputText value="#{node.Userid}"
                    styleClass="AFHVPanelCardTextStyle"
                    id="ot1"/>
            </af:panelLabelAndMessage>
        </af:panelFormLayout>
    </af:showDetailItem>
    ... Remaining showDetailItems omitted
</dvt:panelCard>
</af:panelGroupLayout>
</f:facet>
    ... Remaining zoom levels omitted
</dvt:node>
<dvt:node type="model.SEmpView" width="233" height="233" id="n2">
    ... Second node details omitted
</dvt:node>
</dvt:hierarchyViewer>

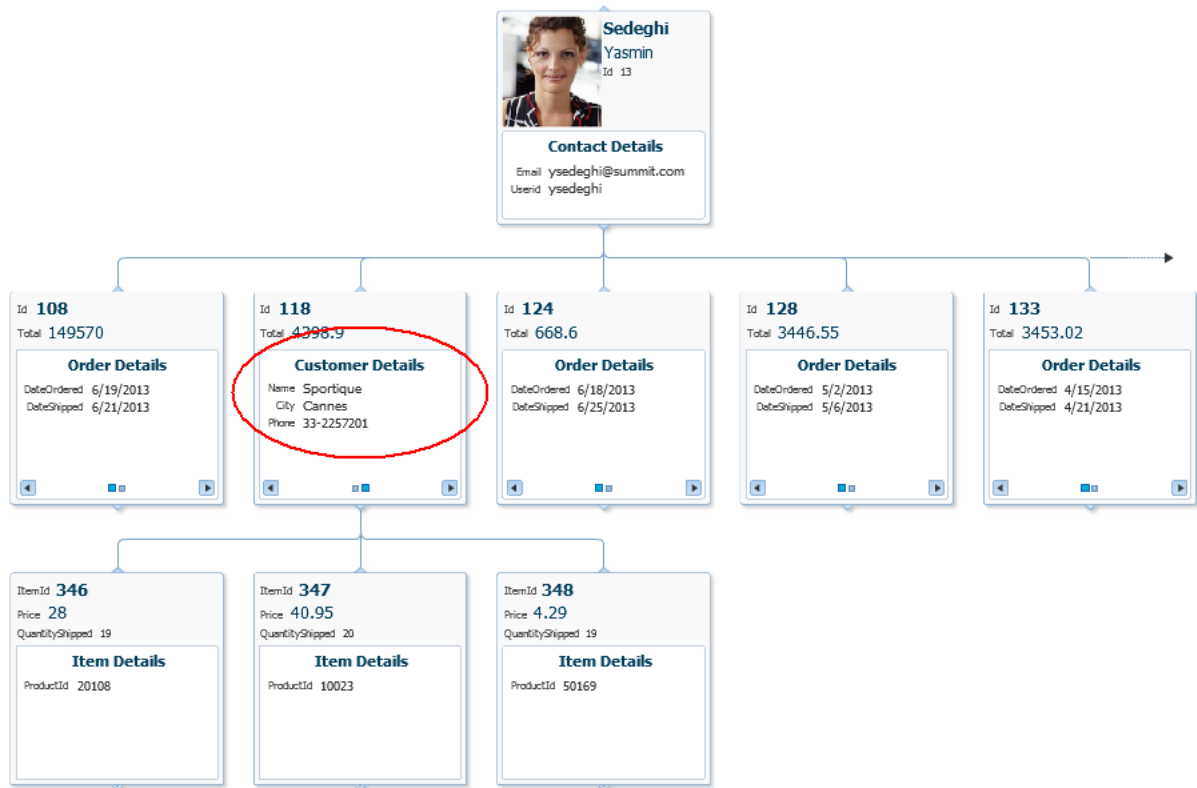

```

### 26.9.3 How to Configure an Alternate View Object for a Databound Panel Card

You can specify an alternate view object as the data source for a panel card when you create or edit a databound hierarchy viewer. For example, you may have a data collection that has a master-detail relationship between sales representatives and orders, but you want your panel card to display details about the customer who placed the order.

[Figure 26–90](#) shows a portion of the runtime view of a hierarchy viewer configured to display the orders and order details for sales representatives. In this example, the hierarchy viewer is configured to use an alternate view object for the Customer Details panel card.

**Figure 26–90 Hierarchy Viewer Panel Card Configured With Alternate View Object**

The alternate view object must be a child of the parent collection. You can establish this parent-child relationship by creating a view link between the parent and child collection.

#### Before you begin:

Create an application module that contains instances of the entity and view objects that you want in your application, as described in [Section 9.2, "Creating and Modifying an Application Module."](#)

Create the data model for the hierarchy viewer. For example, the hierarchy viewer in [Figure 26–90](#) uses a top level view object based on the `SEmp` entity shown in [Figure 26–81](#). In this example, the view object retrieves all sales representatives in the employee database by retrieving all employee records with a `TITLE_ID` of 2. [Figure 26–91](#) shows the `SalesRepViewObj` view object.

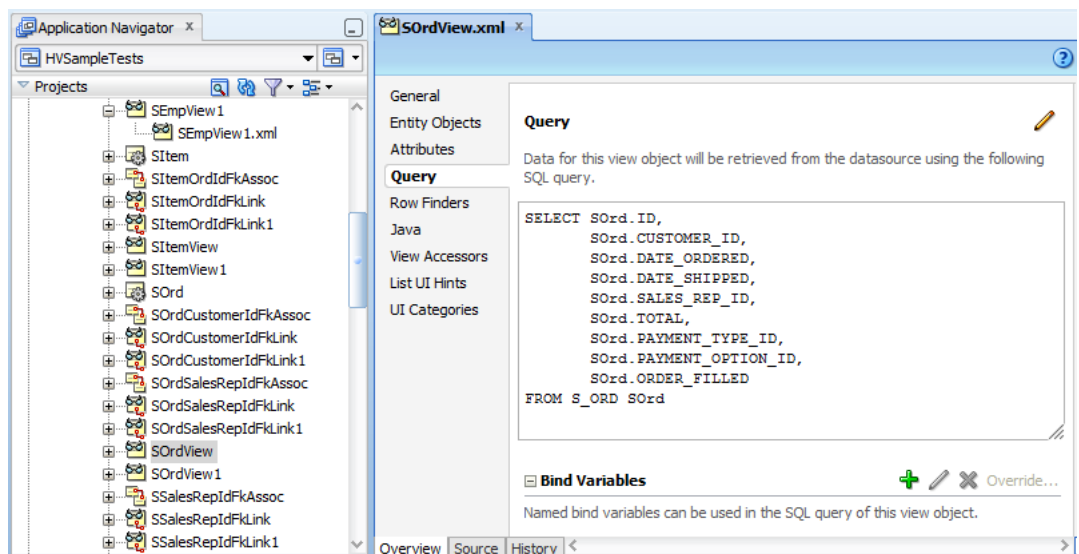

**Figure 26–91 Sales Representatives View Object Showing Query to Retrieve TITLE\_ID**

For information about creating a view object, see [Section 5.2.1, "How to Create an Entity-Based View Object."](#)

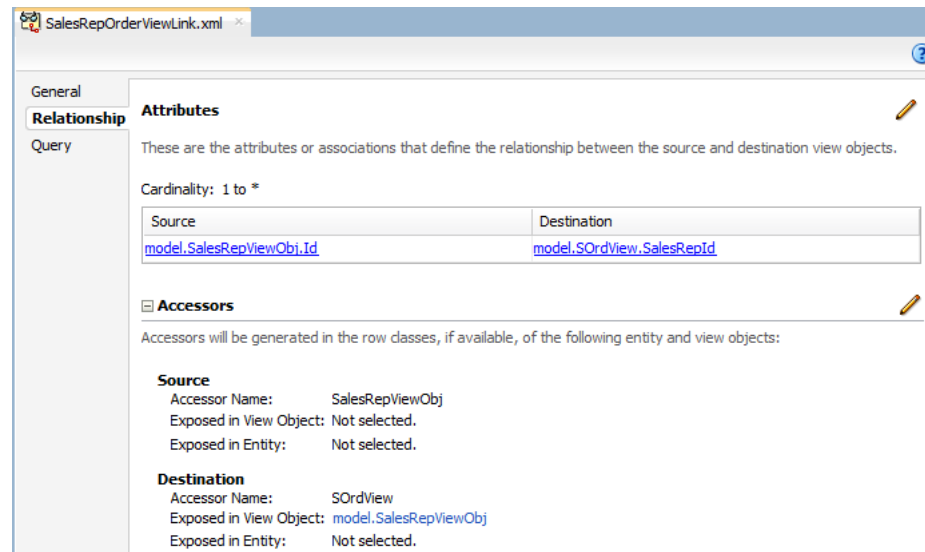

The order view object is based on an order entity object that contains details about an order, including the employee ID of the order’s sales representative. [Figure 26–92](#) shows the SOrdView object and SQL query used to retrieve the columns from the SOrd table.

**Figure 26–92 SOrdView Object for Hierarchy Viewer Example**

The master-detail relationship between the sales representatives and orders is established with a view link between SalesRepViewObj and OrdersViewObj. [Figure 26–93](#) shows the relationship between the view objects.

**Figure 26–93 View Link Between Sales Representatives and Orders**

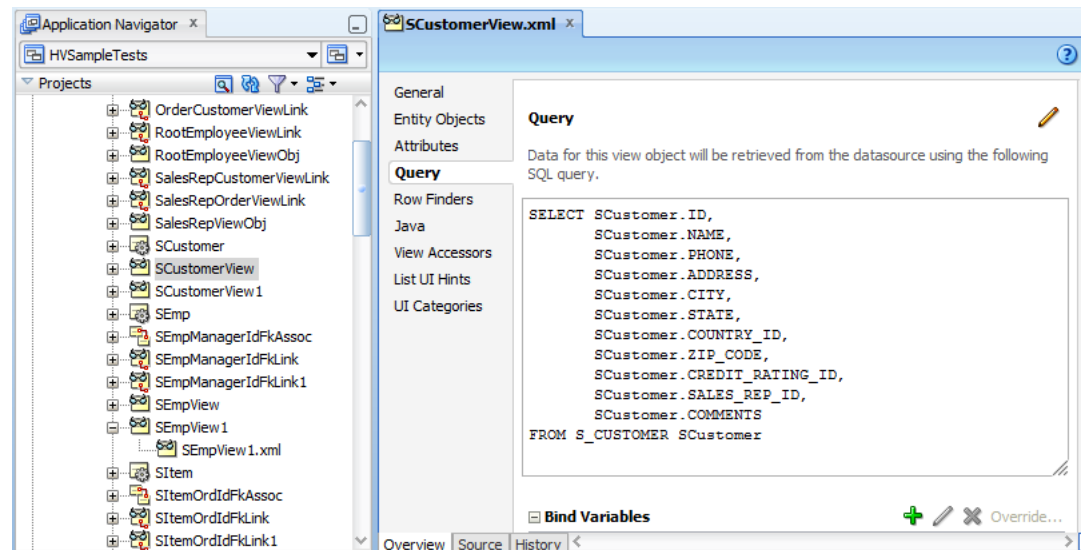

For additional information about establishing the master-detail relationship using view links, see [Section 5.6.2, "How to Create a Master-Detail Hierarchy Based on View Objects Alone."](#)

**To configure an alternate view object for a databound panel card:**

1. If you have not already done so, create the view object that will be the alternate data source for the panel card.

For example, the hierarchy viewer in [Figure 26–90](#) uses a view object based on a `SCustomer` entity object. [Figure 26–94](#) shows the `SCustomerViewObject` and SQL query used to retrieve the values from the `SCustomer` table.

**Figure 26–94 SCustomerView Object for Hierarchy Viewer Example**

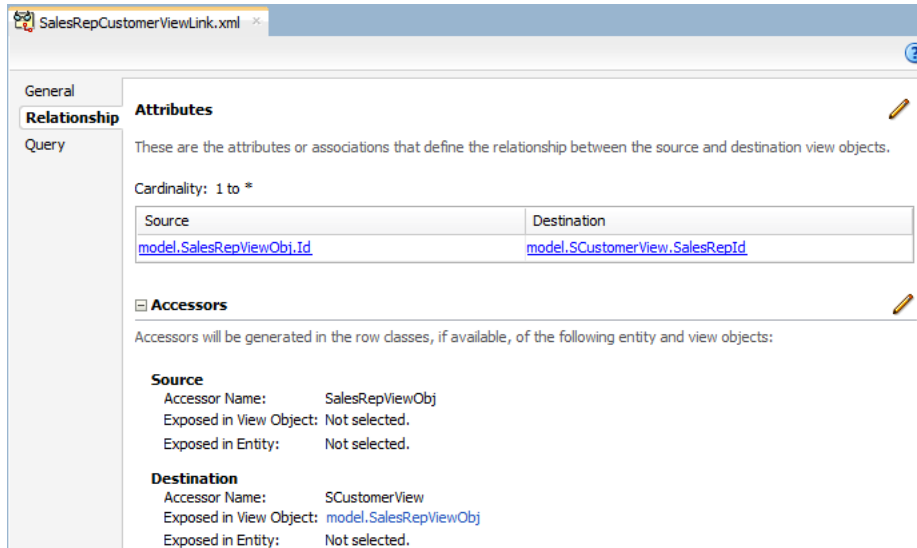

2. Create a view link between the parent collection and the alternate view object.

[Figure 26–95](#) shows the view link between the sales representatives and customers in the hierarchy viewer example. For help with creating view links, see

Section 5.6.2, "How to Create a Master-Detail Hierarchy Based on View Objects Alone."

**Figure 26–95 View Link Between Sales Representatives and Customers**

3. If needed, create a view link to establish the hierarchy between the parent collection and the alternate child collection.

For example, to establish the hierarchy between orders and customers in the hierarchy viewer example, create a view link between the `SOrdView` and `SCustomerView` collections. Figure 26–96 shows the sample view link.

**Figure 26–96 View Link Between Orders and Customers**

### 26.9.3.1 What Happens When You Use an Alternate View Object for a Hierarchy Viewer Panel Card

When you configure your hierarchy viewer to use an alternate view object for the panel card data source, JDeveloper adds the bindings for the hierarchy viewer and alternate source in the page definition file of the JSF page.

Example 26–52 shows the sample bindings for the hierarchy viewer displayed in Figure 26–90. The entries for the alternate source are highlighted. Note that the alternate data source is defined as one of the hierarchy viewer’s node definitions.

**Example 26–52 Bindings For a Hierarchy Viewer Using an Alternate Panel Card Data Source**

```
<bindings>
  <tree IterBinding="SalesRepViewObj1Iterator" id="SalesRepViewObj1">
    <nodeDefinition DefName="model.SalesRepViewObj" Name="SalesRepViewObj10">
      <AttrNames>
        <Item Value="Userid" />
        <Item Value="Email" />
        <Item Value="FirstName" />
        <Item Value="Id" />
        <Item Value="LastName" />
      </AttrNames>
      <Accessors>
        <Item Value="SOrdView">
          <Properties>
            <CustomProperties>
              <Property Name="hierarchyType" Value="children" />
            </CustomProperties>
          </Properties>
        </Item>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.SOrdView" Name="SalesRepViewObj11">
      <AttrNames>
        <Item Value="DateShipped" />
        <Item Value="DateOrdered" />
        <Item Value="Id" />
        <Item Value="Total" />
      </AttrNames>
      <Accessors>
        <Item Value="SItemView">
          <Properties>
            <CustomProperties>
              <Property Name="hierarchyType" Value="children" />
            </CustomProperties>
          </Properties>
        </Item>
        <Item Value="SCustomerView" />
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.SCCustomerView" Name="SalesRepViewObj12">
      <AttrNames>
        <Item Value="Name" />
        <Item Value="Phone" />
        <Item Value="City" />
      </AttrNames>
    </nodeDefinition>
    <nodeDefinition DefName="model.SItemView" Name="SalesRepViewObj13">
      <AttrNames>

### 26.9.4 How to Create a Databound Search in a Hierarchy Viewer

The search function in a hierarchy viewer is based on the searchable attributes or columns of the data collection that is the basis of the hierarchy viewer data model. Using a query results collection defined in data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop an **ExecuteWithParams** operation into an existing hierarchy viewer component on the page.

Figure 26–97 shows the example employee hierarchy viewer configured to search for employees by last name. In this example, the user can enter an employee’s last name in the Search panel or specify a pattern match using % or \_.

**Figure 26–97 Hierarchy Viewer With Search Panel**

**Before you begin:**

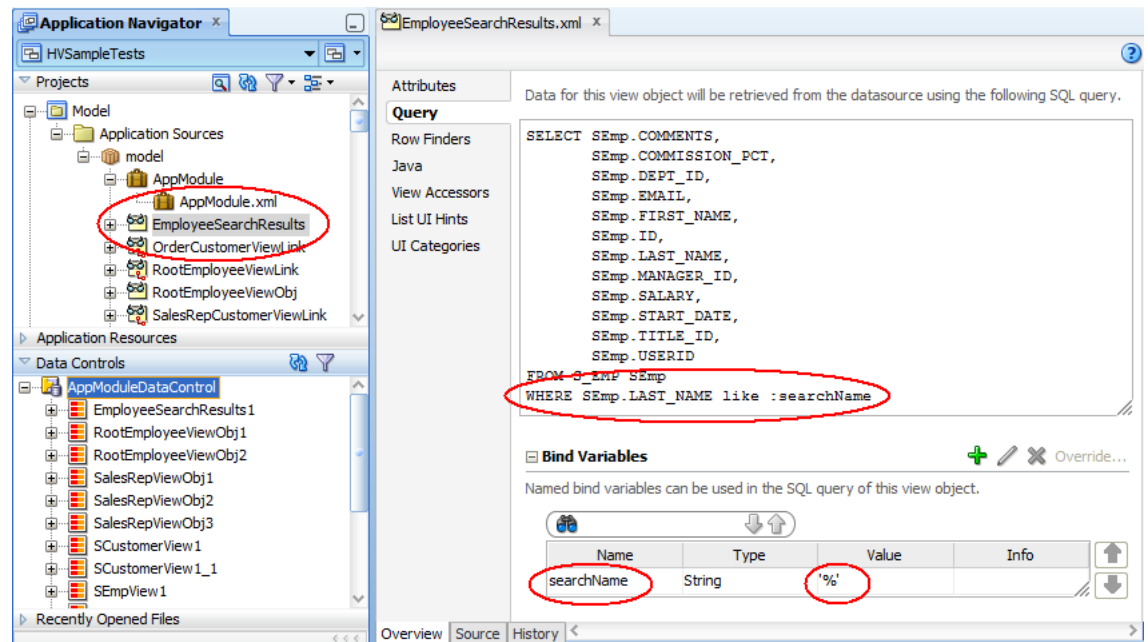

1. Create a databound hierarchy viewer component present on your page.
2. Verify the query that retrieves the root node in the hierarchy viewer.

For example, Figure 26–84 shows retrieving the root node by the EMPNO column.

3. Create a view object that performs the search.

For example, Figure 26–98 shows the EmployeesSearchResults view object that performs the search based on the LastName column in the data collection with a default value of % for matching any value, and a comparison value of like to enable pattern matching.

Figure 26–98 EmployeeSearchResults View Object

For information about creating a view object, see [Section 5.2.1, "How to Create an Entity-Based View Object."](#)

**To create a databound search with a hierarchy viewer:**

1. From the Data Controls panel, select the collection that corresponds to the query results and expand the **Operations** node to display the **ExecuteWithParams** operation.

Figure 26–99 shows the expanded EmployeeSearchResults1 data control that is generated if you create the employee search view object shown in Figure 26–98.

**Figure 26–99 ExecuteWithParams Operation for Hierarchy Viewer Search**

2. Drag the **ExecuteWithParams** operation and drop it onto the hierarchy viewer in the visual editor or onto the component in the Structure window. Alternatively, you can drag the parameter onto the hierarchy viewer.
3. In the Create Hierarchy Viewer Search dialog that displays, use the **Add** icon to specify the list of results to display in the Search Results panel, and specify the following for each result:

- a. **Display Label:** Select the values for the headers of the nodes in the hierarchy. If you select `<default>`, then the text for the header is automatically retrieved from the data binding.
- b. **Value Binding:** Select the columns in the data collection to use for nodes in the tree for the hierarchy viewer.
- c. **Component to Use:** Select the type of component to display in the node. The default is the ADF Output Text component.

After selecting an existing field, use the arrow icons (**Up, Down, Top, Bottom**) to reorder the results or use the **Delete** icon to delete that result.

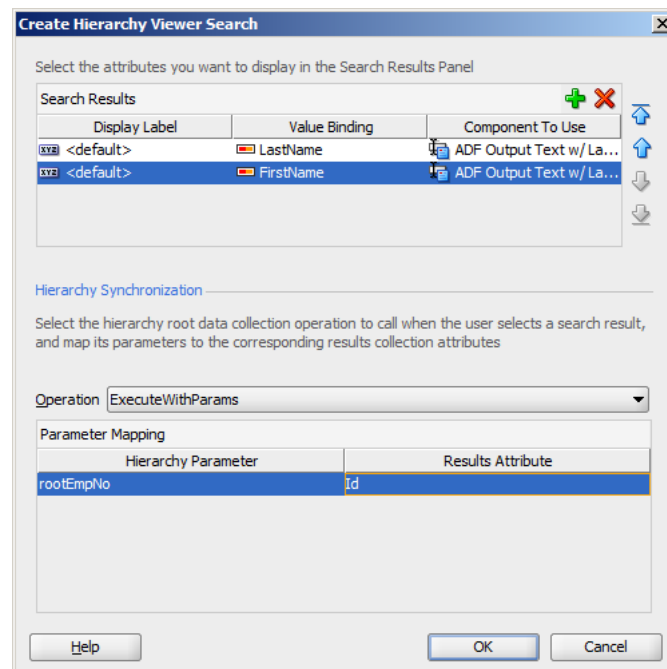

4. In the **Operation** dropdown list select the hierarchy root data collection to use when a search result is selected. Valid values include:
  - `removeRowWithKey`: Uses the row key as a `String` converted from the value specified by the input field to remove the data object in the bound data collection.
  - `setCurrentRowWithKey`: Sets the row key as a `String` converted from the value specified by the input field. The row key is used to set the currency of the data object in the bound data collection.

- `setCurrentRowWithKeyValue`: Sets the current object on the iterator, given a key's value.
  - `ExecuteWithParams`: Sets the values to the named bind variables passed as parameters.
5. In the **Parameter Mapping** table, use the dropdown list in the **Results Attribute** column to select the results collection attribute to map to the parameter displayed in the **Hierarchy Parameter** column.

Figure 26–100 shows the Create Hierarchy Viewer Search dialog that appears if you create a hierarchy viewer using data from a data collection named `EmployeesSearchResults1`.

**Figure 26–100 Create Hierarchy Viewer Search Dialog**

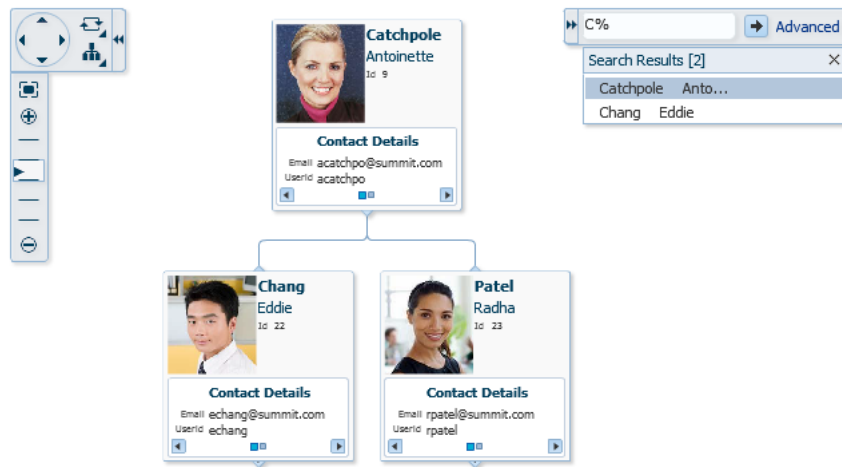

At runtime, the search results are displayed in a table by `LastName` and `FirstName`. Figure 26–102 shows the search results panel if a user enters `C%` in the search box to search for all employees whose last names begin with `C`.

**Figure 26–101 Hierarchy Viewer Search Results Panel**

The user can choose one of the search results to display the associated hierarchy viewer node and any children if they exist. Figure 26–102 shows the hierarchy viewer node if the user chooses `Catchpole` from the search results list.

**Figure 26–102 Hierarchy Viewer Search Results**

## 26.10 Creating Databound Treemaps and Sunbursts

Treemaps and sunbursts are ADF Data Visualization components that display quantitative hierarchical data across two dimensions, represented visually by size and color. For example, you can use a treemap or sunburst to display quarterly regional sales and to identify sales trends, using the size of the node to indicate each region’s sales volume and the node’s color to indicate whether that region’s sales increased or decreased over the quarter.

Treemaps and sunbursts use a shape called a *node* to reference the data in the hierarchy. Treemaps display nodes as a set of nested rectangles. Each branch of the tree is given a rectangle, which is then tiled with smaller rectangles representing sub-branches.

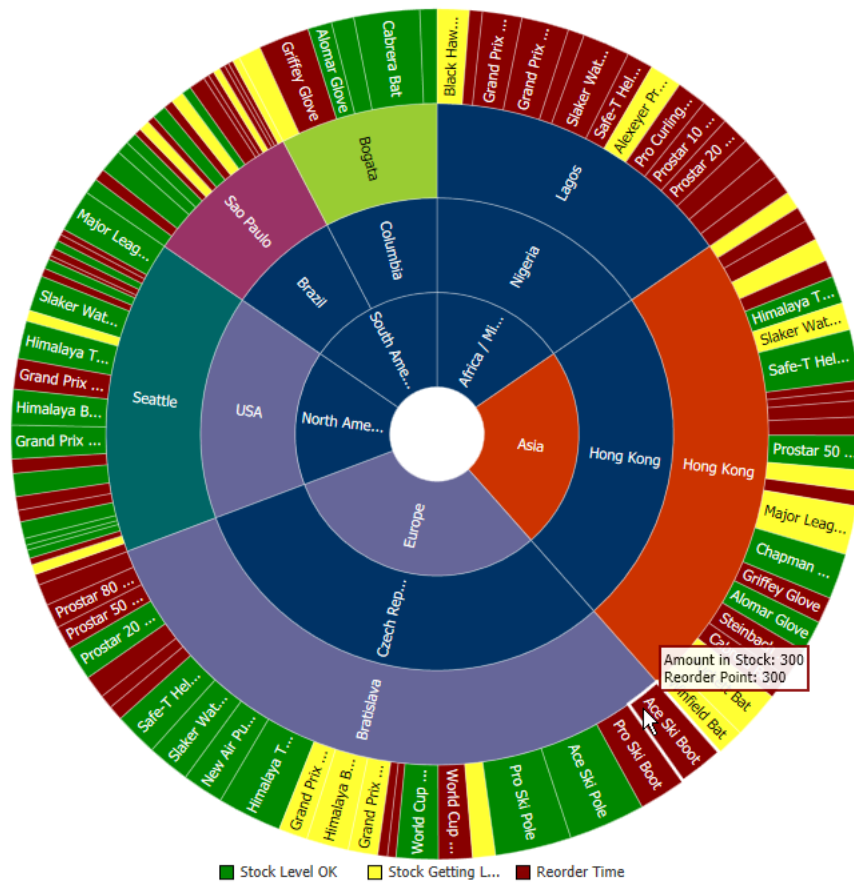

[Figure 26–103](#) shows a treemap displaying products available at a company’s warehouses in different regions around the world. In this example, the node size represents the amount in stock for each product, and node color represents inventory status.

Figure 26–103 Treemap Showing Product Availability and Inventory Levels

Sunbursts display the nodes in a radial rather than a rectangular layout, with the top of the hierarchy at the center and deeper levels farther away from the center. Figure 26–104 shows the same inventory data displayed in a sunburst.

**Figure 26–104 Sunburst Showing Product Availability and Inventory Levels**

The shape and content of the nodes are configurable, as well as the visual layout of the nodes. For detailed information about treemap and sunburst end user and presentation features, use cases, tag structure, and adding special features, see the "Using ADF Treemap and Sunburst Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 26.10.1 How to Create Treemaps and Sunbursts Using ADF Data Controls

Treemaps and sunbursts are based on data collections where a master-detail relationship exists between one or more detail collections and a master data collection. Treemaps and sunbursts also require that the following attributes be set in JDeveloper:

- `value`: the size of the node
- `fillColor`: the color of the node
- `label`: a text identifier for the node

The values for the `value` and `label` attributes must be stored in the treemap's or sunburst's data model or in classes and managed beans if you are using UI-first development. You can specify the `fillColor` values in the data model, classes, and managed beans, or declaratively in the Property Inspector.

In order to configure a treemap or sunburst successfully, ensure that the data adheres to the following rules:

- Each child node can have only one parent node.

- There can be no skipped levels.

Using data controls in Oracle ADF, JDeveloper makes treemap and sunburst creation a declarative task. You drag and drop a data collection from the Data Controls panel that generates one or more nodes onto a JSF page.

**Before you begin:**

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in [Section 9.2, "Creating and Modifying an Application Module."](#)

If you need help working with master-detail relationships, see [Chapter 24, "Displaying Master-Detail Data."](#)

- Create a JSF page as described in the "Creating a View Page" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

**To create a treemap or sunburst using the Data Controls panel:**

1. From the Data Controls panel, select a collection.

[Figure 26–105](#) shows the data collection for the treemap in [Figure 26–103](#) and the sunburst in [Figure 26–104](#). In this example, the application uses a view link between the `SCountriesView2` collection and the `SWarehouseView2` collection to create a hierarchy consisting of the `SRegionView1` and `SWarehouseView2` data collections.

**Figure 26–105 Sample Data Collection for Treemap and Sunburst**

[Table 26–7](#) shows the value, size, and color attributes used to create the treemap or sunburst.

**Table 26–7 Sample Values for Treemap and Sunburst Inventory Example**

Collection	Size Value	Label Value	Color Value
SRegionView1	CountryCount	Name	Default
SCountriesView2	WarehouseCount	Country	Default
SWarehouseView2	ProductCount	City	Default
ProductInventoryView2	AmountInStock	Name	Varies by stock level

2. Drag the collection onto a JSF page and, from the context menu, choose **Treemap** or **Sunburst**.
3. In the Create Treemap dialog or Create Sunburst dialog, in the **Hierarchy** section, select the collections you want to include as nodes in the runtime treemap or sunburst. By default, the root collection is selected.
4. For each collection that you select in the Hierarchy list, enter a value for the following.

- **Value:** From the dropdown list, select the attribute in the data collection that represents the size value for the sunburst. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression. For help with the Expression Builder dialog, press F1 or click **Help**.

For example, to create a treemap or sunburst using the data collection in [Figure 26–105](#), select **CountryCount** for the **SRegionView1** value to represent the size value for the first node.

- **Label:** From the dropdown list, select the attribute in the data collection that represents the label you wish to display for the sunburst node label. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

For example, select **Name** for the **SRegionView1** node label.

- Optionally, in the **View Area** section, click **New** to configure an attribute group for the node. Use attribute groups if you want the node’s display to vary based on color or pattern. You can also specify the node’s fill color or pattern in the node’s `fillColor` and `fillPattern` properties after you create the treemap or sunburst.

If you do not configure an attribute group to vary by color or specify a `fillColor` attribute on the node, the node will display in black. By default, no pattern will be displayed on the node.

In the treemap and sunburst product inventory example, attribute groups are configured for each level in the hierarchy.

To configure an attribute group, enter values for the following:

- **Group by value:** From the dropdown list, select the attribute in the data collection to group by in the attribute group. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

In the treemap and sunburst example, the size value is used as the **Group by value**. For the **SRegionView1** collection, select **CountryCount** as the **Group by value**.

- **Area:** From the dropdown list, select **Color** if you want the attribute group to vary by color or select **Pattern** if you want the attribute group to vary by pattern. To vary the attribute group by both color and pattern, select **Select Multiple Attributes** and select both **Color** and **Pattern**. Click **OK**.

In the treemap and sunburst product inventory example, color is used for each level of the hierarchy.

- **Legend Label:** From the dropdown list, select the attribute in the data collection to display in the treemap’s legend. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

In the treemap and sunburst product inventory example, this value is left blank.

Figure 26–106 shows the Create Treemap dialog completed for the first node in the product inventory example. The entries for the Create Sunburst dialog are identical.

**Figure 26–106** Create Treemap Dialog for a Region Node

- Optionally, click **Value-Specific Rules** to expand the attribute group dialog to specify a match or exception rule. Use match rules to specify colors or patterns for simple true or false conditions or when you want to match a specific value. Use exception rules when you want to specify a color or pattern when the node’s grouped-by value meets a specific condition.

To specify a match rule, in the **Match Rules** section, click **New** and enter values for the following:

- **Group Value:** Enter the category value for the match. This can be a string that represents a category or you can set this to true or false. If you set this to true or false, the **Group by value** field must contain an EL expression that evaluates to true or false as in the following example: `#{row.AmountInStock gt row.ReorderPoint}`.
- **Property:** From the dropdown list, select **Color** if you want the node to vary by color or select **Pattern** if you want the attribute node to vary by pattern.
- **Property Value:** From the dropdown list, select the color or pattern to display when the node's value matches the **Group Value**. For color, you can select one of the provided values or select **Custom Color** to enter a custom color in the Select Custom Color dialog. For pattern, you must select one of the provided values.

Figure 26–107 shows the Create Treemap dialog for a data collection using match rules for the bottom level of the hierarchy. The Create Sunburst dialog entries are identical.

**Figure 26–107 Treemap Showing Match Rules for an Attribute Group**

In this example, the treemap nodes will display in green (RGB hexadecimal #008000) when the inventory levels are acceptable and in red (RGB hexadecimal #ff0000) when the inventory level is at or below the product's reorder level. The attribute group's **Label** field contains the details for the legend display. In this case, the field contains an expression that determines the legend label based on an item's amount in stock:

```
#{(row.AmountInStock gt row.ReorderPoint) ? 'Stock Level OK' : 'Reorder Time'}
```

Figure 26–108 shows the runtime treemap.

**Figure 26–108 Treemap Showing Match Rules at Runtime**

To specify an exception rule, in the **Exception Rules** section, click **New** and enter values for the following:

- **Condition:** Enter a JSF EL expression that evaluates to true or false. You can enter the expression directly in the **Condition** field or select **Expression Builder** to enter the JSF EL expression.

In the treemap and sunburst product inventory example, three exception rules are defined for the bottom level of the hierarchy. When the product’s inventory level is well above the reorder level, the treemap node in [Figure 26–103](#) and the sunburst node in [Figure 26–104](#) display in green. The treemap and sunburst node display in yellow when the inventory level is close to the reorder point and display in red when the inventory level is at or very near the reorder point.

[Figure 26–109](#) shows the Create Sunburst dialog for the sample data collection in [Figure 26–105](#) using exception rules for the bottom level of the hierarchy. The Create Treemap dialog entries are identical.

**Figure 26–109 Sunburst Showing Exception Rules Creation Dialog**

- **Property:** From the dropdown list, select **Color** if you want the node to vary by color. Select **Pattern** if you want the node to vary by pattern.
  - **Property Value:** From the dropdown list, select the color or pattern to display when the node’s value meets the condition you specified in the **Condition** field. For color, you can select one of the provided values or select **Custom Color** to enter a custom color in the Select Custom Color dialog. For pattern, you must select one of the provided values.
  - **Legend Label:** From the dropdown list, select **Select Text Resource** to select a text resource to be used for the legend label. You can also enter text in this field or select **Expression Builder** to enter a JSF EL expression.
5. Click OK.

### 26.10.2 What Happens When You Create a Databound Treemap or Sunburst

Creating a treemap or sunburst from Data Controls panel has the following effect:

- Creates the bindings for the sunburst or treemap in the page definition file of the JSF page
- Adds the necessary tags to the JSF page for the treemap or sunburst component

[Example 26–53](#) displays bindings that JDeveloper generated for a treemap or sunburst component using the data collection in [Figure 26–105](#). Since both components use the same data model, the bindings in the page definition file are identical.

**Example 26–53 Sample Bindings for a Treemap or Sunburst**

```

<executables>
  <variableIterator id="variables"/>
  <iterator Binds="SRegionView1" RangeSize="-1" DataControl="AppModuleDataControl"
    id="SRegionView1Iterator"/>
</executables>
<bindings>
  <tree IterBinding="SRegionView1Iterator" id="SRegionView1">
    <nodeDefinition DefName="model.SRegionView" Name="SRegionView10">
      <AttrNames>
        <Item Value="Id"/>
        <Item Value="Name"/>
        <Item Value="CountryCount"/>
      </AttrNames>
      <Accessors>
        <Item Value="SCountriesView"/>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.SCountriesView" Name="SRegionView11">
      <AttrNames>
        <Item Value="Id"/>
        <Item Value="Country"/>
        <Item Value="RegionId"/>
        <Item Value="WarehouseCount"/>
      </AttrNames>
      <Accessors>
        <Item Value="SWarehouseView"/>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.SWarehouseView" Name="SRegionView12">
      <AttrNames>
        <Item Value="Id"/>
        <Item Value="Address"/>
        <Item Value="City"/>
        <Item Value="State"/>
        <Item Value="CountryId"/>
        <Item Value="ZipCode"/>
        <Item Value="Phone"/>
        <Item Value="ManagerId"/>
        <Item Value="ProductCount"/>
      </AttrNames>
      <Accessors>
        <Item Value="ProductInventoryView"/>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.ProductInventoryView" Name="SRegionView13">
      <AttrNames>
        <Item Value="ProductId"/>
        <Item Value="WarehouseId"/>
        <Item Value="AmountInStock"/>
        <Item Value="ReorderPoint"/>
        <Item Value="MaxInStock"/>
        <Item Value="OutOfStockExplanation"/>
        <Item Value="RestockDate"/>
        <Item Value="Id"/>
        <Item Value="Name"/>
        <Item Value="ShortDesc"/>
      </AttrNames>
    </nodeDefinition>
  </tree>

```

</bindings>

The rules for populating the nodes of the treemap or sunburst are defined in node definitions. The example shows that four node definitions were generated, one for each level of the hierarchy. Each of these node definitions references a view object and associated attributes. Each node definition also references an accessor for the next level of the hierarchy if the next level exists.

Once you create your treemap or sunburst, you can modify the value, label, and attribute group for each node using the Create Treemap or Create Sunburst dialog. To open the dialog, use the **Edit** icon in the Property Inspector for the `treemap` or `sunburst` component. You can also customize the values directly in the code or by setting values in the Property Inspector.

### 26.10.3 What Happens at Runtime: How Databound Sunbursts or Treemaps Are Initially Displayed

By default, a sunburst or treemap displays only the first two levels of the hierarchy and will not display a legend until you configure the `legendSource` attribute on the sunburst or treemap. [Figure 26–110](#) shows the sunburst that is displayed at runtime if you create the sunburst using the data collection in [Figure 26–105](#).

**Figure 26–110 Databound Sunburst Example Before Configuration**

After completing the Create Treemap or Create Sunburst dialog, you can use the Property Inspector to configure the treemap or sunburst level display and `legendSource` attribute. You can also specify settings for other treemap or sunburst attributes and use the child tags associated with the sunburst and treemap tags to customize the components further.

Example 26–54 shows the code on the JSF page code for the treemap in Figure 26–103. In this example, the databound treemap is configured to display all levels in the hierarchy, a legend, and a tooltip when the user hovers the mouse over a node.

**Example 26–54 Sample Code on a JSF Page for a Treemap**

```
<dvt:treemap id="t1" value="#{bindings.SRegionView1.treeModel}"
    var="row" displayLevelsChildren="3"
    legendSource="ag1" summary="Sample Treemap">
  <af:switcher facetName="#{row.hierTypeBinding.name}" id="s1">
    <f:facet name="SRegionView11">
      <dvt:treemapNode value="#{row.WarehouseCount}" label="#{row.Country}"
        id="tn1">
        <dvt:attributeGroups id="ag2" value="#{row.WarehouseCount}" type="color"/>
      </dvt:treemapNode>
    </f:facet>
    <f:facet name="SRegionView10">
      <dvt:treemapNode value="#{row.CountryCount}" label="#{row.Name}" id="tn2">
        <dvt:attributeGroups id="ag3" value="#{row.CountryCount}" type="color"/>
      </dvt:treemapNode>
    </f:facet>
    <f:facet name="SRegionView13">
      <dvt:treemapNode value="#{row.AmountInStock}" label="#{row.Name}" id="tn3"
        shortDesc="Amount in Stock:
        #{row.AmountInStock}&lt;br/>Reorder Point: #{row.ReorderPoint}">
        <dvt:attributeGroups value="#{row.AmountInStock}" type="color" id="ag1">
          <dvt:attributeExceptionRule id="aer1"
            condition="#{(row.AmountInStock.value -
            row.ReorderPoint.value) gt 50}"
            label="Stock OK">
            <f:attribute name="color" value="#008800"/>
          </dvt:attributeExceptionRule>
          <dvt:attributeExceptionRule id="aer2"
            condition="#{((row.AmountInStock.value -
            row.ReorderPoint.value) le 50) and ((row.AmountInStock.value -
            row.ReorderPoint.value) gt 25)}"
            label="Stock Level Getting Low">
            <f:attribute name="color" value="#FFFF33"/>
          </dvt:attributeExceptionRule>
          <dvt:attributeExceptionRule id="aer3"
            condition="#{(row.AmountInStock.value -
            row.ReorderPoint.value) le 25}"
            label="Reorder Time">
            <f:attribute name="color" value="#880000"/>
          </dvt:attributeExceptionRule>
        </dvt:attributeGroups>
      </dvt:treemapNode>
    </f:facet>
    <f:facet name="SRegionView12">
      <dvt:treemapNode value="#{row.ProductCount}" label="#{row.City}" id="tn4">
        <dvt:attributeGroups id="ag4" value="#{row.ProductCount}" type="color"/>
      </dvt:treemapNode>
    </f:facet>
  </af:switcher>
</dvt:treemap>
```

Example 26–55 shows the code on the JSF page code for the sunburst in Figure 26–104. In this example, the databound sunburst is also configured to display all levels in the hierarchy, a legend, and a tooltip when the user hovers the mouse over a node. Note

the similarities between the sunburst code in this example and the treemap code in the previous example.

**Example 26–55 Sample Code on a JSF Page for a Sunburst**

```

<dvt:sunburst id="t1" value="#{bindings.SRegionView1.treeModel}" var="row"
    displayLevelsChildren="3"
    summary="Sample Sunburst" legendSource="ag3">
  <af:switcher facetName="#{row.hierTypeBinding.name}" id="s1">
    <f:facet name="SRegionView10">
      <dvt:sunburstNode value="#{row.CountryCount}" label="#{row.Name}" id="sn1" >
        <dvt:attributeGroups value="#{row.CountryCount}" type="color"
          label="Country Count" id="ag1"/>
      </dvt:sunburstNode>
    </f:facet>
    <f:facet name="SRegionView11">
      <dvt:sunburstNode value="#{row.WarehouseCount}" label="#{row.Country}"
        id="sn4">
        <dvt:attributeGroups value="#{row.WarehouseCount}" type="color" id="ag4"/>
      </dvt:sunburstNode>
    </f:facet>
    <f:facet name="SRegionView12">
      <dvt:sunburstNode value="#{row.ProductCount}" label="#{row.City}" id="sn3">
        <dvt:attributeGroups value="#{row.ProductCount}" type="color" id="ag2"/>
      </dvt:sunburstNode>
    </f:facet>
    <f:facet name="SRegionView13">
      <dvt:sunburstNode value="#{row.AmountInStock}" label="#{row.Name}" id="sn2"
        shortDesc="Amount in Stock:
#{row.AmountInStock}&lt;br/>Reorder Point: #{row.ReorderPoint}">
        <dvt:attributeGroups value="#{row.AmountInStock}" type="color"
          label="Amount in Stock" id="ag3">
          <dvt:attributeExceptionRule id="aer1"
            condition="#{(row.AmountInStock.value - row.ReorderPoint.value) gt 50}"
            label="Stock Level OK">
            <f:attribute name="color" value="#008800"/>
          </dvt:attributeExceptionRule>
          <dvt:attributeExceptionRule id="aer2"
            condition="#{((row.AmountInStock.value -
            row.ReorderPoint.value) le 50) and ((row.AmountInStock.value -
            row.ReorderPoint.value) gt 25)}"
            label="Stock Getting Low">
            <f:attribute name="color" value="#FFFF33"/>
          </dvt:attributeExceptionRule>
          <dvt:attributeExceptionRule id="aer3"
            condition="#{(row.AmountInStock.value - row.ReorderPoint.value) le 25}"
            label="Reorder Time">
            <f:attribute name="color" value="#880000"/>
          </dvt:attributeExceptionRule>
        </dvt:attributeGroups>
      </dvt:sunburstNode>
    </f:facet>
  </af:switcher>
</dvt:sunburst>

```

For information about configuring the sunburst or treemap level display, legendSource attribute, tooltips, additional attributes, or child tags, see the "Using ADF Treemap and Sunburst Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

---

## Creating ADF Databound Search Forms

This chapter describes how to use ADF Faces components and ADF data binding to create search forms to perform complex searches on multiple attributes and search forms to search on a single attribute. For complex query search forms, it describes how to set up the query search form mode, results table, saved searches list, and personalization. For single attribute search forms, it describes how to configure the form layout. In addition, it includes information on using named bind variables and Query-by-Example (QBE) filtered table searches.

This chapter includes the following sections:

- [Section 27.1, "Introduction to Creating Search Forms"](#)
- [Section 27.2, "Creating Query Search Forms"](#)
- [Section 27.3, "Setting Up Search Form Properties"](#)
- [Section 27.4, "Creating Quick Query Search Forms"](#)
- [Section 27.5, "Creating Standalone Filtered Search Tables from Named View Criteria"](#)

### 27.1 Introduction to Creating Search Forms

You can create search forms that allow users to enter search criteria into input fields for known attributes of an object. The search criteria can be entered via input text fields or selected from a list of values in a popup list picker or dropdown list box. The entered criteria is constructed into a query to be executed. *Named bind variables* can be used to supply attribute values during runtime for the query. The results of the query can be displayed as a table, a form, or another UI component.

Search forms are based either on view criteria defined in view objects or on implicit view criteria defined by JDeveloper. Search forms are region-based components that are reusable and personalizable. They encapsulate and automate many of the actions and iterator management operations required to perform a query. You can create several search forms on the same page without any need to change or create new iterators.

The search forms are based on the model-driven `af:query` and `af:quickQuery` components. Because these underlying components are model-driven, the search form will change automatically to reflect changes in the model. The view layer does not need to be changed. For example, if you define a list of values (LOV) on an attribute in the view object or entity object, the LOV will automatically show up in the search form as an LOV component. Or, if you modify a view criteria to include a new attribute for the `WHERE` clause, the search panel using this view criteria will automatically reflect that change by adding a search field for that attribute.

Oracle ADF supports two types of search forms: query and quick query. The *query search form* is a full-featured search form. The *quick query search form* is a simplified form with only one search criteria. Each of these search forms can be combined with a filtered table to display the results, thereby enabling additional search capabilities. You can also create a standalone filtered table to perform searches without the query or quick query search panel.

A *filtered table* is a table that has additional Query-by-Example (QBE) search criteria fields above each searchable column. When the filtering option of a table is enabled, you can enter QBE-style search criteria for each column to filter the query results. For more information about tables, see [Chapter 23, "Creating ADF Databound Tables."](#)

For more information about individual query and table components, see the "Using Query Components" and the "Using Tables, Trees, and Other Collection-Based Components" chapters of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 27.1.1 Query Search Forms

The query search form is the standard form for complex transactional searches. You can build complex search forms with multiple search criteria fields each with a dropdown list of built-in operators. You can also add custom operators and customize the list. The query search form supports lists of values, AND and OR conjunctions, and saving searches for future use.

A query search form has a basic mode and an advanced mode. The user can toggle between the two modes using the basic/advanced button. At design time, you can declaratively specify form properties (such as setting the default state) to be either basic or advanced. [Figure 27-1](#) shows an advanced mode query search form with three search criteria.

**Figure 27-1 Advanced Mode Query Search Form with Three Search Criteria Fields**

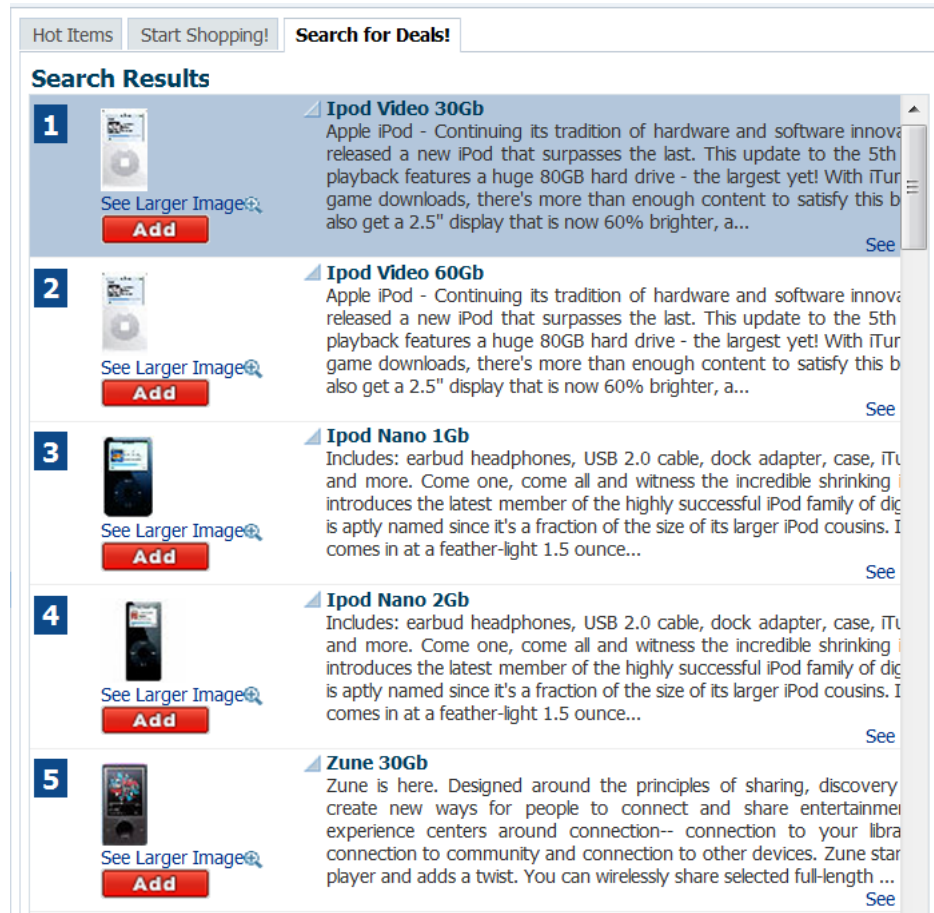

The advanced mode query form features are:

- Selecting search criteria operators from a dropdown list
- Adding custom operators and deleting standard operators
- Selecting WHERE clause conjunctions of either AND or OR (match all or match any)
- Dynamically adding and removing search criteria fields at runtime
- Saving searches for future use
- Personalizing saved searches

Typically, the query search form in either mode is used with an associated results table or tree table. For example, the query results for the search form in [Figure 27-1](#) may be displayed in a table, as shown in [Figure 27-2](#).

**Figure 27-2 Results Table for a Query Search**

The basic mode has all the features of the advanced mode except that it does not allow the user to dynamically add search criteria fields. [Figure 27-3](#) shows a basic mode query search form with one search criteria field. Notice the lack of a dropdown list next to the **Save** button used to add search criteria fields in the advanced mode.

**Figure 27-3 Basic Mode Query Form with One Search Criteria Field**

In either mode, each search criteria field can be modified by selecting operators such as `Greater Than` and `Equal To` from a dropdown list, and the entire search panel can be modified by the **Match All/Any** radio buttons. Partial page rendering is also supported by the search forms in almost all situations. For example, if a `Between` operator is chosen, another input field will be displayed to allow the user to select the upper range.

A `Match All` selection implicitly uses `AND` conjunctions between the search criteria in the `WHERE` clause of the query. A `Match Any` selection implicitly uses `OR` conjunctions in the `WHERE` clause. [Example 27-1](#) shows how a simplified `WHERE` clause may appear (the real `WHERE` in the view criteria is different) when `Match All` is selected for the search criteria shown in [Figure 27-1](#).

**Example 27-1 Simplified WHERE Clause Fragment When "Match All" Is Selected**

```
WHERE (ProductId=4) AND (InStock > 2) AND (ProductName="Ipod")
```

[Example 27-2](#) shows a simplified `WHERE` clause if `Match Any` is selected for the search criteria shown in [Figure 27-3](#).

**Example 27-2 Simplified WHERE Clause Fragment When "Match Any" Is selected**

```
WHERE (ProductId=4) OR (InStock > 2) OR (ProductName="Ipod")
```

If the view criteria for the query has mixed `AND` and `OR` conjunctions between the criteria items, then neither **Match All** nor **Match Any** will be selected when the component first renders. However, the user can select **Match All** or **Match Any** to override the conjunctions defined as the initial state in the view criteria.

Advanced mode query forms allow users to dynamically add search criteria fields to the query panel to perform more complicated queries. These user-created search criteria fields can be deleted, but the user cannot delete existing fields. [Figure 27-4](#) shows how the **Add Fields** dropdown list is used to add the **CategoryId** criteria field to the search form.

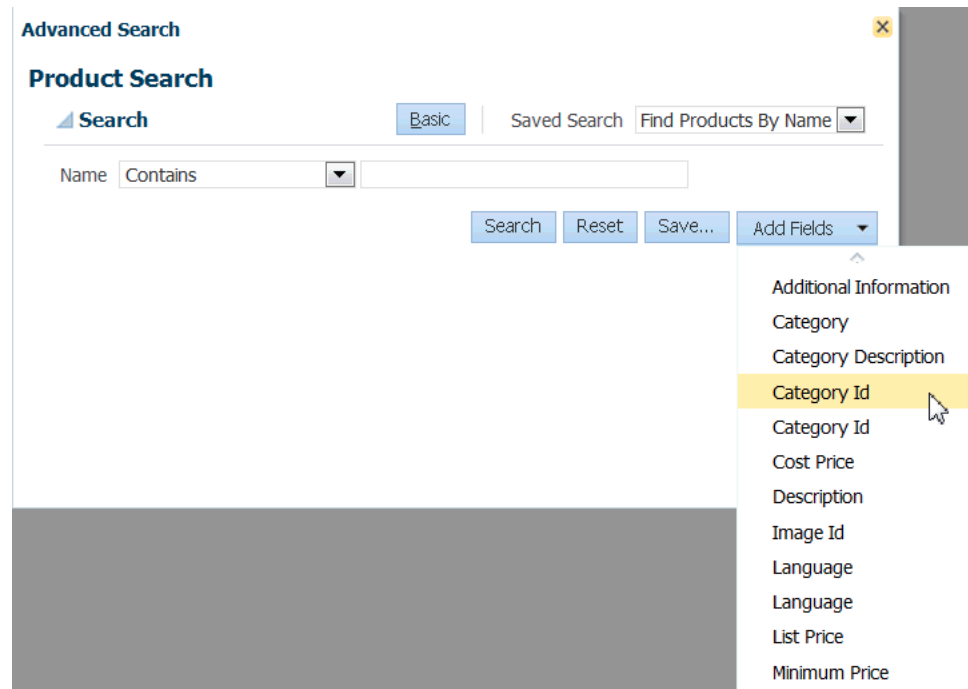

**Figure 27–4** Dynamically Adding Search Criteria Fields at Runtime

Figure 27–5 shows a user-added search criteria with the delete icon to its right. Users can click the delete icon to remove the criteria.

**Figure 27–5** User-Added Search Criteria with Delete Icon

You can organize search fields in the query panel by creating groups in the UI Categories page of the view object overview editor. Note that you must give each UI Categories group a name in the **Label Text** field as shown in Figure 27–6.

**Figure 27–6 View Object Overview Editor UI Categories Page**

The query panel search fields will be displayed within each defined UI Categories group. When you use the **Add Fields** button, the available fields in the dropdown list are also organized into subcategories. [Figure 27–7](#) shows a query component with two UI Categories groups defined (Product Info and Supplier Info).

**Figure 27–7 Dynamically Adding Search Fields in Query with UI Categories Groups**

If either **Match All** or **Match Any** is selected and then the user dynamically adds the second instance of a search criteria, then both **Match All** and **Match Any** will be deselected. The user must reselect either **Match All** or **Match Any** before clicking the **Search** button.

If you intend for a query search form to have both a basic and an advanced mode, you can define each search criteria field to appear only for basic, only for advanced, or for both. When the user switches from one mode to the other, only the search criteria

fields defined for that mode will appear. For example, suppose three search fields for basic mode (A, B, C) and three search fields for advanced mode (A, B, D) are defined for a query. When the query search form is in basic mode, search criteria fields A, B, and C will appear. When it is in advanced mode, then fields A, B, and D will appear. Any search data that was entered into the search fields will also be preserved when the form returns to that mode. If the user entered 35 into search field C in basic mode, switched to advanced mode, and then switched back to basic, field C would reappear with value 35.

Along with using the basic or advanced mode, you can also determine how much of the search form will display. The default setting displays the whole form. You can also configure the query component to display in compact mode or simple mode. The compact mode has no header or border, and the **Saved Search** dropdown lists moves next to the expand/collapse icon. [Figure 27-8](#) shows a query component set to compact mode.

**Figure 27-8 Query Component in Compact Mode**

The simple mode displays the component without the header and footer, and without the buttons normally displayed in those areas. [Figure 27-9](#) shows the same query component set to simple mode.

**Figure 27-9 Query Component in Simple Mode**

A query is associated with the view object that it uses for its query operation. In particular, a query component is the visual representation of the view criteria defined for that view object. If there are multiple view criteria defined, each can be selected from the **Saved Search** dropdown list. These saved searches are created at design time and are called *system searches*. For example, in the StoreFront module of the Fusion Order Demo application, there are two view criteria defined on the `ProductsVO` view object. When the query associated with that view criteria is run, both view criteria are available for selection, as shown in [Figure 27-10](#).

**Figure 27–10 Query Form Saved Search Dropdown List**

If there are no explicitly defined view criteria for a view object, you can use the default implicit view criteria.

Users can also create saved searches at runtime to save the state of a search for future use. The entered search criteria values and the basic/advanced mode state can be saved by clicking the **Save** button to open a Save Search dialog, as shown in [Figure 27–11](#). Saved searches appear in alphabetical order in the Saved Search dropdown list. User-created saved searches persist for the session. If they are intended to be available beyond the session, you must configure a persistent data store to store them. For Oracle ADF, you can use an access-controlled data source such as MDS. For more information about using MDS, see [Chapter 34, "Customizing Applications with MDS."](#) For more information about user customizations, see [Chapter 35, "Allowing User Customizations at Runtime."](#)

**Figure 27–11 Runtime Saved Search Dialog Window**

When you perform a saved search, you can specify whether the layout of the results component is also saved. Creating saved searches and saving the results components layout require that MDS is configured. If you set the query component's `saveResultsLayout` attribute to `always`, the results component layout will be saved. If `saveResultsLayout` is set to `never`, the layout is not saved.

**Example 27–3 web.xml Entry for Saving Query Results Component Layout**

```
<context-param>
  <description>Saving results layout</description>
  <param-name>oracle.adf.view.rich.query.SAVE_RESULTS_LAYOUT</param-name>
  <param-value>true</param-value>
</context-param>
```

If `saveResultsLayout` is not defined, saving layout defaults to the application-level property `oracle.adf.view.rich.query.SAVE_RESULTS_LAYOUT` in the `web.xml` file. The default value of `oracle.adf.view.rich.query.SAVE_RESULTS_LAYOUT` is `true`.

If the user made changes to the layout of a saved search and proceeds without saving, a warning message appears to remind the user to save, otherwise the changes will be lost. In addition, if the user adds or deletes search fields and proceeds without saving, a warning message also appears.

Table 27–1 shows the `saveResultsLayout` and `SAVE_RESULTS_LAYOUT` values and their resultant action. Note that MDS must be configured to save layout.

**Table 27–1 Save Results Component Layout Attributes**

<b>web.xml</b>	<b>Query Component</b>	<b>Resultant action</b>
<b>SAVE_RESULT_LAYOUT</b>	<b>saveResultsLayout</b>	
true	always	Saves layout
true	never	Not saved
true	not defined	Saves layout
false	always	Not saved
false	never	Not saved
false	not defined	Not saved

Table 27–2 lists the possible scenarios for creators of saved searches, the method of their creation, and their availability.

**Table 27–2 Design Time and Runtime Saved Searches**

<b>Creator</b>	<b>Created at Design time as View Criteria</b>	<b>Created at Runtime with the Save Button</b>
Developer	Developer-created saved searches (system searches) are created during application development and typically are a part of the software release. They are created at design time as view criteria. They are usually available to all users of the application and appear in the lower part of the <b>Saved Search</b> dropdown list.	
Administrator		Administrator-created saved searches are created during predeployment by site administrators. They are created before the site is made available to the general end users. Administrators can create saved searches (or view criteria) using the JDeveloper design time when they are logged in with the appropriate role. These saved searches (or view criteria) appear in the lower part of the <b>Saved Search</b> dropdown list.

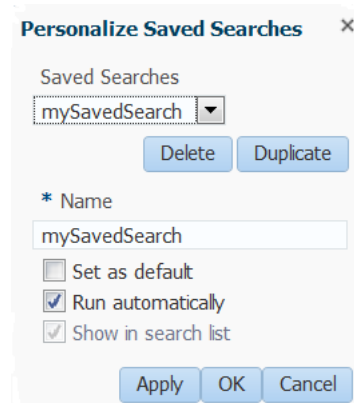

**Table 27–2 (Cont.) Design Time and Runtime Saved Searches**

Creator	Created at Design time as View Criteria	Created at Runtime with the Save Button
End User		End-user saved searches are created at runtime using the query form <b>Save</b> button. They are available only to the user who created them. End-user saved searches appear in the top part of the <b>Saved Search</b> dropdown list.

You can use the **runQueryAutomatically** property as listed in the Property Inspector to specify whether a saved search will run the query automatically. Setting the property to **allSavedSearches** means all system and user-created saved searches will run automatically when the query component is initially loaded, whenever the saved search has changed, or the reset button is pressed. If you set the **runQueryAutomatically** property to **searchDependent**, you can specify at design time whether that specific query will run automatically. **searchDependent** is the default value.

For new user-created saved searches with **runQueryAutomatically** property set to **searchDependent**, the Create Saved Search dialog, as shown in [Figure 27–11](#), will have the **Run Automatically** option set as the default. For new user-created saved searches with **runQueryAutomatically** property set to **allSavedSearches**, the Create Saved Search dialog will not display the **Run Automatically** option, but it will be set implicitly.

End users can manage their saved searches by using the Personalize function in the **Saved Search** dropdown list to bring up the Personalize Saved Searches dialog, as shown in [Figure 27–12](#).

**Figure 27–12 Personalize Saved Searches Dialog**

End users can use the Personalize function to:

- Update a user-created saved search
- Delete a user-created saved search
- Set a saved search as the default
- Set a saved search to run automatically
- Set the saved search to show or hide from the **Saved Search** dropdown list

---

**Note:** The **Show in search list** option is automatically enabled in the Skyros skin. For other skins, you need to add the following property to the skin CSS file.

```
af|query {
    -tr-system-search-show-in-list: enable;
}
```

For a general overview of ADF skins, see the "Customizing the Appearance Using Styles and Skins" chapter in *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

---

Users can set any seeded saved search as the default saved search in any visible customizable layer by selecting the **Set as default** checkbox. For more information about customization layers and seeded customization, see [Chapter 34, "Customizing Applications with MDS."](#) For more information about user customizations, see [Chapter 35, "Allowing User Customizations at Runtime."](#)

---

**Note:** If in you are changing the value of a view criteria item programmatically, you must invoke the `ViewCriteria.saveState()` method to prevent the `searchRegion` binding from resetting the value of the view criteria item to the value that was specified at design time.

---

## 27.1.2 Quick Query Search Forms

A quick query search form is intended to be used in situations where a single search will suffice or as a starting point to evolve into a full query search. Both the query and quick query search forms are ADF Faces components. A quick query search form has one search criteria field with a dropdown list of the available searchable attributes from the associated data collection. Typically, the searchable attributes are all the attributes in the associated view object. You can exclude attributes by setting the attribute's **Display Hint** property in the Control Hints page of the Edit Attribute dialog to **Hide**. The user can search against the selected attribute or search against all the displayed attributes. The search criteria field type will automatically match the type of its corresponding attribute. An **Advanced** link built into the form offers you the option to create a managed bean to control switching from quick query to advanced mode query search form. For more information, see the "Using Query Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

You can configure the form to have a horizontal layout, as shown in [Figure 27–13](#).

**Figure 27–13 Quick Query Search Form in Horizontal Layout**

You can also choose a vertical layout, as shown in [Figure 27–14](#).

**Figure 27–14 Quick Query Search Form in Vertical Layout**

### 27.1.3 Named Bind Variables in Query Search Forms

Instead of specifying a literal operand in a view criteria to be used in a search form, you have the option of specifying a named bind variable. The named bind variable performs like a parameter whose value can change at runtime without the need to change the SQL statement. It must be defined in the view object before it can be used in a view criteria.

If you specify a literal operand in the view criteria and leave the value blank, it will not appear in the SQL preview. When the view criteria is applied as a search form at runtime, that attribute is rendered as a blank input search field. If a value is specified for the literal operand, then the SQL preview will generate a SQL clause for it. When the view criteria is applied as a search form at runtime, the SQL statement is not automatically applied even though the value specified in the view criteria appears in the input search field. The SQL statement won't get applied until the user clicks **Search** (or when auto-execute is set to true).

If a named bind variable is used in the query defined in the view criteria, the SQL preview will display the `WHERE` clause with the bind variable. When the view criteria is applied as a search form at runtime, the bind variable will be rendered with a prompt and an input search field based on the name of the attribute (not on the name of the bind variable). The named bind variable input field may be `NULL`, it may contain the default value, or it may contain a value that has loaded from previous processing, such as from another page. The user can enter values for the named bind variable as in any other search criteria. When the search is executed, the value of the named bind variable will be evaluated with the other criteria, as defined by the SQL query statement.

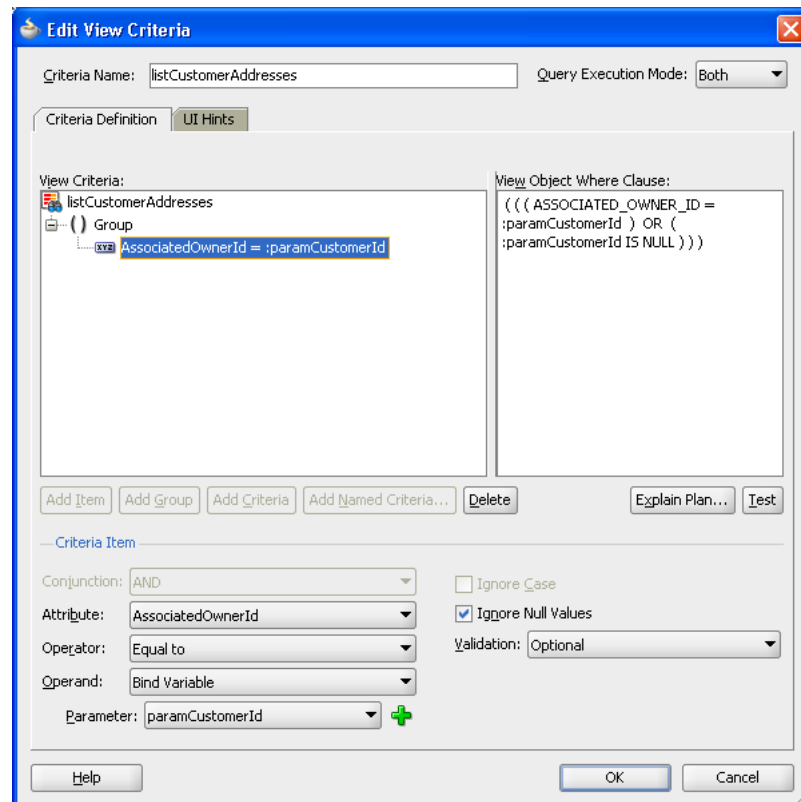

If the bind variable is used more than once in the same view criteria, each occurrence of the bind variable will be rendered as an individual input field. Because there is only one bind variable backing all the input fields, the value of all the fields will be synchronized. For instance, if you specify a view criteria that uses the same bind variable three times, then three input fields will be rendered. When the user enters a value into one input field, the other two input fields will have the same value. Using bind variables in this way eliminates the need for the user to enter the same value multiple times.

Another use of the bind variable is to pass a value from the base row into a search for an LOV search form.

Bind variables can also be used to pass parameter values from one page to another, such as when a customer ID is passed to another page for more detail processing. And, depending on the construct of the SQL statement, using the named bind variable may speed up the query because it may lessen the need to prepare a new statement, which means that the database does not need to reparse. For more information about creating and using named bind variables, see [Section 5.10, "Working with Bind Variables."](#)

For example, in the StoreFront module of the Fusion Order Demo application, in the `listCustomerAddresses` view criteria, the `WHERE` clause checks to see whether the `AssociatedOwnerId` is the same as the value of the `paramCustomerId` named bind variable. This view criteria is in the `AddressesLookupVO` view object. The `listCustomerAddresses` view criteria as defined in the Edit View Criteria dialog is shown in [Figure 27–15](#).

**Figure 27–15** View Criteria with Named Bind Variable

A query search form for a view criteria with a named bind variable will render with a search field for the variable using the `inputText` component. [Figure 27–16](#) shows the `AssociatedOwnerId` search field displayed as an `inputText` component.

**Figure 27–16** Query Search Form with Named Bind Variable

### 27.1.4 Filtered Table and Query-by-Example Searches

A filtered table can be created standalone or as the results table of a query or quick query search form. Filtered table searches are based on Query-by-Example and use the QBE text or date input field formats. The input validators are turned off to allow for

entering characters such as  $>$  and  $\leq$  to modify the search criteria. For example, you can enter  $>1500$  as the search criteria for a number column. Wildcard characters may also be supported. If a column does not support QBE, the search criteria input field will not render for that column. The input field rendered will depend on the attribute's data type. For instance, a date column will have a date picker component rendered and a column for an attribute defined as a List of Values will have the corresponding List of Values component rendered.

The filtered table search criteria input values are used to build the query `WHERE` clause with the `AND` operator. If the filtered table is associated with a query or quick query search panel, the composite search criteria values are also combined to create the `WHERE` clause.

---

**Note:** If the filtered table is used with a query component in a search form and the search region is using an existing named criteria, the results of the query will be filtered by all the view criteria rows in an iterative manner. For example, a filtered table has two view criteria rows: `PersonId` and `DeptId`. The first view criteria row has `PersonId > 1`. When the user enters  $> 100$  in the filter field, then the second view criteria row `DeptId` is used to accept input to further filter the results. This process iterates through all the view criteria rows until the final query result is reached.

---

Figure 27–17 shows a query search form with a filtered results table. When the user enters a QBE search criteria, such as  $>100$  for the `PersonId` field, the query result is the `AND` of the query search criteria and the filtered table search criteria.

**Figure 27–17 Query Search Form with Filtered Table**

**Persons**

Match  All  Any

Gender

LastName

PersonId

Gender	LastName	PersonId
		>100
F	Mikkilineni	126
F	Nayer	125
F	Bissot	129
F	Greenberg	108
F	Baida	116
F	Colmenares	119
F	Vollman	123
F	Lorentz	107
F	Kochhar	101
F	Pataballa	106
F	Bralick	201
F	Berman	203
F	Benghiat	204
F	Hemant	206
F	Chen	209

Table 27-3 lists the acceptable QBE search operators that can be used to modify the search value.

**Table 27-3 Query-by-Example Search Criteria Operators**

Operator	Description
>	Greater than
<	Less than
>=	Greater than or equal to
<=	Less than or equal to
AND	And
OR	Or

### 27.1.5 Implicit and Named View Criteria

When you create data controls, all data collections will automatically include a Named Criteria node with an All Queriable Attributes criteria. This is the default view criteria that includes all the searchable attributes or columns of the data collection. You cannot edit or modify this view criteria. These implicit view criteria can be used in the same way as declaratively created (or named) view criteria during the creation of query and quick query search forms. For more information about creating named view criteria, see [Section 5.11, "Working with Named View Criteria."](#)

When you add additional named view criteria for that view object or collection, the new view criteria will be added to the Named Criteria node.

---

**Note:** Query search forms have certain restrictions for working with expressions that have nested view criteria and may not work with all types of nested expressions. For more information about the nested expressions supported by search forms, see [Section 5.11.4, "What You May Need to Know About Nested Expressions."](#)

---

In the Data Controls panel, a data collection's Named Criteria node will always include the implicit view criteria, regardless of whether any named view criteria were defined. The implicit view criteria is always available for every data collection.

### 27.1.6 List of Values (LOV) Input Fields

List of values (LOV) components are input components that allow the user to enter values by picking from a list that is generated by a query. ADF Faces provides the `af:inputListOfValues` and `af:inputComboBoxListOfValues` components. If you are using dependent LOVs as part of your search form, you must use them with the `af:query` component. For more information about LOV components, see [Section 25.2, "Creating List of Values \(LOV\)."](#)

If an attribute is defined as an LOV, you can set the **Support Multiple Value Selection** control hint in its view criteria to enable users to make multiple selections in the search criteria field. If multiple selection is enabled on an LOV attribute, and the `Equal to` or `Not equal to` operator is chosen, a `selectManyChoice` component will render in the query panel. The user can select multiple items as the search criteria.

When the LOV is in a query component, if the **Support Multiple Value Selection** hint is not set and the `Equal to` or `Not equal to` operator is chosen, the query

component will render a search criteria component according to the **Default List Type** control hint for the corresponding attribute in the view object.

The quick query component does not support multiple selection. It will always render the component specified by the **Default List Type** control hint. [Table 27–4](#) shows the control hint selection and the default list component.

**Table 27–4 Query and Quick Query Search Criteria Field Input Components**

Default List Type Control Hint	Component
Input Text with List of Values	<code>af:inputListOfValues</code>
Combo Box with List of Values	<code>af:inputComboboxListOfValues</code>
Choice List, Combo Box, List Box, Radio Group	<code>af:selectOneChoice</code>

For more information about view criteria options, see [Section 5.11.1, "How to Create Named View Criteria Declaratively,"](#) and [Section 5.11.3, "What You May Need to Know About Bind Variable Options."](#)

## 27.2 Creating Query Search Forms

You create a query search form by dropping a named view criteria item from the Data Controls panel onto a page. You have a choice of dropping only a search panel, dropping a search panel with a results table, or dropping a search panel with a tree table.

If you choose to drop the search panel with a table, you can select the filtering option in the dialog to turn the table into a filtered table.

Typically, you would drop a query search panel with the results table or tree table. JDeveloper will automatically create and associate a results table or tree table with the query panel.

If you drop a query panel by itself and want a results component or if you already have an existing component for displaying the results, you will need to match the query panel's `ResultsComponentId` with the results component's `Id`.

---

---

**Note:** When you drop a named view criteria onto a page, that view criteria will be the basis for the initial search form. All other view criteria defined against that data collection will also appear in the **Saved Search** dropdown list. Users can then select any of the view criteria search forms, and also any end-user created saved searches.

---

---

### 27.2.1 How to Create a Query Search Form with a Results Table or Tree Table

You create a search form by dragging and dropping a view criteria from the Data Controls panel onto the page. You have the option of having a results table or only the query panel.

**Before you begin:**

You should have created a view object to be the basis of the search form. If you intend to create searches using explicitly created view criteria, you need to create them, if you have not already. You can also use the default implicit view criteria, which would include all queryable attributes in the collection.

When you create a view criteria, you should also set some of the search form default properties. For more information about setting the default state of the search form, see [Section 27.3.1, "How to Set Search Form Properties on the View Criteria."](#) For information on how to create view criteria, see [Section 5.11, "Working with Named View Criteria."](#)

If you intend for some or all of your input fields to be LOVs, you should declare those attributes as LOVs in the view object.

If you want to add placeholder text, label, or tooltip, see [Section 27.3.2, "How to Add Placeholder Text, Label, and Tooltip."](#)

#### To create a query search form with a results table or tree table:

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the named view criteria item and drop it onto the page or onto the Structure window.
3. From the context menu, choose **Create > Query > ADF Query Panel with Table** or **Create > Query > ADF Query Panel with Tree Table**, as shown in [Figure 27–18](#).

**Figure 27–18 Data Controls Panel with Query Context Menu**

4. In the Edit Table Columns dialog, you can rearrange any column and select table options. If you choose the filtering option, the table will be a filtered table.

After you have created the form, you may want to set some of its properties or add custom functions. For more information on how to do this, see [Section 27.3, "Setting Up Search Form Properties."](#)

## 27.2.2 How to Create a Query Search Form and Add a Results Component Later

You create a search form by dragging and dropping a view criteria from the Data Controls panel onto the page. You have the option of having a results table or only the query panel.

#### Before you begin:

You should have created a view object to be the basis of the search form. If you intend to create searches using your own view criteria, you need to create them, if you have not already. You can also use the default implicit view criteria, which would include all queryable attributes in the collection.

When you create a view criteria, you should also set some of the search form default properties. For more information about setting the default state of the search form, see [Section 27.3.1, "How to Set Search Form Properties on the View Criteria."](#) For information on how to create view criteria, see [Section 5.11, "Working with Named View Criteria."](#)

If you intend for some or all of your input fields to be LOVs, you should declare those attributes as LOVs in the view object.

If you want to add placeholder text, label, or tooltip, see [Section 27.3.2, "How to Add Placeholder Text, Label, and Tooltip."](#)

**To create a query search form and add a results component in a separate step:**

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the named view criteria item and drop it onto the page or onto the Structure window.
3. Choose **Create > Query > ADF Query Panel** from the context menu, as shown in [Figure 27-18](#).
4. If you do not already have a results component, then drop the data collection associated with the view criteria as a component.
5. In the Property Inspector for the table, copy the value of the **Id** field.
6. In the Property Inspector for the query panel, paste the value of the table's ID into the query's **ResultsComponentId** field.

After you have created the search form, you may want to set some of its properties or add custom functions. See [Section 27.3, "Setting Up Search Form Properties,"](#) for more information.

### 27.2.3 How to Persist Saved Searches into MDS

If you want saved searches to be persisted to MDS, you need to define the `/persdef` namespace in the `adf-config.xml` file. In addition, you need to perform the regular MDS configuration, such as specifying `metadatapath`. [Example 27-4](#) shows an `adf-config.xml` file with the `/persdef` namespace defined.

**Example 27-4 Sample `adf-config.xml` with `/persdef` Namespace**

```
<persistence-config>
  <metadata-namespaces>
    <namespace path="/persdef" metadata-store-usage="mdsstore"/>
  </metadata-namespaces>
  <metadata-store-usages>
    <metadata-store-usage id="mdsstore" deploy-target="true"
      default-cust-store="true">
    </metadata-store-usage>
  </metadata-store-usages>
</persistence-config>
```

In order for the added saved searches to be available the next time the user logs in, `cust-config` needs to be defined as part of the MDS configuration. For more information about setting `cust-config` and MDS, see [Section 34.2.7, "How to Configure the `adf-config.xml` file."](#)

If you are also saving the layout of the results component, the application must have the ADF PageFlow Runtime and ADF Controller Runtime libraries installed. Set the project's technology scope to include **ADF Page Flow** or automatically include these libraries by using the Fusion Web Application (ADF) application template.

### 27.2.4 How to Set Default Search Binding Behavior

A *search binding* provides the model-driven behavior for a search form at runtime. The search binding is related to a particular iterator and the view criteria on that iterator, whose runtime defaults are specified by the `Binds` and `Criteria` properties of the search

binding, respectively. The behavior of the search binding depends on the **Query Automatically** control hint. For more information about creating named view criteria, see [Section 5.11, "Working with Named View Criteria."](#)

The first time a search form is rendered in a task flow, the search binding's runtime behavior, also known as the initial AutoQuery-or-ClearRowSet behavior, is as follows:

- If **Query Automatically** is set to `true`: The search binding automatically executes the iterator when the search binding is initialized in a task flow. The user will be presented with the results of the search based on the view criteria.
- If **Query Automatically** is set to `false`: The search binding clears the row set related to its iterator. The user will be presented with an empty search results component, which allows the user to enter search criteria and click the **Search** button to execute the search.

The **Query Automatically** control hint is available declaratively only for named view criteria. For the All Queriable Attributes view criteria, you can use the `setProperty()` method on the view criteria API interface to configure the hint at runtime. You can also use this method to set the hint on named view criteria. In the method, set the `ViewCriteriaHints.CRITERIA_AUTO_EXECUTE` property to `true`.

If the user changes the search form by selecting a different view criteria from the dropdown **Saved Search** list, the runtime behavior is as follows:

- If **Query Automatically** is set to `true`: The search binding automatically executes the iterator after applying the new view criteria. The user will be presented with the results of the newly selected saved search.
- If **Query Automatically** is set to `false`: The search binding applies the new view criteria only, leaving any existing search results intact. The user is presented with the results of the previous search.

The search binding's `queryPerformed` property evaluates to `true` if the search binding has performed the query, either automatically or by the user clicking the **Search** button. Clicking the **Reset** button in the search form resets the view criteria and sets the `queryPerformed` property to `false`.

The search binding offers two properties that allow you to customize its default behavior: `TrackQueryPerformed` and `InitialQueryOverridden`. You can set the `TrackQueryPerformed` and the `InitialQueryOverridden` properties in the Property Inspector.

A search binding's `TrackQueryPerformed` property controls whether it manages its `queryPerformed` property during runtime at the page flow level or at the individual page or page fragment level. The valid values for `TrackQueryPerformed` are `pageFlow` and `page`, and the default is `pageFlow`. The search binding's behavior is as follows:

- If `TrackQueryPerformed` is set to `pageFlow`, then `queryPerformed` is initialized once per page flow and tracked at the page flow level. The user can navigate away from the search form page, return to the page within the life of the page flow, and the value of the `queryPerformed` flag will remain the same.
- If `TrackQueryPerformed` is set to `page`, then `queryPerformed` is initialized each time the user navigates to the page or page fragment. This happens when the page is navigated to for the first time and when the page is returned from another page within the page flow.

When `TrackQueryPerformed` of a search binding is set to `pageFlow`, its initial AutoQuery-or-ClearRowSet behavior is performed once during the page flow. In

contrast, when `TrackQueryPerformed` is set to `page`, the initial `AutoQuery-or-ClearRowSet` behavior is performed each time the user visits the page or page fragment.

A search binding's `InitialQueryOverridden` property controls whether it should suppress its initial `AutoQuery-or-ClearRowSet` behavior the first time the search binding is used in a page flow. If `InitialQueryOverridden` is `true`, then all valid values, including `true`, `false`, or a boolean-valued EL expression, are suppressed. The default value is `false`.

When you set the `InitialQueryOverridden` property to `true`, you are responsible for writing custom application logic to execute the query. Typically, the query should execute after the code applies some view criteria, sets some bind variables, or performs some other programmatic query setup. If your custom code fails to execute the query as expected with `InitialQueryOverridden` set to `true`, unless **Query Automatically** is set to `false`, the framework will still implicitly execute your query the first time during a user session in which there is an iterator binding reference. This occurs because when **Query Automatically** is not set to `false`, the iterator binding's default `executeQueryIfNeeded` behavior takes effect and executes the query.

When `InitialQueryOverridden` evaluates to `true` or boolean `true`, then the initial `AutoQuery-or-ClearRowSet` behavior is suppressed the first time the search binding is used in a page flow. If `TrackQueryPerformed` is set to `pageFlow`, then only the initial `AutoQuery-or-ClearRowSet` behavior (that would have occurred for this search binding) is suppressed.

In contrast, if a search binding's `TrackQueryPerformed` property is set to `page`, then only the initial `AutoQuery-or-ClearRowSet` behavior is suppressed. Subsequent initial `AutoQuery-or-ClearRowSet` behaviors that occur due to the user's navigating back to the same page (or page fragment) are not affected by the `InitialQueryOverridden` property.

If you want to avoid the search binding's performing any initial `AutoQuery-or-ClearRowSet` behavior, then leave the `TrackQueryPerformed` set to `pageFlow` and set `InitialQueryOverridden` to `true`.

You should not use the `RefreshCondition` property of an iterator to reference the `queryPerformed` property of a search binding. Doing so will inadvertently prevent new rows from being created in that iterator's row set until after the search binding's query has been performed.

## 27.2.5 What You May Need to Know About Dependent Criterion

There are situations when one search criteria is dependent on the value of another criteria. For example, a bug database has a search form with a `Component` and a `Subcomponent` search criteria, both defined as LOVs. When the user selects a value from the `Component` search criteria, that value must be submitted to the model so that `Subcomponent` can be filtered and populated with the appropriate search list for the user to choose from.

If you have a search criteria that has dependents, you must set the root and dependent criteria's underlying view attribute's **Auto Submit** control hint to `true`. You can create a custom listener to trigger a partial submit to update the model and refresh the search panel when the query component detects a value change for the root criteria. You need to create a custom listener because the standard `QueryOperationListener` does not handle this event type. You can create a custom `QueryOperationListener` class using the `QueryOperationListener` interface. You then register this class by implementing it in a managed bean or by directly setting it in the JSF page.

## 27.2.6 What Happens When You Create a Query Form

When you drop a query search form onto a page, JDeveloper creates an `af:query` tag on the page. If you drop a query with table or tree table, then an `af:table` tag or `af:treeTable` tag will follow the `af:query` tag.

Under the `af:query` tag are several attributes that define the query properties. They include:

- The `id` attribute, which uniquely identifies the query.
- The `resultsComponentId` attribute, which identifies the component that will display the results of the query. Typically, this will be the table or tree table that was dropped onto the page together with the query. You can change this value to be the `id` of a different results component. For more information, see [Section 27.2.2, "How to Create a Query Search Form and Add a Results Component Later."](#)

In the page definition file, JDeveloper creates an iterator and a `searchRegion` entry in the `executables` section. [Example 27–5](#) shows the sample code for a page definition file.

In the page definition file `executable` section:

- The iterator `binds` property is set to the name of the data collection. In the example, the value is set to `Products`.
- The iterator `id` property is set to a data collection iterator. In the example, the value is set to `SearchProductsIterator`
- If there is more than one view criteria defined for that data collection, the `searchRegion Criteria` property is set to the name of the view criteria that was dropped. In the example, the value is set to `FindByProductNameCriteria`. If there is only one view criteria defined, then there will not be a `Criteria` property.
- The `searchRegion Binds` property is set to the same value as the iterator `id` property. In the example, the value is set to `SearchProductsIterator`
- The `searchRegion id` property is set to the name of the view criteria concatenated with `Query`. In the example, the value is set to `FindByProductNameCriteriaQuery`.

If the query was dropped onto the page with a table or tree, then in the page definition file `bindings` section, a tree element is added with the `Iterbinding` property set to the search iterator. In this example, the value is set to `SearchProductsIterator`. This should be the same iterator defined in the `executable` section.

### **Example 27–5 Search Form Code in the Page Definition File**

```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
    version="11.1.1.52.34" id="homePageDef"
    Package="oracle.fodemo.storefront.pageDefs"
    EnableTokenValidation="false">
    <parameters/>
<executables>
    ...
    <iterator Binds="Products" RangeSize="25"
        DataControl="StoreServiceAMDataControl"
        id="SearchProductsIterator"/>
    ...
<searchRegion Criteria="FindByProductNameCriteria"
```

```

Customizer="oracle.jbo.uicli.binding.JUSearchBindingCustomizer"
Binds="SearchProductsIterator"
id="FindByProductNameCriteriaQuery" />
...
</executables>
<bindings>
  <tree IterBinding="SearchProductsIterator"
    id="SearchProducts">
    <nodeDefinition DefName="oracle.fodemo.storefront.store.queries.ProductsVO"
      Name="SearchProducts">
      <AttrNames>
        <Item Value="ProductId" />
        <Item Value="ProductName" />
        <Item Value="ListPrice" />
        <Item Value="MinPrice" />
        '''
      </AttrNames>
    </nodeDefinition>
  </tree>
  ...
</bindings>

```

### 27.2.7 What Happens at Runtime: Search Forms

At runtime, the search form displays as a search panel on the page. The search panel will display in either basic mode or advanced mode, depending on the mode control hint when its corresponding view criteria was created. The **Saved Search** dropdown list will contain all the view criteria that are enabled (**Show in List** control hint enabled). The **Match All/Any** conjunction radio button may be enabled.

A search criteria field will be rendered for each search criteria defined in the view criteria. If the **Default List Type** control hint in the view object has been declared as an LOV or a selection list component, the search criteria field component is as shown in [Table 27-4](#).

After the user enters the search criteria and clicks **Search**, a query against the view criteria is executed and the results are displayed in the associated table, tree table, or component.

## 27.3 Setting Up Search Form Properties

A query search form is based on a view criteria defined in a view object. When you create the view criteria, you also specify some of the search form properties. Later on, when you drop the named criteria onto the page to create a query component, you can specify other search form properties.

Search form properties that can be set when the view criteria is being created include:

- Default mode in basic or advanced mode
- Automatic query execution when the page loads
- Rendering of the search criteria field
- Enabling multiple selections for attributes defined as an LOV

Search form properties that can be set after the query component has been added to the JSF page include:

- `id` of the results table or results component

- Show or hide of the basic/advanced button
- Position of the mode button
- Default, simple, or compact mode for display

Search form attribute properties that can be set when the view object is being created include:

- timezone control hint for a timestamp attribute

### 27.3.1 How to Set Search Form Properties on the View Criteria

When you are creating a view criteria, you can declaratively set the initial state of several properties. [Figure 27–19](#) shows the Edit View Criteria dialog for setting default options. For more information about view criteria, see [Section 5.11, "Working with Named View Criteria."](#)

**Figure 27–19** Edit View Criteria Dialog

You must select the default mode of the query search form as either basic or advanced. The default is basic.

You also must declare whether each individual search criteria field will be available only in basic mode, only in advanced mode, available in both modes, or never displayed. If a search criteria field is declared only for basic mode, it will not appear when the user switches to advanced mode, and the reverse is true. If the field is declared for all, then it will appear in all modes. The default for search criteria field rendering is all modes.

**To set the default mode and search criteria field display option:**

1. While creating a view criteria, in the Edit View Criteria dialog, click **UI Hints**.
2. From the **Search Region Mode** dropdown list, select either **Basic** or **Advanced**.
3. In the **Criteria Item UI Hints** section, select the criteria item you want to set.
4. In the **Rendered Mode** dropdown list, select **All**, **Basic**, **Advanced**, or **Never**.

### 27.3.2 How to Add Placeholder Text, Label, and Tooltip

You can add placeholder text to a query and quick query search field to provide hints for the user. For instance, for a query search on a part number attribute in which the smallest value is 1001, you might add a placeholder text such as "Enter a value greater than 1000".

You add placeholder text to the desired attribute as a Watermark custom property in the view object. The message appears dimmed inside the search box.

You can also add a label and tooltip text to a view attribute by defining their values in the view object.

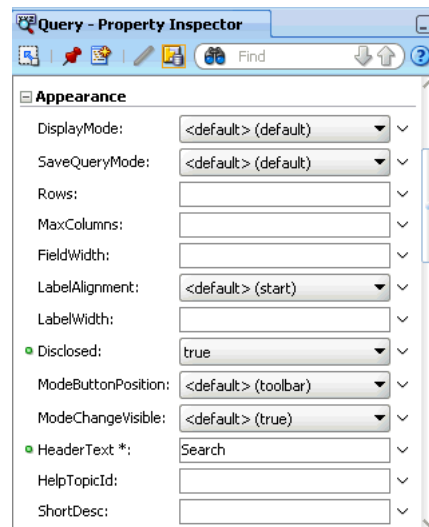

**To create placeholder text, label, and tooltip:**

1. In the Application Navigator, double-click the view object that will be used with the query or quick query component.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute you want to add a placeholder text.
4. In the Custom Properties section, click the **Add** icon and select **Translatable Property** from the dropdown list.
5. In the Select Text Resource dialog, enter values for the resource bundle, if any, and click **Select**.
6. In the **Property** field, enter "Watermark".
7. In the **Value** field, enter the placeholder text you want to display.  
For instance, enter "Please enter 4 digits" in the Value field for the department number attribute that only have values up to 4 digits long.
8. In the Attributes page, double-click the attribute you want to add a label or tooltip.
9. In the Edit Attributes dialog, click **Control Hints**.
10. Enter a value in the **Label Text** hint to add a label.
11. Enter a value in the **Tooltip Text** hint to add a tooltip and click **OK**.

### 27.3.3 How to Set Search Form Properties on the Query Component

After you have dropped the query search form onto a page, you can edit other form properties in the Property Inspector, as shown in [Figure 27–20](#). Some of the common properties you may set are:

- Enabling or disabling the basic/advanced mode button
- Setting the ID of the query search form
- Setting the ID of the results component (for example, a results table)
- Selecting the default, simple, or compact mode for display

**Figure 27–20 Property Inspector for a Query Component**

One common option is to show or hide the basic/advanced button.

**To enable or hide the basic/advanced button in the query form:**

1. In the Structure window, double-click **af:query**.
2. In the Property Inspector, click the **Appearance** tab.
3. To enable the basic/advanced mode button, select **true** from the **ModeChangeVisible** field. To hide the basic/advance mode button, select **false** from the **ModeChangeVisible** field.

### 27.3.4 How to Set Timezone Control Hint for Timestamp Attribute

If a query includes a `timestamp` attribute, you can set its `timezone` using control hints on the view object or entity object where the attribute is defined. For instance, you can set the `hiredate` of an employee to have the correct `timezone` for the employee's local office.

**Before you begin:**

Create the desired view objects as described in [Section 5.2.1, "How to Create an Entity-Based View Object"](#) and [Section 5.2.3, "How to Create an Expert Mode, Read-Only View Object."](#)

**To customize view object timestamp attribute with control hints:**

1. In the Application Navigator, double-click the entity object.
2. In the overview editor, click the **Attributes** navigation tab and select the `timestamp` attribute that you want to customize with control hints.
3. Click the overview editor **Source** navigation tab and enter an entry for `TimeZoneID` expressed as a value of GMT + hours. For instance, the following entry is GMT plus 8 hours.

```
<Attribute
  Name="Hiredate"
  ColumnName="HIREDATE"
  SQLType="TIMESTAMP"
  Type="oracle.jbo.domain.Date"
```

```

        ColumnType="DATE"
        TableName="EMP">
        <DesignTime>
            <Attr Name="_DisplaySize" Value="7"/>
        </DesignTime>
        <Properties>
            <SchemaBasedProperties>
                <AUTOSUBMIT Value="true"/>
                <TimeZoneID Value="GMT+08:00"/>
            </SchemaBasedProperties>
        </Properties>
    </Attribute>

```

### 27.3.5 How to Create Custom Operators or Remove Standard Operators

You can create custom operators for each view criteria item by adding code to the view object XML file. For example, you can create a new operator called `more than a year`, which operates on a date attribute (greater than 365 days from the current date).

You can also remove standard operators from a view criteria item. For example, you can remove the standard operator `before` from the list.

For a list of standard operators, see the "Using Query Components" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

#### To add a custom operator:

1. In the Application Navigator, select the view object for the view criteria in which you want to add a custom operator.
2. In the editor window, click the **Source** tab.
3. In the XML editor, locate the code for the view criteria attribute, and add the `CompOper` code statements after the last item within the `ViewCriteriaItem` group.

In [Example 27-6](#), the `CompOper` code statements appear in bold.

#### **Example 27-6 Adding the Custom Operator Code to the View Object XML**

```

<ViewCriteriaRow
  Name="vcrow50"
  UpperColumns="1">
  <ViewCriteriaItem
    Name="LastUpdateDate"
    ViewAttribute="LastUpdateDate"
    Operator="="
    Conjunction="AND"
    Required="Optional">
    <CompOper
      Name="LastUpdateDate"
      ToDo="1"
      OperDescStrCode="LastUpdateDate_custOp_grt_year"
      Oper=">Y"
      MinCardinality="0"
      MaxCardinality="0" >

```

```

    <TransientExpression><![CDATA[ return " < SYSDATE - 365"
      ]]></TransientExpression>
  </CompOper>
</ViewCriteriaItem>

```

The CompOper properties are:

- Name: Specify an id for the operation.
  - ToDo: Set to 1 to add this custom operator. Set to -1 to remove an operator.
  - OperDescStrCode: Specify the id used in the message bundle to map to the description string, as described in Step 4.
  - Oper: Set to a value that will be used programmatically to denote this operation in the SQL statement. In [Example 27-6](#), Oper was set to >Y to denote greater than 1 year.
  - MinCardinality: If there is an input range, set this property to the minimum value for the range. For example, if the range is months in a year, this value should be set to 1. If there is no range, set it to 0.
  - MaxCardinality: If there is an input range, set this property to the maximum value for the range. For example, if the range is months in a year, this value should be set to 12. If there is no range, set it to 0.
  - TransientExpression: Set the expression to perform the custom operator function. In [Example 27-6](#), the expression is `![CDATA[return " > SYSDATE -365" ]]`, which returns the string `" > SYSDATE -365"`.
4. Open the message bundle file for the view object and add an entry for the custom operator, using the OperDescStrCode identifier defined in the view object XML in Step 3.

[Example 27-7](#) shows the message bundle code for the LastUpdateDate custom operator described in [Example 27-6](#).

#### **Example 27-7 Adding the Custom Operator Entry for LastUpdateDate to the Message Bundle**

```

public class AvailLangImplMsgBundle extends JboResourceBundle {
    static final Object[][] sMessageStrings =
    {
        { "LastUpdateDate_custOp_grt_year", "more than a year old"
    },

```

#### **To remove a standard operator:**

1. In the Application Navigator, select the view object for the view criteria in which you want to remove a standard operator.

---

**Note:** Before you attempt to remove the standard operator, make sure you do not remove the default operator for that view criteria item.

---

2. In the editor window, click the **Source** tab.

- In the XML editor, locate the code for the view criteria attribute, and add the `CompOper` code statements after the last item within the `ViewCriteriaItem` group.

In [Example 27–8](#), the `CompOper` code statements appear in bold. The code in this example removes the `BEFORE` operator from the list of operators for the `LastUpdateDate` attribute.

**Example 27–8 Removing a Standard Operator Code in the View Object XML**

```
<ViewCriteriaRow
  Name="vcrow50"
  UpperColumns="1">
  <ViewCriteriaItem
    Name="LastUpdateDate"
    ViewAttribute="LastUpdateDate"
    Operator="="
    Conjunction="AND"
    Required="Optional">
    <CompOper
      Name="LastUpdateDate"
      ToDo="-1"
      Oper="BEFORE"
    </CompOper>
  </ViewCriteriaItem>
```

The `CompOper` properties are:

- Name: Specify an id for the operation.
- ToDo: Set to -1 to remove an operator. Set to 1 to add an operator. Do not set `ToDo` to -2, which would remove all the operators.
- Oper: Set to the standard operator you want to remove from the list.

## 27.4 Creating Quick Query Search Forms

You can use quick query search forms to let users search on a single attribute of a collection. Quick query search form layout can be either horizontal or vertical. Because they occupy only a small area, quick query search forms can be placed in different areas of a page. You can create a managed bean to enable users to switch from a quick query to a full query search. For more information about switching from quick query to query using a managed bean, see the "Using Query Components" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

If you drop a quick query panel with a results table or tree, JDeveloper will automatically create the results table, as described in [Section 27.4.1, "How to Create a Quick Query Search Form with a Results Table or Tree Table."](#) If you drop a quick query panel by itself and subsequently want a results table or component or if you already have one, you will need to match the quick query Id with the results component's `partialTrigger` value, as described in [Section 27.4.2, "How to Create a Quick Query Search Form and Add a Results Component Later."](#)

---

**Note:** A quick query search creates a dropdown list of all searchable attributes defined in the underlying view object. If you want to show only a subset of those attributes, you can set the attribute's **Display** control hint to **Hide** for those attributes you want to exclude. For more information about setting control hints on view objects, see [Chapter 5, "Defining SQL Queries Using View Objects."](#)

---

### 27.4.1 How to Create a Quick Query Search Form with a Results Table or Tree Table

You can create quick query searches using the full set of searchable attributes and simultaneously add a table or tree table as the results component.

**Before you begin:**

Create a view object to be the basis of the search form.

If you want to add placeholder text, label, or tooltip, see [Section 27.3.2, "How to Add Placeholder Text, Label, and Tooltip."](#)

**To create a quick query search form with a results table:**

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the **All Queriable Attributes** item and drop it onto the page or onto the Structure window.
3. From the context menu, choose **Create > Quick Query > ADF Quick Query Panel with Table** or **Create > Quick Query > ADF Quick Query Panel with Tree Table**, as shown in [Figure 27–21](#).
4. In the Edit Table Columns dialog, you can rearrange any column and select table options. If you choose the filtering option, the table will be a filtered table.

**Figure 27–21 Data Control Panel with Quick Query Context Menu**

### 27.4.2 How to Create a Quick Query Search Form and Add a Results Component Later

You can create quick query searches using the full set of searchable attributes and add a table or tree table as the results component later.

**Before you begin:**

Create a view object to be the basis of the search form.

If you want to add placeholder text, label, or tooltip, see [Section 27.3.2, "How to Add Placeholder Text, Label, and Tooltip."](#)

**To create a quick query search form and add a results component in a separate step:**

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.

2. Drag the **All Queriable Attributes** item and drop it onto the page or onto the Structure window.
3. From the context menu, choose **Create > Quick Query > ADF Quick Query Panel**.
4. If you do not already have a results component, then drop the data collection associated with the view criteria as a component.
5. In the Property Inspector for the quick query panel, copy the value of the **Id** field.
6. In the Property Inspector for the results component (for example, a table), paste or enter the value into the **PartialTriggers** field.

### 27.4.3 How to Set the Quick Query Layout Format

The default layout of the form is horizontal. You can change the layout option using the Property Inspector.

#### To set the layout:

1. In the Structure window, double-click **af:quickQuery**.
2. In the Property Inspector, on the Commons page, select the **Layout** property using the dropdown list to specify **default**, **horizontal**, or **vertical**.

### 27.4.4 What Happens When You Create a Quick Query Search Form

When you drop a quick query search form onto a page, JDeveloper creates an `af:quickQuery` tag. If you have dropped a quick query with table or tree table, then an `af:table` tag or `af:treeTable` tag is also added.

Under the `af:quickQuery` tag are several attributes and facets that define the quick query properties. Some of the tags are:

- The `id` attribute, which uniquely identifies the quick query. This value should be set to match the results table or component's `partialTriggers` value. JDeveloper will automatically assign these values when you drop a quick query with table or tree table. If you want to change to a different results component, see [Section 27.4.2, "How to Create a Quick Query Search Form and Add a Results Component Later."](#)
- The `layout` attribute, which specifies the quick query layout to be default, horizontal, or vertical.
- The `end` facet, which specifies the component to be used to display the **Advanced** link (that changes the mode from quick query to the query). For more information about creating this function, see the "Using Query Components" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 27.4.5 What Happens at Runtime: Quick Query

At runtime, the quick query search form displays a single search criteria field with a dropdown list of selectable search criteria items. If there is only one searchable criteria item, then the dropdown list box will not be rendered. An input component that is compatible with the selected search criteria type will be displayed, as shown in [Table 27-5](#). For example, if the search criteria type is date, then `inputDate` will be rendered.

**Table 27–5 Quick Query Search Criteria Field Components**

Attribute Type	Rendered Component
DATE	af:inputDate
VARCHAR	af:inputText
NUMBER	af:inputNumberSpinBox

If the **Default List Type** control hint in the view object has been declared as an LOV or a selection list component, the search criteria field component appears as shown in [Table 27–4 in Section 27.1.6, "List of Values \(LOV\) Input Fields."](#)

In addition, a **Search** button is rendered to the right of the input field. If the end facet is specified, then any components in the end facet are displayed. By default, the end facet contains an **Advanced** link.

## 27.5 Creating Standalone Filtered Search Tables from Named View Criteria

You use query search forms for complex searches, but you can also perform simple QBE searches using the filtered table. You can create a standalone ADF-filtered table without the associated search panel and perform searches using the QBE-style search criteria input fields. For more information about filtered tables, see [Section 27.1.4, "Filtered Table and Query-by-Example Searches."](#)

When creating a table, you can make almost any table a filtered table by selecting the filtering option if the option is enabled. There are three ways to create a standalone filtered table:

- You can drop a table onto a page from the Component Palette, bind it to a data collection, and set the filtering option. For more information, see the "Using Query Components" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- You can create a filtered table by dragging and dropping a data collection onto a page and setting the filtering option. For more information, see [Section 23.2.1, "How to Create a Basic Table."](#)
- You can also create a filtered table or a read-only filtered table by dropping named criteria onto a page. You can use either the implicitly created named criteria **All Queriable Attributes** or any declaratively created named view criteria. The resulting filtered table will have a column for each searchable attribute and an input search field above each column.

You can set the QBE search criteria for each filterable column to be a case-sensitive or case-insensitive search using the `filterFeature` attribute of `af:column` in the `af:table` component. For more information, see the "Enabling Filtering in Tables" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### Before you begin:

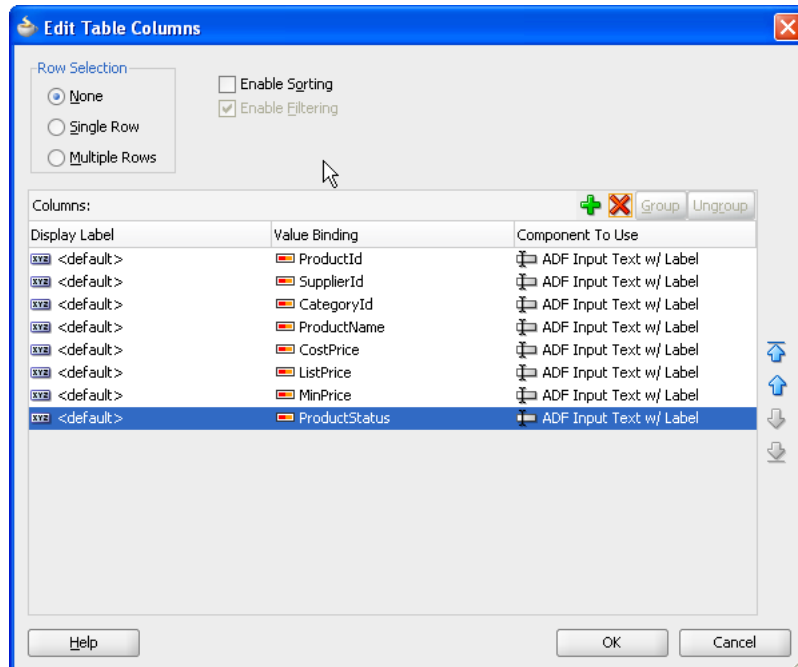

Create a view object to be the basis of the table.

### To create a filtered table using named view criteria:

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.

2. Drag the named view criteria item and drop it onto the page or onto the Structure window.
3. From the context menu, choose **Create > Tables > ADF Filtered Table** or **Create > Tables > ADF Read-Only Filtered Table**.
4. In the Edit Table Columns dialog, you can rearrange any column and select table options. Because the table is created by JDeveloper during quick query creation, the filtering option is automatically enabled and not user-selectable, as shown in [Figure 27-22](#).

**Figure 27-22 Edit Table Columns Dialog for Filtered Table**

## Creating More Complex Pages

This chapter describes how to use ADF data binding to add more complex features to the pages of a Fusion web application. It describes how to use methods that take parameters for creating forms and command components. It also includes information about creating contextual events and using ADF Model-level validation.

This chapter includes the following sections:

- [Section 28.1, "Introduction to More Complex Pages"](#)
- [Section 28.2, "Creating Command Components to Execute Methods"](#)
- [Section 28.3, "Setting Parameter Values Using a Command Component"](#)
- [Section 28.4, "Overriding Declarative Methods"](#)
- [Section 28.5, "Using the ADF Faces Calendar Component"](#)
- [Section 28.6, "Using the ADF Faces Carousel Component"](#)
- [Section 28.7, "Creating Contextual Events"](#)
- [Section 28.8, "Adding ADF Model Layer Validation"](#)
- [Section 28.9, "Displaying Error Messages"](#)
- [Section 28.10, "Customizing Error Handling"](#)

---

---

**Note:** Some of the implementation methods in this chapter are intended for page-level designs. If you are using task flows, you may be able to perform many of the same functions. For more information, see [Chapter 14, "Getting Started with ADF Task Flows."](#)

---

---

### 28.1 Introduction to More Complex Pages

Once you create a basic page and add navigation capabilities, you may want to add more complex features, such as passing parameters between pages or providing the ability to override declarative actions. Oracle ADF provides many features that allow you to add this complex functionality using very little actual code.

Some of the functions described in this chapter may be performed using other methodology. For example, if you are using task flows instead of individual page flows, you should use the task flow parameter passing mechanism. Or, if you are using ADF Business Components, you should use the validation rules on entity objects in the data model project, rather than using ADF Model validation rules. For more information about validation rules for Business Components, see [Chapter 7, "Defining Validation and Business Rules Declaratively."](#)

## 28.2 Creating Command Components to Execute Methods

When your application contains custom methods, these methods appear in the Data Controls panel. You can then drag these methods and drop them as command buttons. When a user clicks the button, the method is executed.

For more information about creating custom methods, see [Section 9.7, "Customizing an Application Module with Service Methods,"](#) and [Section 9.9, "Publishing Custom Service Methods to UI Clients."](#)

---

**Note:** If you are using task flows, you can call methods directly from the task flow definition. For more information, see [Section 15.5, "Using Method Call Activities."](#)

---

For example, the application module in the StoreFront module of the Fusion Order Demo application contains the `updateItemInCart(Integer, Integer, Boolean)` method. This method updates the items in the shopping cart. To allow the user to execute this method, you drag the `updateItemInCart(Integer, Integer, Boolean)` method from the Data Controls panel, as shown in [Figure 28–1](#).

**Figure 28–1** Methods in the Data Controls Panel

### 28.2.1 How to Create a Command Component Bound to a Custom Method

In order to perform the required business logic, many methods require a value for their parameter or parameters. This means that when you create a button bound to the method, you need to specify where the value for the parameter(s) is to be retrieved from.

#### Before you begin:

Create a custom method that can be added to the page.

For example, if you use the `updateItemInCart(Integer, Integer, Boolean)` method, you need to specify the items to be updated.

#### To add a button bound to a method:

1. From the Data Controls panel, drag the method onto the page.

**Tip:** If you are dropping a button for a method that needs to work with data in a table or form, that button must be dropped inside the table or form.

2. From the context menu, choose **Create > Methods > ADF Button**.

If the method takes parameters, the Edit Action Binding dialog opens. In the Edit Action Binding dialog, enter values for each parameter or click the **Show EL Expression Builder** menu selection in the **Value** column of **Parameters** to launch the EL Expression Builder.

## 28.2.2 What Happens When You Create Command Components Using a Method

When you drop a method as a command button, JDeveloper:

- Defines a method action binding for the method.
- If the method takes any parameters, JDeveloper creates `NamedData` elements that hold the parameter values.
- Inserts code in the JSF page for the ADF Faces command component.
- Binds the button to the method using `actionListener`.
- Uses the return value from the method call.

### 28.2.2.1 Defining Method Action Binding

JDeveloper adds an action binding for the method. Action bindings use the `RequiresUpdateModel` property, which determines whether or not the model needs to be updated before the action is executed. For command operations, this property is set to `true` by default, which means that any changes made at the view layer must be moved to the model before the operation is executed.

### 28.2.2.2 Using Parameters in a Method

When you drop a method that takes parameters onto a JSF page, JDeveloper creates a method action binding. This binding is what causes the method to be executed when a user clicks the command component. When the method requires parameters to run, JDeveloper also creates `NamedData` elements for each parameter. These elements represent the parameters of the method.

For example, the `updateItemInCart(Integer, Integer, Boolean)` method action binding contains `NamedData` elements for the parameter. This element is bound to the value specified when you created the action binding. [Example 28-1](#) shows the method action binding created when you drop the `updateItemInCart(Integer, Integer, Boolean)` method, and bind the `Integer` parameter (named `productId`) and the other `Integer` parameter (named `quantity`) and the `Boolean` parameter (named `isSet`) to the appropriate variables.

#### **Example 28-1 Method Action Binding for a Parameter Method**

```
<methodAction id="updateItemInCart"
    InstanceName="StoreServiceAMDataControl.dataProvider"
    DataControl="StoreServiceAMDataControl"
    RequiresUpdateModel="true" Action="invokeMethod"
    MethodName="updateItemInCart" IsViewObjectMethod="false">
  <NamedData NDName="productId" NDType="java.lang.Integer"/>
  <NamedData NDName="quantity" NDType="java.lang.Integer"/>
  <NamedData NDName="isSet" NDType="java.lang.Boolean"/>
</methodAction>
```

### 28.2.2.3 Adding ADF Faces Component Code to JSF Page

JDeveloper adds code for the ADF Faces component to the JSF page. This code is the same as code for any other command button, as described in [Section 22.4.2.3, "EL Expressions Used to Bind to Navigation Operations."](#) However, instead of being bound to the `execute` method of the action binding for a built-in operation, the button is bound to the `execute` method of the method action binding for the method that was dropped.

### 28.2.2.4 Using EL Expressions to Bind to Methods

Like creating command buttons using operations, when you create a command button using a method, JDeveloper binds the button to the method using the `actionListener` attribute. The button is bound to the `execute` property of the action binding for the given method using an EL expression. This EL expression causes the binding's method to be invoked on the application module. For more information about the command button's `actionListener` attribute, see [Section 22.4.4, "What Happens at Runtime: How Action Events and Action Listeners Work."](#)

**Tip:** Instead of binding a button to the `execute` method on the action binding, you can bind the button to the method in a backing bean that overrides the `execute` method. Doing so allows you to add logic before or after the original method runs. For more information, see [Section 28.4, "Overriding Declarative Methods."](#)

Like navigation operations, the `disabled` property on the button uses an EL expression to determine whether or not to display the button. [Example 28–2](#) shows the EL expression used to bind the command button to the `updateItemInCart(Integer, Integer, Boolean)` method.

#### **Example 28–2 JSF Code to Bind a Command Button to a Method**

```
<af:commandButton actionListener="#{bindings.updateItemInCart.execute}"
    text="updateItemInCart"
    disabled="#{!bindings.updateItemInCart.enabled}"/>
```

**Tip:** When you drop a command button component onto the page, JDeveloper automatically gives it an ID based on the number of the same type of component that was previously dropped. For example, `commandButton1`, `commandButton2`. If you change the ID to something more descriptive, you must manually update any references to it in any EL expressions in the page.

### 28.2.2.5 Using the Return Value from a Method Call

You can also use the return value from a method call. [Example 28–3](#) shows a custom method that returns a string value.

#### **Example 28–3 Custom Method That Returns a Value**

```
/**
 * Custom method.
 */
public String getHelloString() {
    return ("Hello World");
}
```

[Example 28–4](#) shows the code in the JSF page for the command button and an `outputText` component.

**Example 28–4 Command Button to Call the Custom Method**

```
<af:commandButton actionListener="#{bindings.getHelloString.execute}"
    text="getHelloString"
    disabled="#{!bindings.getHelloString.enabled}"
    id="helloButtonId"/>
<af:outputText value="#{bindings.return.inputValue}"
    id="helloOutputId"/>
```

When the user clicks the command button, it calls the custom method. The method returns the string "Hello World" to be shown as the value of the `outputText` component.

### 28.2.3 What Happens at Runtime: Command Button Method Bindings

When the user clicks the button, the method binding causes the associated method to be invoked, passing in the value bound to the `NamedData` element as the parameter. For example, if a user clicks a button bound to the `updateItemInCartItem(Integer, Integer, Boolean)` method, the method takes the values of the product `Id` and quantity and updates the shopping cart.

## 28.3 Setting Parameter Values Using a Command Component

There may be cases where an action on one page needs to set parameters that will be used to determine application functionality. For example, you can create a search command button on one page that will navigate to a results table on another page. But the results table will display only if a parameter value is `false`.

You can use a managed bean to pass this parameter between the pages, and to contain the method that is used to check the value of this parameter. The managed bean is instantiated as the search page is rendered, and a method on the bean checks that parameter. If it is `null` (which it will be the first time the page is rendered), the bean sets the value to `true`.

For more information about creating custom methods, see [Section 9.7, "Customizing an Application Module with Service Methods,"](#) and [Section 9.9, "Publishing Custom Service Methods to UI Clients."](#)

---

---

**Note:** If you are using task flows, you can use the task flow parameter passing mechanism. For more information, see [Chapter 16, "Using Parameters in Task Flows."](#)

---

---

A `setPropertyListener` component with `type` property set to `action`, which is nested in the command button that executed this search, is then used to set this flag to `false`, thus causing the results table to display once the search is executed. For information about using managed beans, see [Section 20.4, "Using a Managed Bean in a Fusion Web Application."](#)

## 28.3.1 How to Set Parameters Using `setPropertyListener` Within a Command Component

You can use the `setPropertyListener` component to set values on other objects. This component must be a child of a command component.

### Before you begin:

Create a command component on the page.

### To use the `setPropertyListener` component:

1. In the Component Palette, from the Operations panel, drag a `setPropertyListener` component and drop it as a child to the command component.

Or right-click the component and select **Insert inside Button > ADF Faces > `setPropertyListener`**.

2. In the Insert Set Property Listener dialog, enter the parameter value in the **From** field.
3. Enter the parameter target in the **To** field.

**Tip:** Consider storing the parameter value on a managed bean or in scope instead of setting it directly on the resulting page's page definition file. By setting it directly on the next page, you lose the ability to easily change navigation in the future. For more information, see [Section 20.4, "Using a Managed Bean in a Fusion Web Application."](#) Additionally, the data in a binding container is valid only during the request in which the container was prepared. The data may change between the time you set it and the time the next page is rendered.

4. From the **Type** dropdown menu, select **Action**.
5. Click **OK**.

## 28.3.2 What Happens When You Set Parameters

The `setPropertyListener` component lets the command component set a value before it navigates to the next page. When you set the `from` attribute either to the source of the value you need to pass or to the actual value, the component will be able to access that value. When you set the `to` attribute to a target, the command component is able to set the value on the target. [Example 28-5](#) shows the code on the JSF page for a command component that takes the value `false` and sets it as the value of the `initialSearch` flag on the `searchResults` managed bean.

### *Example 28-5 JSF Page Code for a Command Button Using a `setPropertyListener` Component*

```
<af:commandButton actionListener="#{bindings.Execute.execute}"
  text=Search>
  <af:setPropertyListener from="#{false}"
    to="#{searchResults.initialSearch}"/>
    type="action"/>
</af:commandButton>
```

### 28.3.3 What Happens at Runtime: setPropertyListener for a Command Component

When a user clicks the command component, before navigation occurs, the `setPropertyListener` component sets the parameter value. In [Example 28-5](#), the `setPropertyListener` takes the value `false` and sets it as the value for the `initialSearchattribute` on the `searchResults` managed bean. Now, any component that needs to know this value in determining whether or not to render can access it using the EL expression `{searchResults.initialSearch}`.

## 28.4 Overriding Declarative Methods

When you drop an operation or method as a command button, JDeveloper binds the button to the `execute` method for the operation or method. However, there may be occasions when you need to add logic before or after the existing logic.

---

**Note:** If you are using task flows, you can call custom methods from the task flow. For more information, see [Chapter 14, "Getting Started with ADF Task Flows."](#)

---

JDeveloper allows you to add logic to a declarative operation by creating a new method and property on a managed bean that provides access to the binding container. By default, this generated code executes the operation or method. You can then add logic before or after this code. JDeveloper automatically binds the command component to this new method, instead of to the `execute` property on the original operation or method. Now when the user clicks the button, the new method is executed.

For example, in the Fusion Order Demo application Orders page, the `Commit` operation requires additional processing. The **Commit** button is renamed to **Submit Orders** and logic is added to the `submitOrders` method in the `orderPageBean` managed bean.

In order to override a declarative method, you must have a managed bean to hold the new method to which the command component will be bound. If your page has a backing bean associated with it, JDeveloper adds the code needed to access the binding object to this backing bean. If your page does not have a backing bean, JDeveloper asks you to create one.

### 28.4.1 How to Override a Declarative Method

**Before you begin:**

Create the method that will override the declarative method in a managed bean. Operations are available by default.

---

**Note:** You cannot override the declarative method if the command component currently has an EL expression as its value for the `Action` attribute, because JDeveloper will not overwrite an EL expression. You must remove this value before continuing.

---

**To override a declarative method:**

1. Drag the operation or method to be overridden onto the JSF page and drop it as a UI command component.

The component is created and bound to the associated binding object in the ADF Model layer with the `ActionListener` attribute.

For more information about creating command components using methods on the Data Controls panel, see [Section 28.2, "Creating Command Components to Execute Methods."](#)

For more information about creating command components from operations, see [Section 22.4.2, "What Happens When You Create Command Buttons."](#)

2. On the JSF page, double-click the component.
3. In the Bind Action Property dialog, identify the backing bean and the method to which you want to bind the component, using one of the following techniques:
  - If auto-binding has been enabled on the page, the backing bean is already selected for you, as shown in [Figure 28–2](#).

**Figure 28–2 Bind Action Property Dialog for a Page with Auto-Binding Enabled**

- To create a new method, enter a name for the method in the **Method** field, which initially displays a default name.
  - or
- To use an existing method, select a method from the dropdown list in the **Method** field.
- Select **Generate ADF Binding Code**.
- If the page is not using auto-binding, you can select from an existing backing bean or create a new one, as shown in [Figure 28–3](#).

**Figure 28–3 Bind Action Property Dialog for a Page with Auto-Binding Disabled**

- Click **New** to create a new backing bean. In the Create Managed Bean dialog, name the bean and the class, and set the bean's scope.
  - or
- Select an existing backing bean and method from the dropdown lists.

---

---

**Note:** Whenever there is a value for the `ActionListener` attribute on the command component, JDeveloper understands that the button is bound to the `execute` property of a binding. If you have removed that binding, you will not be given the choice to generate the ADF binding code. You will need to insert the code manually, or to set a dummy value for the `ActionListener` before double-clicking the command component.

---

---

4. After identifying the backing bean and method, click **OK** in the Bind Action Property dialog

JDeveloper opens the managed bean in the source editor. [Example 28–6](#) shows the code inserted into the bean. In this example, a command button is bound to the `Commit` operation.

**Example 28–6 Generated Code in a Backing Bean to Access the Binding Object**

```
public String submitOrder() {
    BindingContainer bindings = getBindings();
    OperationBinding operationBinding =
        bindings.getOperationBinding("Commit");
    Object result = operationBinding.execute();
    if (!operationBinding.getErrors().isEmpty()) {
        return null;
    }
}
```

5. You can now add logic either before or after the binding object is accessed, as shown in [Example 28–7](#).

**Example 28–7 Code Added to the Overridden Method**

```
public String submitOrder() {
    DCBindingContainer bindings =
        (DCBindingContainer)JSFUtils.resolveExpression("#{bindings}");
    OperationBinding operationBinding =
        bindings.getOperationBinding("Commit");
    JUCtrlAttrsBinding statusCode =
        (JUCtrlAttrsBinding)bindings.findNamedObject("OrderStatusCode");
    statusCode.setAttribute("OrderStatusCode", "PENDING");
    JUCtrlAttrsBinding orderDate =
        (JUCtrlAttrsBinding)bindings.findNamedObject("OrderDate");
    orderDate.setAttribute("OrderDate", new Date());
    JUCtrlAttrsBinding orderId =
        (JUCtrlAttrsBinding)bindings.findNamedObject("OrderId");
    JSFUtils.storeOnSession("orderId", orderId.getAttribute("OrderId"));
    JUCtrlAttrsBinding invoiceTotal =
        (JUCtrlAttrsBinding)bindings.findNamedObject("InvoiceTotal");
    JUCtrlAttrsBinding orderTotal =
        (JUCtrlAttrsBinding)bindings.findNamedObject("OrderTotal");
    orderTotal.setAttribute("OrderTotal",
        invoiceTotal.getAttribute("InvoiceTotal"));
    Object result = operationBinding.execute();
    ShoppingCartBean shoppingCartBean =
        (ShoppingCartBean)JSFUtils.resolveExpression("#{shoppingCartBean}");
    shoppingCartBean.removeAllItems();
    return "orderSummary";
}
```

The code in [Example 28–7](#) uses the FOD utility method `JSFUtils.resolveExpression` to resolve EL expressions. The code for such a method would be similar to the code in [Example 28–8](#).

**Example 28–8 Utility Method to Solve EL Expressions**

```
public static Object resolveExpression(String expression) {
    FacesContext facesContext = getFacesContext();
    Application app = facesContext.getApplication();
    ExpressionFactory elFactory = app.getExpressionFactory();
    ELContext elContext = facesContext.getELContext();
    ValueExpression valueExp =
        elFactory.createValueExpression(elContext, expression, Object.class);
    return valueExp.getValue(elContext);
}
```

In addition to any processing logic, you may also want to write conditional logic to return one of multiple outcomes. For example, you might want to return `null` if there is an error in the processing, or another outcome value if the processing was successful. A return value of `null` causes the navigation handler to forgo evaluating navigation cases and to immediately redisplay the current page.

**Tip:** To trigger a specific navigation case, the outcome value returned by the method must exactly match the outcome value in the navigation rule, including case.

The command button is now bound to this new method using the `Action` attribute instead of the `ActionListener` attribute. If a value had previously existed for the `Action` attribute (such as an outcome string), that value is added as the return for the new method. If there was no value, the return is kept as `null`.

## 28.4.2 What Happens When You Override a Declarative Method

When you override a declarative method, JDeveloper adds a managed property to your backing bean with the managed property value of `#{bindings}` (the reference to the binding container), and it adds a strongly typed bean property to your class of the `BindingContainer` type, which the JSF runtime will then set with the value of the managed property expression `#{bindings}`. JDeveloper also adds logic to the UI command action method. This logic includes the strongly typed `getBindings()` method used to access the current binding container.

The code does the following:

- Accesses the binding container.
- Finds the binding for the associated method, and executes it.
- Adds a return for the method that can be used for navigation. By default, the return is `null`. If an outcome string had previously existed for the button's `Action` attribute, that attribute is used as the return value. You can change this code as needed.

JDeveloper automatically rebinds the UI command component to the new method using the `Action` attribute, instead of the `ActionListener` attribute. [Example 28–9](#) shows the code when a `Commit` operation is declaratively added to a page.

**Example 28–9 JSF Page Code for a Command Button Bound to a Declarative Method**

```
<af:commandButton actionListener="#{bindings.Commit.execute}"
    text="Commit"
```

```
disabled="#{!bindings.Commit.enabled}"/>
```

[Example 28–10](#) shows the code after the method on the page’s backing bean is overridden. Note that the `action` attribute is now bound to the backing bean’s method.

**Example 28–10 JSF Page Code for a Command Button Bound to an Overridden Method**

```
<af:commandButton text="#{res['order.cart.submit']}"
  action="#{orderPageBean.submitOrder}"/>
```

**Tip:** If when you click the button that uses the overridden method you receive this error:

```
SEVERE: Managed bean main_bean could not be created
The scope of the referenced object: '#{bindings}' is
shorter than the referring object
```

it is because the managed bean that contains the overriding method has a scope that is greater than `request` (that is, either `session` or `application`). Because the data in the binding container referenced in the method has a scope of `request`, the scope of this managed bean must be set to the same or a lesser scope.

## 28.5 Using the ADF Faces Calendar Component

ADF Faces includes a calendar component that displays activities in daily, weekly, or monthly views. [Figure 28–4](#) shows an ADF Faces calendar in weekly view mode with some sample activities.

**Figure 28–4 ADF Faces Calendar**

The calendar component also includes the following functionality:

- A toolbar that allows users to switch between monthly, weekly, daily, and list views.

**Tip:** When these toolbar buttons are used, attribute values on the calendar are changed. You can configure these values to persist so that they remain for a particular user whenever they access the calendar. For more information, see [Chapter 35, "Allowing User Customizations at Runtime"](#).

- Configurable start of the week days and start of the day hours. For example, a calendar's week might start on Sunday and the day might show 8:00 am at the top.
- Configurable styles using skinning keys.

Additionally, you can implement the following functionality using other ADF Faces components and the rich client framework:

- **Popup functionality:** Components placed in supported faces that respond to certain events and allow the user to act on activities or the calendar. For example, when a user clicks an activity in the calendar, the `CalendarActivityEvent` is invoked and any popup component in the `ActivityDetail` facet is displayed. You might use a dialog component that contains a form where users can view and edit the activity, as shown in [Figure 28–5](#).

**Figure 28–5** Edit Dialog for `ActivityDetail` Facet

- **Drag and drop capability:** You can add the `calendarDropTarget` tag that allows a user to drag an activity to another place on the calendar. You then implement the functionality so that the time is actually changed on the activity and persisted to the data store.
- **Toolbar customization:** By default, the toolbar contains buttons that allow the user to switch between the different views, along with previous and next buttons and a button that returns to the current date. The toolbar also displays the current date range (or the date when in day view). You can customize the toolbar by adding facets that contain additional buttons.
- **Skinning:** The calendar uses skinning keys to determine things like colors and icons used. You can extend the skin to change the appearance of the calendar.

Details for configuring the built-in functionality or for implementing additional functionality can be found in the "Creating a Calendar Application" chapter of the

*Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework.*

An ADF Faces Calendar component must be bound to a `CalendarModel` class. This class can be created for you when you use ADF Business Components to manage your calendar's data. For example, say you have data in your data store that represents the details of an activity, such as the date, time, title, location, and owner. When you create an entity object to represent that data, and then a view object to display the data, you can drag and drop the associated collection from the Data Controls panel to create the calendar. JDeveloper will declaratively create the model and bind the view to that model so that the correct data will display when the calendar is launched. However, in order for the model to be created, your entity objects in the data model project with ADF Business Components and your view objects in the same project must contain date-effective attributes. Additionally, the view objects must contain variables that will be used to modify the query to return the correct activities for the given date range.

## 28.5.1 How to Use the ADF Faces Calendar

Before you can create a calendar on a JSF page, you must first create an entity object with specific attributes that represent attributes on a calendar. You then must create a view object from that entity object, and modify the query to use named bind variables that represent the date range and current time zone to display. This will allow the query to return only the activities that should be displayed in the given view on the calendar.

For example, say you have a database table that represents an activity. It has a column for title, start time, end time, and a reference to a provider object that represents the owner. You would create an entity object and a view object based on that table (ensuring that it meets the requirements, as described in the following steps). To the view object, you would then add named bind variables for the start and end times currently displayed on the calendar, along with the time zone currently in use by the calendar, so that the query returns only those activities that fall within that time range.

Once you add the calendar component to a JSF page, you can configure it and add further needed functionality.

### To create an ADF Faces calendar:

1. Create an entity object based on your data source. The entity object must include the attributes shown in [Table 28–1](#). The attributes do not have to use the names shown in the table; they can be named anything. However, they must be of one of the types noted. You will map these attributes to attributes in the `CalendarModel` in a later step.

**Table 28–1 Required Attributes for a Calendar**

Attribute	Valid Types	Description
Start time	<code>java.util.Date</code> , <code>java.sql.Date</code> , <code>oracle.jbo.domain.Date</code> , <code>oracle.jbo.domain.TimeStamp</code>	Start time for the activity
End time	<code>java.util.Date</code> , <code>java.sql.Date</code> , <code>oracle.jbo.domain.Date</code> , <code>oracle.jbo.domain.TimeStamp</code>	End time for the activity
ID	String	Unique ID

**Table 28–1 (Cont.) Required Attributes for a Calendar**

Attribute	Valid Types	Description
Provider ID	String	ID of the provider object that represents the owner of the activity
Title	String	Short description of the activity

The entity object can also contain the known (but not required) attributes shown in [Table 28–2](#):

**Table 28–2 Optional Attributes for a Calendar**

Attribute	Type	Description
Recurring	String or <code>CalendarActivity.Recurring</code>	Status of recurrence for the activity. Valid values are <code>SINGLE</code> (does not recur), <code>RECURRING</code> , or <code>CHANGED</code> (this activity was part of the recurring activity but has been modified to be different from the parent activity).
Reminder	String or <code>CalendarActivity.Reminder</code>	Whether or not the activity has an associated reminder. Valid values are <code>ON</code> or <code>OFF</code> .
Time Type	String or <code>CalendarActivity.TimeType</code>	Type of time associated with the activity. Valid values are <code>ALLDAY</code> and <code>TIME</code> . Activities that have a value of <code>ALLDAY</code> do not have any time associated with them. They are considered to span the entire day. Activities with a value of <code>TIME</code> have a specific time duration.
Location	String	Location of the activity.
Tags	Set of Strings or a semicolon separated list of Strings	Keywords for the activity.

Your entity objects can also contain other attributes that the `CalendarModel` has no knowledge of. You will be able to add these to the model as custom properties in a later step.

For information on creating entity objects, see [Chapter 4, "Creating a Business Domain Layer Using Entity Objects."](#)

2. Create an associated view object. In the Query page of the overview editor, create named bind variables for the following:
  - A string that represents the time zone
  - A date that represents the start time for the current date range shown on the calendar
  - A date that represents the end time for the current date range shown on the calendar

**Tip:** Dates in an ADF Faces calendar are "half-open," meaning that the calendar will return all activities that start on or after the start time and before (but not on) the end time.

For more information about creating named bind variables, see [Section 5.10, "Working with Bind Variables"](#).

3. Create an entity object that represents the provider (owner) of activities. The entity object must include the attributes shown in [Table 28–3](#). The attributes do not have to use the names shown in the table; they can be named anything. However, they must be of the type noted. You will map these attributes to attributes in the `CalendarProvider` class in a later step.

**Table 28–3 Attributes for a CalendarProvider Class**

Attribute	Type	Description
Id	String	Unique ID.
Display Name	String	The name of the provider that can be displayed in the calendar.

4. Create a view object for the provider.
5. Ensure that the new view objects are part of the application module, and if needed, refresh the Data Controls panel.
6. Create your JSF page, as documented in [Section 20.3, "Creating a Web Page"](#).
7. From the Data Controls panel, drag the collection that represents the view object for the activity created in Step 2 and drop it as a **Calendar**.

**Tip:** The Calendar option will display in the context menu only if the view object contains the required attributes documented in [Table 28–1](#) and the bind variables described in Step 2.

8. Complete the Calendar Bindings dialog to map the bind variables and attributes to the `CalendarModel` and the `CalendarProvider` classes. For additional help, click **Help** or press F1.
9. By default, the calendar will be read-only and will return only those activities currently in the data store. You will need to configure the calendar and implement additional functionality as described in the "Creating a Calendar Application" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

For example, to allow creation of a new activity, you might create an input form in a dialog (as described in the "How to Create a Dialog" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*) using the same data control collection used to create the calendar. For more information about creating input forms, see [Section 22.6, "Creating an Input Form"](#).

## 28.5.2 What Happens When You Create a Calendar

When you drop a collection as a calendar, JDeveloper:

- Defines an iterator binding to the collection of activities, and another iterator binding to the collection of providers.
- Defines an action binding to the `executeWithParams` operation on the activities collection. It is this operation that will be invoked to execute the query to return the activities to display. Because the operation requires parameters to determine the date range and time zone, `NamedData` elements are also created for each of the parameters (created as named bind variables on the view object). For more information about `NamedData` elements, see [Section 28.2.2.2, "Using Parameters in a Method"](#).

- Defines a calendar binding. This binding contains a `node` element that represents a row in the collection and maps the data control attributes to the calendar activity's attributes, as defined when using the wizard. The `value` is the data control attribute and the `type` is the calendar attribute. For any custom defined attributes, the `type` will be `custom` and `value` will be the data control attribute. Each row (node) is represented by a `rowKey`, which is the activity ID.

There is also a `providerDefinition` element that determines the source and mapping of available providers. This mapping allows the calendar model to filter activities based on the state of the provider (either enabled or disabled).

**Tip:** To access a custom attribute, use the `CalendarActivity.getCustomAttributes()` method, passing in the name of the attribute as defined by the `value` element.

[Example 28–11](#) shows the page definition code for a calendar.

### **Example 28–11 Page Definition Code for a Calendar Binding**

```
<executables>
  <iterator Binds="ActivityView1" RangeSize="-1"
    DataControl="AppModuleDataControl" id="ActivityView1Iterator"/>
  <iterator Binds="EmployeesView1" RangeSize="25"
    DataControl="AppModuleDataControl" id="EmployeesView1Iterator"/>
</executables>
<bindings>
  <action IterBinding="ActivityView1Iterator" id="ExecuteWithParams"
    RequiresUpdateModel="true" Action="executeWithParams">
    <NamedData NDName="startTime"
      NDValue="#{bindings.ActivityView1.startDate}"
      NDType="oracle.jbo.domain.Date"/>
    <NamedData NDName="endTime" NDValue="#{bindings.ActivityView1.endDate}"
      NDType="oracle.jbo.domain.Date"/>
    <NamedData NDName="timeZone"
      NDValue="#{bindings.ActivityView1.timeZoneId}"
      NDType="java.lang.String"/>
  </action>
  <calendar IterBinding="ActivityView1Iterator" id="ActivityView1"
    xmlns="http://xmlns.oracle.com/adf/faces/binding"
    ActionBindingName="ExecuteWithParams">
    <nodeDefinition DefName="model.ActivityView">
      <AttrNames>
        <Item Type="id" Value="Id"/>
        <Item Type="providerId" Value="ProviderId"/>
        <Item Type="title" Value="Title"/>
        <Item Type="startTime" Value="StartTime"/>
        <Item Type="endTime" Value="EndTime"/>
      </AttrNames>
    </nodeDefinition>
    <providerDefinition IterBindingName="EmployeesView1Iterator">
      <AttrNames>
        <Item Type="id" Value="EmployeeId"/>
        <Item Type="displayName" Value="FirstName"/>
      </AttrNames>
    </providerDefinition>
  </calendar>
</bindings>
```

JDeveloper inserts code onto the JSF page that binds the calendar value to the `CalendarModel` class, as shown in [Example 28–12](#).

**Example 28–12 JSF Page Code for a Calendar**

```
<af:form>
  <af:calendar value="#{bindings.ActivityView1.calendarModel}"/>
</af:form>
```

### 28.5.3 What Happens at Runtime: How the Calendar Binding Works

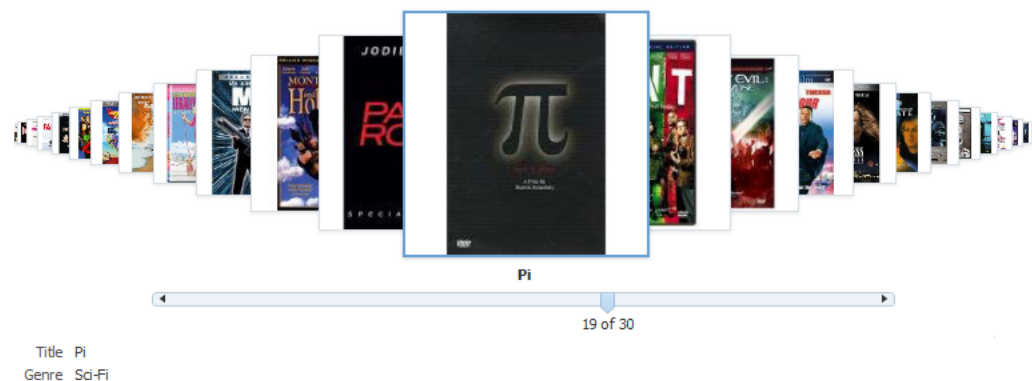

When the calendar is accessed, the `executeWithParams` operation is invoked, with the value of the `startDate` and `endDate` parameters determined by the value of the calendar component's `view` and `activeDay` attributes. For example, if the `view` attribute is set to `month` and the `activeDay` is set to the current date (say, May 5, 2013), then the value for the `startDate` would be May 1, 2013 and the `endDate` value would be May 31, 2013. By default, the time zone value is taken from the `time-zone` setting in the `trinidad-config.xml` file (for more information, see the "Configuration in `trinidad-config.xml`" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*). Therefore, the query would be restricted to return only activities that fall within that date range.

When the query returns data, because the calendar component is bound to the `CalendarModel`, the `CalendarModel` uses the `CalendarActivityDefinition` class to access the calendar binding and map the values from the data source to the calendar, using the mappings provided by the binding.

## 28.6 Using the ADF Faces Carousel Component

You can display images in a revolving carousel, as shown in [Figure 28–6](#). Users can change the image at the front by using either the slider at the bottom or by dragging another image to the front.

**Figure 28–6 Carousel Component**

Instead of containing a child `carouselItem` component for each image to be displayed, and then binding these components to the individual images, the carousel component is bound to a complete collection and repeatedly renders one `carouselItem` component by stamping the value for each item, similar to the way a tree stamps out each row of data. As each item is stamped, the data for the current item is copied into a property that can be addressed using an EL expression using the carousel component's `var` attribute. Once the carousel has completed rendering,

this property is removed or reverted back to its previous value. Carousels contain a `nodeStamp` facet, which is a holder for the `carouselItem` component used to display the text and short description for each item, and is also the parent component to the image displayed for each item. For more information about the carousel component, see the "Displaying Images in a Carousel" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

## 28.6.1 How to Create a Databound Carousel Component

When using a carousel component in a Fusion web application, you create the component using the Data Controls Panel. You also use a managed bean to handle the carousel spin event, and for other logic you may need to display your items.

### Before you begin:

You need to create a view object for the collection to be displayed in the carousel. The view object should contain attributes for at least the following:

- Title, which will be displayed below the image in the carousel
- Short description used for text displayed when the user mouses over the image.

### To create a databound carousel component:

1. From the Data Controls panel, drag the collection for the view object on to the page and select **Carousel** from the context menu.
2. In the Property Inspector, in the Behavior section, bind the **CarouselSpinListener** to a handler method that handles the spinning of the carousel when you need logic to be executed when the carousel spin is executed. [Example 28-13](#) shows the handler methods that might be used to handle the display of product images for the Products view object used to create the carousel:

#### **Example 28-13 Handler for the CarouselSpinEvent**

```
public void handleCarouselSpin(CarouselSpinEvent event)
{
    RichCarousel carousel = getCarousel();
    carousel.setRowKey(event.getNewItemKey());
    detailNodeItem = (JUCtrlHierNodeBinding)carousel.getRowData();
}
public JUCtrlHierNodeBinding getDetailNodeItem()
{
    // Get the initial item
    if(detailNodeItem == null)
    {
        RichCarousel carousel = getCarousel();

        Object oldKey = carousel.getRowKey();
        try
        {
            Object key = carousel.getCurrentItemKey();
            getCarousel().setRowKey(key);
            detailNodeItem = (JUCtrlHierNodeBinding)carousel.getRowData();
        }
        finally
        {
            carousel.setRowKey(oldKey);
        }
    }
}
```

```

return detailNodeItem;
}

```

3. In the Advanced section of the Property Inspector, click the dropdown menu for the **Bindings** attribute and select Edit. In the Edit Property: Binding dialog, select the managed bean used in Step 2. Create a new property called `carousel`. This will allow the handler methods to access the carousel object.
4. In the Structure window, expand the `carousel` component and the `nodeStamp` facet, and select the `carouselItem` component.
5. Bind the `CarouselItem` component's `text` attribute to the associated property in the data model using variable value set on the carousel's `var` attribute, which by default is set to `item`. So the value of the `carouselItem`'s `text` attribute would be `item.title` (given that `title` is the property used to access the text used for the carousel items on the data model).

If you were using the `Products` view object, the value would be `#{item.ProductName}`.

6. In the Advanced section of the Property Inspector, click the dropdown menu for the **Bindings** attribute and select Edit. In the Edit Property: Binding dialog, select the managed bean used in Step 2. Create a new property called `carouselItem`.
7. In the ADF Faces page of the Component Palette, from the Common Components panel, drag an **Image** and drop it as a child to the `carouselItem`.

In the Insert Image dialog, enter the path to the source for the images, being sure to use the variable for the item in the carousel. For example, the path to the image files for the products would normally be:

```
/imageservlet?detail=#{Products.ProductId}
```

For an image in the carousel, you would use:

```
/imageservlet?detail=#{item.ProductId}
```

For information about setting other attributes of the `carousel` and `carouselItem` components, see the "How to Create a Carousel" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

8. If you want to provide additional information about the items in the carousel, you can drag and drop the same view object onto the page, for example, as a form. For the components in the form to redisplay the information for the current item displayed once the carousel is spun, you need to set the `partialTrigger` attribute of the component containing the form to the carousel component's ID.

For example, the form that displays the information for each item in [Figure 28–6](#) is contained in a `panelBox` component. The `partialTrigger` attribute for the `panelBox` component is set to `c1`, which is the carousel component's ID. This means that whenever the `carouselItem` invokes the `CarouselSpinEvent`, the `panelBox` will be refreshed, causing it to display information about the item that was just made current. For more information about partial page rendering and the `partialTriggers` attribute, see the "Rerendering Partial Page Content" chapter of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

[Example 28–14](#) shows the page code for the carousel displayed in [Figure 28–6](#).

**Example 28–14 Partial Trigger Updates the Form to Match the Displayed Carousel Item**

```

<af:carousel
    currentItemKey="#{bindings.Products.treeModel.rootCurrencyRowKey}"
    value="#{bindings.Products.treeModel}" var="item"
    id="c1"
    carouselSpinListener="#{carBean.handleCarouselSpin}">
    <f:facet name="nodeStamp">
        <af:carouselItem id="ci1" text="#{item.ProductName}"
            binding="#{carBean.carouselItem}">
            <af:image source="/imageservlet?detail=#{item.ProductId}"
                id="i1"/>
        </af:carouselItem>
    </f:facet>
</af:carousel>
<af:panelBox text="PanelBox1" id="pb1" partialTriggers="c1">
    <af:panelFormLayout id="pf11">
        <af:panelLabelAndMessage label="#{bindings.ProductName.hints.label}"
            id="plam2">
            <af:outputText value="#{bindings.ProductName.inputValue}"
                id="ot4"/>
        </af:panelLabelAndMessage>
    .
    .
    .
</af:panelBox>

```

**28.6.2 What Happens When You Create a Carousel**

When you drop a collection from the Data Controls panel as a carousel, a tree value binding is created. A tree consists of a hierarchy of nodes, where each subnode is a branch off a higher level node.

The tree binding iterates over the data exposed by the iterator binding. The carousel wraps the result set from the iterator binding in a `treeModel` object, which is an extension of the `collectionModel`. The `collectionModel` allows each item in the collection to be available within the carousel component using the `var` attribute. For more information about the tree binding, see [Section 23.2.2.1, "Iterator and Value Bindings for Tables."](#)

JDeveloper adds both a `carousel` component and its child `carouselItem` component onto the page, as shown in [Example 28–15](#).

**Example 28–15 Page Code for a Carousel Component**

```

<af:carousel
    currentItemKey="#{bindings.Products.treeModel.rootCurrencyRowKey}"
    value="#{bindings.Products.treeModel}" var="item"
    id="c1"
    carouselSpinListener="#{carBean.handleCarouselSpin}">
    <f:facet name="nodeStamp">
        <af:carouselItem id="ci1" text="#{item.ProductName}"/>
    </f:facet>
</af:carousel>

```

The carousel value is bound to the `treeModel` for the associated collection, and the `currentItemKey` attribute of the carousel is bound to the `rootCurrencyRowKey` of the binding object. In this example, the carousel iterates over the items in the `Products` iterator binding. The iterator binding binds to a `rowKeySet` that keeps track of the current product. By default, the `currentItemKey` attribute of the

carousel is bound to the `rootCurrencyRowKey` of the binding object, which causes the product currently displayed at the front of the carousel to be the root and the current item. The `carouselItem` component accesses the current data object for the current item presented to the carousel tag using the `item` variable.

## 28.7 Creating Contextual Events

Often a page or a region within a page needs information from somewhere else on the page or from a different region. While you can pass parameters to obtain that information, doing so makes sense only when the parameters are well known and the inputs are EL-accessible to the page. Parameters are also useful when a task flow may need to be restarted if the parameter value changes.

However, suppose you have a task flow with multiple page fragments that contain various interesting values that could be used as input on one of the pages in the flow. If you were to use parameters to pass the value, the task flow would need to surface output parameters for the union of each of the interesting values on each and every fragment. Instead, for each fragment that contains the needed information, you can define a contextual event that will be raised when the page is submitted. The page or fragment that requires the information can then subscribe to the various events and receive the information through the event.

For example, in the `StoreFront` module, contextual events are used in the customer registration page to display the appropriate informational topic. The user registration page `register.jspx` contains two regions. One region contains the customer registration task flow `customer-registration-task-flow`, and the other contains the informational topic task flow `help-task-flow`. A contextual event is passed from the customer registration region to the informational topic region so that the informational topic task flow can display the information topic. At design time, the event name, producer region, consumer region, consumer handler, and other information is stored in the event map section of the page definition file, as shown in [Example 28-16](#).

### **Example 28-16** Event Map in the `registerPageDef.xml` File

```
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
  <event name="queueHelpTopic">
    <producer region="*">
      <consumer region="helptaskflow1"
        handler="helpPageDef.findHelpTextById">
        <parameters>
          <parameter name="helpTopicId" value="{payload}" />
        </parameters>
      </consumer>
    </producer>
  </event>
</eventMap>
```

At runtime, when a user enters the customer registration task flow, he or she progresses through a series of view activities from **Basic Information** to **Address** and then to **Payment Options** by entering data and clicking the **Next** button. When the user clicks **Next**, a contextual event with a `payload` parameter is broadcasted by the customer registration task flow. This event is then consumed by the information task flow and its handler, the `helpPageDef.findHelpTextById()` method. The consuming method uses the `payload` parameter to determine which information

topic text to display. In the event map, you can specify EL expressions to bind the input parameters to variables and parameters of the page.

Events are configured in the page definition file for the page or region that will raise the event (the producer). In order to associate the producer with the consumer that will do something based on the event, you create an event map also in the page definition (when using events between regions, the page definition file which holds both the regions contains the event map). If the consuming page is in a dynamic region, the event map should be in the page definition file of the consuming page and the producer's attribute region set to "\*". The attribute region is set to "\*" because at design time, the framework cannot determine the relative path to the producer.

You can raise a contextual event for an action binding, a method action binding, a value attribute binding, or a range binding (table, tree, or list binding). You also can conditionally fire an event and conditionally handle an event using EL expressions.

For action and method action bindings, the event is raised when the action or method is executed. The `payload` contains the binding container and event source, and a single parameter that you can define. Action bindings can be published by multiple sources, while value attribute and list bindings can be published only by a single source.

You can also raise a contextual event from an ADF Faces event such as clicking a button or selecting from a menu. The ADF Faces component will use `eventBinding` to act as a contextual event producer.

For a value attribute binding, the event is triggered by the binding container and raised after the attribute is set successfully. The `payload` contains the new value, iterator, binding container and source object, and a single parameter that you can define. [Example 28-17](#) shows a value change event inside an attribute value binding associated with an input component. The event, `valueChangeEvent`, will be dispatched when the user changes the value of `LAST_NAME` in the page.

**Example 28-17 Value Attribute Event in the Page Definition File**

```
<attributeValues IterBinding="DeptView1Iterator" id="Dname"
  xmlns="http://xmlns.oracle.com/adfm/jcuimodel">
  <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
    <event name="valueChangeEvent" />
  </events>
  <AttrNames xmlns="http://xmlns.oracle.com/adfm/uimodel">
    <Item Value="LAST_NAME" />
  </AttrNames>
</attributeValues>
</bindings>
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
  <event name="valueChangeEvent">
    <producer region="LAST_NAME">
      <consumer region="" handler="consumeEvent" />
    </producer>
  </event>
</eventMap>
```

For a range binding (tree, table, list), the event is raised after the currency change has succeeded. The `payload` contains the iterator, row key, binding container and source object, and a single parameter you can define.

Value attribute binding and range binding contextual events may also be triggered by navigational changes. For example, if you create an event inside a tree table binding,

the event will be dispatched when the user selects a different node of the tree in the page.

You create, publish, and subscribe to contextual events using the overview editor for page definition file's **Contextual Events** tab, as shown in [Figure 28-7](#).

**Figure 28-7 Page Definition Contextual Events Tab**

You can also use the Contextual Events page in the Property Inspector to create, publish, and subscribe to contextual events. The Contextual Events panel will only appear when you select eligible components in the page, as shown in [Figure 28-8](#).

**Figure 28–8 Contextual Events Panel in the Property Inspector**

Contextual events are not the same as the business events that can be raised by ADF Business Components or the events raised by UI components. For a description of these types of events, see the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*. Contextual events can be used in, however, in association with UI events. In this case, an action listener that is invoked due to a UI event can, in turn, invoke a method action binding that then raises the event.

### 28.7.1 How to Create Contextual Events Declaratively

You create contextual events by first creating and publishing the event on the producer based on a method action, action, value attribute, or list binding. On the consumer, you subscribe to the event and create a handler to process the event.

---

**Note:** You can also publish an action contextual event from code (for example, from within a managed bean), using the call:

```
getBindingContainer.raiseEvent(myEventName);
```

---

#### Before you begin:

Decide on the type of component you want to use to raise the contextual event. If you plan to use a method action binding, you must have already created the method to be dropped onto the page.

Typically, you create a parent page with regions that contain task flows and view activities. You create contextual events in one region to be published for consumer event handlers in the other region. For more information about using task flows and regions, see [Chapter 17, "Using Task Flows as Regions."](#)

### 28.7.1.1 Creating Contextual Events in the Publisher

You use the overview editor for page definition files to create contextual events in the producer's page.

#### To create a contextual event:

1. In the producer page, drag and drop a component from the Data Controls panel to the page that will trigger the event. It must have a method action, action, value attribute, or list binding. In the StoreFront module, the `setHelpId()` method from the Data Controls panel was added to the page.
2. In the overview editor for the producer page definition, select the **Contextual Events** tab.
3. In the Events section, click the **Add** icon.
4. In the Publish Contextual Events dialog:
  - a. Select **Create New Event**.
  - b. Enter the name of the event.
  - c. Select **Pass Custom Value From** if you want to pass payload data to the consumer.
  - d. If you are passing payload data, select the type of data from the dropdown list.

For example, if you want to pass an attribute value from the producer page to the consumer page, you can select **Page Data** and select the attribute from the tree structure.

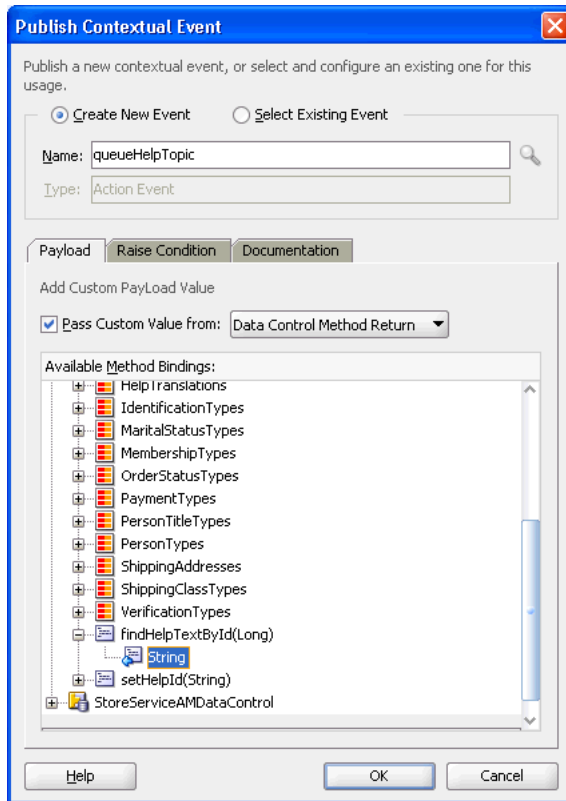

- e. You can conditionally raise the event by entering an EL expression in the **Raise Condition** tab.

For instance, entering an expression such as `${bindings.LAST_NAME.inputValue == 'KING'}` will cause the event to be raised only if the customer's last name is KING.

- f. Click **OK**.

The event is created on the page, but it is not ready for publishing until it is associated with the component binding.

**Figure 28–9 Publish a Contextual Event**

5. In the producer page, select the component you want to trigger the event, open the Contextual Events pane in the Property Inspector, and click the **Add** icon
6. In the Publish Contextual Events dialog:
  - a. Choose **Select Existing Event**.
  - b. Click the **Search** icon next to the Name field.
  - c. In the Select Contextual Event dialog, select the event from the tree structure. The event should be the one you have created in Step 4.
  - d. Click **OK** and click **OK** again.

The event is now ready for publishing.
7. Alternatively, you can create and enable publishing an event in one gesture by accessing the Publish Contextual Events dialog via the Property Inspector for the component when you add the component to the page as described in Step 1. Creating the event in the page definition makes it available for components on that page to publish the event and for other pages to subscribe to that event.

### 28.7.1.2 Subscribing to and Consuming Events

You use the overview editor for page definition files on the parent page to subscribe to contextual events.

#### To subscribe and consume the event:

1. In the consuming page, add the components that may respond to the event.

In the StoreFront module, the `findHelpTextById` method handler return **String** is dropped onto the page as an `outputText` component to display the help information.

2. Create a handler to process the event and its payload data. In the StoreFrontModule example, the `findHelpTextById` handler method was created in the `LookupServiceAMDataControl` module. You can add an EL expression to the handler to conditionally handle the page.
3. In the overview editor for the consumer page definition's **Bindings and Executables** tab, click the **Add** icon in the **Bindings** section.
4. In the Insert Item dialog, select **methodAction** and click **OK**.
5. In the Create Action Binding dialog:
  - a. Select the data collection where you have created your handler.
  - b. From the **Operation** dropdown list, select the handler.
  - c. Click **OK**.
6. In the overview editor for the consumer page definition's **Bindings and Executables** tab, Click the **Add** icon in the **Bindings** section.
7. In the Insert Item dialog, select **attributeValue** and click **OK**.
8. In the Create Attribute Binding dialog:
  - a. From the **Data Source** dropdown list, select **Variable**.
  - b. Select the return value of the handler as the **Attribute**.
  - c. Click **OK**.
9. In the overview editor of the parent page definition (where both regions are located), navigate to the **Contextual Events** tab, and from the **Events** section click the **Add** icon.
10. In the Publish Contextual Events dialog, select **Select Existing Event** and click the **Search** icon.
11. In the Select Contextual Events dialog, select the event you want to publish from the tree and click **OK**.
12. In the Publish Contextual Events dialog, check the event parameters and click **OK**.  
The event appears in the **Events** list in the overview editor for page definition file.
13. In the overview editor of the parent page definition, click **Subscribers** and click the **Add** icon in the **Event Subscribers** section.
14. In the Subscribe to Contextual Event dialog, click the **Search** icon.
15. In the Select Contextual Events dialog, select the event you want to subscribe to from the tree and click **OK**.
16. In the Subscribe to Contextual Event dialog:
  - a. Select the producer or **<Any>** from the **Publisher** dropdown list. A contextual event can have more than one publisher.  
  
Selecting **<Any>** will allow the consumer to subscribe to any event. In the page definition file, the `producer` attribute will be set to the wildcard `"*"`. If your publisher is in a dynamic region, you should set this field to **<Any>** so that the subscriber can consume from any producer.
  - b. Click the **Search** icon next to the **Handler** field.

- c. In the Select Handler dialog, select the event handler from the tree and click **OK**.
- d. If the handler requires parameters, select the **Parameters** tab, click **Add**, and enter name-value pair as parameters.
- e. If you want to conditionally handle the event, select the **Handle** tab, and enter an EL Expression that determines the conditions under which the handler will process the event.
- f. Click **OK**.

**Figure 28–10** *Subscribe to a Contextual Event*

---

**Note:** You can edit the event map by right-clicking the page definition in the Structure window and choosing **Edit Event Map**. You can also edit event attributes in the page definition file or in the Property Inspector.

---

## 28.7.2 How to Create Contextual Events Manually

You create contextual events by first creating the event on the producer. You then determine the consumer of the event and map the producer and consumer.

### Before you begin:

Create a contextual event that has a method binding, action binding, value attribute binding, or list binding on the producer page. If you do not, you must create the binding first. For example, for a method binding, in the Structure window, right-click the binding and choose **Insert inside bindings > Generic Bindings > methodAction** and add the method action binding or use the overview editor for the page definition file to add the binding. For the other bindings, you may need to drop a component such as an input text, table, or tree to the page.

**To create a contextual event:**

1. Open the page definition file that contains the binding for the producer of the event.

A producer must have an associated binding that will be used to raise the event. For example, if a method or operation will be the producer, the associated action binding or method action binding will contain the event.

2. In the Structure window, right-click the binding for the producer and choose **Insert inside *binding name* > events** or **Insert inside *binding name* > Contextual Events > events**.
3. In the Structure window, right-click the **events** element just created, and choose **Insert inside events > event**.
4. In the Insert event dialog, enter a name for the event in the **name** field, and click **Finish**.

The event is now created. By default, any return of the associated method or operation will be taken as the payload for the event and stored in the EL-accessible variable `${payload}`. You now need to map the event to the consumer, and to configure any payload that needs to be passed to the consumer.

5. Open the page definition that contains the binding for the consumer.

The binding container represented by this page provides access to the events from the current scope, including all contained binding containers (such as task flow regions). If regions or other nested containers need to be aware of the event, the event map should be in the page definition of the page in the consuming region.

6. In the Structure window, right-click the topmost node that represents the page definition, and choose **Edit Event Map**.

---

**Note:** If the producer event comes from a page in an embedded dynamic region, you may not be able to edit the event map using the Event Map Editor. You can manually create the event map by editing the page definition file or use **insert inside** steps, as described in [Section 28.7.5, "How to Manually Create the Event Map."](#)

---

7. In the Event Map Editor, click the Add icon to add an event entry.
8. In the Add New EventMap Entry dialog, do the following:
  - a. Use the **Producer** dropdown menu to choose the producer.
  - b. Use the **Event Name** dropdown menu to choose the event.
  - c. Use the **Consumer** dropdown menu to choose the consumer. This should be the actual method that will consume the event.
  - d. If the consuming method or operation requires parameters, click the **Add** icon.

In the **Param Name** field, enter the name of the parameter expected by the method. In the **Param Value** field, enter the value. If this is to be the payload from the event, you can access this value using the `${payload}` expression. If the payload contains many parameters and you don't need them all, use the ellipses button to open the Expression Builder dialog. You can use this dialog to select specific parameters under the **payload** node.

You can also click the **Parameters** ellipses button to launch the selection dialog.

- e. Click OK.
9. In the Event Map Editor, click OK.

### 28.7.3 How to Create Contextual Event Using Managed Beans

You can publish an action contextual event from code such as from within a managed bean. You bind the producer component to the method in the managed bean, as shown in [Example 28–18](#).

In this example, the producer is a command button that invokes an action binding and the consumer is an `outputText` component that displays a string. They are both on the same page.

#### **Example 28–18 Event Producer and Event Consumer on the JSF**

```
<af:form id="f1">
  <af:eventProducerButton value="eventProducerButton1" id="cb1"
    action="#{MyBean.myActionPerformed}"
  />
  <af:panelLabelAndMessage label="#{bindings.return.hints.label}" id="plam1">
    <af:outputText value="#{bindings.return.inputValue}" id="ot1"/>
  </af:panelLabelAndMessage>
</af:form>
```

The page definition file contains the method action bindings for the producer, the consumer, and the event map, as shown in [Example 28–19](#).

#### **Example 28–19 Page Definition with Event Producer, Event Consumer, and Event Map**

```
<executables>
  <variableIterator id="variables">
    <variable Type="java.lang.String" Name="eventConsumer_return"
      IsQueryable="false" IsUpdateable="0"
      DefaultValue="#{bindings.eventConsumer.result}"/>
  </variableIterator>
</executables>
<bindings>
  <methodAction id="eventProducer"
    InstanceName="AppModuleDataControl.dataProvider"
    DataControl="AppModuleDataControl" RequiresUpdateModel="true"
    Action="invokeMethod" MethodName="eventProducer"
    IsViewObjectMethod="false"
    ReturnName="AppModuleDataControl.methodResults.eventProducer_
      AppModuleDataControl_dataProvider_eventProducer_result">
    <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
      <event name="myEvent"/>
    </events>
  </methodAction>
  <methodAction id="eventConsumer" RequiresUpdateModel="true"
    Action="invokeMethod" MethodName="eventConsumer"
    IsViewObjectMethod="false" DataControl="AppModuleDataControl"
    InstanceName="AppModuleDataControl.dataProvider"
    ReturnName="AppModuleDataControl.methodResults.eventConsumer_
      AppModuleDataControl_dataProvider_eventConsumer_result">
    <NamedData NDName="str" NDValue="test" NDType="java.lang.String"/>
  </methodAction>
  <attributeValues IterBinding="variables" id="return">
    <AttrNames>
      <Item Value="eventConsumer_return"/>
    </AttrNames>
  </attributeValues>
</bindings>
```

```

        </AttrNames>
    </attributeValues>
</bindings>
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
    <event name="myEvent">
        <producer region="eventProducer">
            <consumer region="" handler="eventConsumer">
                <parameters>
                    <parameter name="test" value="{payLoad}"/>
                </parameters>
            </consumer>
        </producer>
    </event>
</eventMap>

```

In the managed bean, create a method for the producer method action binding. This method will include code to publish the contextual event. [Example 28–20](#) show the `myBean` managed bean and the `myActionPerformed` method that creates the `eventProducer` contextual event.

#### **Example 28–20 Managed Bean Code to Generate Contextual Events**

```

public class myBean {
    public myBean() {
    }

    public Object myActionPerformed() {
        // Add event code here...
        BindingContainer bc = BindingContext.getCurrent().getCurrentBindingsEntry();
        JUCtrlActionBinding actionBnd =
            (JUCtrlActionBinding)bc.getControlBinding("eventProducer");

        ((DCBindingContainer)bc).getEventDispatcher().queueEvent(actionBnd.
            getEventProducer(), "myString");

        ((DCBindingContainer)bc).getEventDispatcher().processContextualEvents();
        return null;
    }
}

```

When the button is pressed, the `myActionPerformed` method is invoked and calls the following methods to generate the contextual event:

```

((DCBindingContainer)bc).getEventDispatcher().queueEvent(actionBnd.
    getEventProducer(), "myString");

```

### **28.7.4 How to Create a Contextual Event from JavaScript**

Every action and method binding that is accessible from a managed bean can be invoked from JavaScript. ADF Faces provides an `af:serverListener` operation component that can be used to call a managed bean method from client-side JavaScript. To invoke this component using the referenced managed bean method, use the `BindingContext` object to look up the current `BindingContainer` and to access the `OperationBinding` or a `JUEventBinding` binding. The `af:serverListener` component can also be used to send a message payload from the browser client to the managed bean method.

## 28.7.5 How to Manually Create the Event Map

Under most circumstances, you can create the event map using the Event Map Editor as described in [Section 28.7.2, "How to Create Contextual Events Manually."](#) However, in situations such as when the producer event is from a page in an embedded dynamic region, the Event Map Editor at design time cannot obtain the necessary information to create an event map.

### To create the event map manually:

1. Open the page definition that contains the binding for the consumer.
2. In the Structure window, right-click the topmost node that represents the page definition, and choose **Insert inside pagedef name > eventMap**.  
An **eventMap** node appears in the Structure window.
3. Select the **eventMap** node, right-click and choose **Insert inside eventMap > event**.  
In the Insert Event dialog, enter the name of the event and click **OK**.  
An **event** node appears under the **eventMap** node.  
Repeat this step to add more events.
4. Select **event**, right-click and choose **Insert inside event > producer**.  
The Insert Producer dialog appears. Enter the name of the binding that is producing this event. You can also enter the name of the producer region, in which case all the consumers specified under this tag can consume the event. You can also enter "\*" to denote that this event is available for all consumers under this tag. Click **OK**.  
A **producer** node appears under the **event** node.
5. Select **producer**, right-click and choose **Insert inside producer > consumer**.  
The Insert Consumer dialog appears. Enter the name of the handler that will consume the event. Click **OK**.  
A **consumer** node appears under the **producer** node.  
Repeat this step to add more consumers.
6. If there are parameters being passed, add the parameter name and value. Select **consumer**, right-click and choose **Insert inside consumer > parameters**.  
A **parameters** node appears under the **consumer** node.  
Select **parameters**, right-click and choose **Insert inside parameters > parameter**.  
The Insert parameter dialog appears. Enter the name of the parameter and the value of the parameter. The value can be an EL expression. Click **OK**.  
Repeat **Insert inside parameters > parameter** to add more parameters

## 28.7.6 How to Register a Custom Event Dispatcher

By default, the contextual event framework uses `EventDispatcherImpl` to dispatch events that would traverse through the regions. You can create a custom event dispatcher to override the default event dispatcher to provide custom behaviors. After you have created the custom event dispatcher, you must register it in the `Databindings.cpx` file to override the default dispatcher.

**To register a custom event dispatcher:**

1. Create a custom event dispatcher Java class based on the `EventDispatcher` class.
2. Register the custom event dispatcher in the `Databindings.cpx` file with a fully qualified name using the following format:

```
EventDispatcher="package_name.CustomEventDispatcher_name"
```

[Example 28–21](#) shows the code for a custom event dispatcher called `NewCustomEventDispatcher` created in package `NewPackage`.

**Example 28–21 Adding Custom Event Dispatcher in the Databindings.cpx File**

```
<Application xmlns="http://xmlns.oracle.com/adfm/application"
  version="11.1.1.51.60" id="DataBindings" SeparateXMLFiles="false"
  Package="project3" ClientType="JClient"
  EventDispatcher="NewPackage.NewCustomEventDispatcher">
```

3. Create the event in the producer's page definition.
4. Create the event map in the consumer region if the consumer is in a dynamic region. If the consumer is not in a dynamic region, you can also specify the event map in the parent page which holds both the producer and consumer regions.

## 28.7.7 What Happens When You Create Contextual Events

When you create an event for the producer, JDeveloper adds an `events` element to the page definition file. Each event name is added as a child. [Example 28–22](#) shows the event on the `setHelpId` method action binding in the `account_basichinformationPageDef` page definition file of the `StoreFront` module. This is the page definition for the Basic Information view of the customer registration task flow.

**Example 28–22 Event Definition for the Producer**

```
<methodAction id="setHelpId"
  InstanceName="LookupServiceAMDataControl.dataProvider"
  DataControl="LookupServiceAMDataControl"
  RequiresUpdateModel="true" Action="invokeMethod"
  MethodName="setHelpId" IsViewObjectMethod="false"
  ReturnName="LookupServiceAMDataControl.
  methodResults.setHelpId_
  LookupServiceAMDataControl_dataProvider_
  setHelpId_result">
  <NamedData NDName="usage" NDValue="CREATE_PROFILE"
    NDType="java.lang.String"/>
</methodAction>
<events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
  <event name="queueHelpTopic"/>
</events>
```

When the method action binding is invoked, the event is broadcasted to its consumers.

When you configure an event map, JDeveloper creates an event map entry in the corresponding page definition file. [Example 28–23](#) shows the event map on the `registerPageDef` page definition file that maps the `queueHelpTopic` event from

the `customerregistrationtaskflow1` region to the `helptaskflow1` region. It also maps the `helpPageDef.findHelpTextById` handler method bindings that is defined in the `helpPageDef` page definition file. The consumer invokes a method that determine the information text to display based on the parameters that are passed into it. The mapping is in the `registerPageDef` page definition, as that is the parent container for both the `customerregistrationtaskflow1` and the `helptaskflow1` regions.

**Example 28–23 Event Map in the Parent Page Definition File**

```
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
  <event name="queueHelpTopic">
    <producer region="*">
      <consumer region="helptaskflow1"
        handler="helpPageDef.findHelpTextById">
        <parameters>
          <parameter name="helpTopicId" value="{payload}" />
        </parameters>
      </consumer>
    </producer>
  </event>
</eventMap>
```

## 28.7.8 How to Control Contextual Events Dispatch

You can control the dispatch of contextual events to child regions at the application level or at the page level. At the application level, you can disable the event dispatch to regions that has an eventMap with producers as wildCards.

For application level control, set the `dynamicEventSubscriptions` property to `false` in the `adf-config.xml` file, as shown in [Example 28–24](#).

**Example 28–24 Disabling Contextual Event Dispatch at the Application Level Using adf-config.xml**

```
<?xml version="1.0" encoding="windows-1252" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
  xmlns:cef="http://xmlns.oracle.com/adfm/contextualEvent">
  <cef:DynamicRegionEventsConfig dynamicEventSubscriptions="false">
  </cef:DynamicRegionEventsConfig>
</adf-config>
```

You can also disable contextual event dispatch for individual pages by setting the `DynamicEventSubscriptions` property to `false` in the associated page definition file as shown in [Example 28–25](#). Contextual events will not be passed to the page and any of its children.

**Example 28–25 Disabling Contextual Event Dispatch for a Page Using the Page Definition File**

```
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
  version="11.1.1.52.8" id="viewBPageDef" Package="view.pageDefs"
  DynamicEventSubscriptions="false">
```

## 28.7.9 What Happens at Runtime: Contextual Events

If both the event producer and the consumer are defined in the same page definition file, then after the corresponding page is invoked and the binding container is created, the event is raised when:

- The corresponding method or action binding is executed
- A value binding is set successfully
- A range binding currency is set successfully

For a method binding, the result of the method execution forms the payload of the event, and the event is queued. In the Invoke Application phase of the JSF lifecycle, all the queued events will be dispatched. The event dispatcher associated with the binding container checks the event map (also in the binding container, as it is part of the same page definition file) for a consumer interested in that event and delivers the event to the consumer. The payload is then removed from the queue.

When the producer and consumer are in different regions, the event is first dispatched to any consumer in the same container, and then the event propagation is delegated to the parent binding container. This process continues until the parent or the topmost binding container is reached. After the topmost binding container is reached, the event is again dispatched to child binding containers which have regions with pages that have producer set to wildcard "\*" .

## 28.8 Adding ADF Model Layer Validation

In the model layer, ADF Model validation rules can be set for a binding's attribute on a particular page. When a user edits or enters data in a field and submits the form, the bound data is validated against any set rules and conditions. If validation fails, the application displays an error message.

Note that you don't need to add additional ADF Model validation if you have already set validation rules in the business domain layer of your entity objects. In an ADF Business Components-based Fusion web application, unless you use data controls other than your application module data controls, you won't need to use ADF Model validation.

You can set the `skipValidation` property to `true` to bypass the ADF Model validation. You can set `skipValidation` to `skipDataControls` to validate the bound objects without validating the transaction. For instance, set `skipValidation` to `skipDataControls` if you have a table action that opens a popup window to accept data entries and you want to allow the view layer to validate those entries before the commit on the table. The `skipValidation` property can be found in the Property Inspector after you have selected the root node of the page definition file in the Structure window.

### 28.8.1 How to Add Validation

You set ADF Model validation on the page definition file. You define the validation rule, and set an error message to display when the rule is broken.

[Table 28–4](#) describes the ADF Model validation rules that you can configure for a binding's attributes.

**Table 28–4 ADF Model Validation Rules**

Validator Rule Name	Description
Compare	Compares the attribute's value with a literal value
List	Validates whether or not the value is in a list of values
Range	Validates whether or not the value is within a range of values
Length	Validates the value's character or byte size against a size and operand (such as greater than or equal to)
Regular Expression	Validates the data using Java regular expression syntax
Required	Validates whether or not a value exists for the attribute

**Before you begin:**

Create a component on the page. The component must have binding attributes.

**To create an ADF Model validation rule:**

1. Open the page definition that contains the binding for which you want to create a rule.
2. In the Structure window, select the attribute, list, or table binding.
3. In the Property Inspector, select **More** and then **Edit Validation Rule**.
4. In the Edit Validation Rules dialog, expand the binding node, select the attribute name, and click **New**.
5. In the Add Validation Rule dialog, select a validation rule and configure the rule accordingly.
6. Select the **Failure Handling** tab and configure the message to display when the rule is broken.

## 28.8.2 What Happens at Runtime: Model Validation Rules

When a user submits data, as long as the submitted value is a non-null value or a string value of at least one character, then all validators on a component are called one at a time. Because the `f:validator` tag on the component is bound to the `validator` property on the binding, any validation routines set on the model are accessed and executed.

The process then continues to the next component. If all validations are successful, the Update Model Values phase starts and a local value is used to update the model. If any validation fails, the current page is redisplayed along with an error message.

## 28.9 Displaying Error Messages

When you use the Data Controls panel to create input components, JDeveloper inserts the `af:messages` tag at the top of the page. This tag can display all error messages in the queue for any validation that occurs on the server side, in a box offset by color. If you choose to turn off client-side validation for ADF Faces, those error messages are displayed along with any ADF Model error messages. ADF Model messages are shown first. Messages are shown within the `af:messages` tag, and with the associated components.

Figure 28–11 shows the error message for an ADF Model validation rule, which states that the value the user entered is not acceptable.

**Figure 28–11** *Displaying Model Error Messages*

CountryName: MOZAMBIQUE

\* IsoCountryCode: MZ

SourceLang: Y

\* CreatedBy: 0

Buttons: First, Previous, Next, Last, Submit

**Error:**  
 JBO-AM\_CC.pageDefs.mvalidatePageDef.SourceLang\_Rule\_0: There is no Language code for Y.  
 JBO-AM\_CC.pageDefs.mvalidatePageDef.SourceLang\_Rule\_0: There is no Language code for Y.

You can display server-side error messages in a box at the top of a page using the `af:messages` tag. When you drop any item from the Data Controls panel onto a page as an input component, JDeveloper automatically adds this tag for you.

### To display error messages in an error box:

1. In the Structure window, select the `af:messages` tag.

This tag is created automatically whenever you drop an input widget from the Data Controls panel. However, if you need to insert the tag manually, simply add the code, as shown in [Example 28–26](#), within the `af:document` tag.

#### **Example 28–26** *Messages Tag in a Page*

```
<af:document>
  <af:messages globalOnly="false" />
  ...
</af:document>
```

2. In the Property Inspector set the following attributes:

- **globalOnly:** By default, ADF Faces displays global messages (that is, messages that are not associated with components), followed by individual component messages. If you wish to display only global messages in the box, set this attribute to `true`. Component messages will continue to display with the associated component.
- **Inline:** Specify whether to render the message list inline with the page or in a popup window.
- **message:** The main message text that displays just below the message box title, above the list of individual messages.

3. Ensure that client-side validation has been disabled. If you do not disable client-side validation, the alert dialog will display whenever there are any ADF Faces validation errors and prevent propagation of the error to the server.

To disable client-side validation, add an entry for `<client-validation-disable>` and set it to `true` in the `trinidad-config.xml` file, as shown in [Example 28–27](#).

#### **Example 28–27** *Disabling Client-Side Validation in the Trinidad-config.xml*

```
<?xml version="1.0" encoding="windows-1252"?>
<trinidad-config xmlns="http://myfaces.apache.org/trinidad/config">
  <skin-family>blafplus-rich</skin-family>
  <client-validation-disabled>true</client-validation-disabled>
</trinidad-config>
```

## 28.10 Customizing Error Handling

You can report errors using a custom error handler that extends the default `DCErrorHandlerImpl` class. You are not required to write any code to register your custom exception handler class. Instead, you select the root node of the `DataBindings.cpx` file in the Structure window, and then use the Property Inspector to set the `ErrorHandlerClass` property to the fully qualified name of the error handler you want it to use.

Your custom error handler can contain the following overridable methods:

- `reportException()`: Called to report any exception that occurs. It can be overridden to analyze reported exceptions.
- `getDisplayMessage()`: Returns the message that will be reported to JSF for each error that occurs. Returning `null` is the way your custom error handler signals that a given exception should not be reported to the client.
- `getDetailedDisplayMessage()`: Returns the detail portion of the message as a `String` object or HTML that will be reported to JSF for each error that occurs. Returning `null` is the way your custom error handler signals that a given exception should not be reported to the client.
- `skipException()`: Returns a boolean depending on whether you want to display each item from the nested exception in the final error list displayed to the user. This method override lets you implement logic to check for specifics exception types and, based on the business scenario, determine whether to display it in the list.

[Example 28–28](#) illustrates a custom error handler that extends the `DCErrorHandlerImpl` class and shows the override for the `skipException()` method that is needed to skip exceptions that should not appear in the list displayed to the user.

### **Example 28–28 Custom Error Handler**

```
package view.controller.fwkext;

import java.sql.SQLIntegrityConstraintViolationException;

import java.util.ArrayList;
import java.util.List;

import oracle.adf.model.binding.DCBindingContainer;
import oracle.adf.model.binding.DCErrorHandlerImpl;

import oracle.jbo.CSMessageBundle;
import oracle.jbo.DMLConstraintException;
import oracle.jbo.JboException;

public class CustomErrorHandler extends DCErrorHandlerImpl {

    List<ExceptionMapper> exceptionMapperList = new ArrayList<ExceptionMapper>();
    public CustomErrorHandler() {
        this(true);
    }

    public CustomErrorHandler(boolean setToThrow) {
        super(setToThrow);
        exceptionMapperList.add(new DisableJboExceptionCodesMapper());
    }
}
```

```

public void reportException(DCBindingContainer bc, Exception ex) {
    for (ExceptionMapper mapper : exceptionMapperList) {
        if (mapper.canMapException(ex)) {
            ex = mapper.mapException(ex);
        }
    }
    super.reportException(bc, ex);
}

/**
 * If an exception is a RowValException or a TxnValException and they
 * have nested exceptions, then do not display it. This example shows
 * an implementation that skips the SQLIntegrityConstraintViolationException
 * from displaying in the error final list displayed to the user.
 */
@Override
protected boolean skipException(Exception ex) {

    if (ex instanceof DMLConstraintException) {
        return false;
    } else if (ex instanceof SQLIntegrityConstraintViolationException) {
        return true;
    }
    return super.skipException(ex);
}
}

```

You must change the constructor to `MyErrorHandler()`. The exception error handler must have a default constructor, as shown in [Example 28–29](#).

#### **Example 28–29 Default Constructor**

```

ErrorHandlerClass="viewController.MyErrorHandler"
public MyErrorHandler()
{
    super(true);
}

```

### **28.10.1 How to Customize the Detail Portion of a Message**

If you plan to customize and use the detail portion of a message, you can create a custom error handler and implement the `getDetailedDisplayMessage` method to retrieve and process that message. The finalized message will be passed to the view layer to be integrated with other messages.

#### **To customize the detail portion of a message:**

1. Create a custom error handler class that extends the default `DCErrHandlerImpl` class.
2. In that class, override the `getDetailedDisplayMessage` method that returns a `DCErrMessage` object.

[Example 28–30](#) shows an implementation of the `getDetailedDisplayMessage` method in the custom error handler class.

**Example 28–30 Custom Error Handler Class with getDetailDisplayMessage Method**

```
public final class MyErrorMessageHandler extends DCErrorHandlerImpl {
    public MyErrorMessageHandler () {
        super(false);
    }
    public DCErrorMessage getDetailedDisplayMessage(BindingContext ctx,
                                                    RegionBinding ctr,
                                                    Exception ex) {
        ...
        return new MyDCErrorMessage(ctr, ex);
    }
}
```

3. Create a custom class that implements the `DCErrorMessage` interface. The class must implement the `getHTMLText` method and the `getText` method.

You will add code to the `getHTMLText` method to perform the actual processing, but you must also implement `getText` to satisfy the interface requirements.

4. In the `getHTMLText` implementation, add code to create and process the error message.

`getHTMLText` of `getDetailedDisplayMessage` should return the finalized version of the error message as an HTML fragment that will be inserted into the HTML code of the page. For this reason, you should perform all necessary preprocessing on the text message before the message is returned by `getDetailedDisplayMessage`. For instance, you may want to retrieve the localized version of the message or change the right-to-left ordering of the message before it is returned.

[Example 28–31](#) shows an implementation of this interface.

**Example 28–31 Implementing the DCErrorMessage Interface**

```
public final class MyDCErrorMessage implements DCErrorMessage {
    RegionBinding m_regionBinding;
    Exception m_ex;
    public MyDCErrorMessage(RegionBinding ctr, Exception ex) {
        super();
        this.m_regionBinding = ctr;
        this.m_ex = ex;
    }
    public String getText() {
        ...
        return "Message String";
    }
    public String getHTMLText() {
        ...
        /* Add code to process the message, including localization */
        /* and right-to-left directional requirements. */
        /* Return the message as the finalized HTML fragment.*/
        return "<html><b>error</b> message details</html>";
    }
}
```

To format the message using HTML tags, you must enclose the message within `<html></html>` tags, as shown in the example. Note that only the following HTML tags are allowed in error messages:

- `<span>`

- `<b>`
- `<a>`
- `<i>`
- `<em>`
- `<br>`
- `<hr>`
- `<li>`
- `<ol>`
- `<ul>`
- `<p>`
- `<tt>`
- `<big>`
- `<small>`
- `<pre>`

### 28.10.2 How to Write an Error Handler to Deal with Multiple Threads

Oracle ADF constructs an instance of the custom error handler for each `BindingContext` object that is created. Because Oracle ADF serializes simultaneous web requests from the same logical end-user session, multiple threads generally will not use the same error handler at the same time. However, to guarantee a thread-safe custom error handler, use the `setProperty()` API on `JobException`. This method stores in the exception objects themselves any hints you might need later during the phase when exceptions are translated to JSF `FacesMessage` objects for display.

---

## Designing a Page Using Placeholder Data Controls

This chapter describes how to create and use placeholder data controls to aid in designing the user interface (UI) of a Fusion web application. It shows you how to create placeholder data types, including master-detail relationships. It also describes how to create and import sample data.

This chapter includes the following sections:

- [Section 29.1, "Introduction to Placeholder Data Controls"](#)
- [Section 29.2, "Creating Placeholder Data Controls"](#)
- [Section 29.3, "Creating Placeholder Data Types"](#)
- [Section 29.4, "Using Placeholder Data Controls"](#)

### 29.1 Introduction to Placeholder Data Controls

Application development is typically divided into two separate processes: technical implementation and user interface design. More often than not, they are undertaken by separate teams with very different skill sets. The two teams can work together either in a *data-first* approach or a *UI-first* approach, or with some overlap between the two. With either approach, the teams usually work together iteratively, refining the application with each cycle.

In a data-first approach, the model, or data control is built first. Then the designer creates the layout and page flow by dragging and dropping the data controls onto pages as UI components. The model data is automatically bound to the components. This approach requires the data model to be available before the designer can proceed.

In a UI-first approach, the designer creates the layout using components from the Component Palette. When the data controls do become available, UI components are then bound to them. With this approach, you should be able to see most of the layout and page flows to make a development evaluation. However, until the data controls are available and bound to components, the application may not fully convey the intent of its design. For instance, an application that has a master-detail relationship is best reviewed when there is actual data that dynamically drives that relationship.

*Placeholder data controls* are easy-to-create, yet fully functional, stand-in data controls that can efficiently speed up the design-development process. UI designers can use placeholder data controls to create page layouts and page flows without the need to have real data controls available. These placeholder controls can be loaded with sample data to realistically simulate application execution for design evaluations.

When the real data controls are ready, the UI components can be easily rebound to complete the application.

For many complex applications, the UI design may actually drive the development of the model, or data source. In this UI-first scenario, having placeholder data controls with sample data is essential to properly model the behavior of the application. In some cases, even if production data controls are available, UI designers may opt to use placeholder data controls because of their flexibility and ease of use.

Creating placeholder data controls is a purely declarative process and does not require coding. It does not require in-depth knowledge of the underlying model, data source technology, actual database schema, or any of the complex relationships in an actual production data control. Placeholder data controls do not require an existing data source or a database connection. You can define multiple data types with multiple attributes. You can also define nested master-detail hierarchies between data types. Placeholder data controls have the same built-in operations such as Execute, Next, and Create. An implicitly created named criteria item allows the user to create search forms as if view objects and view criteria were available.

Placeholder data controls can be used in many other situations. In addition to being used for design review and development, they can be used to develop realistic runtime mock-ups for usability studies, or for proof-of-concept requirements. They can be used to create demos when the data model is not yet ready.

## 29.2 Creating Placeholder Data Controls

You add placeholder data controls to a project using the New Gallery. After the placeholder data control has been created, it appears as a node in the Data Controls panel. It has a different icon than do standard data controls. Instead of an Operations node, the placeholder data control has a Built-in Operations node. Although the Built-in Operations node contains Commit and Rollback operations, these operations do not perform commits or rollbacks because there is not an actual data source for the data.

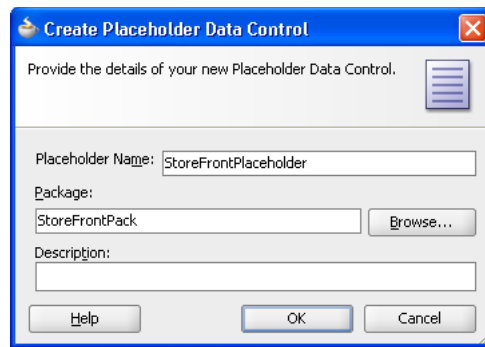

When a data control is initially created, it does not have any data types associated with it. You will need to manually create the data types as described in section [Section 29.3, "Creating Placeholder Data Types"](#).

### 29.2.1 How to Create a Placeholder Data Control

Placeholder data controls are defined at the project level in JDeveloper. You must already have created a project before you can create placeholder data controls.

#### To create a placeholder data control:

1. In the Application Navigator, right-click the project and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **Data Controls** and then **Placeholder Data Control**, and click **OK**.
3. In the Placeholder Data Control dialog, as shown in [Figure 29–1](#), enter:
  - **Placeholder Name:** The name of the placeholder data control.
  - **Directory Name:** The package name that will be used to reference the placeholder data control.
  - **Description:** Optional description of the placeholder data control.

**Figure 29–1 New Placeholder Data Control**

4. Click OK.

## 29.2.2 What Happens When You Create a Placeholder Data Control

When you create a placeholder data control, the package you selected to contain the data control appears under the project node in the Application Navigator. A data control XML file *PlaceholderDataControl.xml* appears under the package, where *PlaceholderDataControl* is the name of the placeholder data control.

[Example 29–1](#) shows a sample file called *StoreFrontPlaceHolder.xml*, which was created when the *StoreFrontPlaceHolder* data control was created.

### **Example 29–1 Sample placeholderdatacontrol.xml**

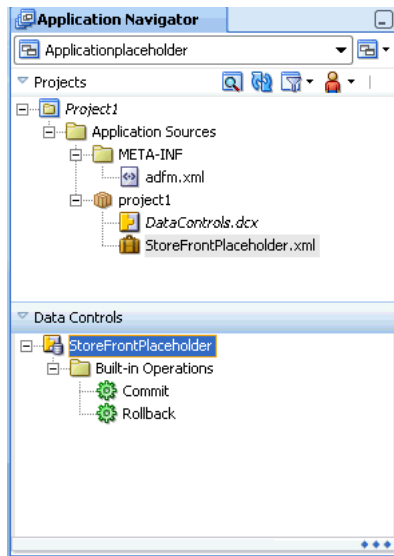

```
<?xml version='1.0' encoding='windows-1252' ?>
<AppModule
  xmlns="http://xmlns.oracle.com/placeholder"
  Name="StoreFrontPlaceholder" >
</AppModule>
```

JDeveloper also creates a *DataControls.dcx* file if it has not yet been defined, and adds entries for the placeholder data control, as shown in [Example 29–2](#).

### **Example 29–2 Placeholder Data Control entry in DataControls.dcx**

```
<?xml version="1.0" encoding="UTF-8" ?>
<DataControlConfigs xmlns="http://xmlns.oracle.com/adfm/configuration"
  version="11.1.1.44.30" id="DataControls"
  Package="storefront">
  <PlaceholderDataControl SupportsTransactions="true" SupportsFindMode="true"
    SupportsResetState="true" SupportsRangesize="true"
    SupportsSortCollection="true"
    FactoryClass=
      "oracle.adf.model.placeholder.DataControlFactoryImpl"
    id="StoreFrontPlaceholder"
    xmlns="http://xmlns.oracle.com/adfm/datacontrol"
    Definition="storefront.StoreFrontPlaceholder"
    Package="storefront"/>
</DataControlConfigs>
```

In the Data Controls panel, the placeholder data control appears alongside other data controls in the root tree. A placeholder data control that does not yet have data types defined will have only the Commit and Rollback built-in operations available, as shown in [Figure 29–2](#).

**Figure 29–2 Application Navigator and Data Controls Panel**

## 29.3 Creating Placeholder Data Types

A standard data control obtains its data collections and attributes from its underlying data source in the model or business service layer. For example, an application module data control obtains its data collections from the view objects and associated database tables.

For a placeholder data control, instead of data collections, it has placeholder data types. A *placeholder data type* is analogous to a data collection. It can be dropped onto a page to create complex components such as forms, tables, and trees. It also has a set of attributes that can be dropped onto pages as individual components such as input text, output text, and select choice. Some attributes may be defined as LOVs.

When you first create a placeholder data control, it is devoid of any data types because there are no underlying database tables for the placeholder data control to reference. You must declaratively create one or more placeholder data types. For each data type, you specify attribute names, types, default UI components, and other options. You can create multiple data types for a data control, similar to the multiple data collections in an application module.

After you have created a placeholder data type, it appears as a child node of the placeholder data control. It also has a Built-in operations node with the standard set of operations. It has a Named Criteria node that contains an All Queriable Attributes item that is analogous to the named view criteria of a view object in a standard data control. You can drag and drop the All Queriable Attributes item onto a page to create a query or quick query search form. In a standard data control, you can create multiple view criteria on a view object. Because there is no real view object in a placeholder data type, only one All Queriable Attributes item is available. For more information about query search forms, see [Chapter 27, "Creating ADF Databound Search Forms"](#).

You can create master-detail relationships between placeholder data types, similar to the master-detail data collections in a standard data control. You can drop master-detail data types onto pages to create master-detail forms and tables. For more information on master-detail forms and tables, see [Chapter 24, "Displaying Master-Detail Data"](#).

JDeveloper allows you to reuse placeholder data types created for other placeholder data controls in the same project. When you are creating a data type, you can select an option to load existing data types from another placeholder data control. If you select the **Copy Data Type** option, the attributes from the imported data type will be added to the list of existing attributes.

You can also select an option to copy the sample data associated with the imported data type when the attributes are added.

---

---

**Note:** Although you do not need sample data until you run the application, you should add sample data to provide a consistent design time rendering of the components.

---

---

### 29.3.1 How to Create a Placeholder Data Type

After you have created a placeholder data control, you can proceed to create data types. You define a name for the data type, and define each of its individual attributes. For each attribute, you then define its type, format, default UI component, and whether it should be an LOV.

In order to simplify the process of creating placeholder data types, you can select from a list of four of the most common types: *String*, *Boolean*, *Date*, and *Number*. Because placeholder attributes are typed, you can create column labels and include UI control hints in the design.

If you have a sample data file in comma-separated value or CSV format, you can automatically create all the attributes and load sample data using the sample data file import function. You do not need to create the attributes. JDeveloper will automatically create them for you from the format of the CSV file, which should be a comma-separated value list of column headings. The attributes default to type *String*. You can manually reset each attribute to another type as required. For instructions to import sample data, see [Section 29.3.6, "How to Add Sample Data"](#).

#### To create a placeholder data type manually:

1. In the Data Controls panel, right-click the placeholder data control and choose **Create Placeholder Data Type**.

[Figure 29-3](#) shows the Create Placeholder Data Type dialog.

**Figure 29–3 Create Placeholder Data Type Dialog**

---

**Note:** If you had already added placeholder data types previously and want only to add or edit them, choose **Edit Placeholder Data Type** from the context menu instead. The dialog that appears will be the Edit Placeholder Data Type dialog. It has the same options as the Create Placeholder Data Type dialog.

---

2. If you already have data types defined for another placeholder data control, and you want to copy or append them, click **Copy Data Type**.
  - a. In the Copy Placeholder Data Type dialog, as shown in [Figure 29–4](#), select the placeholder data type you want. Select **Replace** to replace the current attributes with the attributes from the file, or select **Append** to add the attributes from the file to the list of current attributes.
  - b. Select the **Copy Sample Data** checkbox to load sample data from the file.
  - c. Click **OK**.

**Figure 29–4 Copy Placeholder Data Type**

3. In the Create Placeholder Data Type dialog, enter a name for the placeholder data type, and then in the **Attributes Definition** section, enter:
  - **Name:** Enter a name for the attribute.
  - **Type:** Select a type for the attribute from the dropdown list. The supported types are *String*, *Boolean*, *Date*, and *Number*.
  - **Default Component:** Select a default component for the attribute from the dropdown list. For an LOV, select **Combo Box List of Values**.
  - **Default Value:** Enter the initial value for the attribute.
  - **Label:** Enter a label for the attribute. The label will be used when the component is displayed.
  - **Format Type:** This field is enabled only when the type is *Date* or *Number*. Select a format type from the dropdown list.
  - **Format:** This field is enabled only when a format mask has been defined for that format type.
  - **Searchable:** Select this checkbox to make the attribute searchable.
  - **Use Lov Binding:** Select this checkbox if you want the attribute to be an LOV. To configure the attribute, see [Section 29.3.3, "How to Configure a Placeholder Data Type Attribute to Be an LOV"](#).

Click the **Add** icon to add more attributes.

4. To add data, use the **Sample Data** tab. For that procedure, see [Section 29.3.6, "How to Add Sample Data"](#).

You need sample data for runtime and for a consistent design time.

5. Click **OK**.

## 29.3.2 What Happens When You Create a Placeholder Data Type

When you create a placeholder data type, JDeveloper creates a *PlaceholderDataType.xml* file, where *PlaceholderDataType* is the name of the placeholder data type you had specified.

The *PlaceholderDataType.xml* file has the same format as a view object XML file. It includes the name of the view object and the name and values of each placeholder attribute that was defined.

[Example 29-3](#) shows a *PlaceholderDataType.xml* for the Supplier data type. Two attributes were declarative defined: *Supplier\_Id* and *Supplier\_Name*.

### **Example 29-3 Sample Placeholder Data Type Suppliers.xml file**

```
<?xml version='1.0' encoding='windows-1252' ?>
<ViewObject
  xmlns="http://xmlns.oracle.com/placeholder"
  Name="Suppliers"
  BindingStyle="OracleName"
  CustomQuery="true"
  ComponentClass="oracle.adf.model.placeholder.PlaceholderVOImpl"
  UseGlueCode="false" >
  <ViewAttribute
    Name="Supplier_Id"
    Type="oracle.jbo.domain.Number"
    PrimaryKey="true" >
  </ViewAttribute>
  <ViewAttribute
    Name="Supplier_Name"
    Type="java.lang.String" >
  </ViewAttribute>
  <StaticList
    Name="Suppliers"
    Rows="2"
    Columns="2" >
  </StaticList>
  <ResourceBundle >
    <PropertiesBundle
      xmlns="http://xmlns.oracle.com/bc4j"
      PropertiesFile="storefrontproject.StoreFrontProjectBundle" >
    </PropertiesBundle>
  </ResourceBundle>
</ViewObject>
```

Since a data type is similar to a data collection and is based on a view object, each data type will have a corresponding *PlaceholderDataType.xml* file.

JDeveloper also adds entries for each placeholder data type to the *PlaceholderDataControl.xml* file. For example, after the Suppliers data type has been created, the *StoreFrontPlaceholder.xml* file includes a new *ViewUsage* entry for the Suppliers data type, as shown in [Example 29-4](#).

### **Example 29-4 Sample PlaceholderDataControl.xml File After Addition of Placeholder Data Type**

```
<?xml version='1.0' encoding='windows-1252' ?>
<AppModule
  xmlns="http://xmlns.oracle.com/placeholder"
```

```

Name="StoreFrontPlaceholder" >
<ViewUsage
  Name="Suppliers"
  ViewObjectName="storefrontproject.Suppliers" >
</ViewUsage>
</AppModule>

```

In the Data Controls panel, a placeholder data type node appears under the placeholder data control. Expanding the node reveals the presence of each of the attributes, the Built-in Operations node, and the Named Criteria node.

Figure 29–5 shows a placeholder data control as it appears in the Data Controls panel.

**Figure 29–5 Data Controls Panel Showing Placeholder Data Control**

### 29.3.3 How to Configure a Placeholder Data Type Attribute to Be an LOV

A placeholder data type attribute can be configured to be a list of values (LOV). An LOV-formatted attribute binds to UI components that display dropdown lists or list picker dialogs. For more information about LOVs, see [Section 5.13, "Working with List of Values \(LOV\) in View Object Attributes"](#).

When you are creating a placeholder data type, you can select an option to bring up a dialog to configure that attribute to be an LOV.

If you have only one data source, you can only create a fixed LOV. To create a dynamic LOV, there must be more than one placeholder data type available to be the source.

#### 29.3.3.1 Configuring an Attribute to Be a Fixed LOV

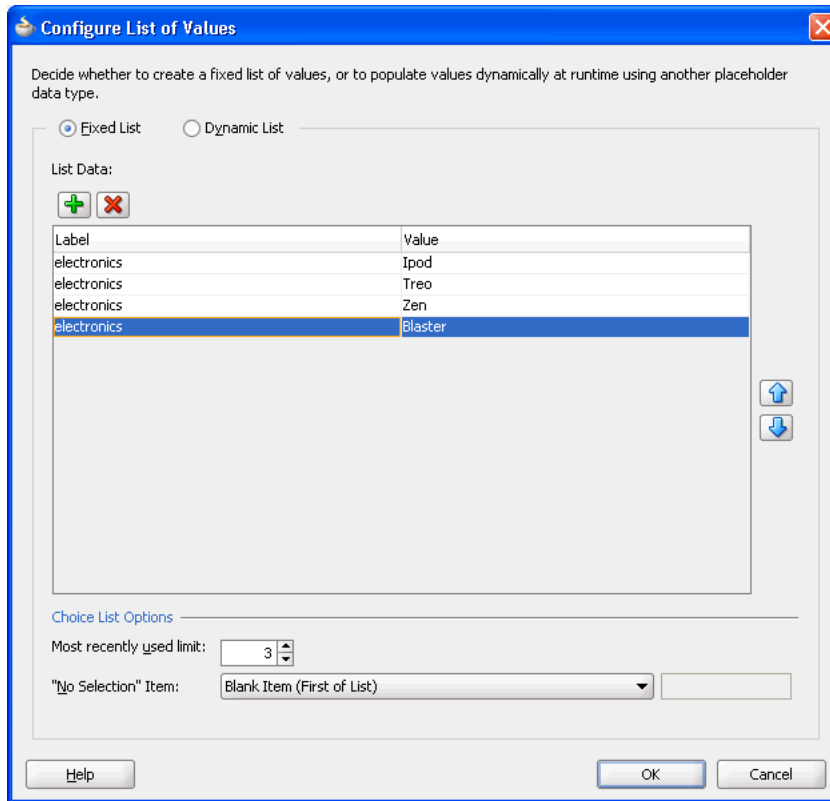

Before you begin, you should determine which attribute you want to be a fixed LOV and which values should be in the fixed list.

##### To configure an attribute to be a fixed LOV:

1. In the Data Controls panel, right-click the placeholder data control and choose **Create Placeholder Data Type** or **Edit Placeholder Data Type**.
2. In the Create Placeholder Data type or Edit Placeholder Datatype dialog, select the **Use Lov Binding** checkbox.

The Configure List of Values dialog appears, as shown in [Figure 29–6](#).

**Figure 29–6 Configure List of Values Dialog for a Fixed LOV**

3. In the dialog, select **Fixed List**.
4. Click the **Add** icon to enable adding an entry to the list of values.
5. For each entry, enter a label and a value.  
When the user selects an item from the list of values, the value entry will be entered into the input field.
6. Select the maximum number of the most recently used items that will be displayed in the dropdown list.
7. From the **No Selection Item** dropdown list, select an option for how you want the "no selection" item to be displayed.  
For instance, selecting **Blank Item (First of List)** will display the "no selection" item as a blank at the beginning of the list.
8. Click **OK**.

### 29.3.3.2 Configuring an Attribute to Be a Dynamic LOV

Before you begin, you should have already created another placeholder data type to serve as the source of the dynamic LOV.

#### To configure an attribute to be a dynamic LOV:

1. In the Data Controls panel, right-click the placeholder data control and choose **Create Placeholder Data Type** or **Edit Placeholder Data Type**.
2. In the Create Placeholder Data type or Edit Placeholder Data type dialog, select the **Use Lov Binding** checkbox.

The Configure List of Values dialog appears, as shown in [Figure 29–7](#).

**Figure 29–7** *Configure List of Values Dialog for a Dynamic LOV*

3. In the dialog, select **Dynamic List**.
4. Select the list data type with the source attribute. You must have a source placeholder data type for this selection to be available.
5. Select the list attribute.
6. Shuttle the attribute from the **Available** list to the **Selected** list.
7. Select the maximum number of the most recently used items that will be displayed in the dropdown list.
8. From the **No Selection Item** dropdown list, select an option for how you want the "no selection" item to be displayed. For instance, selecting **Blank Item (First of List)** will display the "no selection" item as a blank at the beginning of the list.
9. Click **OK**.

### 29.3.4 How to Create Master-Detail Data Types

You create master-detail relationships between data types in the same way you create master-detail hierarchies between tables. In a standard data control, you can use view links to define source and target view objects that would become the master and the detail objects. For more information about master-detail relationships, see [Chapter 24, "Displaying Master-Detail Data"](#).

Before you create a master-detail hierarchy, you must determine the data structure of the master data type and the data structure of the detail data type. You must also determine which attribute in the master will be the source for the detail data type.

You first create a master data type and its attributes. Then you create a detail data type as a child of the master data type. You define the source attribute in the master data type that defines the relationship to the detail data type.

**To create master-detail hierarchical data types:**

1. Create a placeholder data type to be the master as described in [Section 29.3.1, "How to Create a Placeholder Data Type"](#), or select an existing data type to be the master. For example, the `ProductsByCategories` data type is the master.
2. In the Data Controls panel, right-click the master placeholder data type and choose **Create Placeholder Data Type**.

[Figure 29–8](#) shows the Create Placeholder Data Type dialog for entering detail data type attributes.

**Figure 29–8 Create Placeholder Data Type Dialog**

3. In the Create Placeholder Data Type dialog, enter a name for the detail data type.
4. The first attribute in the master data type appears in the **Attributes** section. This attribute provides the foreign key relationship.

Add attributes for the detail data type, copy data type attributes from another data type, or create attributes automatically by importing sample data from a CSV file. For the procedure to add attributes, see [Section 29.3.1, "How to Create a Placeholder Data Type"](#).

5. Click **OK**.

The Data Controls panel should display the detail data type as a child of the master data type, as shown in [Figure 29–9](#).

**Figure 29–9 Master Detail Hierarchy in Placeholder Data Control**

### 29.3.5 What Happens When You Create a Master-Detail Data Type

A master-detail relationship is implemented in the same way as is a standard master-detail relationship, using view object and view links. When you define placeholder data types in a master-detail hierarchy, JDeveloper creates a `DTLink.xml` file that contains metadata entries for view links that define that relationship. For more information about view links, see [Section 5.6, "Working with Multiple Tables in a Master-Detail Hierarchy"](#). For example, in the relationship between the master data type `Video` and the detail data type `Brand` associated with a key `dvdpayer`, JDeveloper creates a `DTLink.xml` file in the form of a view link file to define that relationship, as shown in [Example 29–5](#).

#### **Example 29–5** *DTLink.xml file for Master-Detail Data Type Relationships*

```
<?xml version='1.0' encoding='windows-1252' ?>
<ViewLink
  xmlns="http://xmlns.oracle.com/placeholder"
  Name="DTLink" >
  <ViewLinkDefEnd
    Name="sourceEnd"
    Cardinality="1"
    Owner="project1.ProductsByCategories"
    Source="true" >
    <AttrArray Name="Attributes">
      <Item Value="project1.ProductsByCategories.ProductName" />
    </AttrArray>
  </ViewLinkDefEnd>
  <ViewLinkDefEnd
    Name="destEnd"
    Cardinality="-1"
    Owner="project1.ProductCategoriesToParentProductCategories" >
    <AttrArray Name="Attributes">
      <Item
Value="project1.ProductCategoriesToParentProductCategories.ProductName" />
    </AttrArray>
  </ViewLinkDefEnd>
</ViewLink>
```

### 29.3.6 How to Add Sample Data

If you intend to run an application using the placeholder data control, you will need to add sample data for execution. You can add sample data to the placeholder data type

attributes manually or by importing the data from a CSV file. Although having sample data is mandatory only at runtime, you should add sample data for a consistent design time rendering of the components.

Before you begin to add sample data to a placeholder data type, you should have already created a placeholder data control and a placeholder data type. If you are entering the data manually, you should have the data ready. If you are loading the data from a CSV file, you need to have the location of the file.

### 29.3.6.1 Adding Sample Data Manually

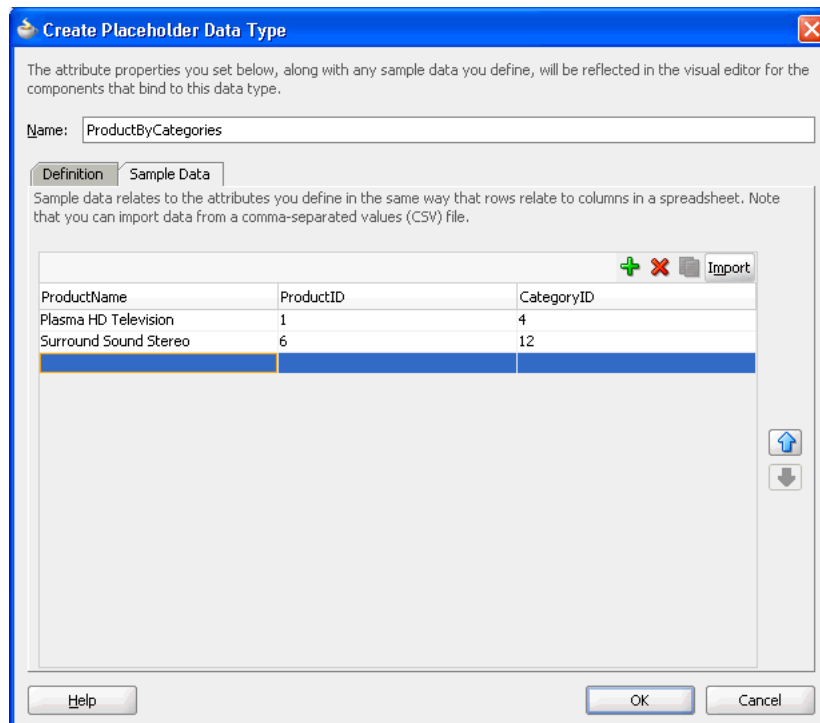

Before you begin, you should have the sample data ready.

**To add sample data to placeholder data types manually:**

1. In the Data Controls panel, right-click the placeholder data control and choose **Create Placeholder Data Type** or **Edit Placeholder Data Type**.
2. In the Create Placeholder Data Type or Edit Placeholder Data Type dialog, click the **Sample Data** tab.
3. For each row of data, enter a value for each attribute that was defined. Click the **Add** icon to create each row.

For example, in [Figure 29–10](#), for the first row, Plasma HD Television was entered for the `ProductName` attribute, 1 was entered for the `ProductID` attribute, and 4 was entered for the `CategoryID` attribute.

**Figure 29–10 Adding Sample Data**

4. Click **OK**.

### 29.3.6.2 Importing Sample Data

Before you begin, you should have the sample data file available on your system so it can be found in the Select/Save File dialog.

#### To import sample data from CSV files into placeholder data types:

1. In the Data Controls panel, right-click the placeholder data control and choose **Create Placeholder Data Type** or **Edit Placeholder Data Type**.
2. In the Create Placeholder Datatype or Edit Placeholder Datatype dialog, click the **Sample Data** tab.

**Tip:** If you already have a CSV file for importing, you do not need to manually create the attributes for each column. JDeveloper automatically creates the attributes from the first row of the CSV file. For more information, see [Section 29.3.1, "How to Create a Placeholder Data Type"](#).

3. If you are also importing attributes, you must delete the default "attribute" in the first row.

This default attribute appears when you first navigate to the **Sample Data** tab. If you do not remove this default attribute, JDeveloper will assume that this is a declaratively created attribute and will not import any other columns except for the first column.

4. Click **Import**.

In the Open dialog, navigate to and select the import file, and click **Open**, as shown in [Figure 29–11](#).

The data from the CSV file, including column heading and values, should appear as sample data.

**Figure 29–11** Importing Placeholder Sample Data

5. Click **OK**.

## 29.3.7 What Happens When You Add Sample Data

Placeholder sample data, whether manually added using the dialog or from an imported CSV file, is stored in message bundle properties files within the placeholder data control packages. JDeveloper creates a text-based file for each data type that has sample data. The properties file name is `placeholderdatatypeNameMsgBundle.properties`. [Example 29–6](#) shows a

sample data properties file for the Televisions data type that has three attributes of brand, size, and type.

**Example 29–6 Sample Data Properties File TelevisionMsgBundle.properties**

```
SL_0_0=sony
SL_0_1=42
SL_0_2=lcd
SL_1_0=panasonic
SL_1_1=50
SL_1_2=plasma
SL_2_0=mitsubishi
SL_2_1=60
SL_2_2=projection
```

## 29.4 Using Placeholder Data Controls

You use placeholder data controls in the same way you would use standard data controls. You can drag data types onto pages and use the context menus to drop the data types as forms, tables, trees, graphs, and other components. You can drop individual attributes onto pages as text, lists of values, single selections, and other components. You can use any of the built-in operations such as Create, Execute, and Next by dropping them as buttons, command links, and menu items.

You can work in several ways to take advantage of placeholder data controls:

- Build a page using the placeholder data controls and rebind to real data controls later.
- Build a page using components, bind them to placeholder data controls, and rebind to real data controls later.
- Build a page using some combination of components from the Component Palette, components from the placeholder data controls, and then bind or rebind to the real data controls later.

### 29.4.1 Limitations of Placeholder Data Controls

You can use placeholder data controls in your application development in many situations. For most UI design evaluations, placeholder data controls should be able to fully substitute for real data controls.

There are a few limitations:

- Because data types are not tied to an underlying data source, the Commit and Rollback operations do not perform real transactions, nor do they update the cache.
- Placeholder data controls can only be created declaratively. You cannot create custom methods like you can with a real application module or data control.
- Placeholder data controls cannot be used when there is a need either for custom data or for filtering or custom code to fetch data. Placeholder data controls will disable those operations.

### 29.4.2 Creating Layout

Use the drag-and-drop feature to create the page using the placeholder data controls, any available real data controls, and components from the Component Palette. If you

intend to run a page or application that requires real data, enter sample data for your placeholder data types. If you have a large amount of sample data, you may be able to create CSV files from the data source and load them into the data type. You may also use spreadsheets and other tools to create CSV sample data files.

### 29.4.3 Creating a Search Form

In a standard data control, you can create view criteria on view objects to modify the query. These view criteria are also used for drag-and-drop creation of query and quick query search forms. The named view criteria items appear under the Named Criteria node for a data collection. For more information about query and quick query search forms, see [Chapter 27, "Creating ADF Databound Search Forms"](#).

For placeholder data controls, there is also a Named Criteria node under each data type node. An automatically created All Queriable Attributes item appears under this node and can be used to drag and drop onto pages to create the query or quick query search forms.

### 29.4.4 Binding Components

Instead of building the page using the data controls, for instance, if you are unsure of the shape of your data, you can lay out the page first using the Component Palette and later bind it to the data types, attributes, or operations of the placeholder data controls.

### 29.4.5 Rebinding Components

After the final data controls are available, you can simply rebind the components. You can select the component in the Structure window and use the context menu to open the relevant rebind dialog. You can also drag and drop the data control item onto the UI component to initiate a rebinding editor. The rebinding procedures are the same whether the component was originally bound to a placeholder data control or a standard data control.

For more information about rebinding components, see [Chapter 22, "Creating a Basic Databound Page"](#) and [Chapter 23, "Creating ADF Databound Tables"](#).

### 29.4.6 Packaging Placeholder Data Controls to ADF Library JARs

A useful feature of placeholder data controls is that they allow parallel development and division of labor among developers and designers. You may be able to leverage that further by packaging placeholder data controls into reusable components as ADF Library JARs. ADF Libraries are JARs that have been packaged to contain all the necessary artifacts of an ADF component. For more information about reusable components and the ADF Library, see [Chapter 33, "Reusing Application Components"](#). You can create libraries of placeholder data controls and distribute them to multiple designers working on the same UI project. Because they are lightweight, you can even use them in place of available real data controls for the earlier phases of UI design.

## Completing Your Application

Part V contains the following chapters:

- [Chapter 30, "Enabling ADF Security in a Fusion Web Application"](#)
- [Chapter 31, "Testing and Debugging ADF Components"](#)
- [Chapter 32, "Refactoring a Fusion Web Application"](#)
- [Chapter 33, "Reusing Application Components"](#)
- [Chapter 34, "Customizing Applications with MDS"](#)
- [Chapter 35, "Allowing User Customizations at Runtime"](#)
- [Chapter 36, "Deploying Fusion Web Applications"](#)

---

---

## Enabling ADF Security in a Fusion Web Application

This chapter describes how you can enable ADF Security in the Fusion web application to define resource grants for Oracle ADF resources and to restrict the user's ability to view web pages associated those resources.

This chapter includes the following sections:

- [Section 30.1, "Introduction to ADF Security"](#)
- [Section 30.2, "ADF Security Process Overview"](#)
- [Section 30.3, "Enabling ADF Security"](#)
- [Section 30.4, "Creating Application Roles"](#)
- [Section 30.5, "Defining ADF Security Policies"](#)
- [Section 30.6, "Creating Test Users"](#)
- [Section 30.7, "Creating a Login Page"](#)
- [Section 30.8, "Testing Security in JDeveloper"](#)
- [Section 30.9, "Preparing the Secure Application for Deployment"](#)
- [Section 30.10, "Disabling ADF Security"](#)
- [Section 30.11, "Advanced Topics and Best Practices"](#)

### 30.1 Introduction to ADF Security

The ADF Security framework is the preferred technology to provide authentication and authorization services to the Fusion web application. ADF Security is built on top of the Oracle Platform Security Services (OPSS) architecture, which itself is well-integrated with Oracle WebLogic Server. While other security-aware models exist that can handle user login and resource protection, ADF Security is ideally suited to provide declarative, permission-based protection for ADF bounded task flows, for top-level web pages that use ADF bindings (pages that are not contained in a bounded task flow), and at the lowest level of granularity, for rows of data defined by ADF entity objects and their attributes. In this document, these specific resources that the ADF Security framework protects are known as *ADF security-aware resources*.

You enable ADF Security for Fusion web applications when you run the Configure ADF Security wizard, as described in [Section 30.3, "Enabling ADF Security."](#) The wizard configures ADF Security for the entire Fusion web application, so that any web page associated with an ADF security-aware resource is protected by default. This

means that after you enable ADF Security, your application is locked down so that the pages are considered secure by default.

After you enable ADF Security you must grant users access rights so that they may view the web pages of the Fusion web application. Access rights that you grant users are known as a *security policy* that you specify for the page's corresponding ADF security-aware resource. Ultimately, it is the security policy on the ADF resource that controls the user's ability to enter a task flow or view a web page.

Because ADF Security is based on Java Authentication and Authorization Service (JAAS), security policies identify the principal (the user or application role), the ADF resource, and the permission (an operation defined by the resource's ADF permission class). For example, the StoreFront module of the Fusion Order Demo application secures the web pages contained by the `checkout-task-flow` task flow to grant access only to logged-in users (also known as *authenticated users*). At runtime, the ADF Security framework performs authorization checking against the task flow's security policy to determine the user's right to complete the view operation. In this case, the security policy must grant the view permission to the user if they are to complete the checkout process.

To simplify the task of defining security policies for users and ADF resources, ADF Security defines a containment hierarchy that lets you define one security policy for the ADF bounded task flow and its contains web pages. In other words, when you define the security policy at the level of the bounded task flow, you protect the flow's entry point and then all pages within that flow are secured by the policy it defines. Additionally, instead of granting access to individual users, you group users into application roles and grant the view permission to the role.

Specifically, you will define security policies in the Fusion web application for the following ADF security-aware resources to make web pages accessible to users:

- ADF bounded task flow protects the entry point to the task flow, which in turn controls the user's access to the pages contained by the flow

For example, a series of web pages may guide new customers through a registration process and the bounded task flow controls page navigation for the process. For a description of bounded task flows, see [Section 14.1.2, "Task Flow Types."](#)

The unbounded task flow is not an ADF security-aware component and thus does not participate in authorization checks. When you need to protect the constituent pages of an unbounded task flow, define grants for the page definition files associated with the pages instead.

- ADF page definition files associated with web pages

For example, a page may display a summary of best selling products with data coordinated by the ADF bindings of the page's associated ADF page definition file. For a description of page definitions and ADF bindings, see [Section 12.6, "Working with Page Definition Files."](#)

- ADF entity objects and attributes of entity objects that reference rows of data and help define collections for display in the user interface

For example, a web page may display an ADF Faces table component that displays columns that ADF bindings map to the attributes of an entity object as its data source. In the case of entity objects, enabling ADF Security does not automatically secure entity objects rows. The data will remain accessible to users until you define a security policy to explicitly protect the entity object or its attributes. For a description of entity objects, see [Section 4.1, "Introduction to Entity Objects."](#)

JDeveloper tools support iterative development of security so you can easily create, test, and edit security policies that you create for ADF resources. You can proceed to create test users in JDeveloper and run the application in Integrated WebLogic Server to simulate how end users will access the secured resources. This chapter describes how to configure the repository of user identities and login credentials known as the *identity store*.

---

---

**Note:** References to the identity store in this chapter are always in the context of *test* user identities that you create for the purpose of running in Integrated WebLogic Server. Typically, you would not migrate these users to the staging environment when you deploy to Oracle WebLogic Server, as described in [Section 30.9, "Preparing the Secure Application for Deployment."](#)

---

---

To avoid a situation where you have enabled ADF Security but have not yet defined security policies to grant access to test users, the Configure ADF Security wizard lets you grant temporary view rights to all existing ADF resources (a view permission grant will be added to the security policy for each ADF resource). This wizard option gives you the choice to disable automatic grants and proceed to define security policies for ADF resources as you create each resource or to enable automatic view grants and gradually replace these grants with security policies that you define. To understand iterative security development choices, see [Section 30.2, "ADF Security Process Overview."](#)

**Tip:** Before you enable ADF Security and define security policies for the ADF security-aware resources, you will want to understand the rules that govern ADF authorization checking. Understanding these rules will help you to implement the security you intend. For a discussion of these rules, see [Section 30.1.2, "Summary of ADF Security."](#)

### 30.1.1 Integration of ADF Security and Java Security

The ADF Security model for securing Fusion web application resources is not based on the URL mapping of a security constraint as exemplified by the Java EE security model. In actual practice, security constraints are not feasible for securing a JavaServer Faces (JSF) web application where page navigation is not supported by specific page URLs. For example, when the user navigates to the next page in a task flow, the URL remains the same throughout the flow. As each new page is displayed, there is no means to trigger a URL-based security constraint.

Instead, ADF Security implements a Java Authentication and Authorization Service (JAAS) security model. The JAAS model is policy-based since JAAS is built on the existing Java security model and integrates with any JAAS implementation, including the Oracle Platform Security Services (OPSS) implementation of the JAAS service. Whereas applications that utilize URL security constraints are security-unaware because they rely on the Java EE container to manage security, Fusion web applications require an explicit call to the ADF Security framework to authorize access to resources based on user-defined policies. Thus, when you enable ADF Security and define access policies for ADF resources, your application is security-aware.

---

---

**Note:** Both OPSS and ADF Security are built on the Java security model known as the Java Authentication and Authorization Services (JAAS), which supports the use of custom permissions to protect the resources of the application. To understand the security features of Oracle Platform Security Services, see the *Oracle Fusion Middleware Security Guide*.

---

---

ADF Security simplifies the implementation of a JAAS authorization model. This implementation minimizes the work needed to create a security-aware application by exposing security policies on ADF resources in a declarative fashion and performing authorization checks on these resources at runtime.

The policy store in JDeveloper is file-based and contains a list of entries known as *grants*, which define the security policy for the ADF resource. The grant entry includes all the permissions granted to the user to perform operations on the protected resource, for instance, accessing a web page associated with an ADF bounded task flow. Permissions are granted in the policy store to an application role principal.

ADF Security expands on the JAAS model by allowing you to define grants using the actions specified by the ADF Security framework permission classes. These classes are specific to the ADF resource and map the actions to an operation supported by the resource. The policy store for the Fusion web application therefore contains grants that specify:

- One or more permissions that associate an action defined by the resource's permission class with an instance of the ADF resource in the application (currently, only the `view` action is supported for bounded task flows and page definitions resources)
- The grantee, which is an application role defined by your application that you populate with member users or, optionally, enterprise roles for whom you wish to confer the same access rights

In the case of entity objects, the permission class defines `read`, `delete`, and `update` actions that correspond to the `read`, `removeCurrentRow`, and `update` operations of the entity object.

For a description of the ADF permission classes and supported actions, see [Appendix C, "Oracle ADF Permission Grants."](#)

### 30.1.2 Summary of ADF Security

The use of ADF Security enables web applications to easily adjust to real-world business security requirements, because rather than securing paths to application resources, you secure the view operation on ADF resources with JAAS. JAAS-based ADF Security provides:

- Declarative security support for ADF resources, such as the bounded task flow  
Because Java EE security is URL-based or page-based, it is not possible to have a navigation control without custom code. With ADF Security, you can control whether or not the user can enter a task flow. Thus, a single security policy for a task flow can control access to multiple web pages. Additionally, because declarative security lets you secure the ADF resource, not the access path, you can reuse the ADF resource elsewhere in the application and it will remain secured.
- Simplified permission assignment by using application roles that allow for the inheritance of permissions

While Java EE security roles that are used by Java EE security constraints are flat, JAAS permissions are granted to application roles, which can be nested and may be mapped to enterprise roles that the Oracle WebLogic Server domain defines.

- Utility methods for use in EL expressions to access ADF resources in the security context

You can use the ADF Security EL expression utility methods to determine whether the user is allowed to perform a known operation. For example, you can determine whether the user is allowed to view a particular task flow.

Additionally, JDeveloper enables you to quickly create test users and passwords to test security in Integrated WebLogic Server. When you are ready to deploy to Oracle WebLogic Server, you can migrate the application-specific authorization policies to the server and the administrator can configure the application to use an LDAP user repository.

[Table 30–1](#) summarizes the effect that enabling ADF Security has on the application and the various ADF security-aware resources. For further discussion about how you can work most effectively with ADF Security, see [Section 30.11.5, "Best Practices for Working with ADF Security."](#)

**Table 30–1 Summary of ADF Security-Aware Resources**

ADF Resource	How ADF Enforces Security	How to Grant Access
Bounded task flows in all user interface projects	Protected by default. Requires a grant to allow users to enter the bounded task flow.	Define the grant for the task flow.  Do <i>not</i> define grants for individual page definition files associated with the web pages of the bounded task flow.
Page definition files in all user interface projects	Protected by default. Requires a grant to allow users to view the page associated with the page definition.	If the web page is contained by a bounded task flow, define the grant for the task flow.  Define the grant for the page definition <i>only</i> when the web page is not contained by a bounded task flow or when the page is contained by an unbounded task flow.  Note that the unbounded task flow is not an ADF security-aware component and allows no grants.
Entity objects in the data model project	Not protected by default. Requires a grant to prevent access by users.	Define a grant on the entity object to protect data only if you need to control access at the level of the entire data collection. The data displayed by <i>all</i> components in the user interface that reference the protected entity object will be protected.  Use entity-level security carefully. Instead, consider defining security at the level of the entity attribute.  Note that grants in the data model project are saved as metadata on the entity object itself and do not appear in the ADF policy store.

**Table 30–1 (Cont.) Summary of ADF Security-Aware Resources**

ADF Resource	How ADF Enforces Security	How to Grant Access
Attributes of entity objects in the data model project	Not protected by default. Requires a grant to prevent access by users.	Define a grant on the entity object attribute to protect data when you need to control access at the level of the columns of the data collection. The data displayed by <i>all</i> components in the user interface that reference the protected entity attribute will be protected.  Note that grants in the data model project are saved as metadata on the entity object itself and do not appear in the ADF policy store.

## 30.2 ADF Security Process Overview

You work in JDeveloper when you want to secure the ADF resources of your Fusion web application. ADF Security will protect your application's bounded task flows and any web pages contained in an unbounded task flow. You enable this protection by running the Configure ADF Security wizard and later by defining ADF security policies to define user access rights for each resource.

As you create the user interface for your application, you may run the Configure ADF Security wizard at any time. You may choose to:

- Iterate between creating web pages in the UI project and defining security policies on their associated ADF resources
- Complete all of the web pages in the UI project and then define security policies on their associated ADF resources

---

**Note:** Before you proceed to secure the Fusion web application, you should become familiar with the ADF Security model, as described in [Section 30.1.2, "Summary of ADF Security."](#)

---

The iterative design and test process is supported by a variety of design time tools.

Each time you create a new bounded task flow or ADF page definition file in your user interface projects, the new ADF resource will be visible in the overview editor for the `jazn-data.xml` file. This editor is also called the overview editor for security policies. You use this overview editor to define security policies for ADF resources associated with web pages for the entire application. You can also use the overview editor to sort ADF resources and easily view those that have no security policy yet defined.

You use another editor to provision a few test users in the ADF identity store. The identity store you create in JDeveloper lets you define user credentials (user ID and password). The editor also displays the relationship between users you create and the application roles that you assign them to for the purpose of conferring the access rights defined by ADF security policies.

At design time, JDeveloper saves all policy store and identity store changes in a single file for the entire application. In the development environment, this is the `jazn-data.xml` file. After you configure the `jazn-data.xml` file using the editors, you can run the application in Integrated WebLogic Server and the contents of the policy store will be added to the domain-level store, the `system-jazn-data.xml`

file, while the test users will be migrated to the embedded LDAP server that Integrated WebLogic Server uses for its identity store. The domain-level store allows you to test the security implementation by logging on as test users that you have created.

You access all design time tools for security under the main menu, using the **Application > Secure** menu, as shown in [Figure 30–1](#).

**Figure 30–1 Accessing the ADF Security Design Time Tools**

## Design Phase

To enable ADF Security and set up the policy store for the application that you will run in JDeveloper:

1. Enable ADF Security to allow dynamic authentication and enforce authorization by running the Configure ADF Security wizard.

When you run the wizard, if you choose to enable *only* dynamic authentication, skip the remaining design phase steps. The wizard configures files that integrate the security framework with OPSS on Oracle WebLogic Server.

2. Create an ADF security-aware resource, such as a bounded task flow with constituent web pages (or regions) or a top-level web page (or region) that is designed using ADF bindings.

**Note:** After you run the Configure ADF Security wizard, any web page associated with an ADF security-aware resource will be protected. This means that you must define security policies to make the web pages accessible *before* you can run the application and test security.

3. Associate the ADF security-aware resource with one or more application roles that you create.

Application roles you create are specific to the application and let you confer the same level of access to a set of users (also known as *member users*). In the test phase you will create some users and add them as members to the application roles you created.

4. Grant view permission to the ADF security-aware resource and each of its associated application roles.

The grant confers access rights to the application role's member users. Without the grant, the user would not be able to access the ADF security-aware resource. In the test phase, you will create some users and add them to your application roles.

### Testing Phase

To provision the identity store and test security using Integrated WebLogic Server:

1. Create some users and, optionally, create their enterprise roles.

You will log in to the application using the user ID and password you define. An *enterprise role* is a logical role that lets you group users and associate these groups with application roles. The enterprise role is not needed for testing. For more information, see [Section 30.4.3, "What You May Need to Know About Enterprise Roles and Application Roles."](#)

2. Associate the users you created and, optionally, the enterprise roles, with one or more application roles.

A member user may belong to more than one application role when you wish to confer the access right granted to multiple application roles.

3. Optionally, replace the default login page with a custom login page.

The default login page generated by the Configure ADF Security wizard cannot utilize ADF Faces components. It is provided only as a convenience for testing ADF security policies. Your custom login page may be designed with ADF Faces components.

4. Run the application in JDeveloper and access any ADF security-aware resource.

The first time you attempt to access an ADF security-aware resource, the security framework will prompt you to log in.

5. Log in and check that you are able to access the page and its resources as you intended.

After you log in, the security framework checks the user's right to access the resource. For example, if you receive an unexpected 401 unauthorized user error, verify that you have created grants as suggested in [Section 30.11.5, "Best Practices for Working with ADF Security."](#)

### Preparation for Staging

To prepare the secure application for deployment to Oracle WebLogic Server in a staging or production environment:

1. Remove any grants to the `test-all` role for all ADF security-aware resources and replace with grants that you define.

Because ADF resources are secure by default, developers testing the application will be granted view access only after security policies are defined. The Configure ADF Security wizard gives you the option to generate grants to the `test-all` role that will make all ADF resources accessible. To avoid compromising enterprise security, you must eventually replace all temporary grants to the `test-all` role with explicit grants that you define.

2. Remove all user identities that you created.

JDeveloper must not be used as an identity store provisioning tool, and you must be careful not to deploy the application with user identities that you create for testing purposes. Deploying user identities with the application introduces the risk that malicious users may gain unintended access. Instead, rely on the system

administrator to configure user identities through the tools provided by the domain-level identity management system.

3. Confirm that the application roles shown in the policy store are the ones that you want an administrator to eventually map to domain-level groups.
4. Decide whether or not you want to define a security constraint to protect ADF Faces resource files.

Resource files including images, style sheets, and JavaScript libraries are files that the Fusion web application loads to support the individual pages of the application. These files are not secured by ADF Security, but you can secure their Java EE access paths if you require all users to be authenticated before they can access the application.

5. Migrate the finalized policy store and credentials store to the target server.

Application policies and credentials can be automatically migrated to the domain policy store when the application is deployed to a server in the Oracle WebLogic environment. Support to automatically migrate these stores is controlled by the target server's configuration. If Oracle Enterprise Manager is used to perform the deployment outside of JDeveloper, then the migration configuration settings can be specified in that tool. For information about migrating the `jazn-data.xml` security policies and the `cwallet.sso` credentials, see the *Oracle Fusion Middleware Security Guide*.

## 30.3 Enabling ADF Security

To simplify the configuration process which allows ADF Security to integrate with OPSS, JDeveloper provides the Configure ADF Security wizard. The wizard is the starting point for securing the Fusion web application using ADF Security. The wizard is an application-level tool that, once run, will enable ADF Security for all user interface projects that your application contains.

---

---

**Note:** Because the Configure ADF Security wizard enables ADF Security for all user interface projects in the application, after you run it, users will be required to have authorization rights to view any web page contained by a bounded task flow and all web pages associated with an ADF page definition. Therefore, after you run the wizard, the application is essentially locked down until you define security policies to grant view rights to the user. For an overview of the process, see [Section 30.2, "ADF Security Process Overview."](#)

---

---

### 30.3.1 How to Enable ADF Security

The Configure ADF Security wizard allows you to choose to enable authentication and authorization separately. You may choose to:

- Enable *only* user authentication.

Although ADF Security leverages Java EE container-managed security for authentication, enabling only authentication means that you want to use the ADF authentication servlet to support user login and logout, but that you intend to define container-managed security constraints to secure web pages.

- Enable user authentication and also enable authorization.

Enabling authorization means you intend to control access to the Fusion web application by creating security policies on ADF resources.

The ADF Security framework supports these two choices to give you the option to implement Java EE Security and still be able to support login and logout using the ADF authentication servlet. The benefit of enabling the ADF authentication servlet is that the servlet will automatically prompt the user to log in the first time the application is accessed. The ADF authentication servlet also allows you to redirect the user to a defined start page after successful authentication. You will also be able to manage the page redirect when the user logs out of the application. These redirect features provided by ADF Security are not available using only container-managed security.

Note that ADF Security does not perform authentication, but relies on the Java EE container to invoke the configured login mechanism, as described in [Section 30.8.4, "What Happens at Runtime: How ADF Security Handles Authentication."](#)

**Best Practice:** Because Java EE security constraints cannot interact with the task flow to secure the current page of a task flow, container-managed security is not a useful solution when your application is designed with ADF task flows. When you use ADF task flows, select the **ADF Authentication and Authorization** option in the Configure ADF Security wizard. This option will allow you to define security policies to protect the task flows of your application.

Because ADF Security delegates authentication to the web container, when you run the Configure ADF Security wizard, the wizard prompts you to configure the authentication method that you want the web container to use. The most commonly used types of authentication are HTTP Basic Authentication and Form-Based Authentication. Basic authentication uses the browser login dialog for the user to enter a user name and password. Note that with basic authentication, the browser caches credentials from the user, thus preventing logout. Basic authentication is useful when you want to test the application without requiring a custom login page. Form authentication allows the application developer to specify a custom login UI. If you choose Form-based authentication, you can also use the wizard to generate a simple login page. The default login page is useful for testing your application with Integrated WebLogic Server.

---

---

**Note:** Because the generated login page is a simple JSP or HTML file, you will not be able to modify it with ADF Faces components. For information about replacing the default login page with a custom login page that uses ADF Faces components, see [Section 30.7, "Creating a Login Page."](#)

---

---

#### **To enable ADF Security for the application:**

1. In the main menu, choose **Application** and then **Secure > Configure ADF Security**.
2. In the ADF Security page, leave the default **ADF Authentication and Authorization** option selected. Click **Next**.

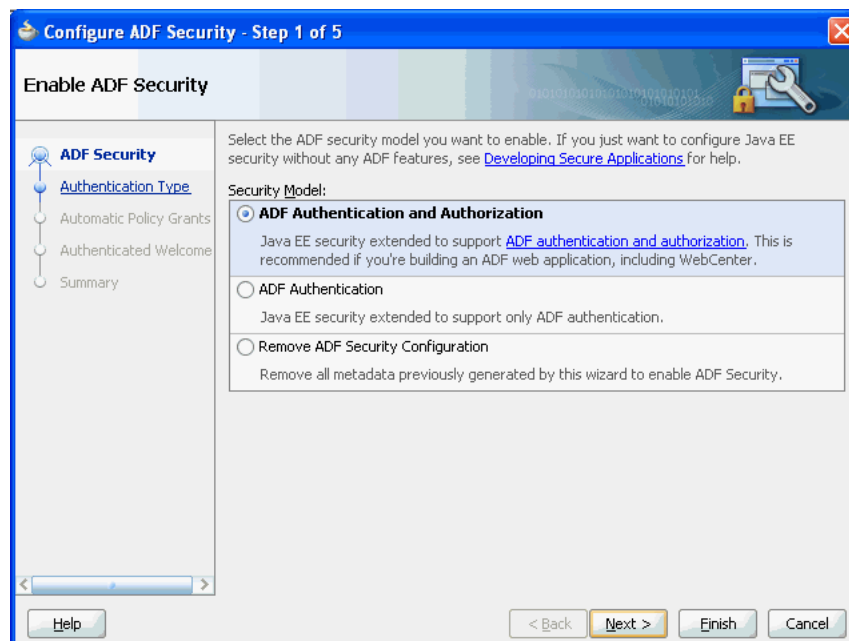

When you run the wizard with the default option selected, your application will enforce authorization for ADF security-aware resources. Enforcing authorization for ADF resources means that you intend to define security policies for these resources to make the web pages of your application accessible. Until you do so, all pages that rely on the ADF bounded task flows and ADF page definitions will remain protected.

The other two wizard options to configure ADF Security should not be used when you want to enable ADF Security. Those options allow you to temporarily disable ADF Security and run your application without security protection, as described in [Section 30.10, "Disabling ADF Security."](#)

Specifically, the first page of the wizard lets you choose among three options, with the default option set to enable **ADF Authentication and Authorization**, as shown in [Figure 30–2](#):

- **ADF Authentication and Authorization** (default) enables the ADF authentication servlet so that you can redirect to a configured web page when the user logs in and logs out. This option also enables ADF authorization to enforce authorization checking against security policies that you define for ADF resources. This option assumes that you will define application roles and assign explicit grants to those roles to manage access to ADF security-aware resources.
- **ADF Authentication** enables the ADF authentication servlet to require the user to log in the first time a page in the application is accessed and supports page redirect by mapping the Java EE application root "/" to a Java EE security constraint that will trigger user authentication. Since the wizard disables ADF authorization, authorization checking is not performed, whether or not security policies exist for ADF resources. Once the user is logged in, all web pages containing ADF resources will be available to the user.
- **Remove ADF Security Configuration** disables the ADF authentication servlet and prevents ADF Security from checking policy grants without altering the existing policy store. In this case, you may require users to log in, become authenticated, and test access rights against URL security constraints using standard Java EE security. Note that running the wizard with this option disables fine-grained security against ADF resources.

**Figure 30–2** Using the Configure ADF Security Wizard to Enable Security-Aware Resources

3. In the Authentication Type page, select the authentication type that you want your application to use when the user submits their login information. Click **Next**.

A known issue prevents the ADF authentication servlet from working with Basic type authentication and allows a user to access resources after logout. Use form-based authentication instead of basic authentication. For details about this issue, see [Section 30.7.7, "What You May Need to Know About ADF Servlet Logout and Browser Caching."](#)

If you select **Form-based Authentication**, you can also select **Generate Default Pages** to allow the wizard to generate a default login and error page. By default the wizard generates the login and error pages at the top level of the user interface project, as shown in [Figure 30-3](#). If you want to change the location, specify the full path relative to the user interface project.

**Figure 30-3 Using the Configure ADF Security Wizard to Generate a Simple Login Page**

4. In the Automatic Policy Grants page, leave the default **No Automatic Grants** option selected. Click **Next**.

When you select **No Automatic Grants**, you must define explicit grants that are specific to your application. The `test-all` application role provides a convenient way to run and test application resources without the restricted access that ADF authorization enforces. However, it increases the risk that your application may leave some resources unprotected.

Alternatively, you can use the wizard to grant to the `test-all` application role. When you enable grants to the `test-all` role, you can postpone defining explicit grants to ADF resources until you are ready to refine the access policies of your application. If you decide to enable automatic grants, do not let application development progress too far and the content of the application become well-established before you replace grants to the `test-all` role with the your application's explicit grants. The explicit grant establishes the necessary privilege (for example, `view` on a page) to allow users to access these resources. For more information about the `test-all` role, see [Section 30.8.3, "How to Use the Built-In test-all Application Role."](#)

5. In the Authenticated Welcome page, select **Redirect Upon Successful Authentication** to direct the user to a specific web page after they log in. Click **Next**.

If you leave the **Redirect Upon Successful Authentication** option unselected, the user will be returned to the page from which the login was initiated. However, when the user presses **Ctrl-N** or **Ctrl-T** to open a new browser window or tab, they will receive a 403 or 404 error unless a welcome page definition appears in the application's `web.xml` file. You can use this option to specify a welcome page so the definition appears in the application's `web.xml` file.

Note that if the web page you specify contains ADF Faces components, you must define the page in the context of `/faces/`. For example, the path for `adffaces_welcome.jspx` would appear in the **Welcome Page** field as `/faces/adffaces_welcome.jspx`.

For details about specifying other redirect options, see [Section 30.7.5, "How to Redirect a User After Authentication."](#)

6. In the Summary page, review your selections and click **Finish**.

### 30.3.2 What Happens When You Enable ADF Security

After you run the Configure ADF Security wizard with the default **ADF Authentication and Authorization** option selected in the ADF Security page, you will have:

- Enabled ADF authentication to prompt the user to log in and to allow page redirects
- Enabled ADF authorization checking so that only authorized users will have access to ADF resources

The wizard updates all security-related configuration files and ensures that ADF resources are secure by default. [Table 30-2](#) shows which files the Configure ADF Security wizard updates.

**Table 30–2 Files Updated for ADF Authentication and Authorization**

File	File Location	Wizard Configuration
web.xml	<p>/public_html/WEB-INF directory relative to the user interface project</p> <p>And, in JDeveloper, in the user interface project under the <b>Web Content-WEB-INF</b> node</p>	<ul style="list-style-type: none"> <li>■ Defines the Oracle <code>JpsFilter</code> filter to set up the OPSS policy provider. The filter defines settings that indicate that your servlet has special privileges. It is important that the <code>JpsFilter</code> be the first filter definition in the <code>web.xml</code> file.</li> <li>■ Adds the Oracle <code>adfAuthentication</code> servlet definition to require the user to log in the first time ADF resources are accessed. Note that ADF Security does not itself perform authentication, but leverages Java EE container-managed security for this purpose.</li> <li>■ When you select the <b>ADF Authentication and Authorization</b> option in the wizard, maps the <code>adfAuthentication</code> servlet to a security constraint that will trigger user authentication dynamically.</li> <li>■ When you select the <b>ADF Authentication</b> option in the wizard, maps the Java EE application root "/" to the <code>allPages</code> security constraint that will trigger user authentication dynamically.</li> <li>■ Sets the authentication method for the Login configuration to handle user login.</li> <li>■ Defines required security roles, including the role <code>valid-users</code>, which is used to trigger the security constraint that enables dynamic authentication.</li> </ul>
adf-config.xml	<p>/.adf/META-INF directory relative to the web application workspace</p> <p>And, in JDeveloper, in the Application Resources panel of the Application Navigator under the <b>Descriptors-ADF META-INF</b> node</p>	<ul style="list-style-type: none"> <li>■ Defines the JAAS security context.</li> <li>■ Enables the use of ADF Security security policies for authorization checking (the <code>authorizationEnforce</code> parameter in the <code>&lt;JaasSecurityContext&gt;</code> element is set to <code>true</code>).</li> <li>■ Enables triggering a login dialog in Java SE applications, including ADF Swing applications (the <code>authenticationRequire</code> parameter in the <code>&lt;JaasSecurityContext&gt;</code> element is set to <code>true</code>). This parameter is not used in Fusion web applications. Fusion web applications rely on settings in the <code>web.xml</code> file to enable authentication.</li> </ul>

**Table 30–2 (Cont.) Files Updated for ADF Authentication and Authorization**

File	File Location	Wizard Configuration
jps-config.xml	<p>/src/META-INF directory relative to the web application workspace</p> <p>And, in JDeveloper, in the Application Resources panel of the Application Navigator under the <b>Descriptors-META-INF</b> node</p>	<ul style="list-style-type: none"> <li>Enables OPSS security services specifically within the JDeveloper design time.</li> </ul> <p>When you test data model projects using the Business Components Browser or run unit tests for security validation this workspace-specific file must be present. Note that this file is not used in the deployed Fusion web application. For example, when you deploy to Integrated WebLogic Server, OPSS security services are enabled by the <code>DefaultDomain/config/fmwconfig/jps-config.xml</code> file.</p>
weblogic.xml	<p>/public_html/WEB-INF directory relative to the web application workspace</p> <p>And, in JDeveloper, in the user interface project under the <b>Web Content-WEB-INF</b> node</p>	<ul style="list-style-type: none"> <li>Maps the <code>valid-users</code> security role to an implicit group called <code>users</code>. Oracle WebLogic Server configures all authenticated users to be members of the <code>users</code> group.</li> </ul>
jazn-data.xml	<p>./src/META-INF directory relative to the web application workspace</p> <p>And, in JDeveloper, in the Application Resources panel of the Application Navigator under the <b>Descriptors- META-INF</b> node</p>	<ul style="list-style-type: none"> <li>Sets the default <code>jazn.com</code> realm name for the XML identity store that you configure for use with Integrated WebLogic Server.</li> </ul> <p>You will use this file to store user identities, user groups, and security policies for the ADF Security-enabled application. This file is used during development and enables support for security when running the Business Components Browser. However, when you deploy your application, for example, to Integrated WebLogic Server, security policies will be migrated into the configured policy store in the <code>DefaultDomain/config/fmwconfig/system-jazn-data.xml</code> file.</p>

Because authentication is delegated to the web container, the wizard only updates the `web.xml` file to enable the ADF authentication servlet to trigger authentication dynamically. It defines servlet mapping for the ADF authentication servlet and adds two Java EE security constraints, `allPages` and `adfAuthentication`, to the `web.xml` file, as shown in [Example 30–1](#).

**Example 30–1 ADF Authentication Descriptors in the web.xml File**

```

<servlet>
  <servlet-name>adfAuthentication</servlet-name>
  <servlet-class>
    oracle.adf.share.security.authentication.AuthenticationServlet
  </servlet-class>
  <load-on-startup>1</load-on-startup>
</servlet>
...
<servlet-mapping>
  <servlet-name>adfAuthentication</servlet-name>
  <url-pattern>/adfAuthentication</url-pattern>
</servlet-mapping>
...
<security-constraint>

```

```
<web-resource-collection>
  <web-resource-name>allPages</web-resource-name>
  <url-pattern>/</url-pattern>
</web-resource-collection>
<auth-constraint>
  <role-name>valid-users</role-name>
</auth-constraint>
</security-constraint>
<security-constraint>
  <web-resource-collection>
    <web-resource-name>adfAuthentication</web-resource-name>
    <url-pattern>/adfAuthentication</url-pattern>
  </web-resource-collection>
  <auth-constraint>
    <role-name>valid-users</role-name>
  </auth-constraint>
</security-constraint>
```

Because the `allPages` constraint maps to the `'/'` URL, it protects the Java EE application root. This mapping enables the Oracle WebLogic Server web container to trigger user authentication dynamically even before ADF Security is accessed. When the user first accesses the application, it forces the container to challenge the user for the user name and password. Then when the user accesses a page protected by ADF Security, there is no longer a need to authenticate the user and no need to redirect to the ADF authentication servlet.

---

---

**Note:** You can remove the `allPages` constraint from the `web.xml` file if you prefer to provide a login link or button to explicitly trigger login. You could also have a link or button to perform logout. For details about creating a custom component to perform login and logout, see [Section 30.7, "Creating a Login Page."](#) If you keep the constraint to allow dynamic authentication, because it covers everything under the Java EE application root, your login page may not display supporting resources at runtime, as described in [Section 30.7.3, "How to Ensure That the Custom Login Page's Resources Are Accessible for Explicit Authentication."](#)

---

---

Because every user of the application is required to be able to log in, the security constraint defined against the `adfAuthentication` resource allows all users to access this web resource. As such, the security role associated with the constraint must encompass all users. To simplify this task, the Java EE `valid-users` role is defined. The `weblogic.xml` file maps this role to an implicit `users` group defined by Oracle WebLogic Server. This mapping ensures that every user will have this role because Oracle WebLogic Server configures all properly authenticated users as members of the `users` group, as described in [Section 30.3.7, "What You May Need to Know About the `valid-users` Role."](#)

---

---

**Note:** The `adfAuthentication` resource constraint provides the definition of a single standard URL pattern against the ADF authentication servlet. Your web pages can provide an explicit login or logout link that references the ADF authentication servlet URL pattern. This explicit login scenario is an alternative to generating a simple login form in the Configure ADF Security wizard and relying on ADF authentication to prompt the user to log in. For details about handling the explicit login scenario, see [Section 30.7, "Creating a Login Page."](#)

---

---

To enable authorization, the wizard updates the `adf-config.xml` file and sets the `authorizationEnforce` parameter in the `<JaasSecurityContext>` element to `true`, as shown in [Example 30-2](#).

**Example 30-2 AuthorizationEnforce Flag Enabled in the `adf-config.xml` File**

```
<JaasSecurityContext
  initialContextFactoryClass="oracle.adf.share.security.JAASInitialContextFactory"
  jaasProviderClass="oracle.adf.share.security.providers.jps.JpsSecurityContext"
    authorizationEnforce="true"
    authenticationRequire="true"/>
```

When authorization is enabled, the ADF security context gets the user principal from the `HttpServletRequest` once the user is authenticated by the container. The user submits a user name and password and that data is compared against the data in the identity store where user information is stored. If a match is found, the originator of the request (the user) is authenticated. The user principal is then stored in the ADF security context, where it can be accessed to obtain other security-related information (such as the group the user belongs to) in order to determine authorization rights. For details about accessing the ADF security context, see [Section 30.11.4, "Getting Information from the ADF Context."](#)

### 30.3.3 What Happens When You Generate a Default Form-Based Login Page

The wizard-generated login and error pages are simple HTML pages that are added to the top-level folder of your user interface project. The generated login page defines an HTML form that will submit the user's login request with the standard `j_security_check` action. This action together with form-based authentication, which is the default option for container authentication provided by the wizard, allows the web container to authenticate users from many different web application resources.

The wizard updates the `web.xml` file to specify form-based authentication and identify the location of the pages, as shown in [Example 30-3](#).

**Example 30-3 Wizard-Generated Login Page Definition Added to in the `web.xml` File**

```
<login-config>
  <auth-method>FORM</auth-method>
  <form-login-config>
    <form-login-page>/login.html</form-login-page>
    <form-error-page>/error.html</form-error-page>
  </form-login-config>
</login-config>
```

Your application will display the wizard-generated login page from a server-side redirect in response to the unauthenticated user attempting to access a protected

resource. This is known as implicit authentication because the redirect to the login page only occurs when user navigates to a page that contains an ADF security-aware resource.

Note that web applications also have a notion of public pages and allow for explicit, as well as implicit authentication. This means that users should be able to log in to the application by clicking a login link before they navigate to secured content. For information about creating and using a login link, see [Section 30.7, "Creating a Login Page."](#)

### 30.3.4 What You May Need to Know About the Configure ADF Security Wizard

The first time you run the Configure ADF Security wizard and enable authentication and authorization, you secure ADF resources at the level of the application. Additionally, you select specific project-level settings for the user interface project, including the authentication type and the authentication welcome. The wizard adds these web application settings to the `web.xml` file in the project you select. When your application contains multiple user interface projects and `web.xml` files, you can return to the wizard and configure these settings in the `web.xml` file for another user interface project that you select.

### 30.3.5 What You May Need to Know About ADF Authentication

ADF applications that use Java EE container-managed authentication for login and ADF authentication for logout integrate with Oracle Single Sign-On (Oracle SSO) with no special requirements. The ADF authentication servlet handles the details of logout and invalidates the session. However, when the application uses login and logout methods provided by Servlet 3.0, Oracle SSO is not supported. Additionally, Servlet 3.0 login and logout is only compatible with application servers that fully support Java EE 6 or later.

On the first access to a page that relies on an ADF security-aware resource, if there is no subject defined, OPSS is configured by the `JpsFilter` to create a subject containing the `anonymous` user principal and the `anonymous-role` role principal. With this role principal, the unauthenticated user will be able to access public web pages that are not associated with any ADF security-aware resources (including ADF bounded task flows or page definitions).

In the case of pages associated with ADF security-aware resources, you must explicitly grant `view` permission to `anonymous-role` to make the page accessible to the anonymous user. For details about granting privileges to the anonymous user, see [Section 30.5.1, "How to Make an ADF Resource Public."](#)

### 30.3.6 What You May Need to Know About the Built-In test-all Role

The Configure ADF Security wizard lets you enable automatic grants to the built-in `test-all` application role for the purpose of granting `view` permission to all ADF security-aware resources in your application. Without a permission grant, either an automatic `view` grant or an explicit grant that you define, ADF Security authorization checking enforcement would prevent you from being able to run the application and access its resources. You can run the wizard with the `test-all` application role feature enabled and then gradually replace automatic `view` grants with explicit grants. Be aware that you must not deploy the application with grants to the `test-all` application role in place, since this feature makes all ADF resources public. If you choose to enable the built-in `test-all` application role in the wizard, see [Section 30.9.1, "How to Remove the test-all Role from the Application Policy Store,"](#) before deploying your application.

### 30.3.7 What You May Need to Know About the valid-users Role

The `valid-users` role is a Java EE security role defined by ADF Security to ensure that all users will access the `adfAuthentication` servlet web resource defined in the `web.xml` file. The Configure ADF Security wizard updates the `weblogic.xml` file to map this ADF Security role to the `users` principal, as shown in [Example 30-4](#). This mapping ensures that every user will have this role, because Oracle WebLogic Server configures all properly authenticated users as members of the `users` group.

**Example 30-4** *valid-users Role Mapping in the weblogic.xml File*

```
<security-role-assignment>
  <role-name>valid-users</role-name>
  <principal-name>users</principal-name>
</security-role-assignment>
```

At runtime, the `users` principal is added automatically to a successfully authenticated subject by OPSS. From a security perspective, the `valid-users` role supports ADF authentication only in the case where you need to control access to web resources using security constraints alone. The end result of this mapping relies entirely on Java EE security and does not involve JAAS Permissions.

## 30.4 Creating Application Roles

You create application roles to represent the policy requirements of the application and to define groups of users with the same view permission rights. The application roles that you create in the application policy store are specific to your application. For example, in the context of the work flow, there may be application roles such as `fod-customer`, `fod-productSpecialist`, `fod-supervisor`, and `fod-admin`, where `fod` identifies these roles as specific to the Fusion Order Demo application.

At runtime, the access rights are conferred on the user through the application role for which the user is defined as a member. Thus, before you can define security policies, the policy store must contain the application roles that you intend to issue grants to. This can be an application role that you define (such as `fod-users`) or it can be one of the two built-in application roles defined by OPSS: `authenticated-role` or `anonymous-role`. JDeveloper provides the built-in application roles to let you make ADF resources public, as described in [Section 30.5.1, "How to Make an ADF Resource Public."](#)

After you create the application role, you will:

- Grant permissions to the application roles, as described in [Section 30.5, "Defining ADF Security Policies."](#)
- Associate test users with each application role, as described in [Section 30.6, "Creating Test Users."](#)

**Best Practice:** The ADF Security framework enforces a role-based access control mechanism with permissions granted either to application roles or to individual users. Although you may only need to test security and therefore might not need to create groups of users, you should still create application roles (with at least one user member). Later when you define security policies on the ADF resources, the overview editor for the application policy store will allow you to select an application role for the grant.

### 30.4.1 How to Create Application Roles

JDeveloper lets you add application roles to the policy store of the `jazn-data.xml` file, which appears in the **Descriptors/META-INF** node of the Application Resources panel.

---

**Note:** When you create application roles, be sure to add the new application roles to the policy store, not the identity store. Roles that you add to the identity store define enterprise security roles and provide a way to conveniently group users in the identity store. For more details about enterprise roles, see [Section 30.4.3, "What You May Need to Know About Enterprise Roles and Application Roles."](#)

---

To create application roles in the policy store of the `jazn-data.xml` file, you use the Application Roles page of the overview editor for the `jazn-data.xml` file. This editor lets you view the relationship between identity store members and the application roles you create.

**To create application roles:**

1. In the main menu, choose **Application** and then **Secure > Application Roles**.
2. In the Application Roles page of the `jazn-data.xml` overview editor, select the policy store for your application from the **Security Policy** dropdown list.  
The policy store that JDeveloper creates in the `jazn-data.xml` file is automatically based on the name of your application.
3. In the **Roles** list, click the **New** icon.
4. In the **Name** field, enter the name of the role and click any other field to add the application role to the policy store.
5. If you have already set up test users in the identity store, you can map users and roles, as described in [Section 30.6.3, "How to Associate Test Users with Application Roles."](#)

### 30.4.2 What Happens When You Create Application Roles

When you add an application role to the policy store, JDeveloper updates the `jazn-data.xml` file located in the `src/META-INF` directory relative to the application workspace. Application roles are defined in `<app-role>` elements under `<policy-store>`, as shown in [Example 30-5](#). Because the policy store `<application>` element names the application, at runtime all application roles that you create will be visible to your application only. Other web applications may define a policy store with their own set of application roles.

**Example 30-5 Application Role Definition in the Policy Store**

```
<policy-store>
  <applications>
    <application>
      <name>StoreFrontModule</name>
      <app-roles>
        <app-role>
          <name>fod-users</name>
          <display-name>FOD Users</display-name>
          <class>oracle.security.jps.service.policystore.
                                ApplicationRole</class>
```

```

        </app-role>
        ...
    </app-roles>
    <jazn-policy>
        ...
    </jazn-policy>
</application>
</applications>
</policy-store>

```

### 30.4.3 What You May Need to Know About Enterprise Roles and Application Roles

An *enterprise role* is a role that is maintained in the domain identity store (as opposed to an application identity store). Enterprise roles are available to every application deployed in the domain and are therefore also called external roles.

An *application role* is a role used by a Fusion web application. It is specific to the application, defined by the application policy, and not necessarily known to the Java EE container. Application roles are scoped in the sense that they can contain only users and roles defined in the application. Application roles must be mapped to enterprise roles.

You use the overview editor for the `jazn-data.xml` file to create enterprise roles to group users that you add to the identity store. You can use this mechanism to assign entire groups of users to application roles that you have defined for the purpose of conferring access rights defined by ADF security policies, as described in [Section 30.6.3, "How to Associate Test Users with Application Roles."](#)

However, Integrated WebLogic Server does not require you to create enterprise roles to run the application within JDeveloper. For the purpose of testing the application, it may be sufficient to create a few test users and assign them directly to application roles. When you run the application in JDeveloper, the users and any enterprise roles you defined will be created in the default security provider (which is embedded LDAP for Integrated WebLogic Server).

Typically, when you deploy the application for staging, you will migrate only the policy store to the target server. You can configure JDeveloper deployment options so that the identity store, including test users and enterprise roles, is not migrated, as described in [Section 30.8.1, "How to Configure, Deploy, and Run a Secure Application in JDeveloper."](#)

After you deploy the secure application, Oracle Fusion Middleware will merge your application's policy store with the policies of the domain-level policy store. To complete this task, the administrator for the Oracle WebLogic Server will eventually map the application roles of your policy store to the existing domain-level enterprise roles. This application role mapping at the domain level allows enterprise users to access application resources according to the ADF security policies you have defined. The domain-level application role mapping by the administrator also allows you to develop the ADF security policies of your application without requiring any knowledge of the identity store in the production environment.

## 30.5 Defining ADF Security Policies

Authorization relies on a policy store that is accessed at runtime and that contains permissions that grant privileges to execute predefined actions, like `view`, on a specified object. Initially, after you run the Configure ADF Security wizard, the policy store defines no grants. And, because the default wizard option **ADF Authentication**

**and Authorization** enables authorization checking, the web pages of your application that rely on the ADF security-aware resources will be inaccessible to users. You must use JDeveloper to define explicit grants for the resources that you want to permit users to access.

**Best Practice:** When you run the Configure ADF Security wizard with the default option **ADF Authentication and Authorization** selected, you will lock down the web pages of your application. This affords the most protection to the Fusion web application possible since you will define explicit grants to allow users to access only the pages you intend. For a discussion of this guideline and others, see [Section 30.11.5, "Best Practices for Working with ADF Security."](#)

Before you can define security policies, the policy store for your application must contain the application roles that you intend to issue grants to. This can be an application role that you define (such as `fod-users`) or it can be one of the two built-in application roles defined by OPSS: `authenticated-role` or `anonymous-role`. You use application roles to classify users, so that each member of the same role possesses the same access rights. As such, the security policy names the application role as the principal of the grant, rather than specific users. For details about defining application roles, see [Section 30.4, "Creating Application Roles."](#)

For the user interface project, you use the overview editor for security policies to secure ADF resources, including ADF task flows and ADF page definitions. You open the editor on the `jazn-data.xml` file by double-clicking the `jazn-data.xml` file (located in the Application Resources panel) or by choosing **Secure > Resource Grants** from the **Application** menu in the main menu.

Note that when you open the `jazn-data.xml` file, the overview editor provides additional editor pages that you use to create test users, enterprise roles, and application roles.

For the data model project, you do not secure entity objects or their attributes using the overview editor for security policies. Instead, you set metadata directly on these objects to manage whether or not the databound UI component displays the data. For details about granting permissions for row-level security, see [Section 30.5.11, "How to Define Policies for Data."](#)

### 30.5.1 How to Make an ADF Resource Public

It is a common requirement that some web pages be available to all users, regardless of their specific access privileges. For example, the home page should be seen by all visitors to the site, while a corporate site should be available only to those who have identified themselves through authentication.

In both cases, the page may be considered public, because the ability to view the page is not defined by the users' specific permissions. Rather, the difference is whether the user is anonymous or a known identity.

In the ADF security model, you differentiate between the absence of security and public access to content by granting access privileges to the `anonymous-role` principal. The anonymous role encompasses both known and anonymous users, thus permission granted to `anonymous-role` allows access to a resource by unauthenticated users, for example, guest users. To provide access to authenticated users only, the policy must be defined for the `authenticated-role` principal.

---

---

**Note:** For details about creating a public home page which contains links to other pages in the application, see [Section 30.7.4, "How to Create a Public Welcome Page."](#)

---

---

**Before you begin:**

1. Create bounded task flows, as described in [Section 14.2, "Creating a Task Flow."](#)
2. Create web pages with an ADF page definition file, as described in [Section 12.6, "Working with Page Definition Files."](#)
3. Run the Configure ADF Security wizard, as described in [Section 30.3, "Enabling ADF Security."](#)
4. Create application roles, as described in [Section 30.4, "Creating Application Roles."](#)

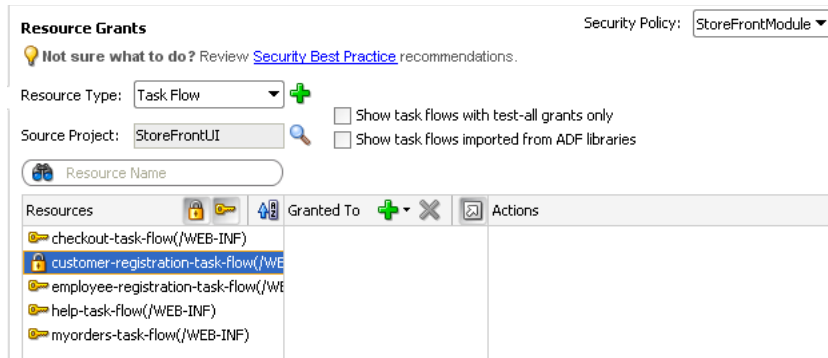

**To grant public access to ADF security-aware resources:**

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, select one of the following resources from the **Resource Type** dropdown list:
  - **Task Flow** when you want to make a bounded task flow public. The application displays the web pages under the permission you define for the task flow itself. Thus, all constituent web pages of the bounded task flow will become public.
  - **Web Page** when you want to make individual web pages public. Typically, these pages are defined by an unbounded task flow and are top-level pages in the application, such as a home page.
3. In the **Resources** column, select the ADF resource for which you want to grant access rights.

The resource you select should display the lock icon in the first column next to the resource name. The lock icon indicates that the resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant. For example, in [Figure 30-4](#), the ADF resource `customer-registration-task-flow` (a bounded task flow) shows the lock icon since no grant has been made.

**Tip:** Click the key toggle icon in the header for the overview editor's first column to hide or show resources that already have grants and display only the resources without grants. The key icon indicates that the resource has a grant that will make the resource accessible to users with sufficient access rights.

**Figure 30–4** Selecting an ADF Security-Aware Resource in the Overview Editor

4. In the **Granted to** column, click the **Add Grantee** icon and choose **Add Application Role**.
5. In the Select Application Roles dialog, select one of these built-in application roles:
  - **anonymous-role** means the resource will be accessible to anyone who visits the site. A grant to this role is necessary if you want to make a web page associated with an ADF security-aware resource accessible before a user logs in. For example, you would grant to `anonymous-role` for a task flow that manages customer registration.
  - **authenticated-role** means the resource will be accessible only to authenticated users (ones who visit the site and log in). For example, you would grant to `authenticated-role` for an employee registration task flow.
6. In the Select Application Roles dialog, click **OK**.
7. In the Resource Grants page of the overview editor, in the **Actions** column, leave the **view** action selected.

By default, the overview editor shows **view** selected, as shown in Figure 30–5. The view action is the only action currently supported for Fusion web applications.

The actions **customize**, **grant**, or **personalize** are implemented for page definition security in Oracle WebCenter Portal: Framework applications or custom applications that are enabled to use Oracle WebCenter Portal’s Composer.

**Figure 30–5** Granting to `anonymous-role` in the Overview Editor

## 30.5.2 What Happens When You Make an ADF Resource Public

When you define a security policy, the overview editor for security policies updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The overview editor writes the policy information to the `<policy-store>` section of the file. The security policy, or grant, contains both a grantee and one or more permissions. The grantee is the application role that the policy is being defined for—in this case, the anonymous role. Each permission defines the resource being secured and the action that can be performed against that resource.

[Example 30-6](#) shows a security policy in the `jazn-data.xml` file that makes a customer registration task flow public. The grant to `anonymous-role` contains a single view permission for a bounded task flow, `customer-registration-task-flow`. With this grant, all users will be able to enter the customer registration task flow and complete the customer registration process. Additional grants to the anonymous role may be made and will appear in the `<permissions>` section of the anonymous role grant.

### **Example 30-6 Grants to anonymous-role in the Application-Level Policy Store**

```
<policy-store>
  ...
  <jazn-policy>
    <grant>
      <grantee>
        <principals>
          <principal>
            <class>oracle.security.jps.internal.core.
              principals.JpsAnonymousRoleImpl</class>
            <name>anonymous-role</name>
          </principal>
        </principals>
      </grantee>
      <permissions>
        <permission>
          <class>oracle.adf.controller.security.TaskFlowPermission</class>
          <name>/WEB-INF/customer-registration-task-flow.xml#
            customer-registration-task-flow</name>
          <actions>view</actions>
        </permission>
        ...
      </permissions>
    </grant>
    ...
  </jazn-policy>
</policy-store>
```

## 30.5.3 What Happens at Runtime: How the Built-in Roles Are Used

The `anonymous-role` and `authenticated-role` names are special roles defined by Oracle Platform Security Services (OPSS).

When you run the Configure ADF Security wizard, the wizard configures the `JpsFilter` definition in the `web.xml` file to enable support for the anonymous role. The enabled anonymous role allows ADF Security to support browsing of the site by anonymous users—those users who have not yet logged in. In contrast, the

authenticated role is not declared and is always recognized by default. ADF Security supports both of these roles.

When an end user first accesses an ADF security-aware resource, the system creates a subject and populates it with the anonymous role principal. As long as the ADF security-aware resource being accessed has the view grant to anonymous role, the user is permitted access. If the anonymous role is not a grantee of the ADF resource, the user is prompted to log in. After logging in, the authenticated role is added to the subject. The wizard also adds the `JpsFilter` definition to the `web.xml` file, where `remove.anonymous.role` set to `false` ensures that the anonymous role principal is available even after the user logs in. With the authenticated role principal, the user may access resources that have an explicit grant to the authenticated role.

### 30.5.4 How to Define Policies for ADF Bounded Task Flows

You define the access policy for an ADF bounded task flow by creating permission grants in the Resource Grants page of the overview editor for security policies. The grants you create will appear as metadata in the policy store section of the `jazn-data.xml` file. This metadata defines a permission target (in this case, the bounded task flow definition name) for which you have issued grants to authorize the members of a specific application role.

**Best Practice:** Do not create permission grants for the individual web pages of a bounded task flow. When the user accesses the bounded task flow, security for all pages will be managed by the permissions you grant to the task flow. And, because the contained web pages (with associated page definitions) will be inaccessible by default, ADF Security prevents users from directly accessing the pages of the task flow. This supports a well-defined security model for task flows that enforces a single entry point for all users. For further information about implementing security policies, see [Section 30.11.5, "Best Practices for Working with ADF Security."](#)

You can sort the task flows in the overview editor by clicking the toggle buttons in the **Task Flow** header, as described in [Table 30–3](#).

**Table 30–3** Resource Grant Toggle Buttons for Bounded Task Flows

Button	Toggle Action	Description
	Shows/hides bounded task flows with no grants	Represents a bounded task flow with no permission grants defined. The web pages that the task flow calls will not be accessible to any user.
	Shows/hides bounded task flows with grants	Represents a bounded task flow with one or more permission grants defined. The web pages that the task flow calls will be accessible to users who are members of the application role that received the grant.

The list of available actions displayed by the overview editor is defined by the task flow permission class (`oracle.adf.controller.security.TaskFlowPermission`). The permission class maps these actions to the operations supported by the task flow. [Table 30–4](#) shows the actions displayed by JDeveloper for ADF bounded task flows.

Note that the `view` action is the only action currently supported for Fusion web applications. Do not select `customize`, `grant`, or `personalize` actions—they are reserved for future use in task flow security.

**Table 30–4 Secured Actions of ADF Bounded Task Flows**

Grantable Action	Effect on the User Interface
view	Controls who can read and execute a bounded task flow in a Fusion web application. This is the only operation that the task flow supports.
customize	Reserved for future use. This action is not checked at runtime.
grant	Reserved for future use. This action is not checked at runtime.
personalize	Reserved for future use. This action is not checked at runtime.

To define a grant for the task flow security policy, use the Resource Grants page of the overview editor for the `jazn-data.xml` file.

#### Before you begin:

1. Create bounded task flows, as described in [Section 14.2, "Creating a Task Flow."](#)

**Best Practice:** If you are creating bounded task flows in separate UI projects of the same application, you will want to assign unique task flow definition names. This is necessary because a grant's task flow definition name is scoped in the `jazn-data.xml` policy store by path (for example, `/WEB-INF/mytaskflow-definition.xml#mytaskflow-definition`). Therefore creating bound task flows with unique definition names is the only way to impose project-level scoping of the grants.

2. Run the Configure ADF Security wizard, as described in [Section 30.3, "Enabling ADF Security."](#)
3. Create application roles, as described in [Section 30.4, "Creating Application Roles."](#)

#### To define a permission grant on an ADF bounded task flow:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, select **Task Flow** from the **Resource Type** dropdown list.

The overview editor displays all the task flows that your application defines. Task flows are defined by task flow definition files (`.xml`) that appear in the Web Content/Page Flows node of the user interface project.

3. In the **Resources** column, select the task flow for which you want to grant access rights.

The first time you make a grant to a bounded task flow, the first column should display the **Resources without any grants** icon (represented by a "lock") next to the task flow name. The overview editor displays the lock icon to indicate that a resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant.

**Tip:** Click the **Resources with grants** icon (represented by the "key" icon) in the header for the **Resources** column to hide all task flows that already have grants. This will display only task flows without grants, as shown in [Figure 30–6](#). Additionally, you can type a partial task flow name in the search field to display only the task flows with character-matching names.

**Figure 30–6 Hiding Task Flows with Grants in the Overview Editor**

4. In the **Granted to** column, click the **Add Grantee** icon and select **Add Application Role**.
5. In the Select Application Roles dialog, select the application role that you want to make a grantee of the permission.

The Select Application Roles dialog displays application roles from the `jazn-data.xml` file. It also displays the built-in OPSS application roles, **anonymous-role** and **authenticated-role**, as described in [Section 30.5.3, "What Happens at Runtime: How the Built-in Roles Are Used."](#)

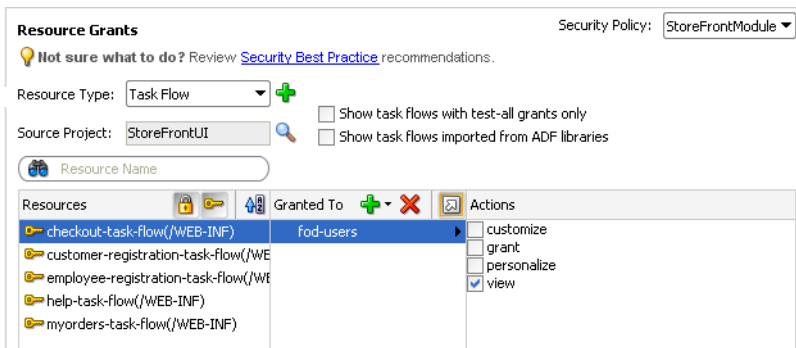

If you do not see application roles that are specific to your application, create the role, as described in [Section 30.4, "Creating Application Roles."](#)

6. In the Select Application Roles dialog, click **OK**.
7. In the Resource Grants page of the overview editor, in the **Actions** column, leave the **view** action selected.

By default, the overview editor shows the **view** action selected, as shown in [Figure 30–7](#). The view action is the only action currently supported for Fusion web applications. Do not select **customize**, **grant**, or **personalize** actions—they are reserved for future use and will not be checked by ADF Security at runtime.

The `TaskFlowPermission` class defines task flow—specific actions that it maps to the task flow’s operations, as described in [Table 30–4](#).

**Figure 30–7 Granting to an Application Role for a Bounded Task Flow Definition in the Overview Editor**

8. You can repeat these steps to make additional grants as desired.

The same task flow definition can have multiple grants made for different application roles. The grants appear in the policy store definition of the `jazn-data.xml` file, as described in [Section 30.5.7, "What Happens When You Define the Security Policy."](#)

### 30.5.5 How to Define Policies for Web Pages That Reference a Page Definition

You define the access policy for an ADF page definition by creating permission grants in the Resource Grants page of the overview editor for security policies. The grants you create will appear as metadata in the policy store section of the `jazn-data.xml` file. This metadata defines a permission target (in this case, the page definition name) for which you have issued grants to authorize the members of a specific application role.

**Best Practice:** Create permission grants for the individual web page only when the page is not a constituent of a bounded task flow. Page-level security is checked for pages that have an associated page definition binding file *only* if the page is directly accessed or if it is accessed in an *unbounded* task flow. For further information about implementing security policies, see [Section 30.11.5, "Best Practices for Working with ADF Security."](#)

You can sort the web page definition resources in the overview editor by clicking the toggle buttons in the **Resources** header, as described in [Table 30-5](#).

**Table 30-5** Resource Grant Toggle Buttons for Web Page Definitions

Button	Toggle Action	Description
	Shows/hides top-level pages with no grants	Represents a page definition with no permission grants defined for a web page that is contained in an unbounded task flow. The web page will not be accessible to any user.
	Shows/hides top-level pages with grants	Represents a page definition with one or more permission grants defined for a web page that is contained in an unbounded task flow. The web page will be accessible to users who are members of the application role that received the grant.
	Shows/hides pages included in a bounded task flow	Represents a page definition associated with a web page that also is contained in a bounded task flow. Do not grant to these web page definitions. Instead, define a security policy for the bounded task flow.
	Shows/hides unsecurable pages (with no page definition)	Represents a web page with no page definition defined that is contained in an unbounded task flow. (Pages like this that are contained by a bounded task flow are secured by the bounded task flow's permission.) The web page will be accessible to all users since it is not secured by an associated ADF security-aware resource. Optionally, you can secure the page by adding an empty page definition file, as described in <a href="#">Section 30.5.9, "What You May Need to Know About Defining Policies for Pages with No ADF Bindings."</a>

The list of available actions displayed by the overview editor is defined by the region permission class (`oracle.adf.share.security.authorization.RegionPermission`). The permission class maps these actions to the operations supported by the ADF page definition for the web page. [Table 30-6](#) shows the actions displayed by JDeveloper for ADF page definitions.

Note that the `view` action is the only action currently supported for Fusion web applications. Do not select `customize`, `grant`, or `personalize` actions—they are implemented for page definition security only in WebCenter Portal: Framework applications.

**Table 30–6 Securable Actions of ADF Page Definitions**

Grantable Action	Effect on the User Interface
view	Controls who can view the page. This is the only operation that the page definition supports.
customize	Controls who can make implicit changes (such as minimize/restore, delete, or move) to a WebCenter Portal customizable component (in a Panel Customizable or Show Detail Frame) contained in a page of a custom application (one enabled to use Oracle WebCenter Portal's Composer) or a WebCenter Portal application. For details, see the <i>Oracle Fusion Middleware Developer's Guide for Oracle WebCenter Portal</i> .
grant	Confers the rights specified by all WebCenter Portal-specific actions combined; it is equivalent to granting all other actions. It also controls who can make grants to other users and who can change security settings on the page using Oracle WebCenter Portal's Composer. For details, see the <i>Oracle Fusion Middleware Developer's Guide for Oracle WebCenter Portal</i> .
personalize	Controls who can make implicit changes (such as minimize/restore, delete, or move) to a WebCenter Portal customizable component (in a Panel Customizable or Show Detail Frame) contained in a page of a custom application (one enabled to use Oracle WebCenter Portal's Composer) or a WebCenter Portal application. For details, see the <i>Oracle Fusion Middleware Developer's Guide for Oracle WebCenter Portal</i> .

To define a grant for the page definition security policy, use the Resource Grants page of the overview editor for security policies.

#### Before you begin:

1. Create the top-level web pages with an ADF page definition file, as described in [Section 12.6, "Working with Page Definition Files."](#)

**Best Practice:** If you are creating top-level web pages in separate UI projects of the same application, you will want to assign unique page file names. This is necessary because a grant's page definition name is scoped in the `jazn-data.xml` policy store by package (for example, `view.pageDefs.mytoppagePageDef`). Therefore creating top-level pages with unique file names is the only way to impose project-level scoping of the grants.

2. Run the Configure ADF Security wizard, as described in [Section 30.3, "Enabling ADF Security."](#)
3. Create application roles, as described in [Section 30.4, "Creating Application Roles."](#)

#### To define a permission grant on an ADF page definition:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, select **Web Page** from the **Resource Type** dropdown list.

The Resource Grants page of the overview editor displays all web pages, including those that have an associated ADF page definition. This includes any web page that uses ADF data bindings or any web page for which you have created an empty page definition. Page definitions are defined by `PageDef.xml` files that appear in the Application Sources node of the user interface project.

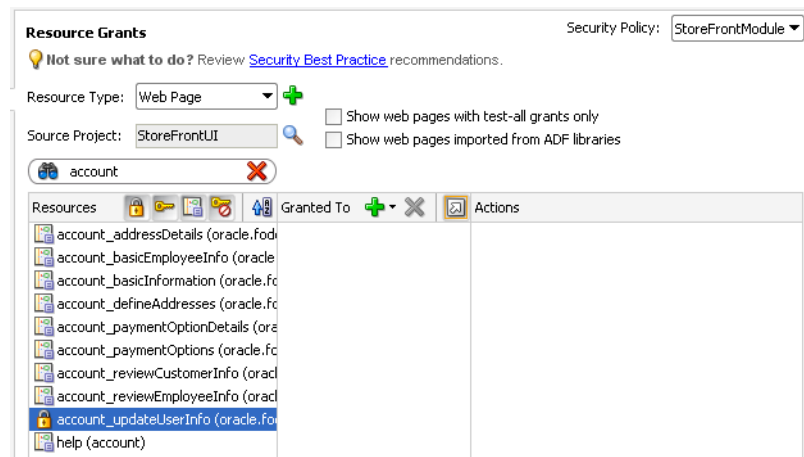

3. In the **Resources** column, select the page definition for which you want to grant access rights.

The first time you make a grant to a page definition, the first column should display the **Resource without any grants** icon (represented by the "lock" icon) next to the page definition name. The editor displays the lock icon to indicate that a resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant. For example, the page definition `account_updateUserInfo` shown in [Figure 30–8](#) displays the lock icon since no grant has been made. Other page definitions in [Figure 30–8](#) show the **Page included in bounded task flow** icon because they are not top-level pages and thus are securable by the containing bounded task flow.

Do not create grants for individual web page definitions that display the **Page included in bounded task flow** icon. Security policies for the associated web pages are secured by their bounded task flow. For example, in [Figure 30–8](#), the page definition associated with the `account_addressDetails.jsff` region will be secured by the containing bounded task flow.

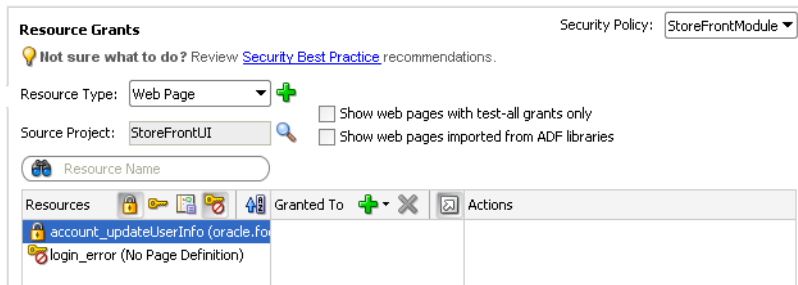

**Tip:** You can type a partial page definition name in the search field to display only the page definitions with character-matching names. For example, a search on the word `account` would display only the page definitions that begin with the word `account`, as shown in [Figure 30–8](#).

**Figure 30–8 Matching Page Definitions by Name in the Overview Editor**

**Tip:** You can click the **Resources with grants** icon (represented by the "key" icon) to hide all page definitions that already have grants. Confirm that the **Show pages included in a bounded task flow** toggle button in the header for the **Resources** column is toggled off to hide all page definitions that are included in a bounded task flow (by default, it is set to hide these pages). This will display top-level pages that have no grants (and unsecurable pages, if any), as shown in [Figure 30–9](#).

**Figure 30–9 Hiding Web Pages with Grants in the Overview Editor**

4. In the **Granted to** column, click the **Add Grantee** icon and select **Add Application Role**.
5. In the Select Application Roles dialog, select the application role that you want to make a grantee of the permission.

The Select Application Roles dialog displays application roles from the `jazn-data.xml` file. It also displays the built-in OPSS application roles, **anonymous-role** and **authenticated-role**, as described in [Section 30.5.3, "What Happens at Runtime: How the Built-in Roles Are Used,"](#)

If you do not see application roles that are specific to your application, create the role, as described in [Section 30.4, "Creating Application Roles."](#)

6. In the Select Application Roles dialog, click **OK**.
7. In the Resource Grants page of the overview editor, in the **Actions** column, leave the **view** action selected.

By default, the overview editor shows **view** selected, as shown in [Figure 30–10](#). The view action is the only action currently supported for Fusion web applications. The actions **customize**, **grant**, or **personalize** are implemented for use in Oracle WebCenter Portal: Framework applications or custom applications that are enabled to use Oracle WebCenter Portal’s Composer.

The `RegionPermission` class defines page definition—specific actions that it maps to the page’s operations, as described in [Table 30–6](#).

**Figure 30–10 Granting to an Application Role for an ADF Page Definition in the Overview Editor**

8. You can repeat these steps to make additional grants as desired.

The same page definition can have multiple grants made for different application roles. The grants appear in the policy store definition of the `jazn-data.xml` file, as described in [Section 30.5.7, "What Happens When You Define the Security Policy."](#)

## 30.5.6 How to Define Policies to Control User Access to ADF Methods

ADF methods that your application defines may be dropped into the user interface as command components. By default, users who have access to the page that displays the command component for the method will also have rights to execute the method. When you want to create additional security to restrict access to the method operation, you must create a resource grant and test the permission at the level of the user interface. ADF Security does not perform authorization checking for ADF methods; you must enable authorization checking in your application. Based on a resource permission you have granted to the user for the ADF method, the user interface will either enable or disable the command component.

To control user access to a method that your page displays as a command component, you complete these steps:

1. Create a resource grant for a custom resource type and resource.
2. Enforce the permission grant in the user interface.

### 30.5.6.1 Creating a Resource Grant to Control Access to ADF Methods

The resource type that you create will be set to the matcher class `oracle.security.jps.ResourcePermission`, which will allow you to grant permission to parts of the application that are not protected by ADF Security. For example, your page may display a button that lets users cancel a product shipment to customers. However, only members of a specific application role may be allowed to cancel a shipment. To enforce this rule, you can create a resource permission that may be checked declaratively in the user interface at runtime to enable or disable the button.

To create a resource permission for user interface components that you want to protect, use the overview editor for security policies.

#### Before you begin:

You will need to complete these tasks:

1. Create the command component that executes the method that you want secure, as described in [Section 28.2, "Creating Command Components to Execute Methods."](#)
2. Run the Configure ADF Security wizard, as described in [Section 30.3, "Enabling ADF Security."](#)
3. Create application roles, as described in [Section 30.4, "Creating Application Roles."](#)

#### To grant a resource permission on a custom resource type:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, next to the **Resource Type** dropdown list, click the **New Resource Type** button.
3. In the Create Resource Type dialog, enter the name of the resource type, a display name to display when granting resource permissions in JDeveloper, and a description.

Enter a resource type and display name that is appropriate for the user interface resource that needs to be protected. For example, if you want to protect a method button that cancels a product shipment, you might enter the resource type `CancelShipment` and display name `Cancel Shipment`.

4. Next to the **Actions** list, click the **Add Action** button and enter the name of the action that you want to protect. Click **OK**.

The action name can be any name that you want to associate with the custom resource type. For example, if you want to protect a button that invokes a method, you might enter the action name `invoke`. You can add multiple actions to the list when you need to support granting instances of the resource permission to separate application roles.

5. In the Resource Grants page of the overview editor for security policies, in the **Resources** column, click the **Add Resource** icon.

The first time you make a grant to a custom resource type, no resource will be defined. You must create a custom resource for the policy that will be used to check user permissions in the user interface at runtime.

6. In the Create Resource dialog, enter the name of the resource and a display name to display when granting resource permissions in JDeveloper, and then click **OK**.

Enter a resource name and a display name that describes the user interface resource that you want to protect. For example, if you want to protect a method button that cancels a product shipment, you might enter the resource name `CancelShipmentButton` and display name `Cancel Shipment Button`.

7. In the **Granted to Roles** column, click the **Add Grantee** icon and select **Add Application Role**.

8. In the Select Application Roles dialog, select the application role that you want to make a grantee of the permission.

The Select Application Roles dialog displays application roles from the `jazn-data.xml` file. It also displays the built-in OPSS application roles, **anonymous-role** and **authenticated-role**, as described in [Section 30.5.3, "What Happens at Runtime: How the Built-in Roles Are Used,"](#)

If you do not see application roles that are specific to your application, create the role, as described in [Section 30.4, "Creating Application Roles."](#)

9. In the Select Application Roles dialog, click **OK**.
10. In the Resource Grants page of the overview editor, in the **Actions** column, select the desired action.

By default, the overview editor shows all actions of the custom resource type unselected. The available actions are defined by the resource type.

11. You can repeat these steps to make additional grants as desired.

The same ADF method resource can have multiple grants made for different application roles. The grants appear in the policy store definition of the `jazn-data.xml` file, as described in [Section 30.5.7, "What Happens When You Define the Security Policy."](#)

### 30.5.6.2 Enforcing the Resource Grant in the User Interface

You use the Expression Builder dialog that you display for the UI component display property to define an EL expression that checks the user's access rights to a previously defined custom resource type. When you run the application, the component will

appear either enabled or disabled based on the outcome of the EL expression resource permission evaluation.

For example, you can define the `userGrantedPermission` expression on the `disabled` attribute of the `af:commandbutton#cb1` button, as shown in [Example 30–7](#). In this case, the expression tests whether the user has permission and then either enables the button or, when the user does not have permission, disables the button. Because the expression is not defined on the button's `rendered` attribute, the page always displays the button.

#### **Example 30–7 Resource Grant Check Expression**

```
<af:commandbutton actionListener="#{bindings.myMethodName.execute}"
  text="myMethodName"
  disabled="#{!securityContext.userGrantedPermission
    ['resourceName=CancelShipmentButton,resourceType=CancelShipment,
      action=invoke']}"
  id="cb1"/>
```

#### **Before you begin:**

You will need to complete this task:

Create the resource grant for a custom resource type, as described in [Section 30.5.6.1, "Creating a Resource Grant to Control Access to ADF Methods."](#)

#### **To check the resource permission using an expression:**

1. In the Application Navigator, double-click the page that contains the command component bound to the ADF method.
2. In the visual editor for the page, select the command component that is used to execute the ADF method.
3. In the Property Inspector, click the **Property Menu** dropdown menu next to the **Disabled** field and choose **Expression Builder**.
4. In the Expression Builder, expand the **ADF Bindings - securityContext** node and select **userGrantedPermission**, and then, in the **Expression** field, enter a concatenated string that defines the permission.

Enter the permission string as a semicolon-separated concatenation of `resourceName=aResourceName;resourceType=aResourceType;action=actionName`. For example, to enable or disable a command button used to invoke the method in a page, you would enter an expression similar to the one shown in [Example 30–7](#).

In [Example 30–7](#), the expression determines whether a resource policy grants invoke privileges for the resource type named `CancelShipment` to the user's defined application role. The resource policy must exist in the application policy store to test the expression at runtime.

5. Click **OK**.

## **30.5.7 What Happens When You Define the Security Policy**

When you define a security policy, the overview editor for security policies updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The overview editor writes the policy information to the <policy-store> section of the file. The security policy, or grant, contains both a grantee and one or more permissions. The grantee is the application role that the policy is being defined for. Each permission defines the resource being secured and the action that can be performed against that resource.

[Example 30–8](#) shows a security policy in the `jazn-data.xml` file that secures a checkout task flow and secures a top-level web page that lets users update account information. The grant to the `fod-users` application role contains a view permission for a bounded task flow, `checkout-task-flow`, and a view permission on the web page with the `account_updateUserInfoPageDef` page definition. With this grant, only users who are authenticated as members of the `fod-users` application role will be able to enter the checkout task flow or view the user information update page.

For the web page, notice that permission has been defined on the `account_updateUserInfoPageDef` page definition created for the user information update page (`updateUserInfo.jspx`). Also, note that this is a top-level web page that is not already secured by a bounded task flow.

### Example 30–8 Grants in the Application-Level Policy Store

```
<policy-store>
  ...
  <jazn-policy>
    <grant>
      <grantee>
        <principals>
          <principal>
            <class>oracle.security.jps.service.policystore.ApplicationRole</class>
            <name>fod-users</name>
          </principal>
        </principals>
      </grantee>
      <permissions>
        <permission>
          <class>oracle.adf.controller.security.TaskFlowPermission</class>
          <name>/WEB-INF/checkout-task-flow.xml#checkout-task-flow</name>
          <actions>view</actions>
        </permission>
        <permission>
          <class>oracle.security.jps.service.policystore.ApplicationRole</class>
          <name>oracle.fodemo.storefront.pageDefs.acct_updateUserInfoPageDef</name>
          <actions>view</actions>
        </permission>
        ...
      </permissions>
    </grant>
    ...
  </jazn-policy>
</policy-store>
```

## 30.5.8 What Happens at Runtime: How ADF Security Policies Are Enforced

Grants that you make for ADF resources are standard JAAS Permissions. When you enable ADF Security in your application, Oracle Platform Security Service (OPSS) running in Oracle WebLogic Server will utilize the grants to allow authorization. In authorization mode, ADF Security uses fine-grained authorization, implemented with JAAS Permissions to perform security checks for access rights to pages. The ADF

Security enforcement logic checks to see whether the user, represented by the JAAS subject, has the right permissions to access the resource.

The subject contains the user's principals, which include a user principal that contains their name (could be anonymous, before logging on, or some user name after logging on), and their list of role principals, which would include `authenticated-role` and some number of other roles that are obtained from the policy and identity stores. The principal is created to represent all of the user's memberships in application roles defined in the policy store. In turn, each application role may have multiple Permissions associated with them. These are the ADF security policies that are created through the overview editor for the `jazn-data.xml` file.

---

**Note:** ADF security policies are scoped by application. This scoping allows two applications to refer to the same permission target, without producing unintentional results. You are not required to name application resources to impose application scoping of the policy store information.

---

Before you run the application using Integrated WebLogic Server, you will need to provision the identity store with test users and add these users to the application roles that you want to configure. The application roles can define members that are specific users or groups of users (also known as *enterprise roles*), as described in [Section 30.6, "Creating Test Users."](#)

Then at runtime, whether the current user has view permission on the page they are trying to access will be determined by the context of the page:

- If the page is an activity of a bounded task flow, the task flow controller determines the permission.
- If the page is a top-level page with an associated page definition file, the ADF Model layer determines the permission.

Oracle Platform Security Services then checks to see whether the subject contains the roles that have the corresponding permissions needed to access the page. If the user is authorized, then the task flow is entered.

In the case of a bounded task flow and top-level pages (defined by an unbounded task flow), if the user is not authorized, ADF Controller throws an exception and passes control to an exception handler that the task flow configuration specifies. For details about specifying an error page, see [Section 30.7.5, "How to Redirect a User After Authentication."](#)

### 30.5.9 What You May Need to Know About Defining Policies for Pages with No ADF Bindings

The default Configure ADF Security wizard option **ADF Authentication and Authorization** enables authorization checking and secures a web page whenever the page is associated with an ADF security-aware resource. Therefore, after you run the wizard, a web page will not be secured if both of these conditions exist:

- The page does not display databound ADF Faces components and therefore no ADF page definition exists for the page.
- The page is not a constituent page of a bounded ADF task flow. (Any page that the user accesses as a process of a bounded task flow is checked under the permission of the task flow.)

JDeveloper will generate an ADF page definition file for you whenever you design a web page using the Data Controls panel to create databound ADF Faces components (for details, see [Section 12.6, "Working with Page Definition Files"](#)). However, if your web page does not use ADF bindings, you can still create an *empty* page definition file by right-clicking the web page in the user interface project and choosing **Go to Page Definition**. The page definition file can remain empty because the page does not need to work with ADF bindings to support databound ADF Faces components.

Once you associate a web page with an ADF page definition file, empty or not, authorization checking will be enforced when the user accesses the associated web page. You can define security policies for the page as you would any other ADF page definition. For details about making grants to an empty ADF page definition, see [Section 30.5.5, "How to Define Policies for Web Pages That Reference a Page Definition."](#)

**To create an empty page definition that you can define security policies for:**

1. In the Application Navigator, locate the web page you want to secure, right-click the node and choose **Go to Page Definition**.
2. In the confirmation dialog, click **Yes** to create a new page definition for the page.

The page definition will be added to the `pageDefs` package.

### 30.5.10 How to Use Regular Expressions to Define Policies on Groups of Resources

When you want to define a grant that applies to multiple resources at once, you can create patterns as defined by the `java.util.regex.Pattern` class to form a regular expression that gets evaluated at runtime. For example, to match a grant to a set of resources, you can enter the expression `.*` (specifies any character zero or more times) on the name of the permission. ADF Security does not support the use of regular expressions on other security objects, such as the principal name.

You might use this feature to group bounded task flows that would have the same permissions into their own subfolders of `WEB-INF` and define the grant for the entire folder, as shown in [Example 30-9](#). In this case, the expression uses the dot character (defined as, any character) followed by the asterisk quantifier (defined as, zero or more times).

**Example 30-9 Task Flow Permission for an Entire Folder Defined in the Application-Level Policy Store**

```
...
<grant>
  <grantee>
    <principals>
      <principal>
        <class>oracle.security.jps.service.policystore.ApplicationRole</class>
        <name>anonymous-role</name>
      </principal>
    </principals>
  </grantee>
  <permissions>
    <permission>
      <class>oracle.adf.controller.security.TaskFlowPermission</class>
      <name>/WEB-INF/.*</name>
      <actions>view</actions>
    </permission>
  </permissions>
</grant>
```

As the overview editor for the `jazn-data.xml` file does not support the use of regular expressions in the user interface, you must edit the file directly. Do not edit the policy store of the `system-jazn-data.xml` file directly. Instead, add grants using regular expressions to the `jazn-data.xml` file. These grants will then be merged to the policy store when you run or deploy the application.

The use of more complex regular expressions enables you to define business rules in the policy, thus creating a very targeted set of permissions. For example, you can grant the view permission on all page definitions and deny specific page definitions at the same time by defining an exclusion set in your regular expression. [Example 30-10](#) shows how the view permission is granted to `anonymous-role` for all pages except those for which the page definition name starts with `custom`.

**Example 30-10 Using Regular Expressions and Metacharacters to Define a Policy Grant**

```
<grant>
  <grantee>
    <principals>
      <principal>
        <class>oracle.security.jps.service.policystore.ApplicationRole</class>
        <name>anonymous-role</name>
      </principal>
    </principals>
  </grantee>
  <permissions>
    <permission>
      <class>oracle.adf.share.security.authorization.RegionPermission</class>
      <name>[^(custom)].*</name>
      <actions>view</actions>
    </permission>
  </permissions>
</grant>
```

[Table 30-7](#) shows some of the basic regular expression metacharacters that you can use in your policy definitions.

**Table 30-7 Description of Metacharacters**

Metacharacter	Description
[abc]	a, b, or c (included in list)
[^abc]	Any character except a, b, or c (negation)
[a-zA-Z]	a to z or A to Z, inclusive (range)
[a-d[m-p]]	a to d, or m to p $\sim$ = [a-dm-p](union)
[a-z&&[def]]	d, e, or f (intersection)
[a-z&&[^bc]]	a through z, without b and c: [a-d-z] (subtraction)
[a-z&&[^m-p]]	a through z, and not m through p
.*	Any number of arbitrary characters (note this expression uses a dot and an asterisk together)

### 30.5.11 How to Define Policies for Data

ADF entity objects in the data model project are security-aware, meaning that predefined resource-specific permissions exist that a developer can grant. Additionally, you can secure just the individual attributes of entity objects.

Entity objects that you secure restrict users from updating data displayed by any web page that renders a UI component bound by an ADF binding to the data accessed by the secured entity object. Additionally, when you secure an entity object, you effectively secure any view object in the data model project that relies on that entity object. As such, entity objects that you secure define an even broader access policy that applies to all UI components bound to this set of view objects.

To secure row data using ADF entity objects:

1. Define a permission map for the specific actions of the entity object or the attributes of the entity object that you want to secure.
2. Grant the permission to an application role that you have added to the policy store.

### 30.5.11.1 Defining Permission Maps on ADF Entity Objects

In the data model project, you use the overview editor for the entity object to define a permission map for the specific actions allowed by the entity object. The metadata consists of a permission class, a permission name, and a set of actions mapped to binding operations.

The list of available operations displayed by the overview editor is defined by the entity object permission class (`oracle.adf.share.security.authorization.EntityPermission`). The permission class maps the operations supported by the entity object to actions. [Table 30–8](#) shows the securable operations of the entity object.

**Table 30–8** *Securable Operations of ADF Entity Objects*

Securable Operation	Expected Mapped Action	Corresponding Implementation
read	read	View the rows of a result set that has been restricted by a <code>WHERE</code> clause fragment.
update	update	Update any attribute of the bound collection.
removeCurrentRow	delete	Delete a row from the bound collection.

---

**Note:** Unlike `read` and `update` operations, the securable operation that maps to the `delete` action is defined with the unique identifier, `removeCurrentRow`. Because authorization checks in Fusion web applications rely on the operation name and not the action name, you must test the `removeCurrentRow` operation name rather than the `delete` privilege name. For details about the entity row API and EL expressions that allow you to test entity object permissions, see [Section 30.11.3, "How to Perform Authorization Checks for Entity Object Operations."](#)

---

To secure all row-level data that the entity object accesses, use the overview editor for the entity object.

#### Before you begin:

You will need to complete this task:

Create entity objects in the data model project, as described in [Chapter 4, "Creating a Business Domain Layer Using Entity Objects."](#)

**To secure an operation on an entity object:**

1. In the Application Navigator, double-click the entity object that you want to secure.
2. In the overview editor, click the **General** navigation tab.
3. In the General page, expand the **Security** section and select the operations you want to secure for the entity object.

The **Security** section displays the securable operations that the `EntityPermission` class defines. The class maps the entity object—specific actions to the entity object’s operations, as described in [Table 30-9](#).

For example, to enable **read** permission, select it as shown in [Figure 30-11](#). The permissions appear in the XML definition of the entity object.

**Figure 30-11** Permission Enabled on read Operation for an ADF Entity Object

☐ Security: OrderEO

Operation	Enabled
read	<input checked="" type="checkbox"/>
update	<input type="checkbox"/>
removeCurrentRow	<input type="checkbox"/>

### 30.5.11.2 Defining Permission Maps on ADF Entity Object Attributes

In the data model project, you use the overview editor for the entity object to define a permission map for the specific actions allowed by the entity object attribute. The metadata consists of a permission class, a permission name, and a set of actions mapped to binding operations.

The list of available operations displayed by the overview editor is defined by the entity object permission class (`oracle.adf.share.security.authorization.EntityPermission`). The permission class maps the operations supported by entity object attributes to actions. [Table 30-9](#) shows the securable operations of entity object attributes.

**Table 30-9** Securable Operations of ADF Entity Object Attributes

Securable Operation	Expected Mapped Action	Corresponding Implementation
update	update	Update a specific attribute of the bound collection.

To secure individual columns of data that the entity object accesses, use the **Attributes** page of the overview editor for the entity object.

**Before you begin:**

You will need to complete this task:

Create entity objects in the data model project, as described in [Chapter 4, "Creating a Business Domain Layer Using Entity Objects."](#)

**To secure an operation on an entity object attribute:**

1. In the Application Navigator, double-click the entity object that defines the attribute you want to secure.

2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute to secure, and then click the **Security** tab and select the **update** operation.

The **Security** tab displays the securable operations that the `EntityAttributePermission` class defines. The class maps the entity object-specific actions to the entity object's operations, as described in [Table 30-9](#).

For example, to enable **update** permission, select it as shown in [Figure 30-12](#). The permission map appears in the XML definition of the entity object.

**Figure 30-12** *Permission Enabled on update Operation for an ADF Entity Object Attribute*

Operation	Enabled
update	<input checked="" type="checkbox"/>

### 30.5.11.3 Granting Permissions on ADF Entity Objects and Entity Attributes

Once a permission target is configured, any data that derives from entity objects or their attributes remains unsecured until you explicitly define policy grants for the entity object's permission target.

To define the access policy for an existing entity object or entity attribute permission target, use the overview editor for security policies.

#### Before you begin:

You will need to complete these tasks:

1. Run the Configure ADF Security wizard, as described in [Section 30.3, "Enabling ADF Security."](#)
2. Create application roles, as described in [Section 30.4, "Creating Application Roles."](#)
3. Define the permission target for the entity object or the attributes of the entity object, as described in [Section 30.5.11.1, "Defining Permission Maps on ADF Entity Objects."](#)

#### To define the access policy for an entity object or entity attribute:

1. In the data model project displayed in the Application Navigator, locate the entity object and select it.
2. In the Structure window for the selected entity object or entity object attribute, right-click and choose **Edit Authorization**.

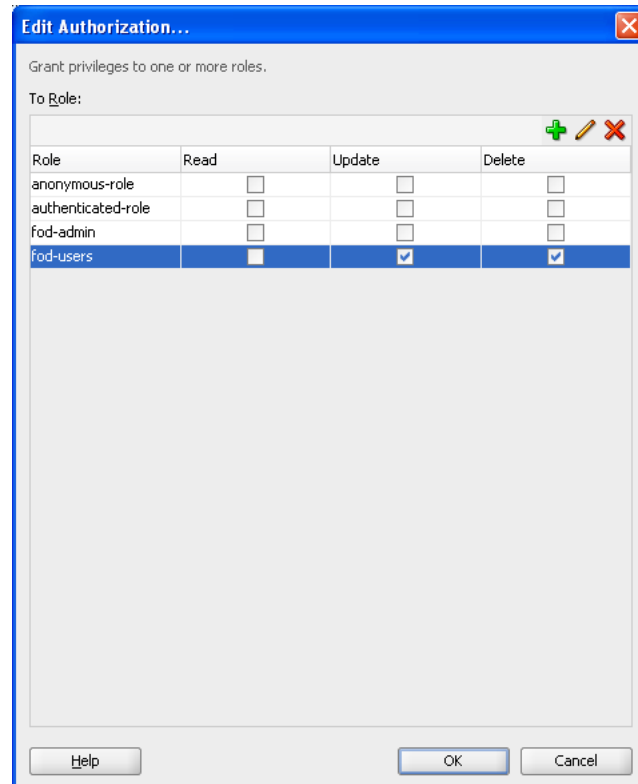

The Edit Authorization dialog displays the available actions of the entity object (or attribute), as described in [Table 30-8](#) and [Table 30-9](#). The dialog also displays the application roles from the `jazn-data.xml` policy store. The built-in application roles **anonymous-role** and **authenticated-role** will appear with application roles that the application developer created.

3. In the dialog, select the action that you want to grant to a specific application role.

For example, to grant **Update** and **Delete** privileges to the **fod-users** application role, select those actions, as shown in [Figure 30–13](#).

The grant to the application role appears in the `jazn-data.xml` file.

**Figure 30–13** Defining the Access Policy for an Entity Object

### 30.5.12 How to Aggregate Resource Grants as Entitlement Grants

You define end user access for individual securable Oracle ADF artifacts by creating resource grants. However, for ease of administration and maintenance, resource grants can also be defined as entitlement grants, in which case multiple securable application artifacts are aggregated into a named security group that can be granted to application roles using a single statement. For example, when you want to authorize access to the data exposed in the application by ADF Business Components entity objects, multiple entity objects may require the same security policy. Instead of individually granting access privileges to each entity object, you can group the privileges as a set in an entitlement and grant them all at once.

You create entitlement grants in the Entitlements Grants page of the overview editor for security policies. The grants you create will appear as metadata in the policy store section of the `jazn-data.xml` file. This metadata defines an entitlement (identified in the XML definition as `<permission-set>`) comprised of resource instance /action pairs that you select. This entitlement is a grantable entity that you then grant to an application role.

The list of resource types appears in the overview editor for security policies. The resource type you select filters the resource instances defined within the projects of your application's workspace. The resource type selection also determines the list of available actions displayed by the overview editor. For example, when you select the **Task Flow Permission** resource type, the overview editor will display all of the task

flows in the user interface projects that you select and also displays the **view** action that you can associate with the available ADF bounded task flow resources.

[Table 30–10](#) lists the resource types displayed in JDeveloper and identifies the associated resource and supported actions for each type.

**Table 30–10 Resource Types of Securable Oracle ADF Artifacts**

Resource Type	Supports These Resources and Actions
Task Flow	Defines view actions on ADF bounded task flows in a user interface project that you select.
Web Page	Defines view actions on regions and web pages backed by ADF page definition files in a user interface project that you select.
ADF Entity Object	Defines read, update, and delete actions on entity objects in a data model project that you select.
ADF Entity Object Attribute	Defines update actions on entity object attributes of a specific entity object in a data model project that you select.

To define an entitlement grant for a securable Oracle ADF artifact, use the Entitlement Grants page of the overview editor for security policies.

**Before you begin:**

You will need to complete this task:

- Create application roles, as described in [Section 30.4, "Creating Application Roles."](#)

**To define an entitlement grant for an Oracle ADF artifact:**

1. In the main menu, choose **Application** and then **Secure > Entitlement Grants**.
2. In the Entitlement Grants page of overview editor for security policies, click the **Add Entitlements** icon in the **Entitlements** section.

The overview editor displays all the resources that your application defines.

3. In the Entitlement Grants page, click the **Resources** tab and then click the **Add Member Resource** icon to add a member resource to the entitlement.

4. In the Select Resources dialog, select the resource from the **Resource Type** dropdown and then select the desired project in the **Source Projects** section.

The dialog displays all the projects in your application workspace.

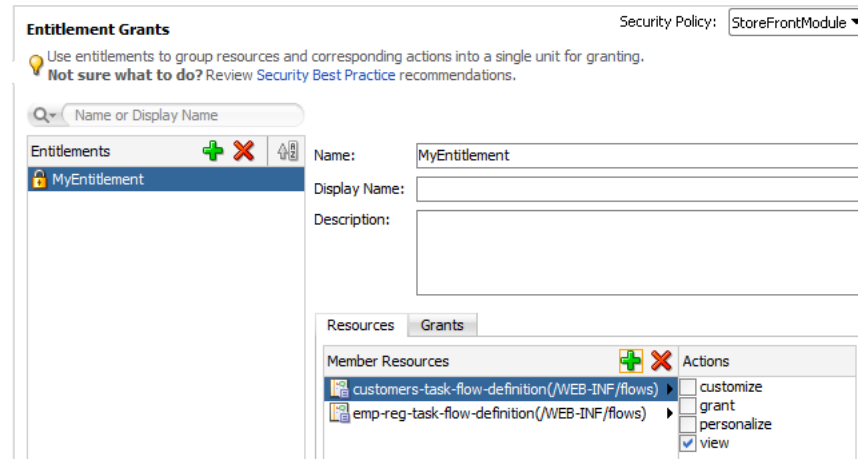

5. In the **Available Resources** section, select the resource and click the **Add** icon.

The dialog displays all the resources define by your selected project.

6. In the **Actions** lists, select the desired action for the selected resource.

[Figure 30–14](#) shows the overview editor with the **View** action selected for the task flow and added to **MyEntitlement**.

**Figure 30–14 Adding a Bounded Task Flow as a Resource in an Entitlement Grant**

7. Add other desired resources to the list.
8. In the Entitlement Grants page, click the **Grants** tab and then click the **Add Role Grants** icon to grant the entitlement to an application role.
9. In the Select Application Roles dialog, select one or more custom application roles.  
The dialog displays all the application roles from the `jazn-data.xml` file. You must not add a grant to a predefined application role (also called *duty roles* in the terminology of Oracle Fusion Applications). Only select custom application roles that either you created in JDeveloper or that were created by an IT security manager for this purpose.
10. Click **OK**.
11. You can repeat these steps to add other resources and make grants on those resources to the same entitlement for the same custom application role.

### 30.5.13 What Happens After You Create an Entitlement Grant

When you use the security policy editor in JDeveloper to create an entitlement grant, JDeveloper modifies the source for the application policy store in the `jazn-data.xml` file. The policy store section of the file contains a `<resource-type>` definition (that identifies the actions supported for resources of the selected type), a `<resource>` definition (to identify the resource instance that you selected from your application and mapped to a resource type), a `<permission-set>` definition (to define the resources and actions to be granted as an entitlement), and a `<grant>` definition with one or more entitlements (defined in the XML as a permission set) granted to the desired application roles (the grantee).

As [Example 30–11](#) shows, entitlement-based security policies in the Oracle Fusion application are defined in the `<jazn-policies>` element and consist of one or more entitlements granted to a single application role.

#### **Example 30–11 Entitlement-Based Policy Definition in the `jazn-data.xml` File**

```
<?xml version="1.0" ?>
<jazn-data>
  <policy-store>
    <applications>
      <application>
        <name>MyApp</name>
```

```

<app-roles>
  <app-role>
    <name>AppRole</name>
    <display-name>AppRole display name</display-name>
    <description>AppRole description</description>
    <guid>F5494E409CFB11DEBFEB11296284F58</guid>
    <class>oracle.security.jps.service.policystore.ApplicationRole</class>
  </app-role>
</app-roles>

<role-categories>
  <role-category>
    <name>MyAppRoleCategory</name>
    <display-name>MyAppRoleCategory display name</display-name>
    <description>MyAppRoleCategory description</description>
  </role-category>
</role-categories>

<!-- resource-specific OPSS permission class definition -->

    </permission-set-ref>
  </permission-set-refs>
</grant>
</jazn-policy>
</application>
</applications>
</policy-store>
</jazn-data>

```

## 30.6 Creating Test Users

JDeveloper provides editors to help you create both the identity and the policy stores. You create both repositories in an application-specific `jazn-data.xml` file. The editor for the identity store section of the file lets you enter the list of valid user IDs and their assigned passwords. The same editor lets you create application roles and assign the test users or enterprise roles as members of the application roles. Once defined, this information appears in the policy store section of the `jazn-data.xml` file.

### 30.6.1 How to Create Test Users in JDeveloper

You seed the identity store of your application with a temporary set of users to simulate the actual users' experience in your production environment. When you run the application in Integrated WebLogic Server, you can log in as any test user and be conferred access rights to view the secure ADF resources of your application.

You can use the identity store to organize users into enterprise roles. Because you typically will configure JDeveloper's deployment options to prevent migrating the identity store to a staging environment, enterprise roles that you create in the `jazn-data.xml` file are for convenience only. For more details about the use of enterprise roles, see [Section 30.4.3, "What You May Need to Know About Enterprise Roles and Application Roles."](#)

---

---

**Caution:** If you choose to deploy the identity store to your standalone server, you must not create users and enterprise roles in your local identity store that are already configured for Oracle WebLogic Server. For example, if you were to deploy the identity store with the user `weblogic` and enterprise role `Administrators`, you would overwrite the default administration configuration on the target server. For a complete list of global roles that Oracle WebLogic Server installs by default, see *Oracle Fusion Middleware Securing Resources Using Roles and Policies for Oracle WebLogic Server*.

---

---

To enable the user to view resources, you make grants against application roles rather than against the users who are the members of those roles. Therefore, after you seed the identity store with test users, you must associate each user or enterprise role group with an application role. This association confers the access rights defined by ADF security policies to users. For details about conferring access rights to users, see [Section 30.6.3, "How to Associate Test Users with Application Roles."](#)

**To create test users and groups:**

1. In the main menu, choose **Application** and then **Secure > Users**.
2. In the Users page of the overview editor for security policies, select the realm for your application from the **Realm** dropdown list and perform the following steps.

JDeveloper uses the realm `jazn.com` by default.

  - a. In the **Users** list, click the **New User** icon.
  - b. In the **Name** field, enter the user name.

You should avoid choosing a user name already configured for Oracle WebLogic Server (for example, do not enter `webcenter`). For the list of user names installed by Oracle WebLogic Server, see *Oracle Fusion Middleware Securing Resources Using Roles and Policies for Oracle WebLogic Server*.
  - c. In the **Password** field, enter the password for the user and click any other field to add the password to the identity store.

The password must contain at least eight characters and at least one of the characters must be a special character (such as `!`, `%`, `^`, `&`, `$` and so on).
3. Optionally, in the overview editor for security policies, click the **Enterprise Roles** navigation tab, select the realm for your application from the **Realm** dropdown list and perform the following steps.

You create enterprise roles only when you want to organize users into groups that you will add to an application role. For the purpose of creating test users to run the application using Integrated WebLogic Server, you do not need to create enterprise role groups.

  - a. In the **Enterprise Roles** list, click the **New Role** icon.
  - b. In the **Name** field, enter the name of the enterprise role and click any other field to add the role to the identity store.

If you create enterprise role groups, you should avoid choosing a role name that is already configured for Oracle WebLogic Server (for example, do not enter `Administrators`). For a complete list of the default group names installed by Oracle WebLogic Server, see *Oracle Fusion Middleware Securing Resources Using Roles and Policies for Oracle WebLogic Server*.

## 30.6.2 What Happens When You Create Test Users

When you provision the identity store with user identities and enterprise role groups, JDeveloper updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The dialog writes the user information to the `<jazn-realm>` section of the file corresponding to the identity store. Each user identity has a user name and a user login password. Each enterprise role contains one or more member users.

[Example 30–12](#) shows the identity store in the `jazn-data.xml` file with two users and two enterprise roles. The users `ahunold` and `sking` are both members of the `fod-users` enterprise role, while only `sking` is a member of the `fod-admin` enterprise role.

### **Example 30–12** Users and Enterprise Roles in the Application-Level Identity Store

```
<jazn-data>
  <jazn-realm default="jazn.com">
    <realm>
      <name>jazn.com</name>
      <users>
        <user>
          <name>sking</name>
          <guid>09FC5C61F68111DCAF1DB790A6B3BAC5</guid>
          <credentials>{903}A0VQ5ozADte7EKIJzcTi6xMZ7YDpRXY5</credentials>
        </user>
        <user>
          <name>ahunold</name>
          <guid>09FEA650F68111DCAF1DB790A6B3BAC5</guid>
          <credentials>{903}/SQSrKZYCLW068VJpHaodILd48mJI47w</credentials>
        </user>
        ...
      </users>
      <roles>
        <role>
          <name>fod-users</name>
          <guid>0A084340F68111DCAF1DB790A6B3BAC5</guid>
          <members>
            <member>
              <type>user</type>
              <name>sking</name>
            </member>
            <member>
              <type>user</type>
              <name>ahunold</name>
            </member>
            ...
          </members>
        </role>
        <role>
          <name>fod-admin</name>
          <guid>0A0CFE30F68111DCAF1DB790A6B3BAC5</guid>
          <members>
            <member>
              <type>user</type>
              <name>sking</name>
            </member>
            ...
          </members>
        </role>
      </roles>
    </realm>
  </jazn-realm>
</jazn-data>
```

```
    ...
    </roles>
  </realm>
  ...
</jazzn-realm>
</jazzn-data>
```

### 30.6.3 How to Associate Test Users with Application Roles

Because the ADF Security framework enforces a role-based access control mechanism with permissions granted to application roles, you define a set of roles in the policy store that are specific to your application. For example, in the context of the work flow, there may be roles such as customer, product specialist, supervisor, and administrator.

After you create an application role, you can proceed to associate users that you created in the identity store with one or more roles. At runtime, users who are members of an application role will be conferred the access rights of their application roles. You can assign a user to more than one application role when you want to confer the right of multiple resource grants to a particular user.

For example, one authenticated user might belong to the supervisor role and an employee role, while another user might belong only to the employee role. The security policy for a bounded task flow that permits customer records to be browsed and edited may confer view permission to the supervisor role and limit view permission to the browse page for the employee role. Thus, grants to application roles support multiple levels of access. If the authenticated user is not a member of an application role with a view permission grant for the target ADF resource, the security framework will return an unauthorized user message.

#### Before you begin:

1. Run the Configure ADF Security wizard, as described in [Section 30.3, "Enabling ADF Security."](#)
2. Create application roles, as described in [Section 30.4, "Creating Application Roles."](#)
3. Define security policies for ADF security-aware resources, as described in [Section 30.5, "Defining ADF Security Policies."](#)
4. Create test users, and, optionally, create enterprise role groups, as described in [Section 30.6.1, "How to Create Test Users in JDeveloper."](#)

#### To associate users with application roles:

1. In the main menu, choose **Application** and then **Secure > Application Roles**.
2. In the Application Roles page of the overview editor for security policies, select the policy store for your application from the **Security Policy** dropdown list.

The policy store that JDeveloper creates in the `jazzn-data.xml` file are automatically based on the name of your application.

3. In the **Roles** list, select an existing application role and complete these tasks as appropriate:
  - a. In the **Mappings** section, click the **Add User or Role** icon dropdown menu and choose **Add User**, then in the Select Users dialog select the previously created user from the list and click **OK**.
  - b. Optionally, if you have defined enterprise roles in the identity store, in the **Mappings** section, click the **Add User or Role** icon dropdown menu and

choose **Add Enterprise Role**, then in the Select Enterprise Roles dialog select the previously created enterprise role from the list and click **OK**.

### 30.6.4 What Happens When You Configure Application Roles

When you associate users with application roles, JDeveloper updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The dialog writes the user information to the `<policy-store>` section of the file. Each application role contains one or more member users or enterprise roles.

[Example 30-13](#) shows the policy store in the `jazn-data.xml` file with the `fod-users` application role, which contains two members, `sking` and `ahunold`.

#### **Example 30-13** Users Associated with Application Roles in the Application-Level Policy Store

```
<policy-store>
  <applications>
    <application>
      <application>
        <name>StoreFrontModule</name>
        <app-roles>
          <app-role>
            <name>fod-users</name>
            <display-name>FOD Users</display-name>
            <class>oracle.security.jps.service.policystore.ApplicationRole</class>
            <members>
              <member>
                <class>oracle.security.jps.internal.core.principals.JpsXmlUserImpl</class>
                <name>sking</name>
              </member>
              <member>
                <class>oracle.security.jps.internal.core.principals.JpsXmlUserImpl</class>
                <name>ahunold</name>
              </member>
              ...
            </members>
          </app-role>
          ...
        </app-roles>
      </jazz-policy>
      ...
    </jazz-policy>
  </application>
</applications>
</policy-store>
```

## 30.7 Creating a Login Page

ADF Security allows for implicit and explicit authentication:

- In an *implicit authentication* scenario, if a user who is not yet authenticated tries to access a web page associated with ADF security-aware resources that are not granted to `anonymous-role`, then authentication is triggered dynamically. After the user successfully logs in, another check will be done to verify whether the authenticated user has view access granted on the requested page's ADF security-aware resource.
- In an *explicit authentication* scenario, your application has a public page that displays a login link, which, when clicked, triggers an authentication challenge to

log in the user. The login link may optionally specify some other target page that should be displayed (assuming the authenticated user has access) after the successful authentication.

The implicit and explicit authentication scenarios are handled for you by default when you run the Configure ADF Security wizard, as described in [Section 30.3.5, "What You May Need to Know About ADF Authentication."](#) However, when you customize the default, generated login page (or supply your own page) to use ADF Faces components, you will need to configure the container-managed deployment descriptor (`web.xml` file).

To explicitly handle user authentication:

---

---

**Note:** The following method of handling explicit authentication assumes that you will deploy the Fusion web application to Oracle WebLogic Server. The documented user interface for a JSF-based login page relies on programmatic authentication and uses APIs that are specific to Oracle WebLogic Server and the login process that it supports. This approach relies on programmatic authentication instead of Form-based authentication because it is the most compatible to use with custom login pages.

---

---

1. Create a login link component and add it to the public home web page for your application.
2. Create a managed bean using API specific to Oracle WebLogic Server to handle the login attempts by the user.
3. Create a JSF login page using ADF Faces components.
4. Ensure that the login page's resources are accessible.

For more information about implicit and explicit authentication, see [Section 30.8.4, "What Happens at Runtime: How ADF Security Handles Authentication."](#)

### 30.7.1 How to Create a Login Link Component and Add it to a Public Web Page for Explicit Authentication

You can create a standard login link component that can be added to any page in your application to enable users to authenticate or subsequently log off. This component keeps track of the authenticated state of the user and returns the appropriate login or logout URLs and icons. The login link component will redirect users back to a specific page once they are authenticated. Hence, using this login link component provides you with a single, consistent object.

To the unauthenticated user, the login link component will look similar to [Figure 30–15](#).

**Figure 30–15** *Component Before User Logs In*

Then when the user clicks the login link and logs in as a user with the appropriate credentials, the component will look similar to [Figure 30–16](#).

**Figure 30–16 Component After User Logs In****Before you begin:**

Copy your login and logout image files (GIF, JPG, or PNG files) to the `public_html` directory of your project.

---

**Note:** The images used should reference the appropriate skin image if your application uses skins. For more information about skins, see the "Customizing the Appearance Using Styles and Skins" chapter in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

---

**To create the login link component and add it to a page:**

1. In the Application Navigator, double-click the web page that will display the component.
2. In the ADF Faces page of the Component Palette, drag a **Go Image Link** component on the page.
3. In the Structure window, right-click `af:goImageLink` and choose **Go to Properties**.
4. In the Property Inspector, to specify the label for the Go Image Link component, enter an Expression Language (EL) expression in the **Text** field.

For example, you can enter an EL expression similar to this to conditionally render the link text:

```
#{securityContext.authenticated ? '&quot;Click to log out&quot;' :
    '&quot;Click to log in&quot;}'
```

The `authenticated` property of the `securityContext` bean will evaluate to true and render the log out option if the current user is authenticated. Otherwise, the link is rendered with the login option.

5. In the Property Inspector, to specify the URL for the Link component, enter an EL expression in the **Destination** field.

For example, this EL expression conditionally renders a URL to forward the user depending on whether or not they are authenticated:

```
#{securityContext.authenticated ?
    '&quot;/adfAuthentication?logout=true&amp;end_url=/faces/welcome&quot;' :
    '&quot;/adfAuthentication?success_url=/faces/welcome&quot;}'
```

When the user clicks the link, the URL parameters `end_url` and `success_url` forward the destination of the target page to the ADF authentication servlet. Note that the view activity name is passed on the URL parameters instead of the web page name. This ensures control flow rules are enforced for page navigation after login. The `authenticated` property of the `securityContext` bean will evaluate to true and forward to the welcome page if the current user is authenticated. When the user is not authenticated, there is no need to forward to the login page because the ADF authentication servlet triggers log in, which is handled by the container-managed security configuration. Note that log out is handled by the ADF authentication servlet which invalidates the session.

- In the Property Inspector, to specify the link component image for the Go Image Link component, enter an EL expression in the **Icon** field.

For example, this EL expression conditionally renders the link component image as the lock GIF if the user is not authenticated; otherwise, renders the image with the key GIF:

```
#{securityContext.authenticated ? '/images/lock.gif' : '/images/key.gif'}
```

Figure 30–17 shows how the login link component appears when added to the global menu facet of the page.

**Figure 30–17 Login Link Component on the Page**

## 30.7.2 How to Create a Login Page Specifically for Explicit Authentication

The default login form that is generated for you when you run the Configure ADF Security wizard is provided as a convenience for testing your application within JDeveloper. The default form does not allow you to customize the page using ADF Faces components to match the user interface of the application. You can replace the default form with an ADF Faces-based login page that enables you to include customizable components, as shown in Figure 30–18.

**Figure 30–18 Login Page**

However, if designing a login page with ADF Faces components is not a requirement, then a simple JSP or HTML login page can be also used. For details about generating a simple login page when running the Configure ADF Security wizard, see [Section 30.3.1, "How to Enable ADF Security."](#)

### 30.7.2.1 Creating Login Code for the Backing Bean

Before you create the login page as an ADF Faces page, you need to create a managed bean to handle login attempts. In this login bean sample, authentication is handled programmatically using Oracle WebLogic Server-specific API for Basic authentication. Consequently, there is no need to invoke the ADF authentication servlet to redirect to a landing page upon login; the bean `doLogin()` method handles this task programmatically. You will add this bean to the `adf-c-config.xml` file and register it with `request` scope.

Note that the Oracle WebLogic Server API used in this backing bean sample can also be used when you want to perform authentication from the user's current page (for example, from a home page) and do not want the application to navigate off the current page to display a login page.

---

---

**Note:** Note that the backing bean you will create in this procedure relies on APIs that are specific to Oracle WebLogic Server and the login process that it supports. Only use this procedure when you will deploy the Fusion web application to Oracle WebLogic Server.

---

---

### Before you begin:

It may be helpful to have an understanding of the login page. For more information, see [Section 30.7.2, "How to Create a Login Page Specifically for Explicit Authentication."](#)

You will need to complete this task:

- In the user interface project where you create the backing bean for login, import the following library into your project:

- WebLogic 10.3 Remote-Client

To import the library, double-click the user interface project node in the Application Navigator. In the Project Properties dialog, select **Libraries and Classpath** and then click **Add Library**. In the Add Library dialog, expand the **Extensions** node and scroll to locate the **WebLogic 10.3 Remote-Client** library to add. This library will allow the user interface project to compile and resolve the following import statements from the backing bean code sample.

```
import weblogic.security.URLCallbackHandler;
import weblogic.servlet.security.ServletAuthentication;
```

For details about creating a library and adding it to a project, refer to the JDeveloper online help.

### To create and register a backing bean for login:

1. In the Application Navigator, under the user interface project, right-click your application and choose **New**.
2. In the New Gallery, expand **General**, select **Java** and then **Java Class**, and click **OK**.
3. In the Create Java Class dialog, enter the name for the login page backing bean class file and disable the default options **Constructors from Superclass** and **Implement Abstract Methods**, and click **OK**.

For convenience, you might name the backing bean based on the name of your login page, for example, *LoginPageName.java*.

4. In the Applications Navigator, expand **Application Sources** and double-click the new *LoginPageName.java* backing bean.
5. In the source editor, create two private fields by adding the following in the declaration section of the *LoginPageName.java* file:

```
private String _username;
private String _password;
```

6. Generate or create public accessors for both fields.

You can right-click in the source editor and choose **Generate Accessors** to add the following public accessors to the file:

```
public void setUsername(String _username) {
    this._username = _username;
```

```
    }

    public String getUsername() {
        return _username;
    }

    public void setPassword(String _password) {
        this._password = _password;
    }

    public String getPassword() {
        return _password;
    }
}
```

7. Add a `doLogin()` method to this Java class to handle user attempts to log in:

```
1 public String doLogin() {
2     String un = _username;
3     byte[] pw = _password.getBytes();
4     FacesContext ctx = FacesContext.getCurrentInstance();
5     HttpServletRequest request =
6         (HttpServletRequest)ctx.getExternalContext().getRequest();
7     try {
8         CallbackHandler handler = new URLCallbackHandler(un, pw);
9         Subject mySubj =
10             weblogic.security.services.Authentication.login(handler);
11         weblogic.servlet.security.ServletAuthentication.runAs(mySubj, request);
12         ServletAuthentication.generateNewSessionID(request);
13         String loginURL = "faces/mylandingpage.jspx";
14         sendForward(loginURL);
15     } catch (FailedLoginException fle) {
16         FacesMessage msg = new FacesMessage(FacesMessage.SEVERITY_ERROR,
17             "Incorrect Username or Password",
18             "An incorrect Username or Password" +
19             " was specified");
20         ctx.addMessage(null, msg);
21         setPassword(null);
22     } catch (LoginException le) {
23         reportUnexpectedLoginError("LoginException", le);
24     }
25     return null;
26 }
```

The `doLogin()` method performs the following tasks:

**Lines 4-6** get an object encapsulating the HTTP request from the `FacesContext`.

**Line 8** creates a `CallbackHandler`, which is an object that retrieves information for security operations. A `URLCallbackHandler` allows security operations to retrieve the username and password that were passed to its constructor; other `CallbackHandler` implementations can obtain the username and password from another source.

**Line 9-10** creates a `Subject`, which is an object that encapsulates credentials, from the information provided by the `CallbackHandler`.

**Line 11** attempts to log in the user issuing the request using the credentials encapsulated by the `Subject`.

**Line 12** ensures that the session ID for the session is changed after the user is successfully authenticated. This is necessary to prevent leaving the application open to a session fixation attack, which would be a security vulnerability.

**Lines 13** constructs a URL to which to forward the user after successful login. Note that in this login bean sample, authentication is being handled entirely by Oracle WebLogic Server. Because the sample is platform-specific, there is no need to invoke the ADF authentication servlet to redirect after login. Enabling the ADF Security authentication servlet is useful when you need to implement platform-independent, Java EE container-managed login and wish to implement implicit authentication.

**Line 14** calls a method, `sendForward()`, which you will implement later in this section to forward the user to the URL specified in Line 13.

**Lines 15-21** handle a `FailedLoginException`, which is the exception thrown when the credentials supplied are incorrect. The lines handle the exception by adding a new message to the `FacesContext`.

**Lines 22-23** handle a `LoginException`, which can be thrown by many different problems with a login. For example, exceptions can result from incorrect credentials or attempts to log into a locked account or uses of an expired password. `FailedLoginException` is a subclass of `LoginException`, but since a `FailedLoginException` will be caught by Line 17, these lines will only be executed when there are login problems other than incorrect credentials. `reportUnexpectedLoginError()` is a method which you will implement to deal with miscellaneous problems with the login process.

**Line 25** returns null so that ADF Controller will not attempt to follow a control flow case.

#### 8. Import the following classes:

```
javax.faces.application.FacesMessage
javax.faces.context.FacesContext
javax.security.auth.Subject
javax.security.auth.callback.CallbackHandler
javax.security.auth.login.FailedLoginException
javax.security.auth.login.LoginException
javax.servlet.http.HttpServletRequest
weblogic.security.URLCallbackHandler
weblogic.servlet.security.ServletAuthentication
```

#### 9. Create stubs for the methods `sendForward()` and `reportUnexpectedLoginError()`.

#### 10. Add a `sendForward()` method with its actions:

```
1 private void sendForward(String forwardUrl) {
2     FacesContext ctx = FacesContext.getCurrentInstance();
3     try {
4         ctx.getExternalContext().redirect(forwardUrl);
5     } catch (IOException ie) {
6         reportUnexpectedLoginError("IOException", ie);
7     }
8     ctx.responseComplete();
9 }
```

The `sendForward()` method performs the following tasks:

**Line 2** gets the ADF Faces `ctx`, which forwards a response to a particular URI.

**Lines 3-4** uses the `ctx` to redirect the current HTTP response to the URL.

**Lines 5-6** handle an `IOException`, which is thrown when the request cannot be read or the response cannot be written to.

**Line 8** marks the HTTP response as complete so that the browser can finish rendering it.

11. Import the following classes:

```
javax.servlet.RequestDispatcher
javax.servlet.ServletException
java.io.IOException
```

12. Implement a `reportUnexpectedLoginError()` method:

```
private void reportUnexpectedLoginError(String errType, Exception e){
    FacesMessage msg =
        new FacesMessage(FacesMessage.SEVERITY_ERROR, "Unexpected error
            during login",
            "Unexpected error during login (" + errType + "),
            please consult logs for detail");
    FacesContext.getCurrentInstance().addMessage(null, msg);
    FacesContext.getCurrentInstance().renderResponse();
}
```

This `reportUnexpectedLoginError()` method adds a summary error message to the `FacesContext`, and then prints the full stack trace of the exception to the console.

13. Save the Java file.
14. In the Application Navigator, double-click the `adfc-config.xml` file in the **WEB-INF** folder.
15. In the editor window for the `adfc-config.xml` file, click the **Overview** tab.
16. In the overview editor for task flows, click the **Managed Beans** navigation tab.
17. In the Managed Beans page, in the **Managed Beans** section click the **Add** icon and enter a name for the bean, enter the fully qualified class name, and select `request` scope.

For example, the class name might look like `oracle.foddemo.security.Login`, as shown in [Figure 30–19](#).

**Figure 30–19 Login Bean Registered in `adfc-config.xml` File**

18. Save all.

### 30.7.2.2 Creating an ADF Faces-Based Login Page Specifically for Explicit Authentication

A simple login page that utilizes ADF Faces layout components and ADF Faces user interface components includes two input fields and a button. You must bind the properties of these UI components to the login handler methods that you defined in the managed bean for the login page.

Note that the page that you can create with this procedure does not support implicit authentication. When you choose to implement implicit authentication, you can customize the default, wizard-generated login form which supports container-managed authentication. The Java EE container expects a form that relies on the `j_security_check` mechanism to handle user-submitted `j_username`, and `j_password` input. In the explicit authentication scenario documented here, Java EE container-managed authentication is not used.

#### Before you begin:

Create the managed bean to handle the user's login attempts, as described in [Section 30.7.2.1, "Creating Login Code for the Backing Bean."](#)

#### To create the ADF Faces-based login page for explicit authentication:

1. In the Application Navigator, under the user interface project, right-click your application and choose **New**.
2. In the New Gallery, expand **Web Tier**, select **JSF** and then **JSF Page**, and click **OK**.
3. In the Create JSF Page dialog, select **Create as XML Document (\*.jspx)**.
4. In the **File Name** field, specify a name for your login page. For example, enter `LoginPage.jsxpx`.

Select no other options and do not select the option to expose UI components in a managed bean. You will manually bind the components to the managed bean you created for the login page.

5. Click **OK**.
6. Save the page.
7. In the ADF Faces page of the Component Palette, from the Layout panel, drag a **Panel Box** and drop it on the Structure window below the **af:form** node.
8. In the Property Inspector, enter values for the **Text**, **Horizontal**, **Width**, and **Height** fields.

For example, to create a basic login page, you can enter:

**Text** set to `Login Information`

**Icon** set to `/images/key_ena.png`

**Width/Height** set to `300/200` pixels

9. From the Component Palette, drag a **Panel Form Layout** and drop it below the **af:panelBox** node in the Structure window, as shown in [Figure 30–20](#).

**Figure 30–20 Login Page Structure with Panel Form Layout**

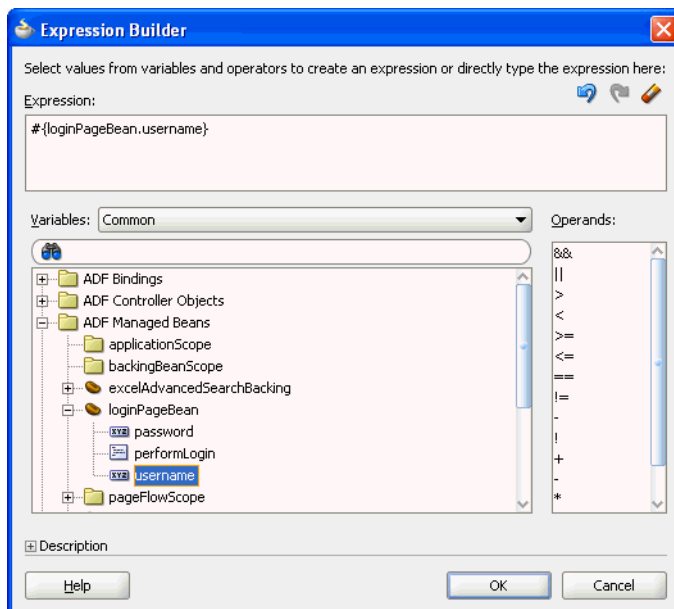

10. From the Common Components panel, drag an **Input Text** and drop it on the **Panel Form Layout** node for the username field and another **Input Text** for the password field.

11. In the Property Inspector for the input fields, enter `Username` and `Password` in the **Label** fields and expand the **Behavior** section and select **true** from both fields' **Required** dropdown list.
12. In the Property Inspector, for the password field, expand the **Appearance** section select **true** from the **Secret** dropdown list.
13. To handle processing of the values for the two input fields, perform these steps for each field:
  - a. In the Structure window, select one of the input fields (for example, select the **af:inputText - Username** node), and then in the Property Inspector, click the **Property Menu** dropdown menu next to the **Value** field and choose **Expression Builder**.
  - b. In the Expression Builder, expand **ADF Managed Beans** and expand your login bean, and then select the expression value corresponding to your bean's handler method.

For example, if you selected the **username** input field in the Structure window, then you would select **username** from the Expression Builder dialog, as shown in [Figure 30–21](#).

**Figure 30–21** *username Selection in Expression Builder Dialog*

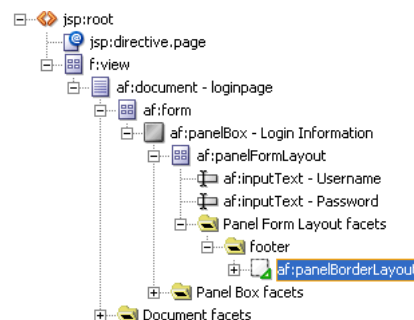

- c. Click **OK**.

The expression shown in the Property Inspector binds the field to the managed bean you created for the login page. For example, for the username input field, the expression is similar to `# {loginPageBean.username}` as shown in [Figure 30–22](#).

**Figure 30–22** *username Value in Property Inspector*

14. From the Component Palette from the Layout panel, drag a **Panel Border Layout** and drop it inside the **footer** node of the **af:panelBox** node, as shown in [Figure 30–23](#).

**Figure 30–23** *Login Page Structure with Panel Border Layout*

15. In the JSP/HTML visual editor, delete the panel border layout facets labeled **End**, **Top**, and **Bottom**. Leave only the **Start** facet.
16. In the Structure window, expand **Panel Border Layout facets** and select the **start** node, and then from the Component Palette drag and drop a **Button**.
17. In the Property Inspector, enter **Login** in the button component's **Text** field.
18. To handle processing of the login button action, perform these steps.
  - a. In the Structure window, select the login **af:commandButton** node under the **start** node, and then in the Property Inspector, click the **Property Menu** dropdown menu next to the **Action** field and choose **Expression Builder**.
  - b. In the Expression Builder, expand **ADF Managed Beans** and expand your login bean, then select the expression value corresponding to your login method.  
  
For example, if you created a method in the login bean named `doLogin()`, then you would select **doLogin** in the Expression Builder dialog.
  - c. Click **OK**.

The expression shown in the Property Inspector binds the button to the managed bean you created for the login page. For example, for the login button, the expression is similar to `#{loginPageBean.doLogin}` as shown in [Figure 30–24](#).

**Figure 30–24** *login Action in Property Inspector*

19. Save the page.

### 30.7.2.3 Ensuring That the Login Page Is Public

Because the application is secured by ADF Security, all web pages defined within bounded task flows and any web page defined by an ADF page definition will be inaccessible by default. Since all users must be allowed to log on, the login page should remain publicly accessible, and thus you should add no databound components to the page. As long as the login page uses no databound components, then it will be accessible by default.

No further steps are required to ensure that the container will always redirect to the defined authentication point before allowing access to the page (which in this case is the authentication page).

## 30.7.3 How to Ensure That the Custom Login Page's Resources Are Accessible for Explicit Authentication

When you run the ADF Security wizard and choose the **ADF Authentication** option (because you do not want to enable ADF authorization) and your application uses a custom login page or a custom error page, you may need to edit the default Java EE security constraint added to the `web.xml` file by ADF Security. As shown in [Example 30–14](#), the default URL pattern (`/*`) defined in the `allPages` security constraint covers everything under the Java EE application root, meaning that the resource files (such as images, style sheets, or JavaScript library) used by the login page are also included.

### **Example 30–14** *Java EE Security Constraint for ADF Authentication Only*

```
<security-constraint>
  <web-resource-collection>
    <web-resource-name>allPages</web-resource-name>
    <url-pattern>/*</url-pattern>
  </web-resource-collection>
  <auth-constraint>
    <role-name>valid-users</role-name>
  </auth-constraint>
</security-constraint>
```

If the pages you create use resources, such as images, CSS files, or JavaScript libraries, the default `allPages` security constraint in the `web.xml` file will prevent those resources from loading at runtime. To allow your application to display those resources, you should save the resources in a folder of their own and then edit the

`allPages` security constraint so that the resources folder is not contained in the URL pattern.

Note that this resource issue does not apply when you run the ADF Security wizard and choose the **ADF Authentication and Authorization** option (the default). Specifically, in that case, the default generated constraint is on the ADF Authentication servlet and the constraint (`/adfAuthentication`) excludes any resource files.

## 30.7.4 How to Create a Public Welcome Page

Because web applications are generally secured, there is always a need for a starting point or home page for unauthenticated users. To create this public welcome page, you create an ADF Faces page to act as the entry point for the application, which contains links to other pages within the application. However, only links to public pages should be rendered to unauthenticated users and, conversely, links to secured pages should be rendered only after the user has logged in and has the appropriate privileges to view the target page.

**Best Practice:** When the user presses Ctrl-N or Ctrl-T to open a new browser window or tab and no welcome page is defined in the application's `web.xml` file, the browser will display a 403 or 404 error. To prevent this error, you must specify a welcome page definition in the application's `web.xml` file. You can create this definition when you run the Configure ADF Security wizard. For details about running the wizard, see [Section 30.3.1, "How to Enable ADF Security."](#)

### 30.7.4.1 Ensuring That the Welcome Page Is Public

After you have created a regular ADF Faces page, the page will, by default, be public and accessible by unauthenticated users. If, however, you have associated the welcome page with an ADF resource, for example, by dropping databound ADF Faces components into the welcome page using the Data Controls panel, then ADF Security will secure the page by default. You can make any ADF resource publicly accessible using the overview editor for security policies to grant a view privilege on the resource to the provided `anonymous-role`. For details about the `anonymous-role` see, [Section 30.5.2, "What Happens When You Make an ADF Resource Public."](#)

### 30.7.4.2 Adding Login and Logout Links

You can add login and logout links to your public welcome page so that users can explicitly log in and out while they are in the application. While Java EE container-managed security supports the concept of authentication when accessing a secured resource, there is no standard way to log out and stay within a secured application. However, it is a common practice in web applications to allow the user to stay on the same page if that page is public or to return the user to the welcome page if that page is secured. While adding the login and logout links to each page would let the user end their login session anywhere within the application (and return to the welcome page), having these links on the welcome page enables users to explicitly authenticate on entering the application.

For example, you can create an ADF Faces panel group with three components, including an output text area, an image, and a go link. To render the appropriate login or logout link, you can use an EL expression that evaluates the user's authentication status. Specifically, you can use `securityContext.authenticated` to access the ADF security context, as shown in [Example 30-15](#). The expression evaluates to `true` or `false` and, in this example, the result determines which login/logout image and link to display. As [Example 30-15](#) shows, the `success_url` and `end_url` parameters

for the ADF authentication servlet are passed as the view activity `welcome` associated with the target page `welcome.jspx`. Passing the view activity name instead of the web page name for the URL parameters ensures the Fusion web application uses task flow control flow rules to handle page navigation.

### Example 30–15 ADF Faces Components and EL Expressions to Render Login/Logout Link

```
<af:panelGroupLayout inlineStyle="width:100%; height:15px;" id="ptpgl3">
  <af:spacer width="7" height="10" id="pts2"/>
  <af:outputText value="Welcome #{securityContext.userName}!"
    inlineStyle="font-weight:bold; width:100px" id="ptot2"
    rendered="#{securityContext.authenticated}"/>
  <af:image source="#{securityContext.authenticated ? '/images/lock.gif' : '/images/key.gif'}"
    id="pti2" inlineStyle="width:16px; height:16px;" shortDesc="switchable icon"/>
  <af:goLink text="#{securityContext.authenticated ? '&quot;Logout&quot;' : '&quot;Login&quot;'}"
    destination="#{securityContext.authenticated ?
      &quot;/adfAuthentication?logout=true&amp;end_url=/faces/welcome&quot; :
      &quot;/adfAuthentication?success_url=/faces/welcome&quot;}"
    inlineStyle="color:Blue; font-size:14px; font-weight:bold;"/>
  <f:facet name="separator">
    <af:spacer width="5" height="10" id="pts1"/>
  </f:facet>
</af:panelGroupLayout>
```

As an alternative to rendering the link directly within a page, you can create a login link component with the login and logout links that you can add to a page template, as described in [Section 30.7.1, "How to Create a Login Link Component and Add it to a Public Web Page for Explicit Authentication."](#)

#### 30.7.4.3 Hiding Links to Secured Pages

Since an anonymous user should not have access to any secured pages, any navigation component on the welcome page that points to a secured page should be hidden from view based on the following two criteria:

- Is the user authenticated with a known user identity?
- Does the specified user identity have permission to view the target?

If either of these criteria has not been met, the `rendered` attribute of any navigation component on a public page that points to a secured resource must have its `rendered` property set to `false`, thus hiding it from the anonymous user. To enforce these rules within your welcome page, see [Section 30.11.1, "Using Expression Language \(EL\) with ADF Security."](#)

#### 30.7.5 How to Redirect a User After Authentication

When you have chosen to implement implicit authentication, after the user accesses a secured web page and logs in, the ADF authentication servlet will redirect back to the original page that initiated the login request. With ADF Security authentication enabled, the ADF authentication servlet automatically passes the original page as the ADF authentication `success_url` parameter on the URL. Typically, this is the desired behavior. However, when you display an explicit login link in your page, the destination of the target will typically be a secured page. You ensure the ADF Authentication servlet redirects to the secured page after authentication by passing the view activity name of the web page as the servlet `success_url` parameter, as shown in [Example 30–16](#).

**Example 30–16 Explicit Login Link with `success_url` in a Web Page**

```
<af:goLink text="Login" destination="/adfAuthentication?success_url=/faces/viewactivityname"/>
```

Additionally, you can specify the `success_url` parameter as an `<init-param>` within the `web.xml` file to handle any cases where it is not possible to redirect to the original page. Thus, when the user accesses the secured web page and gets redirected to log in, the framework automatically passes the original page as the `success_url` parameter on the URL, which supersedes any `web.xml` setting. Therefore, in practice the only scenario in which an `<init-param>` setting in `web.xml` takes effect is when the user explicitly types the `adfAuthentication` URL into the browser.

In cases where the user is authenticated but not authorized to view a web page, you can redirect the ADF authentication servlet to an error page in your application. Error handling in Fusion web applications is under the control of the ADF Controller exception handler unless you have created an application that does not use a task flow in its design. For example, in an unbounded task flow, where you have defined an unbounded task flow with a top-level welcome page and a browse page (secured through its ADF page definition), you would see an error page from the application, named `authorizationErrorPage.jspx`, specified in the `adfc-config.xml` file, as shown in [Example 30–17](#).

**Example 30–17 Error Page Redirect for Applications That Use Task Flows**

```
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <exception-handler>authorizationErrorPage</exception-handler>
  <view id="welcomePage">
    <page>/welcomePage.jspx</page>
  </view>
  <view id="browse">
    <page>/browse.jspx</page>
  </view>
  <view id="authorizationErrorPage">
    <page>/authorizationErrorPage.jspx</page>
  </view>
  <control-flow-rule>
    <from-activity-id>welcomePage</from-activity-id>
    <control-flow-case>
      <from-outcome>goToSecuredPage</from-outcome>
      <to-activity-id>browse</to-activity-id>
    </control-flow-case>
  </control-flow-rule>
</adfc-config>
```

For details about how to specify an error page as a view activity for the ADF Controller exception handler, see [Section 18.7, "Handling Exceptions in Task Flows."](#)

In cases where the user is not authenticated and an authorization failure occurs, the framework redirects to the ADF authentication servlet, which in turn triggers a Java EE constraint that prompts for login. In this case, container-managed security relies on the login page and error page that you specify in the `<login-config>` element of the `web.xml` file.

If you create a Fusion web application without utilizing task flows, then you can specify an `<init-param>` setting in `web.xml` for the ADF binding filter, as shown in [Example 30–18](#). In this case, when no task flow is present in the application, page authorization checking is handled by the ADF binding filter, and the `unauthorizedErrorPage` parameter will be passed to the ADF binding request handler.

---

---

**Note:** The `unauthorizedErrorPage` parameter feature is provided for compatibility with previous releases where ADF Controller was not available. In Fusion web applications, when you need to redirect users to an error page, you use the task flow exception handler to specify the error page, as shown in [Example 30–17](#).

---

---

**Example 30–18 Error Page Redirect for Applications That Don't Use Task Flows**

```
<filter>
  <filter-name>adfBindings</filter-name>
  <filter-class>oracle.adf.model.servlet.ADFBindingFilter</filter-class>
  <init-param>
    <param-name>unauthorizedErrorPage</param-name>
    <param-value>faces/authorizationErrorPage.jsp</param-value>
  </init-param>
</filter>
```

### 30.7.6 How to Trigger a Custom Login Page Specifically for Implicit Authentication

When you have chosen to implement implicit authentication to allow users to access protected resources (which may be by direct URL access or by navigating to an ADF Security protected resource), the ADF Security authentication servlet initiates the Java EE container to display the login form configured in the `web.xml` file. For implicit authentication, when you have customized the default, wizard-generated login form to use ADF Faces components, you must modify the URL pattern for the servlet mapping to reference the ADF Faces servlet.

You can accomplish this in the Authentication Type page of the Configure ADF Security wizard when you configure ADF Security, or in the `web.xml` file directly. If you have already run the Configure ADF Security wizard, you can use the following procedure to confirm that the `web.xml` file has been updated as described.

When you have choose to implement explicit authentication and have created a public page to allow users to login to access protected resources, the login form you create will not be triggered by ADF Security. In the explicit authentication scenario, you do need to configure the `web.xml` file.

---

---

**Caution:** Configuring the `web.xml` file when your application implements explicit authentication programmatically and you have created a login page, as described in [Section 30.7.2.2, "Creating an ADF Faces-Based Login Page Specifically for Explicit Authentication"](#) may produce unpredictable results and login may fail. Only modify the `web.xml` file when you are implementing implicit authentication and you have created a form that relies on the `j_security_check` action, as does the default, wizard-generated login form.

---

---

**To reference an ADF Faces login page for implicit authentication:**

1. In the Application Navigator, expand **WEB-INF** and double-click **web.xml**.
2. In the overview editor for the `web.xml` file, click the **Security** navigation tab.
3. In the Security page, expand the **Login Authentication** section, and set the login page to include a reference to the ADF Faces servlet such that the login page can be part of the ADF Faces lifecycle / `faces/ADFlogin.jsp` page.

When you add a page using the file browser, the path entered in the `web.xml` file will not specify `/faces`. Modify the entry so that the path references the servlet mapping path for the ADF Faces servlet. For example, if the URL pattern specified by the mapping is `/faces/*`, then your path should look like `/faces/yourpage.jspx`, as shown in [Figure 30-25](#).

**Figure 30-25 Adding a Reference to the Faces Servlet in the Login Configuration**

### 30.7.7 What You May Need to Know About ADF Servlet Logout and Browser Caching

When basic type authentication is in effect as specified in the application's `web.xml` file, the browser caches authentication credentials. This is a known issue with basic authentication that re-authenticates users after the logout redirect is performed by the ADF authentication servlet. In this scenario, in order to complete the logout session and prevent users from accessing resources, it is necessary to close the browser and restart a new browser session.

To ensure the ADF application completes logout and prevents a user from being able to access resources after logout, use form-based authentication instead of basic authentication. You can select form-based authentication when you run the Configure ADF Security wizard, as described in [Section 30.3.1, "How to Enable ADF Security."](#)

### 30.7.8 What You May Need to Know About IBM WebSphere Application Server

When you deploy your application to IBM WebSphere application servers and use the same machine to log into the WebSphere administrative console, your application may display the name of the user logged into the administrative console, instead of the name of the user who logs into the application. Normally, an expression that tests for the authenticated user like `#{securityContext.authenticated ? securityContext.userName : ""}` should display the name of the user who logs into the application. However, the administration user's name is displayed on IBM WebSphere application servers when the application is running in Mozilla Firefox, where the session ID is shared across all browsers on the same machine. This behavior is not observed when running on Oracle WebLogic Server or when running the application in Microsoft Internet Explorer.

### 30.7.9 What You May Need to Know About Displaying Error Pages in Internet Explorer

When you enable ADF Security to display a custom error page, any HTTP errors that the application generates in response to a request to view a page, should result in the error page being displayed. However, in certain versions of Internet Explorer, the browser will display either the custom error page or an error message built into Internet Explorer. If Internet Explorer display only an error message you can disable the option to display error message numbers in the Advanced settings of the Internet Options dialog. In Internet Explorer 10, this option is enabled by default. You should disable **Show friendly HTTP error messages** when you want to display a custom error page that you enabled with the Configure ADF Security wizard.

#### To ensure custom error pages display in Internet Explorer 10:

1. In Internet Explorer toolbar, click the **Tools** button.
2. In the Internet Options dialog, click the **Advanced** tab.

3. In the Advanced tab, scroll and locate **Show friendly HTTP error messages**.
4. Click the option to disable it and click **OK**.

## 30.8 Testing Security in JDeveloper

Integrated WebLogic Server enables you to run the application directly within JDeveloper and determine whether or not to migrate security objects, including the application policies, users, and credentials that your application defines. By default, all security objects are migrated to Integrated WebLogic Server each time you run the application.

### 30.8.1 How to Configure, Deploy, and Run a Secure Application in JDeveloper

JDeveloper is configured by default to deploy the security objects from your application repositories to Integrated WebLogic Server each time you run the application. You can change this behavior by selecting security deployment options in the Application Properties dialog to:

- Decide whether to overwrite the domain-level policies with those from the application `jazn-data.xml` file
- Decide whether to overwrite the system credentials from the application's `cwallet.sso` file

The `cwallet.sso` file (located in JDeveloper in the Application Resources panel of the Application Navigator under the **Descriptors-META-INF** node) stores credentials as securely kept objects that are presented to the authentication provider to be matched against identities. The file is encrypted and cannot be browsed or edited within JDeveloper. At design-time, different components make use of `cwallet.sso` file and are responsible for creating the necessary credentials in it.

- Decide whether to migrate the identity store portion of the `jazn-data.xml` file to the domain-level identity store

If you make no changes to the deployment settings, each time you run the application, JDeveloper will overwrite the domain-level security policies and system credentials. Additionally, JDeveloper will migrate new user identities you create for test purposes and update existing user passwords in the embedded LDAP server that Integrated WebLogic Server uses for its identity store. However, if you prefer to run the application without updating the existing security objects in Integrated WebLogic Server, you have this option.

#### To configure security deployment and run the application in JDeveloper:

1. In the main menu, choose **Application** and then **Secure > Configure Security Deployment**.
2. In the Application Properties dialog, in the Deployment page, in the **Security Deployment Options** section, select the security objects that you want to deploy to Integrated WebLogic Server.

By default, each time you run the application, JDeveloper will overwrite the application policies and system credentials at the domain level with those from the application. If you prefer not to overwrite either of these repositories, deselect **Application Policies** or **Credentials**. When deselected, JDeveloper will merge only new polices or credentials into the domain-level stores.

By default, each time you run the application, JDeveloper will migrate new user identities you create for test purposes and update existing user passwords in the embedded LDAP server that Integrated WebLogic Server uses for its identity store. You can disable migration of the application identity store by deselecting **Users and Groups**.

3. Click **OK**.
4. In the Application Navigator, right-click the user interface project that contains the secured web pages and choose **Run**.

When you choose **Run** on the user interface project, JDeveloper will run the application using the default run target you configured for the project. For example, you can configure a task flow activity as the run target to start your application. To configure the default run target, see [Section 14.4, "Testing ADF Task Flows."](#)

The Configure Default Domain dialog appears the first time you run the application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

## 30.8.2 What Happens When You Configure Security Deployment Options

When you run the application using Integrated WebLogic Server, JDeveloper migrates the security policies and credentials to the domain level based on security deployment configuration settings specified in the Application Properties dialog. During the deployment process, JDeveloper updates the `weblogic-application.xml` file that it adds to the deployment archive file with the Application Properties settings, as shown in [Example 30–19](#). Note that these settings are not added to the `weblogic-application.xml` file in the application source directory and thus are not visible.

### **Example 30–19** Default Security Deployment Settings in the Archive `weblogic-application.xml` File

```
<application-param>
  <param-name>jps.credstore.migration</param-name>
  <param-value>OVERWRITE</param-value>
</application-param>
<application-param>
  <param-name>jps.policystore.migration</param-name>
  <param-value>OVERWRITE</param-value>
</application-param>
```

The `OVERWRITE` value allows you to modify the security policies and credentials in your application and redeploy either to Oracle WebLogic Server running in development mode or to Integrated WebLogic Server (set up to run in development mode by default).

---

**Note:** When you eventually deploy to a production environment, the migration settings in the `weblogic-application.xml` file are ignored; it would be considered a security vulnerability to allow existing policies and credentials to be overwritten. For information about deploying to a production environment, see [Section 30.9, "Preparing the Secure Application for Deployment."](#)

---

JDeveloper also updates the `weblogic-application.xml` file with OPSS lifecycle listeners, as shown in [Example 30–20](#). To initiate the migration process before the application runs, the lifecycle listeners observe the migration settings for policies and credentials and overwrite the security objects at the domain level.

**Example 30–20 Security Migration Listeners in the Archive `weblogic-application.xml` File**

```
<listener>
  <listener-class>
    oracle.security.jps.wls.listeners.JpsApplicationLifecycleListener
  </listener-class>
</listener>
<listener>
  <listener-class>
    oracle.security.jps.wls.listeners.JpsAppVersionLifecycleListener
  </listener-class>
</listener>
```

During the migration process, JDeveloper maps the Oracle Platform Security Services (OPSS) application role member classes to the Integrated WebLogic Server member classes and migrates the users to WebLogic Server identity store `users` and migrates the roles to WebLogic Server identity store groups. In Oracle WebLogic Server, `users` is an implicit group equivalent to OPSS `authenticated-role`.

Identity store migration is not controlled by the application lifecycle listener settings in the `weblogic-application.xml` file. Instead, an Oracle WebLogic Mbean handles migrating the identities when running in Integrated WebLogic Server or when deploying from JDeveloper. If the user already exists, the Mbean will not migrate the entire user definition. Only the user password will be updated.

### 30.8.3 How to Use the Built-In test-all Application Role

When you run the Configure ADF Security wizard, you can enable the option to add the `test-all` application role to the policy store in the `jazn-data.xml` file. When you enable this option, you also specify the scope of grants to the application role for your application:

- Select **Grant to Existing Objects Only** when you want JDeveloper to grant view rights to the `test-all` application role and you want this policy to apply to all the ADF task flows and web pages that appear in your user interface project at the time you run the wizard.
- Select **Grant to All Objects** when you want JDeveloper to grant view rights to the `test-all` application role and you want this policy to apply to all existing and future ADF task flows and web pages that developers will create in the user interface project. Note that the wizard displays the option **Grant to New Objects** after you run the wizard the first time with the **Grant to All Objects** option selected.

After you run the wizard, the `test-all` role appears in the `jazn-data.xml` file and is visible in the overview editor for security policies. You will not need to populate the `test-all` role with test users since the wizard assigns the built-in application role `anonymous-role` to the `test-all` role. In this case, all users will automatically have the `anonymous-role` principal and will be permitted to access the application.

---

**Note:** Before you deploy the application, you must remove all occurrences of the `test-all` role from the policy store, as described in [Section 30.9.1, "How to Remove the test-all Role from the Application Policy Store."](#) This will prevent unauthorized users from accessing the web pages of your application.

---

You can rerun the wizard and disable automatic grants at any time. Once disabled, new ADF task flows and web pages that you create will not utilize the `test-all` role and will therefore require that you define explicit grants, as described in [Section 30.5, "Defining ADF Security Policies."](#)

### 30.8.4 What Happens at Runtime: How ADF Security Handles Authentication

When you test the application in JDeveloper using Integrated WebLogic Server, the identity store is migrated to the embedded LDAP server, with information stored in Oracle Internet Directory.

[Figure 30-26](#) illustrates the authentication process when users attempt to access an ADF bounded task flow or any web page containing ADF bindings (such as `mypage.jspx`) without first logging in. Authentication is initiated implicitly because the user does not begin login by clicking a login link on a public page. In the case of the secured page, no grants have been made to the anonymous user.

**Figure 30-26 ADF Security Implicit Authentication**

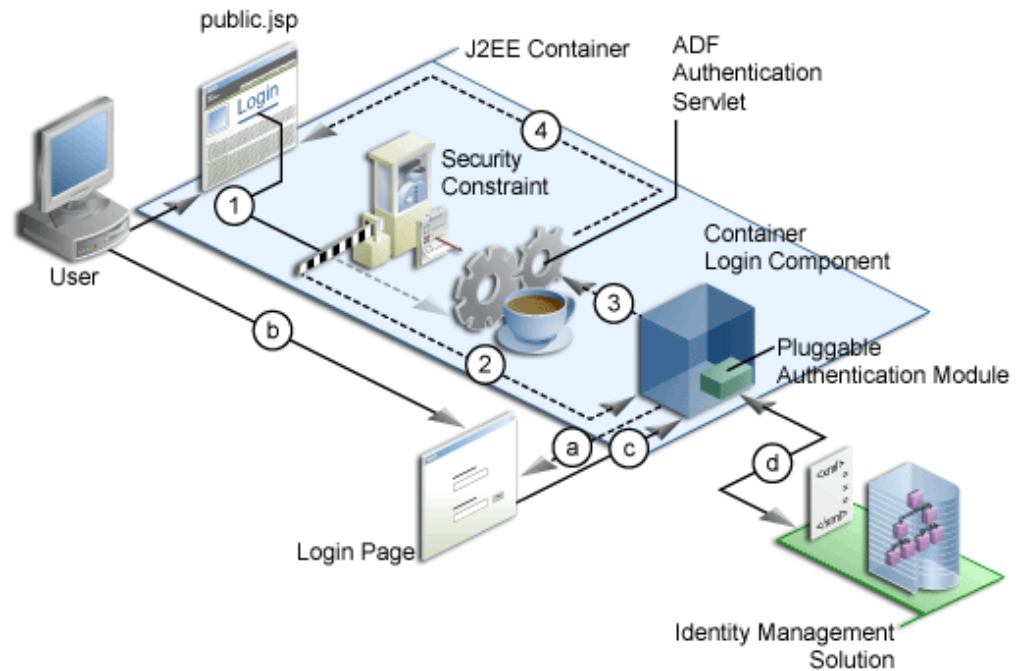

In [Figure 30–26](#), the implicit authentication process assumes that the resource does not have a grant to `anonymous-role`, that the user is not already authenticated, and that the authentication method is Form-based authentication. In this case, the process is as follows:

1. When the bounded task flow or web page (with ADF bindings) is requested, the ADF bindings servlet filter redirects the request to the ADF authentication servlet (in the figure, Step 1), storing the logical operation that triggered the login.
2. The ADF authentication servlet has a Java EE security constraint set on it, which results in the Java EE container invoking the configured login mechanism (in the figure, Step 2). Based on the container's login configuration, the user is prompted to authenticate:
  1. The appropriate login form is displayed for form-based authentication (in the figure, Step 2a).
  2. The user enters their credentials in the displayed login form (in the figure, Step 2b).
  3. The user posts the form back to the container's `j_security_check()` method (in the figure, Step 2c).
  4. The Java EE container authenticates the user, using the configured pluggable authentication module (in the figure, Step 2d).
3. Upon successful authentication, the container redirects the user back to the servlet that initiated the authentication challenge, in this case, the ADF authentication servlet (in the figure, Step 3).
4. On returning to the ADF authentication servlet, the servlet subsequently redirects to the originally requested resource (in the figure, Step 4).

Whether or not the resource is displayed will depend on the user's access rights and on whether authorization for ADF Security is enforced, as explained in [Section 30.8.5, "What Happens at Runtime: How ADF Security Handles Authorization."](#)

[Figure 30–27](#) illustrates the explicit authentication process when the user becomes authenticated starting with the login link on a public page.

**Figure 30–27 ADF Security Explicit Authentication**

In an explicit authentication scenario, an unauthenticated user (with only the anonymous user principal and `anonymous-role` principal) clicks the **Login** link on a public page (in the figure, Step 1). The login link is a direct request to the ADF authentication servlet, which is secured through a Java EE security constraint in the `web.xml` file.

In this scenario, the current page is passed as a parameter to the ADF authentication servlet. As with the implicit case, the security constraint redirects the user to the login page (in the figure, Step 2). After the container authenticates the user, as described in Step a through Step d in the implicit authentication case, the request is returned to the ADF authentication servlet (in the figure, Step 3), which subsequently returns the user to the public page, but now with new user and role principals in place.

### 30.8.5 What Happens at Runtime: How ADF Security Handles Authorization

When ADF authorization is enabled, the ADF bounded task flows and web pages outside of a task flow that have an ADF page definition will be secure by default. When a user attempts to access these web pages, ADF Security checks to determine whether the user has been granted access in the policy store. If the user is not yet authenticated, and the page is not granted to the `anonymous-role`, then the application displays the login page or form. If the user has been authenticated, but does not have permission, a security error is displayed. If you do not configure the policy store with appropriate grants, the pages will remain protected and therefore stay unavailable to the authenticated user.

Figure 30–28 illustrates the authorization process.

Figure 30–28 ADF Security Authorization

The user is a member of the application role *staff* defined in the policy store. Because the user has not yet logged in, the security context does not have a subject (a container object that represents the user). Instead, Oracle Platform Security Services provides ADF Security with a subject with the anonymous user principal (a unique definition of the user) and the `anonymous-role` principal.

With the `anonymous-role` principal, typically the user would be able to access only pages not defined by ADF resources, such as the `public.jsp` page, whereas all pages that are defined either by an ADF task flow or outside of a task flow using an ADF page definition file are secure by default and unavailable to the user. An exception to this security policy would be if you were to grant `anonymous-role` access to ADF resources in the policy store. In this case, the user would not be allowed immediate access to the page defined by an ADF resource.

When the user tries to access a web page defined by an ADF resource, such as `mypage.jsp` (which is specified by an ADF page definition, for example), the ADF Security enforcement logic intercepts the request and because all ADF resources are secured by default, the user is automatically challenged to authenticate (assuming that the `anonymous-role` is not granted access to the ADF resource).

After successful authentication, the user will have a specific subject. The security enforcement logic now checks the policy store to determine which role is allowed to view `mypage.jsp` and whether the user is a member of that role. In this example for `mypage.jsp`, the view privilege has been granted to the *staff* role and because the user is a member of this role, they are allowed to navigate to `mypage.jsp`.

Similarly, when the user tries to access `secpage.jsp`, another page defined by ADF resources, for which the user does not have the necessary view privilege, access is denied.

Users and roles are those already defined in the identity store of the resource provider. Application roles are defined in the policy store of the `jazn-data.xml` file.

## 30.9 Preparing the Secure Application for Deployment

After testing in JDeveloper using Integrated WebLogic Server, you will eventually want to deploy the application to a standalone server. Initially, the server you target will be your staging environment where you can continue development testing using that server's identity store before deploying to the production environment. Thus, you will typically not migrate the test users you created to run with Integrated WebLogic Server. The steps you perform to migrate credentials (in the `cwallet.sso` file) and security policies (in the `jazn-data.xml` file) to standalone Oracle WebLogic Server will depend on the configured mode of the target server and whether you deploy using JDeveloper or a tool outside of JDeveloper.

---

---

**Note:** For details about deploying from JDeveloper to a development environment, see [Section 36, "Deploying Fusion Web Applications."](#)

---

---

When the target server is configured for *development mode*, you can deploy directly from JDeveloper. In this case, JDeveloper automatically handles the migration of the policy store, system credentials, and identity store (users and groups) as part of the deployment process. Application security deployment properties are configured by default to allow the deployment process to overwrite the domain-level policy store and the system credentials. Additionally, the identity store deployment property is configured by default to migrate the identity store consisting of your test users. You can change this default deployment behavior in the Application Properties dialog, as described in [Section 30.8.1, "How to Configure, Deploy, and Run a Secure Application in JDeveloper."](#)

---

---

**Note:** Note that migration of system credentials to Oracle WebLogic Server running in development mode will be performed only if the target server is configured to permit credential overwrite. For details about configuring Oracle WebLogic Server to support overwriting of system credentials, see the *Oracle Fusion Middleware Application Security Guide*.

---

---

When the target server is configured for *production mode*, you typically handle the migration task outside of JDeveloper using tools like Oracle Enterprise Manager. For details about using tools outside of JDeveloper to migrate the policy store to the domain-level in a production environment, see the *Oracle Fusion Middleware Application Security Guide*. Note that Oracle WebLogic Server running in production mode does not support the overwriting of system credentials under any circumstances.

Before you deploy the application, you will want to remove the `test-all` application role if you enabled the automatic grants feature in the Configure ADF Security wizard. Because the `test-all` role makes all ADF resources public, its presence increases the risk that your application may leave some resources unprotected. You must therefore remove the role before you migrate application-level policy store.

Additionally, when you prepare to deploy the application to Oracle WebLogic Server, you will want to remove the test identities that you created in the `jazn-data.xml` file. This will ensure that users you created to test security policies are not migrated to the domain-level identity store.

**Best Practice:** If you deploy your application to the standalone environment, you must not migrate users and enterprise roles in your local identity store that are already configured for Oracle WebLogic Server. For example, if you were to deploy the identity store with the user `weblogic` and enterprise role `Administrators`, you would overwrite the default administration configuration on the target server. To ensure you avoid all possible conflicts, you can disable migration of the identity store, as described in [Section 30.9.2, "How to Remove Test Users from the Application Identity Store."](#)

### 30.9.1 How to Remove the test-all Role from the Application Policy Store

The overview editor for security policies provides the facility to display all resources with view grants made to ADF Security’s built-in `test-all` role. You can use this feature in the overview editor to delete the `test-all` role grant and replace it with a grant to the roles that your application defines.

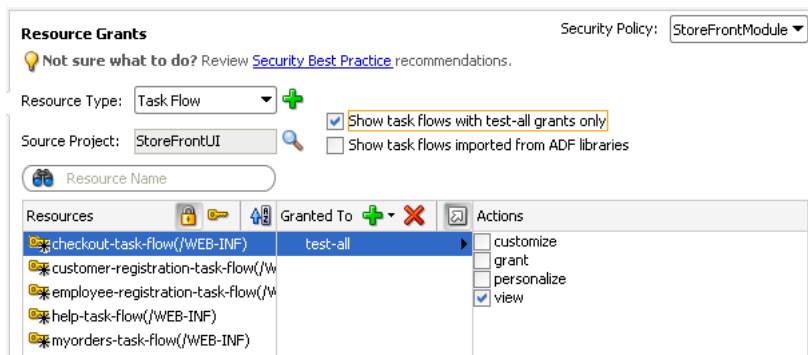

Alternatively, you could delete the `test-all` role using the overview editor for the `jazn-data.xml` file, by selecting the `test-all` role in the Application Roles page of the editor and clicking the **Delete Application Role** button. However, when you remove the `test-all` role this way, you will still need to create a grant to replace the ones that you delete. Because the overview editor lets you combine both of these tasks, the following procedure describes its usage.

**To remove the test-all application role and substitute custom application roles:**

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, select **Task Flow** from the **Resource Type** dropdown list and then select the **Show task flows with test-all grants only** checkbox to view the list of task flows with grants to this built-in role.

If no grant exists for the `test-all` role, then the **Resources** list in the overview editor will appear empty. The `test-all` role is defined only when enabled in the Configure ADF Security wizard. If it is enabled, you will see those task flows with `test-all` grants listed, as shown in [Figure 30–29](#).

**Figure 30–29** Showing Task Flows with test-all Grants in the Overview Editor

3. In the **Resources** column, select the first task flow in the list.
4. In the **Granted to** column, select `test-all` and click the **Remove Grantee** icon.

5. In the **Granted to** column, click the **Add Grantee** icon and choose **Add Application Role** and then use the Select Application Roles dialog to add the desired role.
6. Repeat these steps to remove the `test-all` role and substitute your own application role for all remaining task flows.
7. In the Resource Grants page of the overview editor, select **Web Page** from the **Resource Type** dropdown list and repeat these steps to remove the `test-all` role for all web pages and their ADF page definitions.
8. With the **Show task flows/web pages with test-all grants only** checkbox selected, verify that the overview editor displays no resources with `test-all` grants.

### 30.9.2 How to Remove Test Users from the Application Identity Store

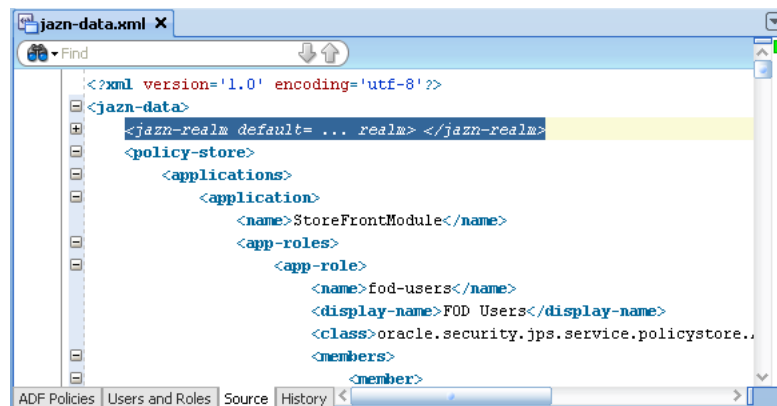

The standalone Oracle WebLogic Server that you will deploy to will have its own identity stored already configured. To ensure that you do not migrate test users and enterprise role groups you created in JDeveloper to the domain level, you should remove the test user realm from the `jazn-data.xml` file.

Alternatively, if you are deploying from JDeveloper, you can disable the migration of users and groups by deselecting the **Users and Groups** option in the Application Properties dialog, as described in [Section 30.8.1, "How to Configure, Deploy, and Run a Secure Application in JDeveloper."](#)

**To remove test users and enterprise role groups from the identity store:**

1. In the main menu, choose **Application** and then **Secure > Users**.
2. In the editor window for the `jazn-data.xml` file, click the **Source** tab.
3. In the source for the `jazn-data.xml` file, click the `-` icon next to the `<jazn-realm>` element so the entire element appears collapsed as shown in [Figure 30–30](#).

**Figure 30–30** Selecting the `<jazn-realm>` Element in the XML Editor

4. With the element selected, press **Delete** and save the file.

### 30.9.3 How to Secure Resource Files Using a URL Constraint

Resource files, including images, style sheets, and JavaScript libraries are files that the Fusion web application loads to support the individual pages of the application. ADF Security does not secure these files. Although securing such files is not a requirement

for securing the web pages of the application, in some cases it may be desirable to protect resource files to fully harden your application. Please note that JavaScript files are downloaded to the browser and, as such, can be read at that time.

To serve up resource files, the ADF Faces framework relies on `org.apache.myfaces.trinidad.webapp.ResourceServlet`, which delegates to a resource loader. The Fusion web application's `web.xml` file contains a servlet mapping that maps the resource servlet to URL patterns. By default, JDeveloper uses the patterns `/adf/*` for MyFaces Trinidad Core, and `/afr/*` for ADF Faces.

Because ADF Security does not protect the resource servlet, you can protect the Java EE access paths for the resource servlet with a security constraint. To implement your own security for the resource files in the `web.xml` file, define a security constraint for the `/adflib/*`, `/adf/*` and `/afr/*` paths and assign a specific security role to them. This security constraint will require all users to be authenticated before they can access the first page of the Fusion web application.

[Example 30-21](#) shows the security role `resource_role` and the constraint with the URL patterns mapped to this role. After you define the security role, the administrator for the target server must map this role to an Oracle WebLogic Server enterprise role (user group) or create an enterprise role with the same name (in which case no mapping is required).

**Example 30-21 URL Constraint in web.xml File for Resource Files**

```
<security-role>
  <description>Java EE role to map to an enterprise role. All users who will
    be allowed to run Fusion web app must be members of that role.
</description>
  <role-name>resource_role</role-name>
</security-role>

<security-constraint>
  <web-resource-collection>
    <web-resource-name>resources</web-resource-name>
    <url-pattern>/adflib/*</url-pattern>
    <url-pattern>/adf/*</url-pattern>
    <url-pattern>/afr/*</url-pattern>
  </web-resource-collection>
  <auth-constraint>
    <role-name>resource_role</role-name>
  </auth-constraint>
</security-constraint>
```

## 30.10 Disabling ADF Security

JDeveloper allows you to disable ADF Security when you want to temporarily run the application without enforcing authorization checks against the application policy store. This will allow you to run the application and access all resources without the protection provided by existing security policies.

### 30.10.1 How to Disable ADF Security

To disable ADF Security at the level of your application, run the wizard and choose one of these options:

- ADF Authentication** disables ADF authorization but leaves the ADF authentication servlet enabled. For example, you may want to run your application in JDeveloper with authorization checking against security policies

temporarily disabled. This option will require the user to log in the first time a page in the application is accessed by mapping the Java EE application root "/" to the `allPages` Java EE security constraint that will trigger user authentication. ADF resources will not be security-aware because authorization checking is not enforced. Thus, once the user is logged in, all web pages containing ADF resources will be available to the user.

- **Remove ADF Security Configuration** disables the ADF authentication servlet and disables authorization checking on ADF resources. In this case, you can run the application with no user authentication and no security for ADF resources in place.

You may select either option with the intention of reenabling ADF Security at any time. The wizard specifically does not alter the application policy store that contains the security policies that application developers defined for ADF resources. This means that you can return to the wizard at any time, select the **ADF Authentication and Authorization** option, and reenable ADF Security against your application's existing policy store and identity store.

#### To disable ADF authorization checking:

1. In the main menu, choose **Application** and then **Secure > Configure ADF Security**.
2. In the ADF Security page, select either the **ADF Authentication** option or the **Disable ADF Security Configuration** option. Click **Next**.

After you run the wizard with either of these options, the ADF resources of your user interface projects will no longer be security-aware.

3. Click **Finish**.

## 30.10.2 What Happens When You Disable ADF Security

If you run the Configure ADF Security wizard with the **Remove ADF Security Configuration** option selected, it removes the ADF-specific metadata in the `web.xml` file and `adf-config.xml` file, as described in [Table 30–2](#).

Similarly, running the wizard with the **ADF Authentication** option selected to disable only authorization checking performs the following updates:

- Leaves the ADF-specific metadata in the `web.xml` file unchanged and adds the `allPages` security constraint.

With the `allPages` security constraint present, users will be expected to authenticate when they first access the application.

- Sets the `authorizationEnforce` parameter in the `<JaasSecurityContext>` element of the `adf-config.xml` file to `false`, as shown in [Example 30–22](#).

#### **Example 30–22 AuthorizationEnforce Flag Disabled in the adf-config.xml File**

```
<JaasSecurityContext
  initialContextFactoryClass="oracle.adf.share.security.JAASInitialContextFactory"
  jaasProviderClass="oracle.adf.share.security.providers.jps.JpsSecurityContext"
  authorizationEnforce="false"
  authenticationRequire="true"/>
```

The `adf-config.xml` file is located in the `/.adf/META-INF` folder of your workspace. In JDeveloper, you can locate the file in the Application Resources panel of the Application Navigator by expanding the **Descriptors-ADF META-INF** node. Note

that if you view the `adf-config.xml` file in an editor outside of JDeveloper, you must save the workspace to see the wizard-applied changes in the file.

## 30.11 Advanced Topics and Best Practices

After you have completed the process of enabling ADF Security, you may want to customize your application to work with ADF Security in the user interface. For example, you can use Expression Language (EL) to render UI components in the web page based on evaluation of custom permissions that you define just for a group of UI components. Additionally, you can define methods within a managed bean to expose information, such as the user name and role membership, in your application.

### 30.11.1 Using Expression Language (EL) with ADF Security

You can use Expression Language (EL) to evaluate the policy directly in the UI, while the use of Java enables you to evaluate the policy from within a managed bean. ADF Security implements several convenience methods for use in EL expressions to access ADF resources in the security context. For example, you can use the EL expression convenience methods to determine whether the user is allowed to access a particular task flow. Good security practice dictates that your application should hide resources and capabilities for which the user does not have access. And for this reason, if the user is not allowed access to a particular task flow, you would evaluate the user's permission grant to determine whether or not to render the navigation components that initiate the task flow.

---

---

**Note:** The ability to evaluate a policy is limited to the current request. For this reason, it is important to understand where the policy evaluation occurs, because evaluating the policy at anything other than the request scope can lead to unexpected results.

---

---

#### 30.11.1.1 How to Evaluate Policies Using EL

The use of EL within a UI component allows for the component's attribute values to be defined dynamically, resulting in modification of the UI component at runtime. In the case of securing resources, the UI component attribute of interest is the `rendered` attribute, which allows you to show and hide components based on available permissions. By default, the `rendered` attribute is set to `true`. By dynamically changing this value based on the permission, you can set the UI component to be shown or hidden. For example, if the user has the appropriate permission, the `rendered` attribute should be set to `true` so that the UI component is shown. If they do not have permission, the attribute should be set to `false` and the UI component hidden from view.

To evaluate a policy using EL, you must use the ADF Security methods in the `securityContext` EL namespace. These methods let you access information in the ADF security context for a particular user or ADF resource.

[Table 30-11](#) shows the EL expression that is required to determine whether a user has the associated permission. If the user has the appropriate permission, the EL expression evaluates to `true`; otherwise, it returns `false`.

**Table 30–11 EL Expression to Determine View Permissions on ADF Resources**

Expression	Expression action
<pre>#{securityContext.taskflowViewable['MyTaskFlow']}</pre> <p>For example:</p> <pre>#{securityContext.taskflowViewable   ['/WEB-INF/audit-expense-report.xml#audit-expense-report']}</pre>	Where <i>MyTaskFlow</i> is the WEB-INF node-qualified name of the task flow being accessed. Returns <code>true</code> if the user has access rights. Returns <code>false</code> if the user does not have sufficient access rights.
<pre>#{securityContext.regionViewable['MyPagePageDef']}</pre>	Where <i>MyPagePageDef</i> is the qualified name of the page definition file associated with the web page being accessed. Returns <code>true</code> if the user has access rights. Returns <code>false</code> if the user does not have sufficient access rights.

---

**Note:** In the case of page permission, the value of the page definition can be specified dynamically by using late-binding EL within a managed bean, as described in [Section 30.3.7, "What You May Need to Know About the valid-users Role."](#)

---

[Table 30–12](#) shows the EL expression that lets you get general information from the ADF security context not related to a particular ADF resource. For example, you can access the current user name when you want to display the user's name in the user interface. You can also check whether the current user is a member of certain roles or granted certain privileges. Your application may use this result to dynamically hide or show menus.

**Table 30–12 EL Expression to Determine User Information in the ADF Security Context**

Expression	Expression Action
<pre>#{securityContext.userName}</pre>	Returns the user name of the authenticated user.
<pre>#{data.adfContext.tenantName}</pre>	Returns the tenant name of the authenticated user. The tenant name is an alias that the user knows for themselves and can use to login.
<pre>#{data.adfContext.tenantId}</pre>	Returns the tenant ID of the authenticated user.
<pre>#{securityContext.authenticated}</pre>	Returns <code>true</code> if the user is logged in. Returns <code>false</code> if the user is not logged in. This is useful for rendering a dynamic link for login/logout, or for rendering a "Welcome, <i>username</i> " message when the user has been authenticated. For an example that uses this expression, see <a href="#">Section 30.7.4.2, "Adding Login and Logout Links."</a>
<pre>#{securityContext.userInRole['roleList']}</pre>	Where <i>roleList</i> is a comma-separated list of role names. Returns <code>true</code> if the user is in at least one of the roles. Returns <code>false</code> if the user is in none of the roles, or if the user is not currently authenticated.

**Table 30–12 (Cont.) EL Expression to Determine User Information in the ADF Security Context**

Expression	Expression Action
<code>#{securityContext.userInAllRoles['roleList']}</code>	Where <i>roleList</i> is a comma-separated list of role names. Returns <code>true</code> if the user is in all of the roles. Returns <code>false</code> if the user is not in all of the roles, or if the user is not currently authenticated.
<code>#{securityContext.userGrantedPermission['permission']}</code>	Where <i>permission</i> is a string containing a semicolon-separated concatenation of <code>permissionClass=&lt;class&gt;;target=&lt;artifact_name&gt;;action=&lt;action&gt;</code> . Returns <code>true</code> if the user has access rights. Returns <code>false</code> if the user does not have sufficient access rights.  Note that the convenience methods <code>taskflowViewable</code> and <code>regionViewable</code> shown in <a href="#">Table 30–11</a> provide the same functionality.
<code>#{securityContext.userGrantedResource['resource']}</code>	Where <i>resource</i> is a string containing a semicolon-separated concatenation of <code>resourceName=&lt;name&gt;;resourceType=&lt;type&gt;;action=&lt;action&gt;</code> . Returns <code>true</code> if the user has access rights. Returns <code>false</code> if the user does not have sufficient access rights.  You can use this expression to test the permission grant in the display property of a resource that is not contained in a task flow (like an ADF Faces panel or a menu item). You first create a custom resource type for the UI component that you want to protect. For more details, see <a href="#">Section 30.11.2, "How to Protect UI Components Using OPSS Resource Permissions and EL."</a>

**To associate the rendering of a navigation component with a user's granted permissions on a target task flow or page definition:**

1. In the Application Navigator, double-click the page that contains the navigation component that you wish to conditionally render.
2. In the visual editor for the page, select the component that is used to navigate to the secured page.
3. In the Property Inspector, click the **Property Menu** dropdown menu displayed next to the **Rendered** field and choose **Expression Builder**, as shown in [Figure 30–31](#).

**Figure 30–31 Binding the Rendered Property to Data**

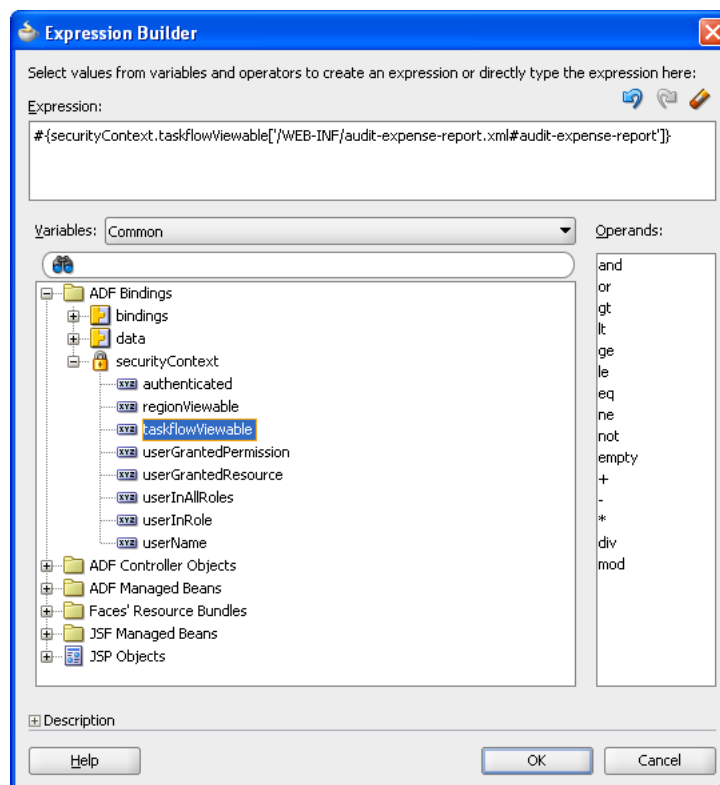

- In the Expression Builder, expand the **ADF Bindings - securityContext** node and select the appropriate EL value, and then in the **Expression** field, enter the qualified name of the ADF resource that the user will attempt to access.

For example, as shown in [Figure 30–32](#), to limit access to a task flow that your application displays, you would create an expression like:

```
#{securityContext.taskflowViewable
  ['/WEB-INF/audit-expense-report.xml#audit-expense-report']}
```

In this example, the expression determines the user's access rights to view the target task flow `audit-expense-report`. If the user has the access rights, then the expression evaluates to `true` and the rendered attribute receives the value `true`.

**Figure 30–32** Defining EL in the Expression Builder Dialog

- Click **OK**.

When you run the application, the component will be rendered or hidden based on the user's ability to view the target page.

### 30.11.1.2 What Happens When You Use the Expression Builder Dialog

When you use the Expression Builder to define an expression for the rendered attribute, JDeveloper updates the component definition in the open `.jspx` file. The component's rendered attribute appears with an expression that should evaluate to either `true` or `false`, as shown in [Example 30–23](#). In this example, the component is a navigation link with the link text `Checkout` defined by another expression. The page that contains the navigation link renders the component only when the user has sufficient rights to access the checkout task flow.

**Example 30–23 EL Expression in Source for .jspx File**

```

<af:commandNavigationItem
    text="#{res['global.nav.checkout']}"
    action="globalCheckout"
    id="cni3"
    rendered="#{securityContext.taskflowViewable
                ['/WEB-INF/checkout-task-flow.xml#checkout-task-flow']}"
/>

```

**30.11.1.3 What You May Need to Know About Delayed Evaluation of EL**

The ability to evaluate a security permission is scoped to the request. If you want to evaluate permissions to access a target page from a managed bean that is scoped to a higher level than request (for example, a global menu that is backed by a managed bean), you must implement delayed EL evaluation (late-binding). By passing in the target page as a managed property of the bean, you ensure that the EL expression is evaluated only after the required binding information is available to the managed bean. Because EL is evaluated immediately when the page is executed, placing the EL expression directly in the properties of a UI component, backed by a managed bean, would result in an out-of-scope error.

[Example 30–24](#) shows a property (`authorized`) of a managed bean that returns `true` or `false` based on a user's ability to view a named target page. In this case, the `_targetPageDef` variable is a managed property containing the name of the target page. Within the UI, the EL expression would reference the `authorized` property.

**Example 30–24 Delayed EL Evaluation in a Managed Bean**

```

public boolean isAuthorized()
{
    if (_targetPageDef != null) {
        FacesContext fctx = FacesContext.getCurrentInstance();
        ADFContext adfCtx = ADFContext.getCurrent();
        SecurityContext secCtx = adfCtx.getSecurityContext();
        boolean hasPermission = secCtx.hasPermission(new RegionPermission
            (_targetPageDef, RegionPermission.VIEW_ACTION));
        if (hasPermission) {
            return hasPermission;
        }
        else {
            fctx.addMessage(null, new FacesMessage (
                FacesMessage.SEVERITY_WARN, "Access Permission not defined! " , null));
            return false;
        }
    }
}

```

**30.11.2 How to Protect UI Components Using OPSS Resource Permissions and EL**

Security expressions in the ADF Security EL namespace described in [Table 30–12](#) let you check the user permission, authentication and role membership status before displaying UI components in your page. When you need fine-grained protection over UI components to secure functional parts of the application that are not part of task flow security or web page security, you use the EL value `userGrantedResource` and a resource grant that you define for a custom resource type. For instance, through a resource grant that you create for a menu item, the application may either enable or disable a Cancel Shipment menu item to limit who may perform customer order updates.

Resource grants for custom resource types rely on the `ResourcePermission` class, which is provided by Oracle Platform Security Services (OPSS) and packaged with the application.

You use the overview editor for security policies to create a security policy for the custom resource type. And, in your web page, you use the security expression to evaluate the user's access rights to the UI component projected by the resource grant.

**Best Practice:** Custom resource types in combination with the `ResourcePermission` matcher class let you extend ADF Security to define custom actions for use in grants. This gives you the flexibility to define security policies to manage the user's ability to view UI components without having to overload the built-in actions defined by the ADF resources' permission classes. Be aware that you do not need to create custom resource types to manage access to web pages. This level of access is provided by the default ADF Security view permission that you work with in the overview editor for security policies.

To grant resource policies for a custom resource type:

1. Create the custom resource type for the UI component you want to protect.
2. Create the resource grant for the custom resource.
3. Associate the rendering of a UI component with a role's granted resource permission.

### 30.11.2.1 Creating the Custom Resource Type

You use the Create Resource Type dialog to create a resource type for the UI component that you want to protect. JDeveloper will match your resource type definition to the OPSS permission class

`oracle.security.jps.ResourcePermission`. This class allows you to specify custom actions that you can grant to functional parts of your application that are not protected by task flow security or web page security. For example, you might want to create a resource type to protect sensitive parts of the application accessed by the user through a menu UI component.

The Create Resource Type dialog lets you identify the type of resource you wish to protect (for example, the name `MenuProtection` would identify the menu UI component), a display name visible in the security policy store (for example, `Menu Protection`), and a description of how the resource type will be used in the resource grant (for example, `Resource permission to grant menu item permissions`). The dialog also lets you enter one or more custom action names that you will use to grant permission. For example, you might name the action process for use in a security policy that grants access to a protected menu item.

**To create the custom resource type:**

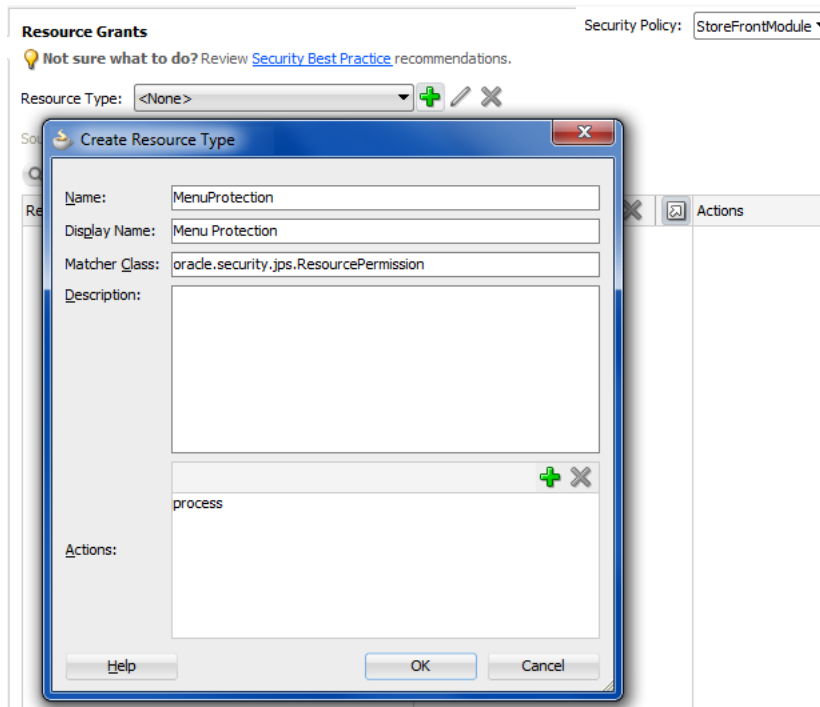

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, click **New Resource Type**.
3. In the Create Resource Type dialog, enter the name and display name that describes the UI component.

For example, to protect menu items, you might enter `MenuProtection` for the name and `Menu Protection` for the display name.

- In the **Actions** list, click **Add** and enter the name of the actions that your permission will grant and click **OK**.

For example, when protecting a menu item, you might enter `process` to signify that permission to process the menu selection is being granted. You can enter multiple action names when you intent to grant specific actions to individual users or roles. The overview editor displays the custom permission grant, as shown in [Figure 30–33](#).

**Figure 30–33** *Creating a Custom Resource Type*

### 30.11.2.2 Creating a Resource Grant for a Custom Resource Type

You use the overview editor for the `jazn-data.xml` file to create the ADF Security policy for a custom resource. The finished source should look similar to the permission grant defined in the policy store, as shown in [Example 30–25](#).

**Example 30–25** *Custom Resource Permission Grant Definition*

```
<grant>
  <grantee>
    <principals>
      <principal>
        <name>AccountManagersadmin</name>
        <class>oracle.security.jps.service.policystore.ApplicationRole</class>
      </principal>
    </principals>
  </grantee>
  <permissions>
    <permission>
      <class>oracle.security.jps.ResourcePermission</class>
      <name>resourceType=MenuProtection, resourceName=CancelShipment</name>
      <actions>process</actions>
    </permission>
  </permissions>
</grant>
```

```
</grant>
```

The `<permission>` target name identifies the custom resource type and name that you assigned the resource. For example, a resource name that lets users cancel shipments from a menu selection in their account might be named `CancelShipment`.

The actions are those that your custom resource type defines. For example, in the Menu Protection resource type defines the single action `process` to grant permission to process the menu selection.

### Before you begin:

You will need to complete this task:

Create the custom resource type, as described in [Section 30.11.2.1, "Creating the Custom Resource Type."](#)

### To create the resource grant for a custom resource type:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, select the custom resource from the **Resource Type** dropdown list.
3. In the **Resources** column, click the **Add Resource** icon.
4. In the Create Resource dialog, enter the name, display name, and description for the resource that the security policy will specifically protect and then click **OK**.
5. In Resource Grants page of the overview editor, in the **Granted to** column, click the **Add Grantee** icon and choose **Add Application Role**.
6. In the **Actions** column, select action that you defined for the custom resource type.

The overview editor displays the resource grant, as shown in [Figure 30–34](#).

**Figure 30–34** *Creating a Grant for a Custom Resource in the Overview Editor*

### 30.11.2.3 Associating the Rendering of a UI Component with a Resource Grant

You use the Expression Builder dialog for the UI component display property to define an EL expression that controls rendering the component. For example, to protect a menu item in an application that allows authorized users to cancel shipments, the application specifies a `userGrantedResource` expression on the **disabled** property of the menu item defined by `af:commandMenuItem`. As [Example 30–26](#) shows, the expression tests whether the user has been granted the resource type and then either displays the menu item or, when the user has not been granted the resource, disables the menu item.

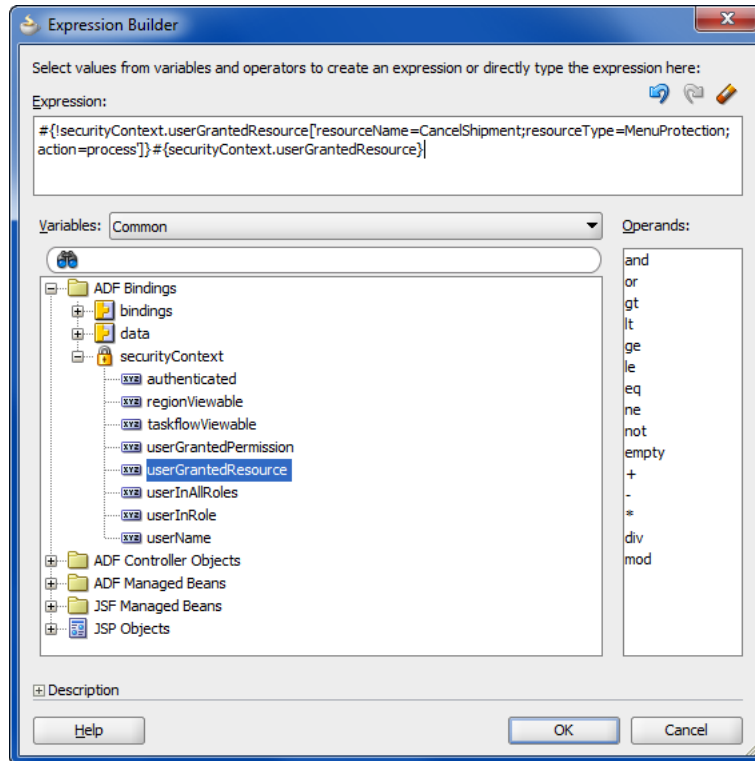

#### **Example 30–26** *Expression to Evaluate User's Resource Grant*

```
#(!securityContext.userGrantedResource
```

```
[ 'resourceName=CancelShipment;resourceType=MenuProtection;action=process' ] }
```

Figure 30–35 shows how the expression appears in the Expression Builder dialog.

**Figure 30–35 Defining EL in the Expression Builder Dialog**

**Before you begin:**

You will need to complete these tasks:

1. Create the custom resource type, as described in [Section 30.11.2.1, "Creating the Custom Resource Type."](#)
2. Create the ADF security policy using the custom permission, as described in [Section 30.11.2.2, "Creating a Resource Grant for a Custom Resource Type."](#)

**To associate the rendering of a UI component with a user's granted resource:**

1. In the Application Navigator, double-click the page that contains the UI component that you wish to conditionally render.
2. In the visual editor for the page, select the component that is used to navigate to the secured page.
3. In the Property window, click the **Property Menu** dropdown menu displayed next to the **Rendered** field and choose **Expression Builder**.
4. In the Expression Builder, expand the **ADF Bindings - securityContext** node and select **userGrantedResource**, and then, in the **Expression** field, enter a concatenated string that defines the permission.

Enter the permission string as a semicolon-separated concatenation of `resourceName=theResourceInstanceName;resourceType=customResourceTypeName;action=actionName`. For example, to protect a menu item in an

application that allows authorized users to cancel shipments, you would enter an expression similar to the one shown in [Example 30–27](#), where the resource type for `userGrantedResource` identifies the resource type used in the custom resource grant.

**Example 30–27 EL Expression to Evaluate User's Resource Grant**

```
#{!securityContext.userGrantedResource
    ['resourceName=CancelShipment;resourceType=MenuProtection;action=process']}
```

In [Example 30–27](#), the expression evaluates the permission based on the custom resource type named `MenuProtection` that you added to the application policy store.

5. Click OK.

### 30.11.3 How to Perform Authorization Checks for Entity Object Operations

In the Fusion web application, you can enable security for the data collection when you secure the operations of the entity object. The user must have sufficient privileges to view, update, or delete the data for the entire row set.

The `oracle.jbo.ViewCriteriaRow` API allows you to perform authorization checks for the standard operations (`read`, `update`, `removeCurrentRow`) at the level of entity rows. [Example 30–28](#) shows how to use the authorization checking API, `getSecurityHints()` and `allowsOperation()`, on the entity row, to test whether the user has permission to delete data.

**Example 30–28 Invoking the Authorization Checking API for Entity Rows**

```
if(row.getSecurityHints().allowsOperation("removeCurrentRow").hasPermission())
    // code for the data
else
    // display error message
```

Note that the `allowsOperation()` method expects as input the secured operation name rather than the name of the action that secures it. The operation name for deleting an entity row is `removeCurrentRow` (where `delete` is the action name).

When you want to perform authorization checks for the entity object that underlies data bound components in a JSF page of the Fusion web application, you can use EL expressions. For example, the following EL expression returns true if the user has been granted the permission to perform the operation specified. The `<operationName>` used in the expression must be the `read`, `update`, or `removeCurrentRow` operation that you enabled for the entity object.

```
#{row.hints.allows.<operationName>}
```

Authorization checking expressions are evaluated in the context of a row collection. When you want to check entity permissions outside of the context of the row collection, you must use the `userGrantedResource` method as shown in [Table 30–12](#).

### 30.11.4 Getting Information from the ADF Context

The implementation of security in a Fusion web application is by definition an implementation of the security infrastructure of the ADF Security framework. As such, the security context of the framework allows access to information that is required as you define the policies and the overall security for your application.

### 30.11.4.1 How to Determine Whether Security Is Enabled

Because the enforcement of ADF Security can be turned on and off at the container level independent of the application, you should determine whether ADF Security is enabled prior to making authorization checks. You can achieve this by calling the `isAuthorizationEnabled()` method of the ADF security context, as shown in [Example 30–29](#).

**Example 30–29 Using the `isAuthorizationEnabled()` Method of the ADF Security Context**

```
if (ADFContext.getCurrent().getSecurityContext().isAuthorizationEnabled()){
    //Authorization checks are performed here.
}
```

### 30.11.4.2 How to Determine Whether the User Is Authenticated

As the user principal in a Fusion web application is never `null` (that is, it is either `anonymous` for unauthenticated users or the actual user name for authenticated users), it is not possible to simply check whether the user principal is `null` to determine if the user has logged on or not. As such, you must use a method to take into account that a user principal of `anonymous` indicates that the user has not authenticated. You can achieve this by calling the `isAuthenticated()` method of the ADF security context, as shown in [Example 30–30](#).

**Example 30–30 Using the `isAuthenticated()` Method of the ADF Context**

```
// ===== User's Authenticated Status =====
private boolean _authenticated;
public boolean isAuthenticated() {
    _authenticated = ADFContext.getCurrent().getSecurityContext().isAuthenticated();
    return _authenticated;
}
```

### 30.11.4.3 How to Determine the Current User Name, Tenant Name, or Tenant ID

Fusion web applications support the concept of public pages that, while secured, are available to all users. Furthermore, components on the web pages, such as portlets, require knowledge of the current user identity. As such, the user name in a Fusion web application will never be `null`. If an unauthenticated user accesses the page, the user name `anonymous` will be passed to page components. When the Fusion web application registers a tenant name for the user, the tenant name may also be obtained. The tenant name is an alias that the user knows for themselves and can use to login.

You can determine the current user's name by evaluating the `getUserName()` method of the ADF security context, as shown in [Example 30–31](#). This method returns the string `anonymous` for all unauthenticated users and the actual authenticated user's name for authenticated users.

**Example 30–31 Using the `getUserName()` Method of the ADF Context**

```
// ===== Current User's Name/PrincipalName =====
public String getCurrentUser() {
    _currentUser = ADFContext.getCurrent().getSecurityContext().getUserName();
    return _currentUser;
}
```

Because the traditional method for determining a user name in a Faces-based application (`FacesContext.getCurrentInstance().getExternalContext().getRemot`

`eUser()` returns `null` for unauthenticated users, you need to use additional logic to handle the public user case if you use that method.

You can determine the current user's tenant name by evaluating the `getTenantName()` method of the ADF context, as shown in [Example 30-32](#).

**Example 30-32 Using the `getTenantName()` Method of the ADF Context**

```
// ===== Current User's Tenant Name =====
public String getTenantName() {
    _tenantName = ADFContext.getCurrent().getTenantName();
    return _tenantName;
}
```

You can determine the current user's tenant ID by evaluating the `getTenantId()` method of the ADF security context, as shown in [Example 30-33](#). This method returns the string `anonymous` for all unauthenticated users and the actual authenticated user's name for authenticated users.

**Example 30-33 Using the `getTenantId()` Method of the ADF Security Context**

```
// ===== Current User's Tenant ID =====
public String getTenantId() {
    _tenantId = ADFContext.getCurrent().getTenantId();
    return _tenantId;
}
```

#### 30.11.4.4 How to Determine Membership of a Java EE Security Role

As Fusion web applications are JavaServer Faces-based applications, you can use the `isUserInRole(roleName)` method of the Faces external context, as shown in [Example 30-34](#), to determine whether a user is in a specified role. Because ADF Security is based around JAAS policies, you should not need to use Java EE security roles to secure pages associated with ADF security-aware resources based on role membership. However, you might use the method to check the role for a page that is not associated with an ADF security-aware resource.

In this example, a convenience method (`checkIsUserInRole`) is defined. The use of this method within a managed bean enables you to expose membership of a named role as an attribute, which can then be used in EL.

**Example 30-34 Using the `isUserInRole(roleName)` Method of the Faces Context**

```
public boolean checkIsUserInRole(String roleName){
    return
    (FacesContext.getCurrentInstance().getExternalContext().isUserInRole(roleName));
}

public boolean isCustomer() {
    return (checkIsUserInRole("fod-users"));
}
```

#### 30.11.4.5 How to Determine Permission Using Java

To evaluate the security policies from within Java, you can use the `hasPermission` method of the ADF security context. This method takes a permission object (defined by the resource and action combination) and returns `true` if the user has the corresponding permission.

In [Example 30–35](#), a convenience function is defined to enable you to pass in the name of the page and the desired action, returning `true` or `false` based on the user's permissions. Because this convenience function is checking page permissions, the `RegionPermission` class is used to define the permission object that is passed to the `hasPermission` method.

**Example 30–35 Using the `hasPermission()` Method to Evaluate Access Policies**

```
private boolean TestPermission (String PageName, String Action) {
    Permission p = new RegionPermission("view.pageDefs." + PageName + "PageDef",
                                       Action);

    if (p != null) {
        return ADFContext.getCurrent().getSecurityContext().hasPermission(p);
    }
    else {
        return (true);
    }
}
```

As it is possible to determine the user's permission for a target page from within a backing bean, you can use this convenience method to dynamically alter the result of a Faces navigation action. In [Example 30–36](#), you can see that a single command button can point to different target pages depending on the user's permission. By checking the view permission from the most secured page (the manager page) to the least secured page (the public welcome page), the command button's backing bean will apply the appropriate action to direct the user to the page that corresponds to their permission level. The backing bean that returns the appropriate action is using the convenience method defined in [Example 30–35](#).

**Example 30–36 Altering a Page Navigation Result Based on an Authorization Check**

```
//Command Button Definition
<af:commandButton text="Goto Your Group Home page"
    binding="#{backing_content.commandButton1}"
    id="commandButton1"

    action="#{backing_content.getSecureNavigationAction}" />

//Backing Bean Code
public String getSecureNavigationAction() {
    String ActionName;
    if (TestPermission("ManagerPage", "view"))
        ActionName = "goToManagerPage";
    else if (TestPermission("EmployeePage", "view"))
        ActionName = "goToEmployeePage";
    else
        ActionName = "goToWelcomePage";
    return (ActionName);
}
```

### 30.11.5 Best Practices for Working with ADF Security

These best practices summarize the rules that govern enforcement of security by the ADF Security framework. Understanding these best practices will help you to secure the application to allow users to access the web pages you intend.

**Do build your application with ADF Security enabled from the start.**

When you enable security, you essentially lock down the application and you will be required to make explicit permission grants to specific ADF security-aware resources you create. Knowing about these resources and making grants on them as you build the application will enable you to iteratively test security to ensure that you structure your application in a way that achieves the desired result.

**Do define permission grants for bounded task flows.**

Pages that the user accesses within the process of executing a bounded task flow will not be individually permission-checked and will run under the permission grants of the task flow. This means that any page that you add to the task flow should not have its own page definition-level security defined. Upon requesting a flow, the user will be allowed either to view all the pages of the task flow or to view none of the pages, depending on their level of access.

**Do not define permission grants for individual pages of a bounded task flow.**

It is important to realize that task flows do not prevent users from accessing pages directly. Any web page that is located in a directory that is publicly accessible can be reached from a browser using a URL. To ensure that pages referenced by a bounded task flow cannot be accessed directly, remove all permission grants that exist for their associated page definition file. When pages require additional security within the context of a bounded task flow, wrap those pages in a sub-task flow with additional grants defined on the nested task flow.

**Do use task flows to reduce the number of access points exposed to end users.**

When you use task flows you can reduce the number of access points that you expose to end users. For example, configure an unbounded task flow to display one page that provides navigation to the remaining pages in your application. Use bounded task flows for the remaining pages in the application. By setting the URL Invoke property of these bounded task flows to `url-invoke-disallowed`, your application has one access point (the page on the unbounded task flow). For more information about the URL Invoke property, see [Section 15.6.4, "How to Call a Bounded Task Flow Using a URL."](#)

**Do define permission grants for individual pages outside of a bounded task flow.**

Page-level security is checked for pages that have an associated page definition binding file *only* if the page is directly accessed or if the page is accessed in an *unbounded* task flow. There is a one-to-one relationship between the page definition file and the web page it secures.

If you want to secure a page that uses no ADF bindings, you can create an empty page definition binding file for the page.

**Do define custom permissions to render UI component based on the user's access rights.**

Custom ADF permission classes let you extend ADF Security to define custom actions for use in grants. This gives you the flexibility to define security policies to manage the user's ability to view UI components without having to overload the built-in actions defined by the ADF resources' permission classes.

**Do define entity object attribute permissions to manage the user's access rights to row-level data displayed by UI components.**

Entity objects and entity object attributes both define permission classes that let you define permissions for the read, update, and delete operations that the entity object

initiates on its data source. In the case of these data model project components, you must explicitly grant permissions to an application role in order to opt into ADF Security authorization. However, once you enable authorization for an entity object, all rows of data defined by the entity object will be protected by the grant. At this level of granularity, your table component would render in the web page either with all data visible or with no data visible—depending on the user’s access rights. As an alternative to securing the entire collection, you can secure individual columns of data. This level of granularity is supported by permissions you set on the individual attributes of entity objects. When entity objects are secured, users may see only portions of the data that the table component displays.

**Do use task flow or page-level permission grants to avoid exposing row-level create/insert operations to users with view-only permission.**

The correct way to control access to a page that should allow only certain users to update new rows in a table is to use task flow or page-level permission grants. However, as an alternative, it is possible to secure table buttons corresponding to particular operations by specifying an EL expression to test the user’s access rights to view the button. When the custom permission is defined and the `userGrantedPermission` expression is set on the `Rendered` property of the button, only users with sufficient privileges will see the button. This may be useful in a case where the user interface displays a page that is not restricted and view-only permission for row-level data is defined for the entity object. In this case, when viewed by the user, the Delete button for the editable table associated with the entity object will appear disabled. However, in the case of an input table, the user interface does not disable the button for the CreateInsert operation even though the user may not have update permission.

**Do not use JDeveloper as a user identity provisioning tool.**

JDeveloper must not be used as an identity store provisioning tool, and you must be careful not to deploy the application with user identities that you create for testing purposes. Deploying user identities with the application introduces the risk that malicious users may gain unintended access. Instead, always rely on the system administrator to configure user identities through the tools provided by the domain-level identity management system. You should delete all users and groups that you create in the `jazn-data.xml` file before deploying the application.

**Do not allow users to access a web page by its file name.**

When you deploy the Fusion web application, you should always permit users to access the web page from a view activity defined in the ADF Controller configuration file. Do not allow users to access the JSPX file directly by its physical name (for example, similar to the file name `AllDepartments.jspx`).

Assuming the view activity is named `AllDepartments`, then there are two ways to call the page:

1. `localhost:7101/myapp/faces/AllDepartments`
2. `localhost:7101/myapp/faces/AllDepartments.jspx`

The difference is that the call 1) is in the context of the ADF Controller task flow, which means that navigation on the page will work and any managed beans that are referenced by the page will be properly instantiated. The call in 2) also serves the page, however, the page may not function fully. This may be considered a security breach.

To prevent direct JSPX file access, move the JSPX file under the `/public_html/WEB-INF` directory so that direct file access is no longer possible. To access a document, users will have to call its view activity name.

Note that this suggestion does not protect documents that are unprotected in ADF Security. It only helps to lock down access to the physical file itself.

Thus, the following security guidelines still apply:

1. Apply ADF Security permissions to all JSPX documents associated with view activities defined in the `adfc-config.xml` file.
2. Move all JSPX documents in the user interface project under the `/public_html/WEB-INF` directory to prevent direct file access.
3. Limit the pages in the `adfc-config.xml` to the absolute minimum and place all other pages into bounded task flows.
4. Make bounded task flows inaccessible from direct URL access (which is the default configuration setting for new task flows).
5. Apply ADF Security permissions to bounded task flows.

---

## Testing and Debugging ADF Components

This chapter describes the tools for logging and testing an application that uses Oracle Application Development Framework (Oracle ADF). It contains debugging procedures for setting breakpoints using the ADF Declarative Debugger. Finally, it explains how to write and run regression tests for your ADF Business Components-based business services.

This chapter includes the following sections:

- [Section 31.1, "Introduction to ADF Debugging"](#)
- [Section 31.2, "Correcting Simple Oracle ADF Compilation Errors"](#)
- [Section 31.3, "Correcting Simple Oracle ADF Runtime Errors"](#)
- [Section 31.4, "Validating ADF Controller Metadata"](#)
- [Section 31.5, "Using the ADF Logger"](#)
- [Section 31.6, "Using the Business Component Browser for Testing and Debugging"](#)
- [Section 31.7, "Using the ADF Declarative Debugger"](#)
- [Section 31.8, "Setting ADF Declarative Breakpoints"](#)
- [Section 31.9, "Setting Java Code Breakpoints"](#)
- [Section 31.10, "Regression Testing with JUnit"](#)

### 31.1 Introduction to ADF Debugging

Like any debugging task, debugging the web application's interaction with Oracle Application Development Framework (Oracle ADF) is a process of isolating specific contributing factors. However, in the case of web applications, generally this process does not involve compiling Java source code. Your web pages contain no Java source code, as such, to compile. In fact, you may not realize that a problem exists until you run and attempt to use the application. For example, these failures are only visible at runtime:

- A page not found servlet error
- The page is found, but the components display without data
- The page fails to display data after executing a method call or built-in operation (like Next or Previous)
- The page displays, but a method call or built-in operation fails to execute at all
- The page displays, but unexpected validation errors occur

The failure to display data or to execute a method call arises from the interaction between the web page's components and the ADF Model layer. When a runtime failure is observed during ADF lifecycle processing, the sequence of preparing the model, updating the values, invoking the actions, and, finally, rendering the data failed to complete.

Fortunately, most failures in the web application's interaction with Oracle ADF result from simple and easy-to-fix errors in the declarative information that the application defines or in the EL expressions that access the runtime objects of the page's ADF binding container.

In your databound Fusion web application, you should examine the declarative information and EL expressions as likely contributing factors when runtime failures are observed. To understand editing the declarative files, see [Section 31.2, "Correcting Simple Oracle ADF Compilation Errors,"](#) and [Section 31.3, "Correcting Simple Oracle ADF Runtime Errors."](#)

One of the most useful diagnostic tools is the ADF Logger. You use this logging mechanism in JDeveloper to capture runtime traces messages. With ADF logging enabled, JDeveloper displays the application trace in the Message Log window. The trace includes runtime messages that may help you to quickly identify the origin of an application error. Read [Section 31.5, "Using the ADF Logger,"](#) to configure the ADF Logger to display detailed trace messages.

Supported Oracle ADF customers can request Oracle ADF source code from Oracle Worldwide Support. This can make debugging ADF Business Components framework code a lot easier. Read [Section 31.7.1, "Using ADF Source Code with the Debugger,"](#) to understand how to configure JDeveloper to use the Oracle ADF source code.

If the error cannot be easily identified, you can utilize the ADF Declarative Debugger in JDeveloper to set breakpoints. When a breakpoint is reached, the execution of the application is paused and you can examine the data that the ADF binding container has to work with, and compare it to what you expect the data to be. Depending on the types of breakpoints, you may be able to use the step functions to move from one breakpoint to another. For more information about the debugger, read [Section 31.7, "Using the ADF Declarative Debugger."](#)

JDeveloper provides integration with JUnit for your Fusion web application through a wizard that generates regression test cases. Read [Section 31.10, "Regression Testing with JUnit,"](#) to understand how to write test suites for your application.

## 31.2 Correcting Simple Oracle ADF Compilation Errors

When you create web pages and work with the ADF data controls to create the ADF binding definitions in JDeveloper, the Oracle ADF declarative files you edit must conform to the XML schema defined by Oracle ADF. When an XML syntax error occurs, the JDeveloper XML compiler immediately displays the error in the Structure window.

Although there is some syntax checking during design time, the JDeveloper compiler is currently limited by an inability to resolve EL expressions. EL expressions in your web pages interact directly with various runtime objects in the web environment, including the web page's ADF binding container. At present, errors in EL expressions can be observed only at runtime. Thus, the presence of a single typing error in an object-access expression will not be detected by the compiler, but will manifest at runtime as a failure to interact with the binding container and a failure to display data in the page. For information about debugging runtime errors, see [Section 31.3, "Correcting Simple Oracle ADF Runtime Errors."](#)

**Tip:** The JDeveloper Expression Builder is a dialog that helps you build EL expressions by providing lists of objects, managed beans, and properties. It is particularly useful when creating or editing ADF databound EL expressions because it provides a hierarchical list of ADF binding objects and their valid properties from which you can select. You should use the Expression Builder to avoid introducing typing errors. For details, see [Section 12.7, "Creating ADF Data Binding EL Expressions."](#)

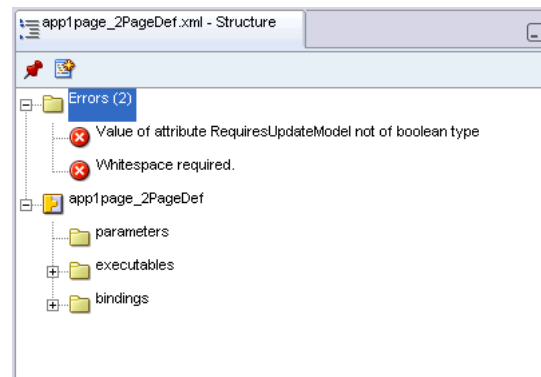

[Example 31-1](#) illustrates two simple compilation errors contained in a page definition file: `tru` instead of `true` and `id="CountryCodesView1Iterator" /` instead of `id="CountryCodesView1Iterator" />` (that is, the ID is missing a closing angle bracket).

#### **Example 31-1 Sample Page Definition File with Two Errors**

```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
  version="11.1.1.42.54" id="app1page_2PageDef"
  Package="project1.pageDefs">
  <parameters/>
  <executables>
    <iterator Binds="CountryCodesView1" RangeSize="10"
      DataControl="AppModuleDataControl"
      id="CountryCodesView1Iterator" /
  </executables>
  <bindings>
    <action id="Find" RequiresUpdateModel="tru" Action="3"
      IterBinding="CountryCodesView1Iterator" />
  </bindings>
</pageDefinition>
```

During compilation, the Structure window displays the XML errors in the page, as shown in [Figure 31-1](#).

**Figure 31-1 The Structure Window Displays XML Errors**

The Compiler-Log window also displays the compilation errors in the page, as shown in [Figure 31-2](#).

**Figure 31–2 The Compiler Window Displays XML Compile Errors****To view and correct schema validation errors:**

1. In the main menu, choose **View** and then **Structure** to open the Structure window or choose **View** and then **Log** to open the Log Window.
2. In either window, double-click the error message.
3. In the XML editor, locate the highlighted lines.  
The highlighted lines will be lines with errors.
4. Correct any errors.  
After an error has been corrected, the corresponding error message will be automatically removed from the Structure window.
5. Optionally, you can recompile the project by choosing **Run > Make** and checking to see whether the compiler still produces the error message.

### 31.3 Correcting Simple Oracle ADF Runtime Errors

Failures of the ADF Model layer cannot be detected by the JDeveloper compiler, in part because the page's data-display and method-execution behavior relies on the declarative ADF page definition files. The ADF Model layer utilizes those declarative files at runtime to create the objects of the ADF binding container.

To go beyond simple schema validation, you will want to routinely run and test your web pages to ensure that none of the following conditions exists:

- The project dependency between the data model project and the user interface project is disabled.

By default, the dependency between projects is enabled whenever you create a web page that accesses a data control in the data model project. However, if the dependency is disabled and remains disabled when you attempt to run the application, an internal servlet error will be generated at runtime:

```
oracle.jbo.NoDefException: JBO-25002: Definition
model.DataControls.dcx of type null not found
```

To correct the error, double-click the user interface project, and select the **Dependencies** node in the dialog. Make sure that the *ModelProjectName.jpr* option appears selected in the panel.

- Page definition files have been renamed, but the `DataBindings.cpx` file still references the original page definition file names.

While JDeveloper does not permit these files to be renamed within the IDE, if a page definition file is renamed outside of JDeveloper and the references in the `DataBindings.cpx` file are not also updated, an internal servlet error will be generated at runtime:

```
oracle.jbo.NoDefException: JBO-25002: Definition
oracle.<path>.pageDefs.<pagedefinitionName> of type Form
Binding Definition not found
```

To correct the error, open the `DataBindings.cpx` file and use the source editor to edit the page definition file names that appear in the `<pageMap>` and `<pageDefinitionUsages>` elements.

- The web page file (`.jsp` or `.jspx`) has been renamed, but the `DataBindings.cpx` file still references the original file name of the same web page.

The page controller uses the page's URL to determine the correct page definition to use to create the ADF binding container for the web page. If the page's name from the URL does not match the `<pageMap>` element of the `DataBindings.cpx` file, an internal servlet error will be generated at runtime:

```
javax.faces.el.PropertyNotFoundException: Error testing
property <propertyname>
```

To correct the error, open the `DataBindings.cpx` file and use the source editor to edit the web page file names that appear in the `<pageMap>` element.

- Bindings have been renamed in the web page EL expressions, but the page definition file still references the original binding object names.

The web page may fail to display information that you expect to see. To correct the error, compare the binding names in the page definition file and the EL expression responsible for displaying the missing part of the page. Most likely the mismatch will occur on a value binding, with the consequence that the component will appear but without data. Should the mismatch occur on an iterator binding name, the error may be more subtle and may require deep debugging to isolate the source of the mismatch.

- Bindings in the page definition file have been renamed or deleted, and the EL expressions still reference the original binding object names.

Because the default error-handling mechanism will catch some runtime errors from the ADF binding container, this type of error can be very easy to find. For example, if an iterator binding named `findUsersByNameIter` was renamed in the page definition file, yet the page still refers to the original name, this error will display in the web page:

```
JBO-25005: Object name <iterator> for type Iterator Binding
Definition is invalid
```

To correct the error, right-click the name in the web page and choose **Go to Page Definition** to locate the correct binding name to use in the EL expression.

- EL expressions were written manually instead of using the expression picker dialog and invalid object names or property names were introduced.

This error may not be easy to find. Depending on which EL expression contains the error, you may or may not see a servlet error message. For example, if the error occurs in a binding property with no runtime consequence, such as displaying a label name, the page will function normally but the label will not be displayed. However, if the error occurs in a binding that executes a method, an internal servlet error `javax.faces.el.MethodNotFoundException: methodname` will display. Or, in the case of an incorrectly typed property name on the method expression, the servlet error

```
javax.faces.el.PropertyNotFoundException: propertyname will
display.
```

If this list of typical errors does not help you to find and fix a runtime error, you can initiate debugging within JDeveloper to find the contributing factor. For an ADF application, start setting ADF declarative breakpoints to find the problem. Using the ADF Declarative Debugger to set ADF declarative breakpoints is described in [Section 31.7, "Using the ADF Declarative Debugger,"](#) and [Section 31.8, "Setting ADF Declarative Breakpoints."](#) This process involves pausing the execution of the application as it proceeds through the application and examining data. You can also use the ADF Declarative Debugger to set Java code breakpoints, as described in [Section 31.9, "Setting Java Code Breakpoints."](#)

## 31.4 Validating ADF Controller Metadata

Basic validation is performed when ADF Controller retrieves metadata. The most serious errors, for example, a task flow that is missing a default activity, result in parsing exceptions.

The `enable-grammar-validation` setting in `adf-config.xml` allows you to validate the grammar in ADF Controller metadata before deploying an application. When `enable-grammar-validation` is set to `true`, ADF Controller metadata is validated against ADF Controller XSDs. For example, invalid characters in ADF Controller metadata, such as a slash (/) in a view activity ID, are flagged as exceptions.

By default, `enable-grammar-validation` is set to `false`. For performance reasons, it should be set to `true` only during application development or when troubleshooting an application.

## 31.5 Using the ADF Logger

If you are not able to easily find the error in either your web page or its corresponding page definition file, you can use the JDeveloper debugging tools to investigate where your application failure occurs.

You configure the logging session by editing the `logging.xml` configuration file using the editor for Oracle Diagnostic Logging Configuration. Logging configuration can be set at any time, even while the application is running in JDeveloper.

Unlike many files in JDeveloper, you cannot directly open the `logging.xml` file. Instead you use menu commands at these locations to open the Oracle Diagnostic Logging Configuration editor:

- Right-click an active server instance in the Application Server Navigator.
- Click the Actions dropdown menu displayed in the Log window's debugger process panel, after you have started the application in debug mode.

You use the Oracle Diagnostic Logging Configuration editor to set the desired logging level to control the level and number of messages that are displayed. You can set the logging level for both persistent and transient loggers and declare handlers for each logger.

JDeveloper creates diagnostic log files in the Oracle Diagnostic Logging (ODL) format, used by Oracle Fusion Middleware components. Log file naming and the format of the contents of log files conform to an Oracle standard. By default, the diagnostic messages are in text format. For more information about the ODL format, see the *Oracle Fusion Middleware Administrator's Guide*.

In the editor, as an alternative to the default ODL format, you can configure the Java Logger to display Java diagnostic messages.

After you have created a log, you can view and filter the log messages with Oracle Diagnostic Log Analyzer. This tool allows you to set filters for different log levels, define message time frames, and search on message text.

You can then use the ADF Declarative Debugger to set breakpoints and examine the the application. For more information, see [Section 31.8, "Setting ADF Declarative Breakpoints,"](#) and [Section 31.9, "Setting Java Code Breakpoints."](#)

### 31.5.1 How to Set ADF Logging Levels

You can use the Oracle Diagnostic Logging Configuration editor to configure the logging levels specified in the `logging.xml` configuration file. The file can be configured before and while the application is running in Integrated WebLogic Server. The changes will apply without the need to restart the server.

When Integrated WebLogic Server is running, you can define both persistent and transient loggers. When Integrated WebLogic Server is not running, you can only define persistent loggers. The transient loggers will last only for the session and will not be entered in the `logging.xml` configuration file. If the server is not running, you must explicitly save the configuration changes to the `logging.xml` file for the updates to take effect in the next server run.

You can access the Oracle Diagnostic Logging Configuration editor from the Application Server Navigator or from the Log window, which is shown in [Figure 31–3](#).

**Figure 31–3 Log Window with Toolbar**

However, while the server is running, when you access the editor via the Log window menu, then the editor has the ability to add transient loggers.

[Figure 31–4](#) shows the Oracle Diagnostic Logging Configuration while the server is running.

**Figure 31–4 Editor for Oracle Diagnostic Logging Configuration**

You can only use JDeveloper menu commands to open the `logging.xml` configuration file and launch the editor for Oracle Diagnostic Logging Configuration. However, you may find the following information about the location of the configuration file useful.

---

**Note:** You can declare and add log handler definitions by clicking the **Source** tab and entering them in the XML editor.

---

If you are using Integrated WebLogic Server in JDeveloper on the Windows platform, you can find the `logging.xml` configuration file in a location similar to:

```
C:\Documents and Settings\username\ApplicationData\JDeveloper\latest_system_folder\DefaultDomain\config\fmwconfig\servers\DefaultServer
```

The log files for Integrated WebLogic Server are in a location similar to:

```
C:\Documents and Settings\username\ApplicationData\JDeveloper\latest_system_folder\DefaultDomain\servers\DefaultServer\logs
```

The log files for a standalone WebLogic Server instance are in a location similar to:

```
$domain_home/servers/your_servername/logs
```

You can configure logging levels before a test run from the Application Server Navigator, or, while the application is running, from the Log window's run panel toolbar, or, during a debug session, from the Log window's debug process toolbar.

**To configure the log levels:**

1. In the main menu, choose **View** and then **Application Server Navigator**.
2. In the Application Server Navigator, expand **Application Servers**, and right-click **IntegratedWebLogicServer** and choose **Configure Oracle Diagnostic Logging for "IntegratedWebLogicServer"**.

Or, after you start the application, from the Log window's Running: IntegratedWebLogicServer panel, choose **Actions - Configure Oracle Diagnostic Logging**. The Running Log window is only visible while you run the application.

Or, while you debug the application, from the Log window's debug process panel, choose **Actions - Configure Oracle Diagnostic Logging**. The debug process panel is only visible in the Log window after you have started the application in debug mode.

3. In the editor for Oracle Diagnostics Logging Configuration, select **ODL Log Levels** or **Java Log Levels** for the logger type you want to view.
4. If you want to see persistent loggers only, select **Hide Transient Loggers**.
5. To add a logger:
  - a. If the server is running, click the **Add** icon dropdown menu and choose **Add Persistent Logger** or **Add Transient Logger**. If the server is not running, click **Add** to add a persistent logger. You cannot add a transient logger.
  - b. In the Add Logger dialog, enter a logger name.
  - c. Select the logging level.
  - d. Click **OK**.
6. For any logger, including a newly created logger, you can specify its handlers by selecting from a list of available handlers by clicking the **Add** icon for the **Handler Declarations** section.

Or, you can select **Use Parent Handlers** to assign its parent's handler to the logger. By default, a logger uses its parent's handler.

---

---

**Note:** You can declare and add log handler definitions by clicking the **Source** tab and entering them in the XML editor.

---

---

## 31.5.2 How to Create an Oracle ADF Debugging Configuration

Oracle ADF leverages the Java Logging API (`java.util.logging.Logger`) to provide logging functionality when you run a debugging session. Java Logging is a standard API that is available in the Java platform at <http://docs.oracle.com/javase/1.4.2/docs/guide/util/logging/overview.html>.

To log a complete hierarchy tree of ADF event messages, you must configure a Java log level that is not more restrictive than `CONFIG` (or an ODL log level that is not more restrictive than `Notification:16`) for the single package:

- `oracle.adfdiagnostics` will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.

Figure 31–5 shows specific the logger configured to enable the most detailed Oracle ADF log messages. Note that the `oracle.adfdiagnostics` package is set to CONFIG and not to a higher, more restrictive log level (where SEVERE, WARNING, and INFO are Java log levels higher than CONFIG and FINE, FINER, and FINEST are lower levels than CONFIG). Enabling a logger for the `oracle.adfdiagnostics` package ensures that the logger records a complete hierarchy of ADF events.

**Figure 31–5 Configuring a Logger for Oracle ADF Debugging**

#### Oracle Diagnostics Logging Configuration

Control logging behavior for specified loggers. If the server is running, changes take effect immediately. Any transient instance loggers you add exist only in the context of the running server, and are not persisted to the logging.xml file.

Loggers:

For backward compatibility, the Java system property `jbo.debugoutput` set to the value `console` or `ADFLogger` (to route diagnostics through the standard Logger implementation, which can be controlled in a standard way through the `logging.xml` file) is supported. The easiest way to set this system property while running your application inside JDeveloper is to edit your project properties and in the Run/Debug/Profile page, select a run configuration and click **Edit**. Then add the string `-Djbo.debugoutput=console` to the **Java Options** field.

#### To create an ADF Model debugging configuration:

1. In the main menu, choose **View** and then **Application Server Navigator**.
2. In the Application Server Navigator, expand **Application Servers**, and right-click **IntegratedWebLogicServer** and choose **Configure Oracle Diagnostic Logging**.

Or, after you start the application, from the Log window's Running: IntegratedWebLogicServer panel, choose **Actions - Configure Oracle Diagnostic Logging**. The Running Log window is only visible while you run the application.

Or, while you debug the application, from the Log window's debug process panel, choose **Actions - Configure Oracle Diagnostic Logging**. The debug process panel is only visible in the Log window after you have started the application in debug mode.

3. In the editor for Oracle Diagnostics Logging Configuration, select **ODL Log Levels** or **Java Log Levels** for the logger type you want to view.

4. Expand the **oracle** node and select a log level that are not more restrictive than `CONFIG` (for Java Log) or that are not more restrictive than `Notification` (for ODL Log) for the following package:
  - **oracle.adfdiagnostics** will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.  
 Enabling a logger for this package ensures that the logger records a complete hierarchy of ADF events.
5. Select the Java log level **FINEST** for other desired Oracle ADF loggers.

**To create an ADF view Javascript logging configuration:**

1. In the Application Navigator, double-click the application or project **web.xml** file.
2. In the source editor, add the following elements to the file:

```
<context-param>
  <param-name>
    oracle.adf.view.rich.LOGGER_LEVEL
  </param-name>
  <param-value>
    FINE
  </param-value>
</context-param>
```

### 31.5.3 How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers

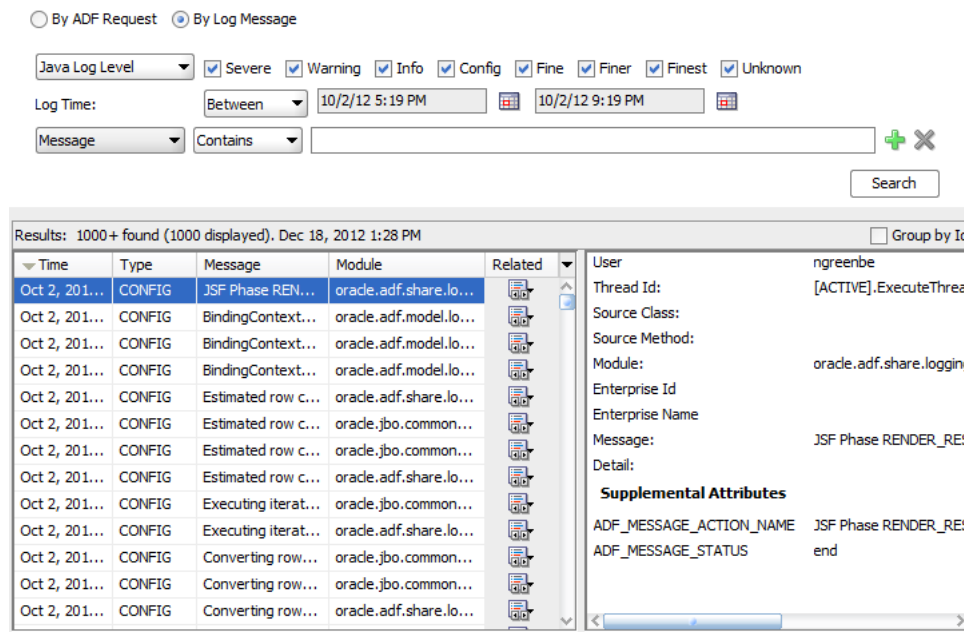

For non-Oracle ADF loggers, before you use the actual debugger, running the application with Java log level set to `FINE`, `FINER`, or `FINEST` will enable framework diagnostics logging. The debug diagnostic messages can be helpful to see what happens when the problem occurs. To enable debug diagnostic messages, use the Oracle Diagnostics Logging Configuration Editor to configure the desired loggers with a Java log level set to `FINEST`. If you have configured diagnostic logging for the supported loggers, JDeveloper will direct debug diagnostics messages to the JDeveloper Log window.

Currently, Oracle ADF does not support logging with Java log level `FINE`, `FINER`, or `FINEST`. For more details about Oracle ADF loggers, see [Section 31.5.2, "How to Create an Oracle ADF Debugging Configuration."](#)

### 31.5.4 How to Use the Log Analyzer to View Log Messages

You can use Oracle Diagnostic Log Analyzer to view the log entries of a log file. The log analyzer allows you to filter the entries by log level, entry type, log time, and entry content (using one or more search criteria). You can also order the messages and show and hide columns for better viewing.

[Figure 31-6](#) shows Oracle Diagnostic Log Analyzer set to view Java Log levels.

**Figure 31–6 Oracle Diagnostic Log Analyzer Displays Java Log Messages**

You can also use the log analyzer on log files created in other test runs. For instance, you can analyze the log sent to you by another developer for another application.

#### 31.5.4.1 Viewing Diagnostic Messages in the Log Analyzer

You can configure logging levels before a test run from the Application Server Navigator or during a debug session from the Log window toolbar. The level you specify will determine the type and quantity of log messages.

In the case of ADF events, all messages are generated for the ODL log at the level Notification or for the Java log at the level Info. Fewer ADF messages will be generated at the Incident Error/Severe and Error/Warning levels.

After you select the log level for the messages you wish to view, you can use the Search panel of the By Log Message page to filter the messages to display from the log file.

---

**Note:** For further details about search criteria that you can specify to search on ADF-specific messages, see [Section 31.5.4.3, "Sorting Diagnostic Messages By ADF Events."](#)

---

You can start the log analyzer before a test run from the **Tools** menu or during a debug session from the log window toolbar.

#### Before you begin:

It may be helpful to have an understanding of logging. For more information, see [Section 31.5, "Using the ADF Logger."](#)

Complete these tasks:

1. Set logging levels, as described in [Section 31.5.1, "How to Set ADF Logging Levels."](#)

2. Enable logging, as described in [Section 31.5.3, "How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers."](#)
3. Create a log file, either from your test run or from another source.

**To start the log analyzer:**

1. In the main menu, choose **Tools** and then **Oracle Diagnostic Log Analyzer**.  
Or, from the Log window **Action** menu, choose **Analyze Log** and then either **Current in Console** or **Open Selected** (to browse log files in the server log directory).
2. In the editor for Oracle Diagnostic Log Analyzer, select **By Log Message**.
3. In the By Log Message page, in the **Log** field, enter the path and name of the log file or click **Browse Log Files** to navigate to the log file.

**Tip:** The Choose Log File dialog helps you to navigate to the directory that contains the log files generated by JDeveloper. Click the **Browse Log Files** icon next to the **Log** text field, and then click the **Server Logs** icon from the scroll list. From the list of log files, you can select more than one log file to analyze at a time.

4. From the dropdown list, select either **ODL Log Level** or **Java Log Level**.
5. Select the corresponding checkbox for each type of log entry you want to view. You must select at least one type.

The available ODL log level types are:

- INCIDENT ERROR
- ERROR
- WARNING
- NOTIFICATION - corresponds to ADF event messages
- TRACE
- UNKNOWN.

The available Java log level types are:

- SEVERE
- WARNING
- INFO
- CONFIG - corresponds to ADF event messages
- FINE
- FINER
- FINEST
- UNKNOWN

6. Specify a time period for the entries you want to view. You can select the most recent *period* or a range.
7. To filter the results, use the Search panel to query the log for a text pattern. For additional search criteria, click **Add**. The supported search criteria include:
  - **Enterprise Name:** Filters the log by the name of the enterprise.

- **Detail:** Filters text in statements from the stack where the method was invoked.
  - **EnterpriseID:** Filters the log by the ID of the enterprise.
  - **Message:** Filters text in the logged messages.
  - **ADF Message Data:** Filters the log for data related to ADF lifecycle phase names, view object names, view object query statements, data control names, binding container names, and iterator binding names logged during the execution of ADF events.
  - **Source Method:** Filters the log by the method where the message is logged. For example, you can filter on the method `execute` to view all messages logged for view object query execution or ADF lifecycle phase execution.
  - **Application:** Filters the log by the application name where the message is logged. This is useful when the application is running in a composite application and you want to view messages for a specific application.
  - **Source Class:** Filters the log by the fully qualified class name of the method where the message is logged. To see more messages, enter a partial package name. For example, you can enter the partial package name `oracle.adf` or the full package name `oracle.jbo` to filter for all classes related to Oracle ADF.
  - **Module:** Filters the log by the fully qualified package name of the class where the message is logged. This is same package as the source class.
  - **Message Id:** Filters the log by the ID of the logged messages. Many messages share the same ID. For example, message ID `ADFC-52008` might have four `INFO` messages and one `Warning` message. You can select **Group by Id** in the log analyzer Results panel to group messages by their common ID.
8. To initiate the filters and display the log messages, click **Search**.
  9. To order the results by the message ID, select the **Group by Id** checkbox.
  10. To group the messages by time period or by request, in the **Related** column, select either **Related by Time** or **Related by Request**.  
When you select **Related by** option, the log analyzer groups the messages in the Results Messages panel according to the selected criteria (time, HTTP request, or enterprise name).
  11. To open the ADF request (if any) that the message is a part of, in the **Related** column, select **Related by ADF Request**.  
When you select **Related by ADF Request**, the log analyzer displays the related request in the By ADF Request page.
  12. To show or hide columns in the **Results** section, click the dropdown list to the right of the column headers and select among the list of displayed columns to change the visibility of a column.

#### 31.5.4.2 Using the Log Analyzer to Analyze the ADF Request

Because Oracle instrumented the Oracle ADF source code to generate log messages during the execution of the ADF lifecycle phases, you can use the log analyzer to investigate the details of the active (or previous) page request in your running application. Specifically, the By ADF Request page of the log analyzer lets you view ADF event messages in a hierarchical list, organized by the sequence of their execution. It also provides a graphical representation of the duration of each event.

When you run your application and start the log analyzer with ADF logging configured, you can use this page to quickly identify whether a component of your application is contributing to a performance bottleneck due to unusually long execution times.

---

**Note:** In contrast to the By Log Message page, the By ADF Request page of the log analyzer displays a hierarchical view of ADF event messages. The difference between these two pages is that the By ADF Request page focuses only on ADF page requests made when a page or region is submitted. For details about the ADF page lifecycle, see [Chapter 21, "Understanding the Fusion Page Lifecycle."](#)

---

You can enter search criteria in the By ADF Request page to display one or more specific requests from the log file. You can combine any of the following search criteria to filter the log file:

- The number of requests to display
- The timestamp for the request recorded in the log
- The logged-in user name, enterprise name, request header (to specify a search based on the page or region name), message, source class, module, server, detail, enterprise ID, ADF message data, application name in a composite application, source method, message ID, or ECID (a globally unique ID associate with every top-level task; sub-tasks invoked by that top-level task operate with an execution context that shares the same ECID)

After the request is completed, the log analyzer displays a summary of the ADF requests in a single table. [Figure 31–7](#) shows the summary table that displays the list of ADF web requests.

**Figure 31–7 Oracle Diagnostic Log Analyzer Displays Summary of ADF Web Requests**

The screenshot shows the Oracle Diagnostic Log Analyzer interface. At the top, there are two radio buttons: "By ADF Request" (selected) and "By Log Message". Below this, there are several search filters: "Most Recent:" with a dropdown set to "20" and "Requests"; "Log Time:" with a "Between" dropdown and two date-time pickers set to "10/2/12 5:06 PM" and "10/2/12 9:06 PM"; and "Request Header" with a "Contains" dropdown and an empty text input field. A "Search" button is located to the right of the input field. Below the filters, the results are displayed in a table. The table has a header row with columns: "ADF Request", "Requ...", "Times...", "Applic...", "User", "Server", and "ECID". The table contains seven rows of data, each with a blue hyperlink in the "ADF Request" column. The results are: "7 requests found, 7 displayed. Dec 18, 2012 1:26:27 PM PST."

ADF Request	Requ...	Times...	Applic...	User	Server	ECID
<a href="#">StoreFrontModule/faces/myorders-task-flow/myOrders</a>	907	2012-1...	StoreFr...	ngreenbe	Default...	d42e28...
<a href="#">StoreFrontModule/faces/adf.login-success</a>	25057	2012-1...	StoreFr...	ngreenbe	Default...	d42e28...
<a href="#">StoreFrontModule/faces/login.ispx</a>	125	2012-1...	StoreFr...	<anon...	Default...	d42e28...
<a href="#">StoreFrontModule/faces/login.ispx</a>	31	2012-1...	StoreFr...	<anon...	Default...	d42e28...
<a href="#">StoreFrontModule/faces/home</a>	406	2012-1...	StoreFr...	<anon...	Default...	d42e28...
<a href="#">StoreFrontModule/faces/home</a>	14341	2012-1...	StoreFr...	<anon...	Default...	d42e28...
<a href="#">StoreFrontModule/faces/home</a>	1702	2012-1...	StoreFr...	<anon...	Default...	d42e28...

For each ADF request displayed in the summary table, you can click the request link to view details about the request event hierarchy. [Figure 31–8](#) shows the ADF Requests

panel with the JSF lifecycle Restore View and Render Response phases displayed and their duration in milliseconds. The bar graph for the root node of the request event hierarchy (**ADF web request**) displays the total execution time.

**Figure 31–8 Oracle Diagnostic Log Analyzer Displays ADF Web Request Event Hierarchy**

**Note:** The **Percentage Request Time** bar graphs (black and gray) indicate which portion of the request's execution time resulted from ADF source code that was instrumented to generate ADF event messages (shown in black) and which portion resulted from ADF source code that is uninstrumented and therefore cannot generate ADF event messages (shown in gray). Additionally, note that the individual phases of the request do not sum to equal the total request time. This is due to the fact that only the useful phases of the lifecycle are represented in the log analyzer.

To examine the request in more detail, you can expand the tree for any ADF lifecycle node to further investigate where in the application the performance bottleneck occurred. Drilling down and then selecting the ADF event node in the request message panel gives you details about the component associated with each ADF event. For instance, expanding the **JSF Phase RENDER\_RESPONSE** node displays all ADF events generated during that phase. [Figure 31–9](#) shows the **JSF Phase RENDER\_RESPONSE** node expanded with a long request duration bar graph for the **Get LOV list** node and the **Execute query** node. The **Execute query** node has been selected to reveal detailed ADF data in the ADF Message Data Details panel, including the view object's name and query statement. By drilling down and selecting the ADF event with the long execution time as indicated by the bar graph, you can obtain, for example, the name of the view object in the data model project that should be tuned for improved performance.

**Figure 31–9 Oracle Diagnostic Log Analyzer Displays ADF Event Messages with ADF Data**

Results: 7 requests found, 7 displayed. Dec 18, 2012 1:26:27 PM PST.

ADF Requests adf.login-success 20:21:22.367

### Before you begin:

It may be helpful to have an understanding of logging. For more information, see [Section 31.5, "Using the ADF Logger."](#)

Complete these tasks:

1. Set logging levels, as described in [Section 31.5.1, "How to Set ADF Logging Levels."](#)

To log a complete hierarchy tree of ADF event messages, you must configure an ODL log level that is not more restrictive than `NOTIFICATION:16` or a Java log level that is not more restrictive than `CONFIG` for the following single package:

- `oracle.adfdiagnostics` will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.

**Tip:** The default log level for the Root Logger displayed by the overview editor for Oracle Diagnostics Logging Configuration ensures that ADF event messages are logged.

2. Enable logging, as described in [Section 31.5.3, "How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers."](#)
3. Create a log file, either from your test run or from another source.

### To display ADF request messages in the log analyzer:

1. In the main menu, choose **Tools** and then **Oracle Diagnostic Log Analyzer**.  
Or, from the Log window **Action** menu, choose **Analyze Log** and then either **Current in Console** or **Open Selected** (to browse log files in the server log directory).
2. In the editor for Oracle Diagnostic Log Analyzer, click the **By ADF Request** tab.
3. In the By ADF Request page, specify how many of the most recent request you want to display.

The default displays only the most recent request.

4. Specify a time period for the entries you want to view. You can select the most recent *period* or a range.
5. To filter the request to display, use the search fields to query the log for a text pattern. For additional search fields, click the **Add Row** icon.
6. To initiate the filters and display matching ADF requests, click **Search**.
7. In the ADF Requests panel, click the desired request link to view the event hierarchy and look for ADF events that display long execution times as indicated by the **Time (ms)** bar graphs.
8. Select the desired ADF event and examine the ADF Message Data Details panel for details about the ADF component associated with the ADF event.
9. Examine the component in your application and determine whether optimization is possible.

### 31.5.4.3 Sorting Diagnostic Messages By ADF Events

Oracle instrumented the Oracle ADF source code to generate log messages during the execution of the ADF lifecycle phases and during operations executed in the ADF Model data binding layer, ADF Controller source, and ADF Business Components source. Combined, the log analyzer refers to these messages as ADF events. You can use the log analyzer to investigate ADF events in your running application. The By Log Message page of the log analyzer lets you view ADF event messages in a flat list, organized by time of execution, with the option to switch to the By ADF Request page to view the ADF events in a hierarchical list, organized by the sequence of their execution.

ADF event messages contain useful information that helps you identify which ADF components in your application generated the event. For example, you can search the log for ADF event messages to identify the components related to displaying data in the page, executing queries, or initiating actions:

- Executing iterator binding: Displays the names of the iterators executed to manage displaying data in the page. This can be useful for diagnosing slow query updates.
- Execute query: Displays the name of the view object associated with the executed query. This can be useful when you want to view the query statement, bind parameters, and name of the view object.
- Executing method binding: Displays the names of the Java methods executed on the bound data source. This can be useful for diagnosing slow method execution.

After you display an ADF event message in the log analyzer, you can organize the event in the context of other logged messages. You can select options from the **Related** column to display:

- All messages leading up to the ADF event (related by time)
- All messages in the same web request as the ADF event (related by request)
- Only ADF event messages in the same web request (related by ADF request)

**Tip:** The **Related by ADF Request** view displays detailed ADF data for the ADF event messages. This is the view to use, for example, when you want to display the query statement associated with the `Execute query` message.

Figure 31–10 shows the log analyzer search result for the ADF event message `Create Application Module`. The Results panel displays all messages that match the search criteria and the bottom panel displays detailed information about the component.

**Figure 31–10 Oracle Diagnostic Log Analyzer Displays ADF Event Messages**

The screenshot shows the Oracle Diagnostic Log Analyzer interface. At the top, there are search filters: radio buttons for 'By ADF Request' and 'By Log Message' (selected), a 'Java Log Level' dropdown, and checkboxes for log levels: Severe, Warning, Info, Config, Fine, Finer, Finest, and Unknown. Below these are 'Log Time' filters with a 'Between' dropdown and two date-time inputs: '10/2/12 5:19 PM' and '10/2/12 9:19 PM'. A search criteria field shows 'Message' containing 'Create Application Module'. A 'Search' button is on the right.

The Results panel shows 'Results: 4 found. Dec 18, 2012 2:34 PM'. It has a 'Group by Id' checkbox. The results table has columns: Time, Type, Message, Module, and Related. The first row is selected, showing 'Oct 2, 2011... CONFIG Create Application Module oracle.adf.s...'. To the right of the table is a detailed view for the selected row, showing fields like User, Thread Id, Source Class, Source Method, Module, Enterprise Id, Enterprise Name, Message, and Detail. Under 'Supplemental Attributes', it shows 'ADF\_MESSAGE\_ACTION\_NAME Create Application Modu' and 'ADF\_MESSAGE\_STATUS end'.

Time	Type	Message	Module	Related
Oct 2, 2011...	CONFIG	Create Application Module	oracle.adf.s...	[icon]
Oct 2, 2011...	CONFIG	Create Application Module	oracle.adf.s...	[icon]
Oct 2, 2011...	CONFIG	Create Application Module	oracle.jbo.c...	[icon]
Oct 2, 2011...	CONFIG	Create Application Module	oracle.jbo.c...	[icon]

When you select **Related by ADF Request** in the **Related** column of the Results panel, the log analyzer switches to display the By ADF Request page with the ADF event messages arranged hierarchically to show their execution dependencies. The By ADF Request page of the log analyzer is the preferred way to diagnose performance issues. For details about the By ADF Request page, see [Section 31.5.4.2, "Using the Log Analyzer to Analyze the ADF Request."](#) In the By Log Message page, the elapsed time is information that you can leave visible or hide from the Results panel.

#### Before you begin:

It may be helpful to have an understanding of logging. For more information, see [Section 31.5, "Using the ADF Logger."](#)

Complete these tasks:

1. Set logging levels, as described in [Section 31.5.1, "How to Set ADF Logging Levels."](#)

To log ADF event messages, do not configure an ODL log level that is more restrictive than `NOTIFICATION:16` or a Java log level that is more restrictive than `CONFIG` for the following package:

- `oracle.adfdiagnostics` will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.

**Tip:** The default log level for the Root Logger displayed by the overview editor for Oracle Diagnostics Logging Configuration ensures ADF event messages are logged.

2. Enable logging, as described in [Section 31.5.3, "How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers."](#)

3. Create a log file, either from your test run or from another source.

**To display messages related by ADF events:**

1. In the main menu, choose **Tools** and then **Oracle Diagnostic Log Analyzer**.

Or, from the Log window **Action** menu, choose **Analyze Log** and then either **Current in Console** or **Open Selected** (to browse log files in the server log directory).

2. In the editor for Oracle Diagnostic Log Analyzer, click the **By Log Message** tab.
3. In the By Log Message page, select the desired logger type, log levels, and log time.

To search the log for ADF event messages, you must minimally select log level **Notification** (for ODL log level) or **Info** (for Java log level).

4. In the search dropdowns, choose the search criteria **Message** and **Contains**, and then enter any of the following ADF event messages and click **Search**.
  - `Executing iterator binding` - this can be useful for diagnosing slow query updates.
  - `Executing method binding` - this can be useful for diagnosing slow method execution.
  - `Execute query` - this can be useful when you want to view the query statement, bind parameters, and name of the view object.

You can also filter the log on these additional ADF event messages:

- `Refreshing binding container`
- `Attaching an iterator binding to a datasource`
- `Converting rows into hierarchical nodes`
- `Estimated row count`
- `Get LOV list`
- `Filter LOV list`
- `Validate Entity`
- `Lock Entity's Parent`
- `Lock Entity`
- `Before posting the entity's changes`
- `Posting the entity's changes`
- `Posting in batches`
- `Before committing the entity's changes`
- `After committing the entity's changes`
- `Before rolling back the entity's changes`
- `After rolling back the entity's changes`
- `Entity notifying an event`
- `Entity notification name`
- `Removing Entity`

- Updating audit columns
- Applying Effective Date change
- Entity DML
- Entity read all attributes
- Create Application Module
- Create nested Application Module
- Passivating Application Module
- Activating Application Module
- Establish database connection
- Commit transaction
- Rollback transaction
- Validate transaction
- Validate value

Examine the data portion of the Results panel for the ADF event information.

5. To view a hierarchical sequence of ADF events, with the desired ADF event message selected in the Results panel, in the **Related** column, click the icon for the desired event row and choose **Related By ADF Request** from the dropdown menu.

The editor for Oracle Diagnostic Log Analyzer displays the By ADF Request page for the selected ADF event. Examine the bottom portion of the Results panel for additional ADF data for the ADF event. For example, you can see the query statement associated with the `Execute query` message in the ADF Data area of the Results panel.

### 31.5.5 What You May Need to Know About the Logging.xml File

By default, the level is set to `WARNING` for all Oracle loggers. For Oracle ADF packages set `level="FINE"` for detailed logging diagnostics.

For the ADF view layer packages `oracle.adf.view.faces` and `oracle.adfinternal.view.faces`, edit these elements:

```
<logger name="oracle.adf" level="FINE"/>
<logger name="oracle.adfinternal" level="FINE"/>
```

For the ADF Model layer packages, edit these elements:

```
<logger name="oracle.adf" level="FINE"/>
<logger name="oracle.jbo" level="FINE"/>
```

For the ADF Controller layer packages, edit these elements:

```
<logger name="oracle.adf.controller" level="FINE"/>
<logger name="oracle.adfinternal.controller" level="FINE"/>
```

Alternatively, you can create a debug configuration in JDeveloper that you can choose when you start a debugging session.

[Example 31–2](#) shows the portion of the `logging.xml` file where you can change the granularity of the log messages. Note in the example that the log for `oracle.adf.faces` has been changed to `FINE` to display more messages.

**Example 31–2 Sample Section of the logging.xml Configuration File**

```

</logging_configuration>
...
<loggers>
  <logger name="oracle.adf" level="INFO"/>
  <logger name="oracle.adf.faces" level="FINE"/>
  <logger name="oracle.adf.controller" level="INFO"/>
  <logger name="oracle.bc4j" level="INFO"/>
  <logger name="oracle.adf.portal" level="INFO"/>
  <logger name="oracle.vcr" level="INFO"/>
  <logger name="oracle.portlet" level="INFO"/>
  <logger name="oracle.adfinternal" level="INFO"/>
  <logger name="oracle.adfdt" level="INFO"/>
  <logger name="oracle.adfdtinternal" level="INFO"/>
</loggers>
</logging_configuration>

```

For the latest information about the different levels of the Java Logging system, go to <http://www.oracle.com/technetwork/java/index.html>. Normally, the Java logging system supports the following log levels:

- SEVERE (most restrictive, highest log level)
- WARNING
- INFO
- CONFIG (the highest low level supported for Oracle ADF)
- FINE
- FINER
- FINEST (least restrictive, lowest log level)

### 31.5.6 What You May Need to Know About ADF Logging and Oracle WebLogic Server

After you have deployed the Fusion web application to Oracle WebLogic Server, the operations performed by the application are logged directly to the Managed Server where the application is running:

```
DOMAIN_HOME/servers/server_name/logs/server_name-diagnostic.log
```

The log files for the different Managed Servers are also available from the Oracle WebLogic Server Administration Console. To verify the logs, access the Oracle WebLogic Server Administration Console `http://<admin_server_host>:<port>/console` and click **Diagnostics-Log Files**.

This log's granularity and logging properties can be changed using Oracle Enterprise Manager Fusion Middleware Control (Fusion Middleware Control). Fusion Middleware Control is a web browser-based, graphical user interface that you can use to monitor and administer a farm.

When the Fusion web application is deployed to a high availability environment, you can receive warning diagnostic messages specific to high availability by setting the level to FINE.

For details about using Fusion Middleware Control to change the log settings of Managed Servers and Oracle ADF, see the *Oracle Fusion Middleware Administrator's Guide*.

## 31.6 Using the Business Component Browser for Testing and Debugging

The Business Component Browser (also referred to as the Browser) is a Java application that you launch from JDeveloper when you want to interact with the business objects of the ADF Business Components data model project. The Business Component Browser runs outside of JDeveloper and provides a full UI for testing and examining the data model project. You can run the Browser to examine the view instances of the ADF application module, navigate the hierarchical relationship of view links, and execute custom methods from the application module's client interface, view object interface, and view row interface. The Browser also interacts with the ADF Declarative Debugger to allow you to set breakpoints on the custom methods of these interfaces.

Additionally, the Browser simulates many features that the user interface might expose by allowing you to view, insert, and update the contents of business objects in the database specified by the application module's configuration file (`bc4j.xcfg`). Specifically, you can use the Browser to verify many aspects of the data model design, including master-detail relationships between view instance, view instances and their attributes, view instance query result sets, search forms using view criteria, validation rules defined for attribute values, and dropdown lists on LOV-defined attributes (list of values). For more information about ways to interact with the Browser to test your business objects, see [Section 6.3, "Testing View Object Instances Using the Business Component Browser."](#) Additional information about testing with the Business Component Browser also appears in sections specific to each business object throughout the chapters in the "[Building Your Business Services](#)" part of this book.

### 31.6.1 How to Run in Debug Mode and Test with the Business Component Browser

Often you will find it useful to analyze and debug custom code in the service methods of your client interface implementation classes. When you use the Business Component Browser, you can do this without needing to run the application with the user interface. You can use the Business Component Browser as a testing tool to complement your debugging process.

---

---

**Caution:** The Business Components Browser that you run in debug mode will not inherit your JDeveloper IDE Java options. To ensure that specific run/debug Java options are used with the tester, you must edit the run configuration for the data model project. You can modify the default run confirmation in the Run/Debug page of the Project Properties dialog.

---

---

#### Before you begin:

You will need to complete these tasks:

1. Set the desired Java options for your preferred run configuration, as described in "Configuring a Project for Running" in the "Developing Java Applications" section of the JDeveloper online help.
2. Set breakpoints in the custom methods of your client interface, as described in [Section 31.8, "Setting ADF Declarative Breakpoints."](#)

#### To launch the Business Component Browser and go into debug mode:

1. In the Application Navigator, right-click the desired application module and choose **Debug**.

2. In the Business Component Browser, open the method testing panel for the desired client interface, as described in [Section 9.9.4, "How to Test Custom Service Methods Using the Business Component Browser."](#)
3. In the method panel, select the desired method from the dropdown list, enter values to pass as method parameters, and click **Execute**.

Return to JDeveloper to step through your code using the ADF Declarative Debugger. When you complete method execution, the method panel displays the return value (if any) and test result. The result displayed in the Business Component Browser will indicate whether or not the method executed successfully.

### 31.6.2 How to Run the Business Component Browser and Test with a Specific Configuration

When you right-click the application module in the Application Navigator and choose **Run** or **Debug**, JDeveloper will run the Business Components Browser using the default configuration defined for the application module. If you want to test your business components with a different application module configuration (which can specify a different data source and its own set of runtime parameters), you can do so from the overview editor for the `bc4j.xcfg` file. The file is not visible in the Application Navigator and is only accessible from the Configurations page of the overview editor for the application module.

#### To run the Business Component Browser with a specific configuration:

1. In the Application Navigator, double-click the application module that you want to test.
2. In the overview editor, click the **Configurations** navigation tab and then click the `bc4j.xcfg` configuration file link.
3. In the overview editor, select the configuration from the **Configurations** list.
4. Right-click the selected configuration and choose **Run** or **Debug** to launch the Business Component Browser.

### 31.6.3 What Happens When You Run the Business Component Browser in Debug Mode

The Business Component Browser behaves as any other Java program. Specifically, it does not inherit Java options that you may have specified for the JDeveloper IDE. The tester instead uses the run configuration that you have specified for the data model project and any Java options that you may have set in that configuration.

JDeveloper lets you run the Business Component Browser in two modes: either in debug mode or non-debug mode. When run in debug mode, the Browser interacts with the ADF Declarative Debugger so that you execute custom methods using breakpoints you insert in custom code of the client interfaces. For instance, if you set a breakpoint on a method in the client interface and execute that method in the Browser, then in debug mode, you can step through the code before the Browser returns a success/fail result. In non-debug mode, the Browser will immediately return a result to indicate whether the method executed successfully. Additionally, in either debug or non-debug mode, the Browser can display runtime artifacts from the system catalog created at runtime for the application module.

### 31.6.4 How to Verify Runtime Artifacts in the Business Component Browser

When you want to run the Business Component Browser, but do not require the use of the ADF Declarative Debugger you can display information about the runtime artifacts from the application module's system catalog. The system catalog displays business object metadata and other information that you may find useful when you need to compare business objects.

#### To launch the Business Component Browser without debugging:

1. In the Application Navigator, right-click the desired application module and choose **Run**.
2. In the Business Component Browser, choose **Create - Create SysCat AM**.
3. In the data model tree, expand the **SysCatAMDefs**, right-click **ViewDefs**, and choose **Show Table**.
4. In the data viewer, scroll vertically to locate the desired view instance in the **SCName** (system catalog name) field.

Exposing the system catalog in the Browser allows access to metadata and other information specific to the runtime objects without running the debugger. For example, you can check whether a view instance has a custom Java implementation class or not.

### 31.6.5 How to Refresh the Business Component Browser with Application Changes

The Business Component Browser is a highly interactive tool. When you run the Browser and determine a change is needed in the data model project, you can return to JDeveloper to edit the desired application module instances and refresh the Business Component Browser data model to display the changes. This way you can verify your changes without needing to rerun the Browser.

#### To reload application metadata in the Business Component Browser:

1. In the data model project, edit your business objects and save the changes in the JDeveloper.
2. Recompile the data model project.

For example, you can right-click the data model project in the Application Navigator and choose **Make** to complete the recompile step.

Although the metadata changes that you make are not involved in compiling the project, the compile step is necessary to copy the metadata to the class path and to allow the Business Component Browser to reload it.

3. In the Business Component Browser, in the toolbar, click **Reload application metadata**.

Alternatively, you can choose **Reload Application** from the **File** menu of the Business Component Browser.

## 31.7 Using the ADF Declarative Debugger

The ADF Declarative Debugger provides declarative breakpoints that you can set at the ADF object level (such as task flows, page definition executables, method and action bindings, ADF lifecycle phases), as well as standard Java breakpoints. ADF declarative breakpoints provide a high-level object view for debugging ADF applications. For example, you can break before a task flow activity to see what

parameters would be passed to the task flow, as shown in [Figure 31–11](#). To perform the same function using only Java breakpoints would require you to know which class or method to place the breakpoint in. ADF declarative breakpoints should be the first choice for ADF applications.

**Figure 31–11 ADF Declarative Breakpoint on a Task Flow Activity**

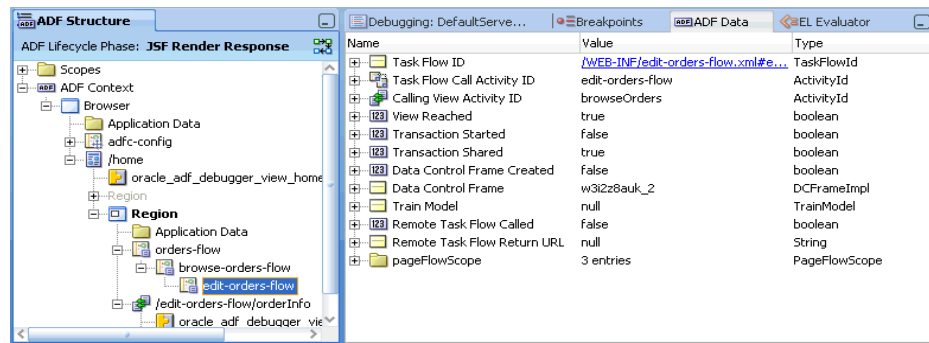

The ADF Declarative Debugger also supports standard Java code breakpoints. You can set Java code breakpoints in any ADF application. You may be able to use Java code breakpoints when an ADF declarative breakpoint does not break in the place you want.

The ADF Declarative Debugger is built on top of the Java debugger, so it has the features and behaviors of the Java debugger. But instead of needing to know the Java class or method, you can set ADF declarative breakpoints in visual editors.

The ADF Declarative Debugger provides standard debugging features such as the ability to examine variable and stack data. When an application pauses at any breakpoint (ADF Declarative or Java code breakpoint), you can examine the application status using a variety of windows. You can check where the break occurs in the Breakpoints window. You can check the call stack for the current thread using the Stack window. When you select a line in the Stack window, information in the Data window, Watches window, and all Inspector windows is updated to show relevant data. You can use the Data window to display information about arguments, local variables, and static fields in your application.

The ADF Structure window displays the runtime structure of the project. The ADF Data window automatically changes its display information based on the selection in the ADF Structure window. For example, if a task flow node is selected, the ADF Data window displays the relevant debugging information for task flows, as shown in [Figure 31–12](#).

**Figure 31–12 ADF Structure Window and ADF Data Window for a Task Flow Selection**

You can mix ADF declarative breakpoints with Java code breakpoints as needed in your debugging session. Although you can use step functions to advance the application from Java code breakpoint to Java code breakpoint, the step functions for ADF declarative breakpoints have more constraints and limitations. For more information about using step functions on ADF declarative breakpoints, see [Table 31–3](#).

For information on how to use ADF declarative breakpoints, see [Section 31.8, "Setting ADF Declarative Breakpoints."](#)

For information on how to use Java breakpoints on classes and methods, see [Section 31.9, "Setting Java Code Breakpoints."](#)

In a JSF application (including Fusion web applications), when a breakpoint breaks, you can use the EL Evaluator to examine the value of an EL expression. The EL Evaluator has the browse function that helps you select the correct expression to evaluate. For more information, see [Section 31.7.4, "How to Use the EL Expression Evaluator."](#)

Whether you plan to use ADF declarative breakpoints or Java breakpoints, you can use the ADF Declarative Debugger with Oracle ADF source code. You can obtain Oracle ADF source code with Debug libraries. For more information about loading source code, see [Section 31.7.1, "Using ADF Source Code with the Debugger."](#)

### 31.7.1 Using ADF Source Code with the Debugger

If you have valid Oracle ADF support, you can obtain complete source code for Oracle ADF by opening a service request with Oracle Worldwide Support. You can request a specific version of the Oracle ADF source code. You may be given download and password information to decrypt the source code ZIP file. Contact Oracle Worldwide Support for more information.

Adding Oracle ADF source code access to your application debugging session will:

- Provide access to the JDeveloper Quick Javadoc feature in the source editor. Without the source code, you will have only standard Javadoc.
- Enhance the use of Java code breakpoints by displaying the Oracle source code that's being executed when the breakpoint is encountered. You can also set breakpoints easier by clicking on the margin in the source code line you want to break on. Without the source code, you will have to know the class, method, or line number in order to set a breakpoint within Oracle code.
- For Java code breakpoints set within the source code, you will be able to see the values of all local variables and member fields in the debugger.

The ADF source code ZIP file may be delivered within an encrypted "outer" ZIP file to protect its contents during delivery. The "outer" ZIP name is sometimes a variant of the service request number.

After you have received or downloaded the "outer" ZIP archive file, unzip it with the provided password to access the actual source code ZIP file. The ADF source code ZIP name should be a variant of the Oracle ADF version number and build number. For example, the Oracle ADF source ZIP file may have a format similar to `adf_vvvv_nnnn_source.zip`, where `vvvv` is the version number and `nnnn` is the build number.

After you have access to the Oracle ADF source code ZIP file, extract its contents to a working directory.

### 31.7.2 How to Set Up the ADF Source User Library

You create a name for the source user library and then associate that name with the source ZIP file.

#### To add the ADF source zip file to the user library

1. In the main menu, choose **Tools** and then **Manage Libraries**.
2. In the Manage Libraries dialog, with the **Libraries** tab selected, click **New**.
3. In the Create Library window, enter a library name for the source that identifies the type of library.
4. Select the **Source Path** node in the tree structure. Click **Add Entry**.

---

---

**Note:** Do not enter a value for the class path. You need to provide a value only for the source path.

---

---

5. In the Select Path Entry window, browse to the directory where the file was extracted and select the source ZIP file. Click **Select**.
6. In the Create Library window, verify that the source path entry has the correct path to the source ZIP file, and deselect **Deployed by Default**. Click **OK**.
7. Click **OK**.

### 31.7.3 How to Add the ADF Source Library to a Project

After the source library has been added to the list of available user libraries, add it to the project you want to debug.

#### To add the ADF source zip file to the project:

1. In the Application Navigator, double-click the project to which you want to add the ADF library or right-click the project and choose **Project Properties**.
2. In the Project Properties dialog, select **Libraries and Classpaths**.
3. Click **Add Library**.
4. In the Add Library dialog, under the **Users** node, select the source library you want to add and click **OK**.

The source library should appear in the **Classpath Entries** section in the Project Properties dialog.

5. Click OK.

### 31.7.4 How to Use the EL Expression Evaluator

When the application is paused at a breakpoint, you can use the EL expression evaluator to enter an EL expression for evaluation. You can enter arbitrary EL expressions for evaluation within the current context. If the EL expression no longer applies within the current context, the value will be evaluated to `null`.

The EL Evaluator is different from the Watches window in that EL evaluation occurs only when stopped at a breakpoint, not when stopped at subsequent debugging steps.

The EL Evaluator is available for debugging any JSF application.

---

---

**Caution:** Be wary when you are evaluating EL expressions that you do not indirectly change application data and therefore the behavior of the application. For example, if you evaluate `#{foo.bar}`, the corresponding `getBar()` method modifies application data.

---

---

#### To use the EL Evaluator:

1. Set a breakpoint in the application.

The application must be a JSF application. It does not need to be an ADF application.

2. Start the debugging process.

You can:

- In the main menu, choose **Run** and then **Debug <project\_name>**.
  - From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
  - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
3. When the breakpoint is reached, the EL Evaluator should appear as a tab in the debugger window area. Click the **EL Evaluator** tab to bring it forward. If it does not appear, in the main menu, choose **View** and then **Debugger > EL Evaluator**.

---

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

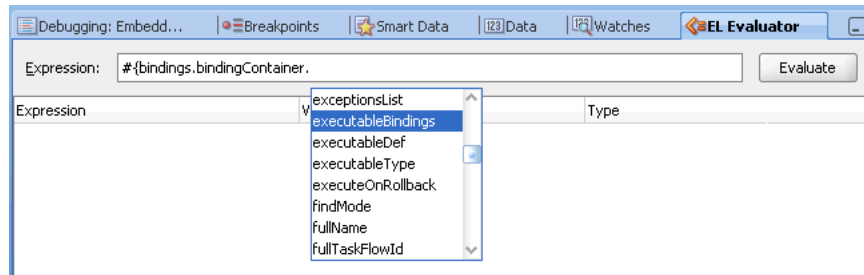

---

4. Enter an EL expression in the **Expression** input field.

When you click in the field after entering `#{` or after a period, a discovery function provides a selectable list of expression items, as shown in [Figure 31-13](#).

Auto-completion will be provided for easy entry. You can evaluate several EL expressions at the same time by separating them with semicolons.

**Figure 31–13 Using the Discovery Function of the EL Evaluator**

- When you finish entering the EL expression, click **Evaluate** and the expression is evaluated, as shown in Figure 31–14.

**Figure 31–14 EL Expression Evaluated**

### 31.7.5 How to View and Export Stack Trace Information

If you are unable to determine what the problem is and you cannot resolve it yourself, typically your next step is to ask someone else for assistance. Whether you post a question in the OTN JDeveloper Discussion Forum or open a service request on Metalink, including the stack trace information in your posting is extremely useful to anyone who will need to assist you further to understand exactly where the problem is occurring.

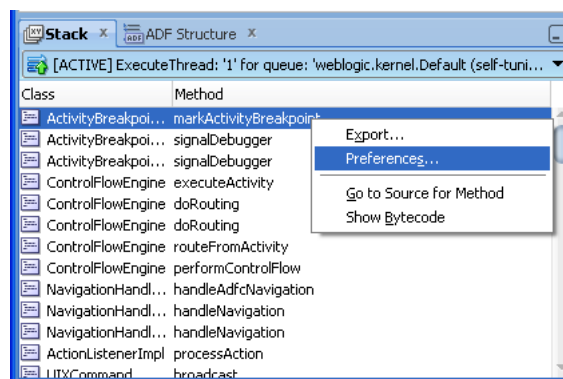

JDeveloper's Stack window makes communicating this information easy. Whenever the debugger is paused, you can view the Stack window to see the program flow as a stack of method calls that got you to the current line. You can use the Preferences dialog to set the Stack window preference to include the line number information, as well as the class and method name that will be there by default. Finally, the Stack window context menu option **Export** lets you save the current stack information to an external text file whose contents you can then post or send to whomever might need to help you diagnose the problem.

#### To save stack information to a text file:

- Set a breakpoint in the application.
  - The application must be a JSF application. It does not need to be an ADF application.
- Start the debugging process by using any of the following techniques.
  - In the main menu, choose **Run** and then **Debug <project\_name>**.

- From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
  - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
3. When the breakpoint is reached and the debugger is paused, the Stack window should appear as a window to the side of the debugger window area. Click the **Stack** tab to bring it forward. If the Stack window does not appear, in the main menu, choose **Window** and then **Debugger > Stack**.
  4. When you want to change the Stack window preference for example to include the line number information in the export file, right-click the Stack window background and choose **Preferences**, as shown in [Figure 31–15](#).

**Figure 31–15 Stack Window Context Menu**

5. Right-click the Stack window background and choose **Export**.
6. In the Export Stack dialog, name the file and choose the location where you want to save the file. Click **OK**.

## 31.8 Setting ADF Declarative Breakpoints

You use the ADF Declarative Debugger features in JDeveloper to declaratively set breakpoints on ADF task flow activities, page definition executables, method, action, and value bindings, and ADF Lifecycle phases. Instead of needing to know all the internal constructs of the ADF code, such as method names and class names, you can set breakpoints at the highest level of object abstraction.

You can add breakpoints to task flow activities in the task flow diagrammer or you can launch the Create ADF Task Flow Activity Breakpoint dialog from the Breakpoints window. In the task flow diagrammer, you can select a task flow activity and use the context menu to toggle or disable breakpoints on that activity, or press the F5 button. After the application pauses at the breakpoint, you can view the runtime structure of the objects in the ADF Structure window as a tree structure. The ADF Data window displays a list of data for a given object selected in the ADF Structure window.

For example, when you set a breakpoint on a task flow call activity in the Browse Orders task flow, a red dot icon appears in the call activity, as shown in [Figure 31–16](#).

**Figure 31-16 ADF Declarative Breakpoint on a Task Flow Activity**

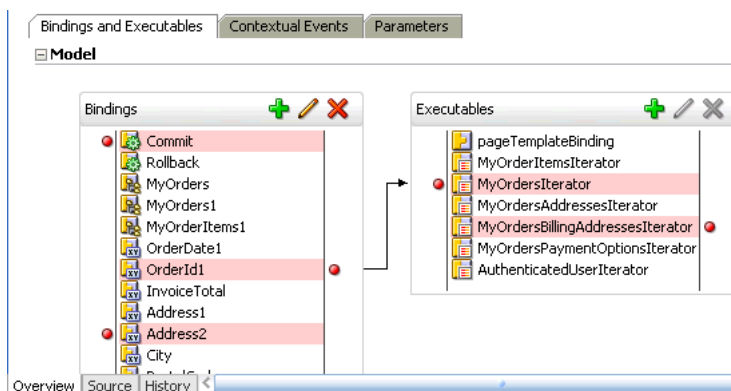

When the breakpoint is reached, the application is paused and the icon changes, as shown in Figure 31-17.

**Figure 31-17 Application Paused at an ADF Declarative Breakpoint**

Similarly, you can set Before and After breakpoints in the page definition file. You set breakpoints for supported value bindings (see Table 31-1 for the list of supported value binding) and for executables by clicking on the left or right margin next to the item or by selecting from the context menu. Clicking on the left margin adds a Before page definition breakpoint, and clicking on the right margin adds an After page definition breakpoint. Again, a red dot icon that indicates the breakpoint is set, as shown in Figure 31-18.

**Figure 31-18 ADF Declarative Breakpoints on ADF Bindings in the Page Definition File**

You can also set Before and After breakpoints on all the ADF lifecycle phases. You can launch the Create ADF Lifecycle Phase Breakpoint dialog from the Breakpoints window, as shown in [Figure 31–19](#).

**Figure 31–19 Breakpoints Window Add Breakpoint Icon Dropdown Menu**

The Create ADF Lifecycle Phase Breakpoint dialog allows you to select different lifecycle breakpoint options, as shown in [Figure 31–20](#).

**Figure 31–20 Create ADF Lifecycle Phase Breakpoint Dialog**

Alternatively, you can use the ADF Lifecycle Breakpoints dialog from the ADF Structure window or the task flow diagrammer to set ADF lifecycle phase breakpoints. For more information about ADF lifecycle phases, see [Chapter 21, "Understanding the Fusion Page Lifecycle."](#)

You can define both ADF declarative breakpoints and standard Java code breakpoints when using the ADF Declarative Debugger. Depending on your debugging scenario, you may only need to use the declarative breakpoints to debug the application. Or you may find it necessary to add additional breakpoints in Java code that are not available declaratively. For information on Java code breakpoints, see [Section 31.9.1, "How to Set Java Breakpoints on Classes and Methods."](#) [Table 31–1](#) lists the available ADF Declarative Debugger breakpoint locations.

**Table 31–1 ADF Declarative Debugger Breakpoints**

<b>ADF Area</b>	<b>Breakpoint Type</b>	<b>Where Inserted</b>	<b>JDeveloper Context Menu Command</b>	<b>Description</b>
ADF lifecycle phase	Before ADF lifecycle phase	ADF Structure window <b>ADF Lifecycle Breakpoints</b> toolbar button		A Before breakpoint pauses debugging before the ADF lifecycle phase.
	Break after ADF lifecycle phase	Task flow diagrammer		An After breakpoint pauses debugging after the ADF lifecycle phase.
		Breakpoints window <b>Add</b> button		<p>The ADF lifecycle JSF Render Response and Prepare Render phase Before and After breakpoints are executed in the following order:</p> <ul style="list-style-type: none"> <li>■ Before jsfRenderResponse.</li> <li>■ Before prepareRender. (prepareRender phase executes).</li> <li>■ After prepareRender. (jsfRenderResponse phase executes).</li> <li>■ After jsfRenderResponse.</li> </ul>

Table 31-1 (Cont.) ADF Declarative Debugger Breakpoints

ADF Area	Breakpoint Type	Where Inserted	JDeveloper Context Menu Command	Description
ADF page definition - bindings and executables	Break before/Break after executable:	Page definition overview editor <b>Bindings and Executables</b> tab, Executables section	Toggle Breakpoint or F5	Pauses debugging before or after executable is refreshed. For task flow bindings, this represents two times per lifecycle: first, during <code>prepareModel</code> (initial region creation), and then again during <code>prepareRender</code> (where dynamic regions swap their corresponding task flow ID).
	<ul style="list-style-type: none"> <li>▪ Iterator</li> <li>▪ Region instantiation</li> </ul>	Breakpoints window <b>Add</b> button	Disable Breakpoint	
	Break before/Break after action binding:	Page definition overview editor <b>Bindings and Executables</b> tab, Bindings section	Toggle Breakpoint or F5	Pauses debugging before or after binding is executed.
	<ul style="list-style-type: none"> <li>▪ <code>methodAction</code></li> <li>▪ Built-in operations</li> </ul>	Breakpoints window <b>Add</b> button	Disable Breakpoint	
	Break before/Break after attribute value binding	Page definition overview editor <b>Bindings and Executables</b> tab, Bindings section	Toggle Breakpoint or F5	Pauses debugging before or after the attribute's <code>setInputValue()</code> ADF source code method is executed. New values will be the parameters to <code>setInputValue()</code> .
		Breakpoints window <b>Add</b> button	Disable Breakpoint	
Break before/Break after table binding	Page definition overview editor <b>Bindings and Executables</b> tab, Bindings section	Toggle Breakpoint or F5	Pauses debugging before or after the ADF hierarchical binding's <code>updateValuesFromRows()</code> source code method is executed. New values will be the parameters to <code>updateValuesFromRows()</code> .	
		Breakpoints window <b>Add</b> button	Disable Breakpoint	
Break before/Break after tree binding	Page definition overview editor <b>Bindings and Executables</b> tab, Bindings section	Toggle Breakpoint or F5	Pauses in either of these two cases:	
		Breakpoints window <b>Add</b> button	1. When making a node selection in the tree, pauses debugging before or after the ADF hierarchical binding's <code>updateValuesFromRows()</code> source code method is executed. New values will be the parameters to <code>updateValuesFromRows()</code> .  2. When expanding the tree, pauses debugging before or after the ADF tree collection model's <code>modifyExpanded()</code> source code method is executed.	
			Disable Breakpoint	

**Table 31–1 (Cont.) ADF Declarative Debugger Breakpoints**

ADF Area	Breakpoint Type	Where Inserted	JDeveloper Context Menu Command	Description
ADF page definition - contextual events	Break before/Break after contextual events	Page Definition overview editor	Toggle Breakpoint or F5	Pauses debugging either before the event is dispatched or after the event, just before the event is consumed by a subscriber to the event.
		Contextual Events tab, Events section		
		Breakpoints window Add button	Disable Breakpoint	
ADF task flow	Break before activity	Task flow diagrammer	Toggle Breakpoint or F5	Pauses debugging before the activity executes within the JSF Invoke Application phase. The activity where the declarative breakpoint is defined has not yet been executed. An exception are view activities; they pause within the JSF Render Response phase after the view activity is executed, but before the new page is rendered. By pausing at that point, the view activity values can be inspected using the ADF Structure and ADF Data windows.
		Breakpoints window Add button	Disable Breakpoint	

The Breakpoints window has a toolbar that includes buttons to add, edit, delete, enable, and disable breakpoints, as shown in [Figure 31–19](#). The add breakpoint dropdown menu includes functions to add Java code breakpoints, ADF lifecycle phase breakpoints, and ADF task flow activity breakpoints. ADF task flow activity breakpoints and page definition declarative breakpoints can also be set in the task flow diagrammer or overview editor for page definition files, respectively.

You can edit the ADF task flow and page definition declarative breakpoints using the edit command from the Breakpoints window on common fields except for the condition and method name.

[Table 31–2](#) lists how an ADF declarative breakpoint will appear in the Breakpoints window under the Description and Type columns. When you double-click an ADF declarative breakpoint in the Breakpoints window, the task flow diagrammer for the corresponding task flow or the overview editor for the corresponding page definition file will appear in the workspace showing the breakpoint location.

**Table 31–2 Breakpoints Window Display of ADF Declarative Breakpoints**

Declarative Breakpoint Type	Description Column	Type Column
Before/After page definition executable:	Before <i>page definition@executable id</i>	Page definition executable breakpoint
<ul style="list-style-type: none"> <li>■ Iterator</li> <li>■ <code>invokeAction</code></li> </ul>	After <i>page definition@executable id</i>	
Before/After page definition action binding:	Before <i>page definition@binding id</i>	Page definition binding breakpoint
<ul style="list-style-type: none"> <li>■ <code>methodAction</code></li> <li>■ Built-in Operations</li> </ul>	After <i>page definition@binding id</i>	
Before/After page definition attribute value binding	Before <i>page definition@binding id</i>	Page definition binding breakpoint
	After <i>page definition@binding id</i>	

**Table 31–2 (Cont.) Breakpoints Window Display of ADF Declarative Breakpoints**

Declarative Breakpoint Type	Description Column	Type Column
Before ADF task flow activity	Before <i>task flow document#task flow id@activity id</i>	Task flow activity breakpoint
Before ADF lifecycle phase	Before <i>adf lifecycle phase</i>	ADF lifecycle phase breakpoint
After ADF lifecycle phase	After <i>adf lifecycle phase</i>	ADF lifecycle phase breakpoint

Table 31–3 lists the step commands that can be used with ADF declarative breakpoints.

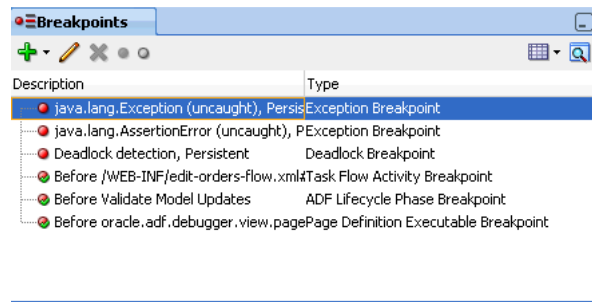

**Table 31–3 ADF Declarative Debugger Step Commands**

ADF Debugger Step Commands	Description
Find Execution Point	Supported for declarative breakpoints to display the current execution point open and active within the corresponding editor.
Step Over (F8)	Supported for task flow activity declarative breakpoints to step from activity to activity within a task flow. If user interaction is required (for example, page displayed), once it is received (for example, button selected), processing will resume and then will pause before the next task flow activity.  supported for page definition executable breakpoints. The application will step to the next page definition executable breakpoint.  Supported for ADF lifecycle phase declarative breakpoints to step to the next Before or After ADF lifecycle phase location.
Step Into (F7)	Supported only for task flow activity declarative breakpoints defined on task flow call activities. Task flow activity declarative breakpoints pause the application just before the activity is executed. The Step Into function provides the ability to pause debugging just prior to executing the called task flow default activity. This action would be the same as placing a task flow activity declarative breakpoint on the called task flow default activity.
Step Out (Shift F7)	Supported for task flow activity declarative breakpoints to step out of the current called task flow and back into the caller (if any). If user interaction is required (for example, page displayed) once user interaction received (for example, button selected), processing will resume and will pause before the next user interaction or activity within the calling task flow.
Continue Step (Shift F8)	Not supported for declarative breakpoints.
Step to End of Method	Not supported for declarative breakpoints.
Run to Cursor	Not supported for declarative breakpoints.
Pop Frame	Not supported for declarative breakpoints, as it is for Java code, to return to a previous point of execution.

The ADF Declarative Debugger uses the standard debugger icons and notations for setting, toggling, and indicating the status of ADF declarative breakpoints.

The Breakpoints window list all breakpoints, including ADF declarative breakpoints, as shown in [Figure 31–21](#).

**Figure 31–21 Breakpoints window Showing ADF Declarative and Java Code Breakpoints**

When an ADF declarative breakpoint is set, it appears as a red dot icon in the task flow activity, in the page definition breakpoint margins, or in the ADF Lifecycle Breakpoints window, as shown in [Figure 31–22](#), [Figure 31–23](#), and [Figure 31–24](#).

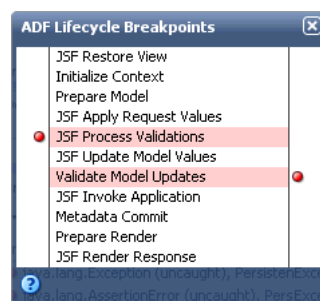

**Figure 31–22 ADF Declarative Breakpoint Enabled on a Task Flow Activity**

**Figure 31–23 ADF Declarative Breakpoints Enabled in the Page Definition Executables**

**Figure 31–24 ADF Lifecycle Phase Breakpoints Enabled in the ADF Lifecycle Breakpoints Window**

When an ADF task flow or page definition declarative breakpoint is disabled, the red icon becomes a gray icon, as shown in [Figure 31–25](#).

**Figure 31–25 ADF Declarative Breakpoint Disabled**

When an ADF task flow declarative breakpoint is active, the red dot icon has a green checkmark, as shown in [Figure 31-26](#).

**Figure 31-26 ADF Declarative Breakpoint Active**

When the application is paused at an ADF declarative breakpoint, an **Execution Point** icon appears, as shown in [Figure 31-27](#).

**Figure 31-27 Application Paused at an Execution Point on a Task Flow**

When the application is paused at an ADF lifecycle declarative breakpoint, an **Execution Point** icon appears next to the lifecycle phase in the ADF Lifecycle Breakpoints window, as shown in [Figure 31-28](#). The name of the current ADF lifecycle phase is also displayed in the ADF Structure window.

**Figure 31-28 Application Paused at an Execution Point on an ADF Lifecycle Phase**

### 31.8.1 How to Set and Use Task Flow Activity Breakpoints

After you have created a task flow diagram, you can set ADF declarative breakpoints on task flow activities.

#### To set a breakpoint on a task flow activity:

1. Open the task flow in the task flow diagrammer, or from the Breakpoints window, click the **Add** icon and select **ADF Task Flow Activity Breakpoint**.

If the Breakpoints window is not already displayed, in the main menu, choose **Window** and then **Breakpoints**.

2. Set the task flow activity breakpoint.
  - If you use the task flow diagrammer, right-click and choose **Toggle Breakpoint** from the context menu, or press F5.

A breakpoint icon appears on the task flow activity.

- If you launched the Create ADF Task Flow Activity Breakpoint dialog from the Breakpoints window, click **Browse** to select a task flow definition, select the task flow from the **Task Flow** dropdown list, select the task flow activity from the **Activity** dropdown list, and click **OK**.
3. Optionally, configure a breakpoint's settings to manage the debugger:
    - a. In the main menu, choose **View** and then **Breakpoints**.
    - b. In the Breakpoints window, select the task flow activity breakpoint you want to configure and click the **Edit** icon.
    - c. In the Edit ADF Task Flow Activity Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
    - d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process.

You can:

- In the main menu, choose **Run** and then **Debug <project\_name>**.
  - From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
  - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon on the task flow activity. You can examine the application using various debugger windows.

---

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

---

Task flow activity declarative breakpoints pause the application just before the task flow activity is executed (except for view activities).

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See [Section 31.8.6, "How to Use the ADF Structure Window,"](#) and [Section 31.8.7, "How to Use the ADF Data Window."](#)
7. In the ADF Structure window, select a node and view pertinent information in the ADF Data window.

Task flow activity declarative breakpoints pause the application just before the task flow activity is executed. You can use the Step Into (F7) function to pause the application just prior to executing the called task flow default activity.

8. Continue debugging the application as required, using the step functions as described in [Table 31–3](#). The key step function is Step Into (F7).

When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

## 31.8.2 How to Set and Use Page Definition Executable Breakpoints

If your page definition has executables, you can set breakpoints to pause the application before or after these executables. For example, you can set breakpoints to pause the application when iterators are refreshed.

---

**Note:** If you are setting an After iterator breakpoint to pause the application after a view object query has been executed, be aware that the application may pause at this breakpoint multiple times. Also be aware that it may pause at this breakpoint even when the query has not been executed. If you need to know whether the query has been executed, select the relevant ADF Business Components in the ADF Structure window and view their corresponding data in the ADF Data window. For more information on how to use these windows, see [Section 31.8.6, "How to Use the ADF Structure Window,"](#) and [Section 31.8.7, "How to Use the ADF Data Window."](#)

For more information about using Java code breakpoints on view object query execution, see [Section 31.9.8, "How to Use Common Oracle ADF Breakpoints."](#)

---

### To set a breakpoint on an executable in the page definition file:

1. In the Application Navigator, double-click the page definition file that contains the executable in which you want to set a breakpoint.
2. In the overview editor, click the **Bindings and Executables** tab, select an executable from the **Executables** list, and click in the breakpoint margin to the left of the item.

A breakpoint icon appears in the margin next to the item.

3. Optionally, configure a breakpoint's settings to manage the debugger:
  - a. In the main menu, choose **View** and then **Breakpoints**.
  - b. In the Breakpoints window, select the executable breakpoint you want to configure and click the **Edit** icon.
  - c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
  - d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process.

You can:

- In the main menu, choose **Run** and then **Debug <project\_name>**.

- From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
  - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears in the margin next to the breakpoint icon of the executable item. You can examine the application using several debugger windows.

The application pauses when the executable binding is refreshed. If this is a taskFlow executable, the pause occurs in the `prepareModel` and the `prepareRender` lifecycles.

---

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Executable Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

---

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See [Section 31.8.6, "How to Use the ADF Structure Window,"](#) and [Section 31.8.7, "How to Use the ADF Data Window."](#)
7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
8. When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 31.8.3 How to Set and Use Page Definition Action Binding Breakpoints

You can set breakpoints in the page definition file on action bindings and `methodAction` bindings. The application pauses when the binding is executed.

#### To set a breakpoint on an action binding in the page definition file:

1. In the Application Navigator, double-click the page definition file that contains the binding in which you want to set a breakpoint.
2. In the overview editor, click the **Bindings and Executables** tab, select a `methodAction` binding or built-in operation item from the **Bindings** list, and click in the breakpoint margin to the left of the item.

A breakpoint icon appears next to the item.

3. Optionally, configure a breakpoint's settings to manage the debugger:
  - a. In the main menu, choose **View** and then **Breakpoints**.
  - b. In the Breakpoints window, select the action binding breakpoint you want to configure and click the **Edit** icon.
  - c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.

- d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process.

You can:

- In the main menu, choose **Run** and then **Debug <project\_name>**.
  - From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
  - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon on the action binding item. You can examine the application using several debugger windows.

The application is paused when the binding is executed.

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See [Section 31.8.6, "How to Use the ADF Structure Window,"](#) and [Section 31.8.7, "How to Use the ADF Data Window."](#)
7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
8. When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 31.8.4 How to Set and Use Page Definition Value Binding Breakpoints

If the page definition has attribute values bindings, you can set breakpoints on the attribute value bindings to pause the application.

#### To set a breakpoint on an attribute value binding in the page definition file:

1. In the Application Navigator, double-click the page definition file that contains the binding in which you want to set a breakpoint.
2. In the overview editor, click the **Bindings and Executables** tab, select an attribute value from the **Bindings** list, and click in the breakpoint margin to the left of the item. A breakpoint icon appears next to the attribute value binding.
3. Optionally, configure a breakpoint's settings to manage the debugger:
  - a. In the main menu, choose **View** and then **Breakpoints**.

- b. In the Breakpoints window, select the binding breakpoint you want to configure and click the **Edit** icon.
- c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
- d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process.

You can:

- In the main menu, choose **Run** and then **Debug <project\_name>**.
  - From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
  - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon on the attribute value binding. You can examine the application using several debugger windows.

The application pauses before the `setInputValue()` method of the ADF source code executes. New values will be the parameters that go into this method.

---

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

---

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See [Section 31.8.6, "How to Use the ADF Structure Window,"](#) and [Section 31.8.7, "How to Use the ADF Data Window."](#)
7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
8. Continue debugging the application as required, using the step functions as described in [Table 31–3](#). The key step function is Step Over (F8).

When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 31.8.5 How to Set and Use ADF Lifecycle Phase Breakpoints

You can set both Before and After ADF lifecycle phase breakpoints on any of the ADF lifecycle phases. For each phase, you can set Before only, After only, or both. You can set breakpoints on as many phases as you want.

You can create the breakpoint and customize the options using the Create ADF Lifecycle Phase Breakpoint dialog from the Breakpoints window menu. Or You can create breakpoints with the default options using the ADF Lifecycle Breakpoints window. After a lifecycle breakpoint has been set, you can edit the options using the Edit ADF Lifecycle Phase Breakpoint dialog, which is also launched from the Breakpoints window.

You can set ADF lifecycle breakpoints on any of the ADF lifecycle phases:

- JSF Restore View
- Initialize Content
- Prepare Model
- JSF Apply Request Values
- JSF Process Validations
- JSF Update Model Values
- Validate Model Updates
- JSF Invoke Application
- Metadata Commit
- Prepare Render
- JSF Render Response

**To set or manage an ADF lifecycle phase breakpoint from the Breakpoints window:**

1. In the main menu, choose **View** and then **Breakpoints**.
2. In the Breakpoints window, click **Add** and choose **ADF Lifecycle Phase Breakpoint**.
3. In the Create ADF Lifecycle Phase Breakpoint dialog **Definition** tab:
  - Select the ADF lifecycle phase where you want to set a breakpoint
  - Select **Before Phase** or **After Phase** breakpoint
4. In the **Conditions** tab, select the options you want and click **OK**.
5. In the **Actions** tab, select the options you want and click **OK**.

**To set an ADF Lifecycle Phase Breakpoint using the breakpoint icon:**

1. In the Application Navigator, double-click any task flow configuration file and in the overview editor click the **Diagram** tab.
2. In the toolbar of the task flow diagrammer or in the title bar of ADF Structure window, click the **ADF Lifecycle Breakpoints** icon, as shown in [Figure 31-29](#).

**Figure 31-29 ADF Lifecycle Breakpoints Icon**

3. In the ADF Lifecycle Breakpoints window, click in the left margin next to the ADF lifecycle phase to set a Before breakpoint, and on the right margin to set an After breakpoint. A red dot icon appears to indicate the breakpoint is set, as shown in

**Figure 31–30.** The breakpoint will be set with the default breakpoint options. To remove the breakpoint, click the red dot icon.

**Figure 31–30** Setting Breakpoints in the ADF Lifecycle Breakpoints Window

4. If you want to edit breakpoint options, select the breakpoint in the Breakpoints window and click the **Edit** icon.

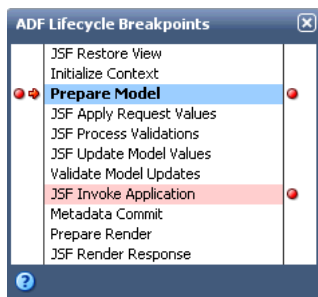

#### To debug an application using ADF Lifecycle Phase Breakpoints:

1. Start the debugging process.

You can:

- In the main menu, choose **Run** and then **Debug** *<project\_name>*.
  - From the Application Navigator, right-click the project, `adfc-config.xml`, `faces-config.xml`, task flow, or page and choose **Debug**.
  - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
2. When the application is paused at an ADF lifecycle phase breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon and the ADF lifecycle phase is in bold in the ADF Lifecycle Breakpoints window, as shown in **Figure 31–31**. You can examine the application using several debugger windows.

**Figure 31–31** Execution Point Displayed in the ADF Lifecycle Breakpoints Window

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window for a breakpoint encounter or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

3. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. The current ADF lifecycle phase is displayed at the top of the ADF Structure window. For more information, see [Section 31.8.6, "How to Use the ADF Structure Window,"](#) and [Section 31.8.7, "How to Use the ADF Data Window."](#)
4. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
5. Continue debugging the application as required, using the step functions as described in [Table 31–3](#). The key step function is Step Over (F8).

When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 31.8.6 How to Use the ADF Structure Window

When the application is paused at a breakpoint, the ADF Structure window displays a tree structure of the ADF runtime objects and their relationships within the application. In particular, it shows the hierarchy of view ports, which represent either the main browser window or contained regions and portlets. When you select different items in the ADF Structure window, the data display in the accompanying ADF Data window changes. For more information about the ADF Data window, see [Section 31.8.7, "How to Use the ADF Data Window."](#)

The ADF Structure window and the ADF Data window are shown by default during a debugging session when either of the following is true:

- The project being debugged contains a `WEB-INF/adfc-config.xml` file.
- The project being debugged contains any ADF Faces tag libraries.

You can launch the ADF Structure window by choosing **View > Debugger > ADF Structure** in the main menu. From the ADF Structure window, you can launch the ADF Lifecycle Breakpoints window using the **ADF Lifecycle Breakpoints** icon.

When a breakpoint is encountered, the ADF Structure window displays the ADF lifecycle phase and a tree structure of the runtime objects, as shown in [Figure 31–32](#).

**Figure 31–32 ADF Structure Window Showing the Runtime Objects**

When you select an item in the ADF Structure window, the data and values associated with that item are displayed in the ADF Data window. [Figure 31–33](#) shows a task flow

selected in the ADF Structure window, with its corresponding information displayed in the ADF Data window.

**Figure 31–33 ADF Structure Window Selection and ADF Data Window Data**

The roots of the hierarchy are the sibling nodes **Scopes** and **ADF Context**. The current view port where processing has stopped appears in bold. Default selections within the tree will be retained from the previous breakpoint, so you can monitor any changes between breakpoints. The ADF object where the ADF declarative breakpoint was defined will be opened in the corresponding JDeveloper editor, either the task flow diagrammer or the overview editor for page definition files.

The ADF Structure tree will be rebuilt each time the application breaks and at subsequent steps to reflect the changed state of the objects. Although the entire tree hierarchy will be displayed, only items within the current view port and its parent view port(s) will be available for selection and further inspection. All other items in the tree hierarchy not in the current context will be dimmed and disabled. You can still use the hierarchy to identify runtime object relationships within the application, but it will be limited to the current context (and its parent view ports).

Table 31–4 lists the different types of items that can be displayed in the ADF Structure window hierarchy tree.

Table 31–4 ADF Structure Window Items

ADF Structure Tree Item	Description
Scopes	Displayed at the top of the ADF Structure hierarchy above its sibling <b>ADF Context</b> node. There is only one <b>Scopes</b> node in the ADF Structure hierarchy. You can expand the <b>Scopes</b> node to show a list of child scope nodes (such as <b>viewScope</b> and <b>pageFlowScope</b> ). If you select a child scope node, the ADF Data window displays the variables and values for that scope.
ADF context	Displayed as the root node of the ADF Structure hierarchy below its sibling <b>Scopes</b> node. There will only be one <b>ADF Context</b> within the ADF Structure hierarchy.
View port	View ports are an ADF Controller concept. For this reason, view ports appear within the ADF Structure hierarchy only when the application being debugged utilizes ADF Controller. View ports can represent one of the following: <ul style="list-style-type: none"> <li>■ <b>Browser:</b> Main browser view ports, also known as root view ports, appear as children of the root <b>ADF Context</b>. If multiple browser windows are open during the debugging runtime session, multiple browser view ports are presented within the hierarchy. The label of each browser view port displays the text "Browser". The view port also provides a tooltip for the view port ID similar to the following example: "Root View Port: 999999".</li> <li>■ <b>Region:</b> Region view ports appear as the children of page or page fragments. They are also known as child view ports. The label of each region view port displays the text "Region". The region also provides a tooltip for the view port ID similar to the following example: "Child View Port: 999999".</li> </ul>
ADF task flows	The page flow stack corresponding to each view port appears as a hierarchy of ADF task flows. The initial ADF task flow called for the stack is a direct child of its corresponding view port. The label of each ADF task flow reflects the corresponding ADF task flow display name (if any) or its task flow ID. Region view ports will not display the item in their page flow stack hierarchy for their implied unbounded task flow. The task flow also provides a tooltip displaying the ADF task flow path, and a context menu item to open to the corresponding ADF task flow within the editor workspace. If ADF Controller is not utilized in the application (or if the page is run outside the context of an ADF task flow), ADF task flows will not appear within the hierarchy.
Page	Represents the page (view) currently displayed within a browser view port. Presented along with its associated binding container (if any) as a child. If the application being debugged utilizes ADF Controller, pages will be children of each browser view port. The label of each page reflects its corresponding runtime view ID. The page also provides a tooltip displaying the page path, and a context menu item to open to the corresponding page within the editor workspace. If a visual user interface is not implemented for the application, the page will not appear within the hierarchy.
Page fragment	Represents the page fragment currently displayed within a region view port. Presented along with its associated binding container (if any) as a child. If the application being debugged utilizes ADF Controller, page fragments will be children of each region view port. The label of each page fragment node reflects its corresponding runtime view ID. The page fragment also provides a tooltip displaying the source file page definition path, and a context menu item to open to the corresponding page fragment within the editor workspace.
Binding container	Represents the binding container for the corresponding page or page fragment. The label of each binding container reflects its corresponding file name (page definition file) without the extension. The binding container node will also provide a tooltip displaying the page fragment path. The binding container also appears under current task flows when used to represent task flow activity bindings (for example, method call activity bindings). If ADF Model is not utilized for the application, binding containers will not appear.
Application data	Represents the application data objects (for example, ADF Business Components objects or ADF Business Components business service objects) instantiated within the data control frame for the corresponding view port (or binding container if ADF Controller is not used). Application data objects don't need to be currently instantiated for the Application Data node to appear.

### 31.8.7 How to Use the ADF Data Window

When an application is paused at an ADF declarative breakpoint, the ADF Data window displays relevant data based on the selection in the ADF Structure window. You can launch the ADF Data window by choosing **View > Debugger > ADF Data** from the main menu. The content of the ADF Data window based on the selection in the ADF Structure window is summarized in [Table 31–5](#).

**Table 31–5 ADF Data Window Content for an ADF Structure Window Selection**

ADF Structure Window	ADF Data Content
Scopes	Displays memory scope values based on the current context. <code>pageFlowScope</code> will also appear within ADF task flow content for the <code>pageFlowScope</code> values specific to a selected ADF task flow (not necessarily the current context). <code>viewScope</code> will also appear within the view port content for the <code>viewScope</code> values specific to a selected view port (not necessarily the current context).
ADF context	Displays the ADF context variables and values hierarchy. ADF context variables and values can be inspected by evaluating the <code>#(data.adfContext)</code> EL expression in the EL Evaluator.
View port	Displays view port details, including the <code>viewScope</code> contents.
Page flow stack entry	Displays information for the selected page flow stack entry, including current transaction status and ADF Model save point status.
Page/page fragment	Displays the page or page fragment UI component tree hierarchy for the selected page or page fragment if the page or page fragment has been rendered.
Binding container	Displays the binding container runtime values, including parameters, bindings, and executables.
Application data	Displays application data objects (for example, ADF Business Components objects) instantiated within the current binding context. If the business service layer is implemented with a technology other than ADF Business Components objects (for example, EJB) the application data objects will be displayed in a more generic form.

The **Scopes** node in the ADF Structure window can be expanded to show a list of child scope nodes. When a child scope node is selected in the ADF Structure window, the ADF Data window displays the current context values for the selected memory scope, as shown in [Figure 31–34](#).

Figure 31–34 Child Scope Selected in the ADF Structure Window

If the **Scopes** node itself is selected, then the full list of memory scopes appears also in the ADF Data windows, which can also be expanded for inspection. Figure 31–35 shows the **Scopes** node selected in the ADF Structure window, and the **viewScope** child node being selected with its values displayed in the ADF Data window. You can inspect the values of `requestScope`, `viewScope`, `pageFlowScope`, `applicationScope`, and `sessionScope` by expanding each corresponding node. `pageFlowScope` will also appear within the ADF Task Flow content to reflect the values of the specific ADF task flow currently selected in the ADF Structure window. `viewScope` will also appear within the view port content to reflect the values of the specific view port currently selected in the ADF Structure window.

Figure 31–35 Scopes Node Selected in the ADF Structure Window

When the ADF context is selected in the ADF Structure window, as shown in Figure 31–36, the current value of the ADF context variables will be displayed in the ADF Data window. You can also inspect ADF context variables and values by evaluating the `#(data.adfContext)` EL expression in the EL Evaluator. For more information, see Section 31.7.4, "How to Use the EL Expression Evaluator."

**Figure 31–36 ADF Context Selected for the ADF Data Window**

Selecting a view port within the ADF Structure hierarchy will display the view port's current view port details in the ADF Data window, as shown in Figure 31–37. Values displayed for each view port are summarized in Table 31–6.

**Figure 31–37 View Port Selected for the ADF Data Window**

**Table 31–6 ADF Data Window Content for View Port**

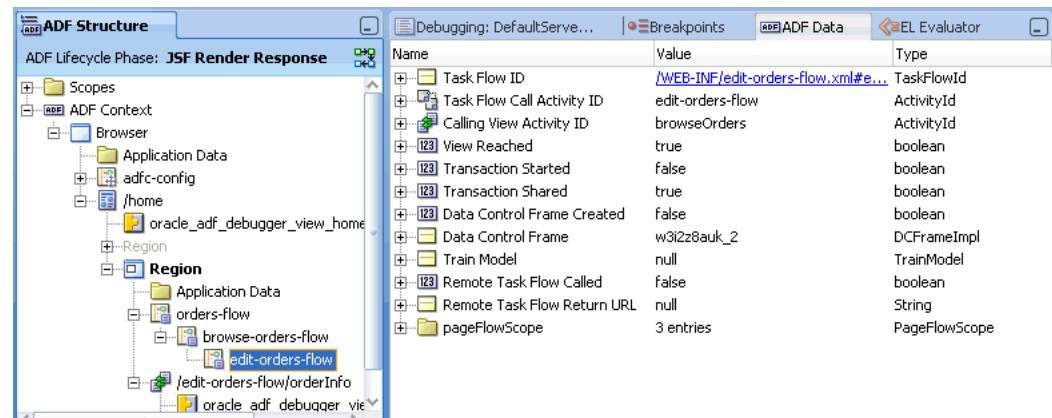

View Port	Description
View port ID	It is displayed
Client ID	It is displayed
Initial task flow ID	Initial ADF task flow on the view ports page flow stack. Not displayed for unbounded task flows. Appears as a link to open the corresponding task flow definition in the editor workspace.
Current task flow ID	Displayed for bounded task flows and not displayed for unbounded task flows. Current ADF task flow on the view port's page flow stack. Appears as a link to open the corresponding task flow definition in the editor workspace.
View activity ID	Current ADF task flow view activity ID. Applicable only if the current ADF task flow activity is a view activity.
Submitted activity ID	ADF task flow activity submitting the current request.
Final activity ID	ADF task flow activity receiving the current request.
Bookmark redirect outstanding	(Boolean)

**Table 31–6 (Cont.) ADF Data Window Content for View Port**

View Port	Description
Exception	(If any)
View memory scope	View memory scope variables and values for the selected view port.

In the ADF Structure window, each individual ADF task flow within a page flow stack hierarchy is selectable. An ADF task flow selected in the ADF Structure window will display the current task flow information in the ADF Data window, as shown in [Figure 31–38](#). Task flow templates utilized by the selected ADF task flow will be determined by manually navigating to the ADF task flow source file. This is the same way similar functionalities are handled for Java source files. Current information for a selected ADF task flow is summarized in [Table 31–7](#).

**Figure 31–38 Task Flow Selected for the ADF Data Window****Table 31–7 ADF Data Window Content for Task Flow**

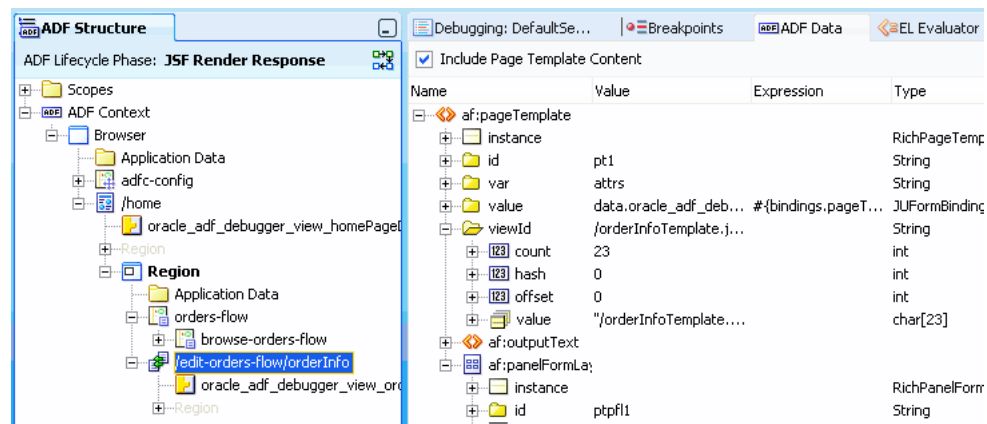

Task Flow	Description
ADF task flow reference	ADF task flow reference
Task flow call activity ID	Task flow activity ID for the calling task flow. Will be null for the first ADF task flow within each view port task flow Calls window.
Calling view activity ID	The calling view activity of the current view activity displayed by the ADF task flow, if any.
View reached	(Boolean)
Train model	Only applicable if the ADF task flow is created as a train.
Transaction started	(Boolean) Identifies the current status of the ADF task flow transactional state. For example, did the ADF task flow begin a new transaction?
Transaction shared	(Boolean) Identifies the current status of the ADF task flow transactional state. For example, did the ADF task flow join an existing transaction?
Save point	Identifies the current status of the ADF task flow's ADF Model save point creation state. For example, was a model save point created upon ADF task flow entry?.
Remote task flow called	(Boolean)

**Table 31–7 (Cont.) ADF Data Window Content for Task Flow**

Task Flow	Description
Remote task flow return URL	Applies only when calling an ADF task flow remotely. Identifies the URL for return once the task flow called remotely completes.
Data control frame created	(Boolean)
Data control frame	Name of data control frame associated with the ADF task flow.
Page flow memory scopes	Appears as an expandable node to allow inspection of the values of the page flow memory scopes for the task flow selected in the ADF Structure window.  The page flow memory scopes will also be displayed within the ADF Structure window’s <b>Scopes</b> node. However, the page flow memory scope for the <b>Scopes</b> node will always be based on the application’s current context, not the selected task flow.

When you select a page or page fragment node in the ADF Structure hierarchy, the corresponding UI component tree is displayed within the ADF Data window, as shown in [Figure 31–39](#). If a page or page fragment is based on a page template, you can include the content coming from the page template outside any facet reference elements by selecting the **Include Page Template Content** checkbox at the top of the ADF Data window. If the page template content is not included, the page or page fragment UI component tree will appear structurally similar to its source file.

**Figure 31–39 Page Selected for the ADF Data Window**

When you select a binding container in the ADF Structure hierarchy, it displays within the ADF Data window the node selection listed in [Table 31–8](#).

**Table 31–8 ADF Data Window Content for Binding Container**

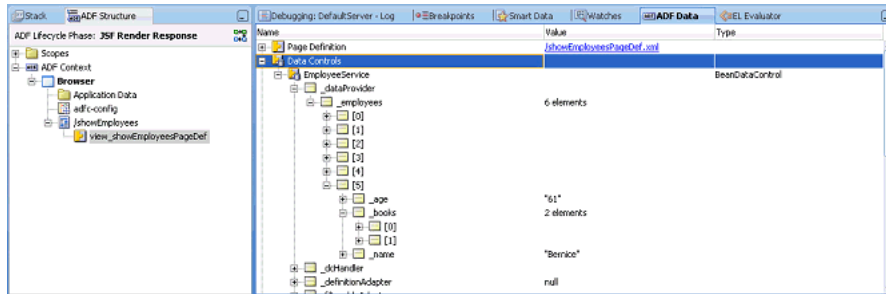

Binding Container	Description
Page definition link	Navigates to the corresponding page definition source file and opens it within the editor workspace.

**Table 31–8 (Cont.) ADF Data Window Content for Binding Container**

Binding Container	Description
Data Controls	<p data-bbox="764 260 1252 287">Displays the binding container's data controls.</p> <p data-bbox="764 302 1419 590">Data controls implemented by ADF Business Components objects and non-ADF Business Components objects will be presented slightly different. ADF Business Components-based data controls will appear similar to the actual business service implementation using row collections. Non-ADF Business Components-based data controls will typically appear as raw member variables similar to what is displayed in the ADF Declarative Debugger Data window. The ADF Data window shows only cached information such as member variables and arrays. Standard debugger functionality can also be used to customize each element.</p> <p data-bbox="764 604 1419 659">Each ADF Business Components data control will display the following information:</p> <ul data-bbox="764 674 1419 989" style="list-style-type: none"> <li data-bbox="764 674 976 701">■ Row collections</li> <li data-bbox="764 716 1192 743">■ Query string for each row collection</li> <li data-bbox="764 758 1354 812">■ Query string with variable substitution for each row collection</li> <li data-bbox="764 827 1045 854">■ Application data rows</li> <li data-bbox="764 869 1045 896">■ Current row indicator</li> <li data-bbox="764 911 997 938">■ Change indicator</li> <li data-bbox="764 953 1403 989">■ Current and original values (if changed within the same request)</li> </ul>
Parameters	Current values of all binding container parameters.
Executables	<p data-bbox="764 1058 1451 1136">Displays executables showing current row indicators, and current and original values (if changed within the same request). This includes the following types of executables:</p> <ul data-bbox="764 1150 1451 1436" style="list-style-type: none"> <li data-bbox="764 1150 1419 1205">■ Iterator - presents corresponding attribute bindings along with their <code>Refresh</code> and <code>RefreshCondition</code> properties.</li> <li data-bbox="764 1220 1451 1373">■ task flow - current value of the task flow ID assigned to the task flow binding and all of its associated parameter values. Task flow IDs will appear as links navigating to open the corresponding task flow definition source file within the editor workspace. Link text consists of <code>&lt;task flow source document&gt;#&lt;task flow id&gt;</code>.</li> <li data-bbox="764 1388 1435 1436">■ Search region - presented similar to iterators, but also displays criteria and criteria with substitution information.</li> </ul>
Bindings	<p data-bbox="764 1457 1419 1514">Displays value, table, tree, and method bindings. Each binding will display the following information:</p> <ul data-bbox="764 1528 1419 1646" style="list-style-type: none"> <li data-bbox="764 1528 1045 1556">■ Associated executables</li> <li data-bbox="764 1570 997 1598">■ Change indicator</li> <li data-bbox="764 1612 1403 1646">■ Current and original values (if changed within the same request)</li> </ul>
Binding container of page template	If the corresponding page or page fragment utilized a page template, the binding container of the page template will appear as a child of page or page fragment binding container content.

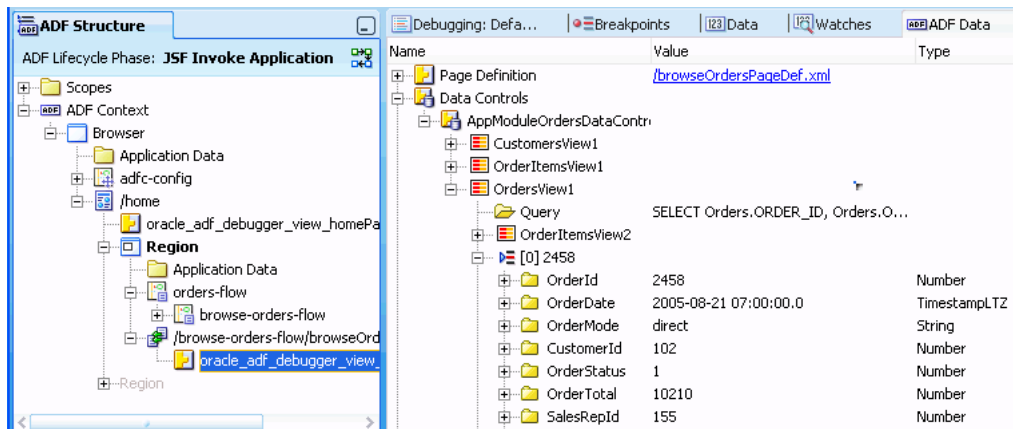

When you select a binding container for an application based on non-ADF Business Components objects, the ADF Data window displays the binding container content, as shown in [Figure 31-1](#).

**Figure 31-40 Binding Container (Non-Business Components) Selected for the ADF Data Window**

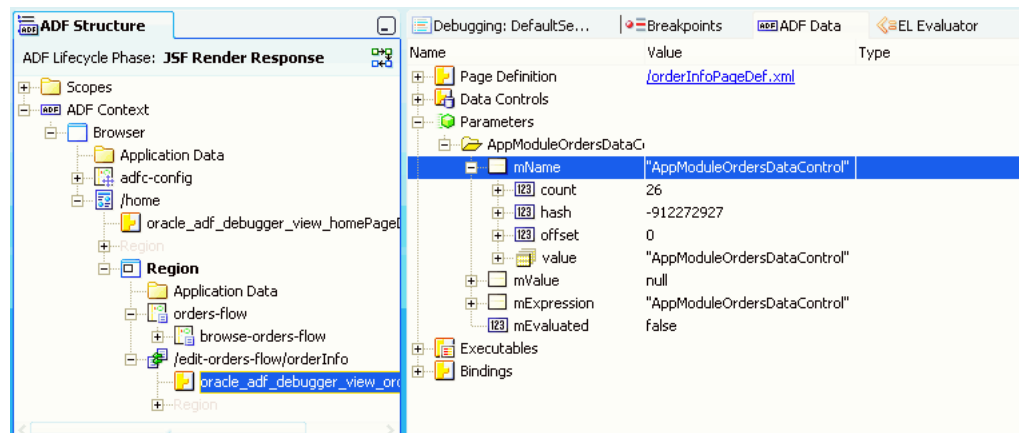

When you select a binding container for an application based on ADF Business Components objects, the ADF Data window displays standard row collection icons, as shown in [Figure 31-2](#).

**Figure 31-41 Binding Container (Business Components) Selected for the ADF Data Window**

Expanding the Parameters node in the ADF Data window displays information similar to that shown in [Figure 31-42](#).

Figure 31-42 Parameters Selected for the ADF Data Window

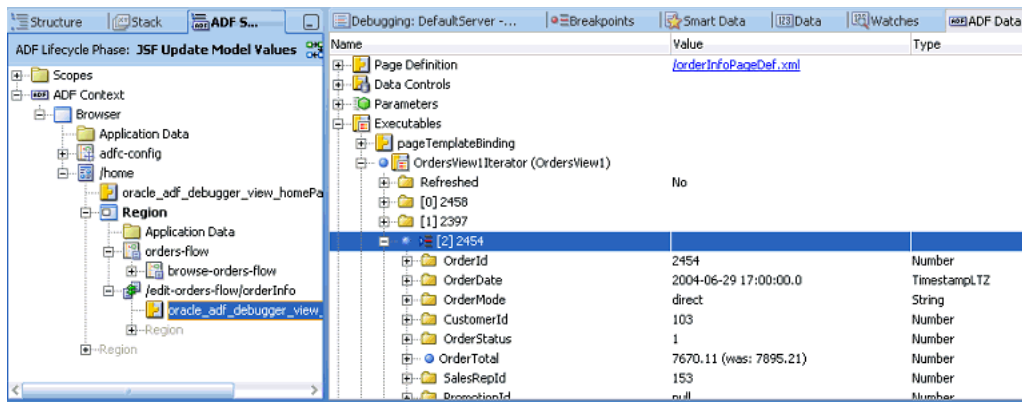

Expanding the Executables node in the ADF Data window displays information similar to that shown in Figure 31-43.

Figure 31-43 Executables Selected for the ADF Data Window

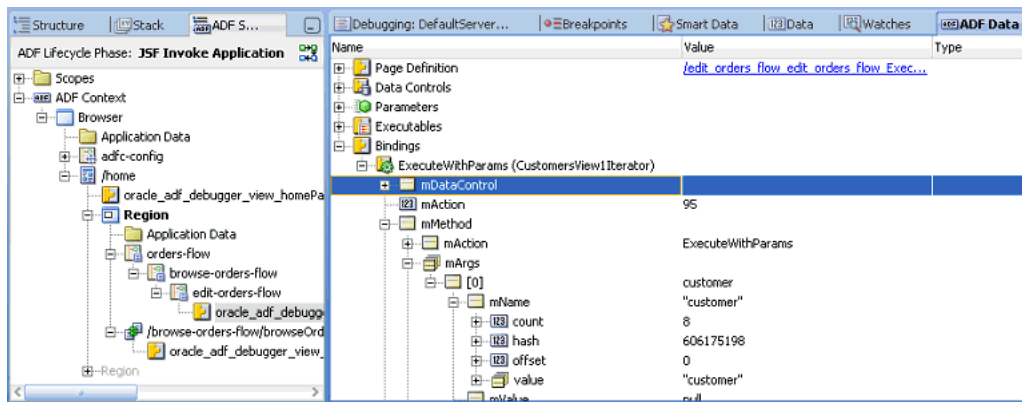

If a value has changed, the changed item will be marked with a blue dot to its left and the previous value is displayed in parenthesis. For instance, suppose the `OrderTotal` value has changed from 7895.81 to 7670.11. The ADF Data window places a blue dot next to `OrderTotal` and its parent `OrdersViewIterator` and displays the current and previous values in the **Value** column, as shown in Figure 31-44.

**Figure 31–44 A Value Change Is Indicated by a Blue Dot in the ADF Data Window**

Method binding information is displayed in the ADF Data window similar to what is shown in [Figure 31–45](#).

**Figure 31–45 Method Bindings Selected for the ADF Data Window**

When you select an Application Data node from the ADF Structure window, the ADF Data window displays the application objects, such as ADF Business Components objects, instantiated within the current data control frame for the corresponding view port (or binding context if ADF Controller is not used).

Business services implemented by ADF Business Components objects display the application data content, as shown in [Figure 31–46](#) and described in [Table 31–9](#).

**Figure 31–46 Application Data for ADF Business Components Business Services****Table 31–9 ADF Data Window Content for Application Data**

Binding Container	Description
Application module	<p>The application module(s) of the corresponding view port data control frame will appear within the application data hierarchy as the root node(s). An application module design time icon will be used to identify the node(s). The application module node(s) will provide the following information:</p> <ul style="list-style-type: none"> <li>Application module link - link to open the corresponding application module source file within the editor workspace.</li> <li>Transaction - the application module current transaction status, if applicable.</li> <li>View objects</li> <li>Entity objects</li> </ul>

**Table 31–9 (Cont.) ADF Data Window Content for Application Data**

Binding Container	Description
View object	<p>View objects instantiated within the corresponding view port data control frame will appear underneath the corresponding application module root node as subordinate nodes. Design time icons will be used to identify them. Child view objects will appear subordinate to their parent view objects within the hierarchy. Named row sets will appear similar to view objects. Named iterators for a view object will appear similar to child view objects. Each view object node will provide the following information:</p> <ul style="list-style-type: none"> <li>■ View object link - link to open the corresponding view object source file within the editor workspace.</li> <li>■ Query - last executed view object SQL statement. Displays bind variables without value substitution.</li> <li>■ Query with substitution - last executed view object SQL statement. Displays bind variables with value substitution.</li> <li>■ Bind variables - last executed view object SQL statement bind variables and their values.</li> <li>■ View object rows - each row displayed will be identified by its concatenated key values. The current row will be identified with a special icon.</li> <li>■ Attributes - attributes contained on each row will display their current values along with their originating entity object. Transient attributes will also be displayed.</li> <li>■ Modifications - changes made within the same request will be identified by a blue dot to left of attribute, row, and view objects node labels. Both the old and new value of the modification will be displayed.</li> </ul>
Entity object	<p>Entity objects instantiated within the corresponding view port data control frame will appear underneath the application module root node as subordinate nodes. Design time icons will be used to identify them. Each entity object node will provide the following information:</p> <ul style="list-style-type: none"> <li>■ Entity object link - link to open the corresponding entity object source file within the editor workspace.</li> <li>■ Entity object rows - each row displayed will be identified by its concatenated key values. The current entity-state and post-state of the row (e.g., <code>STATUS_MODIFIED</code>) will also be presented.</li> <li>■ Attributes - attributes contained on each row will display their current values.</li> <li>■ Modifications - changes made within the same request will be identified by a blue dot to left of attribute, row, and entity objects node labels. Both the old and new value of the modification will be displayed.</li> </ul>

Business services implemented by non-ADF Business Components objects display application data content using raw member variables. The format is similar to the display of non-ADF Business Components content for the binding container, as shown in [Figure 31–40](#).

### 31.8.8 What Happens When You Set an ADF Declarative Breakpoint

When you set an ADF declarative breakpoint, JDeveloper adds the breakpoint to the appropriate class, method, or other construct in the ADF source Java code that corresponds to the breakpoint. Once the breakpoint is set in the code, the standard Java debugger mechanism pauses application execution when the breakpoint is reached. When the breakpoint is reached, it will be identified by a red dot icon in the Breakpoints window. Depending on the type of declarative breakpoint that was reached, it will also appear as a red dot icon in the task flow activity, in the page definition breakpoint margins, or in the ADF Lifecycle Breakpoints window.

For task flow activity breakpoints, the debugger pauses the application within the JSF Invoke Application phase before the activity where the breakpoint is set. In other words, the activity where the breakpoint is set is not executed.

For task flow view activities, however, the application is paused within the JSF Render Response phase after the view activity is executed, but before the new page is rendered.

For a page definition Before executable breakpoint, the debugger pauses the application when the executable is refreshed. For a page definition Before action binding breakpoint, the debugger pauses the application when the binding is executed. For a page definition Before attribute value binding breakpoint, the debugger pauses the application before the attribute's `setInputValue()` method in the ADF source code is executed.

For a Before lifecycle breakpoint, the debugger pauses the application before it enters the next lifecycle phase. For an After lifecycle breakpoint, the debugger pauses the application after the lifecycle phase and before the next phase.

## 31.9 Setting Java Code Breakpoints

You can use the ADF Declarative Debugger to set breakpoints on Java classes and methods, as in any standard Java code debugger. You can use Java code breakpoints in combination with ADF declarative breakpoints or by themselves. For most ADF applications, ADF declarative breakpoints will provide enough debugging information to troubleshoot the application. For information about using ADF declarative breakpoints, see [Section 31.8, "Setting ADF Declarative Breakpoints."](#) However, you may need to set breakpoints on specific classes or methods for further inspection. Or, you may be debugging a non-ADF application, in which case, you can use Java code breakpoints.

JDeveloper provides a class locator feature that assists you in finding the class you want to break on. If you can obtain Oracle ADF source code, you can enhance your debugging by having access to various ADF classes and methods. For more information about getting ADF source code, see [Section 31.7.1, "Using ADF Source Code with the Debugger."](#) If you obtained the ADF source, you can further enhance the debugging experience by using the debug library version of the ADF source, as described in [Section 31.9.4, "How to Use Debug Libraries for Symbolic Debugging."](#)

### 31.9.1 How to Set Java Breakpoints on Classes and Methods

You can set Java breakpoints on your classes and methods. If you have ADF source code, you can set Java breakpoints in the source as well. If you are debugging an ADF application, you should check to see whether ADF declarative breakpoints can be used instead of Java code breakpoints. For more information, see [Section 31.8, "Setting ADF Declarative Breakpoints."](#)

Before you attempt to use breakpoints, you should try to run the application and look for missing or incomplete data, actions and methods that are ignored or incorrectly executed, or other unexpected results. If you did not find the problem, create a debugging configuration that will enable the ADF Log and send Oracle ADF messages to the Log window. For more information, see [Section 31.5.2, "How to Create an Oracle ADF Debugging Configuration."](#)

**To set Java breakpoints to debug an application:**

1. In the main menu, choose **Navigate** and then **Go To Java Type** (or press Ctrl+Minus) and use the dialog to locate the Oracle ADF class that represents the entry point for the processing failure.

---

---

**Note:** JDeveloper will locate the class from the user interface project with current focus in the Application Navigator. If your workspace contains more than one user interface project, be sure that the one with the current focus is the one you want to debug.

---

---

2. Open the class file in the source editor and find the Oracle ADF method call that will enable you to step into the statements of the method.
3. Set a breakpoint on the desired method and run the debugger.
4. When the application stops on the breakpoint, use the Data window to examine the local variables and arguments of the current context.

**Tip:** If you are using the **Go to source** context menu command in the Data, Watches, or Smart Data window, you can go back to the execution point by using the back button. You can also access the back button through the **Navigate** menu.

Once you have set breakpoints to pause the application at key points, you can proceed to view data in the Data window. To effectively debug your web page's interaction with the ADF Model layer, you need to understand:

- The ADF page lifecycle and the method calls that get invoked
- The local variables and arguments that the ADF Model layer should contain during the course of application processing

Awareness of Oracle ADF processing will give you the means to selectively set breakpoints, examine the data loaded by the application, and isolate the contributing factors.

---

---

**Note:** JSF web pages may also use backing beans to manage the interaction between the page's components and the data. Debug backing beans by setting breakpoints for them as you would with any other Java class file.

---

---

## 31.9.2 How to Optimize Use of the Source Editor

Once you have added the ADF source library to your project, you have access to the helpful Quick Javadoc feature (Ctrl+D) that the source editor makes available.

[Figure 31-47](#) shows Quick Javadoc for a method like `findSessionCookie()`.

**Figure 31–47 Using Quick Javadoc on ADF API in the Source Editor**

### 31.9.3 How to Set Breakpoints and Debug Using ADF Source Code

After loading the ADF source code, you can debug any Oracle ADF code for the current project the same way that you do your own Java code. This means that you can press `Ctrl+Minus` to type in any class name in Oracle ADF, and JDeveloper will open its source file automatically so that you can set breakpoints as desired.

### 31.9.4 How to Use Debug Libraries for Symbolic Debugging

When debugging Oracle ADF source code, by default you will not see symbol information for parameters or member variables of the currently executing method.

For example, in a debugging session without ADF source code debug libraries, you may see unrecognizable names such as `"_slot"`, as shown in [Figure 31–48](#).

**Figure 31–48 Local Symbols Are Hard to Understand Without Debug Libraries**

These names are hard to decipher and make debugging more difficult. You can make debugging easier by using the debug versions of the ADF JAR files supplied along with the source while debugging in your development environment.

---

**Note:** The supplied debug libraries should not be used in a test or production environment, since they typically have slightly slower runtime performance than the optimized JAR files shipped with JDeveloper.

---

The debug library JARs are versions of Oracle ADF JARs that have been compiled with additional debug information. When you use these debug JAR files instead of the default optimized JARs, you will see all of the information in the debugger. For example, the variable `evid` is now identified by its name in the debugger, as shown in Figure 31–49.

**Figure 31–49 Symbol Information Displayed in the Debugger**

Before you replace the standard library JAR, make sure that JDeveloper is not running. If it's currently running, exit from the product before proceeding.

### To replace the standard library JARs with the debug library JARs:

1. With JDeveloper closed, make a backup subdirectory of all existing optimized JAR files in the `./BC4J/lib` directory of your JDeveloper installation. For example, assuming `jdev11` is the JDeveloper home directory:
 

```
C:\jdev11\BC4J\lib> mkdir backup
C:\jdev11\BC4J\lib> copy *.jar backup
```
2. For each ADF library that you want debug symbols for while debugging, copy the `_g.jar` version of the matching library over the existing, corresponding library in the `C:\jdev11\BC4J\lib` directory.

This is safe to do since you made a backup of the optimized JAR files in the backup directory in Step 2.

Since debug libraries typically run a little slower than libraries compiled without debug information, this diagnostic message is to remind you not to use debug libraries for performance timing:

```
*****
*** WARNING: Oracle BC4J debug build executing - do not use for timing ***
*****
```

3. To change back to the optimized libraries, simply copy the JAR file(s) in question from the `./BC4J/lib/backup` directory back to the `./BC4J/lib` directory.

### 31.9.5 How to Use Different Kinds of Java Code Breakpoints

You first need to understand the different kinds of Java code breakpoints and where to create them.

To see the debugger Breakpoints window, choose **View** and then **Breakpoints** in the main menu (or press Ctrl+Shift+R).

You can create a new Java code breakpoint by choosing **Create Breakpoint** from the context menu in the Breakpoints window. The **Breakpoint Type** dropdown list controls what kind of breakpoint you will create, as shown in [Table 31–10](#).

---

**Note:** You can also use the Create Breakpoint dialog to create an ADF lifecycle phase declarative breakpoint. For information about creating ADF declarative breakpoints, see [Section 31.8.5, "How to Set and Use ADF Lifecycle Phase Breakpoints."](#)

---

**Table 31–10** *Different Types of Java Breakpoints*

Breakpoint Type	The Breakpoint Occurs Whenever	Usage
Exception	An exception of this class (or a subclass) is thrown.	An Exception breakpoint is useful when you don't know where the exception occurs, but you know what kind of exception it is (for example, <code>java.lang.NullPointerException</code> , <code>java.lang.ArrayIndexOutOfBoundsException</code> , <code>oracle.jbo.JboException</code> ). The checkbox options allow you to control whether to break on caught or uncaught exceptions of this class. The <b>Browse</b> button helps you find the fully qualified class name of the exception. The Exception Class combobox remembers the most recently used exception breakpoint classes. Note that this is the default breakpoint type when you create a breakpoint in the breakpoints window.
Source	A particular source line in a particular class in a particular package is run.	You rarely create a source breakpoint in the Create Breakpoint dialog, because it's much easier to create it by first using the <b>Navigate &gt; Go to Java Type</b> menu (accelerator Ctrl+Minus), then scrolling to the line number you want — or using <b>Navigate &gt; Go to Line</b> (accelerator Ctrl+G) — and finally clicking in the breakpoint margin at the left of the line you want to break on. This is equivalent to creating a new source breakpoint, but it means you don't have to type in the package, class, and line number by hand.
Method	A method in a given class is invoked.	The Method breakpoint is useful for setting breakpoints on a particular method you might have seen in the call stack while debugging a problem. If you have the source, you can set a source breakpoint wherever you want in that class, but this kind of breakpoint lets you stop in the debugger even when you don't have source for a class.

**Table 31–10 (Cont.) Different Types of Java Breakpoints**

Breakpoint Type	The Breakpoint Occurs Whenever	Usage
Class	Any method in a given class is invoked.	The Class breakpoint can be used when you might know the class involved in the problem, but not the exact method you want to stop on. This kind of breakpoint does not require source. The <b>Browse</b> button helps you quickly find the fully qualified class name you want to break on.
Watchpoint	A given field is accessed or modified.	The Watchpoint breakpoint can be used to find a problem if the code inside a class modifies a member field directly from several different places (instead of going through setter or getter methods each time). You can pause the debugger when any field is modified. You can create a breakpoint of this type by using the <b>Toggle Watchpoint</b> menu item on the context menu when pointing at a member field in your class's source.

### 31.9.6 How to Edit Breakpoints for Improved Control

After creating a Java code breakpoint you can edit the breakpoint in the Breakpoints window by right-clicking it and choosing **Edit** in the context menu.

---

**Note:** You can use the Edit Breakpoint dialog to edit an ADF declarative breakpoint. However, you cannot edit some of the other information such as the information in the **Definition** tab. You can launch the Edit Breakpoint dialog by choosing **Edit** from the context menu in the Breakpoints window. For information about creating ADF declarative breakpoints, see [Section 31.8, "Setting ADF Declarative Breakpoints."](#)

---

Some of the features you can use by editing your breakpoint are:

- Associate a logical "breakpoint group" name to group this breakpoint with others of the same group name. Breakpoint groups make it easy to enable/disable an entire set of breakpoints in one operation.
- Associate a debugger action to a breakpoint when the breakpoint is hit. The default action is to stop the debugger so that you can inspect the application states, but you can add a sound alert, write information to a log file, and enable or disable group of breakpoints.
- Associate a conditional expression with the breakpoint so that the debugger stops only when that condition is met. The expressions can be virtually any boolean expression, including:
  - `expr ==value`
  - `expr.equals("value")`
  - `expr instanceof.fully.qualified.ClassName`

---

**Note:** Use the debugger Watches window to evaluate the expression first to make sure it's valid.

---

### 31.9.7 How to Filter Your View of Class Members

You can use the debugger to filter the members that are displayed in the debugger window for any class. In the debugger's Data window, selecting any item and choosing **Preferences** from the context menu brings up a dialog that lets you customize which members appear in the debugger and (more importantly sometimes) which members *don't* appear. You can filter by class type to simplify the amount of scrolling you need to do in the debugger Data window. This is especially useful when you might be interested only in a handful of a class's members.

### 31.9.8 How to Use Common Oracle ADF Breakpoints

If you loaded Oracle ADF source code, you can use the breakpoints listed in [Table 31-11](#) to debug your application.

By looking at the Stack window when you hit these breakpoints, and stepping through the source, you can get a better idea of what's going on.

**Table 31-11 Commonly Used ADF Breakpoints**

Breakpoint	Breakpoint Type	Usage
<code>oracle.jbo.JboException</code>	Exception	This breakpoint useful for setting a breakpoint on the base class of all ADF Business Components runtime exceptions.
<code>oracle.jbo.DMLException</code>	Exception	This is the base class for exceptions originating from the database, like a failed DML operation due to an exception raised by a trigger or by a constraint violation.
<code>doIt()</code>	Method	<p>You can also perform the same debugging function by setting an ADF declarative breakpoint on the page definition action binding. See <a href="#">Section 31.8.3, "How to Set and Use Page Definition Action Binding Breakpoints."</a></p> <p>If you prefer to use this Java breakpoint, you can find it in the <code>JUCtrlActionBinding</code> class (<code>oracle.jbo.uicli.binding</code> package).</p> <p>This is the method that will execute when any ADF action binding is invoked, and you can step into the logic and look at parameters if relevant.</p>
<code>oracle.jbo.server.ViewObjectImpl.executeQueryForCollection</code>	Method	This is the method that will be called when a view object executes its SQL query.
<code>oracle.jbo.server.ViewRowImpl.setAttributeInternal</code>	Method	This is the method that will be called when any view row attribute is set.
<code>oracle.jbo.server.EntityImpl.setAttributeInternal</code>	Method	<p>You can also perform the same debugging function by setting an ADF declarative breakpoint on the page definition attribute value binding. See <a href="#">Section 31.8.4, "How to Set and Use Page Definition Value Binding Breakpoints."</a></p> <p>This is the method that will be called when any entity object attribute is set.</p>

## 31.10 Regression Testing with JUnit

Testing your business services is an important part of your application development process. By creating a set of JUnit regression tests that exercise the functionality provided by your application module, you can ensure that new features, bug fixes, or refactorings do not destabilize your application. JDeveloper's integrated support for creating JUnit regression tests makes it easy to test your application. Its integrated support for running JUnit tests means that any developer on the team can run the test suite with a single mouse click, greatly increasing the chances that every team member can run the tests to verify their own changes to the system. Furthermore, by using JDeveloper's integrated support for creating and running Apache Ant build scripts, you can easily incorporate running the tests into your automated build process as well. You can create a JUnit test for your application module, run it, and integrate the tests into an Ant build script.

JDeveloper provides the ability to generate JUnit test cases, test fixtures, and test suites. You can create test cases to test individual Java files containing single or multiple Java classes. You can create JUnit test fixtures that can be reused by JUnit test cases. You can group all these test cases into a JUnit test suite, which you can run together as a unit.

You can also use the JUnit BC4J Test Suite wizard to generate a test suite when there is an application module in the project. The wizard generates a test suite, test fixture, and a test case for each view object in the application module.

You can create a separate project to contain your regression tests or to integrate the test files into an existing project. If you are creating an ADF Business Components test, you should create a separate project for testing.

Creating separate projects for testing has the following advantages:

- The ability to compile the base project without having a dependency on JUnit
- The ability to package the base project for deployment without having to exclude the test classes.

If you are creating separate projects for JUnit testing, you should create directory structures that mirror the structure of the packages being tested. You may want to name the test classes using a naming convention that can easily identify the package being tested. For example, if you are testing `myClass.java`, you can name the test class `myClassTest.java`.

Although having separate projects has many advantages, in certain cases it may be easier to include the tests within the project. For example, the Fusion Order Demo application has a JUnit regression test suite in the `FODCustomization` workspace `Customization Extension` project.

You can use the Create Test wizards in the context of the project to create a JUnit test case, test fixture, or test suite. However, if you do not want to include these tests as part of the deployment, you may want to separate the tests out in their own project.

**Tip:** If you don't see the Create Test wizards, use JDeveloper's **Help > Check for Updates** feature to install the JUnit Integration extension before continuing.

Each test case class contains a `setUp()` and `tearDown()` method that JUnit invokes to allow initializing resources required by the test case and to later clean them up. These test case methods invoke the corresponding `setUp()` and `tearDown()` methods to prepare and clean up the test fixture for each test case execution. Any time a test in the test case needs access to the application module, it uses the test fixture's

`getApplicationModule()` method. The method returns the same application module instance, saved in a member field of the test fixture class, between the initial call to `setUp()` and the final call to `tearDown()` at the end of the test case.

JDeveloper supports JUnit 4, which allows annotations to be used instead of explicitly having to name the methods `setUp()` and `tearDown()`. These annotations — `@Before`, `@After` — allow you to have multiple setup and teardown methods, including inherited ones if required.

The generated `ExampleModuleConnectFixture` is a JUnit test fixture that encapsulates the details of acquiring and releasing an application. It contains a `setUp()` method that uses the `createRootApplicationModule()` method of the `Configuration` class to create an instance of an application module. Its `tearDown()` method calls the matching `releaseRootApplicationModule()` method to release the application module instance.

Your own testing methods can use any of the programmatic APIs available in the `oracle.jbo` package to work with the application module and view object instances in its data model. You can also cast the `ApplicationModule` interface to a custom interface to have your tests invoke your custom service methods as part of their job. During each test, you will call one or more `assertXxx()` methods provided by the JUnit framework to assert what the expected outcome of a particular expression should be. When you run the test suite, if any of the tests in any of the test cases contains assertions that fail, the JUnit Test Runner window displays the failing tests with a red failure icon.

The JUnit test generation wizard generates skeleton test case classes for each view object instance in the data model, each of which contains a single test method named `testAccess()`. This method contains a call to the `assertNotNull()` method to test that the view object instance exists.

```
// In ViewInstanceNameTest.java test case class
public void testSomeMeaningfulName() {
    // test assertions here
}
```

Each generated test case can contain one or more test methods that the JUnit framework will execute as part of executing that test case. You can add a test to the test case simply by creating a public void method in the class whose name begins with the prefix `test` or use the annotation `@Test`.

### 31.10.1 How to Obtain the JUnit Extension

JUnit must be loaded as an extension to JDeveloper before it becomes available and appears in the menu system.

#### To load the JUnit extension:

1. In the main menu, choose **Help** and then **Check For Updates**.
2. In the Source page of the Check for Updates dialog, select **Search Update Centers** and **Official Oracle Extensions and Updates** and click **Next**.

If you have the JUnit zip file or if the JUnit selection does not appear in the **Available Updates** list, select **Install From Local File** to load the JUnit zip file.

3. In the Updates page, select **JUnit Integration** and click **Next**, as shown in [Figure 31-50](#).

**Figure 31–50 Check for Updates Wizard for Adding JUnit Extension**

4. On the License Agreements page, click **I Accept** and click **Finish**.

### 31.10.2 How to Create a JUnit Test Case

Before you create a JUnit test case, you must have created a project that is to be tested.

#### To generate a JUnit test case:

1. In the Application Navigator, right-click the project in which you want to create a test case and choose **New**.
2. In the New Gallery, expand **General**, select **Unit Tests(JUnit)** and then **Test Case**, and click **OK**.
3. In the Select the Class to Test page of the Create Test Case dialog, enter the class under test or click **Browse**.
4. In the Class Browser dialog, locate the class you want to test or enter the beginning letters in the **Match Class Name** field. The **Match Class** list will be filtered for easier identification.

For example, entering FOD filters the list down to three items, as shown in [Figure 31–51](#).

**Figure 31–51 Class Browser for Selecting Class Files to Test**

Select the class and click **OK** to close the dialog. Click **Next**.

5. Select the individual methods you want to test, and click **Next**.

For example, in [Figure 31–52](#), the four methods that are checked are to be tested.

**Figure 31–52 Create Test Case Dialog for Selecting Methods to Test**

6. In the Setup Test Case Class page, enter the name of the test case, the package, and the class it extends and select the list of built-in functions JUnit will create stubs for. Click **Next**.

For example, in [Figure 31–53](#), JUnit will create a stub for the `setUp()` method for the `FodCompanyCustomizationLayerTest` test case in the `oracle.fodemo.customization` package.

**Figure 31–53 Create Test Case Dialog for Setting Up Classes to Test**

7. In the Select Test Fixtures page, select any test fixtures you want to add to the test case or click **Browse**.
8. Make sure that all the test fixtures you want to add to the test case are selected in the list and click **Finish**.

### 31.10.3 How to Create a JUnit Test Fixture

You should create a JUnit test fixture if you require more than one test for a class or method. A JUnit text fixture allows you to avoid duplicating test code that is needed to initialize testing.

#### To generate a JUnit test fixture:

1. In the Application Navigator, right-click the project in which you want to create a test fixture and choose **New**.
2. In the New Gallery, expand **General**, select **Unit Tests(JUnit)** and then **Test Fixture**, and click **OK**.
3. In the Create Test Fixture dialog, enter the name of the test fixture, the package, and any class it extends.
4. Click **OK**.

### 31.10.4 How to Create a JUnit Test Suite

Before you create a JUnit test suite, you should have already created JUnit test cases that can be added to the test suite.

#### To generate a JUnit test suite:

1. In the Application Navigator, right-click the project in which you want to create a test suite and choose **New**.
2. In the New Gallery, expand **General**, select **Unit Test** and then **Test Suite**, and click **OK**.

3. In the Setup Test Suite Class page of the Create Test Suite dialog, enter the name of the test suite, the package, and the class it extends. Click **Next**.

For example, in [Figure 31–54](#), an `AllTests` test suite is created that extends the `java.lang.Object` class.

**Figure 31–54** Create Test Suite Wizard

4. In the Select Test Cases page of the Create Test Suite dialog, check that all the test cases you want included in the test suite have been selected. The test cases you have created will populate the list. Deselect any test cases that you do not want included. Click **Finish**.

For example, in [Figure 31–55](#), both test cases are selected to be in the test suite.

**Figure 31–55** Selecting Test Cases for a Test Suite

### 31.10.5 How to Create a Business Components Test Suite

The test fixture that is created is a singleton class to reduce the number of connections. If you want to connect or disconnect for each test case, customize the test case using the JUnit 4 annotations `@Before` and `@After`.

The JUnit BC4J Test Suite wizard will generate tests for each view object in the application module. If the application module does not have exported methods, the

wizard will also generate a test for the application module itself. A generated view object class has the format `view_objectVOTest.java` and is placed into a package with the format `package.view.viewobjectVO`, where `package` is the application module package. A generated application module test has the format `application_moduleAMTest.java` and is placed into a package with the format `package.applicationModule`. A generated test fixture class has the format `applicationmoduleAMFixture.java` and is placed in the same package as the application module test.

The generated all test suite class has the format `AllapplicationmoduleTest.java` and is placed into the package with the same name as the application module package name.

A test case XML file is also generated for each application module or view object test. The XML file contains test methods defined in the application module or view object test cases. It does not include the test methods from the base classes (if any) because there may be too many duplicates.

For instance, after you created a test suite for an application module named `StoreAAppModule` with view objects `Employees1View1` and `Employees1View2` in the package `StoreAPack`, the Application Navigator displays the test hierarchy as shown in [Figure 31–19](#).

**Figure 31–56 Business Components Test Suite in the Application Navigator**

### Before you begin:

Create application modules in the project.

### To create a business components test suite:

1. In the main menu, choose **File** and then **New**.  
You will create a separate project for the business components tests.
2. In the New Gallery, expand **General**, select **Projects** and then **Java Projects**, and click **OK**.
3. In the Project Name page of the Create Java Project wizard, enter a name and the directory path for the test project, and click **Next**.
4. In the Project Java Settings page, enter the package name, the directory of the Java source code in your project, and output directory where output class files will be placed, and click **Finish**.
5. In the Application Navigator, double-click the application module you want to test.
6. In the overview editor, click the **Java** navigation tab and then click the **Edit** icon for the **Java Class** section.

7. In the Select Java Options dialog, select **Generate Application Module Class** and click **OK**.
8. In the Java page of the overview editor, click the **Edit** icon for the **Class Interface** section.
9. In the Edit Client Interface dialog, shuttle the methods you want to test to the **Selected** pane, and click **OK**.
10. In the Application Navigator, right-click the test project you have created and choose **New**.
11. In the New Gallery, expand **General**, select **Unit Tests** and then **Business Components Test Suite**, and click **OK**.
12. In the Configure Tests page of the JUnit BC4J Test Suite wizard, select values for the following and click **Next**:
  - **Business Component Project**: Select the project that has the application module you want to test.
  - **Application Module**: Select the application module you want to test.
  - **Configuration**: Choose a local or shared application module.
  - **Test Base Class-Application Module Extends**: You can specify different base cases. The generated test case classes will extend from that base class where all public abstract methods in the base class will have simple and default implementation method bodies.
  - **Test Base Class-View Object Extends**: You can specify which class the view object extends. The generated test case classes will extend from that base class where all public abstract methods in the base class will have simple and default implementation method bodies.
13. In the Summary page, verify the selections and click **Finish**.

### 31.10.6 How to a Create Business Components Test Fixture

When you create a business components test suite, a business components test fixture is created with it. You can also create Business Components test fixtures independently.

A generated test fixture class has the format `applicationmoduleAMFixture.java` and put into a package with the format `package.applicationModule`, where `package` is the application module package.

#### Before you begin:

Create application modules in the project.

#### To create a business components test fixture:

1. In the main menu, choose **File** and then **New**.  
You will create a separate project for the business components tests.
2. In the New Gallery, expand **General**, select **Projects** and then **Java Projects**, and click **OK**.
3. In the Project Name page of the Create Java Project dialog, enter a name and the directory path for the test project, and click **Next**.
4. In the Project Java Settings page, enter the package name and the source and output directories, and click **Finish**.

5. In the Application Navigator, double-click the application module you want to test.
6. In the overview editor, click the **Java** navigation tab.
7. In the Java page of the overview editor, click the **Edit** icon for the **Java Class** section.
8. In the Select Java Options dialog, select **Generate Application Module Class**, and click **OK**.
9. In the overview editor, click the **Edit** icon for the **Class Interface** section.
10. In the Edit Client Interface dialog, shuttle the methods you want to test to the **Selected** pane, and click **OK**.
11. In the Application Navigator, right-click the test project you have created and choose **New**.
12. In the New Gallery, expand **General**, select **Unit Tests** and then **Business Components Test Fixture**, and click **OK**.
13. In the Configure Tests page of the JUnit BC4J Test Fixture wizard, select values for the following and click **Next**:
  - **Business Component Project**: Select the project that has the application module you want to test.
  - **Application Module**: Select the application module you want to test.
  - **Configuration**: Choose a local or shared application module.
14. In the Summary page, verify the test fixture class and click **Finish**.

### 31.10.7 How to Run a JUnit Test Suite as Part of an Ant Build Script

Apache Ant is a popular, cross-platform build utility for which JDeveloper offers design time support. You can incorporate the automatic execution of JUnit tests and test output report generation by using Ant's built-in `junit` and `junitreport` tasks. [Example 31-3](#) shows a task called `tests` from the `FODCustomizations` Ant `build.xml` file in the `CustomizationExtension` project. It depends on the `build` and `buildTests` targets that Ant ensures have been executed before running the `tests` target.

#### **Example 31-3** Ant Build Target Runs JUnit Test Suite

```
<target name="testCustomizations" depends="compileExtensionClasses">
  <junit printsummary="yes" haltonfailure="yes">
    <classpath refid="customization.classpath">
      <pathelement location="\${customization.build.dir}"/>
    </classpath>
    <formatter type="plain"/>
    <test name="oracle.fodemo.customization.tests.AllTests"/>
  </junit>
</target>
```

The `junit` tag contains a nested `test` tag that identifies the test suite class to execute and specifies a directory in which to report the results. The `junitreport` tag allows you to format the test results into a collection of HTML pages that resemble the format of Javadoc.

To try running the JUnit test from Ant, select the `build.xml` file in the Application Navigator, and choose **Run Ant Target > tests** from the context menu.

---

## Refactoring a Fusion Web Application

This chapter describes considerations for renaming, moving, and deleting files, configuration files, objects, attributes, and elements in a Fusion web application. In most cases, JDeveloper automatically performs refactoring. However, you may need to complete some manual steps to refactor.

This chapter includes the following sections:

- [Section 32.1, "Introduction to Refactoring a Fusion Web Application"](#)
- [Section 32.2, "Renaming Files"](#)
- [Section 32.3, "Moving JSF Pages"](#)
- [Section 32.4, "Refactoring pagedef.xml Bindings Objects"](#)
- [Section 32.5, "Refactoring ADF Business Components"](#)
- [Section 32.6, "Refactoring ADF Business Component Object Attributes"](#)
- [Section 32.7, "Refactoring Named Elements"](#)
- [Section 32.8, "Refactoring ADF Task Flows"](#)
- [Section 32.9, "Refactoring the DataBindings.cpx File"](#)
- [Section 32.10, "Refactoring Across Abstraction Layers"](#)
- [Section 32.11, "Refactoring Limitations"](#)
- [Section 32.12, "Refactoring the .jspx Project File"](#)

### 32.1 Introduction to Refactoring a Fusion Web Application

JDeveloper provides refactoring options to rename, move, and delete the ADF Business Components objects, attributes, and named elements that your application uses. These refactoring options synchronize your changes with other parts of the application that are dependent on the changes. For example, renaming an ADF Business Components object such as a view using the **Rename** option renames any references to it in other XML source files.

### 32.2 Renaming Files

You can rename files such as configuration files using the following methods:

- In the Application Navigator, select the file and choose **File > Rename** from the main menu.
- In the Application Navigator, right-click the file and choose **Refactor > Rename**.

- In the source editor, select a class name, right-click it, and choose **Rename**.

### 32.3 Moving JSF Pages

In the Application Navigator, you can right-click a JSF page and choose **Refactor > Move to Package** to move the page to another package.

Moving the JSF page to another package updates:

- `faces-config.xml` files that reference the page and its package
- ADF task flows containing views associated with the page
- `DataBindings.cpx` mappings to the page

### 32.4 Refactoring pagedef.xml Bindings Objects

The `pagedef.xml` binding objects that you can refactor include bindings and executables. For more information, see [Section 12.6, "Working with Page Definition Files."](#)

**To refactor pagedef.xml binding objects:**

1. In the Application Navigator, select the page node on which you have added a bound object such as an ADF Form or selection list.
2. Right-click the page node and choose **Go to Page Definition**.

If the page does not already have a page definition, the Create Page Definition dialog displays. Click **OK** to create a page definition for the page.

3. In the overview editor, expand the **Model** section.

Data bindings such as list bindings and iterator bindings defined for the page display under **Bindings** and **Executables**, as shown in [Figure 32–1](#).

**Figure 32–1 Page Data Binding Definition Overview Tab**

4. Right-click a data binding or executable, choose **Refactor** and a refactoring option such as **Rename** or **Delete**.
5. To display the usages between bindings, executables, and data controls, right-click a binding or executable and choose **Find Usages**.

## 32.5 Refactoring ADF Business Components

ADF Business Components includes objects such as view objects and entity objects. [Table 32–1](#) shows support for refactoring ADF Business Components.

**Table 32–1 Refactoring ADF Business Components**

Action	Result
Move	Moves the object to a different package or directory and updates all references.
Delete	JDeveloper shows all dependencies on the object and permits a forced delete. The application may not work at this point. You may need to resolve broken references.
Rename	ADF Business Components objects are defined by an XML file. The XML file has a file name identical to the object name. For example, the name of the XML file for a view object named <code>Persons1View</code> is <code>Persons1View.xml</code> . Renaming results in changing the <code>Name</code> attribute, renaming the XML file, and updating all references.  For example, the name of an entity ( <code>Customer</code> ) is stored as an attribute in the XML file ( <code>name=Customer</code> ). The XML file has the same name the entity name ( <code>Customer.xml</code> ).
Find Usages	JDeveloper shows all dependencies on the object.

### To refactor ADF Business Components objects:

1. In the Application Navigator, expand the **Projects** node containing the object you want to refactor.
2. Within the project, expand the **Application Sources** node and then the package containing the object you want to refactor.
3. Right-click the object and choose **Refactor > Rename** or **Refactor > Move**.
4. To delete the object, choose **Delete**.

If the object is used elsewhere in the application, a dialog displays with the following options:

- **Ignore:** Unresolved usages will remain in the code as undefined references.
- **View Usages:** Display a preview of the usages of the element in the Compiler log. You can use the log to inspect and resolve the remaining usages.

## 32.6 Refactoring ADF Business Component Object Attributes

[Table 32–1](#) shows support for refactoring attributes of ADF Business Component entity objects and view objects.

**Table 32–2 Refactoring Attributes**

Action	Result
Move	Not supported.

**Table 32–2 (Cont.) Refactoring Attributes**

Action	Result
Delete	JDeveloper shows all dependencies on the attribute and permits a forced delete. The application may not work at this point. You may need to resolve broken references.
Rename	Attributes share data elements represented in entity and view objects (see <a href="#">Section 4.1, "Introduction to Entity Objects"</a> for more information). References to the attribute are updated when you rename the attribute. Renaming results in changing the Name attribute and updating all references.  Renaming an attribute does not change the data it represents, nor does it rename the underlying table column.
Find Usages	JDeveloper shows all dependencies on the attribute.

**To refactor attributes:**

1. In the Application Navigator, expand the **Projects** node containing the object you want to refactor.
2. Within the project, expand the **Application Sources** node and then the package containing the object you want to refactor.
3. Double-click the object.
4. In the overview editor, select **Attributes**.
5. In the **Name** column, select an attribute.
6. Right-click and choose **Rename** or **Delete**.
7. To delete the attribute, choose **Delete**.

If the attribute is used elsewhere in the application, a dialog displays with the following options:

- **Ignore:** Unresolved usages will remain in the code as undefined references.
- **View Usages:** Display a preview of the usages of the attribute in the Compiler log. You can use the log to inspect and resolve the remaining usages.

## 32.7 Refactoring Named Elements

[Table 32–3](#) shows support for refactoring named elements in an XML schema. Named elements are any elements in the XML schema that can be referenced by a Name attribute. A named element is not an object or an attribute.

**Table 32–3 Refactoring Named Elements**

Action	Result
Move	Not supported.
Delete	Not supported.
Rename	One exception to the definition of named elements is the design time element <code>Attr</code> , which does have a <code>Name</code> attribute. <code>Attr</code> is a name-value pair, is not accessible from the code editor, and should not be renamed.
Find Usages	JDeveloper shows all dependencies on the named element.

**To refactor named elements:**

1. In the Application Navigator, expand the **Projects** node containing the object you want to refactor.
2. Within the project, expand the **Application Sources** node and then the package containing the object you want to refactor.
3. Double-click the object.
4. In the overview editor, click the **Source** tab.
5. Scroll down to a named element.

Named elements are indicated by `Name="<element>"` in the source code, for example:

```
<Key Name="PersonsAffContactChk">
```

A named element is not an object or attribute.

6. To rename the element, right-click the element and choose **Rename**.
7. To delete the element, choose **Delete**.

If the element is used elsewhere in the application, a dialog displays with the following options:

- **Ignore:** Unresolved usages will remain in the code as undefined references.
- **View Usages:** Display a preview of the usages of the element in the Compiler log. You can use the log to inspect and resolve the remaining usages.

## 32.8 Refactoring ADF Task Flows

For more information, see [Section 14.5, "Refactoring to Create New ADF Task Flows and Templates."](#)

## 32.9 Refactoring the DataBindings.cpx File

The `DataBindings.cpx` file defines the Oracle ADF binding context for the entire application and provides the metadata from which the Oracle ADF binding objects are created at runtime (see [Section A.7.1, "DataBindings.cpx Syntax"](#) for more information). This file is a registry used to quickly find all `.cpx`, `.dcx`, `.jpx`, and `.xcfg` files, which are themselves registries of metadata.

If you rename the `DataBindings.cpx` file to a new name, such as `DataBindingsNew.cpx`, the change is added to the `adfm.xml` file.

[Example 32-1](#) shows the contents of the `adfm.xml` file after `DataBindings.cpx` is refactored to `DataBindingsNew.cpx`.

**Example 32-1 Renamed DataBindings.cpx file in adfm.xml**

```
<?xml version="1.0" encoding="UTF-8" ?>
<MetadataDirectory xmlns="http://xmlns.oracle.com/adfm/metainf"
version="11.1.1.0.0">
<DataBindingRegistry path="adf/sample/view/DataBindingsNew.cpx" />
</MetadataDirectory>
```

After this change, the application won't run because the data control cannot be found.

[Example 32-2](#) shows the old ID in the `DataBindingsNew.cpx` file. To enable the

application to access the correct bindings file, update the ID value in the `DataBindingsNew.cpx` file to the new file.

**Example 32–2 DataBindingsNew.cpx ID**

```
<Application xmlns="http://xmlns.oracle.com/adfm/application"
version="11.1.1.49.28" id="DataBinding" SeparateXMLFiles="false"
Package="adf.sample.view" ClientType="Generic">
```

This should be changed to an ID similar to the one shown in [Example 32–3](#).

**Example 32–3 Updated DatabindingNew.cpx ID**

```
<Application xmlns="http://xmlns.oracle.com/adfm/application"
version="11.1.1.49.28" id="DataBindingNew" SeparateXMLFiles="false"
Package="adf.sample.view" ClientType="Generic">
```

## 32.10 Refactoring Across Abstraction Layers

Refactoring does not cross abstraction layers. For example, when a view object is created based on the entity `Dept`, it is named `DeptView` by default. Renaming `Dept` updates the entity usage in `DeptView`, but does not change the name of the view object.

## 32.11 Refactoring Limitations

[Table 32–4](#) summarizes the limitations of JDeveloper’s refactoring support.

**Table 32–4 Refactoring Limitations**

Area	Limitation
Database	When a database artifact used in an ADF Business Components object is renamed, the object needs to be updated. This type of refactoring is currently not supported.
Service interface	A service interface defines a contract between two separate pieces of software. For example, the ADF Business Components service interface is responsible for exposing business components to the view and model layers. Changing the name of a service interface can cause a conflict. While developing the application, consider removing the service interface, refactoring the object, and regenerating the service interface. Additionally, if your service interface defines a find operation based on a view criteria that specifies bind variables, changing the number or order of the bind variables in the underlying view criteria will require that you regenerate the service interface.  For more information, see <a href="#">Chapter 11, "Integrating Service-Enabled Application Modules."</a>
Java literal references	The Java code generated by ADF Business Components has literal references to the XML metadata. These literal references are updated during refactoring operations. Generated (type safe) methods are also updated. However, if the application directly refers to the metadata, these references are not updated.

**Table 32–4 (Cont.) Refactoring Limitations**

Area	Limitation
Domain	<p>If a domain needs to be renamed or moved, you must create the new domain, then change the type of existing domain usages.</p> <p>For example, you might rename a domain called <code>EmployeeID</code> to <code>EmployeeNumber</code>. In addition, the entity <code>Emp</code> has an attribute called <code>Empno</code> that is of type <code>EmployeeID</code>.</p> <p>After creating the new domain <code>EmployeeNumber</code>, go to the attributes page for the entity, right-click <b>Empno</b> and choose <b>Change Type</b>. This switches <code>Empno</code> from <code>EmployeeID</code> to <code>EmployeeNumber</code>.</p>
Security	Entity object and attribute security policies in the policy store may reference the name of an entity object or attribute. These policy definitions are not updated in response to the refactoring of an entity object or attribute.
Resource Bundles	Entity object definitions can reference a resource in one or more arbitrary resource bundle ( <code>.properties</code> ) files that you create. You can use this file to define labels for the attributes of entity objects. However, if you rename the <code>.properties</code> file you created, JDeveloper will not update the entity object definitions to reflect the new file name. As an alternative to resource bundle files that you create, you can specify a project setting to generate a single, default resource bundle file for the ADF Business Components project. In this case, JDeveloper will not allow you to rename this generated file. However, if you attempt to change the project-level default resource bundle file, JDeveloper will warn you about the change. The data model project will honor the new ADF Business Components project-level setting for any objects that have not yet been linked to the default resource bundle file; all existing Business Components that have already been linked to the original default file will continue to use it instead.
.jpx project file	<p>Renaming the ADF Business Components (<code>.jpx</code>) project file is not supported.</p> <p>In previous versions of JDeveloper, ADF Business Components <code>.jpx</code> files were created only in the root package of the <code>src</code> directory of a project and were named with the same base name as the project. The ADF Business Components objects (entities, views, and application modules) were all created in the model package (for example, <code>/model/AppModule.xml</code>), but the <code>/Model.jpx</code> is not.</p> <p>This may cause a reusability problem when attempting to package them in ADF JAR files for use on the class path. There may be name conflicts because several projects are named <code>Model</code>.</p>

## 32.12 Refactoring the .jpx Project File

JDeveloper supports refactoring ADF Business Components.

### To manually move the .jpx project file:

1. Move the `.jpx` file to the new source tree location.

For example, you can move the `Model.jpx` file from `src/Model.jpx` to `src/packagenames/go/here/Model.jpx`.

2. Change the `.jpx` file contents. The `PackageName` attribute of the root element `JboProject` needs to have the correct value.

For example, you can specify `PackageName="packagenames.go.here"`.

3. Change the `jbo.project` attributes in all `common/bc4j.xcfg` files that contain elements referred to in the `.jpx` file to include the new package name.

For example:

```
<AppModuleConfig name="ScottDeptAMLocal "  
ApplicationName="packagenames.go.here.ScottDeptAM"  
DeployPlatform="LOCAL" JDBCName="scottdb"  
jbo.project="packagenames.go.here.Model">
```

4. Change the JDeveloper project file (the .jpr file) contents:

- Set the new .jpx package location. If you later change the default package in the project properties, you will again raise a `NotFound` error for the .jpx file.

For example:

```
<value n="defaultPackage" v="packagenames.go.here"/>
```

- Fix any `ownerURL` elements in the `ownerMap` that contain references to the old location of the .jpx file.

For example:

```
<url n="ownerURL"  
path="src/packagenames/go/here/Model.jpx"/>
```

---

---

## Reusing Application Components

This chapter describes how to package certain ADF components into the ADF Library for reuse in ADF applications. Reusable ADF components are application modules, business components (entity objects, view objects, associations), data controls, task flows, page templates, and declarative components.

This chapter includes the following sections:

- [Section 33.1, "Introduction to Reusable Components"](#)
- [Section 33.2, "Packaging a Reusable ADF Component into an ADF Library"](#)
- [Section 33.3, "Adding ADF Library Components into Projects"](#)
- [Section 33.4, "Removing an ADF Library JAR from a Project"](#)

### 33.1 Introduction to Reusable Components

In the course of application development, certain components will often be used more than once. Whether the reuse happens within the same application, or across different applications, it is often advantageous to package these reusable components into a library that can be shared between different developers, across different teams, and even across departments within an organization.

In the world of Java object-oriented programming, reusing classes and objects is just standard procedure. With the introduction of the model-view-controller (MVC) architecture, applications can be further modularized into separate model, view, and controller layers. By separating the data (model and business services layers) from the presentation (view and controller layers), changes to any one layer do not affect the integrity of the other layers. You can change business logic without having to change the UI, or redesign the web pages or front end without having to recode domain logic.

Oracle ADF and JDeveloper support the MVC design pattern. When you create an application in JDeveloper, you can choose many application templates that automatically set up model and view-controller projects. Because the different MVC layers are decoupled from each other, development can proceed on different projects in parallel and with a certain amount of independence.

ADF Library further extends this modularity of design by providing a convenient and practical way to create, deploy, and reuse high-level components. When you first design your application, you design it with component reusability in mind. If you created components that can be reused, you can package them into JAR files and add them to a reusable component repository. If you need a component, you may look into the repository for those components and then add them into your project or application.

For example, you can create an application module for a domain and package it to be used as the data model project in several different applications. Or, if your application will be consuming components, you may be able to load a page template component from a repository of ADF Library JARs to create common look and feel pages. Then you can put your page flow together by stringing together several task flow components pulled from the library.

An ADF Library JAR contains ADF components and does not and cannot contain other JARs. It should not be confused with JDeveloper library, Java EE library or Oracle WebLogic shared library.

Table 33–1 lists the reusable components supported by ADF.

**Table 33–1 Oracle ADF Reusable Components**

Reusable Component	Description
Data control	Any data control can be packaged into an ADF Library JAR. Some of the data controls supported by Oracle ADF include application modules, Enterprise JavaBeans, web services, URL services, JavaBeans, and placeholder data controls.
Application module	When you are using ADF Business Components and you generate an application module, an associated application module data control is also generated. When you package an application module data control, you also package up the Business Components associated with that application module. The relevant entity objects, view objects, and associations will be a part of the ADF Library JAR and available for reuse.
Business components	Business components are the entity objects, view objects, and associations used in the ADF Business Components data model project. You can package business components by themselves or together with an application module.
Task flows and taskflow templates	<p>Task flows can be packaged into an ADF Library JAR for reuse.</p> <p>ADF bounded task flows built using pages can be dropped onto pages. The drop will create a link to call the bounded task flow. A task flow call activity and control flow will automatically be added to the task flow, with the view activity referencing the page. If there is more than one existing task flow with a view activity referencing the page, it will prompt for the application developer to select the one to automatically add a task flow call activity and control flow. If you drop a bounded task flow that uses page fragments, JDeveloper adds a region to the page and binds it to the dropped task flow.</p> <p>If an ADF task flow template was created in the same project as the task flow, the ADF task flow template will be included in the ADF Library JAR and will be reusable.</p>
Page templates	You can package a page template and its artifacts into an ADF Library JAR. If the template uses image files and they are included in a directory within your project, these files will also be available for the template during reuse.
Declarative components	You can create declarative components and package them for reuse. The tag libraries associated with the component will be included and loaded into the consuming project.

You can also package up projects that have several different reusable components if you expect that more than one component will be consumed. For example, you can create a project that has both an application module and a bounded task flow. When this ADF Library JAR file is consumed, the application will have both the application module and the task flow available for use. You can package multiple components into one JAR file, or you can package a single component into a JAR file. Oracle ADF and JDeveloper give you the option and flexibility to create reusable components that best suit you and your organization.

You create a reusable component by using JDeveloper to package and deploy the project that contains the components into a ADF Library JAR file. You use the

components by adding that JAR to the consuming project. At design time, the JAR is added to the consuming project's class path and so is available for reuse. At runtime, the reused component runs from the JAR file by reference. For the procedure to add the JAR manually, see [Section 33.3.2, "How to Add an ADF Library JAR into a Project Manually."](#) For the procedure to add the JAR using the JDeveloper Resource Catalog, see [Section 33.3.1, "How to Add an ADF Library JAR into a Project using the Resource Palette"](#).

Before you proceed to create reusable components, you should review the guidelines for creating reusable components.

### 33.1.1 Creating Reusable Components

Creating and consuming reusable components should be included in the early design and architectural phases of software projects. You and your development team should consider which components are candidates for reuse, not only in the current applications but also for future applications and including those applications being developed in other departments.

You and your team should decide on the type of repository needed to store the library JARs, where to store them and how to access them. You should consider how to organize and group the library JARs in a structure that fits your organizational needs. You should also consider creating standardized naming conventions so that both creators and consumers of ADF Library JARs can readily identify the component functionality.

**Tip:** If, in the midst of development, you and your team find a module that would be a good candidate for reuse, you can use the extensive refactoring capabilities of JDeveloper to help eliminate possible naming conflicts and adhere to reusable component naming conventions.

#### 33.1.1.1 Naming Conventions

When you create reusable components, you should try to create unique and relevant names for the application, project, application module, task flow, connection, or any other file or component. Do not accept the JDeveloper wizard default names such as Application, Project, ViewController, AppModule, `task-flow-definition.xml`, or Connection. You want to try to have unique names to avoid naming conflicts with other projects, components, or connections in the application. Naming conflicts could arise from components created in the consuming application and those loaded from other JAR files. [Table 33–2](#) lists the objects that you may be required to rename.

**Table 33–2 Example Unique and Relevant Names for Reusable Components**

Type	JDeveloper Default	Example
Application	Application	FusionOrderDemo
Project	Model	OrderBookingService
	ViewController	StoreFrontUI
	Project	
Package	Various possibilities. For more information, see <a href="#">Section 33.1.1.1.1</a> .	<code>oracle.foddemo.storefront</code>
Application module	AppModule	StoreServiceAMDataControl

**Table 33–2 (Cont.) Example Unique and Relevant Names for Reusable Components**

Type	JDeveloper Default	Example
Connection	Connection1	oracle_apps_foddb
Task flow	task-flow-defintion.xml	checkout-task-flow.xml
Page template	templateDef.jspx	StoreFrontTemplate.jspx
Declarative Component	componentDef componentDef.jspx	FODsuperwidgetDef FODsuperwidgetDef.jspx
ADF Library JAR file	adflib<string or 3-digit random number>N  For more information, see <a href="#">Section 33.1.1.2</a> .	adflibStoreFrontService

#### 33.1.1.1.1 Naming Considerations for Packages

Be aware that some components use the default package name of the project without allowing the name to be explicitly set. In this situation, you must take extra care to avoid package name collisions. You can set the package name in the application creation wizard and you should check the names in the Project Properties dialog afterwards. If you don't set the package name, it will default to a variant of the project name, typically with the first letter being lowercase. For example, a project with the name `Project1` will have a default package name of `project1`. You should manually change the package name to a more unique name before you proceed to build the project.

---

**Note:** The basic package naming requirement is that ADF metadata registries (`.dcx`, `.cpx`, and so on) are generated based on the project's package name, and you should avoid metadata naming conflicts between projects that will be combined at runtime.

---

When you are creating a reusable component's web resources files, such as JSPs, HTMLs, and task flows, you should create them in their own relative directories. When the JAR is deployed into another application, there will be less chance for conflict between the reusable component's files and the consuming application's files.

#### 33.1.1.1.2 Naming Considerations for Connections

Oftentimes, several modules in an application will connect to the same data source. You should standardize the connection name to the same data source to avoid confusion because there is only one namespace for connections across the application. This would require coordination with other developers, component producers, and component consumers. For example, if `module1` and `module2` both have a connection to the same database, the connection name should be standardized to an agreed upon name, such as `orders_db`.

ADF Library JARs (with connections) may be used in different applications with different connection requirements. ADF Library JAR producers should choose connection names that are at least representative of the connection source, if not the actual standardized connection name. Be aware that consumers of the JAR that was created with connections will be required to satisfy the connection requirements when they add the component to the application.

For example, for a database connection, choosing an endpoint host name is usually not appropriate. The most appropriate name is a complete representative for the schema. Acceptable names for connections are `oracle-appsdb` and `oracle-scottdb`. You should realize that if many reusable components use different names for the same logical connection, then the customer of the component will have to satisfy each one individually with duplicate information. The consumer will have to supply connection details for several different connection names, when in fact they all refer to the same instance.

### 33.1.1.1.3 Naming Considerations for Applications with EJB Projects

If an application has both EJB projects and a web application project with data binding, you should check to see that the EJB component names are not in conflict with any other web application project component names. The EJB project components may have global scope because the project is automatically added to the global class path of all web projects in the application. Web application projects may mistakenly access a component with the same name in the EJB project rather than within its own project.

For example, if both an EJB project and a web-based project have a `test1.jspx` page, when the web-based project is run, it may try to run the EJB project `test1.jspx` page.

At runtime, JDeveloper detects if there are EJB projects and web application projects with data binding in the same application. If there are both types in the application, when the project is run and the server starts up, a warning message will appear in the Log window.

### 33.1.1.2 The Naming Process for the ADF Library JAR Deployment Profile

Before you package the project, you must create a deployment profile with the name and path for the JAR file. You should choose a name that follows you and your development team's naming convention and that is descriptive of the function of the component. You should realize that the consuming project may also include other JAR files from other software authors.

For example, if the component is a task flow for self-service paying, you might name it `mycompany.hcm.pay.selfservice.taskflows.jar`. Other examples are `oracle.apps.hcm.pay.model.jar` and `mycompany.hcm.pay.model.overrides.jar`.

If you do not enter a name, JDeveloper will present a default name with the following format:

```
adflibidentifiern
```

Where *identifier* is created with the following order of precedence:

1. Name of the project, other than Model, ViewController, or Project.
2. Name of the application, other than application.
3. A random three-digit number.

And *n* is a number that starts with 1 and increments by 1 for each iteration of the profile.

For example, if the project name were `StoreFrontService`, the profile name would be `adflibStoreFrontService1`. If the project name were `Model`, JDeveloper would reject this name and move to the second order of precedence, application name. If the application name were `FusionOrderDemoShared`, then the project name would be `adflibFusionOrderDemoShared1`. If neither the model nor the

application name is usable, then a random three-digit number would be used instead, for example, `adf11b7491`.

### 33.1.1.3 Keeping the Relevant Project

When you are creating reusable components, you should eliminate any projects that are not relevant to the reusable component. For example, if you want to create a reusable application module, you would need a data model project, but you would not need a view-controller project. In this instance, if you had created an application with both a data model and a view-controller project, you could delete the view-controller project. Of course, you should rename the default name `Model` to something more relevant, such as `StoreFrontService`. Similarly, if you are creating a reusable task flow that is not databound, you can delete any data model project from the application.

### 33.1.1.4 Selecting the Relevant Technology Scope

If you know the technology scope of your consuming projects, you can design your component with technologies that will be compatible. For example, if the consuming application uses only standard JSF Faces, then it may not be compatible with a declarative component that is built with ADF Faces.

When you create your application, you can define the technology scope using the Create Application Wizard by selecting from the application template.

After the project has been created, you can define the technology using the Technology Scope page of the Project Properties dialog.

### 33.1.1.5 Selecting Paths and Folders

If you are using the file system to store your ADF Library JARs, you should select file system locations that can function as repositories. You may want to put groups of JARs into a common directory folder, for example, `C:\ADF11\jdev\DevTeamADFRepository`. If your team or organization plans to share ADF Library JARs, you should consider setting up network accessible repository folders, directories, or services. The Resource Palette has provisions to connect to different repository sources and make multiple connections. For more information about accessing ADF Library JARs using the Resource Palette, see [Section 33.1.2, "Using the Resource Palette."](#)

### 33.1.1.6 Including Connections Within Reusable Components

If the project you are packaging into an ADF Library JAR includes a connection, that information can be included in the JAR and may be available to the consuming project. Oracle ADF uses connection architecture which defines a connection as two parts, the connection name and the connection details (or endpoint definition). JDeveloper will present the producer of the JAR the option to package the connection name only or to include connection details with the connection name.

If a connection is present in the project, the packaged ADF Library JAR will contain a `jar-connections.xml` file and a `jar-adf-config.xml` file. They will be added to the META-INF directory. The `jar-connections.xml` file contains the connection name and other relevant connection information. The `jar-adf-config.xml` file stores the information about the credentials used for the connections. If connection credentials were also specified, then a `jar-credential-jazn-data.xml` will also be included for the credential store. You can select the individual connections or connection types that you want to be packaged with the ADF Library JAR when you create the ADF Library JAR deployment profile. You make connection selections in the

Create or Edit ADF Library Deployment Profile Properties dialog Connections page as described in [Section 33.2.1, "How to Package a Component into an ADF Library JAR."](#)

When an ADF Library JAR is being added to a project, JDeveloper checks for conflicts between the application's connections and the JAR's connections. A dialog will be presented to allow you to decide whether to proceed with adding the JAR to the project. Connections defined in the ADF Library JAR may be added to the consuming project, depending on the following conditions:

- If the connection defined in the JAR is fully configured and there are no connection name conflicts with the consuming project, a new connection will be added.
- If the connection defined in the JAR is partially configured, a new connection will be added to the consuming project but it must be configured before use. Connection dialogs may appear to allow the user to enter connection information. This partially configured connection may be indicated by an incomplete icon.
- If the connection defined in the JAR has the same name as the application's connection, it will not be added to the project. The application's existing connection will be used.
- If the connection defined in the JAR has the same name as the application's connection but is of different type, the JAR's connection will not be added to the project. For example, if a database connection in the JAR and a URL connection in the application have the same name, the database connection will not be added to the application.

For instructions on how to add an ADF Library to a project that includes connections, see [Section 33.3.1, "How to Add an ADF Library JAR into a Project using the Resource Palette."](#)

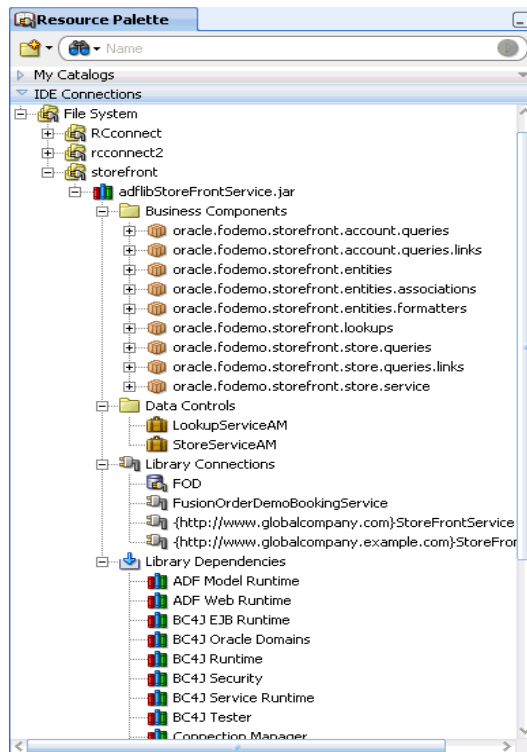

### 33.1.2 Using the Resource Palette

ADF Library JARs can be packaged, deployed, discovered, and consumed like any other Oracle Library component. Creating an ADF Library JAR is the action of packaging all the artifacts (and additional control files) of a project into a JAR. Consuming a reusable component from an ADF Library JAR is the action of loading that ADF Library JAR into the project's set of libraries.

However, the easiest way to manage and use ADF Library JAR components is by using JDeveloper's Resource Palette. With the Resource Palette, developers who want to consume reusable components can easily find and discover available components and add them to their projects. The Resource Palette provides search and browse functions across different data management systems to locate the component. It provides multiple connections to access different sources. It has a structure tree view for displaying different connections and the ADF Library JAR component types. [Figure 33-1](#) shows the Resource Palette window with three file system connections, RCconnect, rcconnect2, and StoreFront. In this example, StoreFront contains the ADF Library component, `adflibStorFrontService.jar`.

The Resource Palette tree structure displays each JAR as subcategories. Separate nodes are created for each type of reusable component. For example, application modules are under the Data Controls node, and task flows are under the ADF Task Flows node.

The tree structure for the ADF Library JAR lists any connection information under a Library Connections node and lists all the producing project's extension libraries under the Library Dependencies node.

**Figure 33–1 Resource Palette Showing ADF Library Structure**

### 33.1.3 Extension Libraries

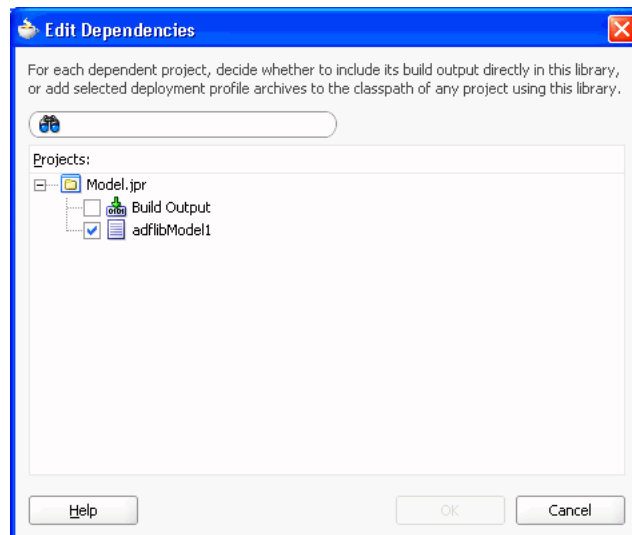

An ADF project usually includes a list of extension libraries that it needs to run. These libraries are loaded in the class path of the project. You can view a project's dependent libraries by selecting the **Libraries and Classpath** node of the Project Properties dialog. Some of the libraries that may appear are JSP Runtime, ADF Page Flow Runtime, Connection Manager, and Oracle JDBC.

When a project is packaged into an ADF Library JAR, its extension libraries are packaged with it. And when an ADF Library JAR is being consumed by another project, JDeveloper automatically resolves any extension library conflicts between them. During the consuming process, JDeveloper checks to see whether the consuming project already has the extension libraries of the ADF Library JAR in its class path and loads only those libraries that it does not have. For example, if JSP Runtime already exists in the consuming project, it will not be loaded again if the ADF Library JAR also includes it. The consuming project's extension libraries will be a union of its own libraries and the libraries in the ADF Library JAR.

If the project you want to package into an ADF Library has a dependent project, you can include the dependent project's extension libraries directly in the JAR or, if the dependent project has a deployment profile, you can add the dependent project's JAR to the ADF Library. For more information about setting up the deployment process, see [Section 33.2.1, "How to Package a Component into an ADF Library JAR."](#)

For example, project `View` is being packaged into ADF Library `adflibView1.jar`. It has a dependency on the `Model` project. For project `View`, the `Model` project is a dependent project with the deployment profile option (`adflibmodel1`) selected, as shown in [Figure 33–2](#).

**Figure 33–2 Edit Dependencies Dialog with Deployment Profile Option**

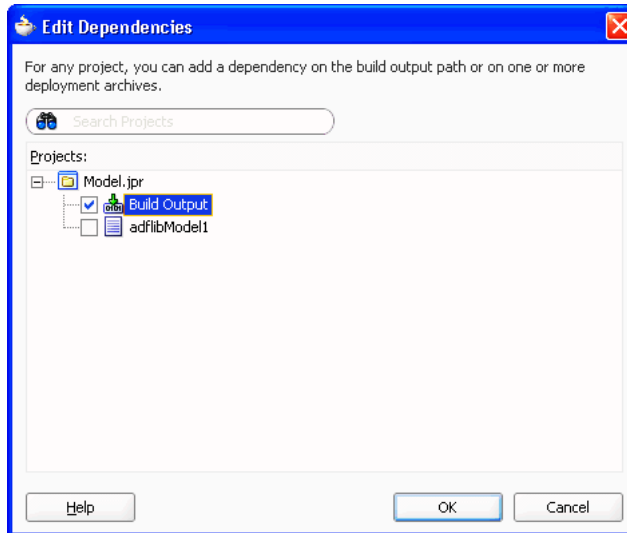

When the deployment profile is selected, the dependent project's JAR file will be added to the ADF Library JAR. As a result, the extension libraries of the dependent project will also be made available to any consuming project. In [Figure 33–3](#), the ADF Library being packaged, `adflibView1.jar`, includes the dependent `adflibModel1.jar` as listed under the Library Dependencies node.

**Figure 33–3 Resource Palette Showing `adflibView1.jar` and `adflibModel1.jar` Extension Libraries**

Alternately, you can include the dependent project's artifacts and extension libraries directly into the ADF Library JAR.

For example, project `View` can also be packaged into ADF Library `adflibView2.jar`. It also has a dependency on the `Model` project. But in this second deployment profile, the `Model` project is a dependent project with the **Build Output** option selected (as opposed to the deployment profile (`adflibModel1`) being selected), as shown in [Figure 33-4](#).

**Figure 33-4** *Edit Dependencies Dialog Used to Built `adflibview2.jar`*

When **Build Output** is selected, the dependent project's classes and extension libraries will be added directly to the ADF Library JAR. [Figure 33-5](#) shows the ADF Library `adflibView2.jar`, which includes artifacts of the `Model` project and its extension libraries. Note that the extension libraries under the `adflibView2.jar` Library Dependencies node are the same as the combined extension libraries under the `adflibView1.jar` and `adflibModel.jar` shown in [Figure 33-3](#).

**Figure 33-5** *Resource Palette Showing `adflibView2.jar` Extension Libraries*

How you decide to package the dependent project depends on how you intend the ADF Library to be used. Including the dependent project as a JAR may be advantageous when the dependent project is itself a reusable component, or when it is a dependent project for several projects that will be packaged into an ADF Library JAR. In the example, the dependent project `Model` may be a dependent project for several view projects. On the other hand, packaging the dependent project as **Build Output** is straightforward and eliminates the need for multiple JARs.

---

---

**Note:** If you are creating an ADF Library JAR that is included in a JDeveloper extension library, you should include the additional manifest `JDevLibrary: extension_library_name` entry in the JAR. When you use **Add to Project** from the Resource Palette to add a ADF Library JAR that has a `JDevLibrary` manifest entry, the JDeveloper extension library containing this JAR will be added instead of the ADF Library JAR itself.

---

---

## 33.2 Packaging a Reusable ADF Component into an ADF Library

Once you have decided that a certain component or components can be reused, create an application and a project to develop that component. Follow the guidelines in [Section 33.1.1, "Creating Reusable Components"](#) to name your application, project, package, and other objects and files. A project corresponds to one ADF Library JAR. If you create multiple projects and want to reuse components from each of the projects, you may need to create an ADF Library JAR for each project. In other situations, you may be able to involve multiple components under one project to create a single ADF Library JAR. For example, you may be able to create application modules, business components (entity object, view objects, associations), task flows, and page templates all under one project and create one ADF Library JAR.

Creating an ADF Library JAR involves compiling the project and validating the components, creating a resource service file, control files, an `adfLibREADME.txt`, and adding the relevant project files into a JAR. For more information about the ADF Library JAR, see [Section 33.2.2, "What Happens When You Package a Project to an ADF Library JAR."](#)

If you are packaging a component that itself uses another ADF Library component, the final consuming project must have both ADF Library JARs added to the project. For example, say you created a reusable task flow that contains tables dropped from a data control in another ADF Library JAR. When you add the task flow from an ADF Library JAR into a consuming project, that project will also require the data control ADF Library JAR.

If you are packaging a component that has dependent JARs, such as third-party JARs, you have two options:

- If the consuming environment has control over the placement of JARs, you can place the ADF Library JAR and its dependent JARs in a JDeveloper Extension Library. The advantage of using a JDeveloper Extension Library is that it does not clutter the consuming project with specific references to the dependent JARs.
- If using JDeveloper Extension Library is not possible, you can place the dependent JARs in the same location as the ADF Library JAR and include a manifest classpath entry for each dependent JAR.

### 33.2.1 How to Package a Component into an ADF Library JAR

To package up a reusable component, you first create a deployment profile that specifies the archive type, the name of the JAR file, and the directory path where the JAR will be created. Then you deploy the project using the deployment profile.

#### Before you begin:

You should already created a project and determine whether it has dependent projects and JAR that need to be packaged.

#### To package and deploy a project into the ADF Library JAR:

1. In the Application Navigator, double-click the project that contains the component you want to make reusable.
2. In the Project Properties dialog's left pane, select **Deployment** and then click **New**.
3. In the Create Deployment Profile dialog, select **ADF Library JAR file** for archive type, enter a name for the deployment profile, and click **OK**.

**Figure 33–6 Create Deployment Profile Dialog**

4. In the Project Properties dialog, select the deployment profile and click **Edit**.
5. In the Edit ADF Library JAR Deployment Profile Properties dialog, select the **Library Dependencies** node, as shown in [Figure 33–7](#).

**Figure 33–7 ADF Library JAR Deployment Profile Properties Dialog**

The Library Dependencies pane shows a list of dependent projects for the project being packaged. You can add the dependent project's build output directly into the packaging project's library, or you can add selected deployment profile archives to the class path.

- a. To add dependent projects, click the **Edit** icon to bring up the Edit Dependencies dialog, as shown in [Figure 33–8](#).

If you select **Build Output**, the dependent project's extension libraries will be added directly to the ADF Library JAR. If you select deployment profile, the dependent project's JAR file (which includes its own extension libraries) will be added to the ADF Library JAR. For more information about library dependencies, see [Section 33.1.3, "Extension Libraries."](#)

In this example, the `OrderBookingService` project can be set as a dependency only as **Build Output**. However, the `StoreFrontUI` project can be set as a dependency either as **Build Output**, or as a deployment profile (`FOD_webapp`).

**Figure 33–8 ADF Library Deployment Edit Dependencies Dialog**

- b. For each dependent project, select the **Build Output** node for the project or select the dependent profile and click **OK**.
6. In the Edit ADF Library JAR Deployment Profile Properties dialog, select the **Connections** node, as shown in [Figure 33–9](#).

You can select:

- **Connection Details (excluding secure content):** If the project has a connection, select this checkbox if you want to add any available connection details in addition to the connection name. For more information, see [Section 33.1.1.6, "Including Connections Within Reusable Components."](#)
- **Connection Name Only:** Select this checkbox if you want to add the connection name without any connection details such as security.

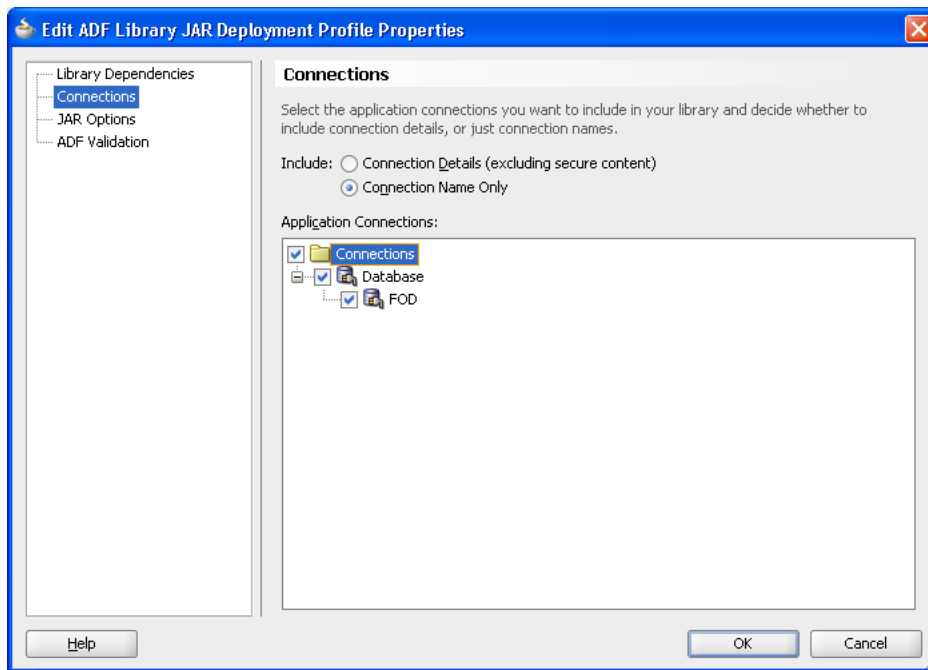

---

**Note:** The connection options available depends on the JDeveloper role. **Connection Details (excluding secure content)** and **Connection Name Only** are the selections available for the Default Role. If your JDeveloper is set to a different role, you may have different options and defaults.

---

In the Applications Connections tree structure, select the checkbox for the level of connection you want to include.

**Figure 33–9** Connections Page of the Edit ADF Library JAR Deployment Profile Properties Dialog

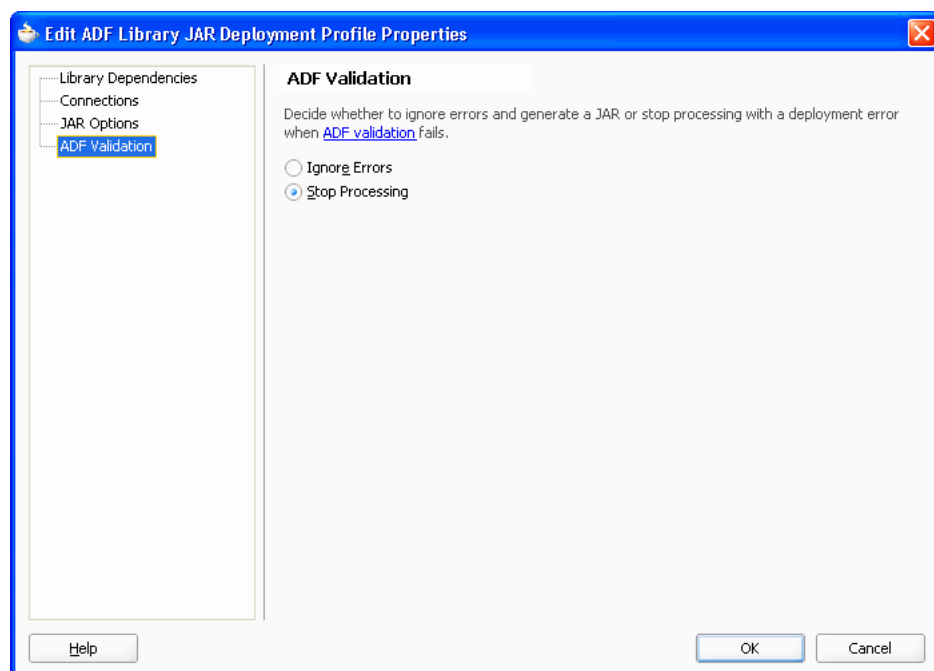

7. In the Edit ADF Library JAR Deployment Profile Properties dialog **JAR Options** node, as shown in [Figure 33–10](#), verify the default directory path or enter a new path to store your ADF Library JAR file.

If the ADF Library JAR is to be included in a JDeveloper extension library, create a text file with a `JDevLibrary: extension_library_name` entry and place the file in the project root directory. Click **Add** to locate and merge that file into the `Manifest.mf` file.

When you create your manifest text file, make sure the `JDevLibrary` entry starts in column 1 with a space after the colon, and that there is a blank line at the end of the file.

**Figure 33–10 ADF Library JAR Deployment Profile Properties Dialog JAR Option**

8. In the Edit ADF Library JAR Deployment Profile Properties dialog **ADF Validation** node, select:
  - **Ignore Errors**: Select this option to create the JAR file even when validation fails. This is the default option.
  - **Stop Processing**: Select this option to stop processing when validation fails.

**Figure 33–11 ADF Library JAR Deployment Profile Properties Dialog ADF Validation**

9. Click **OK** to finish setting up the deployment profile.

10. In the Application Navigator, right-click the project and choose **Deploy > deployment**, where *deployment* is the name of the deployment profile.
11. In the Deploy dialog Deployment Action page, click **Next** and then click **Finish**.  
JDeveloper will create the ADF Library JAR in the directory specified in Step 7. You can check that directory to see whether the JAR was created.

### 33.2.2 What Happens When You Package a Project to an ADF Library JAR

When you deploy the library JAR, JDeveloper packages up all the necessary artifacts, adds the appropriate control files, generates the JAR file, and places it in the directory specified in the deployment profile. During deployment, you will see compilation messages in the Log window.

When you deploy a project into an ADF Library JAR, JDeveloper performs the following actions:

- Package the HTML root directory artifacts into the JAR. When the JAR is added to the consuming project, JDeveloper will make the reusable component's `public_html` resources available by adding it to the class path.
- Add the `adf.xml` file to the JAR. If there are multiple `META-INF/adf.xml` files in the workspace, only the `adf.xml` in the project being deployed is added. JDeveloper modifies this file to include relevant content from any dependent project's `adf.xml` file.
- Add a service resources file, `oracle.adf.common.services.ResourceService.sva`, into the `META-INF` directory of the JAR. The addition of this file differentiates an ADF Library JAR file from standard JAR files. This file defines the service strategies of the JAR and allows the Resource Palette to properly discover and display the contents of the JAR.
- Add a `Manifest.mf` file to the JAR. The `Manifest.mf` file is used to specify dependencies between JAR files, and whether to copy and include the contents of a JAR file or to reference it. JDeveloper will create a default manifest file. For example:  

```
Manifest-Version: 1.0
```
- Adds a `jar-connections.xml` file to the JAR for components that require a connection and that use the connections architecture. Note that in the consuming application, connection information in configuration files that are defined in the class path and accessible at runtime may be merged together. If the same connection is named multiple times in the class path, the connection in the main application will be given priority.

Different types of reusable components have different artifact files and different entries in the service resource file.

#### 33.2.2.1 Application Modules

For application modules, JDeveloper adds three control files to the JAR: `oracle.adf.common.services.ResourceService.sva`, `Manifest.mf`, and `adf.xml`. The service resource file for an application module includes entries for the business components associated with the application module, as well as an entry for the application module data control.

The `jar-connections.xml` file may appear for components that use the connection architecture and that contain connection information regarding the data source.

### 33.2.2.2 Data Controls

For data controls such as placeholder data controls, JDeveloper includes three control files in the JAR: `oracle.adf.common.services.ResourceService.sva`, `Manifest.mf`, and `DataControl.dcx` file. Data controls are used when the data source is not based on ADF Business Components, and so business components are not included in the JAR file, as is the case in an application module JAR file. The service resource file for a standard data control has an entry for the data control.

The JAR also includes the `Datacontrol.dcx` file from the project to describe the data control type.

### 33.2.2.3 Task Flows

For task flows, JDeveloper includes three control files in the JAR: `oracle.adf.common.services.ResourceService.sva`, `Manifest.mf`, and `task-flow-registry.xml`. The service resource file for a task flow includes an entry that indicates that one or more task flows are in the JAR.

### 33.2.2.4 Page Templates

For page templates, JDeveloper includes two control files in the JAR: `oracle.adf.common.services.ResourceService.sva` and `Manifest.mf`.

### 33.2.2.5 Declarative Components

For declarative components, JDeveloper includes two control files in the JAR: `oracle.adf.common.services.ResourceService.sva` and `Manifest.mf`.

## 33.2.3 How to Place and Access JDeveloper JAR Files

If you have JAR files that can be reused by other projects, such as third-part JAR files, you can use JDeveloper to place them in an accessible location and create a library file (`.library`) to designate them. The consumer can use JDeveloper to navigate to this location and add the JAR to the project.

An ADF Library JAR contains ADF components and does not and cannot contain other JARs.

#### Before you begin:

Place the JAR files in a accessible location for both the producer and the consumer of these JAR files. For example, the directory may be on a network drive where other shared files are located.

#### To place and access a JDeveloper Library JAR:

1. From the main menu, choose **Tools > Manage Libraries**.
2. In the Manage Libraries dialog, click **Load Dir**.
3. In the Load Directory dialog, select the directory where the secondary JAR files are located.
4. In the Manage Libraries dialog, click **New**.
5. In the Create Library dialog, enter a library name and click **Add Entry**.

You have created a library file (with a `.library` extension). You should place library files in source control systems.

6. In the Select Path Entry dialog, select the JARs you want to add and click **Select**.

7. In the Create Library dialog, be sure that the **Deployed by Default** option is set correctly for your JAR, click **OK** and click **OK** again.
8. In the JDeveloper of the consuming project.
  - a. From the main menu, choose **Tools > Manage Libraries**.
  - b. In the Manage Libraries dialog, click **Load Dir**.
  - c. In the Load Directory dialog, select the directory where the secondary JAR files are located and click **OK**. This should be the same location specified by the producer in step 3.
  - d. In the Application Navigator, right-click the project and select **Project Properties**.
  - e. In the Project Properties dialog, select **Libraries and Classpath** and click **Add Library**.
  - f. In the Add Library dialog, select the library, click **OK** and click **OK** again.

### 33.3 Adding ADF Library Components into Projects

After ADF Library JARs are created, they must be distributed to the developers who will use these JARs. Distributing the ADF Library JARs may include putting the JARs into network file system to be searched, browsed, and discovered. It may include using other forms of data store or services to access and retrieve these JARs. Since ADF Library JARs are simply binary files, they can distributed like any other file such as ftp and email.

Once you have access to the ADF Library JARs, you can use JDeveloper to access them and add them to your consuming projects. Using the JDeveloper Resource Palette is the easiest and most efficient way. You can also use JDeveloper to manually add the JARs into the project by entering them into the class path.

When a project is packaged into an ADF Library JAR, it captures the list of dependent JARs the project needs for deployment and run time. This list is based on the project's dependent profiles and the information in the project's Libraries and Classpath with **Deployed By Default** selected. When the ADF Library JAR is added to the consuming project, this list of dependent JARs is placed in a library called *ADF Library Dependencies*. This is a locked library in the consuming project and its content will not be shown in the Data Control panel, Component Palette, or other places in JDeveloper. The library is maintained and updated as different ADF Library JARs are added and deleted from the project. If the dependencies changed, (for example, the producer project was rebuilt), then you can refresh the dependencies in the consuming project using a JDeveloper menu command.

Once reusable components have been added, how they are used depends on the type of component.

#### 33.3.1 How to Add an ADF Library JAR into a Project using the Resource Palette

You can use the Resource Palette to search, discover, and add the ADF Library JAR to your project.

##### **Before you begin:**

You should already have an ADF Library JAR in a repository folder. If you do not already have a Resource Palette connection to this repository, you must know the location of this folder.

**To add a component to the project using the Resource Palette:**

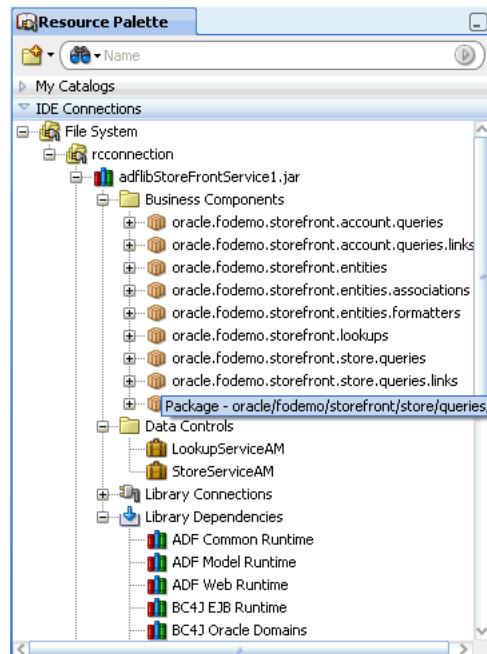

1. From the **View** menu, choose **Resource Palette**.
2. In the Resource Palette, click the **New** icon, and then choose **New Connection > File System**.
3. In the Create File System Connection dialog, enter a name and the path of the folder that contains the JAR. For file path guidelines, see [Section 33.1.1.5, "Selecting Paths and Folders."](#)
4. Click **OK**.

The new ADF Library JAR appears under the connection name in the Resource Palette.

5. To examine each item in the JAR structure tree, use tooltips. The tooltip shows pertinent information such as the source of the selected item.

[Figure 33–12](#) shows a Resource Palette with a tooltip message that shows package information for a business component.

**Figure 33–12** *Tooltip Message for a Connection in the Resource Palette*

6. To add the ADF Library JAR or one of its items to the project, right-click the item and choose **Add to Project**. In the confirmation dialog that appears, click **Add Library**, as shown in [Figure 33–13](#).

**Figure 33–13** *Confirm Add ADF Library Dialog*

If you had previously added that library JAR, you will get a Confirm Refresh ADF Library dialog asking you whether you want to refresh the library.

7. If the ADF Library JAR has changes to its dependencies, you can refresh the project with the new changes. From the Application Navigator, right-click the project and select **Refresh ADF Library Dependencies in *project.jpr***.

For application modules and data controls, you have the option to drag and drop the application module or data control from the Resource Palette into the Data Controls panel.

---

---

**Note:** JDeveloper will load whichever ADF Library JAR extension libraries are not already in the consuming project. Extension libraries from the ADF Library's dependent JARs will also be checked and loaded if not already part of the consuming project. For more information, see [Section 33.1.3, "Extension Libraries"](#)

---

---

### 33.3.2 How to Add an ADF Library JAR into a Project Manually

You can add an ADF Library JAR in the same way as you would other library JARs.

**Before you begin:**

You should already have an ADF Library JAR.

**To add a component to a project manually:**

1. In the Application Navigator, double-click the project to which the component is to be added.
2. In the Project Properties dialog, select the **Libraries and Classpath** node and then click **Add Library**.
3. In the Add Library dialog, click **New**.
4. In the Create Library dialog, select **Project** in the **Location** dropdown list and enter a name for the ADF Library. The preferable name is "ADF Library". Select **Deploy by Default**, and click **Add Entry**.
5. In the Select Path Entry dialog, enter or browse to the ADF Library JAR file and click **Select**.
6. The Create Library dialog reappears with the path of the JAR file filled in under the **Class Path** node. Click **OK**.
7. The Add Library dialog reappears with the ADF Library entry filled in under the **Project** node. Click **OK**.

**Figure 33–14 Add Library Dialog**

8. The Project Properties dialog reappears with the JAR file added to the list of libraries. Click **OK**.

### 33.3.3 What Happens When You Add an ADF Library JAR to a Project

When you add an ADF Library JAR to a project, either by using the Resource Palette or by manually adding the JAR, an ADF Library definition is created in the project. The ADF Library JAR file will be added to the class path of the project. The project will access and consume the components in the JAR by reference.

By default, the **ADF Library Deployed by Default** option in the Create Library dialog is set to true. If this option is set, when the application or module is further archived or built into a WAR file, the contents of the ADF Library JAR will be copied to that archive or WAR file. If the Deploy by Default option is not set, then the JARs in the ADF Library must be loaded in some other way, such as by deploying them in a shared library.

Figure 33–15 shows the empty Data Controls panel for a consuming project before the ADF Library was added.

**Figure 33–15** *Data Controls Panel of the Consuming Project*

Figure 33–16 shows the `adflibStoreFrontService` ADF Library being added to the consuming project.

**Figure 33–16** *Adding the ADF Library JAR to the Project*

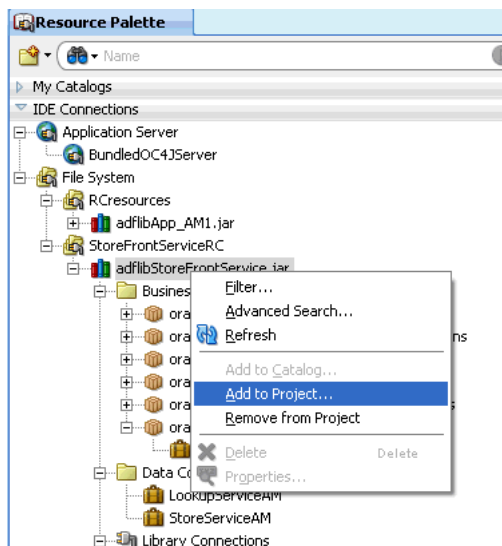

Figure 33–17 shows several data controls from the ADF Library added to the Data Controls panel in the consuming project.

**Figure 33–17 Consuming Project Data Controls Panel with Added Application Modules**

After adding the ADF Library JAR, you may notice some changes to some of the JDeveloper windows. These changes are different depending on the type of components being added. [Table 33–3](#) lists the effects on several JDeveloper windows.

**Table 33–3 JDeveloper Window After Adding an ADF Library**

Added Component	Data Controls Panel	Creation Wizards	Component Palette
Data controls	Data control appears.		
Application module	Application module appears.		
Business components		Entity objects available in view object creation wizard. View objects in JAR also available for use.	
Task flows			Task flows appear in Component Palette.
Page template		Page template available during JSF creation wizard.	
Declarative components			Tag library appears in Component Palette. Declarative component appears in the list.

### 33.3.4 What You May Need to Know About Using ADF Library Components

Although the procedure to add an ADF Library JAR to a project is standardized, the component type determines where it appears in JDeveloper and how it can be reused.

### 33.3.4.1 Using Data Controls

When you add a data control to a project, the data control appears in the Data Controls panel. If you are using the Resource Palette, you have the option of dragging and dropping the data control from the Resource Palette onto the Data Controls panel, and then dragging and dropping from the Data Controls panel onto the page.

### 33.3.4.2 Using Application Modules

When you add an application module to a project, the application module appears in the Data Controls panel. If you are using the Resource Palette, you have the option of dragging and dropping the application module item from the Resource Palette onto the Data Controls panel, and then dragging and dropping from the Data Controls panel onto the page.

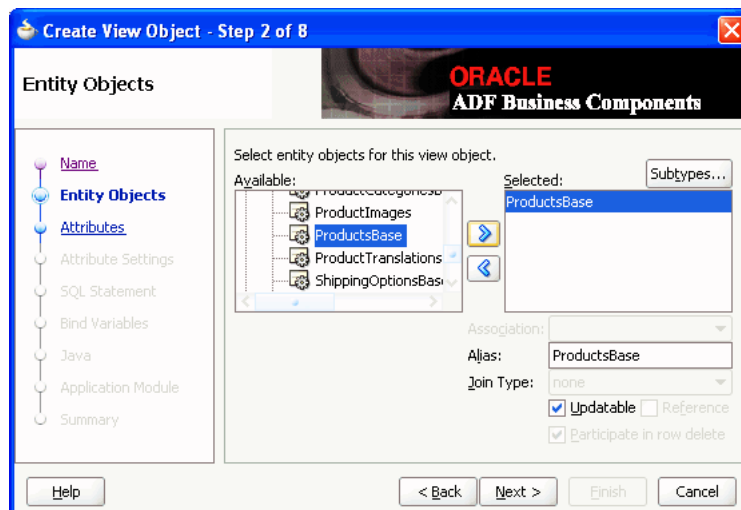

Application modules are associated with business components. When the reusable application module was packaged, the JAR includes the business components used to create the application module. These components will be available for reuse.

### 33.3.4.3 Using Business Components

Business components can also be packaged and reused. The entity objects, view objects, and associations can be packaged together and added to a consuming project. By default, packaged application modules will include the business components in the JAR, but business components can be reused by themselves without the accompanying application module.

One way to reuse business components is to create new view objects using the entity objects from an ADF Library JAR. When you add view objects using the wizard, the entity objects will become available within the wizard to support view object generation. For instructions on creating view objects, see [Section 5.2.1, "How to Create an Entity-Based View Object."](#) When the wizard presents a screen for entity objects used to create view objects, the entity objects from the ADF Library will be available in the shuttle window, as shown in [Figure 33–18](#).

**Figure 33–18** *Creating View Object Using Entity Objects from ADF Library*

If the consuming project has the **Initialize Project for Business Component** option selected (in the Project Properties dialog Business Components page) before the ADF Library JAR is added, the business components within the JAR will automatically be made available to the project.

If you add the ADF Library JAR first, and then select **Initialize Project for Business Component**, JDeveloper will automatically load the business components.

#### 33.3.4.4 Using Task Flows

Task flows added to a project will appear in the Component Palette when you are adding components to a JSF page. If you are using the Resource Palette, you can also drag and drop the task flow directly from the Resource Palette onto another task flow or page, as shown in [Figure 33–19](#).

**Figure 33–19 Using the Resource Palette to Drag and Drop Task Flows**

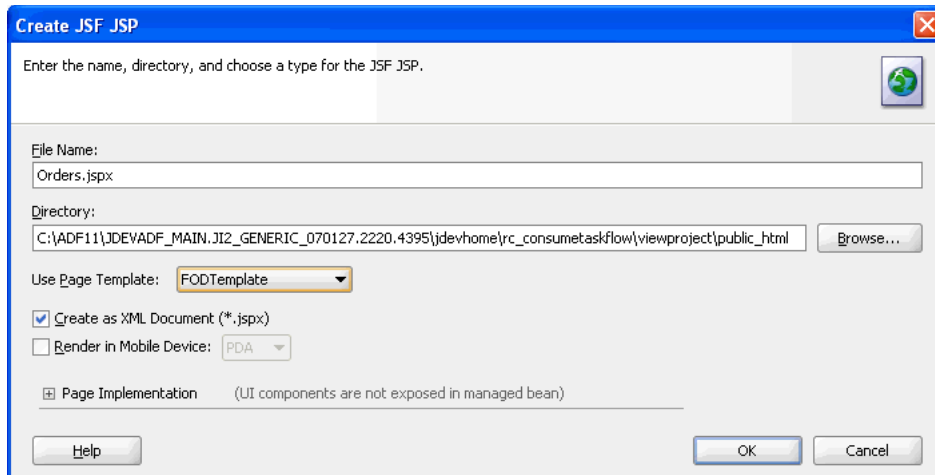

For more information about creating task flows, see [Chapter 14, "Getting Started with ADF Task Flows."](#)

#### 33.3.4.5 Using Page Templates

When you add a page template to a project, the template will not be exposed in the Application Navigator. You will not have direct access to individual supporting files, such as image files. However, the template retains its access to its supporting files inside the JAR and is fully reusable within the project. When you apply the template, it will retain all the images that were loaded with the template.

The page template is exposed and accessible when you create a new JSF JSP page using the wizard. When the wizard presents you with the option to use a page template, the ADF Library template will appear in the dropdown list. For example, if you loaded a page template called `FODTemplate` from an ADF Library, when you use the wizard to create a JSF JSP page, `FODTemplate` will appear in the wizard, as shown in [Figure 33–20](#). For information on how to use page templates and create a JSF JSP page, see [Section 20.2, "Using Page Templates"](#) and the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

**Figure 33–20 Using a Page Template from ADF Library**

### 33.3.4.6 Using Declarative Components

When you add a declarative component to a project, the JSP tag libraries that contain the component will be added to the project. The tag libraries will appear in the Component Palette, and the declarative components will be available for selection. For information about creating and using declarative components, see the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

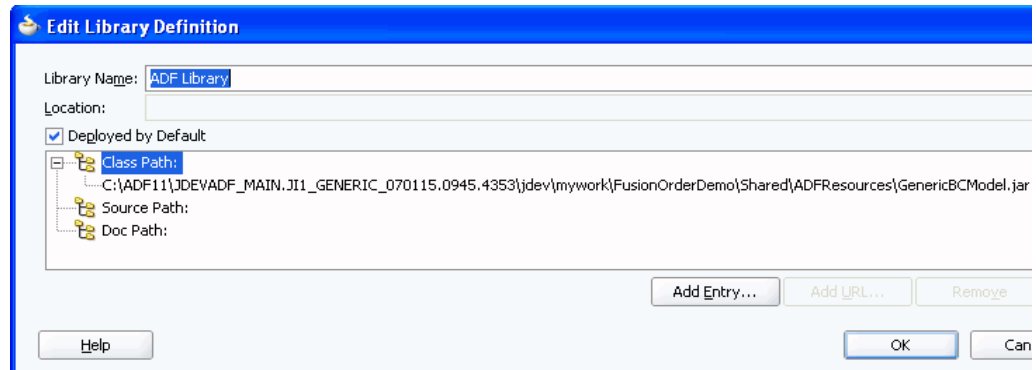

## 33.3.5 What You May Need to Know About Differentiating ADF Library Components

If you mix components created during application development with components imported from the ADF Library, you may be able to differentiate between them by using the tooltips feature of JDeveloper.

Move the cursor over an application module or data control and you will see the full path of the source. If you see the ADF Library JAR file in the path, that means the component source is the ADF Library.

## 33.3.6 What Happens at Runtime: Adding ADF Libraries

After an ADF Library JAR has been added to a project and to the class path, it behaves like any other library file. During runtime, any component that uses the component in the ADF Library JAR will reference that object. The process is transparent and there is no need to distinguish between components that were developed for the project and those that are in ADF Library JARs. [Figure 33–21](#) shows the ADF Library and the path to the JAR as defined for a project.

**Figure 33–21** Edit Library Definition dialog showing the ADF Library in the Class Path

## 33.4 Removing an ADF Library JAR from a Project

You can use the Resource Palette to remove an ADF Library JAR from a project, or you can manually remove the JAR using the Project Properties dialog. You can remove an ADF Library JAR only if the components in the project do not have any dependencies on the components in the ADF Library JAR.

When you remove a JAR, it will no longer be in the project class path and its components will no longer be available for use.

### 33.4.1 How to Remove an ADF Library JAR from a Project Using the Resource Palette

The Resource Palette allows you to remove previously added ADF Library JARs from a project using a simple command.

#### To remove an ADF Library JAR from the project using the Resource Palette:

1. From the **View** menu, choose **Resource Palette**.
2. In the Application Navigator, select the project that has the ADF Library JAR you want to remove.
3. In the Resource Palette, locate the ADF Library JAR you want to remove from the current project.
4. Right-click the JAR and choose **Remove from Project**.

### 33.4.2 How to Remove an ADF Library JAR from a Project Manually

When you remove an ADF Library JAR manually, be sure to remove the correct library. Be aware of other libraries that are critical to the operation of the project.

#### To remove an ADF Library JAR from the project manually:

1. In the Application Navigator, double-click the project.
2. In the Project Properties dialog, select the **Libraries and Classpath** node.
3. In the **Classpath Entries** list, select **ADF Library** and click **Edit**.
4. In the Edit Library Definition dialog, select the ADF Library JAR you want to remove under the **Class Path** node, and click **Remove**.
5. Click **OK** to accept the deletion, and click **OK** again to exit the dialog.

---

## Customizing Applications with MDS

This chapter describes how to develop ADF applications that can be customized and subsequently deployed by a customer based on the Oracle Metadata Services (MDS) framework. It also covers how to implement customizations on such applications.

This chapter includes the following sections:

- [Section 34.1, "Introduction to Customization and MDS"](#)
- [Section 34.2, "Developing a Customizable Application"](#)
- [Section 34.3, "Customizing an Application"](#)
- [Section 34.4, "Extended Metadata Properties"](#)
- [Section 34.5, "Enabling Runtime Modification of Customization Configuration"](#)

For information on how to deploy customized applications, see [Section 36.4, "Deploying the Application."](#)

### 34.1 Introduction to Customization and MDS

Using the customization features provided by MDS, you can create applications that fall into the following customization patterns:

- Seeded customization

Seeded customization of an application is the process of taking a generalized application and making modifications to suit the needs of a particular group, such as a specific industry or site. Seeded customizations exist as part of the deployed application, and endure for the life of a given deployment. This chapter describes how to create a customizable application, and then customize the application using JDeveloper.

- User customization (change persistence)

User customization allows an end user to change the content of the application at runtime to suit individual preferences (for example, which columns are visible in a table), and have those changes "remembered" the next time the user opens the application. For information about user customization, see [Chapter 35, "Allowing User Customizations at Runtime."](#)

- Design time at runtime

Using the features of Oracle WebCenter Portal, you can create applications that are customizable at runtime. This allows business analysts or administrators, using a Web browser interface, to customize the application for their end users. For information about runtime customization, refer to the *Oracle Fusion Middleware Developer's Guide for Oracle WebCenter Portal*.

For more information about the MDS architecture and metadata repositories (database and file-based) and archives (EAR, MAR), refer to the section about managing the MDS repository in the *Oracle Fusion Middleware Administrator's Guide*.

### 34.1.1 Customizations and Layers

A customized application contains a base application and one or more layers containing customizations. MDS stores the customizations in a metadata repository and retrieves them at runtime to merge the customizations with the base metadata to reveal the customized application. Since the customizations are saved separately from the base, the customizations are upgrade safe; a new patch to base can be applied without breaking customizations. When a customized application is launched, the customization content is applied over the base application.

For example, say you have a generalized payroll application with a validation rule that limits the salary field to 4000. Then you create a customization of that validation rule that limits the salary field to 3300. At runtime, the customization is applied to the base application and the validation rule for the salary field limits it to 3300.

A customizable application can have multiple *customization layers*. Examples of customization layers are `industry` and `site`. Each layer can have multiple *customization layer values*, but typically only one such layer value from each layer is applied at runtime. For example, the `industry` layer for a customizable application can contain values for `healthcare` and `financial` industries; but in the deployed customized application, only one of the values from this layer is used at a time.

Layer values from multiple customization layers can be applied, in a specified order of precedence, on top of the base metadata. For example, a customized application can contain customizations in the `financial` layer value of the `industry` layer and the `Financial Company #1` layer value of the `site` layer. Each customization layer corresponds to a customization document that contains a set of instructions that change the underlying metadata.

The *customization context* of a customized application is defined by the set of customization layer values applied to it.

[Figure 34–1](#) illustrates how layers are applied in a customized application.

**Figure 34–1 Example of Layered Customization**

To support this, you use JDeveloper to create customization classes, define layers and values, and specify the order of precedence. These processes are described in [Section 34.2, "Developing a Customizable Application."](#)

### 34.1.2 Static and Dynamic Customization Content

Customizations can be categorized as either static or dynamic. Static customizations have only one layer value in effect for all executions of the application, while dynamic customizations can have values that vary based on the execution context of the application. If a customization can vary for different users executing the application, then it is dynamic. If a customization has the same value for all users executing the application then it is static.

When you implement customizations in ADF Business Components objects, the customizations remain the same for entire runtime of the application. This is because these objects are loaded only once for an application and reused for the duration of the application. For example, you can have a customized validation rule in the Healthcare Company #1 value of the site layer that limits salaries for that site to 3300. This is static customization content.

However, you can also implement customizations at the controller or view level that allow the layer value to be determined at runtime, based on user roles (responsibilities) or other application-specific criteria. For example, you can design an application so that users from different organizations see different sets of fields on a given screen. This is dynamic customization content.

The determination of whether a customization is static or dynamic is made in the customization class. In the customization class, if the `getCacheHint()` method returns `ALL_USERS`, then the customization layer is static. For more information about `CacheHint` values, see [Section 34.2.2, "What You May Need to Know About Customization Classes."](#)

All objects could have a static customization layer, depending on how the customization classes are implemented. But for ADF Business Components objects, customizations can only be static.

## 34.2 Developing a Customizable Application

To create a customizable application, create the base application and perform the following procedures:

### To prepare an application for customization:

1. Create the customization classes that will be used, as described in [Section 34.2.1, "How to Create Customization Classes."](#)
2. Enable seeded customization in the application, as described in [Section 34.2.4, "How to Enable Seeded Customizations for View Projects."](#)
3. Specify the customization classes in the `adf-config.xml` file, as described in [Section 34.2.7, "How to Configure the adf-config.xml file."](#)
4. You can optionally restrict runtime customizations on the application, as described in [Section 34.4.1, "How to Edit Extended Metadata Properties."](#)
5. After you have prepared the application for customization, you must prepare JDeveloper so you can use it to implement the customizations, as described in [Section 34.3.4, "How to Configure Customization Layers."](#)

### 34.2.1 How to Create Customization Classes

A customization class is the interface that MDS uses to define which customization applies to the base definition metadata. Each customization class defines a customization layer (for example, `industry` or `site`) and can contain multiple layer values. The customization classes that are used in the application must be available to JDeveloper when customizing the application, and included in the deployed application.

#### 34.2.1.1 Customization Classes

A customization class evaluates the current context and returns a `String` result. This `String` result is used to locate the customization layer.

The customization class provides the following information:

- A name, that represents the name of the layer.
- An array of values, that represent the customization layer values. Typically, each layer returns a single value. If multiple values are returned, the customizations available in the MDS repository for those values are applied in the order in which they appear in the array. For more information, see [Section 34.2.1.2, "Implementing the `getValue\(\)` Method in Your Customization Class."](#)
- An `IDPrefix`, for objects created in the layer. When new objects are created in a customization layer they need a unique ID. The `IDPrefix` is added to the autogenerated identifier for the object to create an ID for the newly added object. Each layer needs a unique `IDPrefix` so that objects created at different customization layers will have unique IDs.
- A cache hint, for the layer defined by the customization class. The cache hint defines whether a layer is static or dynamic. If the `getCacheHint()` method returns `ALL_USERS`, then the customization layer is static. For more information about dynamic customizations, see [Section 34.1.2, "Static and Dynamic Customization Content."](#) For more information about `CacheHint` values, see [Section 34.2.2, "What You May Need to Know About Customization Classes."](#)

Customizations can be used to tailor an application to suit a specific industry domain (verticalization). Each such domain denotes a customization layer and is depicted using a customization class.

To implement seeded customizations using your customization classes:

- The `cust-config` section (under `mds-config`) in the `adf-config.xml` must contain a reference to the customization classes (as shown in [Example 34-6](#)).

The customization configuration (`cust-config`) section provides the customization classes and their precedence for a customized application. See [Section 34.2.7, "How to Configure the adf-config.xml file."](#)

- The customization classes must be available on JDeveloper's class path to support seeded customizations.

After creating your customization classes, you can create an extension library that is included in JDeveloper's class path. (For more information, see [Section 34.2.3.1, "Making Customization Classes Available to JDeveloper."](#)) At runtime, your customization classes must be available in the EAR-level application class loader.

- The layer values must be listed in the `CustomizationLayerValues.xml` file.

This file is located in the `jdev_install\jdev` directory. The names of the layers in this file must be consistent with the customization classes. (For more information, see [Section 34.3.4, "How to Configure Customization Layers."](#)) JDeveloper uses this file to retrieve layer values at design time.

When JDeveloper is launched in the Customization Developer role, the Customization Context window displays the available customization layers and layer values. You can select the layer and value to which you want to apply customizations in the Customization Context window. For more information about working in the Customization Developer role, see [Section 34.3.1, "Introducing the Customization Developer Role."](#) The layer you choose to customize is called the *tip layer*. For more information, see [Section 34.3.3, "Introducing the Tip Layer."](#)

[Example 34-1](#) shows a sample customization class. Note that all customization classes should have a single, no-argument constructor.

**Example 34-1 Sample IndustryCC customization class in the mycompany package**

```
package mycompany;

import java.io.IOException;
import java.io.InputStream;
import java.util.Properties;
import oracle.mds.core.MetadataObject;
import oracle.mds.core.RestrictedSession;
import oracle.mds.cust.CacheHint;
import oracle.mds.cust.CustomizationClass;

public class IndustryCC extends CustomizationClass {
    private static final String DEFAULT_LAYER_NAME = "industry";
    private String mLayerName = DEFAULT_LAYER_NAME;

    public IndustryCC() {
    }
    public CacheHint getCacheHint() {
        return CacheHint.ALL_USERS;
    }
    public String getName() {
        return mLayerName;
    }
}
```

```
    }

    public String generateIDPrefix(RestrictedSession sess, MetadataObject mo) {
        return new String ("I");
    }

    public String[] getValue(RestrictedSession sess, MetadataObject mo) {
        // This needs to return the appropriate value at runtime.
        return new String[] {"financial"};
    }
}
```

This example shows the four methods that define how the customization class will work: `getCacheHint()`, `getName()`, `generateIDPrefix()`, and `getValue()`.

The return value for `getCacheHint()` indicates to MDS how widely visible a metadata object with this customization is, and therefore its likely duration in memory. It also defines whether or not a layer is static or dynamic. In this example, the `getCacheHint()` method returns `ALL_USERS`, which means the customization layer is static. For more information about `CacheHint` values, see [Section 34.2.2, "What You May Need to Know About Customization Classes."](#)

The `getName()` method returns the name of the customization layer. A `SiteCC` customization class, for example, might return "site." In this example, the `getName()` method returns "industry."

The `generateIDPrefix()` method creates an `IDPrefix`. The `IDPrefix` is a unique, abbreviated string that identifies the name and value of the layer. It is used as the prefix of the ID for objects created in the customization layer. The default implementation (if no `IDPrefix` is specified) returns name of the layer concatenated with customization value. For performance reasons, the `IDPrefix` should be kept short (4 characters or less). Therefore, the default implementation should be overridden. The related `getIDPrefix()` method returns the `IDPrefix` of the customization layer. In this example, the `getIDPrefix()` method would return "I" (for "industry").

The `getValue()` method returns the customization value (or values) for the customization class. In this example, the `getValue()` method returns a single value, "financial," that defines the customization context when combined with the layer name. There are additional techniques for using the `getValue()` method described in [Section 34.2.1.2, "Implementing the getValue\(\) Method in Your Customization Class."](#)

---

---

**Note:** The possible layer values corresponding to a layer name are retrieved by `JDeveloper` in the `Customization Developer` role from the `CustomizationLayerValues.xml` file. The precedence of layers is defined by the order of the customization classes specified in the `adf-config.xml` file. The names of the layers must be consistent in these files and in the customization classes.

---

---

### 34.2.1.2 Implementing the `getValue()` Method in Your Customization Class

The `getValue()` method is used to retrieve the layer value(s) of the customization class based on the application context and the metadata. For example, calling `getValue()` on a `SiteCC` customization class might return an array with single entry "headquarters." Typically, the `getValue()` method returns an array with a single value, as shown in [Example 34-1](#).

You can also return multiple values from the `getValue()` method, as shown in [Example 34-2](#).

**Example 34–2 The `getValue()` Method Returning Multiple Values**

```
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
    return new String[]{"North America", "US", "CA"}
}
```

When multiple values are returned, customizations applicable to all values are applied. Customizations are applied in the order in which they appear in the array. In this example, `North America` customizations are applied over the base application, then `US` customizations are applied, and finally `CA`.

---

**Note:** Returning multiple values for a customization layer is an advanced concept that is typically unnecessary.

---

The `getValue()` method can return a layer value based on the current execution context for the current user, pulled either from static or thread local state maintained by the client, or from properties set by the client on the MDS session and based on the metadata object name. [Example 34–3](#) shows this type of implementation.

**Example 34–3 The `getValue()` Method Returning a Layer Value Based on the Current Execution Context**

```
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
    if (mo.getName().equals("/sample/abc.jspx"))
    {
        return new String[]{"Headquarters"};
    }
    else
    {
        return new String[]{"RemoteSite"};
    }
}
```

In this example, the `getValue()` method uses the `getName()` method on the metadata object to determine if the name of the metadata document is `/sample/abc.jspx`. If so, `getValue()` returns `Headquarters` to apply headquarters customizations. If not, it returns `RemoteSite` to apply customizations for remote sites.

---

**Note:** Coding the `getValue()` method to return a value based on the metadata object is an advanced concept that is typically unnecessary. Customization context for dynamic layers is typically determined through facets of the application context, such as user name or responsibility.

---

An additional technique that can be useful during the development cycle is to use an external properties file to specify layer values. [Example 34–4](#) references a properties file (`customization.properties`) that stores the layer values.

**Example 34–4 The `getValue()` Method Using a Properties File to Specify Layer Values**

```
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
    Properties properties = new Properties();
    String configuredValue = null;
    Class clazz = IndustryCC.class;
    InputStream is = clazz.getResourceAsStream("/customization.properties");
```

```

    if (is != null){
        try {
            properties.load(is);
            String propValue = properties.getProperty(mLayerName);
            if (propValue != null){
                configuredValue = propValue;
            }
        } catch (IOException e) {
            e.printStackTrace();
        }
        finally {
            try {
                is.close();
            } catch (IOException e) {
                e.printStackTrace();
            }
        }
    }
    return new String[] {configuredValue};
}

```

When an application using this technique is run in JDeveloper, you can change the layer value in the properties file and refresh the browser to see new customizations being applied. This customization class and properties file combination allows you to maintain the layer value in a separate file so you don't need to modify and recompile Java code to change it for a particular deployment. If you use a `customization.properties` file, it must be packaged with the customization classes so that they are loaded from the same class loader.

[Example 34-5](#) shows a sample `customization.properties` file. When the `IndustryCC` class is loaded with this properties file, the layer value `healthcare` is applied.

**Example 34-5 Sample Contents of a customization.properties File**

```

#Configured values for the default layer values
industry=healthcare
site=headquarters

```

### 34.2.1.3 Creating a Customization Class

When creating customization classes, put them in a separate extension project. This allows you to deploy them to a JAR and import the JAR into your lowest level project (which is typically the model project). This approach increases modularity, making it easier to include them in multiple applications across your company, and easier to patch them centrally. For more information about this approach, see [Section 34.2.3, "How to Consume Customization Classes."](#)

Alternatively, if you are creating customization classes that will be used in a single application only, you can put the customization classes in the model project.

Make sure that there is only one copy of the customization classes in the application and that they are packaged in a JAR so that they are loaded at the EAR level application class loader. By default, adding project dependencies will add the customization classes to the WAR, which will not work correctly after the application is packaged and deployed. For more information about packaging your application for deployment, see [Section 36.3.2, "How to Create Deployment Profiles."](#)

Use the following procedure to create a customization class.

**To create a customization class in an extension project:**

1. Launch JDeveloper using the Default role, and open (or create) the application that will hold the customization classes.
2. From the **File** menu, choose **New**.
3. In the New Gallery, select **Projects** and then **Extension Project**, and click **OK**.

This opens the Create Extension Project dialog. For more information about the options in this dialog, see the online help.

---

**Note:** If you don't see **Extension Project**, click the **All Technologies** tab.

---

4. Specify the appropriate settings for your extension project, and click **OK**.

---

**Note:** You should use a single extension project to hold all of your customization classes.

---

5. In the Application Navigator, right-click your extension project and choose **Project Properties**.
6. In the Project Properties dialog, click **Libraries and Classpath**, and then click **Add Library**.
7. In the Add Library dialog, select **MDS Runtime**, and click **OK**.
8. In the Application Navigator, right-click the extension project and choose **New**.
9. In the New Gallery, expand **General**, select **Java** and then **Java Class**, and click **OK**.
10. In the Create Java Class dialog, enter a name for the class and the appropriate package.

---

**Note:** Customization classes are typically named for the layer name they return. For example, a customization class that returns the layer name `industry` would be named `IndustryCC`.

---

11. In the **Extends** field, enter `oracle.mds.cust.CustomizationClass`.
12. Make sure **Implement Abstract Methods** is checked and click **OK**.
13. Replace the code in the generated file with code like that shown in [Example 34-1](#).
14. Save your changes and rebuild the project.

This creates the customization class. The sample code uses the package name `mycompany` and the class name `IndustryCC`. You will need to change these as appropriate for your application.

## 34.2.2 What You May Need to Know About Customization Classes

As described in [Section 34.2.1.1, "Customization Classes,"](#) the customization class defines a `CacheHint` which specifies the visibility of metadata objects in a customization layer, and therefore its likely duration in memory. This information is used by MDS to decide whether or not to cache a customization, and where to cache it.

Any customization layers constructed using a given customization class have the same cache hint.

The following constants are supported values of `CacheHint`:

- `ALL_USERS` -- The customization is applied globally (non-conditionally) for a given deployment. This constant is used for static customization layers.
- `MULTI_USER` -- The customization is applied to multiple users.
- `REQUEST` -- The customization is applied for the duration of the request only.
- `USER` -- The customization is applied for a single user to documents which are accessed throughout the user's application session. (In web applications the application session is typically a servlet session.)

---

---

**Note:** Customization classes can be executed frequently, once for each document being accessed to get the layer name and layer value, so take care to ensure their efficiency.

---

---

### 34.2.3 How to Consume Customization Classes

After you have created your customization classes, you can use them at design time in the Customization Developer role, and at run time in the application. To be consumed in an application or in JDeveloper, the classes must be packaged appropriately.

When you define the deployment profiles for your application, you will need to add the customization classes JAR to the EAR assembly, and to avoid duplication make sure the WAR does not include the customization classes JAR. For more information, see [Section 36.3.2, "How to Create Deployment Profiles."](#)

#### 34.2.3.1 Making Customization Classes Available to JDeveloper

After you create the customization classes, you must make them available to JDeveloper so that you can use them when implementing customizations. When working in the Customization Developer role, your customization classes must be available on JDeveloper's class path.

Because the customization classes are reusable components, you can create a JDeveloper extension to contain them and make them available to JDeveloper. For information about creating and using JDeveloper extensions, see the Writing JDeveloper Extensions topic in JDeveloper Online Help.

However, when you package and deploy your customized application or run it from JDeveloper, the customization classes must be available at the application level on the application's class path. Therefore it is important to include them in the consuming application (for example, in the model project), and not just as a JDeveloper extension. For more information about making your customization classes available at runtime, see [Section 34.2.3.2, "Consuming Customization Classes from an Extension Project."](#)

#### To package your customization classes as a JDeveloper extension:

1. Create your customization classes in the extension project, as described in [Section 34.2.1.3, "Creating a Customization Class."](#)
2. In the Application Navigator, right-click your extension project and choose **Rebuild *project.jpr***.
3. In the Application Navigator, right-click your extension project and choose **Deploy to Target Platform**.

This deploys the customization classes to JDeveloper, so they can be used in the Customization Developer role.

### 34.2.3.2 Consuming Customization Classes from an Extension Project

When you package and deploy your customized application or run it from JDeveloper, the customization classes must be available in the EAR level application class loader.

---

---

**Note:** This procedure is not required if you created your customization classes in model project of the consuming application.

---

---

#### Before you begin:

With the application containing the customization classes open in JDeveloper in the Default role, create a JAR using the procedure described in [Section 36.3.2.1, "Adding Customization Classes into a JAR."](#)

Use the following procedure to make the customization classes visible to the application, and then add the customization classes to the `cust-config` section of the `adf-config.xml` file, as described in [Section 34.2.7, "How to Configure the adf-config.xml file."](#) This makes the customization classes available to the application when you run it locally from JDeveloper.

#### To use customization classes from an extension project:

1. Open the application you want to customize in JDeveloper in the Default role.
2. In the Application Navigator, right-click the model project and choose **Project Properties**.
3. In the Project Properties dialog, click **Libraries and Classpath**.
4. Click **Add JAR/Directory**.
5. In the Add Archive or Directory dialog, select the JAR you created that contains the customization classes, and click **Select**.
6. Click **OK** to close the Project Properties dialog.

Now the customization classes are available if you are running your project locally in JDeveloper. However, if you are deploying your application remotely, you must also add the customization classes JAR to the EAR class path, as described in [Section 36.3.2.4, "Creating an Application-Level EAR Deployment Profile."](#)

## 34.2.4 How to Enable Seeded Customizations for View Projects

Like all customizable components, the XML elements of a customizable metadata object must be uniquely identifiable by MDS, and therefore must have a unique, non-null identifier. The component's identifier is used to refer to the element in the customization instructions in the customization layer. The ID property is the identifier for each type of component in an ADF Faces `.jspx` or `.jsff` file.

To allow for customizations on your JSF and JSP pages, you must enable seeded customizations in the application's view project, which drives some defaults for your pages. This is not necessary for your model and controller projects.

---

**Note:** MDS requires that pages be XML-based to be customized. Therefore, customizations are not allowed on `.jsp` files; use `.jspx` files instead.

---

**To enable seeded customizations in your view project:**

1. Launch JDeveloper using the Default role, and open the application that you want to make customizable.
2. In the Application Navigator, right-click the view project and choose **Project Properties**.
3. In the Project Properties dialog, click **ADF View**.
4. Select the **Enable Seeded Customizations** checkbox, as shown in [Figure 34–2](#).
5. Click **OK**.
6. Save the changes to your project.

**Figure 34–2 Project Properties - Enable Seeded Customizations**

### 34.2.5 How to Enable Seeded Customizations in Existing Pages

If you have pages in your project that were created in an earlier version of JDeveloper, you must make sure that these pre-existing pages are also enabled for seeded customizations. This is only necessary if you migrated the application from an earlier version of JDeveloper and did not generate ids during migration.

**To enable seeded customizations in an existing page:**

1. Launch JDeveloper using the Default role, and open the application that you want to make customizable.
2. Create an audit profile to implement ID tokens for all XML objects in your page.
  - a. From the **Tools** menu, choose **Preferences**.

- b. In the Preferences dialog, select **Audit > Profiles**.
  - c. In the **Rules** tab on the Profiles page, deselect all rules.
  - d. Select the rule **ADF Faces > Component ID Rules > Check for ID When ADF Faces is Present**.
  - e. From the **Default Fix** dropdown list, select **Generate a unique ID**.
  - f. Click **Save As**, then enter an identifiable name for the profile (such as **Generate Unique IDs**), and click **Save**.
  - g. Click **OK** to close the Preferences dialog.
3. In the Application Navigator, select the page for which you want to enable seeded customizations. Alternatively, you can select a project to run the audit on all the files it contains.
  4. From the **Build** menu, choose **Audit filename**.
  5. In the Audit dialog, select the profile you created to generate ids and click **Run**.
  6. Use the Log window to review issues and apply fixes.
  7. When the audit is complete, save your changes.

### 34.2.6 How to Enable Customizations in Resource Bundles

If you plan to create new resource keys when implementing customizations, you can specify the affected resource bundles using the Application Properties dialog.

#### To enable customizations in resource bundles:

1. From the application context menu, choose **Application Properties**.
2. In the Application Properties dialog, click **Resource Bundles**.
3. Click **Add**.
4. In the Select Resource Bundle dialog, navigate to and select the resource bundles for which you want to enable customization.
5. Click **Open**.
6. In the Application Properties dialog, select the checkbox in the **Overridden** column of the **Bundle** table.
7. Click **OK**.

### 34.2.7 How to Configure the adf-config.xml file

The application's `adf-config.xml` file must have an appropriate `cust-config` element in the `mds-config` section. The `cust-config` element allows clients to define an ordered and named list of customization classes. You use the overview editor for the `adf-config.xml` file to add customization classes (see [Figure 34-3](#)).

#### To identify customization classes in the adf-config.xml file:

1. With the application you want to customize open in JDeveloper, open the Application Resources panel in the Application Navigator.
2. Expand **Descriptors**, then expand **ADF META-INF**.
3. Right-click `adf-config.xml`, and choose **Open**.

4. In the overview editor, click the **MDS Configuration** navigation tab, and then click the **Add** icon.
5. In the Edit Customization Classes dialog, search for or navigate to the customization class you have already created.
6. Select the appropriate class and click **OK**.
7. After you have added all of the customization classes, you can use the arrow icons to put them in the appropriate order.

Figure 34–3 shows the overview editor for the `adf-config.xml` file with two customization classes added.

**Figure 34–3** *adf-config.xml Overview Editor*

The order of the customization-class elements defines the precedence of customization layers. For example, in the code shown in Example 34–6, the `IndustryCC` class is listed before the `SiteCC` class. This means that customizations at the industry layer are applied to the base application, and then customizations at the site layer are applied.

**Example 34–6** *Customization Class Order in the adf-config.xml File*

```
<adf-config xmlns="http://xmlns.oracle.com/adf/config">
  <adf-mds-config xmlns="http://xmlns.oracle.com/adf/mds/config">
    <mds-config xmlns="http://xmlns.oracle.com/mds/config" version="11.1.1.000">
      <cust-config>
        <match path="/">
          <customization-class name="com.mycompany.IndustryCC"/>
          <customization-class name="com.mycompany.SiteCC"/>
        </match>
      </cust-config>
    </mds-config>
  </adf-mds-config>
</adf-config>
```

## 34.2.8 What Happens When You Create a Customizable Application

When you create a customizable application, you have a base application that includes the pieces necessary for you or someone else to use as the basis for a customized application.

To perform the customization, you must open the application in JDeveloper using the Customization Developer role, as described in [Section 34.3, "Customizing an Application."](#)

### 34.2.9 What You May Need to Know About Customizable Objects and Applications

Oracle ADF components (such as controller, model, and business components objects) must have a unique identifier so that they can be customized. ADF components generated by JDeveloper are created with identifiers by default, with the exception of JSP and JSF pages in your view controller projects. To cause JDeveloper to generate identifiers for components on pages in your view controller projects, you must explicitly specify this at the project level (as explained in [Section 34.2.4, "How to Enable Seeded Customizations for View Projects"](#)).

Before you implement customizations in an application, make sure that all objects that you intend to customize have the necessary identifiers. In many cases, you can run an audit rule to catch and fix any omissions (as explained in [Section 34.2.5, "How to Enable Seeded Customizations in Existing Pages"](#)).

Also, take care to ensure the efficiency of your customization classes, because they can be executed frequently, once for each document being accessed to get the layer name and layer value.

## 34.3 Customizing an Application

Using the Customization Developer role, you can create customizations in a customizable application.

### 34.3.1 Introducing the Customization Developer Role

The Customization Developer role is used to customize the metadata in a project. Customization features are available only in this role. When you are in the Customization Developer role, you can do the following:

- Create and update customizations
- Select and edit the tip layer of a customized application
- Remove existing customizations

When you are in the Customization Developer role, the source editor is read-only and the following JDeveloper features are disabled:

- Workspace migration
- Creation, deletion, and modification of application and IDE connections. You must configure connections in Default role before opening an application in Customization Developer role.

When working with an application in the Customization Developer role, new objects cannot be created, and noncustomizable objects cannot be modified. However, the following content types are customizable:

- WebCenter Portal modules
- ADF modules, including ADF Faces, ADF Model, ADF Business Components, and ADF Controller

---

---

**Note:** ADF Business Components objects are customizable only if a static customization class is selected in the Customization Context window. Otherwise, business components objects are read-only.

---

---

When working in the Customization Developer role, you cannot edit noncustomizable files, such as Java classes, resource bundles, security policies, deployment descriptors, and configuration files. Noncustomizable files are indicated by a lock icon when you are working in the Customization Developer role.

You are also restricted from modifying project settings and customizing certain ADF Business Components features, including service interfaces and business event definitions. Additionally, you cannot refactor, or make changes to customizable files that would, in turn, necessitate changes in noncustomizable files.

### 34.3.2 How to Switch to the Customization Developer Role in JDeveloper

The customization features of JDeveloper are available to you in the Customization Developer role. To work in this role, you can either choose it when you start JDeveloper or, if JDeveloper is already running, you can use the Preferences dialog to switch to the Customization Developer role.

**To switch to the Customization Developer role in JDeveloper:**

1. From the **Tools** menu, choose **Preferences**.
2. In the Preferences dialog, click the **Roles** node.

The Roles page of the Preferences dialog displays the different roles that are available to you.

3. Select **Customization Developer**, and click **OK**.

### 34.3.3 Introducing the Tip Layer

When working in the Customization Developer role, the layer and layer value combination that is selected in the Customization Context window is called the *tip layer*. The changes you make while in the Customization Developer role are applied to this layer.

The metadata displayed in the JDeveloper editors is a combination of the base metadata and the customization layers up to and including the tip layer, according to the precedence set in `adf-config.xml`, with the values specified in the Customization Context window for each layer.

When working in the Customization Developer role, you can also see the noncustomized state of the application. When you select **View without Customizations** in the Customization Context window, there is no current tip layer. Therefore, what you see is the noncustomized state. While you are in this view, all customizable files show the lock icon (in the Application Navigator), indicating that these files are read-only.

When you make customizations in a tip layer, these customizations are indicated by an orange icon in the Property Inspector. A green icon indicates non-tip layer customizations. When you see an orange icon beside a property, you have the option of deleting that customization by choosing **Remove Customization** from the dropdown menu for that property.

### 34.3.4 How to Configure Customization Layers

To customize an application, you must specify the customization layers and their values in the `CustomizationLayerValues.xml` file so that they are recognized by JDeveloper.

You can define the customization layers either globally for JDeveloper or in an application-specific file. If you use an application-specific file, it takes precedence over the global file. For more information on configuring layer values globally for JDeveloper, see [Section 34.3.4.1, "Configuring Layer Values Globally."](#) For more information on configuring application-specific layer values, see [Section 34.3.4.2, "Configuring Workspace-Level Layer Values from the adf-config Editor."](#)

When you open a customizable application in the Customization Developer role, JDeveloper reads the `adf-config.xml` file to determine the customization classes to use and their order of precedence. JDeveloper also reads the `CustomizationLayerValues.xml` file to determine the layer values to make available in the Customization Context window. If there are layers included in the `CustomizationLayerValues.xml` file that are not defined in the customization classes listed in the `adf-config.xml` file, they are not displayed in the Customization Context window.

Therefore, when you specify the customization layers globally for JDeveloper, you can have a comprehensive list of layer values for all of your customization applications in the `CustomizationLayerValues.xml` file, and only those appropriate for the current application are available in the Customization Context window. Conversely, you could have a comprehensive list of customization classes for an application in the `adf-config.xml` file, and only the subset of layer values that you will work on in your `CustomizationLayerValues.xml` file.

---

**Note:** At design time, JDeveloper retrieves customization layer values from the `CustomizationLayerValues.xml` file. But at runtime, the layer values are retrieved from the customization class.

---

The names of the layers that you enter in the `CustomizationLayerValues.xml` file must be consistent with those specified in your customization classes. [Section 34–7, "Layers and Layer Values Defined in CustomizationLayerValues.xml"](#) shows the contents of a sample `CustomizationLayerValues.xml` file.

**Example 34–7 Layers and Layer Values Defined in CustomizationLayerValues.xml**

```
<cust-layers xmlns="http://xmlns.oracle.com/mds/dt">
  <cust-layer name="industry" id-prefix="i">
    <cust-layer-value value="financial" display-name="Financial" id-prefix="f"/>
    <cust-layer-value value="healthcare" display-name="Healthcare" id-prefix="h"/>
  </cust-layer>
  <cust-layer name="site" id-prefix="s">
    <cust-layer-value value="headquarters" display-name="HQ" id-prefix="hq"/>
    <cust-layer-value value="remoteoffices" display-name="Remote" id-prefix="rm"/>
  </cust-layer>
</cust-layers>
```

For each layer and layer value, you can add an `id-prefix` token. This helps to ensure the uniqueness of the `id`, so that customizations are applied accurately. When you add a new element (such as a command button) to a page during customization, JDeveloper adds the `id-prefix` of the layer and layer value (determined by the selected tip layer) to the autogenerated identifier for the element to create an `id` for the

newly added element in the customization metadata file. For example, in [Example 34-7](#), the site layer has an `id-prefix` of "s" and the headquarters layer value has an `id-prefix` of "hq". So, when you select site/headquarters as the tip layer and add a command button to a page, the command button will have an `id` of "shqcb1" in the metadata customization file.

For each layer value, you can also add a `display-name` token to provide a human-readable name for the layer value. When you are working in the Customization Developer role, the value of the `display-name` token is shown in the Customization Context window for that layer value.

#### 34.3.4.1 Configuring Layer Values Globally

The following procedure describes how to configure the `CustomizationLayerValues.xml` file globally for JDeveloper.

##### To configure design time customization layer values globally for JDeveloper:

1. Locate and open the `CustomizationLayerValues.xml` file.  
You can find this file in the `jdev` subdirectory of your JDeveloper installation directory (`jdev_install\jdev\CustomizationLayerValues.xml`).
2. For each layer, enter a `cust-layer` element, as shown in [Example 34-7](#).
3. For each layer value, enter a `cust-layer-value` element, as shown in [Example 34-7](#).
4. Save and close the `CustomizationLayerValues.xml` file.
5. Make sure that the customization class JARs (created in [Section 34.2.3.1, "Making Customization Classes Available to JDeveloper"](#)) are available in the JDeveloper class path.
6. After you have made changes to the global `CustomizationLayerValues.xml` file, you must restart JDeveloper.

#### 34.3.4.2 Configuring Workspace-Level Layer Values from the adf-config Editor

When configuring layer values for an application, you can use either the `adf-config` editor (in the Default role or the Customization Developer role) or the Customization Context window (in the Customization Developer role). For information on how to do this from the Customization Context window, see [Section 34.3.4.3, "Configuring Workspace-Level Layer Values from the Customization Context Window."](#)

When you create an application-specific `CustomizationLayerValues.xml` file, JDeveloper stores it in an application-level directory (for example, `workspace-directory\.mds\dt\customizationLayerValues\CustomizationLayerValues.xml`). You can access this file in the **Application Resources** section of the Application Navigator, under the **MDS DT** folder.

The following procedure describes how to configure the `CustomizationLayerValues.xml` file for a specific application from the `adf-config` editor.

##### To configure design time customization layer values at the workspace level from the adf-config editor:

1. In the Application Navigator, double-click the `adf-config.xml` file.  
The `adf-config.xml` file is in the Application Resources panel of the Application Navigator, under **ADF META-INF** in the **Descriptors** node.

2. In the overview editor, click the **MDS Configuration** tab.
3. Below the table of customization classes, click the **Configure Design Time Customization Layer Values** link to open the workspace-level `CustomizationLayerValues.xml` file.

When you click the link, JDeveloper opens the file in the editor. If the workspace-level `CustomizationLayerValues.xml` file doesn't already exist, JDeveloper displays a confirmation dialog. Click yes to create and open a copy of the global file.

4. Specify layer values as necessary, as described in [Section 34.3.4, "How to Configure Customization Layers."](#)
5. Save your changes.

Unlike the global `CustomizationLayerValues.xml` file, the layer values of workspace-level `CustomizationLayerValues.xml` file can be changed in Customization Developer role. Additionally, when you save your changes, the modified values are reflected in the Customization Context window without restarting the JDeveloper. If the customization context that was active prior to modifying the file becomes invalid with the modified customization layer values, the customization context is deselected. You will need to select the customization context from the updated customization layer values.

#### 34.3.4.3 Configuring Workspace-Level Layer Values from the Customization Context Window

When configuring layer values for an application, you can use either the Customization Context window (in the Customization Developer role) or the `adf-config` editor (in the Default role or the Customization Developer role). For information on how to do this from the `adf-config` editor, see [Section 34.3.4.2, "Configuring Workspace-Level Layer Values from the `adf-config` Editor."](#)

When you create an application-specific `CustomizationLayerValues.xml` file, JDeveloper stores it in an application-level directory (for example, `workspace-directory\.mds\dt\customizationLayerValues\CustomizationLayerValues.xml`). You can access this file in the **Application Resources** section of the Application Navigator, under the **MDS DT** folder.

The following procedure describes how to configure the `CustomizationLayerValues.xml` file for a specific application from the Customization Context window in the Customization Developer role.

#### To configure design time customization layer values at the workspace level from the Customization Context window:

1. Click the **Override global layer values** link in the Customizations window.

When you click the link, JDeveloper opens the `CustomizationLayerValues.xml` file in the overview editor. If the workspace-level `CustomizationLayerValues.xml` file doesn't already exist, JDeveloper displays a confirmation dialog. Click yes to create and open a copy of the global file.

2. Specify layer values as necessary, as described in [Section 34.3.4, "How to Configure Customization Layers."](#)
3. Save your changes.

Unlike the global `CustomizationLayerValues.xml` file, the layer values of workspace-level `CustomizationLayerValues.xml` file can be changed in

Customization Developer role. Additionally, when you save your changes, the modified values are reflected in the Customization Context window without restarting the JDeveloper. If the customization context that was active prior to modifying the file becomes invalid with the modified customization layer values, the customization context is deselected. You will need to select the customization context from the updated customization layer values.

### 34.3.5 How to Customize Metadata in JDeveloper

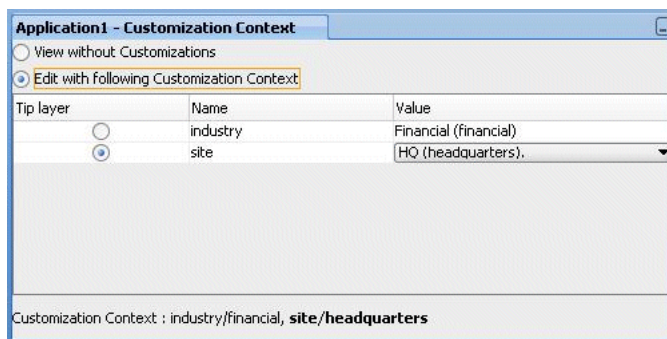

You use the same development procedures and techniques to customize metadata that you use when developing the base application. To implement customizations, however, you must be working in the Customization Developer role and specify the customization context by selecting a tip layer and layer value before editing the metadata. For an application to be customizable, customizations must be enabled in your project. For more information, see [Section 34.2, "Developing a Customizable Application."](#)

#### To customize metadata in JDeveloper:

1. Launch JDeveloper using the Customization Developer role.
2. Open the customizable application.
3. In the Customization Context window, select the layer and value for which you want to implement customizations.

The **Customization Context** (displayed at the bottom of the Customization Context window) changes to reflect your selection, as shown in [Figure 34–4](#).

**Figure 34–4** Customization Context Window with *site/headquarters* Selected as the Tip Layer

---

**Note:** The selection you make in the Customization Context window indicates the context for the customizations that you will implement in JDeveloper. This selection does not directly impact the runtime for the application. At runtime, the customization context is returned from your customization classes. For more information, see [Section 34.2.1, "How to Create Customization Classes."](#)

---

4. Edit the metadata as you typically would during development. For example, right-click an entity object and choose **Open**. Then edit the object using the overview editor.

While you use the same techniques for editing metadata during customization that you would during development, certain restrictions apply. For example, some

string properties, such as button labels, cannot be edited directly in the Property Inspector: they must be edited using the Select Text Resource dialog or the Expression Builder. For more information about restrictions to editing during customization, see [Section 34.3.1, "Introducing the Customization Developer Role."](#) For information about using the Expression Builder, see [Section 12.7.1.1, "Opening the Expression Builder from the Property Inspector."](#)

Even though you use the overview editor to implement customizations, you do not make changes to the base metadata file. Your changes are stored separately in a customization metadata file.

---

---

**Note:** To see the uncustomized base metadata, you can select **View without Customizations** in the Customization Context window.

---

---

5. You can optionally choose **Remove Customization** from the dropdown menu for a property (in the Property Inspector) to clear the existing customization.

---

---

**Note:** In the Property Inspector, tip layer customizations are indicated by an orange icon, while non-tip layer changes are indicated by a green icon. Remove customization can only be performed in the context in which the customization was added. So you can remove only those customizations that have an orange indicator in the Property Inspector.

---

---

6. Choose **Save** from the **File** menu to save your changes.

After you have completed your customizations, you can run and test the customized application.

### 34.3.6 How to Fix Incongruencies Between the Tip Layer and Base Metadata

If a base metadata document is upgraded or if the base document type definition is changed (for backward compatibility, type definition changes should be avoided), it is possible for customizations on that document to become invalid.

For example, say an element in the XSD has `minOccurs=0, maxOccurs=1` and the base document initially has no occurrences of the element. So you insert an occurrence of the element as a customization. Then the base document is upgraded to add an occurrence of the same element. In this situation, applying the customization results in two occurrences of the element, violating the `maxOccurs` rule of the XSD.

If this happens, JDeveloper alerts you to such tip customization issues in Structure window when you open the document in the Customization Developer role. When a document is opened in JDeveloper, any errors (for example, errors due to schema validation) are displayed in the Structure window. For some error conditions, audit fix actions are provided. You can double-click the error to go to the source of the problem in the document. Note that the Structure window reports only the validation errors introduced by customizations in the current tip layer. If there are validation errors in layers other than the tip layer, they are not reported.

To fix tip layer customization errors, the JDeveloper Customization Developer role provides a default audit action named **Fix all tip customization validation errors**. This action fixes validation violations on the merged document by removing the tip layer customizations.

### 34.3.7 What Happens When You Customize an Application

When you implement customizations in an application, JDeveloper creates a metadata file for the customizations and a subpackage to store them in.

The metadata file contains the customizations for the customized object, which are applied over the base metadata at runtime. The new metadata file is named the same as the base file for the object with an additional `.xml` extension. For example, if you implement customizations for the `browseOrders.jsff` page, the customization metadata file is named `browseOrders.jsff.xml`. Or if you implement customizations on the `OrderItems` entity object, the base metadata file is named `OrderItems.xml` and the customization metadata file is named `OrderItems.xml.xml`.

The customization metadata files are stored in a subpackage hierarchy that is created at the same level as the object you customize. The first-level package is named `mdssys`, and it contains a package named `cust`. The `cust` package contains a package for each customization layer for which you have implemented customizations.

For example, say you have a base application that has a package called `oracle.fod.model` containing your entity objects, and you have a customization layer named `site` with two layer values: `headquarters` and `remoteoffices`. Then you implement customizations for the `OrderItems` entity object at the `headquarters` layer value. When you implement these customizations, JDeveloper creates the subpackage hierarchy `oracle.fod.model.mdssys.cust.site.headquarters` and stores the customization metadata files there.

Similarly, for pages in your view controller project, JDeveloper creates a directory structure to store the customization metadata files. For example, if you customize the `BrowseOrders.jsff` page in the Web Content folder of your view controller project, JDeveloper creates the directory structure `mdssys/cust/site/headquarters` under Web Content and stores the customization metadata file there.

### 34.3.8 How to Customize Business Logic using Groovy Triggers

In the Customization Developer role, you can use JDeveloper to implement Groovy script to respond to the following predefined trigger points for an entity object:

- After Create
- Before Modify
- Before Invalidate
- Before Remove
- Before Insert in Database
- After Insert in Database
- Before Update in Database
- After Update in Database
- Before Delete in Database
- After Delete in Database
- Before Commit in Database
- After Commit in Database

- Before Rollback in Database
- After Rollback in Database

These trigger points are available on the **Business Rules** tab of the overview editor for entity objects.

#### To add a trigger for an entity object

1. In the Application Navigator, right-click an entity object and choose Open.
2. In the overview editor, click the **Business Rules** navigation tab.
3. Click the Add icon and choose **Trigger**.
4. In the Add Trigger dialog, select the trigger point to use and enter an expression that will be executed in response to the trigger point.
5. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the trigger fails.
6. Click **OK**.

### 34.3.9 How to Customize ADF Library Artifacts in JDeveloper

In the Customization Developer role, you can use JDeveloper to customize artifacts in an ADF library. This need can arise when, for example, one development team produces task flows as part of a framework service and makes them available to other teams as an ADF library. Then another development team uses one of the task flows in a consuming application, and needs to fine-tune it to fit the requirements of the application.

You can add an ADF library to your project in the Customization Developer role just as you would add it in the Default role. However, in the Customization Developer role, content from an ADF library appears as editable to allow you to implement customizations, whereas in the Default role it is read-only. For more information about working with ADF libraries, see [Chapter 33, "Reusing Application Components."](#)

#### To customize an ADF library artifact:

1. Open your customizable application in the Customization Developer role.
2. In the Application Navigator, click the **Navigator Display Options** icon and choose **Show Libraries**.

This displays the libraries in the Application Navigator, so that you can explore them and access their artifacts.

3. Add the desired library to your project if it is not already shown among the libraries in the Application Navigator.

For information about how to do this, see [Section 33.3, "Adding ADF Library Components into Projects."](#)

4. Customize the artifacts just as you would customize other content in your project.

For example, you can drag and drop taskflows from a library to `.jspx` or `.jsff` pages in a consuming project, drag and drop taskflows from a library to a page or fragment in another library, drag and drop library content or taskflows from the Resource catalog, drag and drop data controls from Data Controls panel to `.jspx` or `.jsff` pages in a library, edit business components, and drag and drop a data control from a library to the Data Controls panel and then drop to a page in another palette. All these actions would result in customizations of the library.

### 34.3.9.1 Specifying a Location for ADF Library Customizations

The location where ADF library customizations are stored is `project-dir\libraryCustomizations` by default. If your workspace contains multiple projects, you should change this to an workspace-level location for each project (for example, `workspace-dir\.mds\ADFLibraryCustomizations`).

You can change the location of ADF library customizations on the **Project Source Paths > ADF Library Customizations** page of the Project Properties dialog. If you change this location after you have implemented customizations on an ADF library, you must move the customization metadata files to the new location. To do this, use the file system to move the customization metadata (XML) files from the old directory to the new one.

If you have more than one project in the workspace with existing ADF library customizations that need to be moved to the common location, move the customizations to the new location one project at a time. For each project, change the location of ADF library customizations in the Project Properties dialog, and then move the customization metadata files from the old location to the new location. To mitigate conflicts where an ADF library artifact has customizations in more than one project, you have following options:

- From both projects, open the ADF Library artifact for which there are conflicting customizations, and decide upon which customizations you want. Preserve the customizations you want to keep and delete the others.
- If both customizations are important, open the ADF library artifact from the first project and implement the customizations that were previously done in second project. Then save the customizations in the first project and remove the customizations from the second project.

Do not open ADF library customization metadata files from multiple projects in a text editor and merge their contents. This can corrupt the customization metadata file.

Additionally, the location where ADF library customizations are stored is automatically included when you create a MAR deployment profile. If you change this location after you have created a MAR profile, you must also change the corresponding entry in the contributors list on the **User Metadata** file group page of the Edit MAR Deployment Profile Properties dialog before packaging. Alternatively, you can re-create the MAR profile to pick up this change. For more information about creating a MAR deployment profile, see [Section 36.3.2, "How to Create Deployment Profiles."](#)

### 34.3.9.2 Viewing ADF Library Runtime Customizations from Exported JARs

When working in the JDeveloper Customization Developer role, you can view runtime customizations implemented on ADF library artifacts contained in an exported JAR.

#### To make runtime customizations viewable from JDeveloper:

1. Open the customized application in the Customization Developer role.
2. From the Application Navigator popup menu, choose **Application Properties**.
3. In the Application Properties dialog, click **Customization Libraries**.
4. Click **Browse**, and navigate to the location of the exported JAR.
5. Select the JAR file and click **Select**.
6. Click **OK** to close the Application Properties dialog.

Now the JAR is available so that JDeveloper can look up customizations on ADF library artifacts. When you open an object that contains ADF library artifacts, JDeveloper looks for customizations in this JAR and displays them if appropriate. JDeveloper decides what to display for a given artifact in a given customization context as follows:

- If the artifact has no runtime customizations or seeded customizations associated with it, the artifact from the ADF library is displayed.
- If the artifact has only runtime customizations or seeded customizations associated with it (but not both), the customized artifact is displayed.
- If the artifact has both runtime customizations and seeded customizations associated with it, the seeded customization takes precedence and is displayed.

Additionally, when you run the application locally from JDeveloper, the runtime customizations are displayed. However, the runtime customizations are not included in any packaging of the application for deployment.

### 34.3.10 What Happens When You Customize ADF Library Artifacts

During the development of enterprise applications, there might be artifacts (such as task flows) that can be reused in multiple applications. To facilitate reuse of these common artifacts they are usually packaged into an ADF library and distributed. This allows you to add the ADF library to the list of libraries on which the consuming application depends on. Then when the application is packaged, the customizations from all such ADF libraries are included in the MAR, which is later deployed to the MDS repository.

---

---

**Note:** The ADF library provider should take care to ensure that no name conflicts arise due to customizations in the library. In the event that name conflicts arise between customizations packaged in an ADF library and the customizations from the consuming project, the customizations from the ADF library are ignored.

---

---

When you implement customizations on objects from an ADF library, the customization metadata is stored by default in a subdirectory of the project called `libraryCustomizations`. And although you create ADF library customizations at the project level, they are merged together during packaging to be available at the application level at runtime. Essentially, ADF libraries are JARs that are added at the project level, which map to library customizations being created at the project level. However, although projects map to web applications at runtime, the MAR (which contains the library customizations) is at the EAR level, so the library customizations are seen from all web applications.

Therefore, you can customize an ADF library artifact in only one place in an application for a given customization context (customization layer and layer value). Customizing the same library content in different projects for the same customization context would result in duplication in MAR packaging. To avoid duplicates that would cause packaging to fail, implement customizations for a given library in only one project in your application.

For example, say the ADF library you are using contains a page fragment `text.jsff`. In the consuming application, customize this library page in only one project. By doing so, customizations are available for all projects in the application that consume this library at runtime.

You are also restricted from customizing an object from an ADF library when your project already contains an object with the same name. In case of duplication, you must fix the projects by deleting one of the duplicate documents or deleting one and merging the differences into the other.

Similarly, if the ADF library contains seeded customizations for an artifact within a given customization context (customization layer and layer value), you cannot implement customizations for that artifact within the same customization context. In this situation, the ADF library artifact is read-only. You can, however, implement customizations for the artifact within other customization contexts.

For example, say the ADF library you are using contains seeded customizations for the `Headquarters` layer value in the `Site` layer. When you select this as your tip layer in the Customization Context window, the customized objects in that ADF library are read-only. However, if you select `Site/Remote Site 1` as your tip layer, then the objects are customizable.

---

---

**Note:** When the consuming application implements customizations on content from an ADF library, the customizations are written to the local project directories, but they are not automatically injected with the `web-app-root` during packaging. For more information, see [Section 36.3.2.3, "Creating a MAR Deployment Profile."](#)

---

---

## 34.3.11 How to Package and Deploy Customized Applications

After you customize the application, you will want to deploy it. Before you deploy the customized application, you must follow the configuration procedures for setting up your MDS repository, as described in the *Oracle Fusion Middleware Administrator's Guide*.

An enterprise application can contain model and user interface projects, and both types of projects can contain customized metadata. The customized metadata is packaged into a MAR for deployment. By default, the customizations from both types of projects are added to a single MAR. For information about how to create a MAR profile, see [Section 36.3.2.3, "Creating a MAR Deployment Profile."](#)

### 34.3.11.1 Implicitly Creating a MAR

When you use JDeveloper to package an ADF application, JDeveloper creates an auto-MAR that includes default metadata (such as customizations), when *either* of the following conditions are met.

- The **Enable User Customizations > Across Sessions using MDS** checkbox is selected on the ADF View settings page of the Project Properties dialog for the user interface project.
- The MDS configuration section of the `adf-config.xml` file contains a `<metadata-store-usage>` element that is marked as `deploy-target="true"`, as shown in [Example 34-8](#).

#### **Example 34-8** *metadata-store-usage Element in adf-config.xml*

```
< . . . >
<persistence-config>
  <metadata-namespaces>
    <namespace path="/oracle/apps" metadata-store-usage="repos1"/>
  </metadata-namespaces>
</metadata-store-usages>
```

```

<metadata-store-usage id="repos1" deploy-target="true">
. . .
</metadata-store-usage>
</metadata-store-usages>
</persistence-config>
< . . . >

```

### 34.3.11.2 Explicitly Creating a MAR

For customizations created in JDeveloper to take effect in the application when it is deployed, these customizations need to be made available to the application at runtime. There are two techniques you can use to accomplish this:

- Package the customizations along with the application using a MAR.

Create a MAR profile that includes the customization metadata. The MAR profile should be included in the deployed EAR to ensure that the customizations are available at runtime. Your customization classes must be packaged in the EAR file such that they are in the application-level class loader.

---

**Note:** If you have seeded customizations only, you do not need to create a MAR to import them into the MDS repository unless you also want to support runtime customizations. If you have seeded customizations and do not have cross-session persistence enabled, the seeded customizations will be packaged in the EAR, by default, and loaded from the class path.

---

- Import the customizations to the runtime repository used by the application.

You typically use this approach if customizations to library metadata need to be applied to an application that is deployed separately. Using this approach, you package the customizations into a JAR and then use the command `importMetadata` with Oracle WebLogic Scripting Tool (WLST) to import them to the MDS runtime repository. For more information about this and other WLST commands, see the *Oracle Fusion Middleware WebLogic Scripting Tool Command Reference*.

If your application has customizations on objects from an ADF library, the customization metadata is implicitly included when you create the MAR profile. If you change the location of ADF library customizations in the Project Properties dialog, you must re-create the MAR profile before packaging.

If you plan to use design time at runtime capabilities to add or edit resource keys in the override bundle at runtime, the override bundle must be packaged as part of the MAR. By default, the override bundle is packaged as part of the autogenerated MAR if the application contains seeded customizations. However, if the application doesn't contain seeded customizations, you must explicitly create the MAR deployment profile to package the override bundle. When the MAR profile is created explicitly, the override bundle is added and included by default as part of the user metadata.

When you package and deploy the completed customized application, you should do so from the Default role, rather than from the Customization Developer role. For information about how to create a MAR profile, see [Section 36.3.2, "How to Create Deployment Profiles."](#)

### 34.3.12 What Happens at Runtime in a Customized Application

At runtime, the application applies the customization metadata files over the base application in the order of precedence defined in the `cust-config` section of the `adf-config.xml` file.

The layer value is retrieved from the customization class at runtime and evaluated in the context the application is running, and the appropriate customizations for that layer value are applied.

### 34.3.13 What You May Need to Know About Customized Applications

When you are customizing an application, you might be using integrated source control or customizing resource strings. When you use these features, there is additional information you need to know.

#### 34.3.13.1 Customization and Integrated Source Control

When working in the Customization Developer role, your source control integration complements the process of customization. If JDeveloper is configured to automatically check out and add new files to source control and you attempt to customize a base document that is available from a source control system, JDeveloper behaves in the following way:

- If the corresponding customization file is not already available, then a new customization file is created in source control and the customizations are written to it.
- If the corresponding customization file exists, it is checked out and customizations are written to it.
- If the corresponding customization file exists and it is already checked out or not yet in version control, customizations are written to it without any further version control operation.

Since the base document is not modified in the Customization Developer role, the base document is not checked out.

If JDeveloper is not configured to automatically check out or add new files to source control, you must manually make the customization files editable and check in newly created customization files to source control. For more information about using source control in JDeveloper, see section [Section 1.4.2, "Using a Source Control System."](#)

#### 34.3.13.2 Editing Resource Bundles in Customized Applications

During the course of customizing your application, you might want to customize the content to use different resource bundle keys or define and use new resource keys.

You can open a customizable application in the Customization Developer role and use the Property Inspector to customize the usages of resource bundle strings. You can change a document to use another already existing resource key in a resource bundle, or create a new resource. For more information about resource bundles, see [Section 4.7, "Working with Resource Bundles."](#)

New resource keys (created in the Customization Developer role) are saved to an application-level override bundle (in XLIFF format), and JDeveloper adds an entry to the `adf-config.xml` file like the one shown in [Example 34-9](#) to configure the application-level override bundle.

You must also configure the `adf-config.xml` file to support the overriding of the base resource bundle. As shown in [Example 34-9](#), you must tag the `bundleId`

element with `override="true"` to make it overrideable. After it is marked as overridden, customizations of that bundle are stored in the application's override bundle.

**Example 34–9** *adf-resourcebundle-config* Section in *adf-config.xml*

```
<adf-resourcebundle-config
xmlns="http://xmlns.oracle.com/adf/resourcebundle/config">
  <applicationBundleName>
    path-to-resource-bundle/bundle-name
  </applicationBundleName>
  <bundleList>
    <bundleId override="true">
      package.BundleID
    </bundleId>
  </bundleList>
</adf-resourcebundle-config>
```

---

**Note:** If an application is not configured for customization, you can open it in the Customization Developer role and define new resource keys by choosing **Edit Resource Bundles** from the **Application** menu. However, you cannot change a document to use the new resource keys if it is not configured for customization.

---

## 34.4 Extended Metadata Properties

Extended metadata is data that describes the metadata content. The extended metadata file contains additional information about the metadata file. One use of this extended information is to identify which parts of the metadata can be customized at runtime (design time at runtime customizations) and who can customize them. For more information about this use of extended metadata properties, see [Section 34.4.2, "How to Enable Customization for Design Time at Runtime."](#)

You can open a metadata file (such as a `.jspx` file) in JDeveloper and use the Property Inspector to view and edit its extended metadata properties. When you open a metadata file, its extended metadata properties are displayed in the Property Inspector. These properties can be edited to add metadata information at either of the following levels:

- **File-level:** These properties are displayed in the Property Inspector when the root element is selected in the Structure window.
- **Element-level:** These properties are displayed in the Property Inspector when an element is selected in the Structure window. The selected element should have a non-null identifier.

Extended metadata properties are supported for file types that support customizations and can be packaged in a MAR, such as `.jsff` and `.jspx` files.

Extended metadata for a metadata document is stored in an associated resource description framework (RDF) file. RDF is a W3C standard used to define an XML framework for defining metadata. The RDF file associated with the metadata document is created when the first property value is specified using the Property Inspector. Extended metadata properties are editable only when JDeveloper is in the Default role. RDF files are read-only in the Customization Developer role.

The RDF file is stored in the `mdssys` directory. For example, if the metadata being described is stored in the file system as `/myapp/data/page1.jsx`, the

corresponding extended metadata document would be stored as `/myapp/data/mdssys/mdx/page1.jspx.rdf`. The extended metadata document must then be packaged with the corresponding metadata base file and added to the same deployment profile. For more information about creating a MAR deployment profile, see [Section 36.3.2, "How to Create Deployment Profiles."](#)

---

---

**Note:** Don't edit the extended metadata documents directly. Use the Property Inspector.

---

---

### 34.4.1 How to Edit Extended Metadata Properties

You can use extended metadata properties to provide additional metadata information that is not covered in the metadata file (such as a `.jspx` file). When you open the metadata file in JDeveloper, extended metadata properties are displayed in the Property Inspector, which you can use to edit these properties when you are using JDeveloper in the Default role.

For example, suppose you want to deliver a metadata file in some form to external customers. Along with metadata file, you need to provide additional information about the file, such as the creator, subject, description, format, and rights. You can accomplish this by creating an extended metadata property file for your metadata file.

**To edit extended metadata properties:**

1. Launch JDeveloper using the Default role.
2. In JDeveloper, open the appropriate application and project.
3. In the Application Navigator, select the object for which you want to edit extended metadata properties.
4. In the Structure window, select the appropriate element (typically the root element).
5. In the Property Inspector, expand the appropriate node to edit the properties.

To display the Property Inspector with the values for the selected component, choose **Property Inspector** from the **View** menu.

6. Edit the value for the desired property and press Enter.
7. Choose **Save** from the **File** menu to save your work.

If you have edited extended metadata properties for a metadata file, you must package your extended metadata (or RDF) files with the metadata files when you deploy the application.

### 34.4.2 How to Enable Customization for Design Time at Runtime

You can also use extended metadata properties to provide information about which parts of the metadata can be customized at runtime and who can customize the metadata content.

By default, many components (such as tables and `panelSplitters`) that you can add to a `.jspx` page are preconfigured to allow runtime customization to support implicit user personalization (such as changing the order of columns in a table). Some WebCenter Portal components (such as `panelCustomizable`) also allow customization in their type definition. For more information about user customization, see [Chapter 35, "Allowing User Customizations at Runtime."](#) For more information about WebCenter

Portal components, see the *Oracle Fusion Middleware Developer's Guide for Oracle WebCenter Portal*.

Components that are preconfigured to allow customization need no further modification to enable design time at runtime customizations. If you use them in a `.jspx` page, then they are customizable by default. However, the root elements of metadata objects (such as `.jspx` pages and page definition files) and other components (such as buttons) that you can add to a `.jspx` page are not preconfigured to be customizable at runtime, and must be explicitly configured to allow runtime customizations.

Therefore, depending on the requirements of your application, you will need to modify Customization properties in the following situations:

- For components that are preconfigured to allow customization, you can override the default settings to disallow customization.
- For components that are not preconfigured to allow customization and metadata objects (such as `.jspx` pages), you can override the default settings to allow customization.
- For components that are configured to allow customization, you can optionally restrict who is allowed to perform customizations at runtime.

In the Customization group in the Property Inspector, there are two properties that allow you to specify whether customizations for an object are permitted at runtime and who is permitted to do them. The **CustomizationAllowed** property can be set on any element to specify whether or not it can be customized. The **CustomizationAllowedBy** property controls which users can customize the element. These settings are not enforced when implementing seeded customizations using JDeveloper, but are instead enforced when customizing the application at runtime (design time at runtime customizations).

For example, say you have a `.jspx` page with a form that contains two panels, and you need to allow runtime customization for content in Panel1, but not Panel2. You would set **CustomizationAllowed** to `true` for Panel1, and set it to `false` for Panel2. If you need to allow runtime customization on an entire page, you would set **CustomizationAllowed** to `true` for the `.jspx` page root.

#### To edit customization properties:

1. Launch JDeveloper using the Default role.
2. In JDeveloper, open the appropriate application and project.
3. In the Application Navigator, select the object for which you want to edit customization properties.
4. In the Structure window, select the appropriate element.
5. In the Property Inspector, expand the **Customization** node to edit the customization properties.

To display the Property Inspector with the values for the selected component, choose **Property Inspector** from the **View** menu.

6. Edit the property value and press Enter.

For example, to allow runtime customizations on a `.jspx` file, select the file and set the **CustomizationAllowed** property to `true`.

7. Choose **Save** from the **File** menu to save your work.

If you have edited customization properties, you must package your extended metadata (RDF) files with the metadata files when you deploy the application.

## 34.5 Enabling Runtime Modification of Customization Configuration

You can prepare your customized application to accept overrides to the customization configuration (the `cust-config` section of the `adf-config.xml` file) at runtime on a per-session basis, thus allowing the user to change the way customizations are applied for a given session (or web request).

Consider a scenario where an application is configured with a `site` layer and a `user` layer and you want to make design time at runtime customizations to the `site` layer. If you use the application's customization configuration (defined in the `adf-config.xml` file), any customizations that you implement are applied to the `user` layer. So, you need to be able to adjust the customization configuration for a given session to allow your customizations to be applied to the `site` layer.

Or you have a requirement that an administrator wants to see the base metadata document with the `site` layer customizations alone. For cases like this, you need to specify a modified customization configuration, other than what was originally specified in application's `adf-config.xml` file.

For each web request, Oracle ADF creates an MDS session. For any MDS customization configuration modifications that apply to a session (web request), the user could programmatically provide modified MDS session options with a new customization configuration to Oracle ADF that would be applied on top of the original MDS configuration while creating a MDS session.

To implement this functionality, use the following ADF interfaces for `sessionOptionsFactory`:

- `oracle.adf.share.mds.SessionOptionsFactory` is the interface you use to specify modified MDS session options for a web request in an ADF application.

```
SessionOptionsFactory :: oracle.mds.core.SessionOptions
createSessionOptions(oracle.mds.core.SessionOptions defaultOptions)
```

You implement this method to return the modified MDS `sessionOptions` to ADF.

- `oracle.adf.share.config.ConfigUtils` is the public class you can use to register your session options factory with ADF.

```
ConfigUtils :: public static void setSessionOptionsFactory(ADFContext context,
SessionOptionsFactory factory)
```

See your ADF API documentation for further detail on these interfaces.

---

**Note:** If you are using Oracle WebCenter Portal's Composer components, you can use the `ComposerSessionOptionsFactory` interface to specify modified MDS session options with Composer.

```
ComposerSessionOptionsFactory :: public SessionOptions
createSessionOptions(SessionOptions defaultOptions, String mode);
```

`oracle.adf.view.page.editor.webapp.WebCenterComposerFilter` loads your `ComposerSessionOptionsFactory` implementation from the current thread context class loader. See the *Oracle Fusion Middleware Developer's Guide for Oracle WebCenter Portal* for more information.

---

You register your `sessionOptionsFactory` with Oracle ADF or Oracle WebCenter Portal's Composer in a filter implementation so that Oracle ADF can get modified session options from your implementation before the MDS session is created in request lifecycle.

[Example 34–10](#) shows how you can implement `sessionOptionsFactory`. This example sets a modified customization configuration for the session to use the site customization layer alone regardless of the customization configuration specified in the `adf-config.xml` file. See the Javadoc for `oracle.mds` for more information.

**Example 34–10 Sample sessionOptionsFactory Class**

```
package mycompany;

import oracle.adf.share.mds.SessionOptionsFactory;
import oracle.mds.config.CustClassListMapping;
import oracle.mds.config.CustConfig;
import oracle.mds.config.MDSConfigurationException;
import oracle.mds.core.SessionOptions;
import oracle.mds.cust.CustClassList;
import oracle.mds.cust.CustomizationClass;

public class MySessionOptionsFactory implements SessionOptionsFactory {
    public MySessionOptionsFactory() {
        super();
    }
    /**
     * Called to allow the application code to create a new SessionOptions object.
     * The application code should make sure to read the values from the
     * defaultOptions object as part of construction of their new object and make
     * sure they only override the intended values.
     * @param defaultOptions
     * @return modified MDS session options
     */
    public SessionOptions createSessionOptions(SessionOptions defaultOptions) {
        // create new mds Customization configuration
        CustConfig custconfig = null;

        // create customization class array. Just put SiteCC implementation as we
        // wish to apply site customizations alone.
        CustomizationClass[] custclassarray = new CustomizationClass[] {new SiteCC()};

        CustClassList custclasslist = new CustClassList(custclassarray);

        // specify the base metadata package namespace mapping on which site
```

```
// customizations would apply
CustClassListMapping[] mappings =
    new CustClassListMapping[] {new CustClassListMapping("mycompany/package",
        null, null, custclasslist)};

// create new customization configuration
try{
    custconfig = new CustConfig(mappings);
}
catch (Exception ex){
    //do nothing
}

// now return modified sessionOptions to ADF with new mds customization
// configuration. Only use newly created customization configuration in here.
// For rest of option, use whatever available in defaultOptions.
return new SessionOptions(defaultOptions.getIsolationLevel(),
    defaultOptions.getLocale(),
    custconfig,
    defaultOptions.getVersionContext(),
    defaultOptions.getVersionCreatorName(),
    defaultOptions.getCustomizationPolicy(),
    defaultOptions.getServletContextAsObject());
}
}
```

---

---

## Allowing User Customizations at Runtime

This chapter describes how to use the ADF Faces change persistence framework to create JSF pages that users can customize at runtime.

This chapter includes the following sections:

- [Section 35.1, "Introduction to Allowing User Customizations"](#)
- [Section 35.2, "Enabling Runtime User Customizations for a Fusion Web Application"](#)
- [Section 35.3, "Configuring User Customizations"](#)
- [Section 35.4, "Controlling User Customizations in Individual JSF Pages"](#)
- [Section 35.5, "Implementing Custom User Customizations"](#)
- [Section 35.6, "Creating Implicit Change Persistence in Custom Components"](#)

### 35.1 Introduction to Allowing User Customizations

Certain ADF Faces components have attributes that can be saved for a specific user. For example, the value of the `disclosed` attribute on a `panelBox` component can be saved for a specific user during the current session. The `myOrders` page in the `StoreFront` module application contains four `panelBox` components that display order information. By default, they are expanded, as shown in [Figure 35-1](#).

---

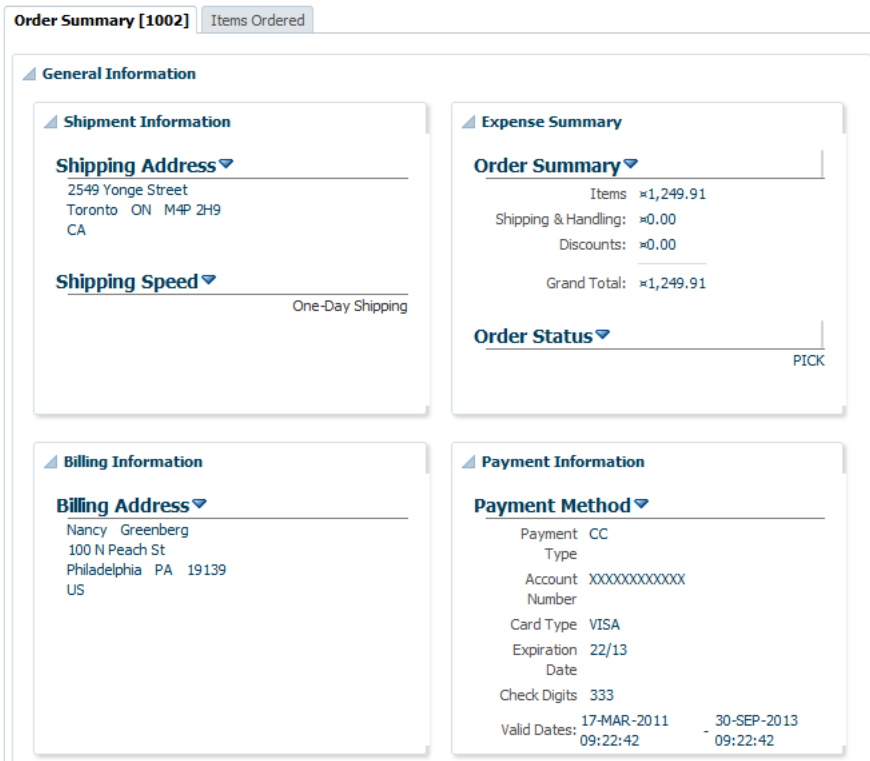

---

**Note:** The `query` component, which is not discussed in this chapter, can be used to implement saved searches, another type of user customization. For information about the `query` component, see [Chapter 27, "Creating ADF Databound Search Forms."](#) The configuration required for using MDS to store saved searches is discussed in [Section 27.2.3, "How to Persist Saved Searches into MDS."](#)

---

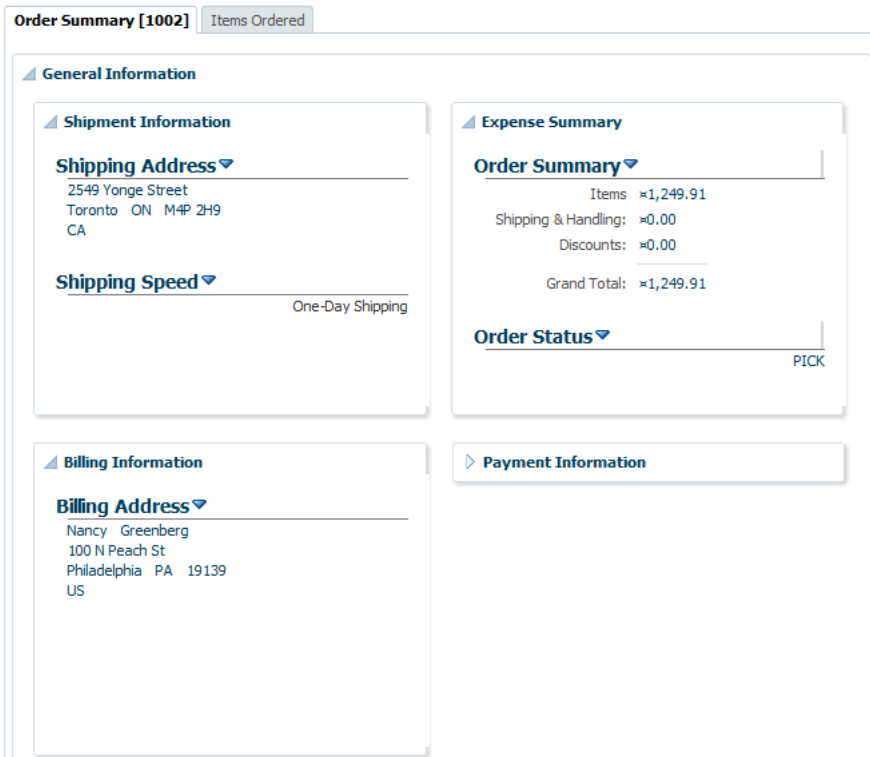

---

**Figure 35–1** *panelBox Components are Expanded by Default*

However, suppose a user decides to collapse one of the boxes, as shown in Figure 35–2.

**Figure 35–2** *panelBox Component Remains Collapsed*

Because this application is configured to allow user customizations, then during the user's session, anytime that user returns to the page, the Payment Information box remains collapsed. You need only to enable user customizations for the project in order for these changes to be persisted to the user's session.

---

**Note:** The user session begins when the user logs in to the application, and ends when the user leaves the application. It is possible that while using an application, the user could navigate across application boundaries (for example, to a peer application) and thereby leave the application, at which point the user session would end.

---

Table 35–1 shows the attribute value changes persisted by an ADF Faces application, after you configure the application to allow user customizations.

**Table 35–1** *Implicitly Persisted Attribute Values*

Component	Attribute	Affect at Runtime
panelBox showDetail showDetailHeader showDetailItem	disclosed	Users can display or hide content using an icon in the header. Detail content will either display or be hidden, based on the last action of the user.
showDetailItem (used in a panelAccordion component)	flex	The height of multiple showDetailItem components are determined by their relative value of the flex attribute. The showDetailItem components with larger flex values will be taller than those with smaller values. Users can change these proportions, and the new values will be persisted.
showDetailItem (used in a panelAccordion component)	inflexibleHeight	Users can change the size of a panel, and that size will remain.
panelSplitter	collapsed	Users can collapse either side of the splitter. The collapsed state will remain as last configured by the user.
panelSplitter	splitterPosition	The position of the splitter in the panel will remain where last moved by the user.
richTextEditor	editMode	The editor will display using the mode (either WYSIWYG or source) last selected by the user.
calendar	activeDay	The day considered active in the current display will remain the active day.
calendar	view	The view (either day, week, month, or list), that currently displays activities will be retained

**Table 35–1 (Cont.) Implicitly Persisted Attribute Values**

<b>Component</b>	<b>Attribute</b>	<b>Affect at Runtime</b>
panelWindow dialog	contentHeight	Users can change the height of a panelWindow or dialog popup component, and that height will remain.
panelWindow dialog	contentWidth	Users can change the width of a panelWindow or dialog popup component, and that width will remain.
activeCommandToolbar Button commandButton commandImageLink commandLink commandMenuItem commandNavigationItem commandToolbarButton	windowHeight	When users change the contentHeight attribute value of a panelWindow or dialog component, any associated windowHeight value on a command component is also changed and will remain.
activeCommandToolbar Button commandButton commandImageLink commandLink commandMenuItem commandNavigationItem commandToolbarButton	windowWidth	When users change the contentWidth attribute value of a panelWindow or dialog component, any associated windowWidth value on a command component is also changed and will remain.
column	displayIndex	ADF Faces columns can be reordered by the user at runtime. The displayIndex attribute determines the order of the columns. (By default, the value is set to -1 for each column, which means that the columns will display in the same order as the data source). When a user moves a column, the value on each column is changed to reflect the new order. These new values will be persisted.
column	frozen	ADF Faces columns can be frozen so that they will not scroll. When a column's frozen attribute is set to true, all columns before that column (based on the displayIndex value) will not scroll. When you use the table with a panelCollection component, you can configure the table so that a button appears that allows the user to freeze a column. For more information, see the "Displaying Table Menus, Toolbars, and Status Bars" section of the <i>Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework</i> .

**Table 35–1 (Cont.) Implicitly Persisted Attribute Values**

Component	Attribute	Affect at Runtime
column	noWrap	The content of the column will either wrap or not. You need to create code that allows the user to change this attribute value. For example, you might create a context menu that allows a user to toggle the value from <code>true</code> to <code>false</code> .
column	selected	The selected column is based on the column last selected by the user.
column	visible	The column will either be visible or not, based on the last action of the user. You will need to write code that allows the user to change this attribute value. For example, you might create a context menu that allows a user to toggle the value from <code>true</code> to <code>false</code> .
column	width	The width of the column will remain the same size as the user last set it.
table	filterVisible	ADF Faces tables can contain a component that allows users to filter the table rows by an attribute value. For a table that is configured to use a filter, the filter will either be visible or not, based on the last action of the user. You will need to write code that allows the user to change this attribute value. For example, you might create a button that allows a user to toggle the value from <code>true</code> to <code>false</code> .

You can also configure an application so that the value of these attributes can be persisted across sessions using the MDS repository. For example, if the StoreFront module allowed persistence to the MDS repository, then anytime that user entered the application, the Payment Information box would be collapsed.

---

**Note:** Before you can enable persistence to the repository, you must first follow all MDS configuration procedures as documented in the *Oracle Fusion Middleware Administrator's Guide*.

---

Along with the automatic persistence available through ADF Faces, you can create your own custom user customization capabilities for the following types of changes:

- Changing an attribute value
- Adding or removing a facet
- Adding or removing a child component
- Reordering child components
- Moving a child component to a different parent

If you want to create these types of custom user customizations, you need to add code (for example, in an event handler) that will call the APIs to handle the persistence.

Enabling an application to use the change persistence framework requires that you first enable your application to allow user customizations. Part of this process is determining where those changes should be persisted, either to the session or the MDS repository.

If you choose to persist changes to the session, by default all values as shown in [Table 35–1](#) will be saved for the user’s session. However if you choose to persist changes to a repository, you must explicitly configure which of these attribute values will be persisted to the repository. Instead of persisting all these attribute values, you can restrict changes so that only certain attribute value changes for a component are persisted, or so that only specific instances of the components persist changes.

---

---

**Note:** You cannot persist changes to a component that is contained inside (anywhere in the subtree) of `af:forEach` or `af:iterator` tags. While such structure results in multiple copies of a component in the view tree, each component has only a single representation in the JSP document. Therefore, customizations of the component cannot be persisted in MDS.

---

---

For any applications that persist changes to an MDS repository, when you deploy your application, you must create a metadata archive (MAR) profile in the application’s EAR assembly. For more information, see [Section 36.3.2, "How to Create Deployment Profiles."](#)

## 35.2 Enabling Runtime User Customizations for a Fusion Web Application

Enabling an application to allow user customizations (whether for the default changes that some ADF Faces components provide, or for custom capabilities that you create) requires that you configure your application to use the change persistence framework and that you also determine where those changes should be persisted (either the session or the MDS repository).

---

---

**Note:** If you are planning on persisting changes to the MDS repository, before configuring an ADF Faces application to use change persistence, you must first follow all MDS configuration procedures as documented in the *Oracle Fusion Middleware Administrator’s Guide*.

---

---

### 35.2.1 How to Enable User Customizations

You enable your application to use the change persistence framework by editing the `web.xml` and `adf-config.xml` files.

**To enable user customizations:**

1. Double-click the web project in your application to open the Project Properties dialog. In the tree on the left, select the **ADF View** node.
2. On the ADF View page, select the **Enable User Customizations** checkbox. If you want the changes to be persisted to only the session, select the **For Duration of Session** radio button. If you want the changes to persist to the MDS repository, select **Across Sessions Using MDS**.

3. If you chose to persist to the repository, you now need to declare each component tag and associated attribute values that you want persisted to the repository (if you chose to persist only to the session, all values will be persisted). For procedures, see [Section 35.3, "Configuring User Customizations."](#) After that configuration is complete, you can override those settings on a per component instance basis. For procedures, see [Section 35.4, "Controlling User Customizations in Individual JSF Pages."](#)

---

**Note:** If you have created custom user customization capabilities as documented in [Section 35.5, "Implementing Custom User Customizations,"](#) then you also need to declare those attribute values or operations.

---

## 35.2.2 What Happens When You Enable User Customizations

When you elect to save changes only to the session, JDeveloper adds the `CHANGE_PERSISTENCE` context parameter to the `web.xml` file, and sets the value to `session`. This context parameter registers the `ChangeManager` class that will be used to handle persistence. If you instead elect to save the changes to the MDS repository, the value is set to `oracle.adf.view.rich.change.FilteredPersistenceChangeManager`, as shown in [Example 35-1](#).

### **Example 35-1** Context Parameter in `web.xml` Used For Change Persistence

```
<context-param>
  <param-name>org.apache.myfaces.trinidad.CHANGE_PERSISTENCE</param-name>
  <param-value>
    oracle.adf.view.rich.change.FilteredPersistenceChangeManager
  </param-value>
</context-param>
```

**Tip:** If needed, you can manually set this value to `oracle.adf.view.rich.change.MDSDocumentChangeManager`, if you do not want any customizations to be restricted based on configurations in the `adf-config.xml` file or on the individual JSF pages, and you always want the changes to be persisted to the MDS repository and not the session.

When you elect to persist to the repository, JDeveloper also does the following:

- Adds the following JARs to the class path if they don't exist:
  - `javatools-nodep.jar`
  - `facesconfigmodel.jar`
  - `taglib.jar`
- Ensures the `ADFBindingFilter` is registered. If not, it adds the following entry to the `web.xml` file.

```
<filter>
  <filter-name>adfBindings</filter-name>
  <filter-class>oracle.adf.model.servlet.ADFBindingFilter</filter-class>
</filter>
```

- Adds another context parameter to `web.xml` to register the `MDSJSPPProviderHelper` class to handle merging MDS customization documents with the base JSP document, as shown in [Example 35-2](#)

**Example 35-2 Context Parameter in `web.xml` Used For Merging Changes**

```
<context-param>
  <param-name>oracle.adf.jsp.provider.0</param-name>
  <param-value>oracle.mds.jsp.MDSJSPPProviderHelper</param-value>
</context-param>
```

- Adds the ADF Faces Change Manager Runtime 11 library to the project.
- In the `adf-config.xml` descriptor file, sets the `persistent-change-manager` element to the `MDSDocumentChangeManager`, which is the class that will be used to persist the changes. [Example 35-3](#) shows the configuration for persisting to the MDS repository.

**Example 35-3 Registered ChangeManager Class for Restricted Change Persistence**

```
<persistent-change-manager>
  <persistent-change-manager-class>
    oracle.adf.view.rich.change.MDSDocumentChangeManager
  </persistent-change-manager-class>
</persistent-change-manager>
```

- Creates JSF JSP pages as XML documents. For more information, see [Section 35.4, "Controlling User Customizations in Individual JSF Pages."](#)

## 35.3 Configuring User Customizations

If you choose to persist changes to an MDS repository, you must decide which of the attribute values that are by default persisted to the session (as shown in [Table 35-1](#)) should also be persisted to the repository. Alternatively, you can configure which changes you do not want persisted.

**Tip:** Often, a system administrator is the one to set the configurations in the `adf-config.xml`. The `persist` and `dontPersist` attributes on a component allow page authors to override that setting as needed.

For example, suppose you decide that you don't want the value for the `width` attribute on columns to be persisted to the repository, but you do want all other default attribute changes for columns to be persisted. You must explicitly set the other default column values that you want to be persisted, and you also must explicitly configure the application to NOT persist the `width` attribute.

---

**Note:** If you have created custom user customization capabilities as documented in [Section 35.5, "Implementing Custom User Customizations,"](#) then you must explicitly declare those attribute values or operations as well.

---

You set (and unset) these values using the overview editor for the `adf-config.xml` file. [Figure 35-3](#) shows the overview editor where only certain attribute values for the `column` component will be persisted.

**Figure 35–3 Overview Editor for the adf-config.xml File**

Once set, you can override persistence for a specific component on a page. For example, suppose you want to disallow change on the `width` attribute on only one table's columns. You want the rest of the tables in the application to persist changes to that attribute. You would configure the columns to globally persist changes to the `width` attribute, but then for that one table, you would override the global configuration directly on the JSF page. For more information, see [Section 35.4, "Controlling User Customizations in Individual JSF Pages."](#)

---

**Note:** If you've enabled just session persistence, then all attribute values shown in [Table 35–1](#) will be persisted to the session. There is no way to override this either globally or on an instance.

---

### 35.3.1 How to Configure Change Persistence

By default, when you configure your application to use any type of change persistence (that is, to either the session or a repository), the values of all attributes shown in [Table 35–1](#) will always be persisted to the user's session. If you configured your changes to be persisted to a repository, then you must declare the attributes whose values should be persisted to that repository. If there are any values that you don't want persisted, then you need to configure those values as well.

#### To declare attribute value persistence to a repository:

1. In the Application Navigator, expand the **Application Resources** pane, expand the **Descriptor > ADF META-INF** node, and double-click **adf-config.xml** to open that file.
2. In the overview editor, click the **View** tab.
3. In the **Tags** table, select the component whose changes you want to persist (or not persist) to the repository. If the component does not appear in the table, click the **Add** icon, and select and add it.

---

---

**Note:** The filter rules specified in the `adf-config.xml` file are applicable only when you have chosen to persist to the MDS repository (see [Section 35.2.1, "How to Enable User Customizations"](#)). These rules do not apply for persistence within session scope.

If persistence fails for any reason, (for example if one of the filter rules fails or the MDS repository errors), then the values will be stored only within the session scope.

---

---

4. The **Tag Attributes** table displays all the attributes for the selected component whose values can be persisted. Select **Persist Changes** for all attributes whose values you want persisted. Deselect any if you do not want the values persisted.

---

---

**Note:** If you are implementing custom user customizations (see [Section 35.5, "Implementing Custom User Customizations"](#)), then you will need to edit the `adf-config.xml` manually to add the configuration. See [Example 35-4](#) for an example on how to configure user customizations.

---

---

### 35.3.2 What Happens When You Configure Change Persistence

When you select the component tags and attribute values to be persisted in the `adf-config.xml` file, JDeveloper enters tag library information for the components and attributes that are to be persisted. [Example 35-4](#) shows the entry for persisting the value of the `disclosed` attribute on the `panelBox` component.

#### *Example 35-4 Registration of Attribute Changes in `adf-config.xml`*

```
<taglib-config>
  <taglib uri="http://xmlns.oracle.com/adf/faces/rich">
    <tag name="panelBox">
      <attribute name="disclosed">
        <persist-changes>
          true
        </persist-changes>
      </attribute>
    ...
  </tag>
</taglib>
</taglib-config>
```

## 35.4 Controlling User Customizations in Individual JSF Pages

Once you have enabled your application to use user customizations, you can control user customizations for specific components on the page.

By default, the framework persists changes for all component instances, based on the configuration in the `adf-config.xml` file. You can override this default behavior by explicitly setting what should be persisted and what should not be persisted on each component instance using the `persist` and `dontPersist` attributes.

---

---

**Note:** The filter rules specified using the `persist` and `dontPersist` attributes are applicable only when you have chosen to persist to the MDS repository (see [Section 35.2.1, "How to Enable User Customizations"](#)). These rules do not apply for persistence within session scope.

If persistence fails for any reason, (for example if one of the filter rules fails or the MDS repository errors), then the values will be stored only within the session scope.

---

---

The following components support the `persist` and `dontPersist` attributes:

- `panelBox`
- `showDetail`
- `showDetailHeader`
- `showDetailItem`
- `column`
- `tree`
- `treeTable`
- `panelSplitter`
- `calendar`

### 35.4.1 How to Implement User Customizations on a JSF Page

You can override any globally set persistence configuration for a component using its `persist` and `dontPersist` attributes.

**Tip:** Often, a system administrator is the one to set the configurations in the `adf-config.xml`. The `persist` and `dontPersist` attributes allow page authors to override that setting as needed.

#### To implement user customizations on a JSF Page:

1. Add components to the page, as needed, including components that will be persisting changes.
2. If you want to persist all persistable attributes for a component:
  - a. In the Property Inspector, expand the **Advanced** section.
  - b. Click the drop-down list for the **Persist** field and choose **All Available**.
3. If you do not want to persist any attributes, repeat Step 2 for the **Don'tPersist** field.
4. If more than one attribute can be persisted for the component, and you do not want to persist all of them:
  - a. Click the drop-down menu to the right of the **Persist** field and choose **Edit** to open the Edit Property dialog.
  - b. Shuttle any attributes to be persisted from **Available** to **Selected**.

5. If you do not want to persist an attribute value, repeat Step 4 for the **Don't Persist** field.

---

**Note:** The filter rules specified using the `persist` and `dontPersist` attributes take precedence over any `adf-config.xml` configuration set for global component-level restrictions.

Values specified for the `dontPersist` attribute take precedence over values specified for the `persist` attribute. For example, if for a `panelBox` component you set `disclosed` as the value for both the `persist` and `dontPersist` attributes, the value of the `disclosed` attribute will not be persisted.

If you set the value of the `persist` or `dontPersist` attribute to `All Available`, then any values entered as choices using the Edit dialog and the shuttle will be ignored and all available attribute values will be persisted or not persisted.

---

### 35.4.2 What Happens at Runtime: How Changes Are Persisted and Restored

When an application is configured to persist changes to the session, any changes made during the session are recorded in a session variable in a data structure that is indexed according to the view ID and the component's ID attribute value. Every time the page is requested, in the subsequent create View or Restore View phase, all changes are applied in the same order as they were added. This means that the changes registered through the session will be applied only during subsequent requests in the same session.

When an application is configured to persist changes to the MDS repository, any changes made during the session are recorded by mutating the Document Object Model that MDS maintains for the JSP document behind the view. A JSF phase listener registered by ADF controller triggers a commit on the MDS session during the appropriate lifecycle phase, resulting in the change document being persisted in the MDS store. Every time the page is requested, Oracle's JSP engine seeks the JSP document from an MDS JSP provider, which provides a flattened document after merging the stored changes to the base document. MDS records the change against the unique value of the component's ID attribute.

**Tip:** If changes are applied in response to a partial submit of the page (for example, a `commandButton` with the `partialSubmit` attribute set to `true`), the component for which changes are applied must be set as the value for the `partialTarget` attribute.

Additionally, be aware that when you run the application from JDeveloper in the Integrated WebLogic Server, MDS creates a local file-based repository to persist metadata customizations. Whereas when the application is deployed to a test or production environment, customizations are persisted to the configured MDS repository. For more information about MDS repository configuration, see the *Oracle Fusion Middleware Administrator's Guide*. For more information about deploying an application, see [Section 36.4, "Deploying the Application."](#)

### 35.4.3 What You May Need to Know About Using Change Persistence on Templates, Regions, and Declarative Components

The way that changes are persisted for components in templates, regions, and declarative components is handled differently, depending on whether the changes are

persisted to the session or to the MDS repository. With session persistence, changes are recorded and restored on components against the `viewId` for the given session. As a result, when the change is applied on a component that belongs to one of these objects (region, page template, or declarative component), that change is applicable only in the scope of the page that uses the object. It does not span all pages that consume the object.

For example, suppose you have `pageOne.jspx` and `pageTwo.jspx`, and they both contain the region defined in `region.jsff`, which in turn contains a `showDetail` component. When `pageOne.jspx` is rendered and the `disclosed` attribute on the `showDetail` component changes, the implicit attribute change is recorded and will be applied only for `pageOne.jspx`. If the user navigates to `pageTwo.jspx`, no attribute change is applied.

When you persist changes to the MDS repository, MDS records and restores customizations for a document identified by a combination of the JSP page path and customization name/value configuration setting as set on the customization class (for more information, see [Section 34.2.1.1, "Customization Classes"](#)). As a result, for a given page that is rendered, when MDS applies a change on a component within one of these objects (region, template, or declarative object), it is applicable for all pages that consume the object and that have the same customization name and value as the source page.

In the previous example, assume that the `showDetail` component uses the ID of `myShowDetail`. When `pageOne.jspx` is rendered and the `disclosed` attribute on the `showDetail` component changes, the attribute change is recorded for `region.jsff` (and not the page that consumes it). This change is applied when any page that contains the region is rendered, as long as the ID remains the same.

Additionally, user customizations are allowed through the persistence change manager on components that are direct children of a page template or a declarative component only if the definition of the page template or declarative component is not private. If it is private, the customization is written into the session store.

---

---

**Note:** The definition of the page template or declarative component is a tag-only, nonbindable attribute. For declarative components, it is `af:componentDef`. For page templates, it is `af:pageTemplateDef`.

---

---

## 35.5 Implementing Custom User Customizations

In addition to the user customization capabilities built in to certain ADF Faces components, you can create your own custom user customization capabilities. The change persistence framework supports the following types of user customizations:

- Changing an attribute value
- Adding or removing a facet
- Adding or removing a child component
- Reordering child components
- Moving a child component to a different parent

To create custom user customizations, you must create a customization class for each type of user customization and then configure your application to use that class. You also need to set up the layers of customization for your application. For more

information about both of these procedures, see [Section 34.2, "Developing a Customizable Application."](#)

Once those prerequisites are satisfied, you add logic that calls methods on the ADF Faces classes that handle persisting change either to the session or the MDS repository. To handle the change, you create code that uses the APIs from one of the ADF Faces specialized component change classes. For most cases, you add this code to the event handler method on a managed bean associated with the page the persisting component is on. If you want all instances of a component to persist the same change, you need to add this code for each page on which that component appears.

If you are creating a custom component, you can implement user customizations for the component by adding code directly to the custom component class. In that case, you will need to add the code only to the component class, and not once for each instance of the component. For more information, see [Section 35.6, "Creating Implicit Change Persistence in Custom Components."](#)

### 35.5.1 Change Persistence Framework API

To better understand what you need to do to create custom user customizations, it may help to have a deeper understanding of the change persistence and MDS frameworks. When you elect to persist changes to the MDS repository, the change persistence framework works in conjunction with the MDS framework. Where and how the customizations are saved are determined by how you set up your MDS repository, your customization layers, and your customization classes. Details about the MDS framework and the repository and how to use it are covered in [Chapter 34, "Customizing Applications with MDS."](#)

The change persistence framework uses the underlying change manager classes from Apache MyFaces Trinidad (in the `org.apache.myfaces.trinidad.change` package) along with a few ADF Faces-specific classes (in the `oracle.adf.view.rich.change` package). The instance of the registered `ChangeManager` class is accessible through the `RequestContext` object. It is responsible for gathering changes as they are created and added during a request, and then persisting them. The `SessionChangeManager` class is an implementation of `ChangeManager` which handles persistence within a session only, while the `MDSDocumentChangeManager` class is an implementation that persists to the MDS repository only. The `FilteredPersistenceChangeManager` class is an implementation of `ChangeManager` that stores the changes that pass the filter rules into the repository using the registered persistence change manager. Any change that does not get persisted to the repository will be persisted to the session when `FilteredPersistenceChangeManager` is used.

Additional classes are used to describe the changes to a component. You use these APIs to handle persisting any changes to components other than the implicit value changes the ADF Faces framework provides (as shown in [Table 35–1](#)). `ComponentChange` is the base class for all classes used to implement specific changes that act on the JSF component hierarchy, such as adding or removing a facet or a child component. These changes are automatically applied during subsequent creation of the view, in the same order in which they were added. Classes that extend the `ComponentChange` class and that also implement the `DocumentChange` interface can directly persist changes to the MDS repository. Classes that do not implement the `DocumentChange` interface can persist changes only to the session.

[Table 35–2](#) describes the specialized classes that handle specific customizations. If "yes" appears in the `Repository` column, then the class implements the `DocumentChange` interface and it can persist changes to the MDS repository.

**Table 35–2** *Classes Used to Handle Change Persistence*

Class Name	Repository	Description
AddChildDocumentChange	Yes	Adds a child component using document mark up. While applying this change, the child component is created and added to the document.
AttributeComponentChange	No	Changes the value of an attribute.
AttributeDocumentChange	Yes	Changes the value of an attribute.
MoveChildComponentChange	Yes	Moves a child from one container to another.
RemoveChildComponentChange	Yes	Removes a child component.
SetFacetChildComponentChange	No	Adds a child component to the facet using a document markup. While applying this change, the markup will be added to the document.
SetFacetChildDocumentChange	Yes	Adds a child component to a facet. While applying this change, the DOM element corresponding to the child component is added to the document. If the facet doesn't exist, it will be created. If the facet does exist, all of its content will be removed and the new content added.
RemoveFacetComponentChange	Yes	Removes a facet.
ReorderChildrenComponentChange	Yes	Reorders children of a component.

Aside from a `ChangeManager` class, you may also need to implement and register the `DocumentChangeFactory` interface with the `ChangeManager` class. If the `DocumentChangeFactory` implementation can provide an equivalent `DocumentChange` for a `ComponentChange`, the `ChangeManager` will use it to persist the `DocumentChange` to the repository.

### 35.5.2 How to Create Code for Custom User Customizations

You need to add code to handle any explicit changes you want to create, and to configure the components on the JSF page to handle customization. As with the default user customizations, you also must register the custom changes in the `adf-config.xml` file.

---

---

**Note:** When the changes are expressible in more than one form, the change must be recorded in the form with highest precedence. For example:

- Attribute change for a component: The attribute can be specified on the component tag or it can be expressed using the `<f:attribute>` tag. In a JSF JSP document, `<f:attribute>` takes lesser precedence over the attribute specified on the component tag. Therefore, the attribute change on the component tag will be recorded for customization.
  - Column header text in a column component: The header text for the column can be specified using either the `headerText` attribute or using header facet. In this case, the facet component will have precedence.
- 
- 

#### To create custom user customizations:

1. Create a managed bean for the page that contains the component.
2. Add code to the event handler method for the component that will be used to make the change. This code should obtain the component that contains the change. It should then use the component and the appropriate APIs to create, record, and persist the change.

[Example 35–5](#) shows the code on the action event handler for a command button for a change that will be persisted to the MDS repository. When a user clicks the button, that source graphic file changes. The event handler method accesses the component and changes the source attribute for the graphic. It then calls the private `addAttributeChange` method, which first uses the component API to record the change, and then uses the `AttributeComponentChange` class to set the new source attribute value.

#### **Example 35–5** *Persisting Change to the Repository from an Event Handler on a Managed Bean*

```
public void modifyObjectImage(ActionEvent event) {
    UIComponent uic = event.getComponent().findComponent("oil");
    String source = "/images/mediumAd.gif";
    uic.getAttributes().put("source", source);
    _addAttributeChange(uic, "source", source);
}

.
.
.

private static void _addAttributeChange(UIComponent uic, String attribName,
                                       Object attribValue) {
    FacesContext fc = FacesContext.getCurrentInstance();
    ChangeManager cm =
        RequestContext.getCurrentInstance().getChangeManager();
    ComponentChange cc =
        new AttributeComponentChange(attribName, attribValue);
    apm.addComponentChange(fc, uic, cc);
}
```

---

---

**Note:** When you persist changes, in addition to explicitly recording a change on the component (which is done in [Example 35-5](#) using `uic.getAttributes().put("source", source)` method), you must also directly apply the change using the component API, as was done using the private `_addAttributeChange(uic, "source", source)` method. Applying the change in this way allows the user to see the change in response to the same request. If the change is recorded on the component, then the change will not be seen until a subsequent request.

Additionally, if you know that the component will always persist to the repository regardless of any restricted change persistence settings, you can instead call the `AdfFacesContext.getCurrentInstance().getPersistentChangeManager()` method.

---

---

3. The `ChangeManager` class provides support for automatically converting an `AttributeComponentChange` into an `AttributeDocumentChange`, thereby allowing persistence to a repository. However, if you need to convert another type of change and you use a specialized change manager class that does not implement the `DocumentChange` class, you need to create a custom `DocumentFactory` implementation that converts the component change to a document change.

---

---

**Note:** Automatic conversion of `AttributeComponentChange` into an `AttributeDocumentChange` assumes that the component attribute is represented as an attribute of the same name on the associated element in the JSPX document.

Only those attribute values that are expressible in the JSPX document can be persisted using `AttributeDocumentChange`. In other words, `CharSequence`, `Number`, `Boolean` and `ValueExpression` are the only supported data types.

Only values that implement `java.io.Serializable` can be persisted using `AttributeComponentChange`.

---

---

4. If you create a custom `DocumentFactory` implementation, you need to register it with the appropriate change manager class using the following method in your bean:

```
public static void registerDocumentFactory(String targetClassName,
                                         String converterClassName)
```

Where `targetClassName` is the name of the `ComponentChange` class and `converterClassName` is the name of your `DocumentChangeFactory` extension that is capable of converting the target `ComponentChange` into a `DocumentChange`. The semantics of name for these classes is same as that of `getName()` in the `java.lang.Class` class.

5. If the class you use to create the component change adds a child that has a subtree of components, and you want to persist the changes to the repository, you must create a `DocumentFragment` to represent the change.

[Example 35-6](#) shows how to use the `AddComponentDocumentChange` specialized class to create a `DocumentChange` object and use a `DocumentFragment` to represent the change.

**Example 35-6 Converting a ComponentChange Object to a DocumentChange Object**

```
public void appendChildToDocument(ActionEvent event)
{
    UIComponent eventSource = event.getComponent();
    UIComponent uic = eventSource.findComponent("pg1");
    // only allow the image to be added once
    if (_findChildById(uic,"oi3") != null)
        return;
    FacesContext fc = FacesContext.getCurrentInstance();
    DocumentFragment imageFragment = _createDocumentFragment(_IMAGE_MARK_UP);
    DocumentChange change = new AddChildDocumentChange(imageFragment);
    ChangeManager apm = AdfFacesContext.getCurrentInstance().getChangeManager();
    apm.addDocumentChange(fc, uic, change);
}

private static final String _IMAGE_MARK_UP =
"<af:objectImage id='oi3' height='100' width='120' " +
    "source='http://www.somewhere.com/someimage.jpg' " +
    "xmlns:af='http://xmlns.oracle.com/adf/faces'/>";

private static DocumentFragment _createDocumentFragment(
    String markup)
{
    // prepend XML declaration
    markup = "<?xml version = '1.0' encoding = 'ISO-8859-1'?>" + markup;
    DocumentBuilderFactory factory = DocumentBuilderFactory.newInstance();
    factory.setNamespaceAware(true);
    factory.setValidating(false);
    DocumentBuilder builder;
    try
    {
        builder = factory.newDocumentBuilder();
    }
    catch (ParserConfigurationException pce)
    {
        _LOG.log(Level.WARNING, "Unable to get XML Parser:", pce);
        return null;
    }
    try
    {
        // use a version explicitly with ISO-8859-1 instead
        byte[] markupBytes = markup.getBytes();
        Document newDoc = builder.parse(new ByteArrayInputStream(markupBytes));
        DocumentFragment fragment = newDoc.createDocumentFragment();
        // add the document's root element to the fragment
        fragment.appendChild(newDoc.getDocumentElement());
        return fragment;
    }
    catch (SAXException se)
    {
        _LOG.log(Level.WARNING, "Unable to parse markup:" + markup, se);
        return null;
    }
    catch (IOException ioe)
    {
        _LOG.log(Level.WARNING, "IO Problem with markup:" + markup, ioe);
    }
}
```

```

    return null;
}
}

```

6. Register the user customizations in the `adf-config.xml` file, as documented in [Section 35.3, "Configuring User Customizations."](#) If the custom changes are of any type other than `AttributeDocumentChange`, you will need to manually edit the `adf-config.xml` file and indicate that all changes are allowed for the component, as shown in [Example 35-7](#).

**Example 35-7 Custom Registration in `adf-config.xml`**

```

<tag name="inputText">
  <attribute name="label">
    <persist-changes>true</persist-changes>
  </attribute>
  <persist-operations>ALL</persist-operations>
</tag>

```

## 35.6 Creating Implicit Change Persistence in Custom Components

When you create a custom component, you may decide that you want certain attribute values on that component to be persisted whenever change persistence is enabled in an application. Setting implicit change on a custom component is similar to setting explicit change persistence on existing components. You add code that executes the actual persistence, but instead of you placing that code on a managed bean, that code can be handled directly by the component class. If your component's attribute values are synchronized with the server using events, then you can use the broadcast method to persist the changes. If the attribute value that you want to persist does not use events, then you need to add code in the renderer and component class.

### 35.6.1 How to Set Implicit Change Persistence For Attribute Values that Use Events

When an attribute value uses events, you need to add code to the component class.

**To set implicit change persistence for attribute values that use events:**

1. Open the custom component class java file.
2. Add code to the broadcast method that will use the specialized class to create a new `ComponentChange` object and then call the `ChangeManager` to add the change.

[Example 35-8](#) shows the code added to the `UIXShowDetail` class that persists a change to the `disclosed` attribute. In this case, the `AttributeComponentChange` class is used.

**Example 35-8 Persisting Change from a Component Class**

```

public class UIXShowDetail extends UIXComponentBase
{
    ...
    public void broadcast(FacesEvent event) throws AbortProcessingException
    {
        super.broadcast(event);
        ...
        if (event instanceof DisclosureEvent)
        {

```

```

        boolean isDisclosed = ((DisclosureEvent) event).isExpanded();
        setDisclosed(isDisclosed);
        //Record a Change for 'disclosed' attribute
        AttributeComponentChange aa =
            new AttributeComponentChange('disclosed', isDisclosed ? Boolean.TRUE :
Boolean.FALSE);
        AdfFacesContext adfContext = AdfFacesContext.getCurrentInstance();
        adfContext.getChangeManager().addComponentChange(getFacesContext(), this,
aa);
        ...
    }
}
...

```

### 35.6.2 How to Set Implicit Change Persistence For Other Attribute Values

When an attribute does not use events, you need to place code in the component's renderer class.

#### To set implicit change persistence for other attribute values:

1. Open the custom component's render class java file.
2. Use the `findTypeConstants` method, which takes a `ClientMetadata` instance and use the `addPersistedProperty` method to mark certain properties as persisted. [Example 35–9](#) shows a code snippet from the renderer class used for the ADF Faces `PanelSplitter` component, which implicitly persists the `splitterPosition` attribute value.

#### **Example 35–9 Method in Component Renderer Class to Implicitly Persist Changes**

```

// Code snippet from PanelSplitterRenderer.java
protected void findTypeConstants(
    FacesBean.Type type,
    ClientMetadata metadata)
{
    super.findTypeConstants(type, metadata);
    metadata.addRequiredProperty(
        _orientationKey = type.findKey("orientation"));
    metadata.addRequiredProperty(
        _positionedFromEndKey = type.findKey("positionedFromEnd"));
    metadata.addRequiredProperty(
        _disabledKey = type.findKey("disabled"));
    metadata.addRequiredProperty(
        _splitterPositionKey = type.findKey("splitterPosition"));
    metadata.addPersistedProperty(_splitterPositionKey);
}

```

3. In the JavaScript component peer class, define the attribute value to be persisted, using the `setProperty` function. This function needs to be invoked with the attribute name (as defined in the renderer in the previous step), the value, and "true", meaning the value of the attribute will be set. [Example 35–10](#) shows a code snippet from the `panelSplitter` class that sets the splitter position.

#### **Example 35–10 Method in Component Class to Implicitly Persist Changes**

```

// Code snippet from AdfDhtmlPanelSplitterPeer.js file where we set the
splitter position

```

```
var component = this.getComponent();  
component.setProperty("splitterPosition",position, true);  
// position is the value to be set
```

---

---

## Deploying Fusion Web Applications

This chapter describes how to deploy ADF applications to a target application server. It describes how to create deployment profiles, how to create deployment descriptors, and how to load ADF runtime libraries. It includes instructions for running an application in JDeveloper using the Integrated WebLogic Server, as well as deploying to a standalone Oracle WebLogic Server or IBM WebSphere Application Server.

This chapter includes the following sections:

- [Section 36.1, "Introduction to Deploying Fusion Web Applications"](#)
- [Section 36.2, "Running an ADF Application in Integrated WebLogic Server"](#)
- [Section 36.3, "Preparing the Application"](#)
- [Section 36.4, "Deploying the Application"](#)
- [Section 36.5, "Postdeployment Configuration"](#)
- [Section 36.6, "Testing the Application and Verifying Deployment"](#)

### 36.1 Introduction to Deploying Fusion Web Applications

Deployment is the process of packaging application files as an archive file and transferring this file to a target application server. You can use JDeveloper to deploy ADF applications directly to the application server (such as Oracle WebLogic Server or IBM WebSphere Application Server), or indirectly to an archive file as the deployment target, and then install this archive file to the target server. For application development, you can also use JDeveloper to run an application in Integrated WebLogic Server. JDeveloper supports deploying to server clusters. You cannot use JDeveloper to deploy to individual Managed Servers within a cluster.

[Figure 36-1](#) shows the flow diagram that describes the overall deployment process. Note that preparing the target application server for deployment by installing the ADF runtime is described in the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

**Figure 36–1** Deployment Overview Flow Diagram

---

**Note:** Normally, you use JDeveloper to deploy applications for development and testing purposes. If you are deploying ADF applications for production purposes, you can use Enterprise Manager or scripts to deploy to production-level application servers.

For more information about deployment to later-stage testing or production environments, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

---

ADF Java EE applications are based on standardized, modular components and can be deployed to the following application servers:

- Oracle WebLogic Server
 

Oracle WebLogic Server provides a complete set of services for those modules and handles many details of application behavior automatically, without requiring programming. For information about which versions of Oracle WebLogic Server are compatible with JDeveloper, see the certification information website at <http://www.oracle.com/technetwork/developer-tools/jdev/documentation/index.html>.
- IBM WebSphere Application Server

For information about which versions of IBM WebSphere are compatible, see the *Oracle Fusion Middleware Third-Party Application Server Guide*.

Deploying a Fusion web application is slightly different from deploying a standard Java EE application. JSF applications that contain ADF Faces components have a few additional deployment requirements:

- ADF Faces requires Sun's JSF Reference Implementation 1.2 and MyFaces 1.0.8 (or later).

You can use JDeveloper to:

- Run applications in Integrated WebLogic Server

You can run and debug applications using Integrated WebLogic Server and then deploy to a standalone WebLogic Server or to WebSphere.

Integrated IBM WebSphere Application Server is not supported for this release.

- Deploy directly to the standalone application server

You can deploy applications directly to the standalone application server by creating a connection to the server and choosing the name of that server as the deployment target.

- Deploy to an archive file

You can deploy applications indirectly by choosing an EAR file as the deployment target. The archive file can subsequently be installed on a target application server.

The StoreFront module of the Fusion Order Demo application demonstrates the use of the Fusion web application technology stack to create transaction-based web applications. You can run the StoreFront module of the Fusion Order Demo application in JDeveloper using Integrated WebLogic Server. You cannot run the Fusion Order Demo module in JDeveloper. You must deploy the Fusion Order Demo application to a SOA-enabled Oracle WebLogic Server. For more information about the StoreFront module and the Fusion Order Demo application, see [Section 2.3, "Running the Fusion Order Demo Application StoreFront Module."](#)

### 36.1.1 Developing Applications with Integrated WebLogic Server

If you are developing an application in JDeveloper and you want to run the application in Integrated WebLogic Server, you do not need to perform the tasks required for deploying directly to Oracle WebLogic Server or to an archive file. JDeveloper has a default connection to Integrated WebLogic Server and does not require any deployment profiles or descriptors. Integrated WebLogic Server has a preconfigured domain that includes the ADF libraries, as well as the `-Djps.app.credential.override.allowed=true` setting, both of these are required to run ADF applications. You can run an application by choosing **Run** from the JDeveloper main menu.

You debug the application using the features described in [Chapter 31, "Testing and Debugging ADF Components."](#)

### 36.1.2 Developing Applications to Deploy to Standalone Application Servers

Typically, for deployment to standalone application servers, you test and develop your application by running it in Integrated WebLogic Server. You can then test the application further by deploying it to testing Oracle WebLogic Server (in development mode) or to IBM WebSphere Application Server to more closely simulate the production environment.

In general, you use JDeveloper to prepare the application or project for deployment by:

- Creating a connection to the target application server
- Creating deployment profiles (if necessary)
- Creating deployment descriptors (if necessary, and that are specific to the application server)
- Updating `application.xml` and `web.xml` to be compatible with the application (if required)
- Enabling the application for Real User Experience Insight (RUEI) in `web.xml` (if desired)
- Migrating application-level security policy data to a domain-level security policy store
- Configuring the Oracle Single Sign-On (Oracle SSO) service and properties in the domain `jps-config.xml` file when you intend the web application to run using Oracle SSO

You must already have an installed application server. For Oracle WebLogic Server, you can use the Oracle 11g Installer or the Oracle Fusion Middleware 11g Application Developer Installer to install one. For other applications servers, follow the instructions in the applications server documentation to obtain and install the server.

You also must prepare the application server for ADF application deployment. For more information, see the "Preparing the Standalone Application Server for Deployment" section of the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

- Installing the ADF runtime into the application server installation:
  - For WebLogic Server
    - If you installed Oracle WebLogic Server together with JDeveloper using the Oracle 11g Installer for JDeveloper, the ADF runtime should already be installed.
    - If the ADF runtime is not installed and you want to use Oracle Enterprise Manager to manage standalone ADF applications (which are applications without Oracle SOA Suite or Oracle WebCenter Portal components), use the Oracle Fusion Middleware 11g Application Developer Installer. This installer will install the necessary Oracle Enterprise Manager components into the Oracle WebLogic installation.
    - If the ADF runtime is not installed and you do not need to install Enterprise Manager, use the Oracle 11g Installer for JDeveloper.
  - For WebSphere
    - \* Use the Oracle Fusion Middleware 11g Application Developer Installer to install the ADF runtime and the necessary Oracle Enterprise Manager components into the WebSphere installation. For information about installing WebSphere, see the *Oracle Fusion Middleware Third-Party Application Server Guide*.
- Extending Oracle WebLogic Server domains or WebSphere Cells to be ADF-compatible using the ADF runtime

- For WebLogic, setting the Oracle WebLogic Server credential store overwrite setting as required (`-Djps.app.credential.override.allowed=true` setting)
- Creating a global JDBC data source for applications that require a connection to a data source

After the application and application server have been prepared, you can:

- Use JDeveloper to:
  - Directly deploy to the application server using the deployment profile and the application server connection.
  - Deploy to an EAR file using the deployment profile. For ADF applications, WAR and MAR files can be deployed only as part of an EAR file.
- Use Enterprise Manager, scripts, or the application's administration tool to deploy the EAR file created in JDeveloper. For more information, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

## 36.2 Running an ADF Application in Integrated WebLogic Server

JDeveloper is installed with Integrated WebLogic Server which you can use to test and develop your application. For most development purposes, Integrated WebLogic Server will suffice. When your application is ready to be tested, you can select the run target and then choose the **Run** command from the main menu.

---

---

**Note:** The first time you run an application in Integrated WebLogic Server, the Configure Default Domain dialog appears for you to define an administrative password for the new domain.

---

---

When you run the application target, JDeveloper detects the type of Java EE module to deploy based on artifacts in the projects and workspace. JDeveloper then creates an in-memory deployment profile for deploying the application to Integrated WebLogic Server. JDeveloper copies project and application workspace files to an "exploded EAR" directory structure. This file structure closely resembles the EAR file structure that you would have if you were to deploy the application to an EAR file. JDeveloper then follows the standard deployment procedures to register and deploy the "exploded EAR" files into Integrated WebLogic Server. The "exploded EAR" strategy reduces the performance overhead of packaging and unpacking an actual EAR file.

In summary, when you select the run target and run the application in Integrated WebLogic Server, JDeveloper:

- Detects the type of Java EE module to deploy based on the artifacts in the project and application
- Creates a deployment profile in memory
- Copies project and application files into a working directory with a file structure that would simulate the "exploded EAR" file of the application.
- Performs the deployment tasks to register and deploy the simulated EAR into Integrated WebLogic Server
- Automatically migrates identities, credentials, and policies

Later on, if you plan to deploy the application to a standalone WebLogic Server instance, you will need to migrate this security information. For more information, see [Section 36.3.4, "How to Deploy Applications with ADF Security Enabled."](#)

---

---

**Note:** JDeveloper ignores the deployment profiles that were created for the application when you run the application in Integrated WebLogic Server.

---

---

The application will run in the base domain in Integrated WebLogic Server. This base domain has the same configuration as a base domain in a standalone WebLogic Server instance. In other words, this base domain will be the same as if you had used the Oracle Fusion Middleware Configuration Wizard to create a base domain with the default options in a standalone WebLogic Server instance.

JDeveloper will extend this base domain with the necessary domain extension templates, based on the JDeveloper technology extensions. For example, if you have installed JDeveloper Studio, JDeveloper will automatically configure the Integrated WebLogic Server environment with the ADF runtime template (JRF Fusion Middleware runtime domain extension template).

You can explicitly create a default domain for Integrated WebLogic Server. You can use the default domain to run and test your applications. Open the Application Server Navigator, right-click **IntegratedWebLogicServer** and choose **Create Default Domain**.

## 36.2.1 How to Run an Application in Integrated WebLogic Server

You can test an application by running it in Integrated WebLogic Server. You can also set breakpoints and then run the application within the ADF Declarative Debugger.

### To run an application in Integrated WebLogic Server:

1. In the Application Navigator, select the project, unbounded task flow, JSF page, or file as the run target.
2. Right-click the run target and choose **Run** or **Debug**.

The Configure Default Domain dialog displays the first time you run the application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

## 36.2.2 How to Run an Application with Metadata in Integrated WebLogic Server

When an application is running in Integrated WebLogic Server, the Metadata Archive (MAR) profile itself will not be deployed to a repository, but a simulated MDS repository will be configured for the application that reflects the metadata information contained in the MAR. This metadata information is simulated, and the application runs based on this location in source control.

Any customizations or documents created by the application that are not configured to be stored in other MDS repositories are written to this simulated MDS repository directory. For example, if you customize an object, the customization is written to the simulated MDS repository. If you execute code that creates a new metadata object, then this new metadata object is also written to the same location in the simulated MDS repository. You can keep the default location for this directory (`ORACLE_HOME\jdeveloper\systemXX.XX\o.mds.dt\adrs\Application\AutoGenera`

tedMar\mds\_adrs\_writedir), or you can set it to a different directory. You also have the option to preserve this directory across different application runs, or to delete this directory before each application run.

If your workspace has different working sets, only the metadata from the projects defined in the working set and their dependent projects will be included in the MAR. You can view and change a project's dependencies by right-clicking the project in the Application Navigator, choosing **Project Properties**, and then selecting **Dependencies**. For instance, an application may have several projects but `workingsetA` is defined to be `viewController2` and `viewController5`; and `viewController5` has a dependency on `modelproject1`. When you run or debug `workingsetA`, only the metadata for `viewController2`, `viewController5`, and `modelproject1` will be included in the MAR for deployment.

**Before you begin:**

There should already be a MAR profile, either generated automatically by JDeveloper, or manually generated by a user.

**To deploy the MAR profile to Integrated WebLogic Server:**

1. In the Application Navigator, right-click the application and choose **Application Properties**.
2. In the Application Properties dialog, expand **Run** and choose **MDS**.
3. In the Run MDS page:
  - Select the MAR profile from the **MAR Profile** dropdown list
  - Enter a directory path in **Override Location** if you want to customize the location of the simulated MDS repository.
  - Select the **Directory Content** option. You can choose to preserve the customizations across application runs or delete customizations before each run.

Select the MAR profile from the **MAR Profile** dropdown list. [Figure 36–2](#) shows **Demometadata1** selected as the MAR profile.

**Figure 36–2** Setting the Run MDS options

### 36.3 Preparing the Application

Before you deploy an ADF application to a standalone application server, you must perform prerequisite tasks within JDeveloper to prepare the application for deployment.

Figure 36–3 shows the process flow to prepare the application for deployment. After the application has been prepared and the application server has been prepared as described in the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*, you can proceed to deploy the application as described in Section 36.4, "Deploying the Application."

**Figure 36–3 Preparing the Application for Deployment Flow Diagram**

### 36.3.1 How to Create a Connection to the Target Application Server

You can deploy applications to the application server via JDeveloper application server connections.

If your application involves customization using MDS, you should register your MDS repository with the application server:

- **WebLogic:** register the MDS into the WebLogic Domain  
For more information about registering MDS in WebSphere, see the *Oracle Fusion Middleware Administrator's Guide*.
- **WebSphere:** register the MDS into the WebSphere Cell  
For more information about registering MDS in WebSphere, see the *Oracle Fusion Middleware Third-Party Application Server Guide*.

#### To create a connection to an application server:

1. Launch the Application Server Connection wizard.

You can:

- In the Application Server Navigator, right-click **Application Servers** and choose **New Application Server Connection**.
- In the New Gallery, expand **General**, select **Connections** and then **Application Server Connection**, and click **OK**.

- In the Resource Palette, choose **New > New Connections > Application Server**.
2. In the Create AppServer Connection dialog Usage page, select **Standalone Server**.
  3. In the Name and Type page, enter a connection name.
  4. In the **Connection Type** dropdown list, choose:
    - **WebLogic 10.3** to create a connection to Oracle WebLogic Server
    - **WebSphere Server 7.x** to create a connection to IBM WebSphere Server
  5. Click **Next**.
  6. On the Authentication page, enter a user name and password for the administrative user authorized to access the application server.
  7. Click **Next**.
  8. On the Configuration page, enter the information for your server:

For WebLogic:

- The Oracle WebLogic host name is the name of the WebLogic Server instance containing the TCP/IP DNS where your application (.jar, .war, .ear) will be deployed.
- In the **Port** field, enter a port number for the Oracle WebLogic Server instance on which your application (.jar, .war, .ear) will be deployed.  
If you don't specify a port, the port number defaults to 7001.
- In the **SSL Port** field, enter an SSL port number for the Oracle WebLogic Server instance on which your application (.jar, .war, .ear) will be deployed.  
Specifying an SSL port is optional. It is required only if you want to ensure a secure connection for deployment.  
If you don't specify an SSL port, the port number defaults to 7002.
- Select **Always Use SSL** to connect to the Oracle WebLogic Server instance using the SSL port.
- Optionally enter a **WebLogic Domain** only if Oracle WebLogic Server is configured to distinguish nonadministrative server nodes by name.

For WebSphere:

- In the **Host Name** field, enter the name of the WebSphere server containing the TCP/IP DNS where your Java EE applications (.jar, .war, .ear) are deployed. If no name is entered, the name defaults to localhost.
- In the **SOAP Connector Port** field, enter the port number. The host name and port are used to connect to the server for deployment. The default SOAP connector port is 8879.
- In the **Server Name** field, enter the name assigned to the target application server for this connection.
- In the **Target Node** field, enter the name of the target node for this connection. A node is a grouping of Managed Servers. The default is machineNode01, where machine is the name of the machine the node resides on
- In the **Target Cell** field, enter the name of the target cell for this connection. A cell is a group of processes that host runtime components. The default is

machineNode01Cell, where machine is the name of the machine the node resides on.

- In the **Wsadmin script location** field, enter, or browse to, the location of the wsadmin script file to be used to define the system login configuration for your IBM WebSphere application server connection. Note that you should not use the wsadmin files from the `ORACLE_HOME/oracle_common/common/bin` directory, which are not the correct version. The default location is `websphere-home/bin/wsadmin.sh` for Unix/Linux and `websphere-home/bin/wsadmin.bat` for Windows.

9. Click **Next**.

10. If you have chosen WebSphere, the JMX page appears. On the JMX page, enter the JMX information (optional):

---

---

**Note:** JMX configuration is optional and is not required for connecting to the WebSphere Application Server.

---

---

- Select **Enable JMX** for this connection to enable JMX.
- In the **RMI Port** field, enter the port number of WebSphere's RMI connector port. The default is 2809.
- In the **WebSphere Runtime Jars Location** field, enter or browse to the location of the WebSphere runtime JARs.
- In the **WebSphere Properties Location (for secure MBEAN access)** field, enter or browse to the location of the file that contains the properties for the security configuration and the mbeans that are enabled. This field is optional.

11. Click **Next**.

12. If the SSL Signer Exchange Prompt dialog appears, click **Y**.

13. On the Test page, click **Test Connection** to test the connection.

JDeveloper performs several types of connections tests. The JSR-88 test must pass for the application to be deployable. If the test fails, return to the previous pages of the wizard to fix the configuration.

14. Click **Finish**.

### 36.3.2 How to Create Deployment Profiles

A *deployment profile* defines the way the application is packaged into the archive that will be deployed to the target environment. The deployment profile:

- Specifies the format and contents of the archive file that will be created
- Lists the source files, deployment descriptors, and other auxiliary files that will be packaged
- Describes the type and name of the archive file to be created
- Highlights dependency information, platform-specific instructions, and other information

You need a WAR deployment profile for each web view-controller project that you want to deploy in your application. If you want to package seeded customizations or place base metadata in the MDS repository, you need an application-level metadata archive (MAR) deployment profile as well. For more information about seeded

customizations, see [Chapter 34, "Customizing Applications with MDS."](#) If the application has customization classes, you need a JAR file for those classes and you need to add that JAR when you create the EAR file. Finally, you need an application-level EAR deployment profile and you must select the projects you want to include from a list, such as WAR and MAR profiles and customization classes JAR files. When the application is deployed, the EAR file will include all the projects that were selected in the deployment profile.

---

---

**Note:** If you create your project or application using the Fusion Web Application (ADF) template, JDeveloper automatically creates default WAR, EAR, MAR, and JAR deployment profiles. Typically, you would not need to edit or create deployment profiles manually.

---

---

For ADF applications, you can deploy the application only as an EAR file. The WAR and MAR files that are part of the application should be included in the EAR file when you create the deployment profile.

---

---

**Note:** If your ADF application has business services that you want to deploy, you will need to create a Business Component Service Interface deployment profile and deploy it. For more information about business services, see [Section 11.2.22, "How to Deploy Web Services to Oracle WebLogic Server."](#)

---

---

### 36.3.2.1 Adding Customization Classes into a JAR

If your application has customization classes, create a JAR that contains only these customization classes. When you create your EAR, you can add the JAR to the EAR assembly. And when you create WAR profiles for your web projects, you must make sure they don't include the customization classes JAR.

#### Before you begin:

Make sure that your project has customization classes. You do not need to perform this procedure if the application does not have customization classes. For more information about customization classes, see [Section 34.2.1, "How to Create Customization Classes."](#)

#### To add customization classes into a JAR:

1. In the Application Navigator, right-click the data model project that contains the customization classes you want to create a JAR for, and choose **New**.
2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **JAR File**, and click **OK**.

Alternatively, if you want to create a shared library, select **Shared Library JAR File** from the list of profile types, and click **OK**.

---

---

**Note:** If you don't see **Deployment Profiles** in the **Categories** tree, click the **All Technologies** tab.

---

---

3. In the Create Deployment Profile -- JAR File dialog, enter a name for the project deployment profile (for example, CCArchive) and click **OK**.
4. In the Edit JAR Deployment Profile Properties dialog, select **JAR Options**.

5. Enter the location for the JAR file.
6. Expand **Files Groups > Project Output > Filters**.
7. In the **Files** tab, select the customization classes you want to add to the JAR file. If you are using a `customization.properties` file, it needs to be in the same class loader as the JAR file. You can select the `customization.properties` file to package it along with the customization classes in the same JAR.
8. Click **OK** to exit the Edit JAR Deployment Profile Properties dialog.
9. Click **OK** again to exit the Project Properties dialog.
10. In the Application Navigator, right-click the project containing the JAR deployment profile, and choose **Deploy > deployment profile > to JAR file**.

---

**Note:** If this is the first time you deploy to a JAR from this deployment profile, you choose **Deploy > deployment profile** and select **Deploy to JAR** in the wizard.

---

### 36.3.2.2 Creating a WAR Deployment Profile

You will need to create a WAR deployment profile for each web-based project you want to package into the application. Typically, the WAR profile will include the dependent model projects it requires.

#### Before you begin:

Create web-based projects. If you used the Fusion Web Application (ADF) template, you should already have a default WAR deployment profile.

#### To create WAR deployment profiles for an application:

1. In the Application Navigator, right-click the web project that you want to deploy and choose **New**.

You will create a WAR profile for each web project.

2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **WAR File**, and click **OK**.

If you don't see **Deployment Profiles** in the **Categories** tree, click the **All Technologies** tab.

3. In the Create Deployment Profile -- WAR File dialog, enter a name for the project deployment profile and click **OK**.
4. In the Edit WAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.

- If you have customization classes in your application, they must be loaded from the EAR-level application class loader and not from the WAR. You will later add these customization classes to the EAR.

By default, customization classes are added to the model project's WAR class path. So for each WAR, you must exclude the customization classes.

If you created your customization classes in an extension project of the application, be sure to deselect any customization class archive on the **Library Dependencies** page of the WAR deployment profile for each view controller project.

If you created your customization classes in the model project of the application, deselect any customization classes on the **File Groups > WEB-INF/classes > Filters** page of the WAR deployment profile for each view controller project. If you are using a `customization.properties` file, it should also be deselected.

- You might also want to change the Java EE web context root setting (choose **General** in the left pane).

By default, when **Use Project's Java EE Web Context Root** is selected, the associated value is set to the project name, for example, `Application1-Project1-context-root`. You need to change this if you want users to use a different name to access the application.

If you are using custom JAAS LoginModule for authentication with JAZN, the context root name also defines the application name that is used to look up the JAAS LoginModule.

5. Click **OK** to exit the Deployment Profile Properties dialog.
6. Click **OK** again to exit the Project Properties dialog.
7. Repeat Steps 1 through 7 for all web projects that you want to deploy.

### 36.3.2.3 Creating a MAR Deployment Profile

If you have seeded customizations or base metadata that you want to place in the MDS repository, you need to create a MAR deployment profile.

The namespace configuration under `<mds-config>` for MAR content in the `adf-config.xml` file is generated based on your selections in the MAR Deployment Profile Properties dialog.

Although uncommon, an enterprise application (packaged in an EAR) can contain multiple web application projects (packaged in multiple WARs), but the metadata for all these web applications will be packaged into a single metadata archive (MAR). The metadata contributed by each of these individual web applications can be global (available for all the web applications) or local to that particular web application.

To avoid name conflicts for metadata with global scope, make sure that all metadata objects and elements have unique names across all the web application projects that forms part of the enterprise application.

JDeveloper creates an auto-generated MAR when the **Enable User Customizations** and **Across Sessions using MDS** options are selected in the ADF View page of the Project Properties dialog or when you explicitly specify the deployment target directory in the `adf-config.xml` file.

#### Before you begin:

Create an MDS repository for your customization requirements to deploy metadata using the MAR deployment profile. If you used the Fusion Web Application (ADF) template, you should already have a default MAR deployment profile.

#### To create a MAR deployment profile:

1. In the Application Navigator, right-click the application and choose **New**.  
You will create a MAR profile if you want to include customizations.
2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **MAR File**, and click **OK**.

If you don't see **Deployment Profiles** in the **Categories** tree, click the **All Technologies** tab.

3. In the Create Deployment Profile -- MAR File dialog, enter a name for the MAR deployment profile and click **OK**.
4. In the Edit MAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane.

Figure 36-4 shows a sample **User Metadata** directory tree.

**Figure 36-4** Selecting Items for the MAR Deployment Profiles

Note the following important points:

- To include all customizations, you need only create a file group with the desired directories.
- ADF Model and ADF view directories are added by default. No further action is required to package the ADF Model and ADF view customizations into the MAR. ADF view content is added to **HTML Root dir**, while ADF Model and Business Components content is added to **User Metadata**.
- To include the base metadata in the MDS repository, you need to explicitly select these directories in the dialog.

When you select the base document to be included in the MAR, you also select specific packages. When you select one package, all the documents (including subpackages) under that package will be used. When you select a package, you cannot deselect individual items under that package.

- To include files from other than ADF Model and ADF view, users should create a new file group under **User Metadata** with the desired directories and explicitly select the required content in the Directories page.

- If a dependent ADF library JAR for the project contains seeded customizations, they will automatically be added to the MAR during MAR packaging. They will not appear in the MAR profile.
  - If ADF Library customizations were created in the context of the consuming project, those customizations would appear in the MAR profile dialog by default.
5. Click **OK** to exit the Deployment Profile Properties dialog.
  6. Click **OK** again to exit the Application Properties dialog.

#### 36.3.2.4 Creating an Application-Level EAR Deployment Profile

The EAR file contains all the necessary application artifacts for the application to run in the application server. For more information about the EAR file, see [Section 36.4.3, "What You May Need to Know About EAR Files and Packaging."](#)

##### Before you begin:

Add classes into a JAR file, as described in [Section 36.3.2.1, "Adding Customization Classes into a JAR."](#) Create the WAR deployment profiles, as described in [Section 36.3.2.2, "Creating a WAR Deployment Profile."](#)

If you used the Fusion Web Application (ADF) template, you should already have a default EAR deployment profile.

##### To create an EAR deployment profile for an application:

1. In the Application Navigator, right-click the application and choose **New**.  
You will create an EAR profile for the application.
2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **EAR File**, and click **OK**.  
If you don't see **Deployment Profiles** in the Categories tree, click the **All Technologies** tab.
3. In the Create Deployment Profile -- EAR File dialog, enter a name for the application deployment profile and click **OK**.
4. In the Edit EAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.

Be sure that you:

- Select **Application Assembly** and then in the **Java EE Modules** list, select all the project profiles that you want to include in the deployment, including any **WAR** or **MAR** profiles.
- Select **Platform**, and select the application server you are deploying to, and then select the target application connection from the **Target Connection** dropdown list.

---

**Note:** If you are using custom JAAS LoginModule for authentication with JAZN, the context root name also defines the application name that is used to look up the JAAS LoginModule.

---

5. If you have customization classes in your application, configure these classes so that they load from the EAR-level application class loader.

- a. In the Edit EAR Deployment Profile Properties dialog, select **Application Assembly**.
- b. Select the JAR deployment profile that contains the customization classes, and enter `lib` in the **Path in EAR** field at the bottom of the dialog.

---

**Note:** You should have created this JAR as described in [Section 36.3.2.1, "Adding Customization Classes into a JAR."](#)

---

The JAR file containing the customization classes is added to the EAR file's `lib` directory.

---

**Note:** If you have customization classes in your application, you must also make sure they are not loaded from the WAR. By default, customization classes that are added to the model project's Libraries & Classpath are packaged to the WAR class path.

To make sure customization classes from an extension project are not duplicated in the WAR, be sure to deselect any customization class archive on the **Library Dependencies** page for the WAR.

If you created your customization classes in the model project of the consuming application, deselect any customization classes on the **File Groups > WEB-INF/classes > Filters** page for the WAR.

---

6. Click **OK** to exit the Deployment Profile Properties dialog.
7. Click **OK** again to exit the Application Properties dialog.

---

**Note:** To verify that your customization classes are put correctly in the EAR class path, you can deploy the EAR profile to file system. Then you can examine the EAR to make sure that the customization class JAR is available in the EAR class path (the `EAR/lib` directory) and not available in the WAR class path (the `WEB-INF/lib` and `WEB-INF/classes` directories).

---

### 36.3.2.5 Delivering Customization Classes as a Shared Library

As an alternative to adding your customization classes to the EAR, as described in [Section 36.3.2.4, "Creating an Application-Level EAR Deployment Profile,"](#) you can also include the customization classes in the consuming application as a shared library.

#### Before you begin:

With the application containing the customization classes open in JDeveloper in the Default role, use the procedure described in [Section 36.3.2.1, "Adding Customization Classes into a JAR,"](#) making sure that you select **Shared Library JAR File** as the type of archive to create.

---

**Note:** This procedure describes how to create and use a shared library if you are deploying to Oracle Weblogic Server.

---

**To create and use a shared library for your customization classes:**

1. In the Application Navigator, right-click the customization classes project, and choose **Deploy > deployment-profile**.
2. In the Deploy wizard, select **Deploy to a Weblogic Application Server** and click **Next**.
3. Select the appropriate application server, and click **Finish**.  
This makes the shared library available on the application server. You must now add a reference to the shared library from the consuming application.
4. Open the application you want to customize in JDeveloper in the Default role.
5. In the Application Resources panel of the Application Navigator, double-click the `weblogic-application.xml` file to open it.
6. In the overview editor, click the Libraries tab.
7. In the **Shared Library References** section, click the add icon.
8. In the **Library Name** field of the newly created row in the **Shared Library References** table, enter the name of the customization classes shared library you deployed, and save your changes.

**36.3.2.6 Viewing and Changing Deployment Profile Properties**

After you have created a deployment profile, you can view and change its properties.

**To view, edit, or delete a project's deployment profile:**

1. In the Application Navigator, right-click the project and choose **Project Properties**.
2. In the Project Properties dialog, click **Deployment**.  
The **Deployment Profiles** list displays all profiles currently defined for the project.
3. In the list, select a deployment profile.
4. To edit or delete a deployment profile, click **Edit** or **Delete**.

**36.3.3 How to Create and Edit Deployment Descriptors**

*Deployment descriptors* are server configuration files that define the configuration of an application for deployment and that are deployed with the Java EE application as needed. The deployment descriptors that a project requires depend on the technologies the project uses and on the type of the target application server. Deployment descriptors are XML files that can be created and edited as source files, but for most descriptor types, JDeveloper provides dialogs or an overview editor that you can use to view and set properties. If you cannot edit these files declaratively, JDeveloper opens the XML file in the source editor for you to edit its contents.

In addition to the standard Java EE deployment descriptors (for example, `application.xml` and `web.xml`), you can also have deployment descriptors that are specific to your target application server. For example, if you are deploying to Oracle WebLogic Server, you can also have `weblogic.xml`, `weblogic-application.xml`, and `weblogic-ejb-jar.xml`.

For WebLogic Server, make sure that the application EAR file includes a `weblogic-application.xml` file that contains a reference to `adf.oracle.domain`, and that it includes an `ADFApplicationLifecycleListener` to clean up application resources between

deployment and undeployment actions. [Example 36–1](#) shows a sample `weblogic-application.xml` file.

**Example 36–1 Sample `weblogic-application.xml`**

```
<weblogic-application xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
  xsi:schemaLocation="http://www.bea.com/ns/weblogic/weblogic-application.xsd"
  xmlns="http://www.bea.com/ns/weblogic/weblogic-application">
  <listener>
    <listener-class>oracle.adf.share.weblogic.listeners.
      ADFApplicationLifecycleListener</listener-class>
  </listener>
  <listener>
    <listener-class>oracle.mds.lcm.weblogic.WLLifecycleListener</listener-class>
  </listener>
  <library-ref>
    <library-name>adf.oracle.domain</library-name>
  </library-ref>
</weblogic-application>
```

If you are deploying web services, you may need to modify your `weblogic-application.xml` and `web.xml` files as described in [Section 11.2.22, "How to Deploy Web Services to Oracle WebLogic Server."](#)

If you want to enable the application for Real User Experience Insight (RUEI) monitoring, you must add a parameter to the `web.xml` file, as described in [Section 36.3.3.5, "Enabling the Application for Real User Experience Insight."](#)

During deployment to WebLogic, the application's security properties are written to the `weblogic-application.xml` file to be deployed with the application in the EAR file. For more information, see [Section 30.8.2, "What Happens When You Configure Security Deployment Options."](#)

Because the application server runs on Java EE 5, you may need to modify the `application.xml` and `web.xml` files to be compatible with the application server.

For IBM WebSphere, the deployment descriptors are created at runtime and cannot be edited. Some of the relevant descriptors are shown in [Table 36–1](#).

**Table 36–1 IBM WebSphere Deployment Descriptors**

WebSphere	Action
<code>ibm-application-bnd.xml</code>	This references the security role just mapped in <code>application.xml</code> and maps it to the well-known name "AllAuthenticatedUsers". Similar to <code>weblogic.xml</code> for WebLogic Server. Maps the "valid-users" JEE security role to the well-known name "Users".
<code>application.xml</code>	A standard Java EE deployment description, but it is also used to populate a security mapping for the "valid-users" role (which is defined in <code>web.xml</code> when using ADF Security).
<code>&lt;EAR_ROOT&gt;/META-INF/manifest.mf</code>	References application-shared libraries such as <code>adf.oracle.domain</code> .
<code>&lt;EAR_ROOT&gt;/META-INF/deployment.xml</code>	References WAR-shared libraries such as <code>adf.oracle.domain.webapp</code> .

### 36.3.3.1 Creating Deployment Descriptors

JDeveloper automatically creates many of the required deployment descriptors for you. If they are not present, or if you need to create additional descriptors, you can use JDeveloper to create them.

#### Before you begin:

Check to see whether JDeveloper has already generated deployment descriptors.

#### To create a deployment descriptor:

1. In the Application Navigator, right-click the project for which you want to create a descriptor and choose **New**.
2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then a descriptor type, and click **OK**.

If you can't find the item you want, make sure that you chose the correct project, and then choose the **All Technologies** tab or use the **Search** field to find the descriptor. If the item is not enabled, check to make sure that the project does not already have a descriptor of that type. A project is allowed only one instance of a descriptor.

JDeveloper starts the Create Deployment Descriptor wizard and then opens the file in the overview or source editor, depending on the type of deployment descriptor you choose.

---

---

**Note:** For EAR files, do not create more than one deployment descriptor file of the same type per application or workspace. These files can be assigned to projects, but have application workspace scope. If multiple projects in an application have the same deployment descriptor, the one belonging to the launched project will supersede the others. This restriction applies to `application.xml`, `weblogic-jdbc.xml`, `-data.xml`, and `weblogic.xml`.

The best place to create an application-level descriptor is in the **Descriptors** node of the Application Resources panel in the Application Navigator. This ensures that the application is created with the correct descriptors.

Application-level descriptors created in the project will be ignored by the runtime. Only the application resources descriptors or descriptors generated at the EAR level will be used by the runtime.

---

---

### 36.3.3.2 Viewing or Modifying Deployment Descriptor Properties

After you have created a deployment descriptor, you can change its properties by using JDeveloper dialogs or by editing the file in the source editor. The deployment descriptor is an XML file (for example, `application.xml`) typically located under the Application Sources node.

#### To view or change deployment descriptor properties:

1. In the Application Navigator or in the Application Resources panel, double-click the deployment descriptor.
2. In the overview editor, select either the **Overview tab** or the **Source tab**, and configure the descriptor by setting property values.

If the overview editor is not available, JDeveloper opens the file in the source editor.

### 36.3.3.3 Configuring the application.xml File for Application Server Compatibility

You may need to configure your `application.xml` file to be compliant with Java EE 5.

---

---

**Note:** Typically, your project has an `application.xml` file that is compatible and you would not need to perform this procedure.

---

---

#### To configure the application.xml file:

1. In the Application Navigator, right-click the application and choose **New**.
2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then **Java EE Deployment Descriptor**, and click **OK**.
3. In the Select Descriptor page of the Create Java EE Deployment Descriptor dialog, select **application.xml** and click **Next**.
4. In the Select Version page, select **5.0** and click **Next**.
5. In the Summary page, click **Finish**.
6. Edit the `application.xml` file with the appropriate values.

### 36.3.3.4 Configuring the web.xml File for Application Server Compatibility

You may need to configure your `web.xml` file to be compliant with Java EE 5 (which corresponds to servlet 2.5 and JSP 1.2). For more information, see [Section A.13](#), "[web.xml](#)."

---

---

**Note:** Typically, your project has a `web.xml` file that is compatible and you would not need to perform this procedure. JDeveloper creates a starter `web.xml` file when you create a project.

If the application uses ADF Security and will be deployed to WebSphere, you need to manually edit the `web.xml` file. For more information, see [Section 36.3.4.3.3](#), "[Editing the web.xml File to Protect the Application Root for WebSphere](#)."

---

---

#### To configure the web.xml file:

1. In the Application Navigator, right-click the project and choose **New**.
2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then **Java EE Deployment Descriptor Wizard**, and click **OK**.
3. In the Select Descriptor page of the Create Java EE Deployment Descriptor dialog, select **web.xml** and click **Next**.
4. In the Select Version page, select **2.5** and click **Next**.
5. In the Summary page, click **Finish**.

### 36.3.3.5 Enabling the Application for Real User Experience Insight

Real User Experience Insight (RUEI) is a web-based utility to report on real-user traffic requested by, and generated from, your network. It measures the response times of

pages and transactions at the most critical points in the network infrastructure. Session diagnostics allow you to perform root-cause analysis.

RUEI enables you to view server and network times based on the real-user experience, to monitor your Key Performance Indicators (KPIs) and Service Level Agreements (SLAs), and to trigger alert notifications on incidents that violate their defined targets. You can implement checks on page content, site errors, and the functional requirements of transactions. Using this information, you can verify your business and technical operations. You can also set custom alerts on the availability, throughput, and traffic of all items identified in RUEI.

For more information about RUEI, see the *Oracle Real User Experience Insight User's Guide* at [http://download.oracle.com/docs/cd/E16339\\_01/doc.60/e16359/toc.htm](http://download.oracle.com/docs/cd/E16339_01/doc.60/e16359/toc.htm).

You must enable an application for RUEI by adding the following `context-param` tag to the `web.xml` file, as shown in [Example 36–2](#).

**Example 36–2 Enabling RUEI Monitoring for an Application in web.xml**

```
<context-param>
  <description>This parameter notifies ADF Faces that the
    ExecutionContextProvider service provider is enabled.
    When enabled, this will start monitoring and aggregating
    user activity information for the client initiated
    requests. By default this param is not set or is false.
  </description>
  <param-name>
    oracle.adf.view.faces.context.ENABLE_ADF_EXECUTION_CONTEXT_PROVIDER
  </param-name>
  <param-value>true</param-value>
</context-param>
```

Note that the context-parameter `oracle.adf.view.faces.context.ENABLE_ADF_EXECUTION_CONTEXT_PROVIDER` needs to be set when an `EndUserMonitoringService` provider is used within an ADF application.

### 36.3.4 How to Deploy Applications with ADF Security Enabled

If you are developing an application in JDeveloper using Integrated WebLogic Server, application security deployment properties are configured by default, which means that the application and security credentials and policies will be overwritten each time you redeploy for development purposes. You can change the default behavior in the Application Properties dialog, as described in [Section 30.8.1, "How to Configure, Deploy, and Run a Secure Application in JDeveloper."](#)

#### 36.3.4.1 Applications That Will Run Using Oracle Single Sign-On (SSO)

Before you can deploy and run the web application with ADF Security enabled on the application server, the administrator of the target server must configure the domain-level `jps-config.xml` file for the Oracle Access Manager (OAM) security provider. To complete this configuration task, you use Oracle WebLogic Scripting Tool (WLST) provided with the JDeveloper install. You can also use this command for configuring WebSphere for OAM. For details about running WLST (with command `addOAMSSOProvider(loginuri, logouturi, autologinuri)`), see the procedure for configuring Oracle WebLogic Server for a web application using ADF Security, OAM SSO, and OPSS SSO in the *Oracle Fusion Middleware Application Security Guide*.

Running the `addOAMSSOProvider()` command ensures that the ADF Security framework defers to the OAM service provider to clear the SSO cookie token. OAM uses this token to save the identity of authenticated users and, unless it is cleared during logout, the user will be unable to log out.

After the system administrator runs the script on the target server, the domain `jps-config.xml` file will contain the following security provider definition that is specific for ADF Security:

```
<propertySet name="props.auth.uri">
  <property name="login.url.FORM" value="{app.context}/adfAuthentication"/>
  <property name="logout.url" value="" />
</propertySet>
```

Additionally, the authentication type required by SSO is `CLIENT-CERT`. The `web.xml` authentication configuration for the deployed application must specify the `<auth-method>` element as one of the following `CLIENT-CERT` types.

WebLogic supports two types of authentication methods:

- For `FORM`-type authentication method, specify the elements like this:

```
<login-config>
  <auth-method>CLIENT-CERT,FORM</auth-method>
  <realm-name>myrealm</realm-name>
  <form-login-config>
    <form-login-page>/login.html</form-login-page>
    <form-error-page>/error.html</form-error-page>
  </form-login-config>
</login-config>
```

- For `BASIC`-type authentication method, specify the elements like this:

```
<login-config>
  <auth-method>CLIENT-CERT,BASIC</auth-method>
  <realm-name>myrealm</realm-name>
</login-config>
```

WebSphere supports a single authentication method. Specify the elements like this:

```
<login-config>
  <auth-method>CLIENT-CERT</auth-method>
  <realm-name>myrealm</realm-name>
  <form-login-config>
    <form-login-page>/login.html</form-login-page>
    <form-error-page>/error.html</form-error-page>
  </form-login-config>
</login-config>
```

You can configure the `web.xml` file either before or after deploying the web application. For further details about setting up the authentication method for Single Sign-On, see the *Oracle Fusion Middleware Application Security Guide*.

### 36.3.4.2 Configuring Security for WebLogic Server

In a development environment, JDeveloper will automatically migrate application-level credentials, identities, and policies to the standalone WebLogic Server instance only if the server is set up to be in development mode. Integrated WebLogic Server is set up in development mode by default. You can set up a standalone WebLogic Server to be in development mode during Oracle WebLogic Server domain creation using the Oracle Fusion Middleware Configuration Wizard.

For more information about configuring Oracle WebLogic Server domains, see *Oracle Fusion Middleware Creating Domains Using the Configuration Wizard*.

JDeveloper will not migrate application-level security credentials to WebLogic Server set up in production mode. Typically, in a production environment, administrators will use Enterprise Manager or WLST to deploy an application, including its security requirements.

When you deploy an application to WebLogic Server, credentials (in the `cwallet.sso` and `jazn-data.xml` files) will either overwrite or merge with the WebLogic Server domain-level credential store, depending on whether `OVERWRITE` or `MERGE` is set in `weblogic-application.xml`. In production-mode WebLogic Server, to avoid security risks, only `MERGE` is allowed. For development-mode WebLogic Server, you can set to `OVERWRITE` to test user names and passwords. You can set the property by running `setDomainEnv.cmd` or `setDomainEnv.sh` with the following option added to the command (usually located in `ORACLE_HOME/user_projects/domains/MyDomain/bin`).

For `setDomainEnv.cmd`:

```
set EXTRA_JAVA_PROPERTIES=-Djps.app.credential.override.allowed=true
  %EXTRA_JAVA_PROPERTIES%
```

For `setDomainEnv.sh`:

```
EXTRA_JAVA_PROPERTIES="-Djps.app.credential.override.allowed=true
  ${EXTRA_JAVA_PROPERTIES}"
export EXTRA_JAVA_PROPERTIES
```

If the Administration Server is already running, you must restart it for this setting to take effect.

You can check to see whether WebLogic Server is in production mode by using the Oracle WebLogic Server Administration Console or by verifying the following line in the WebLogic Server `config.xml` file:

```
<production-mode-enabled>true</production-mode-enabled>
```

By default, JDeveloper sets the application's credentials, identities, and policies to `OVERWRITE`. That is, the **Application Policies, Credentials, and Users and Groups** options are selected by default in the Application Properties dialog Deployment page. However, an application's credentials will be migrated only if the target WebLogic Server instance is set to development mode with `-Djps.app.credential.override.allowed=true`

When your application is ready for deployment to a production environment, you should remove the identities from the `jazn-data.xml` file or disable the migration of identities by deselecting **Users and Groups** from the Application Properties dialog. Application credentials must be manually migrated outside of JDeveloper.

---

---

**Note:** Before you migrate the `jazn-data.xml` file to a production environment, check that the policy store does not contain duplicate permissions for a grant. If a duplicate permission (one that has the same name and class) appears in the file, the administrator migrating the policy store will receive an error and the migration of the policies will be halted. You should manually edit the `jazn-data.xml` file to remove any duplicate permissions from a grant definition.

---

---

---

For more information about migrating application credentials and `jazn-data` policies, see the *Oracle Fusion Middleware Application Security Guide*.

#### 36.3.4.2.1 Applications with JDBC URL for WebLogic

If your application has components that use JDBC URL connections, the connection user names and passwords are also stored in the application-level credential and policy stores. For the deployed application to be able to connect to the database using the JDBC URL, these credentials and policies must be migrated. That is, if WebLogic Server is in production mode, system administrators must migrate this security information. If WebLogic Server is in development mode, it must have domain-level credential and policy stores set to `OVERWRITE` to allow the migration of security information.

#### 36.3.4.2.2 Applications with JDBC Data Source for WebLogic

If your application uses application-level JDBC data sources with password indirection for database connections, you may need to create credential maps in WebLogic Server to enable the database connection. For more information, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

#### 36.3.4.3 Configuring Security for WebSphere Server

Applications with credentials and policies in the `jazn-data.xml` and `cwallet.sso` files can be migrated to WebSphere. You will need to perform additional tasks in WebSphere. Be aware that the `opss-application.xml` file is not included in the application EAR file if it is intended for WebSphere.

---

---

**Note:** Before you migrate the `jazn-data.xml` file to a production environment, check that the policy store does not contain duplicate permissions for a grant. If a duplicate permission (one that has the same name and class) appears in the file, the administrator migrating the policy store will receive an error and the migration of the policies will be halted. You should manually edit the `jazn-data.xml` file to remove any duplicate permissions from a grant definition.

---

---

For more information about setting up WebSphere to accept credentials and policies, see the *Oracle Fusion Middleware Third-Party Application Server Guide*.

#### 36.3.4.3.1 Applications with JDBC URL for WebSphere

If your application has components that use JDBC URL connections, the connection user names and passwords are also stored in the application-level credential and policy stores. For the deployed application to be able to connect to the database using the JDBC URL, OPSS migration must be enabled.

#### 36.3.4.3.2 Applications with JDBC Data Source for WebSphere

If your application uses application-level JDBC data sources with password indirection for database connections, you will need to create a JDBC data source in WebSphere. For more information, see IBM WebSphere documentation.

#### 36.3.4.3.3 Editing the `web.xml` File to Protect the Application Root for WebSphere

When you enable ADF Security for your web application, the `web.xml` file includes the Java EE security constraint `allPages` to protect the Java EE application root. By

default, to support deploying to Oracle WebLogic Server, JDeveloper specifies the URL pattern for the security constraint as / (backslash). If you intend to deploy the application to IBM WebSphere, the correct URL pattern is /\* (backslash-asterisk). Before you deploy the application to WebSphere, manually edit the `web.xml` file for your application to change the `allPages` security constraint as follows:

```
<security-constraint>
  <web-resource-collection>
    <web-resource-name>allPages</web-resource-name>
    <url-pattern>/*</url-pattern>
  </web-resource-collection>
  . . .
</security-constraint>
```

### 36.3.5 How to Replicate Memory Scopes in a Clustered Environment

If you are deploying an application that is intended to run in a clustered environment, you need to ensure that all managed beans with a lifespan longer than one request are serializable, and that the ADF framework is aware of changes to managed beans stored in ADF scopes (view scope and page flow scope).

For more information, see [Section 20.4.3, "How to Set Managed Bean Memory Scopes in a Server-Cluster Environment."](#)

### 36.3.6 How to Enable the Application for ADF MBeans

An ADF application uses many XML files for setting configuration information. Three of these configuration files have ADF MBean counterparts that are deployed with the application. After the application has been deployed, you can change configuration properties by accessing the ADF MBeans using the Enterprise Manager Fusion Middleware Control MBean browser.

To enable ADF MBeans, you must register them in the `web.xml` file. [Example 36-3](#) shows a `web.xml` file with listener entries for connections, configuration, and business components.

#### **Example 36-3 Enabling ADF MBeans in the web.xml File**

```
<listener>
  <listener-class>
    oracle.adf.mbean.share.connection.ADFConnectionLifecycleCallBack
  </listener-class>
</listener>
<listener>
  <listener-class>
    oracle.adf.mbean.share.config.ADFConfigLifecycleCallBack</listener-class>
</listener>
<listener>
  <listener-class>
    oracle.bc4j.mbean.BC4JConfigLifecycleCallBack</listener-class>
</listener>
```

Additionally, you must configure a writable MDS repository to enable post-deployment configuration of `connections.xml` using ADF Connections MBeans and `bc4j.xcfg` using ADF Business Components MBeans.

MDS configuration entries in the `adf-config.xml` file for a database-based MDS are shown in [Example 36-4](#). For more information about configuring MDS, see the *Oracle Fusion Middleware Administrator's Guide*.

**Example 36–4 MDS Configuration Entries in the `adf-config.xml` File**

```
<adf-mds-config xmlns="http://xmlns.oracle.com/adf/mds/config">
  <mds-config xmlns="http://xmlns.oracle.com/mds/config" version="11.1.1.000">
    <persistence-config>
      <metadata-store-usages>
        <metadata-store-usage
          default-cust-store="true" deploy-target="true" id="myStore">
        </metadata-store-usage>
      </metadata-store-usages>
    </persistence-config>
  </mds-config>
</adf-mds-config>
```

In a production environment, an MDS repository that uses a database is required. You can use JDeveloper, Enterprise Manager Fusion Middleware Control, or WLST / `wsadmin` commands to switch from a file-based repository to a database MDS repository.

Additionally, if several applications are sharing the same MDS configuration, each application can achieve distinct customization layers by defining a `adf:adf-properties-child` property in the `adf-config.xml` file. JDeveloper automatically generates this entry when creating applications. If your `adf-config.xml` file does not have this entry, add it to the file with code similar to that of [Example 36–5](#).

**Example 36–5 Adding MDS Partition Code to the `adf-config.xml` File**

```
<adf:adf-properties-child xmlns="http://xmlns.oracle.com/adf/config/properties">
  <adf-property name="adfAppUID" value="Application3-4434"/>
  <adf-property name="partition_customizations_by_application_id"
    value="true"/>
</adf:adf-properties-child>
```

The `value` attribute is either generated by JDeveloper or you can set it to any unique identifier within the server farm where the application is deployed. This value can be set to the `value` attribute of the `adfAppUID` property.

When `adf-property name` is set to `adfAppUID`, then the corresponding `value` property should be set to the name of the application. By default, JDeveloper generates the `value` property using the application's package name. If the package name is not specified, JDeveloper generates the `value` property by using the workspace name and a four digit random number.

For more information about configuring ADF applications using ADF MBeans, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

### 36.3.7 What You May Need to Know About JDBC Data Source for Oracle WebLogic Server

ADF applications can use either a JDBC data source or a JDBC URL for database connections. You use the Oracle WebLogic Server Administration Console to configure a JDBC data source. For more information about database access, see [Section 9.3, "Configuring Your Application Module Database Connection."](#)

---

---

**Best Practice:** Fusion web applications are not compatible with data sources defined with the JDBC XA driver. When creating a data source on Oracle WebLogic Server, be sure to change the Fusion web application data source's JDBC driver from "Oracle's Driver (Thin XA)" to "Oracle's Driver (Thin)". Because XA data sources close all cursors upon commit, random JBO-27122 and closed statement errors may result when running the Fusion web application with an XA data source.

---

---

The ADF application module in the data model project can be configured to use a JDBC URL connection type, a JDBC data source connection type, or a combination of both types. By default, ADF application modules use a JDBC URL connection. A component that uses a JDBC URL will attempt to connect directly to the database using the JDBC URL, and it will ignore any JDBC data sources (global or application-level) that are available in WebLogic Server. For more information about migrating JDBC URL security information (user names and passwords) from the application to WebLogic Server, see [Section 36.3.4, "How to Deploy Applications with ADF Security Enabled."](#)

An ADF application can use a JDBC data source to connect to the database. A JDBC data source has three types: global, application level, and application level with password indirection. You generally set up a global JDBC data source in WebLogic Server. Any application that requires access to that database can use that JDBC data source. An application can also include application-level JDBC data sources. When the application is packaged for deployment, if the **Auto Generate and Synchronize weblogic-jdbc.xml Descriptor During Deployment** option is selected, JDeveloper creates a `connection_name-jdbc.xml` file for each connection that was defined. Each connection's information is written to the corresponding `connection_name-jdbc.xml` file (entries are also changed in `weblogic-application.xml` and `web.xml`). When the application is deployed to WebLogic Server, the server looks for application-level data source information before it looks for the global data source.

If the application is deployed with password indirection set to `true`, WebLogic Server will look for the `connection_name-jdbc.xml` file for user name information and it will then attempt to locate application-level credential maps for these user names to obtain the password. If you are using JDeveloper to directly deploy the application to WebLogic Server, JDeveloper automatically creates the credential map and populates the map to the server using an MBean call.

However, if you are deploying to an EAR file, JDeveloper will not be able to make the MBean call to WebLogic Server. You must set up the credential maps using the Oracle WebLogic Administration Console. Even if you have a global JDBC data source set up, if you do not also have credential mapping set up, WebLogic Server will not be able to map the credentials with passwords and the connection will fail. For more information about JDBC data sources, password indirection, and how to set up application credential mappings, see "JDBC Data Sources" in the "Deploying Applications" section of the JDeveloper online help.

Once the data source has been created in Oracle WebLogic Server, it can be used by an application module. For more information, see the "Preparing the Standalone Application Server for Deployment" section of the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

## 36.4 Deploying the Application

You can use JDeveloper to deploy ADF applications directly to the standalone application server or create an archive file and use other tools to deploy to the application server.

---

---

**Note:** Before you begin to deploy applications that use Oracle ADF to the standalone application server, you need to prepare the application server environment by performing tasks such as installing the ADF runtime and creating and extending domains or cells. For more information, see the "Preparing the Standalone Application Server for Deployment" section of the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

---

---

[Figure 36-5](#) shows the process flow for deploying an application and also for deploying customizations to the target standalone application server.

**Figure 36–5 Application Deployment Flow Diagram**

Table 36–2 describes some common deployment techniques that you can use during the application development and deployment cycle. The deployment techniques are listed in order from deploying on development environments to deploying on production environments. It is likely that in the production environment, the system administrators deploy applications by using Enterprise Manager Fusion Middleware Control or scripts.

**Table 36–2 Deployment Techniques for Development or Production Environments**

Deployment Technique	Environment	When to Use
Run directly from JDeveloper	Test or Development	When you are developing your application. You want deployment to be quick because you will be repeating the editing and deploying process many times.  JDeveloper contains Integrated WebLogic Server, on which you can run and test your application.
Use JDeveloper to directly deploy to the target application server	Test or Development	When you are ready to deploy and test your application on an application server in a test environment.  On the test server, you can test features (such as LDAP and Oracle Single Sign-On) that are not available on the development server.  You can also use the test environment to develop your deployment scripts, for example, using Ant.
Use JDeveloper to deploy to EAR file, then use the target application server's tools for deployment	Test or Development	When you are ready to deploy and test your application on an application server in a test environment. As an alternative to deploying directly from JDeveloper, you can deploy to an EAR file, and then use other tools to deploy to the application server.  On the test server, you can test features (such as LDAP and Oracle Single Sign-On) that are not available on the development server.  You can also use the test environment to develop your deployment scripts, for example, using Ant.
Use Enterprise Manager or WLST to deploy applications	Production	When your application is in a test and production environment. In production environments, system administrators usually use Enterprise Manager or run scripts to deploy applications.

Any necessary MDS repositories must be registered with the application server. If the MDS repository is a database, the repository maps to a data source with MDS-specific requirements.

If you are deploying the application to Oracle WebLogic Server, make sure to target this data source to the WebLogic Administration Server and to all Managed Servers to which you are deploying the application. For more information about registering MDS, see the *Oracle Fusion Middleware Administrator's Guide*.

If you are using the application server's administrative consoles or scripts to deploy an application packaged as an EAR file that requires MDS repository configuration in `adf-config.xml`, you must run the `getMDSArchiveConfig` command to configure MDS before deploying the EAR file. MDS configuration is required if the EAR file contains a MAR file or if the application is enabled for DT@RT (Design Time At Run Time).

For more information about WLST commands, see the *Oracle Fusion Middleware WebLogic Scripting Tool Command Reference*. For more information about `wsadmin` commands, see the *Oracle Fusion Middleware Third-Party Application Server Guide* and the *Oracle Fusion Middleware Configuration Guide for IBM WebSphere Application Server*.

---

---

**Note:** For IBM WebSphere Application Server, after you have deployed the application, you need to perform additional tasks such as starting the server.

For more information about IBM WebSphere Application Server, wsadmin commands, and using the WebSphere Administrative Console, see the *Oracle Fusion Middleware Third-Party Application Server Guide*.

For more information about ADF-specific wsadmin commands and installing the ADF runtime into the IBM WebSphere Application Server, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

---

---

---

---

**Note:** If you are deploying to IBM WebSphere Application Server, you must prevent concurrent access to a session in a server instance so that concurrent modifications to a session does not occur. In the WebSphere Administrative Console, you can set the "Serializing Access to Session Data" feature to **Allow serial access**. For more information, see IBM WebSphere documentation.

---

---

If you plan to configure ADF connection information, ADF Business Components information, or `adf-config.xml` using ADF MBeans after the application has been deployed, make sure that the application is configured with MDS and have the MBean listeners enabled in the `web.xml` file. For more information, see [Section 36.3.6, "How to Enable the Application for ADF MBeans."](#)

---

---

**Note:** If your ADF application has business services that you want to deploy to WebLogic Server, see [Section 11.2.22, "How to Deploy Web Services to Oracle WebLogic Server."](#)

---

---

## 36.4.1 How to Deploy to the Application Server from JDeveloper

### Before you begin:

Create an application-level deployment profile that deploys to an EAR file.

---

---

**Note:** When you are deploying to Oracle WebLogic Server from JDeveloper, ensure that the HTTP Tunneling property is enabled in the Oracle WebLogic Server Administration Console. This property is located under **Servers > ServerName > Protocols**. *ServerName* refers to the name of Oracle WebLogic Server.

---

---

---

---

**Note:** For WebLogic Server, JDeveloper does not support deploying applications to individual Managed Servers that are members of a cluster. You may be able to target one or more Managed Servers within a cluster using the Oracle WebLogic Server Administration Console or other Oracle WebLogic tools; however, the cluster can be negatively affected. For more information about deploying to Oracle WebLogic Server clusters, see the *Oracle Fusion Middleware Administrator's Guide*.

---

---

**To deploy to the target application server from JDeveloper:**

1. In the Application Navigator, right-click the application and choose **Deploy > deployment profile**.
2. In the Deploy wizard Deployment Action page, select **Deploy to Application Server** and click **Next**.
3. In the Select Server page, select the application server connection, and click **Next**.
4. If you are deploying to a WebLogic Server instance, the WebLogic Options page appears. Select a deploy option and click **Next**.

---

---

**Note:** If you are deploying an ADF application, do not use the **Deploy to all instances in the domain** option.

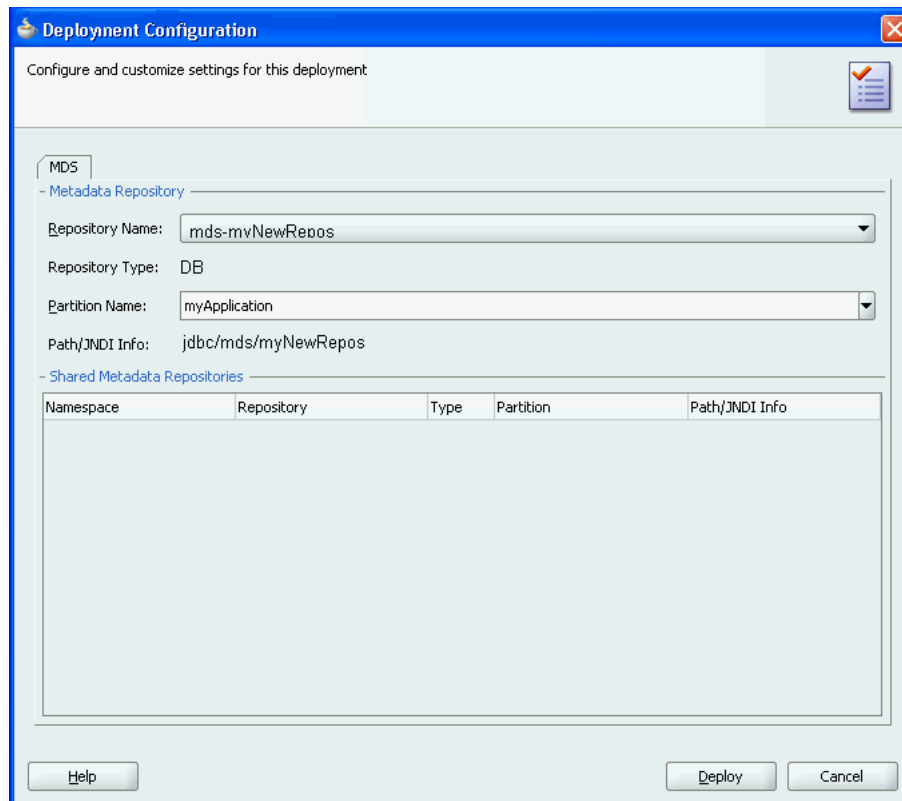

---

---

5. Click **Finish**.

During deployment, you can see the process steps displayed in the deployment Log window. You can inspect the contents of the modules (archives or exploded EAR) being created by clicking on the links that are provided in the log window. The archive or exploded EAR file will open in the appropriate editor or directory window for inspection.

If the `adf-config.xml` file in the EAR file requires MDS repository configuration, the Deployment Configuration dialog appears for you to choose the target metadata repository or shared metadata repositories, as shown in [Figure 36-6](#). The **Repository Name** dropdown list allows you to choose a target metadata repository from a list of metadata repositories registered with the Administration Server. The **Partition Name** dropdown list allows you to choose the metadata repository partition to which the application's metadata will be imported during deployment. You can use Oracle WebLogic Scripting Tool (WLST) / `wsadmin` commands and the Oracle WebLogic Server Administration Tool / WebSphere Administrative Tool, respectively, to configure and register MDS. For more information about managing the MDS repository, see the *Oracle Fusion Middleware Administrator's Guide*.

**Figure 36–6 MDS Configuration and Customization for Deployment**

---

**Note:** If you are deploying a Java EE application, click the application menu next to the Java EE application in the Application Navigator.

---

For more information on creating application server connections, see [Section 36.3.1, "How to Create a Connection to the Target Application Server."](#)

## 36.4.2 How to Create an EAR File for Deployment

You can also use the deployment profile to create an archive file (EAR file). You can then deploy the archive file using Enterprise Manager, Oracle WebLogic Scripting Tool (WLST) / WebSphere wsadmin tool, Oracle WebLogic Server Administration Console / WebSphere Administrative Console, respectively.

Although an ADF application is encapsulated in an EAR file (which usually includes WAR, MAR, and JAR components), it may have parts that are not deployed with the EAR. For instance, ADF Business Services can be deployed as a JAR. For more information about business services, see [Section 11.2.22, "How to Deploy Web Services to Oracle WebLogic Server."](#)

### To create an EAR archive file:

- In the Application Navigator, right-click the application containing the deployment profile, and choose **Deploy > deployment profile > to EAR file**.

If an EAR file is deployed at the application level, and it has dependencies on a JAR file in the data model project and dependencies on a WAR file in the

view-controller project, then the files will be located in the following directories by default:

- *ApplicationDirectory/Deploy/EARdeploymentprofile.EAR*
- *ApplicationDirectory/ModelProject/Deploy/JARdeploymentprofile.JAR*
- *ApplicationDirectory/ViewControllerProject/Deploy/WARdeploymentprofile.WAR*

**Tip:** Choose **View >Log** to see messages generated during creation of the archive file.

### 36.4.3 What You May Need to Know About EAR Files and Packaging

When you package an ADF application into an EAR file, it can contain the following:

- WAR files: Each web-based view controller project should be packaged into a WAR file.
- MAR file: If the application has customizations that are deployed with the application, it should be packaged into a MAR.
- ADF Library JAR files: If the application consumes ADF Library JARs, these JAR files may be packaged within the EAR.
- Other JAR files: The application may have other dependent JAR files that are required. They can be packaged within the EAR.

### 36.4.4 How to Deploy the Application Using Scripts and Ant

You can deploy the application using commands and automate the process by putting those commands in scripts. The `ojdeploy` command can be used to deploy an application without JDeveloper. You can also use Ant scripts to deploy the application. JDeveloper has a feature to help you build Ant scripts. Depending on your requirements, you may be able to integrate regular scripts with Ant scripts.

You can also use the application server commands for deployment. For WebLogic Server, you can use WLST commands and for IBM WebSphere Application Server, you can use wsadmin commands.

For more information about WLST and wsadmin commands, scripts, and Ant, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

### 36.4.5 How to Deploy New Customizations Applied to ADF Library

If you have created new customizations for an ADF Library, you can use the MAR profile to deploy these customizations to any deployed application that consumes that ADF Library. For instance, `applicationA`, which consumes `ADFLibraryB`, was deployed to a standalone application server. Later on, when new customizations are added to `ADFLibraryB`, you only need to deploy the updated customizations into `applicationA`. You do not need to repackage and redeploy the whole application, nor do you need to manually patch the MDS repository.

---

---

**Note:** This procedure is for applying ADF Library customization changes to an application that has already been deployed to a standalone application server. It is not for the initial packaging of customizations into a MAR that will eventually be a part of an EAR. For information about the initial packaging of the customization using a MAR, see [Section 36.3.2.3, "Creating a MAR Deployment Profile."](#)

---

---

To deploy ADF Library customizations, create a new MAR profile that includes only the customizations to be deployed and then use JDeveloper to:

- Deploy the customizations directly into the MDS repository in the standalone application server.
- Deploy the customizations to a JAR. And then import the JAR into the MDS repository using tools such as the Fusion Middleware Control.

#### 36.4.5.1 Exporting Customization to a Deployed Application

You can export the customizations directly from JDeveloper into the MDS repository for the deployed application on the standalone application server.

##### **Before you begin:**

Create new customizations to the ADF Library using the customization developer role in JDeveloper.

##### **To export the customizations directly into the application server:**

1. In the Application Navigator, right-click the application and choose **Deploy > metadata**.
2. In the Deploy Metadata dialog Deployment Action page, select **Export to a Deployed Application** and click **Next**.  
If the MAR profile is included in any of the application's EAR profiles, **Export to a Deployed Application** will be dimmed and disabled.
3. In the Application Server page, select the application server connection and click **Next**.
4. For WebLogic Server, the Server Instance page appears. In this page, select the server instance where the deployed application is located and click **Next**.
5. In the Deployed Application page, select the application you want to apply the customizations to and click **Next**.
6. In the Sandbox Instance page, if you want to deploy to a sandbox, select **Deploy to an associated sandbox**, choose the sandbox instance and click **Next**.
7. In the Summary page, verify the information and click **Finish**.

#### 36.4.5.2 Deploying Customizations to a JAR

When you deploy the ADF Library customizations to a JAR, you are packaging the contents as defined by the MAR profile.

##### **Before you begin:**

Create new customizations to the ADF Library using the customization developer role in JDeveloper.

**To deploy the customizations as a JAR**

1. In the Application Navigator, right-click the application and choose **Deploy > metadata**.
2. In the Deploy Metadata dialog Deployment Action page, select **Deploy to MAR**.
3. In the Summary page, click **Finish**.
4. Use Enterprise Manager Fusion Middleware Control or the application server's administration tool to import the JAR into the MDS repository.

**36.4.6 What You May Need to Know About ADF Libraries**

An ADF Library is a JAR file that contains JAR services registered for ADF components such as ADF task flows, pages, or application modules. If you want the ADF components in a project to be reusable, you create an ADF Library deployment profile for the project and then create an ADF Library JAR based on that profile.

An application or project can consume the ADF Library JAR when you add it using the Resource Palette or manually by adding it to the library classpath. When the ADF Library JAR is added to a project, it will be included in the project's WAR file if the **Deployed by Default** option is selected.

For more information, see [Chapter 33, "Reusing Application Components."](#)

**36.4.7 How to Deploy ADF Faces JARs with the Application**

You can develop applications that only use ADF Faces without using ADF Model. In that case, you can deploy the ADF Faces JARs with the application into the application server.

**Before you begin:**

Create an application with a web-based project. If you used the Fusion Web Application (ADF) template, you should already have a default WAR deployment profile.

**To deploy ADF Faces JARs as part of the application:**

1. In the Application Navigator, right-click the web project that you want to deploy and choose **Project Properties**.
2. In the Project Properties dialog, select **Deployment** and then the deployment profile and click **Edit**.

If your project does not have a WAR deployment profile, follow Steps 1 to 3 in [Section 36.3.2.2, "Creating a WAR Deployment Profile,"](#) to create a new WAR deployment profile.

3. Navigate to **File Groups > WEB-INF/lib > Contributors** and select **ADF Faces Runtime 11**.
4. Click **OK** to exit the Deployment Profile Properties dialog.
5. Click **OK** again to exit the Project Properties dialog.
6. Deploy your application as described in this chapter either directly using JDeveloper or by creating a EAR and deploying it using the Enterprise Manager Fusion Middleware Control, the Oracle WebLogic Server Administration Console, or other methods.

Make sure your application-level EAR contains the WAR file as described in [Section 36.3.2.4, "Creating an Application-Level EAR Deployment Profile."](#)

### 36.4.8 What You May Need to Know About JDeveloper Runtime Libraries

When an application is deployed, it includes some of its required libraries with the application. The application may also require shared libraries that have already been loaded to WebLogic Server as JDeveloper runtime libraries. It may be useful to know which JDeveloper libraries are packaged within which WebLogic Server shared library. For a listing of the contents of the JDeveloper runtime libraries, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

## 36.5 Postdeployment Configuration

After you have deployed your application to WebLogic Server, you can perform configuration tasks.

### 36.5.1 How to Migrate an Application

If you want to migrate an ADF application from one application server to another application server, you may need to perform some of the same steps you did for a first time deployment.

In general, to migrate an application, you would:

- Load the ADF runtime (if it is not already installed) to the target application server. For more information, see the "Preparing the Standalone Application Server for Deployment" section of the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.
- Configure the target application server with the correct database or URL connection information.
- Migrate security information from the source to the target. For instructions, see [Section 36.3.4, "How to Deploy Applications with ADF Security Enabled."](#)
- Deploy the application using Enterprise Manager, administration console, or scripts. For more information, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

### 36.5.2 How to Configure the Application Using ADF MBeans

If ADF MBeans were enabled and packaged with the deployed application, you can configure ADF properties using the Enterprise Manager MBean Browser. For instructions to enable an application for MBeans, see [Section 36.3.6, "How to Enable the Application for ADF MBeans."](#)

For information on how to configure ADF applications using ADF MBeans, see the *Oracle Fusion Middleware Administrator's Guide for Oracle Application Development Framework*.

## 36.6 Testing the Application and Verifying Deployment

After you deploy the application, you can test it from Oracle WebLogic Server. To test-run your ADF application, open a browser window and enter a URL:

- For non-Faces pages: `http://<host>:port/<context root>/<page>`

- For Faces pages: `http://<host>:port/<context root>/faces/<view_id>`

where `<view_id>` is the view ID of the ADF task flow view activity.

**Tip:** The context root for an application is specified in the view-controller project settings by default as *ApplicationName/ProjectName/context-root*. You can shorten this name by specifying a name that is unique across the target application server. Right-click the view-controller project, and choose **Project Properties**. In the Project Properties dialog, select **Java EE Application** and enter a unique name for the context root.

---

---

**Note:** `/faces` has to be in the URL for Faces pages. This is because JDeveloper configures your `web.xml` file to use the URL pattern of `/faces` in order to be associated with the Faces Servlet. The Faces Servlet does its per-request processing, strips out `/faces` part in the URL, then forwards the URL to the JSP. If you do not include the `/faces` in the URL, then the Faces Servlet is not engaged (since the URL pattern doesn't match). Your JSP is run without the necessary JSF per-request processing.

---

---

# Part VI

---

## Advanced Topics

Part VI contains the following chapters:

- [Chapter 37, "Advanced Business Components Techniques"](#)
- [Chapter 38, "Advanced Entity Object Techniques"](#)
- [Chapter 39, "Advanced View Object Techniques"](#)
- [Chapter 40, "Application State Management"](#)
- [Chapter 41, "Tuning Application Module Pools and Connection Pools"](#)
- [Chapter 42, "Using the Active Data Service"](#)

---

---

## Advanced Business Components Techniques

This chapter describes advanced techniques that you can use to incorporate custom code with all types of business components and to extend the ADF Business Components framework behavior.

This chapter includes the following sections:

- [Section 37.1, "Extending the ADF Business Components Framework"](#)
- [Section 37.2, "Customizing Framework Behavior with Extension Classes"](#)
- [Section 37.3, "Creating Generic Extension Interfaces"](#)
- [Section 37.4, "Invoking Stored Procedures and Functions"](#)
- [Section 37.5, "Accessing the Current Database Transaction"](#)
- [Section 37.6, "Working with Libraries of Reusable Business Components"](#)
- [Section 37.7, "Customizing Business Components Error Messages"](#)
- [Section 37.8, "Creating Extended Components Using Inheritance"](#)
- [Section 37.9, "Substituting Extended Components in a Delivered Application"](#)

### 37.1 Extending the ADF Business Components Framework

One of the powerful features of framework-based development is the ability to extend the base framework to change a built-in feature to behave differently or to add a new feature that can be used by all of your applications.

The base classes of the ADF Business Components framework may be extended by creating extension classes that incorporate custom code to extend the ADF Business Components framework behavior when you need to:

- Augment a built-in feature with additional, generic functionality
- Change how a built-in feature works
- Workaround a bug you encounter in a generic way

An ADF Business Components framework extension class is a Java class that you write to extend one of the framework's base classes for any type of ADF business component.

When used without customization, your business component is completely defined by its XML component definition and it will be fully functional without custom Java code or even a Java class file for the component. If you have no need to extend the built-in

functionality of a component in ADF Business Components, and no need to write any custom code to handle its built-in events, you can use the component in this XML-only fashion. However, when you do extend base classes of the ADF Business Components framework, you can still work with XML documents in JDeveloper.

Before you begin to develop application-specific business components, Oracle recommends that you consider creating a complete layer of framework extension classes and set up your project-level preferences to use that layer by default. You might not have any custom code in mind to put in these framework extension classes initially, but this practice will help when customization becomes practical.

This way, substantial inconvenience can be avoided if you discover mid-project that all of your entity objects, for example, require a new generic feature, augmented built-in feature, or a generic bug workaround.

Once you have created framework extension classes, any new ADF components you create can be based on your *customized* framework class instead of the base one. Of course, you can also update the definitions of existing components to use the new framework extension class as well.

---

---

**Note:** To experiment with the examples in this chapter, use the `AdvancedExamples` workspace in the `StandaloneExamples` module of the Fusion Order Demo application, as described in [Section 2.4.3, "Standalone Applications in the AdvancedExamples Application Workspace."](#) For information about how to obtain and install the Fusion Order Demo, see [Section 2.2, "Setting Up the Fusion Order Demo Application."](#)

---

---

### 37.1.1 How To Create a Framework Extension Class

When you need to add custom code to extend the base functionality of the ADF Business Components framework, you can enable a custom Java class for any of the key types of ADF business components you create. You enable the generation of custom classes for a component on the Java page of its respective overview editor in JDeveloper. When you enable this option, JDeveloper creates a Java source file for a custom class related to the component whose name follows a configurable naming standard. This class, whose name is recorded in the component's XML document, provides a place where you can write the custom Java code required by that component.

#### To create a framework extension class:

1. Identify a project to contain the framework extension class.  
You can create it in the same project as your business service components if you believe it will only be used by components in that project. Alternatively, if you believe you might like to reuse the framework extension class across multiple Fusion web applications, create a separate model project to contain the framework extension classes.
2. Ensure the **BC4J Runtime** library is in the project's libraries list.  
Use the **Libraries and Classpath** page of the **Project Properties** dialog to verify this and to add the library if missing.
3. In the **New Gallery**, in the **General** category, select **Java Class** to create the new class.

4. In the Create Java Class dialog, specify the appropriate framework base class from the `oracle.jbo.server` package in the **Extends** field.

Figure 37–1 illustrates what it would look like to create a custom framework extension class named `CustomAppModuleImpl` in the `com.yourcompany.fwkext` package to customize the functionality of the base application module component. To quickly find the base class you're looking for, use the **Browse** button next to the **Extends** field that launches the JDeveloper **Class Browser**. Using its **Search** tab, you can type in part of the class name (including using `*` as a wildcard) to quickly subset the list of classes to find the one you're looking for.

**Figure 37–1** *Creating a Framework Extension Class for an Application Module*

When you click **OK**, JDeveloper creates the custom framework extension class for you in the directory of the project's source path corresponding to the package name you've chosen.

---

**Note:** Some ADF Business Components component classes exist in both a server-side and a remote-client version. For example, if you use the JDeveloper **Class Browser** and type `ApplicationModuleImpl` into the **Match Class Name** field on the **Search** tab, the list will show two `ApplicationModuleImpl` classes: one in the `oracle.jbo.server` package and the other in the `oracle.jbo.client.remote` package. When creating framework extension classes, use the base ADF classes in the `oracle.jbo.server` package.

---

### 37.1.2 What Happens When You Create a Framework Extension Class

After creating a new framework extension class, it will not automatically be used by your application. You must decide which components in your project should make use

of it. The following sections describe the available approaches for basing your ADF components on your own framework extension classes.

### 37.1.3 What You May Need to Know About Customizing Framework Extension Bases Classes

To make your framework extension layer classes easier to package as a reusable library, create them in a separate project from the projects that use them.

A common set of customized framework base classes in a package name of your own choosing like *com.yourcompany.fwkext*, each importing the `oracle.jbo.server.*` package, would consist of the following classes:

- `public class CustomEntityImpl extends EntityImpl`
- `public class CustomEntityDefImpl extends EntityDefImpl`
- `public class CustomViewObjectImpl extends ViewObjectImpl`
- `public class CustomViewRowImpl extends ViewRowImpl`
- `public class CustomApplicationModuleImpl extends ApplicationModuleImpl`
- `public class CustomDBTransactionImpl extends DBTransactionImpl2`
- `public class CustomDatabaseTransactionFactoryImpl extends DatabaseTransactionFactory`

For details about using the custom `DBTransactionImpl2` and `DatabaseTransactionFactory` classes, see [Section 37.7.5.2, "Configuring an Application Module to Use a Custom Database Transaction Class."](#)

---

---

**Note:** For your convenience, the `FrameworkExtensions` project of the `AdvancedExamples` workspace in the `StandaloneExamples` module of the Fusion Order Demo application contains a set of these classes. You can select the `com.yourcompany.fwkext` package in the Application Navigator and choose the **Refactor > Rename** option from the context menu to change the package name of all the classes to a name you prefer.

---

---

For completeness, you may also want to create customized framework classes for the following classes as well, note however that overriding anything in these classes would be a fairly rare requirement.

- `public class CustomViewDefImpl extends ViewDefImpl`
- `public class CustomEntityCache extends EntityCache`
- `public class CustomApplicationModuleDefImpl extends ApplicationModuleDefImpl`

### 37.1.4 How to Base an ADF Component on a Framework Extension Class

You can set the base classes for any ADF component using the **Java** page of any ADF Business Components wizard or editor.

**Before you begin:**

- Create the framework extension class as described in [Section 37.1.1, "How To Create a Framework Extension Class."](#)
- If you created your framework extension classes in a separate project, visit the **Dependencies** page of the Project Properties dialog for the project containing your business components and select **Build Output** to add the framework extension project as a project dependency.
- If you have packaged your framework extension classes in a Java archive (JAR) file, create a named library definition to reference its JAR file and also list that library in the library list of the project containing your business components. To create a library if missing, use the Manage Libraries dialog available from the **Tools > Manage Libraries** main menu item. To verify or adjust the project's library list, use the **Libraries** page of the Project Properties dialog.

After you ensure the framework classes are available to reference, you can create the ADF component. Every ADF Business Components wizard and editor displays the same **Class Extends** button on the **Java** page so you can use the technique to choose your desired framework extension base class(es) both for new components or existing ones.

There is no fixed limit on how many levels of framework extension classes you create. For example, after creating a company-level `CustomAppModuleImpl` to use for all application modules in all Fusion web applications that your company creates, some later project team might encounter the need to further customize that framework extension class. That team could create a `SomeProjectCustomAppModuleImpl` class that extends the `CustomAppModuleImpl` and then include the project-specific custom application module code in there as shown in [Example 37-1](#).

**Example 37-1 Extending a Custom Class**

```
public class SomeProjectCustomAppModuleImpl
    extends CustomAppModuleImpl {
    /*
     * Custom application module code specific to the
     * "SomeProject" project goes here.
     */
}
```

Then, any application modules created as part of the implementation of this specific project can use the `SomeProjectCustomAppModuleImpl` as their base class instead of the `CustomAppModuleImpl`.

**To create an ADF component based on a framework extension class:**

1. In the Application Navigator, double-click the desired component.
2. In the overview editor, click the **Java** navigation tab and click the **Edit Java options** button.
3. In the Select Java Options dialog, click **Classes Extends**.
4. In the Override Base Classes dialog, enter the fully-qualified name of the framework base classes you wish to override. You can also use the **Browse** button to use the JDeveloper Class Browser to find the classes quickly.

When you use the Class Browser to select a custom base class for the component, the list of available classes is automatically filtered to show only classes that are appropriate. For example, when clicking **Browse** in [Figure 37-2](#) to select an application module **Object** base class, the list will only show classes available in

the current project's library list which extend the `oracle.jbo.server.ApplicationModule` class either directly or indirectly. If you don't see the class you're looking for, either you extended the incorrect base class or you have chosen the wrong component class name to override.

**Figure 37–2 Specifying a Custom Base Class for a New Application Module**

### 37.1.5 How to Define Framework Extension Classes for All New Components

If you decide to use a specific set of framework extension classes as a standard for a given project, you can use the Project Properties dialog to define your preferred base classes for each component type. Setting these preferences for base classes does not affect any existing components in the project, but the component wizards will use the preferences for any new components created.

**To define project-level preferences for framework extension classes:**

1. In the Application Navigator, right-click the model project that will contain the extension classes and choose **Project Properties**.
2. In the Project Properties dialog, expand **Business Components > Base Classes** in the tree.
3. On the Business Components page, enter the fully-qualified name of that class in the **Application Module Object** class name field.

For example, to indicate that any new application modules created in the project should use the `CustomAppModuleImpl` class by default, enter the fully-qualified name of that class in the *componentName* **Object** class name field as shown in [Figure 37–3](#).

**Figure 37-3** Setting Project-Level Preferences for ADF Component Base Classes

### 37.1.6 How to Define Framework Extension Classes for All New Projects

When you want to apply the same base class preferences to each new project that you create in JDeveloper, you can define the preferences at a global level using the Preferences dialog. Base classes that you specify at the global level will not alter your existing projects containing ADF components.

#### To define global preferences for framework extension classes:

1. In the Tools menu, choose Preferences.
2. In the Preferences dialog, expand **Business Components > Base Classes** in the tree.
3. On the Business Components page, enter the fully-qualified name of that class in *componentName* **Object** class name field.

The page displays the same options for specifying the preferred base classes for each component type as shown in [Figure 37-3](#).

### 37.1.7 What Happens When You Base a Component on a Framework Extension Class

When an ADF component you create extends a custom framework extension class, JDeveloper updates its XML component definition to reflect the custom class name you've chosen.

#### 37.1.7.1 XML-Only Components

For example, assume you've created the *YourService* application module in the `com.yourcompany.yourapp` package, with a custom application module base class of `CustomAppModuleImpl`. If you have opted to leave the component as an XML-only component with no custom Java file, its XML component definition (*YourService.xml*) will look like what you see in [Example 37-2](#). The value of the

ComponentClass attribute of the <AppModule> tag is read at runtime to identify the Java class to use to represent the component.

**Example 37-2 Custom Base Class Names Are Recorded in XML Component Definition**

```
<AppModule
  Name="YourService"
  ComponentClass="com.yourcompany.fwkext.CustomAppModuleImpl" >
  <!-- etc. -->
</AppModule>
```

Figure 37-4 illustrates how the XML-only YourService application module relates to your custom extension class. At runtime, it uses the CustomAppModuleImpl class which inherits its base behavior from the ApplicationModuleImpl class.

**Figure 37-4 XML-Only Component Reference an Extended Framework Base Class**

**37.1.7.2 Components with Custom Java Classes**

If your component requires a custom Java class, as you've seen in previous chapters you open the **Java** page of the component editor and check the appropriate checkbox to enable it. For example, when you enable a custom application module class for the YourServer application module, JDeveloper creates the appropriate YourServiceImpl.java class. As shown in Example 37-3, it also updates the component's XML component definition to reflect the name of the custom component class.

**Example 37-3 Custom Component Class Recorded in XML Component Definition**

```
<AppModule
  Name="YourService"
  ComponentClass="com.yourcompany.yourapp.YourServiceImpl" >
  <!-- etc. -->
</AppModule>
```

JDeveloper also updates the component's custom Java class to modify its extends clause to reflect the new custom framework base class, as shown in Example 37-4.

**Example 37-4 Component's Custom Java Class Updates to Reflect New Base Class**

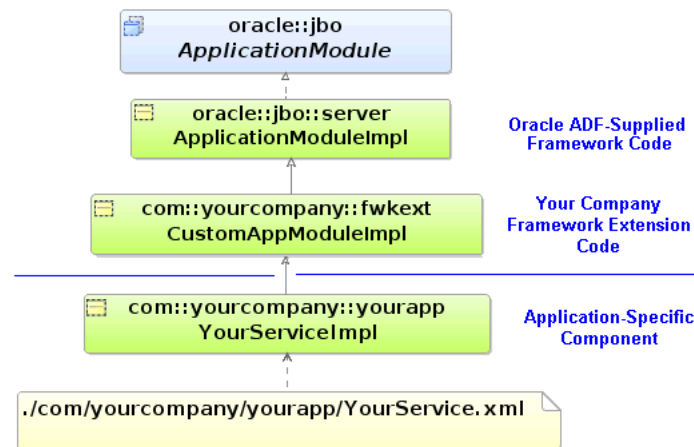

```
package com.yourcompany.yourapp;
import com.yourcompany.fwkext.CustomAppModuleImpl;
// -----
// --- File generated by Oracle ADF Business Components Design Time.
// --- Custom code may be added to this class.
// --- Warning: Do not modify method signatures of generated methods.
// -----
```

```

public class YourServiceImpl extends CustomAppModuleImpl {
    /**This is the default constructor (do not remove) */
    public YourServiceImpl() {}
    // etc.
}
    
```

Figure 37–5 illustrates how the `YourService` application module with its custom `YourServiceImpl` class is related to your framework extension class. At runtime, it uses the `YourServiceImpl` class which inherits its base behavior from the `CustomAppModuleImpl` framework extension class which, in turn, extends the base `ApplicationModuleImpl` class.

**Figure 37–5 Component with Custom Java Extending Customized Framework Base Class**

### 37.1.8 What You May Need to Know About Updating the Extends Clause in Custom Component Java Files

If you have an ADF component with a custom Java class and later decide to base the component on a framework extension class, use the **Class Extends** button in the Select Java Options dialog to change the component's base class. You can open the dialog from the **Java** page of the component's overview editor. Doing this updates the component's XML component definition to reflect the new base class, and *also* modifies the `extends` clause in the component's custom Java class.

---

**Caution:** If you manually update the `extends` clause without using the component editor, the component's XML document will not reflect the new inheritance and the next time you open the editor, your manually modified `extends` clause will be overwritten with what the component editor believes is the correct component base class.

---

### 37.1.9 How to Package Your Framework Extension Layer in a JAR File

Use the **Create Deployment Profile: JAR File** dialog to create a JAR file containing the classes in your framework extension layer. This is available in the **New Gallery** in the **General > Deployment Profiles** category.

Give the deployment profile a name like `FrameworkExtensions` and click **OK**. By default the JAR file will include all class files in the project. Since this is exactly what

you want, when the **JAR Deployment Profile Properties** dialog appears, you can just click **OK** to finish.

---

---

**Note:** Do not use the **ADF Library JAR** archive type to package your framework extension layer. You create the ADF Library JAR file when you want to package reusable components to share in the JDeveloper Resource Catalog. For details about working with ADF components and the ADF Library JAR archive type, see [Section 33.2, "Packaging a Reusable ADF Component into an ADF Library."](#)

---

---

Finally, to create the JAR file, right-click the project folder in the Application Navigator and choose **Deploy - YourProfileName - to JAR File** on the context menu. A **Deployment** tab appears in the JDeveloper **Log window** that should display feedback like:

```
---- Deployment started. ---- Feb 14, 2013 1:42:39 PM
Running dependency analysis...
Wrote JAR file to ...FrameworkExtensions\deploy\FrameworkExtensions.jar
Elapsed time for deployment: 2 seconds
---- Deployment finished. ---- Feb 14, 2013 1:42:41 PM
```

### 37.1.10 How to Create a Library Definition for Your Framework Extension JAR File

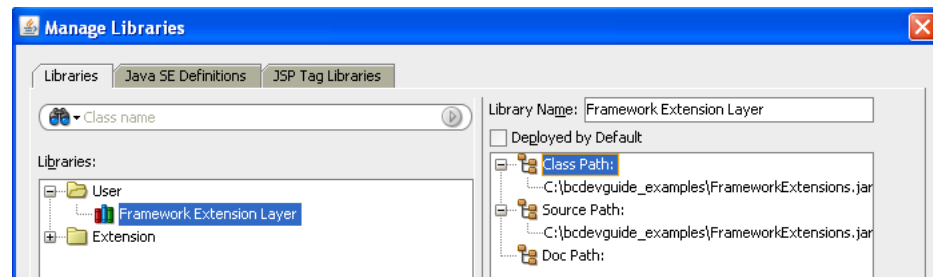

JDeveloper uses named libraries as a convenient way to organize the one or more JAR files that comprise reusable component libraries.

**To define a library for your framework extensions JAR file:**

1. Choose **Tools > Manage Libraries** from the JDeveloper main menu.
2. In the **Manage Libraries** dialog, select the **Libraries** tab.
3. Select the **User** folder in the tree and click the **New** button.
4. In the **Create Library** dialog that appears, name the library "Framework Extension Layer" and select the **Class Path** node and click **Add Entry**.
5. Use the **Select Path Entry** dialog that appears to select the `FrameworkExtensions.jar` file that contains the class files for the framework extension components, then click **Select**.
6. Select the **Source Path** node and click **Add Entry**.
7. Use the **Select Path Entry** dialog that appears to select the `..\FrameworkExtensions\src` directory where the source files for the framework extension classes reside, then click **Select**.
8. Click **OK** to dismiss the **Create Library** dialog and define the new library.

When finished, you will see your new "Framework Extension Layer" user-defined library, as shown in [Figure 37-6](#). You can then add this library to the library list of any project where you will be building business services, and your custom framework extension classes will be available to reference as the preferred component base classes.

**Figure 37–6** *New User-Defined Library for Your Framework Extensions Layer*

## 37.2 Customizing Framework Behavior with Extension Classes

One of the common tasks you'll perform in your framework extension classes is implementing custom application functionality. Since framework extension code is written to be used by all components of a specific type, the code you write in these classes often needs to work with component attributes in a generic way. To address this need, ADF provides API's that allow you to access component metadata at runtime. It also provides the ability to associate custom metadata properties with any component or attribute. You can write your generic framework extension code to leverage runtime metadata and custom properties to build generic functionality, which if necessary, only is used in the presence of certain custom properties.

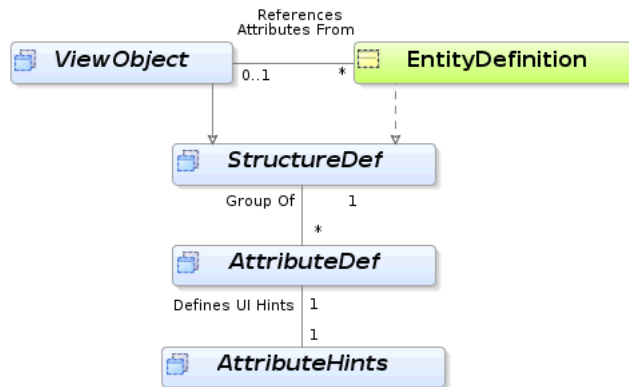

---

**Note:** The example in this section refers to the `ProgrammaticallySetProperties` project of the `AdvancedExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

### 37.2.1 How to Access Runtime Metadata For View Objects and Entity Objects

Figure 37–7 illustrates the three primary interfaces ADF provides for accessing runtime metadata about view objects and entity objects. The `ViewObject` interface extends the `StructureDef` interface. The class representing the entity definition (`EntityDefImpl`) also implements this interface. As its name implies, the `StructureDef` defines the structure and the component and provides access to a collection of `AttributeDef` objects that offer runtime metadata about each attribute in the view object row or entity row. Using an `AttributeDef`, you can access its companion `AttributeHints` object to reference hints like the display label, format mask, tooltip, etc.

**Figure 37–7 Runtime Metadata Available for View Objects and Entity Objects**

### 37.2.2 How to Implement Generic Functionality Using Runtime Metadata

In Section 6.4.1, "ViewObject Interface Methods for Working with the View Object's Default RowSet" you learned that for read-only view objects the `findByKey()` method and the `setCurrentRowWithKey` builtin operation only work if you override the `create()` method on the view object to call `setManageRowsByKey(true)`. This can be a tedious detail to remember if you create a lot of read-only view objects, so it is a great candidate for automating in a framework extension class for view objects.

Assume a `FrameworkExtensions` project contains a `FODViewObjectImpl` class that is the base class for all view objects in the application. This framework extension class for view objects extends the base `ViewObjectImpl` class and overrides the `create()` method as shown in Example 37–5 to automate this task. After calling the `super.create()` to perform the default framework functionality when a view object instance is created at runtime, the code tests whether the view object is a read-only view object with at least one attribute marked as a key attribute. If this is the case, it invokes `setManageRowsByKey(true)`.

The `isReadOnlyNonEntitySQLViewWithAtLeastOneKeyAttribute()` helper method determines whether the view object is read-only by testing the combination of the following conditions:

- `isFullSql()` is true
 

This method returns true if the view object's SQL query is completely specified by the developer, as opposed to having the select list derived automatically based on the participating entity usages.
- `getEntityDefs()` is null
 

This method returns an array of `EntityDefImpl` objects representing the view object's entity usages. If it returns null, then the view object has no entity usages.

It goes on to determine whether the view object has any key attributes by looping over the `AttributeDef` array returned by the `getAttributeDefs()` method. If the `isPrimaryKey()` method returns true for any attribute definition in the list, then you know the view object has a key.

#### **Example 37–5 Automating Setting Manage Rows By Key**

```

public class FODViewObjectImpl extends ViewObjectImpl {
    protected void create() {
        super.create();
        if (isReadOnlyNonEntitySQLViewWithAtLeastOneKeyAttribute()) {

```

```

        setManageRowsByKey(true);
    }
}
boolean isReadOnlyNonEntitySQLViewWithAtLeastOneKeyAttribute() {
    if (getViewDef().isFullSql() && getEntityDefs() != null) {
        for (AttributeDef attrDef : getAttributeDefs()) {
            if (attrDef.isPrimaryKey()) {
                return true;
            }
        }
    }
    return false;
}
// etc.
}

```

### 37.2.3 How to Implement Generic Functionality Driven by Custom Properties

In JDeveloper, when you create application modules, view objects, and entity objects you can select the **General** navigation tab in the overview editor for these business components and expand the **Custom Properties** section to define custom metadata properties for any component. These are name/value pairs that you can use to communicate additional declarative information about the component to the generic code that you write in framework extension classes. You can use the `getProperty()` method in your code to conditionalize generic functionality based on the presence of, or the specific value of, one of these custom metadata properties.

For example, the `FODViewObjectImpl` framework extension class overrides the view object's `insertRow()` method as shown in [Example 37-6](#) to conditionally force a row to be inserted and to appear as the last row in the row set. If any view object extending this framework extension class defines a custom metadata property named `InsertNewRowsAtEnd`, then this generic code executes to insert new rows at the end. If a view object does not define this property, it will have the default `insertRow()` behavior.

#### **Example 37-6** *Conditionally Inserting New Rows at the End of a View Object's Default RowSet*

```

public class FODViewObjectImpl extends ViewObjectImpl {
    private static final String INSERT_NEW_ROWS_AT_END = "InsertNewRowsAtEnd";
    public void insertRow(Row row) {
        super.insertRow(row);
        if (getProperty(INSERT_NEW_ROWS_AT_END) != null) {
            row.removeAndRetain();
            last();
            next();
            getDefaultRowSet().insertRow(row);
        }
    }
}
// etc.
}

```

In addition to defining component-level custom properties, you can also define properties on view object attributes, entity object attributes, and domains. At runtime, you access them using the `getProperty()` method on the `AttributeDef` interface for a given attribute.

### 37.2.4 How to Configure Design Time Custom Property Names

Once you have written framework extension classes that depend on custom properties, you can set a JDeveloper preference so that your custom property names show in the list on the **Custom Properties** section of the corresponding component editor. To set up these pre-defined custom property names, choose **Tools > Preferences** from the JDeveloper main menu and open the **Business Components > Property Names** tab in the **Preferences** dialog.

### 37.2.5 What You May Need to Know About the Kinds of Attributes

In addition to providing information about an attribute's name, Java type, SQL type, and many other useful pieces of information, the `AttributeDef` interface contains the `getAttributeKind()` method that you can use to determine the kind of attribute it represents. This method returns a byte value corresponding to one of the public constants in the `AttributeDef` interface listed in [Table 37-1](#).

**Table 37-1 Entity Object and View Object Attribute Kinds**

Public AttributeDef Constant	Attribute Kind Description
<code>ATTR_PERSISTENT</code>	Persistent attribute
<code>ATTR_TRANSIENT</code>	Transient attribute
<code>ATTR_ENTITY_DERIVED</code>	View object attribute mapped to an entity-level transient attribute
<code>ATTR_SQL_DERIVED</code>	SQL-Calculated attribute
<code>ATTR_DYNAMIC</code>	Dynamic attribute
<code>ATTR_ASSOCIATED_ROWITERATOR</code>	Accessor attribute returning a <code>RowSet</code> of set of zero or more Rows
<code>ATTR_ASSOCIATED_ROW</code>	Accessor attribute returning a single Row

### 37.2.6 What You May Need to Know About Custom Properties

You may find it handy to programmatically set custom property values at runtime. While the `setProperty()` API to perform this function is by design not available to clients on the `ViewObject`, `ApplicationModule`, or `AttributeDef` interfaces in the `oracle.jbo` package, code you write *inside* your ADF components' custom Java classes can use it.

## 37.3 Creating Generic Extension Interfaces

In addition to creating framework extension classes, you can create custom interfaces that all of your components can implement by default. The client interface is very useful for exposing methods from your application module that might be invoked by UI clients, for example. This section considers an example for an application module, however, the same functionality is possible for a custom extended view object and view row interface as well. For more information about client interfaces, see also [Section 9.9, "Publishing Custom Service Methods to UI Clients"](#) and [Section 9.10, "Working Programmatically with an Application Module's Client Interface."](#)

Assume that you have a `CustomApplicationModuleImpl` class that extends `ApplicationModuleImpl` and that you want to expose two custom methods like this:

```
public void doFeatureOne(String arg);
public int anotherFeature(String arg);
```

Perform the following steps to create a custom extension interface `CustomApplicationModule` and have your `CustomApplicationModuleImpl` class implement it.

1. Create a custom interface that contains the methods you would like to expose globally on your application module components. For this scenario, that interface would look like this:

```
package devguide.advanced.customintf.fwkext;
/**
 * NOTE: This does not extend the
 * ===== oracle.jbo.ApplicationModule interface.
 */
public interface CustomApplicationModule {
    public void doFeatureOne(String arg);
    public int anotherFeature(String arg);
}
```

Notice that the interface does *not* extend the `oracle.jbo.ApplicationModule` interface.

2. Modify your `CustomApplicationModuleImpl` application module framework extension class to implement this new `CustomApplicationModule` interface.

```
package devguide.advanced.customintf.fwkext;
import oracle.jbo.server.ApplicationModuleImpl;
public class CustomApplicationModuleImpl
    extends ApplicationModuleImpl
    implements CustomApplicationModule {
    public void doFeatureOne(String arg) {
        System.out.println(arg);
    }
    public int anotherFeature(String arg) {
        return arg == null ? 0 : arg.length();
    }
}
```

3. Rebuild your project.

The ADF wizards will only "see" your interfaces after they have been successfully compiled.

After you have implemented your `CustomApplicationModuleImpl` class, you can create a new application module which exposes the global extension interface and is based on your custom framework extension class. For this purpose you use the overview editor for application modules.

#### To create a custom application module interface:

1. In the Application Navigator, double-click the application module for which you want to create the custom interface.

For example, you might create a new `ProductModule` application module which exposes the global extension interface `CustomApplicationModule` and is based on the `CustomApplicationModuleImpl` framework extension class.

2. In the overview editor, select the **Java** navigation tab and click the **Edit Java options** icon.

The Java Classes page should show an existing Java class for the application module identified as **Application Module Class**.

By default, JDeveloper generates the Java class for application modules you create. However, if you disabled this feature, click the **Edit Java options** button in the Java Classes section and select **Generate Application Module Class**. Click **OK** to add a Java class to the project from which you will create the custom interface.

3. In the Select Java Options dialog, click **Class Extends**.
4. In the Override Base Classes dialog, specify the name of the framework base class you want to override and click **OK**.

For example, you might select `CustomApplicationModuleImpl` as the base class for the application module.

5. In the Java Classes page of the overview editor, expand the **Client Interface** section and click the **Edit application module client interface** button.
6. In the Edit Client Interface dialog, click the **Interfaces** button.
7. In the Select Interfaces to Extend dialog, select the desired custom application module interface from the available list and click **OK**.

For example, you might shuttle the `CustomApplicationModule` interface to the **Selected** list to be one of the custom interfaces that clients can use with your component.

8. In the Edit Client Interfaces dialog, ensure that at least one method appears in the **Selected** list.

---

**Note:** You need to select at least one method in the **Selected** list in the Edit Client Interfaces dialog, even if it means redundantly selecting one of the methods on the global extension interface. Any method will do in order to get JDeveloper to generate the custom interface.

---

9. Click **OK**.

The Java Classes page displays the new custom interface for the application module identified as **Application Module Client Interface**.

When you dismiss the Edit Client Interfaces dialog and return to the application module overview editor, JDeveloper generates the application module custom interface. For example, the custom interface `ProductModule` automatically extends *both* the base `ApplicationModule` interface and your `CustomApplicationModule` extension interface like this:

```
package devguide.advanced.customintf.common;
import devguide.advanced.customintf.fwkext.CustomApplicationModule;

import oracle.jbo.ApplicationModule;
// -----
// ---   File generated by Oracle ADF Business Components Design Time.
// -----
public interface ProductModule
    extends CustomApplicationModule, ApplicationModule {
    void doSomethingProductRelated();
}
```

Once you've done this, then client code can cast your `ProductModule` application module to a `CustomApplicationModule` interface and invoke the generic extension methods it contains in a strongly-typed way.

---

---

**Note:** The basic steps are the same for exposing methods on a `ViewObjectImpl` framework extension class, as well as for a `ViewRowImpl` extension class.

---

---

## 37.4 Invoking Stored Procedures and Functions

You can write code in the custom Java classes for your business components to invoke database stored procedures and functions. Here you'll consider some simple examples based on procedures and functions in a PL/SQL package; however, using the same techniques, you also can invoke procedures and functions that are not part of a package.

Consider the PL/SQL package shown in [Example 37-7](#).

### **Example 37-7 PL/SQL Package with Example Procedures**

```
create or replace package devguidepkg as
  procedure proc_with_no_args;
  procedure proc_with_three_args(n number, d date, v varchar2);
  function  func_with_three_args(n number, d date, v varchar2) return varchar2;
  procedure proc_with_out_args(n number, d out date, v in out varchar2);
end devguidepkg;
```

The following sections explain how to invoke each of the example procedures and functions in this package.

---

---

**Note:** The example in this section refers to the `StoredProcedureInvocation` project of the `AdvancedExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

### 37.4.1 How to Invoke Stored Procedures with No Arguments

If you need to invoke a stored procedure that takes no arguments, you can use the `executeCommand()` method on the `DBTransaction` interface (in the `oracle.jbo.server` package as shown in [Example 37-8](#)).

#### **Example 37-8 Executing a Stored Procedure with No Arguments**

```
// In StoredProcTestModuleImpl.java
public void callProcWithNoArgs() {
    getDBTransaction().executeCommand(
        "begin devguidepkg.proc_with_no_args; end;");
}
```

### 37.4.2 How to Invoke Stored Procedure with Only IN Arguments

Invoking stored procedures that accept only IN-mode arguments — which is the default PL/SQL parameter mode if not specified — requires using a JDBC `PreparedStatement` object. The `DBTransaction` interface provides a `createPreparedStatement()` method to create this object for you in the context of the current database connection. You could use a helper method like the one shown in [Example 37-9](#) to simplify the job of invoking a stored procedure of this kind using a `PreparedStatement`. Importantly, by using a helper method, you can encapsulate

the code that closes the JDBC `PreparedStatement` after executing it. The code performs the following basic tasks:

1. Creates a JDBC `PreparedStatement` for the statement passed in, wrapping it in a PL/SQL `begin...end` block.
2. Loops over values for the bind variables passed in, if any.
3. Sets the value of each bind variable in the statement.

Notice that since JDBC bind variable API's use one-based numbering, the code adds one to the zero-based for loop index variable to account for this.

4. Executes the statement.
5. Closes the statement.

**Example 37–9 Helper Method to Simplify Invoking Stored Procedures with Only IN Arguments**

```
protected void callStoredProcedure(String stmt, Object[] bindVars) {
    PreparedStatement st = null;
    try {
        // 1. Create a JDBC PreparedStatement for
        st = getDBTransaction().createPreparedStatement("begin "+stmt+"end;",0);
        if (bindVars != null) {
            // 2. Loop over values for the bind variables passed in, if any
            for (int z = 0; z < bindVars.length; z++) {
                // 3. Set the value of each bind variable in the statement
                st.setObject(z + 1, bindVars[z]);
            }
        }
        // 4. Execute the statement
        st.executeUpdate();
    }
    catch (SQLException e) {
        throw new JboException(e);
    }
    finally {
        if (st != null) {
            try {
                // 5. Close the statement
                st.close();
            }
            catch (SQLException e) {}
        }
    }
}
```

With a helper method like this in place, calling the `proc_with_three_args` procedure shown in [Example 37–7](#) would look like this:

```
// In StoredProcTestModuleImpl.java
public void callProcWithThreeArgs(Number n, Date d, String v) {
    callStoredProcedure("devguidepkg.proc_with_three_args(?,?,?)",
        new Object[]{n,d,v});
}
```

Notice the question marks used as JDBC bind variable placeholders for the arguments passed to the function. JDBC also supports using named bind variables, but using these simpler positional bind variables is also fine since the helper method is just setting the bind variable values positionally.

### 37.4.3 How to Invoke Stored Function with Only IN Arguments

Invoking stored functions that accept only IN-mode arguments requires using a JDBC `CallableStatement` object in order to access the value of the function result after executing the statement. The `DBTransaction` interface provides a `createCallableStatement()` method to create this object for you in the context of the current database connection. You could use a helper method like the one shown in [Example 37–10](#) to simplify the job of invoking a stored function of this kind using a `CallableStatement`. The helper method encapsulates both the creation and clean up of the JDBC statement being used.

The code performs the following basic tasks:

1. Creates a JDBC `CallableStatement` for the statement passed in, wrapping it in a PL/SQL `begin...end` block.
2. Registers the first bind variable for the function return value.
3. Loops over values for the bind variables passed in, if any.
4. Sets the value of each bind user-supplied bind variable in the statement.

Notice that since JDBC bind variable API's use one-based numbering, and since the function return value is already the first bind variable in the statement, the code adds *two* to the zero-based for loop index variable to account for these.

5. Executes the statement.
6. Returns the value of the first bind variable.
7. Closes the statement.

#### **Example 37–10 Helper Method to Simplify Invoking Stored Functions with Only IN Arguments**

```
// Some constants
public static int NUMBER = Types.NUMERIC;
public static int DATE = Types.DATE;
public static int VARCHAR2 = Types.VARCHAR;

protected Object callStoredFunction(int sqlReturnType, String stmt,
                                   Object[] bindVars) {
    CallableStatement st = null;
    try {
        // 1. Create a JDBC CallabledStatement
        st = getDBTransaction().createCallableStatement(
            "begin ? := "+stmt+";end;",0);
        // 2. Register the first bind variable for the return value
        st.registerOutParameter(1, sqlReturnType);
        if (bindVars != null) {
            // 3. Loop over values for the bind variables passed in, if any
            for (int z = 0; z < bindVars.length; z++) {
                // 4. Set the value of user-supplied bind vars in the stmt
                st.setObject(z + 2, bindVars[z]);
            }
        }
        // 5. Set the value of user-supplied bind vars in the stmt
        st.executeUpdate();
        // 6. Return the value of the first bind variable
        return st.getObject(1);
    }
    catch (SQLException e) {
        throw new JboException(e);
    }
}
```

```

    }
    finally {
        if (st != null) {
            try {
                // 7. Close the statement
                st.close();
            }
            catch (SQLException e) {}
        }
    }
}

```

With a helper method like this in place, calling the `func_with_three_args` procedure shown in [Example 37-7](#) would look like this:

```

// In StoredProcTestModuleImpl.java
public String callFuncWithThreeArgs(Number n, Date d, String v) {
    return (String)callStoredFunction(VARCHAR2,
        "devguidepkg.func_with_three_args(?,?,?)",
        new Object[]{n,d,v});
}

```

Notice the question marks are used as JDBC bind variable placeholders for the arguments passed to the function. JDBC also supports using named bind variables, but using these simpler positional bind variables is also fine since the helper method is just setting the bind variable values positionally.

### 37.4.4 How to Call Other Types of Stored Procedures

Calling a stored procedure or function like `devguidepkg.proc_with_out_args` that includes arguments of `OUT` or `IN OUT` mode requires using a `CallableStatement` as in the previous section, but is a little more challenging to generalize into a helper method. [Example 37-11](#) illustrates the JDBC code necessary to invoke the `devguidepkg.proc_with_out_args` procedure.

The code performs the following basic tasks:

1. Defines a PL/SQL block for the statement to invoke.
2. Creates the `CallableStatement` for the PL/SQL block.
3. Registers the positions and types of the `OUT` parameters.
4. Sets the bind values of the `IN` parameters.
5. Executes the statement.
6. Creates a `JavaBean` to hold the multiple return values

The `DateAndStringBean` class contains bean properties named `dateVal` and `stringVal`.

7. Sets the value of its `dateVal` property using the first `OUT` param.
8. Sets value of its `stringVal` property using second `OUT` param.
9. Returns the result.
10. Closes the JDBC `CallableStatement`.

**Example 37-11 Calling a Stored Procedure with Multiple OUT Arguments**

```

public Date callProcWithOutArgs(Number n, String v) {
    CallableStatement st = null;

```

```

try {
    // 1. Define the PL/SQL block for the statement to invoke
    String stmt = "begin devguidepkg.proc_with_out_args(?,?,?); end;";
    // 2. Create the CallableStatement for the PL/SQL block
    st = getDBTransaction().createCallableStatement(stmt,0);
    // 3. Register the positions and types of the OUT parameters
    st.registerOutParameter(2,Types.DATE);
    st.registerOutParameter(3,Types.VARCHAR);
    // 4. Set the bind values of the IN parameters
    st.setObject(1,n);
    st.setObject(3,v);
    // 5. Execute the statement
    st.executeUpdate();
    // 6. Create a bean to hold the multiple return values
    DateAndStringBean result = new DateAndStringBean();
    // 7. Set value of dateValue property using first OUT param
    result.setDateVal(new Date(st.getDate(2)));
    // 8. Set value of stringValue property using 2nd OUT param
    result.setStringVal(st.getString(3));
    // 9. Return the result
    return result;
} catch (SQLException e) {
    throw new JboException(e);
} finally {
    if (st != null) {
        try {
            // 10. Close the JDBC CallableStatement
            st.close();
        }
        catch (SQLException e) {}
    }
}
}

```

The `DateAndString` bean used in [Example 37–11](#) is a simple `JavaBean` with two bean properties like this:

```

package devguide.advanced.storedproc;
import java.io.Serializable;
import oracle.jbo.domain.Date;
public class DateAndStringBean implements Serializable {
    Date dateVal;
    String stringVal;
    public void setDateVal(Date dateVal) {this.dateVal=dateVal;}
    public Date getDateVal() {return dateVal;}
    public void setStringVal(String stringVal) {this.stringVal=stringVal;}
    public String getStringVal() {return stringVal;}
}

```

---

**Note:** In order to allow the custom method to be a legal candidate for inclusion in an application module's custom service interface (if desired), the bean needs to implement the `java.io.Serializable` interface. Since this is a "marker" interface, this involves simply adding the `implements Serializable` keywords without needing to code the implementation of any interface methods.

---

## 37.5 Accessing the Current Database Transaction

Since the ADF Business Components components abstract all of the lower-level database programming details for you, you typically won't need *direct* access to the JDBC `Connection` object. Unless you use the reserved release mode described in [Section 40.2.2.3.3, "About Reserved Release Level,"](#) there is no guarantee at runtime that your application will use the exact same application module instance or JDBC `Connection` instance across different web page requests. Since inadvertently holding a reference to the JDBC `Connection` object in this type of pooled services environment can cause unpredictable behavior at runtime, by design, the ADF Business Components layer has no direct API to obtain the JDBC `Connection`. This is an intentional attempt to discourage its direct use and inadvertent abuse.

However, on occasion it may come in handy when you're trying to integrate third-party code with ADF Business Components, so you can use a helper method like the one shown in [Example 37–12](#) to access the connection.

### **Example 37–12** Helper Method to Access the Current JDBC Connection

```
/**
 * Put this method in your XXXXImpl.java class where you need
 * to access the current JDBC connection
 */
private Connection getCurrentConnection() throws SQLException {
    /* Note that we never execute this statement, so no commit really happens */
    PreparedStatement st = getDBTransaction().createPreparedStatement("commit",1);
    Connection conn = st.getConnection();
    st.close();
    return conn;
}
```

---

---

**Caution:** Never cache the JDBC connection obtained using the helper method from [Example 37–12](#) in your own code anywhere. Instead, call the helper method each time you need it to avoid inadvertently holding a reference to a JDBC `Connection` that might be used in another request by another user at a later time do to the pooled services nature of the ADF runtime environment.

---

---

## 37.6 Working with Libraries of Reusable Business Components

As with other Java components, you can create a JAR file containing one or more packages of reusable ADF components. Then, in other projects you can import one or more packages of components from this component library to reference those in a new application.

### 37.6.1 How To Create a Reusable Library of Business Components

Use the **Create Business Components Archive Profile** dialog to create a JAR file containing the Java classes and XML component definitions that comprise your business components library. This is available in the **New Gallery** in the **General > Deployment Profiles** category.

---

---

**Note:** If you don't see the **Deployment Profiles** category in the **New Gallery**, set the **Filter By** dropdown list at the top of the dialog to the **All Technologies** choice to make it visible.

---

---

Give the deployment profile a name like `ReusableComponents` and click **OK**. As the Project Properties dialog shows in [Figure 37–8](#), the `ReusableComponents` business components deployment archive profile contains two nested JAR deployment profiles:

- `Common.deploy`
- `MiddleTier.deploy`

These two nested profiles are standard JAR deployment profiles that are pre-configured to bundle:

- All of the business components custom java classes and XML component definitions into a `ReusableComponentsCSMT.jar` archive
- All of the client interfaces, message bundle classes, and custom domains into a `ReusableComponentsCSCommon.jar`

They are partitioned this way in order to simplify deployment of ADF Business Components-based applications. The `*CSMT.jar` is an archive of components designed to be deployed only on the middle tier application server. The `*CSCommon.jar` is common both to the application server and to the remote client tier in the deployment scenario when the client interacting with the application module is running in a different physical server from the application module with which it is working.

**Figure 37–8 Business Components Archive Deployment Profile Contains Nested Profiles**

To create the JAR files, in the Application Navigator right-click the `Business Components` project folder and choose **Deploy** and the `ReusableComponents` profile. A `Deployment` tab appears in the JDeveloper Log window that should display feedback like:

```
---- Deployment started. ---- Apr 28, 2009 7:04:02 PM
Running dependency analysis...
Wrote JAR file to ...\.ReuseableComponents\deploy\ReuseableComponentsCSMT.jar
Running dependency analysis...
```

```
Wrote JAR file to ...\\ReuseableComponents\\deploy\\ReuseableComponentsCSCommon.jar
Elapsed time for deployment: less than one second
---- Deployment finished. ---- Apr 28, 2009 7:04:02 PM
```

## 37.6.2 How To Import a Package of Reusable Components from a Library

Once you have created a reusable library of business components, you can import one or more packages of components from that library in other projects to reference them. When you import a package of business components from a library, the components in that package are available in the various **Available** lists of the ADF Business Components component wizards and editor, however they do not display in the Application Navigator nor are they editable. The only components that appear in the Application Navigator are the ones in the source path for the current project.

**Tip:** If you require components that are editable and display in the Application Navigator. Add additional business components from a directory that is not currently part of your project's source path, then open the **Project Content** page of the **Project Properties** dialog and add the parent directory for these other components as one of the directories in the **Java Content** list. In contrast to imported packages of components, additional components added to your project's source path will be fully editable and will appear in the Application Navigator.

### To import a package of business components from a library:

1. Define a library for your JAR file on the **Libraries** tab of the **Project Properties** dialog of the importing project.  
  
You can define the library as a project-level library or a user-level library. Be sure to include both the `*CSMT.jar` and the `*CSCommon.jar` in the class path of the library definition.
2. Include the new library in your importing project's library list.
3. With the importing project selected in the Application Navigator, choose **Import** from the **File** menu.
4. In the Import dialog, select **Business Components** from the list.
5. Use the file open dialog to navigate *into* your library's `*CSMT.jar` file — as if it were a directory — and select the XML component definition file from any components in the package whose components you want to import.
6. Acknowledge the alert that confirms the successful importing of the package.
7. Repeat steps 3-6 again for each package of components you want to import.

Assuming that there was an entity object like `Product` in the package(s) of components you imported, you could then create a new view object in the importing project using the imported `Product` component as its entity usage. This is just one example. You can reference any of the imported components as if they were in the source path of your project. The only difference is that you cannot *edit* the imported components. In fact, the reusable component library JAR file might only contain the XML component definition files and the Java `*.class` files for the components without any source code.

### 37.6.3 How to Remove an Imported Package from a Project

If you mistakenly import a package of components, or wish to remove an imported package of components that you are not using, you can use the Project Properties dialog to do this.

#### To unimport a package:

1. In the Application Navigator, right-click the model project that contains the package you want to unimport and choose **Project Properties**.
2. In the Project Properties dialog, select **Business Components > Imports**.
3. Select the project from the list of imported projects and click **Delete**.
4. Click **OK** to save the changes to the workspace in JDeveloper.

---

---

**Caution:** Do not remove an imported package if your project still has components that reference it. If you do, JDeveloper will throw exceptions when the project is opened, or your application may have unpredictable behavior. In the Business Components: Imports page of the Project Properties dialog, click the **Show Usages** button to ensure that there are no references to any of the components in the imported package before manually removing the package entry from the `*.jpx` file.

---

---

### 37.6.4 What Happens When You Import a Package of Reusable Components from a Library

When you import a package of components into a project named *YourImportingProjectName*, JDeveloper adds a reference to that package in the *YourImportingProjectName.jpx* file in the root directory of your importing project's source path. As part of this entry, it includes a design time project named `_LocationURL` whose value points to the JAR file in which the imported components reside.

### 37.6.5 What You May Need to Know About Imported Projects

Components in imported libraries are not editable. If a project imports a package containing business components, the importing project cannot add new components to that same package. The importing project can reference the imported components in new components created in any other package, but cannot add new components to the imported package.

Additionally, if you make changes to your imported components and update the JAR file that contains them, you need to close and reopen any importing projects in order to pickup the changes. This does not require exiting out of JDeveloper. You can select your importing project in the Application Navigator, choose **Close** from the **File** menu, and then re-expand the project's nodes to close and reopen the project. When you do this, JDeveloper will reread the components from the updated version of the imported JAR file.

## 37.7 Customizing Business Components Error Messages

---

**Note:** The example in this section refers to the `CustomizedErrorMessage`s project of the `AdvancedExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

You can customize any of the builtin ADF Business Components error messages by providing an alternative message string for the error code in a custom message bundle.

---

**Note:** For your convenience, the `CustomizedErrorMessage`s project in the `AdvancedExamples` workspace of the Fusion Order Demo lets you test the custom message bundle sample described in this section. Before you run the `ProductModule`, you will need to run the `addProductsTableConstraint.sql` script to set up the sample with the corresponding database constraint. When you run the `ProductModule` application module in the Business Component Browser, you can blank out the **ProductId** attribute and click the **Validate** button. This will show the custom error message for the JBO error. Rollback the change and then enter `undefined` in the **ProductName** attribute. You can view the custom error message for the database error by clicking **Commit** (clicking **Validate** won't perform a commit to the database, so the database error is not generated in that case).

---

### 37.7.1 How to Customize Base ADF Business Components Error Messages

Assume you want to customize the builtin error message:

```
JBO-27014: Attribute Name is Product is required
```

If you have requested the Oracle Application Development Framework (Oracle ADF) source code from Oracle Worldwide Support, you can look in the `CSMessageBundle.java` file in the `oracle.jbo` package to see that this error message is related to the combination of the following lines in that message bundle file:

```
public class CSMessageBundle extends CheckedListResourceBundle {
    // etc.
    public static final String EXC_VAL_ATTR_MANDATORY = "27014";
    // etc.
    private static final Object[][] sMessageStrings = {
        // etc.
        {EXC_VAL_ATTR_MANDATORY, "Attribute {2} in {1} is required"},
        // etc.
    }
}
```

The numbered tokens `{2}` and `{1}` are error message placeholders. In this example the `{1}` is replaced at runtime with the name of the entity object and the `{2}` with the name of the attribute.

**To create a custom message bundle file:**

1. In the Application Navigator, right-click the model project that you want to add the message bundle file to and choose **Project Properties**.
2. In the Project Properties dialog, select **Business Components > Options**.

The **Custom Message Bundles to use in this Project** list displays at the bottom of the dialog.

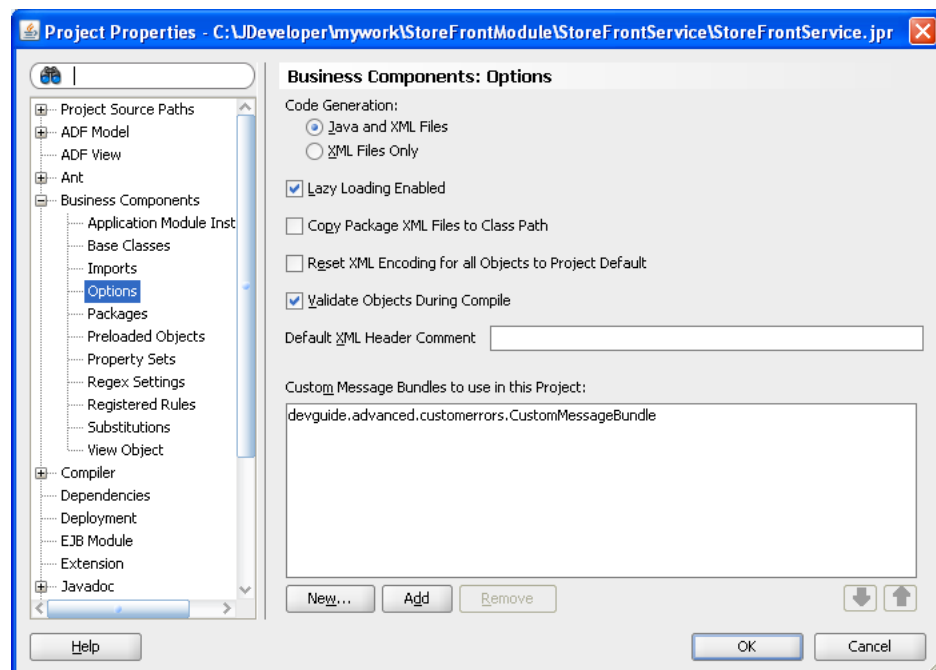

3. Click **New**.
4. Enter a name and package for the custom message bundle in the **Create MessageBundle** class dialog and click **OK**.

---

**Note:** If the fully-qualified name of your custom message bundle file does not appear in the **Custom Message Bundles to use in this Project** list, click the **Remove** button, then click the **Add** button to add the new message bundle file created. When the custom message bundle file is correctly registered, its fully-qualified class name should appear in the list, as shown in [Figure 37–9](#).

---

**Figure 37–9** *Project Properties Displays Message Resource Bundles*

5. Click **OK** to dismiss the **Project Properties** dialog and open the new custom message bundle class in the source editor.
6. Edit the two-dimensional `String` array in the custom message bundle class to contain any customized messages you'd like to use.

[Example 37–13](#) illustrates a custom message bundle class that overrides the error message string for the JBO-27014 error.

**Example 37–13** *Custom ADF Business Components Message Bundle*

```
package devguide.advanced.customerrors;
import java.util.ListResourceBundle;
```

```
public class CustomMessageBundle extends ListResourceBundle {
    private static final Object[][] sMessageStrings
        = new String[][] {
        {"27014", "You must provide a value for {2}"}
    };
    protected Object[][] getContents() {
        return sMessageStrings;
    }
}
```

## 37.7.2 What Happens When You Customize Base ADF Business Components Error Messages

After adding this message to your custom message bundle file, if you test the application using the Business Component Browser and try to blank out the value of a mandatory attribute, you'll now see your custom error message instead of the default one:

```
JBO-27014: You must provide a value for Name
```

You can add as many messages to the message bundle as you want. Any message whose error code key matches one of the built-in error message codes will be used at runtime instead of the default one in the `oracle.jbo.CSMessageBundle` message bundle.

## 37.7.3 How to Display Customize Error Messages as Nested Exceptions

When you customize ADF Business Components error messages, you will also need to customize the display of nested error messages. To accomplish this, you must create and register a custom error handler class.

When your business method throws an error, the ADF binding layer intercepts the error and invokes the registered custom error handler class. In general, the error handler class is responsible for formatting the exception to be readable. During this process, the default error handler `DCErrorHandlerImpl` normally skips the top-level `JboException`, as this object is a wrapper over other business exceptions and does not have any business significance.

Although skipping the top-level exception is the desired behavior in the case of ADF Business Components errors, the default behavior will result in skipping the custom message you set for replacing the `SQLException`. To avoid this situation, while displaying each item in a nested exception, your custom error handler class must override `DCErrorHandlerImpl::skipException(Exception ex)` to decide whether to display the corresponding exception to the user in the final list or not.

### Before you begin:

It may be helpful to have an understanding of application modules. For more information, see [Section 37.9, "Substituting Extended Components in a Delivered Application."](#)

You will need to complete this task:

Create the error message in the resource bundle, as described in [Section 37.7.1, "How to Customize Base ADF Business Components Error Messages."](#)

### To provide custom messages for `SQLExceptions` in your project:

1. Create an error handler class that extends the default error handler `DCErrorHandlerImpl` interface provided by the ADF binding layer.

2. In the error handler class, override the default error handler behavior for the `DCErrorHandlerImpl::skipException(Exception ex)` method, as shown in [Example 37-14](#).

This overridden method is necessary to display each item in a nested exception, such as the ones returned for database-level error messages. You must implement logic to check for specific exception types and, based on the business scenario, determine whether to display it in the list.

3. You can then register the custom error handler in your project's `DataBindings.cpx` file, as described in [Section 28.10, "Customizing Error Handling."](#)

[Example 37-14](#) shows a custom implementation of the error handler that skips the `SQLIntegrityConstraintViolationException` from displaying in the error final list displayed to the user. You can choose to skip other database-level error message resulting from errors, such as unique constraint violations or foreign key constraint violations.

#### **Example 37-14 DDL Statement Specifies Constraint Name**

```
package view;

import java.sql.SQLIntegrityConstraintViolationException;

import oracle.adf.model.BindingContext;
import oracle.adf.model.RegionBinding;
import oracle.adf.model.binding.DCBindingContainer;
import oracle.adf.model.binding.DCErrorHandlerImpl;

import oracle.adf.model.binding.DCErrorMessage;

import oracle.jbo.DMLConstraintException;
import oracle.jbo.JboException;

public class CustomErrorHandler extends DCErrorHandlerImpl {

    public CustomErrorHandler() {
        super(false);
    }

    public CustomErrorHandler(boolean b) {
        super(b);
    }

    /**
     * If an exception is a RowValException or a TxnValException
     * and they have nested exceptions, then do not display
     * it.
     */
    @Override
    protected boolean skipException(Exception ex) {

        if (ex instanceof DMLConstraintException) {
            return false;
        } else if (ex instanceof SQLIntegrityConstraintViolationException) {
            return true;
        }
        return super.skipException(ex);
    }
}
```

)

### 37.7.4 How to Customize Error Messages for Database Constraint Violations

If you enforce constraints in the database, you might want to provide a custom error message in your Fusion web application to display to the end user when one of those constraints is violated. For example, assume a constraint called `NAME_CANNOT_BEGIN_WITH_U` gets added to the application's `PRODUCTS_BASE` table using the following DDL statement shown in [Example 37-15](#).

**Example 37-15 DDL Statement Specifies Constraint Name**

```
alter table products_base add (
  constraint name_cannot_begin_with_u
    check (upper(substr(product_name,1,1)) != 'U')
);
```

To define a custom error message in your application, you add a message to a custom message bundle with the constraint name as the message key. [Example 37-16](#) shows the `CustomMessageBundle.java` class when it defines a message with the key `NAME_CANNOT_BEGIN_WITH_U` which matches the name of the database constraint name defined in [Example 37-15](#).

**Example 37-16 Customizing Error Message for Database Constraint Violation**

```
package devguide.advanced.customerrors;
import java.util.ListResourceBundle;
public class CustomMessageBundle extends ListResourceBundle {
  private static final Object[][] sMessageStrings
    = new String[][] {
    {"NAME_CANNOT_BEGIN_WITH_U",
     "The name cannot begin with the letter u!"}
  };
  protected Object[][] getContents() {
    return sMessageStrings;
  }
}
```

### 37.7.5 How to Implement a Custom Constraint Error Handling Routine

If the default facility for assigning a custom message to a database constraint violation does not meet your needs, you can implement your own custom constraint error handling routine. Doing this requires creating a custom framework extension class for the ADF transaction class, which you then configure your application module to use at runtime.

#### 37.7.5.1 Creating a Custom Database Transaction Framework Extension Class

To write a custom framework extension class for the ADF transaction, create a class like the `CustomDBTransactionImpl` shown in [Example 37-17](#). This example overrides the transaction object's `postChanges()` method to wrap the call to `super.postChanges()` with a `try/catch` block in order to perform custom processing on any `DMLConstraintException` errors that might be thrown. In this simple example, the only custom processing being performed is a call to `ex.setExceptions(null)` to clear out any nested detail exceptions that the `DMLConstraintException` might have. Instead of this, you could perform any other kind of custom exception processing required by your application, including

throwing a *custom* exception, provided your custom exception extends `JboException` directly or indirectly.

**Example 37–17 Custom Database Transaction Framework Extension Class**

```
package devguide.advanced.customerrors;
import oracle.jbo.DMLConstraintException;
import oracle.jbo.server.DBTransactionImpl2;
import oracle.jbo.server.TransactionEvent;
public class CustomDBTransactionImpl extends DBTransactionImpl2 {
    public void postChanges(TransactionEvent te) {
        try {
            super.postChanges(te);
        }
        /*
         * Catch the DML constraint exception
         * and perform custom error handling here
         */
        catch (DMLConstraintException ex) {
            ex.setExceptions(null);
            throw ex;
        }
    }
}
```

### 37.7.5.2 Configuring an Application Module to Use a Custom Database Transaction Class

In order for your application module to use a custom database transaction class at runtime, you must:

1. Provide a custom implementation of the `DatabaseTransactionFactory` class that overrides the `create()` method to return an instance of the customized transaction class.
2. Configure the value of the `TransactionFactory` property to be the fully-qualified name of this custom transaction factory class.

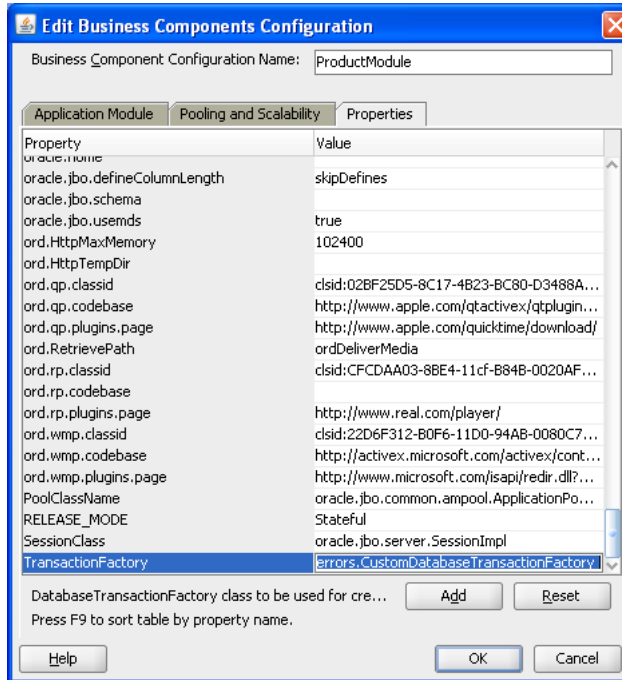

[Example 37–18](#) shows a custom database transaction factory class that does this. It returns a new instance of the `CustomDBTransactionImpl` class when the framework calls the `create()` method on the database transaction factory.

**Example 37–18 Custom Database Transaction Factory Class**

```
package devguide.advanced.customerrors;
import oracle.jbo.server.DBTransactionImpl2;
import oracle.jbo.server.DatabaseTransactionFactory;
public class CustomDatabaseTransactionFactory
    extends DatabaseTransactionFactory {
    public CustomDatabaseTransactionFactory() {
    }
    /**
     * Return an instance of our custom ToyStoreDBTransactionImpl class
     * instead of the default implementation.
     *
     * @return instance of custom CustomDBTransactionImpl implementation.
     */
    public DBTransactionImpl2 create() {
        return new CustomDBTransactionImpl();
    }
}
```

To complete the job, use the Properties tab of the Create Business Components Configuration dialog to assign the value `devguide.advanced.customerrors.CustomDatabaseTransactionFactory` to the `TransactionFactory` property, as shown in [Figure 37–10](#). You can open the Create Business Components Configuration dialog from the Configuration page of the overview editor for the application module by clicking the **Create new configuration objects** button. When you run the application using this configuration, your custom transaction class will be used.

**Figure 37–10 ADF Business Components Can Use Custom Database Transaction Class**

## 37.8 Creating Extended Components Using Inheritance

Whenever you create a new business component, if necessary, you can extend an existing one to create a customized version of the original. As shown in [Figure 37–11](#), the `ProductsByName` view object extends the `ProductsBase` view object to add a named bind variable named `TheStatus` and to customize the `WHERE` clause to reference that bind variable.

**Figure 37–11 ADF Business Components Can Extend Another Component**

While the figure shows a view object example, this component inheritance facility is available for all component types. When one component extends another, the extended component inherits all of the metadata and behavior from the parent it extends. In the extended component, you can add new features or customize existing features of its parent component both through metadata and Java code.

---

---

**Note:** The example in this section refers to the `BaseProject` project of the `AdvancedExamples` workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

### 37.8.1 How To Create a Component That Extends Another

To create an extended component, use the component wizard in the **New Gallery** for the type of component you want to create. For example, to create an extended view object, you use the Create View Object wizard. On the **Name** page of the wizard — in addition to specifying a name and a package for the new component — provide the fully-qualified name of the component that you want to extend in the **Extends** field. To pick the component name from a list, use the **Browse** button next to the **Extends** field. Then, continue to create the extended component in the normal way using the remaining panels of the wizard.

### 37.8.2 How To Extend a Component After Creation

After you define an extended component, JDeveloper lets you change the parent component from which an extended component inherits. You can use the overview editor for the component to accomplish this.

**To change the parent component after creation:**

1. Double-click the component.
2. In the overview editor for the component, click the **General** navigation tab and click the **Refactor object extends** button next to the **Extends** field.
3. In the Select Parent dialog, choose the desired component to extend from the package list.

To change the extended component to not inherit from any parent, select the **None** checkbox in the Select Parent dialog. This has the same effect as if you deleted the component and recreated to accomplish this.

### 37.8.3 What Happens When You Create a Component That Extends Another

ADF business components you create are comprised of an XML component definition and an optional Java class. When you create a component that extends another, JDeveloper reflects this component inheritance in both the XML component definition and in any generated Java code for the extended component.

#### 37.8.3.1 Attributes in an Extended Component Inherited from the Parent Component

When you create an extended component, the extended component inherits the attributes and attribute properties of the parent component. This connection is maintained because the inherited attributes are not defined in the extended component, they are simply passed through from the parent component. Therefore, if after creating an extended component you subsequently modify an attribute in the parent component, the extended component's attribute reflects that modification.

For example, say you create a `ProductViewEx` extended view object that extends a `ProductView` view object. Then you decide to set the **Display UI** hint for the `ShortDesc` attribute to **Hide** in the `ProductView` parent view object. When you do this, the `ShortDesc` attribute is hidden in the `ProductViewEx` extended view object as well.

However, if you override an attribute in the extended object, this connection is severed because the overridden attribute is redefined in the extended object. This allows you to make a change in an extended object without impacting the parent object or any other objects derived from that parent object. Note that the override applies only to the selected attribute, the other inherited attributes are unaffected.

For example, say you have a `ProductView` view object and two extended view objects, `ProductViewEx1` and `ProductViewEx2`. After setting the **Display UI** hint for the `ShortDesc` attribute to **Hide** in the `ProductView` parent view object, you decide to set it to **Show** in the `ProductViewEx1` extended view object. When you override `ShortDesc` in `ProductViewEx1` and set the **Display UI** hint to **Show**, the change is only reflected in the `ProductViewEx1` extended view object, not in the `ProductViewEx2` extended view object or the `ProductView` parent view object.

### 37.8.3.2 Attributes Added to the Extended Component's XML Descriptor

JDeveloper notes the name of the parent component in the new component's XML component definition by adding an `Extends` attribute to the root component element. Any new declarative features you add or any aspects of the parent component's definition you've overridden appear in the extended component's XML component definition. In contrast, metadata that is purely inherited from the parent component is not repeated for the extended component.

[Example 37–19](#) shows what the `ProductsByName.xml` XML component definition for the `ProductsByName` view object looks like. Notice the `Extends` attribute on the `<ViewObject>` element, the `<Variable>` element related to the additional bind variable added in the extended view object, and the overridden value of the `Where` attribute for the `WHERE` clause that was modified to reference the `theProductName` bind variable.

#### **Example 37–19** Extended Component Reflects Parent in Its XML Descriptor

```
<ViewObject
  xmlns="http://xmlns.oracle.com/bc4j"
  Name="ProductsByName"
  Extends="devguide.advanced.baseproject.extsub.Products"
  Where="UPPER(PRODUCT_NAME) LIKE UPPER(:theProductName) || '%'"
  BindingStyle="OracleName"
  CustomQuery="false"
  RowClass="devguide.advanced.baseproject.extsub.ProductsByNameRowImpl"
  ComponentClass="devguide.advanced.baseproject.extsub.ProductsByNameImpl"
  ...
  <Variable
    Name="theProductName"
    Kind="where"
    Type="java.lang.String"/>
  ...
</ViewObject>
```

### 37.8.3.3 Java Classes Generated for an Extended Component

If you enable custom Java code for an extended component, JDeveloper automatically generates the Java classes to extend the respective Java classes of its parent component. In this way, the extended component can override any aspect of the parent component's programmatic behavior as necessary. If the parent component is an XML-only component with no custom Java class of its own, the extended component's Java class extends whatever base Java class the parent would use at runtime. This could be the default ADF Business Components framework class in the `oracle.jbo.server` package, or could be your own framework extension class if you have specified that in the **Extends** dialog of the parent component.

In addition, if the extended component is an application module or view object and you enable client interfaces on it, JDeveloper automatically generates the extended component's client interfaces to extend the respective client interfaces of the parent component. If the respective client interface of the parent component does not exist, then the extended component's client interface directly extends the appropriate base ADF Business Components interface in the `oracle.jbo` package.

## 37.8.4 What You May Need to Know About Extending Components

### 37.8.4.1 Parent Classes and Interfaces for Extended Components

Since an extended component is a customized version of its parent, code you write that works with the *parent* component's Java classes or its client interfaces works without incident for either the parent component *or* any customized version of that parent component.

For example, assume you have a base `Products` view object with custom Java classes and client interfaces like:

- `class ProductsImpl`
- `row class ProductsRowImpl`
- `interface Products`
- `row interface ProductsRow`

If you create a `ProductsByName` view object that extends `Products`, then you can use the base component's classes and interface to work both with `Products` and `ProductsByName`.

[Example 37–20](#) illustrates a test client program that works with the `Products`, `ProductsRow`, `ProductsByName`, and `ProductsByNameRow` client interfaces. A few interesting things to note about the example are the following:

1. You can use parent `Products` interface for working with the `ProductsByName` view object that extends it.
2. Alternatively, you can cast an instance of the `ProductsByName` view object to its own more specific `ProductsByName` client interface.
3. You can test if row `ProductsRow` is actually an instance of the more specific `ProductsByNameRow` before casting it and invoking a method specific to the `ProductsByNameRow` interface.

#### **Example 37–20 Working with Parent and Extended Components**

```
package devguide.advanced.baseproject.extsub;
```

```

/* imports omitted */
public class TestClient {
    public static void main(String[] args) {
        String      amDef = "devguide.advanced.baseproject.extsub.ProductModule";
        String      config = "ProductModuleLocal";
        ApplicationModule am =
        Configuration.createRootApplicationModule(amDef,config);
        Products products = (Products)am.findViewObject("Products");
        products.executeQuery();
        ProductsRow product = (ProductsRow)products.first();
        printAllAttributes(products,product);
        testSomethingOnProductsRow(product);
        // 1. You can use parent Products interface for ProductsByName
        products = (Products)am.findViewObject("ProductsById");
        // 2. Or cast it to its more specific ProductsByName interface
        ProductsByName productsById = (ProductsByName)products;
        productsById.setProductName("Ice");
        productsById.executeQuery();
        product = (ProductsRow)productsById.first();
        printAllAttributes(productsById,product);
        testSomethingOnProductsRow(product);
        am.getTransaction().rollback();
        Configuration.releaseRootApplicationModule(am,true);
    }
    private static void testSomethingOnProductsRow(ProductsRow product) {
        try {
            // 3. Test if row is a ProductsByNameRow before casting
            if (product instanceof ProductsByNameRow) {
                ProductsByNameRow productByName = (ProductsByNameRow)product;
                productByName.someExtraFeature("Test");
            }
            product.setName("Q");
            System.out.println("Setting the Name attribute to 'Q' succeeded.");
        }
        catch (ValidationException v) {
            System.out.println(v.getLocalisedMessage());
        }
    }
    private static void printAllAttributes(ViewObject vo, Row r) {
        String viewObjName = vo.getName();
        System.out.println("Printing attribute for a row in VO '"+
            viewObjName+"'");
        StructureDef def = r.getStructureDef();
        StringBuilder sb = new StringBuilder();
        int numAttrs = def.getAttributeCount();
        AttributeDef[] attrDefs = def.getAttributeDefs();
        for (int z = 0; z < numAttrs; z++) {
            Object value = r.getAttribute(z);
            sb.append(z > 0 ? " " : "")
                .append(attrDefs[z].getName())
                .append("=")
                .append(value == null ? "<null>" : value)
                .append(z < numAttrs - 1 ? "\n" : "");
        }
        System.out.println(sb.toString());
    }
}

```

Running the test client produces the results shown in [Example 37–21](#).

**Example 37–21 Results of Running TestClient.java**

```

Printing attribute for a row in VO 'Products'
ProdId=100
    Name=Washing Machine W001
    Checksum=I am the Product Class
Setting the Name attribute to 'Q' succeeded.
Printing attribute for a row in VO 'ProductsById'
ProdId=119
    Name=Ice Maker I012
    Checksum=I am the Product Class
    SomeExtraAttr=SomeExtraAttrValue
## Called someExtraFeature of ProductsByNameRowImpl
Setting the Name attribute to 'Q' succeeded.

```

---

**Note:** In this example, `Products` is an entity-based view object based on the `Product` entity object. The `Product` entity object includes a transient `Checksum` attribute that returns the string "I am the Product class". You'll learn more about why this was included in the example in [Section 37.9, "Substituting Extended Components in a Delivered Application."](#)

---

**37.8.4.2 Generated Classes for Extended Components**

When you create an extended component, the **Class Extends** button on the Java page of the extended component's wizard is disabled. Additionally, in the application module editor's Java page, when you click **Edit java options**, the **Class Extends** button in the Java dialog appears disabled. This is due to the fact that JDeveloper automatically extends the appropriate class of its parent component, so it does not make sense to allow you to select a different class.

**37.8.4.3 Business Component Types****Entity Objects**

When you create an extended entity object, you can introduce new attributes, new associations, new validators, and new custom code. You can override certain declarative aspects of existing attributes as well as overriding any method from the parent component's class.

**View Objects**

When you create an extended view object, you can introduce new attributes, new view links, new bind variables, and new custom code. You can override certain declarative aspects of existing attributes as well as overriding any method from the parent component's class.

**Application Modules**

When you create an extended application module, you can introduce new view object instances or new nested application module instance and new custom code. You can also override any method from the parent component's class.

**37.8.4.4 New Attributes in an Extended Component**

If you add new attributes in an extended entity object or view object, the attribute index numbers are computed relative to the parent component. For example, consider the `Products` view object mentioned in [Section 37.8.4.1, "Parent Classes and Interfaces for Extended Components."](#) If you enable a custom view row class, it might have attribute index constants defined in the `ProductsRowImpl.java` class like this:

```
public class ProductsRowImpl extends ViewRowImpl
    implements ProductsRow {
    public static final int PRODID = 0;
    public static final int NAME = 1;
    public static final int CHECKSUM = 2;
    //etc.
}
```

When you create an extended view object like `ProductsByName`, if that view object adds an addition attribute like `SomeExtraAttr` and has a custom view row class enabled, then its attribute constants will be computed relative to the maximum value of the attribute constants in the parent component:

```
public class ProductsByNameRowImpl extends ProductsRowImpl
    implements ProductsByNameRow {
    public static final int MAXATTRCONST =
        ViewDefImpl.getMaxAttrConst("devguide.advanced.baseproject.extsub.Products");
    public static final int SOMEEXTRAATTR = MAXATTRCONST;
```

Additional attributes would have index values of `MAXATTRCONST+1`, `MAXATTRCONST+2`, etc.

## 37.9 Substituting Extended Components in a Delivered Application

If you deliver packaged applications that can require on-site customization for each potential client of your solution, ADF Business Components offers a useful feature to simplify that task.

---

---

**Note:** The example in this section refers to the `BaseProject` project and the `ExtendAndSubstitute` project of the `AdvancedExamples` workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

All too often, on-site application customization is performed by making direct changes to the source code of the delivered application. This approach demonstrates its weaknesses whenever you deliver patches or new feature releases of your original application to your clients. Any customizations they had been applied to the base application's source code need to be painstakingly re-applied to the patched or updated version of the base application. Not only does this render the application customization a costly, ongoing maintenance expense, it can introduce subtle bugs due to human errors that occur when reapplying previous customizations to new releases.

ADF Business Components offers a superior, component-based approach to support application customization that doesn't require changing — or even having access to — the base application's source code. To customize your delivered application, your customers can:

1. Import one or more packages of components from the base application into a new project.
2. Create new components to effect the application customization, extending appropriate parent components from the base application as necessary.
3. Define a list of global component substitutions, naming their customized components to substitute for your base application's appropriate parent components.

When the customer runs your delivered application with a global component substitution list defined, their customized application components are used by your delivered application without changing any of its code. When you deliver a patched or updated version of the original application, their component customizations apply to the updated version the next time they restart the application without needing to re-apply any customizations.

### 37.9.1 How To Substitute an Extended Component

To define global component substitutions, use the Project Properties dialog in the project where you have created extended components based on the imported components from the base application.

---

**Note:** You can only substitute a component in the base application with an extended component that inherits directly or indirectly from the base one.

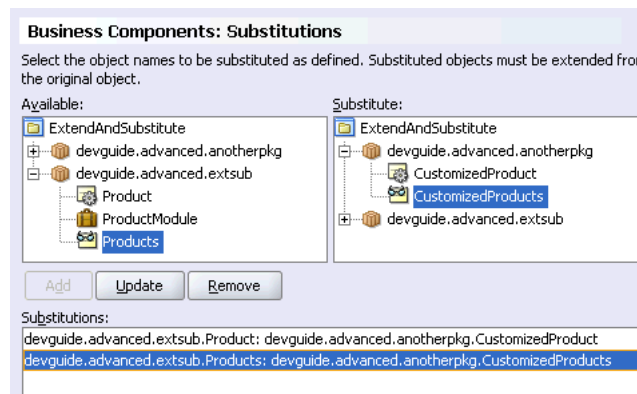

---

#### To substitute an extended component:

1. In the Application Navigator, right-click the model project that you want to add the extended component to and choose **Project Properties**.
2. In the Project Properties dialog, select **Business Components > Substitutions**.
3. In the Substitutions page, select the base application's component in the **Available** list.
4. Select the customized, extended component to substitute in the **Substitute** list.
5. Click **Add**.

For example, assume that you have created the view object `CustomizedProducts` in a package that extends the base view object `Products`. To substitute the `CustomizedProducts` view object for the legacy `Products` view object, you would select these view objects as shown in [Figure 37–12](#) to define the component substitution.

**Figure 37–12** Defining Business Components Substitutions

### 37.9.2 What Happens When You Substitute

When you define a list of global component substitutions in a project named *YourExtendsAndSubstitutesProject*, the substitution list is saved in the

*YourExtendsAndSubstitutesProject.jpx* in the root directory of the source path.

The file will contain `<Substitute>` elements as shown in [Example 37–22](#), one for each component to be substituted.

**Example 37–22 Component Substitution List Saved in the Project's JPX File**

```
<JboProject
  Name="ExtendAndSubstitute"
  SeparateXMLFiles="true"
  PackageName=" " >
  <Containeer
    Name="anotherpkg"
    FullName="devguide.advanced.anotherpkg.anotherpkg"
    ObjectType="JboPackage" >
  </Containeer>
  <Containeer
    Name="extsub"
    FullName="devguide.advanced.extsub"
    ObjectType="JboPackage" >
    <DesignTime>
      <Attr Name="_LocationURL"
        Value="../../../BaseProject/deploy/BaseProjectCSMT.jar" />
    </DesignTime>
  </Containeer>
  <Substitutes>
    <Substitute OldName="devguide.advanced.extsub.Product"
      NewName="devguide.advanced.anotherpkg.CustomizedProduct" />
    <Substitute OldName="devguide.advanced.extsub.Products"
      NewName="devguide.advanced.anotherpkg.CustomizedProducts" />
  </Substitutes>
</JboProject>
```

### 37.9.3 How to Enable the Substituted Components in the Base Application

To have the original application use the set of substituted components, define the Java system property `Factory-Substitution-List` and set its value to the name of the project whose `*.jpx` file contains the substitution list. The value should be just the project name without any `*.jpr` or `*.jpx` extension.

Consider a simple example that customizes the `Product` entity object and the `Products` view object described in [Section 37.8.4.1, "Parent Classes and Interfaces for Extended Components."](#) To perform the customization, assume you create new project named `ExtendsAndSubstitutes` that:

- Defines a library for the JAR file containing the base components
- Imports the package containing `Product` and `Products`
- Creates new extended components in a distinct package name called `CustomizedProduct` and `CustomizedProducts`
- Defines a component substitution list to use the extended components.

When creating the extended components, assume that you:

- Added an extra view attribute named `ExtraViewAttribute` to the `CustomizedProducts` view object.
- Added a new validation rule to the `CustomizedProduct` entity object to enforce that the product name cannot be the letter "Q".

- Override the `getChecksum()` method in the `CustomizedProduct.java` class to return "I am the CustomizedProduct Class".

If you define the `Factory-Substitution-List` Java system property set to the value `ExtendsAndSubstitutes`, then when you run the exact same test client class shown in [Example 37-20](#) the output of the sample will change to reflect the use of the substituted components as shown in [Example 37-23](#).

**Example 37-23 Results of Running TestClient.java with System Property Set**

```
Printing attribute for a row in VO 'Products'
ProdId=100
  Name=Washing Machine W001
  Checksum=I am the CustomizedProduct Class
  ExtraViewAttribute=Extra Attr Value
The name cannot be Q!
Printing attribute for a row in VO 'ProductsById'
ProdId=119
  Name=Ice Maker I012
  Checksum=I am the CustomizedProduct Class
  SomeExtraAttr=SomeExtraAttrValue
## Called someExtraFeature of ProductsByNameRowImpl
The name cannot be Q!
```

Compared to the output from [Example 37-20](#), notice that in the presence of the factory substitution list, the `Products` view object in the original test program now has the additional `ExtraViewAttribute`, now reports a `Checksum` attribute value of "I am the CustomizedProduct Class", and now disallows the assignment of the product name to have the value "Q". These component behavior changes were performed without needing to modify the original Java or XML source code of the delivered components.

---

---

## Advanced Entity Object Techniques

This chapter describes advanced techniques for use in ADF entity objects in an ADF Business Components data model project.

This chapter includes the following sections:

- [Section 38.1, "Creating Custom, Validated Data Types Using Domains"](#)
- [Section 38.2, "Updating a Deleted Flag Instead of Deleting Rows"](#)
- [Section 38.3, "Using Update Batching"](#)
- [Section 38.4, "Advanced Entity Association Techniques"](#)
- [Section 38.5, "Basing an Entity Object on a PL/SQL Package API"](#)
- [Section 38.6, "Basing an Entity Object on a Join View or Remote DBLink"](#)
- [Section 38.7, "Using Inheritance in Your Business Domain Layer"](#)
- [Section 38.8, "Controlling Entity Posting Order to Avoid Constraint Violations"](#)
- [Section 38.9, "Implementing Custom Validation Rules"](#)
- [Section 38.10, "Creating New History Types"](#)

---

**Note:** To experiment with the examples in this chapter, use the `AdvancedEntityExamples` workspace in the `StandaloneExamples` module of the Fusion Order Demo application, as described in [Section 2.4.4, "Standalone Applications in the AdvancedEntityExamples Application Workspace."](#) For information about how to obtain and install the Fusion Order Demo, see [Section 2.2, "Setting Up the Fusion Order Demo Application."](#)

---

### 38.1 Creating Custom, Validated Data Types Using Domains

When you find yourself repeating the same sanity-checking validations on the values of similar attributes across multiple entity objects, you can save yourself time and effort by creating your own data types that encapsulate this validation. For example, imagine that across your business domain layer there are numerous entity object attributes that store strings that represent email addresses. One technique you could use to ensure that end users always enter a valid email address everywhere one appears in your business domain layer is to:

- Use a basic `String` data type for each of these attributes
- Add an attribute-level method validator with Java code that ensures that the `String` value has the format of a valid email address for each attribute

However, these approaches can become tedious quickly in a large application. Fortunately, ADF Business Components offers an alternative that allows you to create your own `EmailAddress` data type that represents an email address. After centralizing all of the sanity-checking regarding email address values into this new custom data type, you can use the `EmailAddress` as the type of every attribute in your application that represents an email address. By doing this, you make the intention of the attribute values more clear to other developers and simplify application maintenance by putting the validation in a single place. ADF Business Components calls these developer-created data types domains.

Domains are Java classes that extend the basic data types like `String`, `Number`, and `Date` to add constructor-time validation to insure the candidate value passes relevant sanity checks. They offer you a way to define custom data types with cross-cutting behavior such as basic data type validation, formatting, and custom metadata properties in a way that are inherited by any entity objects or view objects that use the domain as the Java type of any of their attributes.

---

---

**Note:** The example in this section refers to the `SimpleDomains` project in the `AdvancedEntityExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

### 38.1.1 How to Create a Domain

To create a domain, use the Create Domain wizard. This is available in the **New Gallery** in the **ADF Business Components** category.

**To create a domain:**

1. In the Application Navigator, right-click the project for which you want to create a domain and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components**, and then select **Domain** and click **OK**.

This launches the Create Domain wizard.

3. On the **Name** page, specify a name for the domain and a package in which it will reside. To create a domain based on a simple Java type, leave **Domain for an Oracle Object Type** unchecked.
4. Click **Next**.
5. On the **Settings** page, indicate the base type for the domain and the database column type to which it will map. For example, if you were creating a domain called `ShortEmailAddress` to hold eight-character short email addresses, you would set the base type to `String` and the **Database Column Type** to `VARCHAR2 (8)`. You can set other common attribute settings on this panel as well.
6. Click **Finish** to create your domain.

### 38.1.2 What Happens When You Create a Domain

When you create a domain, JDeveloper creates its XML component definition in the subdirectory of your project's source path that corresponds to the package name you chose. For example, if you created the `ShortEmailAddress` domain in the `devguide.advanced.domains` package, JDeveloper would create the `ShortEmailAddress.xml` file in the `./devguide/advanced/domains` subdirectory. A domain always has a corresponding Java class, which JDeveloper

creates in the `common` subpackage of the package where the domain resides. This means it would create the `ShortEmailAddress.java` class in the `devguide.advanced.domains.common` package. The domain's Java class is automatically generated with the appropriate code to behave in a way that is identical to one of the built-in data types.

### 38.1.3 What You May Need to Know About Domains

The sections that follow describe some of the things you may need to know about when working with domains.

#### 38.1.3.1 Using Domains for Entity and View Object Attributes

After you've created a domain in a project, it appears among the list of available data types in the **Attribute Type** dropdown list in the entity object and view object wizards and dialogs. To use the domain as the type of a given attribute, just pick it from the list.

---

**Note:** The entity-mapped attributes in an entity-based view object inherit their data type from their corresponding underlying entity object attribute, so if the entity attribute uses a domain type, so will the matching view object attribute. For transient or SQL-derived view object attributes, you can directly set the type to use a domain since it is not inherited from any underlying entity.

---

#### 38.1.3.2 Validate Method Should Throw `DataCreationException` If Sanity Checks Fail

Typically, the only coding task you need to do for a domain is to write custom code inside the generated `validate()` method. Your implementation of the `validate()` method should perform your sanity checks on the candidate value being constructed, and throw a `DataCreationException` in the `oracle.jbo` package if the validation fails.

In order to throw an exception message that is translatable, you can create a message bundle class similar to the one shown in [Example 38-1](#). Create it in the same `common` package as your domain classes themselves. The message bundle returns an array of `{MessageKeyString, TranslatableMessageString}` pairs.

##### **Example 38-1 Custom Message Bundle Class for Domain Exception Messages**

```
package devguide.advanced.simplesdomains.common;

import java.util.ListResourceBundle;

public class ErrorMessage extends ListResourceBundle {
    public static final String INVALID_SHORTEMAIL = "30002";
    public static final String INVALID_EVENNUMBER = "30003";
    private static final Object[][] sMessageStrings = new String[][] {
        { INVALID_SHORTEMAIL,
          "A valid short email address has no @-sign or dot."},
        { INVALID_EVENNUMBER,
          "Number must be even."}
    };

    /**
     * Return String Identifiers and corresponding Messages
     */
}
```

```

        * in a two-dimensional array.
        */
protected Object[][] getContents() {
    return sMessageStrings;
}
}

```

### 38.1.3.3 String Domains Aggregate a String Value

Since `String` is a base JDK type, a domain based on a `String` aggregates a private `mData` `String` member field to hold the value that the domain represents. Then, the class implements the `DomainInterface` expected by the ADF runtime, as well as the `Serializable` interface, so the domain can be used in method arguments or returns types of ADF components custom client interfaces.

[Example 38–2](#) shows the `validate()` method for a simple `ShortEmailAddress` domain class. It tests to make sure that the `mData` value does not contain an at-sign or a dot, and if it does, then the method throws `DataCreationException` referencing an appropriate message bundle and message key for the translatable error message.

#### **Example 38–2 Simple ShortEmailAddress String-Based Domain Type with Custom Validation**

```

public class ShortEmailAddress
    extends Object implements DomainInterface, Serializable {
    private String mData;
    // . . .
    /**Implements domain validation logic and throws a JboException on error. */
    protected void validate() {
        int atpos = mData.indexOf('@');
        int dotpos = mData.lastIndexOf('.');
        if (atpos > -1 || dotpos > -1) {
            throw new DataCreationException(ErrorMessages.class,
                ErrorMessages.INVALID_SHORTEMAIL,null,null);
        }
    }
    // . . .
}

```

### 38.1.3.4 Other Domains Extend Existing Domain Type

Other simple domains based on a built-in type in the `oracle.jbo.domain` package extend the base type as shown in [Example 38–3](#). It illustrates the `validate()` method for a simple `Number`-based domain called `EvenNumber` that represents even numbers.

#### **Example 38–3 Simple EvenNumber Number-Based Domain Type with Custom Validation**

```

public class EvenNumber extends Number {
    // . . .
    /**
     * Validates that value is an even number, or else
     * throws a DataCreationException with a custom
     * error message.
     */
    protected void validate() {
        if (getValue() % 2 == 1) {
            throw new DataCreationException(ErrorMessages.class,
                ErrorMessages.INVALID_EVENNUMBER,null,null);
        }
    }
}

```

```

    }
    // . . .
}

```

### 38.1.3.5 Simple Domains Are Immutable Java Classes

When you create a simple domain based on one of the basic data types, it is an *immutable* class. This just means that once you've constructed a new instance of it like this:

```
ShortEmailAddress email = new ShortEmailAddress("emailaddress1");
```

You cannot change its value. If you want to reference a different short email address, you just construct another one:

```
ShortEmailAddress email = new ShortEmailAddress("emailaddress2");
```

This is not a new concept since it's the same way that `String`, `Number`, and `Date` classes behave, among others.

### 38.1.3.6 Creating Domains for Oracle Object Types When Useful

The Oracle database supports the ability to create user-defined types in the database. For example, you could create a type called `POINT_TYPE` using the following DDL statement:

```
create type point_type as object (
    x_coord number,
    y_coord number
);
```

If you use user-defined types like `POINT_TYPE`, you can create domains based on them, or you can reverse-engineer tables containing columns of object type to have JDeveloper create the domain for you.

#### Manually Creating Oracle Object Type Domains

To create a domain yourself, perform the following steps in the Create Domain wizard:

1. In the Application Navigator, right-click the project for which you want to create a domain and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components**, and then select **Domain** and click **OK**.  
This launches the Create Domain wizard.
3. On the **Name** page, check the **Domain for an Oracle Object Type** checkbox, then select the object type for which you want to create a domain from the **Available Types** list.
4. Click **Next**.
5. On the **Settings** page, use the **Attribute** dropdown list to switch between the multiple domain properties to adjust the settings as appropriate.
6. Click **Finish** to create the domain.

#### Reverse-Engineering Oracle Object Type Domains

In addition to manually creating object type domains, when you use the Business Components from Tables wizard and select a table containing columns of an Oracle object type, JDeveloper creates domains for those object types as part of the

reverse-engineering process. For example, imagine you created a table like this with a column of type `POINT_TYPE`:

```
create table interesting_points(  
  id number primary key,  
  coordinates point_type,  
  description varchar2(20)  
);
```

If you create an entity object for the `INTERESTING_POINTS` table in the Business Components from Tables wizard, then you will get both an `InterestingPoints` entity object and a `PointType` domain. The latter will have been automatically created, based on the `POINT_TYPE` object type, since it was required as the data type of the `Coordinates` attribute of the `InterestingPoints` entity object.

Unlike simple domains, object type domains are mutable. JDeveloper generates getter and setter methods into the domain class for each of the elements in the object type's structure. After changing any domain properties, when you set that domain as the value of a view object or entity object attribute, it is treated as a single unit. ADF does not track which domain properties have changed, only that a domain-valued attribute value has changed.

---

---

**Note:** Domains based on Oracle object types are useful for working programmatically with data whose underlying type is an Oracle object type. They also can simplify passing and receiving structure information to stored procedures. However, support for working with object type domains in the ADF binding layer is complete, so it's not straightforward to use object domain-valued attributes in declaratively-databound user interfaces.

---

---

### 38.1.3.7 Quickly Navigating to the Domain Class

After selecting a domain in the Application Navigator, you can quickly navigate to its implementation class using one of the following methods:

- In the Application Navigator, right-click the domain and choose **Go to Domain Class** from the context menu.
- In the Structure window, double-click the domain class.

### 38.1.3.8 Domains Get Packaged in the Common JAR

When you create a business components archive, as described in [Section 37.6, "Working with Libraries of Reusable Business Components,"](#) the domain classes and message bundle files in the `*.common` subdirectories of your project's source path get packaged into the `*CSCommon.jar`. They are classes that are common to both the middle-tier application server and to an eventual remote-client you might need to support.

### 38.1.3.9 Entity and View Object Attributes Inherit Custom Domain Properties

You can define custom metadata properties on a domain. Any entity object or view object attribute based on that domain inherits those custom properties as if they had been defined on the attribute itself. If the entity object or view object attribute defines the same custom property, its setting takes precedence over the value inherited from the domain.

### 38.1.3.10 Domain Settings Cannot Be Less Restrictive at Entity or View Level

JDeveloper enforces the declarative settings you impose at the domain definition level; they cannot be made *less* restrictive for the entity object or view object for an attribute based on the domain type. For example, if you define a domain to have its **Updatable** property set to **While New**, then when you use your domain as the Java type of an entity object attribute, you can set **Updatable** to be **Never** (more restrictive) but you cannot set it to be **Always**. Similarly, if you define a domain to be **Persistent**, you cannot make it transient later. When sensible for your application, set declarative properties for a domain to be as lenient as possible so you can later make them more restrictive as needed.

## 38.2 Updating a Deleted Flag Instead of Deleting Rows

For auditing purposes, once a row is added to a table, sometimes your requirements may demand that rows are never physically deleted from the table. Instead, when the end user deletes the row in the user interface, the value of a `DELETED` column should be updated from "N" to "Y" to mark it as deleted. You can use two method overrides to alter an entity object's default behavior to achieve this effect. For example, say you want to change the `Products` entity from the Fusion Order Demo application to behave in this way.

### 38.2.1 How to Update a Deleted Flag When a Row Is Removed

To update a deleted flag when a row is removed, enable a custom Java class for your entity object and override the `remove()` method to set the deleted flag before calling the `super.remove()` method. [Example 38–4](#) shows what this would look like in the custom Java class of an entity object. It is important to set the attribute *before* calling `super.remove()` since an attempt to set the attribute of a deleted row will encounter the `DeadEntityAccessException`.

This example presumes that you've altered the `PRODUCTS` table to have an additional `DELETED` column, and synchronized the `Products` entity with the database to add the corresponding `Deleted` attribute.

#### **Example 38–4** Updating a Deleted Flag When a Products Entity Row Is Removed

```
// In your custom Java entity class
public void remove() {
    setDeleted("Y");
    super.remove();
}
```

The row will still be removed from the row set, but it will have the value of its `Deleted` flag modified to "Y" in the entity cache. The second part of implementing this behavior involves forcing the entity to perform an `UPDATE` instead of an `DELETE` when it is asked to perform its DML operation. You need to implement both parts for a complete solution.

### 38.2.2 Forcing an Update DML Operation Instead of a Delete

To force an entity object to be updated instead of deleted, override the `doDML()` method and write code that conditionally changes the `operation` flag. When the `operation` flag equals `DML_DELETE`, your code will change it to `DML_UPDATE` instead. [Example 38–5](#) shows what this would look like in the custom Java class of an entity object.

This example presumes that you've altered the `PRODUCTS` table to have an additional `DELETED` column, and synchronized the `Products` entity with the database to add the corresponding `Deleted` attribute.

**Example 38–5 Forcing an Update DML Operation Instead of a Delete**

```
// In your custom Java entity class
protected void doDML(int operation, TransactionEvent e) {
    if (operation == DML_DELETE) {
        operation = DML_UPDATE;
    }
    super.doDML(operation, e);
}
```

With this overridden `doDML()` method in place to complement the overridden `remove()` method described in [Section 38.2.1](#), any attempt to remove an entity through any view object with a corresponding entity usage will update the `DELETED` column instead of physically deleting the row. Of course, in order to prevent "deleted" products from appearing in your view object query results, you will need to appropriately modify their `WHERE` clauses to include only products `WHERE DELETED = 'N'`.

## 38.3 Using Update Batching

You can use update batching to reduce the number of DML statements issued with multiple entity modifications.

By default, the ADF Business Components framework performs a single DML statement (`INSERT`, `UPDATE`, `DELETE`) for each modified entity of a given entity definition type. For example, say you have an `Employee` entity object type for which multiple instances are modified during typical use of the application. If two instances were created, three existing instances modified, and four existing instances deleted, then at transaction commit time the framework issues nine DML statements (2 `INSERTS`, 3 `UPDATES`, and 4 `DELETES`) to save these changes.

If you will frequently be updating more than one entity of a given type in a transaction, consider using the update batching feature for that entity definition type. In the example, update batching (with a threshold of 1) causes the framework to issue just three DML statements: one bulk `INSERT` statement processing two inserts, one bulk `UPDATE` statement processing three updates, and one bulk `DELETE` statement processing four deletes.

---

---

**Note:** The batch update feature is disabled if any of following conditions are present:

- The entity object has attributes of BLOB or CLOB type. Batch DML with streaming data types is not supported.
  - The entity object has attributes that are set to **Refresh After Insert** or **Refresh After Update**. There is no method to bulk-return all of the trigger-assigned values in a single round trip, so retrieving and updating attributes doesn't work with batch DML.
  - The entity object was created from a table that did not have a primary key. If an entity object is reverse-engineered from a table that does not have a primary key, a ROWID-valued attribute is created and assigned as the primary key instead. The ROWID value is managed as a Retrieve-on-Insert value, so it will not work with batch DML.
- 
- 

#### To enable update batching for an entity

1. Open the appropriate entity object in the overview editor.
2. In the Application Navigator, double-click the appropriate entity to open it in the overview editor.
3. On the General page of the overview editor, expand the **Tuning** section, select the **Use Update Batching** checkbox, and specify the appropriate threshold.

This establishes a batch processing threshold beyond which ADF will process the modifications in a bulk DML operation.

## 38.4 Advanced Entity Association Techniques

This section describes several advanced techniques for working with associations between entity objects.

### 38.4.1 Modifying Association SQL Clause to Implement Complex Associations

When you need to represent a more complex relationship between entities than one based only on the equality of matching attributes, you can modify the association's SQL clause to include more complex criteria. For example, sometimes the relationship between two entities depends on effective dates. A `Product` may be related to a `Supplier`, however if the name of the supplier changes over time, each row in the `SUPPLIERS` table might include additional `EFFECTIVE_FROM` and `EFFECTIVE_UNTIL` columns that track the range of dates in which that product row is (or was) in use. The relationship between a `Product` and the `Supplier` with which it is associated might then be described by a combination of the matching `SupplierId` attributes and a condition that the product's `RequestDate` lie between the supplier's `EffectiveFrom` and `EffectiveUntil` dates.

You can setup this more complex relationship in the overview editor for the association. First add any additional necessary attribute pairs on the **Relationship** page, which in this example would include one (`EffectiveFrom`, `RequestDate`) pair and one (`EffectiveUntil`, `RequestDate`) pair. Then on the **Query** page you can edit the **Where** field to change the `WHERE` clause to be:

```
(:Bind_SupplierId = Product.SUPPLIER_ID) AND
(Product.REQUEST_DATE BETWEEN :Bind_EffectiveFrom
```

```
AND :Bind_EffectiveUntil)
```

For more information about creating associations, see [Section 4.3, "Creating and Configuring Associations."](#)

### 38.4.2 Exposing View Link Accessor Attributes at the Entity Level

When you create a view link between two entity-based view objects, on the **View Link Properties** page, you have the option to expose view link accessor attributes both at the view object level as well as at the entity object level. By default, a view link accessor is only exposed at the view object level of the destination view object. By checking the appropriate **In Entity Object: *SourceEntityName*** or **In Entity Object: *DestinationEntityName*** checkbox, you can opt to have JDeveloper include a view link attribute in either or both of the source or destination entity objects. This can provide a handy way for an entity object to access a related set of related view rows, especially when the query to produce the rows only depends on attributes of the current row.

## 38.5 Basing an Entity Object on a PL/SQL Package API

If you have a PL/SQL package that encapsulates insert, update, and delete access to an underlying table, you can override the default DML processing event for the entity object that represents that table to invoke the procedures in your PL/SQL API instead. Often, such PL/SQL packages are used in combination with a companion database view. Client programs read data from the underlying table using the database view, and "write" data back to the table using the procedures in the PL/SQL package.

For example, say you want to create a `Product` entity object based on such a combination of a view and a package.

Given the `PRODUCTS` table in the Fusion Order Demo schema, consider a database view named `PRODUCTS_V`, created using the following DDL statement:

```
create or replace view products_v
as select product_id,name,image,description from products;
```

In addition, consider the simple `PRODUCTS_API` package shown in [Example 38–6](#) that encapsulates insert, update, and delete access to the underlying `PRODUCTS` table.

#### **Example 38–6 Simple PL/SQL Package API for the `PRODUCTS` Table**

```
create or replace package products_api is
  procedure insert_product(p_prod_id number,
                          p_name varchar2,
                          p_supplier_id number,
                          p_list_price number,
                          p_min_price number,
                          p_ship_code varchar2);
  procedure update_product(p_prod_id number,
                           p_name varchar2,
                           p_supplier_id number,
                           p_list_price number,
                           p_min_price number,
                           p_ship_code varchar2);
  procedure delete_product(p_prod_id number);
end products_api;
```

To create an entity object based on this combination of database view and PL/SQL package, you would perform the following tasks:

- Create a view-based entity object, as described in [Section 38.5.1, "How to Create an Entity Object Based on a View."](#)
- Create a base class for the entity, as described in [Section 38.5.3, "Centralizing Details for PL/SQL-Based Entities into a Base Class."](#)
- Implement the appropriate stored procedure calls, as described in [Section 38.5.4, "Implementing the Stored Procedure Calls for DML Operations."](#)
- Handle selecting and locking functionality, if necessary, as described in [Section 38.5.5, "Adding Select and Lock Handling."](#)

---

**Note:** The example in these sections refers to the `EntityWrappingPLSQLPackage` project of the `AdvancedEntityExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

### 38.5.1 How to Create an Entity Object Based on a View

To create an entity object based on a view, you use the Create Entity Object wizard as described in [Section 4.2.2, "How to Create Single Entity Objects Using the Create Entity Wizard,"](#) with the following exceptions:

- On the **Name** page, give the entity a name like `Product` and check the **Views** checkbox at the bottom of the **Database Objects** section.  
  
This enables the display of the available database views in the current schema in the **Schema Object** list.
- Select the desired database view in the **Schema Object** list.
- On the **Attribute Settings** page, use the **Select Attribute** dropdown list to choose the attribute that will act as the primary key, then enable the **Primary Key** setting for that property.

---

**Note:** When defining the entity based on a view, JDeveloper cannot automatically determine the primary key attribute since database views do not have related constraints in the database data dictionary.

---

### 38.5.2 What Happens When You Create an Entity Object Based on a View

By default, an entity object based on a view performs all of the following directly against the underlying database view:

- `SELECT` statement (for `findByPrimaryKey()`)
- `SELECT FOR UPDATE` statement (for `lock()`), and
- `INSERT`, `UPDATE`, `DELETE` statements (for `doDML()`)

To use stored procedure calls, you will need to override the `doDML()` operations (as described in [Section 38.5.3, "Centralizing Details for PL/SQL-Based Entities into a Base Class"](#)), and possibly override the `lock()` and `findByPrimaryKey()` handling (as described in [Section 38.5.4, "Implementing the Stored Procedure Calls for DML Operations"](#)).

### 38.5.3 Centralizing Details for PL/SQL-Based Entities into a Base Class

If you plan to have more than one entity object based on a PL/SQL API, it's a smart idea to abstract the generic details into a base framework extension class. In doing this, you'll be using several of the concepts described in [Chapter 37, "Advanced Business Components Techniques."](#) Start by creating a `PLSQLEntityImpl` class that extends the base `EntityImpl` class that each one of your PL/SQL-based entities can use as their base class. As shown in [Example 38–7](#), you'll override the `doDML()` method of the base class to invoke a different helper method based on the operation.

---

**Note:** If you are already using an extended entity implementation class for your entity, you can extend it further with the `PLSQLEntityImpl` class. For example, if you have a framework extension class named `zzEntityImpl`, you would create a `PLSQLEntityImpl` class that extends the `zzEntityImpl` class.

---

#### **Example 38–7** *Overriding doDML() to Call Different Procedures Based on the Operation*

```
// In PLSQLEntityImpl.java
protected void doDML(int operation, TransactionEvent e) {
    // super.doDML(operation, e);
    if (operation == DML_INSERT)
        callInsertProcedure(e);
    else if (operation == DML_UPDATE)
        callUpdateProcedure(e);
    else if (operation == DML_DELETE)
        callDeleteProcedure(e);
}
```

In the `PLSQLEntityImpl.java` base class, you can write the helper methods so that they perform the default processing like this:

```
// In PLSQLEntityImpl.java
/* Override in a subclass to perform non-default processing */
protected void callInsertProcedure(TransactionEvent e) {
    super.doDML(DML_INSERT, e);
}
/* Override in a subclass to perform non-default processing */
protected void callUpdateProcedure(TransactionEvent e) {
    super.doDML(DML_UPDATE, e);
}
/* Override in a subclass to perform non-default processing */
protected void callDeleteProcedure(TransactionEvent e) {
    super.doDML(DML_DELETE, e);
}
```

After putting this infrastructure in place, when you base an entity object on the `PLSQLEntityImpl` class, you can use the **Source > Override Methods** menu item to override the `callInsertProcedure()`, `callUpdateProcedure()`, and `callDeleteProcedure()` helper methods and perform the appropriate stored procedure calls for that particular entity.

---

**Note:** If you do not override these helper methods in a subclass, they will perform the default processing as defined in the superclass. You only need to override the operations in the `doDML()` method that you want to provide alternative processing for.

---

To simplify the task of implementing these calls, you could add the `callStoredProcedure()` helper method (described in [Chapter 37.4, "Invoking Stored Procedures and Functions"](#)) to the `PLSQLEntityImpl` class as well. This way, any PL/SQL-based entity objects that extend this class can leverage the helper method.

### 38.5.4 Implementing the Stored Procedure Calls for DML Operations

To implement the stored procedure calls for DML operations, you will need to create a custom Java class for the entity object and override the operations in it.

#### To create the custom Java class with the override methods:

1. In the Application Navigator, double-click the `Product` entity object to open it in the overview editor.
2. On the Java page of the overview editor, click the **Edit Java options** icon.
3. In the Select Java Options dialog, click **Classes Extend**.
4. In the Override Base Classes dialog, in the **Row** field, enter the package and class of the `PLSQLEntityImpl` class, or click **Browse** to search and select it.
5. Then select **Generate Entity Object Class**, and click **OK**.
6. In the Application Navigator, double-click `ProductsImpl.java` to open it in the overview editor.
7. From the **Source** menu, choose **Override Methods**.
8. In the Override Methods dialog, select the `callInsertProcedure()`, `callUpdateProcedure()`, and `callDeleteProcedure()` methods, and click **OK**.
9. Then enter the necessary code to override these procedures.

[Example 38–8](#) shows the code you would write in these overridden helper methods.

#### **Example 38–8 Leveraging a Helper Method to Invoke Insert, Update, and Delete Procedures**

```
// In ProductsImpl.java
protected void callInsertProcedure(TransactionEvent e) {
    callStoredProcedure("products_api.insert_product(?,?,?,?,?)",
        new Object[] { getProductId(), getProductName(), getSupplierId(),
            getListPrice(), getMinPrice(), getShippingClassCode() });
}
protected void callUpdateProcedure(TransactionEvent e) {
    callStoredProcedure("products_api.update_product(?,?,?,?,?)",
        new Object[] { getProductId(), getProductName(), getSupplierId(),
            getListPrice(), getMinPrice(), getShippingClassCode() });
}
protected void callDeleteProcedure(TransactionEvent e) {
    callStoredProcedure("products_api.delete_product(?)",
        new Object[] { getProductId() });
}
```

At this point, if you create a default entity-based view object called `Products` for the `Products` entity object and add an instance of it to a `ProductsModule` application module you can quickly test inserting, updating, and deleting rows from the `Products` view object instance in the Business Component Browser.

Often, overriding just the insert, update, and delete operations will be enough. The default behavior that performs the `SELECT` statement for `findByPrimaryKey()` and the `SELECT FOR UPDATE` statement for the `lock()` against the database view works for most basic kinds of views.

However, if the view is complex and does not support `SELECT FOR UPDATE` or if you need to perform the `findByPrimaryKey()` and `lock()` functionality using additional stored procedures APIs, then you can use the technique described in [Section 38.5.5, "Adding Select and Lock Handling."](#)

### 38.5.5 Adding Select and Lock Handling

You can handle the `lock()` and `findByPrimaryKey()` functionality of an entity object by invoking stored procedures if necessary. Imagine that the `PRODUCTS_API` package were updated to contain the two additional procedures shown in [Example 38–9](#). Both the `lock_product` and `select_product` procedures accept a primary key attribute as an `IN` parameter and return values for the remaining attributes using `OUT` parameters.

#### **Example 38–9 Additional Locking and Select Procedures for the PRODUCTS Table**

```
/* Added to PRODUCTS_API package */
procedure lock_product(p_prod_id number,
                     p_name OUT varchar2,
                     p_supplier_id OUT number,
                     p_list_price OUT number,
                     p_min_price OUT number,
                     p_ship_code OUT varchar2);

procedure select_product(p_prod_id number,
                        p_name OUT varchar2,
                        p_supplier_id OUT number,
                        p_list_price OUT number,
                        p_min_price OUT number,
                        p_ship_code OUT varchar2);
```

#### **38.5.5.1 Updating PLSQLEntityImpl Base Class to Handle Lock and Select**

You can extend the `PLSQLEntityImpl` base class to handle the `lock()` and `findByPrimaryKey()` overrides using helper methods similar to the ones you added for insert, update, delete. At runtime, both the `lock()` and `findByPrimaryKey()` operations end up invoking the lower-level entity object method called `doSelect(boolean lock)`. The `lock()` operation calls `doSelect()` with a `true` value for the parameter, while the `findByPrimaryKey()` operation calls it passing `false` instead.

[Example 38–10](#) shows the overridden `doSelect()` method in `PLSQLEntityImpl` to delegate as appropriate to two helper methods that subclasses can override as necessary.

#### **Example 38–10 Overriding doSelect() to Call Different Procedures Based on the Lock Parameter**

```
// In PLSQLEntityImpl.java
protected void doSelect(boolean lock) {
    if (lock) {
        callLockProcedureAndCheckForRowInconsistency();
    } else {
        callSelectProcedure();
    }
}
```

```
}

```

The two helper methods are written to just perform the default functionality in the base `PLSQLEntityImpl` class:

```
// In PLSQLEntityImpl.java
/* Override in a subclass to perform non-default processing */
protected void callLockProcedureAndCheckForRowInconsistency() {
    super.doSelect(true);
}
/* Override in a subclass to perform non-default processing */
protected void callSelectProcedure() {
    super.doSelect(false);
}

```

Notice that the helper method that performs locking has the name `callLockProcedureAndCheckForRowInconsistency()`. This reminds developers that it is their responsibility to perform a check to detect at the time of locking the row whether the newly-selected row values are the same as the ones the entity object in the entity cache believes are the current database values.

To assist subclasses in performing this old-value versus new-value attribute comparison, you can add one final helper method to the `PLSQLEntityImpl` class like this:

```
// In PLSQLEntityImpl
protected void compareOldAttrTo(int attrIndex, Object newVal) {
    if ((getPostedAttribute(attrIndex) == null && newVal != null) ||
        (getPostedAttribute(attrIndex) != null && newVal == null) ||
        (getPostedAttribute(attrIndex) != null && newVal != null &&
         !getPostedAttribute(attrIndex).equals(newVal))) {
        throw new RowInconsistentException(getKey());
    }
}

```

### 38.5.5.2 Implementing Lock and Select for the Product Entity

With the additional infrastructure in place in the base `PLSQLEntityImpl` class, you can override the `callSelectProcedure()` and `callLockProcedureAndCheckForRowInconsistency()` helper methods in the Product entity object's `ProductImpl` class. Since the `select_product` and `lock_product` procedures have OUT arguments, as described in [Section 37.4.4, "How to Call Other Types of Stored Procedures,"](#) you need to use a JDBC `CallableStatement` object to perform these invocations.

[Example 38–11](#) shows the code required to invoke the `select_product` procedure. It's performing the following basic steps:

1. Creating a `CallableStatement` for the PLSQL block to invoke.
2. Registering the OUT parameters and types, by one-based bind variable position.
3. Setting the IN parameter value.
4. Executing the statement.
5. Retrieving the possibly updated column values.
6. Populating the possibly updated attribute values in the row.
7. Closing the statement.

**Example 38–11 Invoking the Stored Procedure to Select a Row by Primary Key**

```

// In ProductsImpl.java
protected void callSelectProcedure() {
    String stmt = "begin products_api.select_product(?,?,?,?);end;";
    // 1. Create a CallableStatement for the PLSQL block to invoke
    CallableStatement st =
        getDBTransaction().createCallableStatement(stmt, 0);
    try {
        // 2. Register the OUT parameters and types
        st.registerOutParameter(2, VARCHAR2);
        st.registerOutParameter(3, NUMBER);
        st.registerOutParameter(4, NUMBER);
        st.registerOutParameter(5, NUMBER);
        st.registerOutParameter(6, VARCHAR2);

        // 3. Set the IN parameter value
        st.setObject(1, getProductId());
        // 4. Execute the statement
        st.executeUpdate();
        // 5. Retrieve the possibly updated column values
        String possiblyUpdatedName = st.getString(2);
        String possiblyUpdatedSupplierId = st.getString(3);
        String possiblyUpdatedListPrice = st.getString(4);
        String possiblyUpdatedMinPrice = st.getString(5);
        String possiblyUpdatedShipCode = st.getString(6);

        // 6. Populate the possibly updated attribute values in the row
        populateAttribute(PRODUCTNAME, possiblyUpdatedName, true, false,
            false);
        populateAttribute(SUPPLIERID, possiblyUpdatedSupplierId, true,
            false, false);
        populateAttribute(LISTPRICE, possiblyUpdatedListPrice, true, false,
            false);
        populateAttribute(MINPRICE, possiblyUpdatedMinPrice, true, false,
            false);
        populateAttribute(SHIPPINGCLASSCODE, possiblyUpdatedShipCode, true,
            false, false);
    } catch (SQLException e) {
        throw new JboException(e);
    } finally {
        if (st != null) {
            try {
                // 7. Closing the statement
                st.close();
            } catch (SQLException e) {
            }
        }
    }
}

```

[Example 38–12](#) shows the code to invoke the `lock_product` procedure. It's doing basically the same steps as those in [Example 38–11](#), with just the following two interesting differences:

- After retrieving the possibly updated column values from the OUT parameters, it uses the `compareOldAttrTo()` helper method inherited from the `PLSQLEntityImpl` to detect whether or not a `RowInconsistentException` should be thrown as a result of the row lock attempt.

- In the catch (`SQLException e`) block, it is testing to see whether the database has thrown the error:

```
ORA-00054: resource busy and acquire with NOWAIT specified
```

and if so, it again throws the ADF Business Components `AlreadyLockedException` just as the default entity object implementation of the `lock()` functionality would do in this situation.

### **Example 38–12 Invoking the Stored Procedure to Lock a Row by Primary Key**

```
// In ProductsImpl.java
protected void callLockProcedureAndCheckForRowInconsistency() {
    String stmt = "begin products_api.lock_product(?,?,?,?);end;";
    CallableStatement st =
        getDBTransaction().createCallableStatement(stmt, 0);
    try {
        st.registerOutParameter(2, VARCHAR2);
        st.registerOutParameter(3, NUMBER);
        st.registerOutParameter(4, NUMBER);
        st.registerOutParameter(5, NUMBER);
        st.registerOutParameter(6, VARCHAR2);
        st.setObject(1, getProductId());
        st.executeUpdate();
        String possiblyUpdatedName = st.getString(2);
        String possiblyUpdatedSupplierId = st.getString(3);
        String possiblyUpdatedListPrice = st.getString(4);
        String possiblyUpdatedMinPrice = st.getString(5);
        String possiblyUpdatedShipCode = st.getString(6);
        compareOldAttrTo(PRODUCTNAME, possiblyUpdatedName);
        compareOldAttrTo(SUPPLIERID, possiblyUpdatedSupplierId);
        compareOldAttrTo(LISTPRICE, possiblyUpdatedListPrice);
        compareOldAttrTo(MINPRICE, possiblyUpdatedMinPrice);
        compareOldAttrTo(SHIPPINGCLASSCODE, possiblyUpdatedShipCode);
    } catch (SQLException e) {
        if (Math.abs(e.getErrorCode()) == 54) {
            throw new AlreadyLockedException(e);
        } else {
            throw new JboException(e);
        }
    } finally {
        if (st != null) {
            try {
                st.close();
            } catch (SQLException e) {
            }
        }
    }
}
```

With these methods in place, you have a `Products` entity object that wraps the `PRODUCTS_API` package for all of its database operations. Due to the clean separation of the data querying functionality of view objects and the data validation and saving functionality of entity objects, you can now leverage this `Products` entity object in any way you would use a normal entity object. You can build as many different view objects that use `Products` as their entity usage as necessary.

### 38.5.5.3 Refreshing the Entity Object After RowInconsistentException

You can override the `lock()` method to refresh the entity object after a `RowInconsistentException` has occurred. [Example 38–13](#) shows code that can be added to the entity object implementation class to catch the `RowInconsistentException` and refresh the entity object.

**Example 38–13 Overridden `lock()` Method to Refresh Entity Object on `RowInconsistentException`**

```
// In the entity object implementation class
@Override
public void lock() {
    try {
        super.lock();
    }
    catch (RowInconsistentException ex) {
        this.refresh(REFRESH_UNDO_CHANGES);
        throw ex;
    }
}
```

## 38.6 Basing an Entity Object on a Join View or Remote DBLink

If you need to create an entity object based on either of the following:

- Synonym that resolves to a remote table over a DBLINK
- View with `INSTEAD OF` triggers

Then you will encounter the following error if any of its attributes are marked as **Refresh on Insert** or **Refresh on Update**:

```
JBO-26041: Failed to post data to database during "Update"
## Detail 0 ##
ORA-22816: unsupported feature with RETURNING clause
```

These types of schema objects do not support the `RETURNING` clause, which by default the entity object uses to more efficiently return the refreshed values in the same database roundtrip in which the `INSERT` or `UPDATE` operation was executed.

**To disable the use of the `RETURNING` clause for an entity object of this type:**

1. Enable a custom entity definition class for the entity object.
2. In the custom entity definition class, override the `createDef()` method to call:
 

```
setUseReturningClause(false)
```
3. If the **Refresh on Insert** attribute is the primary key of the entity object, you must specify some other attribute in the entity as an alternate unique key by setting the **Unique Key** property on it.

At runtime, when you have disabled the use of the `RETURNING` clause in this way, the entity object implements the **Refresh on Insert** and **Refresh on Update** behavior using a separate `SELECT` statement to retrieve the values to refresh after insert or update as appropriate.

## 38.7 Using Inheritance in Your Business Domain Layer

Inheritance is a powerful feature of object-oriented development that can simplify development and maintenance when used appropriately. As shown in [Section 37.8, "Creating Extended Components Using Inheritance,"](#) ADF Business Components supports using inheritance to create new components that extend existing ones in order to add additional properties or behavior or modify the behavior of the parent component. Inheritance can be useful in modeling the different kinds of entities in your reusable business domain layer.

---

---

**Note:** The example in this section refers to the `InheritanceAndPolymorphicQueries` project of the `AdvancedEntityExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

### 38.7.1 Understanding When Inheritance Can Be Useful

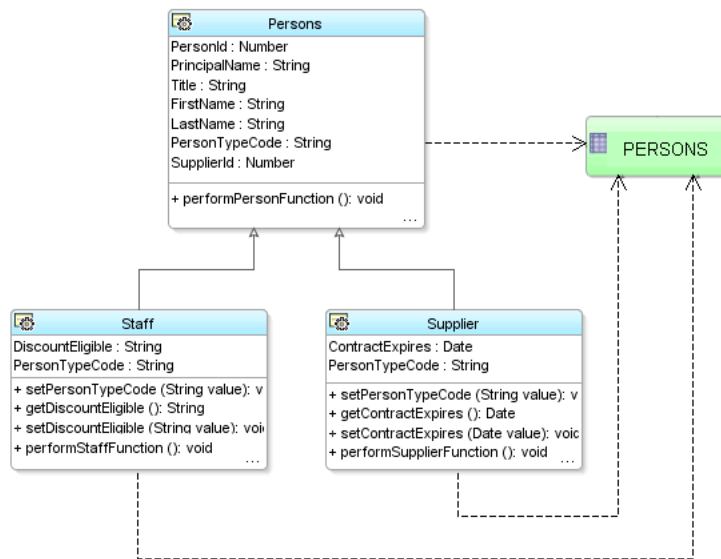

Your application's database schema might contain tables where different logical kinds of business information are stored in rows of the same table. These tables will typically have one column whose value determines the kind of information stored in each row. For example, the Fusion Order Demo's `PERSONS` table stores information about customers, suppliers, and staff in the same table. It contains a `PERSON_TYPE_CODE` column whose value — `STAFF`, `CUST`, or `SUPP` — determines what kind of `PERSON` the row represents.

While the Fusion Order Demo implementation doesn't yet contain this differentiation in this release, it's reasonable to assume that a future release of the application might require:

- Managing additional database-backed attributes that are specific to suppliers or specific to staff
- Implementing common behavior for all users that is different for suppliers or staff
- Implementing new functionality that is specific to only suppliers or only staff

[Figure 38–1](#) shows what the business domain layer would look like if you created distinct `Persons`, `Staff`, and `Supplier` entity objects to allow distinguishing the different kinds of business information in a more formal way inside your application. Since suppliers and staff are special *kinds* of persons, their corresponding entity objects would extend the base `Persons` entity object. This base `Persons` entity object contains all of the attributes and methods that are common to all types of users. The `performPersonFunction()` method in the figure represents one of these common methods.

Then, for the `Supplier` and `Staff` entity objects you can add specific additional attributes and methods that are unique to that kind of user. For example, `Supplier` has an additional `ContractExpires` attribute of type `Date` to track when the supplier's current contract expires. There is also a `performSupplierFunction()` method that is specific to suppliers. Similarly, the `Staff` entity object has an additional `DiscountEligible` attribute to track whether the person qualifies for a staff discount. The `performStaffFunction()` is a method that is specific to staff.

**Figure 38–1 Distinguishing Persons, Suppliers, and Staff Using Inheritance**

By modeling these different kinds of persons as distinct entity objects in an inheritance hierarchy in your domain business layer, you can simplify having them share common data and behavior and implement the aspects of the application that make them distinct.

## 38.7.2 How to Create Entity Objects in an Inheritance Hierarchy

To create entity objects in an inheritance hierarchy, you use the Create Entity Object wizard to create each entity. The example described here assumes that you've altered the FOD application's `PERSONS` table by executing the following DDL statement to add two new columns to it:

```
alter table persons add (
    discount_eligible varchar2(1),
    contract_expires date
);
```

### 38.7.2.1 Start by Identifying the Discriminator Column and Distinct Values

Before creating entity objects in an inheritance hierarchy based on a table containing different kinds of information, you should first identify which column in the table is used to distinguish the kind of row it is. In the FOD application's `PERSONS` table, this is the `PERSON_TYPE_CODE` column. Since it helps partition or "discriminate" the rows in the table into separate groups, this column is known as the *discriminator column*.

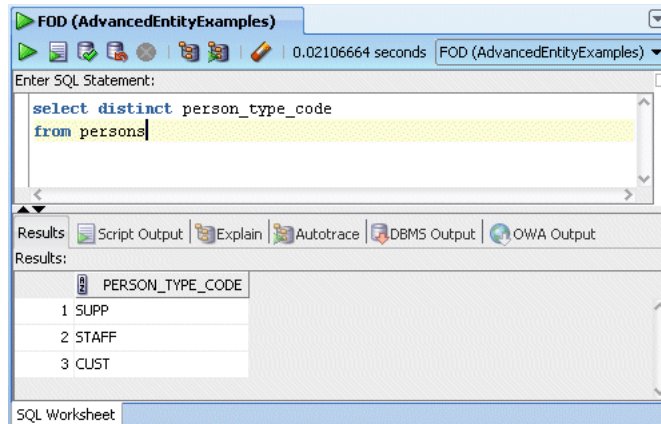

Next, determine the valid values that the discriminator column takes on in your table. You might know this off the top of your head, or you could execute a simple SQL statement in the JDeveloper **SQL Worksheet** to determine the answer. To access the worksheet:

1. Choose **Database Navigator** from the **View** menu.
2. Expand the **AdvancedEntityExamples** folder and select the FOD connection.
3. Right-click FOD, and choose **Open SQL Worksheet** from the context menu.

**Figure 38–2** shows the results of performing a `SELECT DISTINCT` query in the SQL Worksheet on the `PERSON_TYPE_CODE` column in the `PERSONS` table. It confirms that

the rows are partitioned into three groups based on the `PERSON_TYPE_CODE` discriminator values: `SUPP`, `STAFF`, and `CUST`.

**Figure 38–2 Using the SQL Worksheet to Find Distinct Discriminator Column Values**

### 38.7.2.2 Identify the Subset of Attributes Relevant to Each Kind of Entity

Once you know how many different kinds of business entities are stored in the table, you will also know how many entity objects to create to model these distinct items. You'll typically create one entity object per kind of item. Next, in order to help determine which entity should act as the base of the hierarchy, you need to determine which subset of attributes is relevant to each kind of item.

For example, assume you determine that all of the attributes except `ContractExpires` and `DiscountEligible` are relevant to all users, that `ContractExpires` is specific to suppliers, and that `DiscountEligible` is specific to staff. This information leads you to determine that the `Persons` entity object should be the base of the hierarchy, with the `Supplier` and `Staff` entity objects each extending `Persons` to add their specific attributes.

### 38.7.2.3 Creating the Base Entity Object in an Inheritance Hierarchy

To create the base entity object in an inheritance hierarchy, use the Create Entity Object wizard.

#### To create the base entity object

1. In the Application Navigator, right-click the project you want to add the entity object to, and choose **New**.
2. In the New Gallery, expand **Business Tier**, click **ADF Business Components**, select **Entity Object**, and click **OK**.
3. In the Create Entity Object wizard, on the **Name** Page, provide a name and package for the entity, and select the schema object on which the entity will be based.

For example, name the entity object `Persons` and base it on the `PERSONS` table.

4. On the **Attributes** page, select the attributes in the **Entity Attributes** list that are not relevant to the base entity object (if any) and click **Remove** to remove them.

For example, remove the `DiscountEligible` and `ContractExpires` attributes from the list.

5. On the **Attribute Settings** page, use the **Select Attribute** dropdown list to choose the attribute that will act as the discriminator for the family of inherited entity objects and check the **Discriminator** checkbox to identify it as such. Importantly, you must also supply a **Default Value** for this discriminator attribute to identify rows of this base entity type.

For example, select the `PersonTypeCode` attribute, mark it as a discriminator attribute, and set its **Default Value** to the value "cust".

---

---

**Note:** Leaving the **Default Value** blank for a discriminator attribute is legal. A blank default value means that a row with the discriminator column value `IS NULL` will be treated as this base entity type.

---

---

6. Then click **Finish** to create the entity object.

#### 38.7.2.4 Creating a Subtype Entity Object in an Inheritance Hierarchy

To create a subtype entity object in an inheritance hierarchy, you use the Create Entity Object wizard.

##### **Before you begin:**

1. Determine the entity object that will be the parent entity object from which your new entity object will extend.

For example, the parent entity for a new `Manager` entity object will be the `User` entity.

2. Ensure that the parent entity has a discriminator attribute already identified.

If it does not, use the overview editor to set the **Discriminator** property on the appropriate attribute of the parent entity before creating the inherited child.

##### **To create the new subtype entity object in the hierarchy:**

1. In the Application Navigator, right-click the project you want to add the entity object to, and choose **New**.
2. In the New Gallery, expand **Business Tier**, click **ADF Business Components**, select **Entity Object**, and click **OK**.
3. In the Create Entity Object wizard, on the **Name** Page, provide a name and package for the entity, and click the **Browse** button next to the **Extends** field to select the parent entity from which the entity being created will extend.

For example, name the new entity `Staff` and select the `Persons` entity object in the **Extends** field.

4. On the **Attributes** page, the **Entity Attributes** list displays the attributes from the underlying table that are not included in the base entity object. Select the attributes you do not want to include in this entity object and click **Remove**.

For example, since you are creating the `Staff` entity remove the `ContractExpires` attribute and leave the `DiscountEligible` attribute.

5. Click **Override** to select the discriminator attribute so that you can customize the attribute metadata to supply a distinct **Default Value** for the `Staff` subtype.

For example, override the `PersonTypeCode` attribute.

6. On the **Attribute Settings** page, use the **Select Attribute** dropdown list to select the discriminator attribute. Change the **Default Value** field to supply a distinct

default value for the discriminator attribute that defines the entity subtype being created.

For example, select the `PersonTypeCode` attribute and change its **Default Value** to the value "staff".

7. Click **Finish** to create the subtype entity object.

---

**Note:** You can repeat the same steps to define the `Supplier` entity object that extends `Persons` to add the additional `ContractExpires` attribute and overrides the **Default Value** of the `UserRole` discriminator attribute to have the value "supp".

---

### 38.7.3 How to Add Methods to Entity Objects in an Inheritance Hierarchy

To add methods to entity objects in an inheritance hierarchy, enable the custom Java class for the entity object and use the source editor to add the method.

#### 38.7.3.1 Adding Methods Common to All Entity Objects in the Hierarchy

To add a method that is common to all entity objects in the hierarchy, enable a custom Java class for the base entity object in the hierarchy and add the method in the source editor. For example, if you add the following method to the `PersonsImpl` class for the base `User` entity object, it will be inherited by all entity objects in the hierarchy:

```
// In PersonsImpl.java
public void performPersonFunction() {
    System.out.println("## performPersonFunction as Customer");
}
```

#### 38.7.3.2 Overriding Common Methods in a Subtype Entity

To override a method in a subtype entity that is common to all entity objects in the hierarchy, enable a custom Java class for the subtype entity and choose **Override Methods** from the **Source** menu to launch the Override Methods dialog. Select the method you want to override, and click **OK**. Then, customize the overridden method's implementation in the source editor. For example, imagine overriding the `performPersonFunction()` method in the `StaffImpl` class for the `Staff` subtype entity object and change the implementation to look like this:

```
// In StaffImpl.java
public void performPersonFunction() {
    System.out.println("## performPersonFunction as Staff");
}
```

When working with instances of entity objects in a subtype hierarchy, sometimes you will process instances of multiple different subtypes. Since `Staff` and `Supplier` entities are special kinds of `Persons`, you can write code that works with all of them using the more generic `PersonsImpl` type that they all have in common. When doing this generic kind of processing of classes that might be one of a *family* of subtypes in a hierarchy, Java will always invoke the most specific override of a method available.

This means that invoking the `performPersonFunction()` method on an instance of `PersonsImpl` that happens to really be the more specific `StaffImpl` subtype, will the result in printing out the following:

```
## performPersonFunction as Staff
```

instead of the default result that regular `PersonsImpl` instances would get:

```
## performPersonFunction as Customer
```

### 38.7.3.3 Adding Methods Specific to a Subtype Entity

To add a method that is specific to a subtype entity object in the hierarchy, enable a custom Java class for that entity and add the method in the source editor. For example, you could add the following method to the `SupplierImpl` class for the `Supplier` subtype entity object:

```
// In SupplierImpl.java
public void performSupplierFunction() {
    System.out.println("## performSupplierFunction called");
}
```

## 38.7.4 What You May Need to Know About Using Inheritance

When using inheritance, you can also introduce a new base entity, find subtype entities using a primary key, and create view objects with polymorphic entity usages.

### 38.7.4.1 Sometimes You Need to Introduce a New Base Entity

In the `InheritanceAndPolymorphicQueries` example project, the `Persons` entity object corresponded to a concrete kind of row in the `PERSONS` table and it also played the role of the base entity in the hierarchy. In other words, all of its attributes were common to all entity objects in the hierarchy. You might wonder what would happen, however, if the `Persons` entity required a property that was specific to customers, but not common to staff or suppliers. Imagine that customers can participate in customer satisfaction surveys, but that staff and suppliers do not. The `Persons` entity would require a `LastSurveyDate` attribute to handle this requirement, but it wouldn't make sense to have `Staff` and `Supplier` entity objects inherit it.

In this case, you can introduce a new entity object called `BasePersons` to act as the base entity in the hierarchy. It would have all of the attributes common to all `Persons`, `Staff`, and `Supplier` entity objects. Then each of the three entities the correspond to concrete rows that appear in the table could have some attributes that are inherited from `BasePersons` and some that are specific to its subtype. In the `BasePersons` type, so long as you mark the `PersonTypeCode` attribute as a discriminator attribute, you can just leave the **Default Value** blank (or some other value that does *not* occur in the `PERSON_TYPE_CODE` column in the table). Because at runtime you'll never be using instances of the `BasePersons` entity, it doesn't really matter what its discriminator default value is.

### 38.7.4.2 Finding Subtype Entities by Primary Key

When you use the `findByPrimaryKey()` method on an entity definition, it only searches the entity cache for the entity object type on which you call it. In the `InheritanceAndPolymorphicQueries` example project, this means that if you call `PersonsImpl.getDefinitionObject()` to access the entity definition for the `Persons` entity object when you call `findByPrimaryKey()` on it, you will only find entities in the cache that happen to be customers. Sometimes this is exactly the behavior you want. However, if you want to find an entity object by primary key allowing the possibility that it might be a subtype in an inheritance hierarchy, then you can use the `EntityDefImpl` class' `findByPKExtended()` method instead. In the `Persons` example described here, this alternative finder method would find an entity object by primary key whether it is a customer, supplier, or staff. You can then use the Java `instanceof` operator to test which type you found, and then cast the

PersonsImpl object to the more specific entity object type in order to work with features specific to that subtype.

### 38.7.4.3 You Can Create View Objects with Polymorphic Entity Usages

When you create an entity-based view object with an entity usage corresponding to a base entity object in an inheritance hierarchy, you can configure the view object to query rows corresponding to multiple different subtypes in the base entity's subtype hierarchy. Each row in the view object will use the appropriate subtype entity object as the entity row part, based on matching the value of the discriminator attribute. See [Section 39.6.2, "How To Create a View Object with a Polymorphic Entity Usage,"](#) for specific instructions on setting up and using these view objects.

## 38.8 Controlling Entity Posting Order to Avoid Constraint Violations

Due to database constraints, when you perform DML operations to save changes to a number of related entity objects in the same transaction, the order in which the operations are performed can be significant. If you try to insert a new row containing foreign key references *before* inserting the row being referenced, the database can complain with a constraint violation. You must understand the default order for processing of entity objects during commit time and how to programmatically influence that order when necessary.

---

---

**Note:** The example in this section refers to the `ControllingPostingOrder` project of the `AdvancedEntityExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

### 38.8.1 Understanding the Default Post Processing Order

By default, when you commit the transaction the entity objects in the pending changes list are processed in chronological order, in other words, the order in which the entities were added to the list. This means that, for example, if you create a new `Product` and then a new `Supplier` related to that product, the new `Product` will be inserted first and the new `Supplier` second.

### 38.8.2 How Compositions Change the Default Processing Ordering

When two entity objects are related by a *composition*, the strict chronological ordering is modified automatically to ensure that composed parent and child entity rows are saved in an order that avoids violating any constraints. This means, for example, that a new parent entity row is inserted before any new composed children entity rows.

### 38.8.3 Overriding `postChanges()` to Control Post Order

If your related entities are associated but *not* composed, then you need to write a bit of code to ensure that the related entities get saved in the appropriate order.

#### 38.8.3.1 Observing the Post Ordering Problem First Hand

Consider the `newProductForNewSupplier()` custom method from an `PostModule` application module in [Example 38-14](#). It accepts a set of parameters and:

1. Creates a new `Product`.

2. Creates a new `Supplier`.
3. Sets the product ID to which the server request pertains.
4. Commits the transaction.
5. Constructs a `Result` Java bean to hold new product ID and supplier ID.
6. Returns the result.

---

**Note:** The code makes the assumption that both `Products.ProductId` and `Suppliers.SupplierId` have been set to have `DBSequence` data type to populate their primary keys based on a sequence.

---

**Example 38–14** *Creating a New Product, Then a New Supplier, and Returning the New IDs*

```
// In PostModuleImpl.java
public Result newProductForNewSupplier(String supplierName,
                                       String supplierStatus,
                                       String productName,
                                       String productStatus,
                                       Number listPrice,
                                       Number minPrice,
                                       String shipCode) {
    oracle.jbo.domain.Date today = new Date(Date.getCurrentDate());
    Number objectId = new Number(0);
    // 1. Create a new product
    ProductsBaseImpl newProduct = createNewProduct();
    // 2. Create a new supplier
    SuppliersImpl newSupplier = createNewSupplier();
    newSupplier.setSupplierName(supplierName);
    newSupplier.setSupplierStatus(supplierStatus);
    newSupplier.setCreatedBy("PostingModule");
    newSupplier.setCreationDate(today);
    newSupplier.setLastUpdatedBy("PostingModule");
    newSupplier.setLastUpdateDate(today);
    newSupplier.setObjectVersionId(objectId);
    // 3. Set the supplier id to which the product pertains
    newProduct.setSupplierId(newSupplier.getSupplierId().getSequenceNumber());
    newProduct.setProductName(productName);
    newProduct.setProductStatus(productStatus);
    newProduct.setListPrice(listPrice);
    newProduct.setMinPrice(minPrice);
    newProduct.setShippingClassCode(shipCode);
    newProduct.setCreatedBy("PostingModule");
    newProduct.setCreationDate(today);
    newProduct.setLastUpdatedBy("PostingModule");
    newProduct.setLastUpdateDate(today);
    newProduct.setObjectVersionId(objectId);
    // 4. Commit the transaction
    getDBTransaction().commit();
    // 5. Construct a bean to hold new supplier id and product id
    Result result = new Result();
    result.setProductId(newProduct.getProductId().getSequenceNumber());
    result.setSupplierId(newSupplier.getSupplierId().getSequenceNumber());
    // 6. Return the result
    return result;
}
```

```

private ProductsBaseImpl createNewProduct(){
    EntityDefImpl productDef = ProductsBaseImpl.getDefinitionObject();
    return (ProductsBaseImpl) productDef.createInstance2(getDBTransaction(), null);
}

private SuppliersImpl createNewSupplier(){
    EntityDefImpl supplierDef = SuppliersImpl.getDefinitionObject();
    return (SuppliersImpl) supplierDef.createInstance2(getDBTransaction(), null);
}

```

If you add this method to the application module's client interface and test it from a test client program, you get an error:

```

oracle.jbo.DMLConstraintException:
JBO-26048: Constraint "PRODUCT_SUPPLIER_FK" violated during post operation:
"Insert" using SQL Statement
"BEGIN
  INSERT INTO PRODUCTS(
    SUPPLIER_NAME,SUPPLIER_STATUS,PRODUCT_NAME,
    PRODUCT_STATUS,LIST_PRICE,MIN_PRICE, SHIPPING_CLASS_CODE)
  VALUES (?, ?, ?, ?, ?, ?, ?)
  RETURNING PRODUCT_ID INTO ?;
END;".
## Detail 0 ##
java.sql.SQLException:
ORA-02291: integrity constraint (FOD.PRODUCT_SUPPLIER_FK) violated
        - parent key not found

```

When the `PRODUCTS` row is inserted, the database complains that the value of its `SUPPLIER_ID` foreign key doesn't correspond to any row in the `SUPPLIERS` table. This occurred because:

- The code created the `Product` before the `Supplier`
- `Products` and `Suppliers` entity objects are associated but not composed
- The DML operations to save the new entity rows is done in chronological order, so the new `Product` gets inserted before the new `Supplier`.

### 38.8.3.2 Forcing the Supplier to Post Before the Product

To remedy the problem of attempting to add a product with a not-yet-valid supplier ID, you could reorder the lines of code in the example to create the `Supplier` first, then the `Product`. While this would address the immediate problem, it still leaves the chance that another application developer could create things in an incorrect order.

The better solution is to make the entity objects *themselves* handle the posting order so it will work correctly regardless of the order of creation. To do this you need to override the `postChanges()` method in the entity that contains the foreign key attribute referencing the associated entity object and write code as shown in [Example 38-15](#). In this example, since it is the `Product` that contains the foreign key to the `Supplier` entity, you need to update the `Product` to conditionally force a related, new `Supplier` to post before the service request posts itself.

The code tests whether the entity being posted is in the `STATUS_NEW` or `STATUS_MODIFIED` state. If it is, it retrieves the related product using the `getSupplier()` association accessor. If the related `Supplier` also has a post-state of `STATUS_NEW`, then *first* it calls `postChanges()` on the related parent row before calling `super.postChanges()` to perform its own DML.

**Example 38–15 Overriding `postChanges()` in `ProductsBaseImpl` to Post Supplier First**

```
// In ProductsBaseImpl.java
public void postChanges(TransactionEvent e) {
    /* If current entity is new or modified */
    if (getPostState() == STATUS_NEW ||
        getPostState() == STATUS_MODIFIED) {
        /* Get the associated supplier for the product */
        SuppliersImpl supplier = getSupplier();
        /* If there is an associated supplier */
        if (supplier != null) {
            /* And if it's post-status is NEW */
            if (supplier.getPostState() == STATUS_NEW) {
                /*
                 * Post the supplier first, before posting this
                 * entity by calling super below
                 */
                supplier.postChanges(e);
            }
        }
    }
    super.postChanges(e);
}
```

If you were to re-run the example now, you would see that without changing the creation order in the `newProductForNewSupplier()` method's code, entities now post in the correct order — first new `Supplier`, then new `Product`. Yet, there is still a problem. The constraint violation still appears, but now for a different reason!

If the primary key for the `Suppliers` entity object were user-assigned, then the code in [Example 38–15](#) would be all that is required to address the constraint violation by correcting the post ordering.

---

---

**Note:** An alternative to the programmatic technique discussed here, which solves the problem at the Java EE application layer, is the use of deferrable constraints at the database layer. If you have control over your database schema, consider defining (or altering) your foreign key constraints to be `DEFERRABLE INITIALLY DEFERRED`. This causes the database to defer checking the constraint until transaction commit time. This allows the application to perform DML operations in any order, provided that by `COMMIT` time all appropriate related rows have been saved and would alleviate the parent/child ordering. However, you would still need to write the code to cascade-update the foreign key values if the parent's primary key is assigned from a sequence, as described in [Section 38.8.3.3, "Understanding Associations Based on DBSequence-Valued Primary Keys"](#) and [Section 38.8.3.4, "Refreshing References to DBSequence-Assigned Foreign Keys."](#)

---

---

In this example, however, the `Suppliers.SupplierId` is assigned from a database sequence, and not user-assigned in this example. So when a new `Suppliers` entity row gets posted its `SupplierId` attribute is refreshed to reflect the database-assigned sequence value. The foreign key value in the `Products.SupplierId` attribute referencing the new supplier is "orphaned" by this refreshing of the supplier's ID value. When the product's row is saved, its `SUPPLIER_ID` value still doesn't match a row in the `SUPPLIERS` table, and the constraint violation occurs again. The next two sections discuss the solution to address this "orphaning" problem.

### 38.8.3.3 Understanding Associations Based on DBSequence-Valued Primary Keys

Recall from [Section 4.10.10, "How to Get Trigger-Assigned Primary Key Values from a Database Sequence"](#) that when an entity object's primary key attribute is of `DBSequence` type, during the transaction in which it is created, its numerical value is a unique, temporary negative number. If you create a number of associated entities in the same transaction, the relationships between them are based on this temporary negative key value. When the entity objects with `DBSequence`-value primary keys are posted, their primary key is refreshed to reflect the correct database-assigned sequence number, leaving the associated entities that are still holding onto the temporary negative foreign key value "orphaned".

For entity objects based on a *composition*, when the parent entity object's `DBSequence`-valued primary key is refreshed, the composed children entity rows automatically have their temporary negative foreign key value updated to reflect the owning parent's refreshed, database-assigned primary key. This means that for composed entities, the "orphaning" problem does not occur.

However, when entity objects are related by an association that is not a composition, you need to write a little code to insure that related entity rows referencing the temporary negative number get updated to have the refreshed, database-assigned primary key value. The next section outlines the code required.

### 38.8.3.4 Refreshing References to DBSequence-Assigned Foreign Keys

When an entity like `Suppliers` in this example has a `DBSequence`-valued primary key, and it is referenced as a foreign key by other entities that are associated with (but not composed by) it, you need to override the `postChanges()` method as shown in [Example 38–16](#) to save a reference to the row set of entity rows that might be referencing this new `Suppliers` row. If the status of the current `Suppliers` row is `New`, then the code assigns the `RowSet`-valued return of the `getProduct()` association accessor to the `newProductsBeforePost` member field before calling `super.postChanges()`.

#### **Example 38–16 Saving Reference to Entity Rows Referencing This New Supplier**

```
// In SuppliersImpl.java
RowSet newProductsBeforePost = null;
public void postChanges(TransactionEvent transactionEvent) {
    /* Only bother to update references if Product is a NEW one */
    if (getPostState() == STATUS_NEW) {
        /*
         * Get a rowset of products related
         * to this new supplier before calling super
         */
        newProductsBeforePost = (RowSet)getProductsBase();
    }
    super.postChanges(transactionEvent);
}
```

This saved `RowSet` object is then used by the overridden `refreshFKInNewContainees()` method shown in [Example 38–17](#). It gets called to allow a new entity row to cascade update its refreshed primary key value to any other entity rows that were referencing it before the call to `postChanges()`. It iterates over the `ProductsBaseImpl` rows in the `newProductsBaseBeforePost` row set (if non-null) and sets the new supplier ID value of each one to the new sequence-assigned supplier value of the newly posted `Suppliers` entity.

**Example 38–17 Cascade-Updating Entity Rows with New SupplierId Value**

```
// In SuppliersImpl.java
protected void refreshFKInNewContainees() {
    if (newProductsBeforePost != null) {
        Number newSupplierId = getSupplierId().getSequenceNumber();
        /*
         * Process the rowset of products that referenced
         * the new supplier prior to posting, and update their
         * SupplierId attribute to reflect the refreshed SupplierId value
         * that was assigned by a database sequence during posting.
         */
        while (newProductsBeforePost.hasNext()) {
            ProductsBaseImpl svrReq =
                (ProductsBaseImpl)newProductsBeforePost.next();
            product.setSupplierId(newSupplierId);
        }
        closeNewProductRowSet();
    }
}
```

After implementing this change, the code in [Example 38–14](#) runs without encountering any database constraint violations.

## 38.9 Implementing Custom Validation Rules

ADF Business Components comes with a base set of built-in declarative validation rules that you can use. However, a powerful feature of the validator architecture for entity objects is that you can create your own custom validation rules. When you notice that you or your team are writing the same kind of validation code over and over, you can build a custom validation rule class that captures this common validation "pattern" in a parameterized way.

After you've defined a custom validation rule class, you can register it in JDeveloper so that it is as simple to use as any of the built-in rules. In fact, you can even bundle your custom validation rule with a custom UI panel that JDeveloper leverages to facilitate developers' using and configuring the parameters your validation rule might require.

### 38.9.1 How to Create a Custom Validation Rule

To write a custom validation rule for entity objects, you need a Java class that implements the `JboValidatorInterface` in the `oracle.jbo.rules` package. You can create a skeleton class from the New Gallery.

**To create a custom validator:**

1. In the Application Navigator, right-click the project where you want to create the validator, and choose **New** from the context menu.
2. In the New Gallery, expand **Business Tier**, click **ADF Business Components**, select **Validation Rule** and click **OK**.

As shown in [Example 38–18](#), `JboValidatorInterface` contains one main `validate()` method, and a getter and setter method for a `Description` property.

**Example 38–18 All Validation Rules Must Implement the JboValidatorInterface**

```
package oracle.jbo.rules;
public interface JboValidatorInterface {
    void validate(JboValidatorContext valCtx) { }
```

```

    java.lang.String getDescription() { }
    void setDescription(String description) { }
}

```

If the behavior of your validation rule will be parameterized to make it more flexible, then add additional bean properties to your validator class for each parameter. For example, the code in [Example 38–19](#) implements a custom validation rule called `DateMustComeAfterRule` which validates that one date attribute must come after another date attribute. To allow the developer using the rule to configure the names of the date attributes to use as the initial and later dates for validation, this class defines two properties `initialDateAttrName` and `laterDateAttrName`.

[Example 38–19](#) shows the code that implements the custom validation rule. It extends the `AbstractValidator` to inherit support for working with the entity object's custom message bundle, where `JDeveloper` saves the validation error message when a developer uses the rule in an entity object.

The `validate()` method of the validation rule gets invoked at runtime whenever the rule class should perform its functionality. The code performs the following basic steps:

1. Ensures validator is correctly attached at the entity level.
2. Gets the entity row being validated.
3. Gets the values of the initial and later date attributes.
4. Validate that initial date is before later date.
5. Throws an exception if the validation fails.

#### **Example 38–19 Custom DateMustComeAfterRule**

```

// NOTE: package and imports omitted
public class DateMustComeAfterRule extends AbstractValidator
    implements JboValidatorInterface {
    /**
     * This method is invoked by the framework when the validator should do its job
     */
    public void validate(JboValidatorContext valCtx) {
        // 1. If validator is correctly attached at the entity level...
        if (validatorAttachedAtEntityLevel(valCtx)) {
            // 2. Get the entity row being validated
            EntityImpl eo = (EntityImpl)valCtx.getSource();
            // 3. Get the values of the initial and later date attributes
            Date initialDate = (Date) eo.getAttribute(getInitialDateAttrName());
            Date laterDate = (Date) eo.getAttribute(getLaterDateAttrName());
            // 4. Validate that initial date is before later date
            if (!validateValue(initialDate, laterDate)) {
                // 5. Throw the validation exception
                RulesBeanUtils.raiseException(getErrorMessageClass(),
                    getErrorMsgId(),
                    valCtx.getSource(),
                    valCtx.getSourceType(),
                    valCtx.getSourceFullName(),
                    valCtx.getAttributeDef(),
                    valCtx.getNewValue(),
                    null, null);
            }
        }
        else {
            throw new RuntimeException("Rule must be at entity level");
        }
    }
}

```

```

    }
}
/**
 * Validate that the initialDate comes before the laterDate.
 */
private boolean validateValue(Date initialDate, Date laterDate) {
    return (initialDate == null) || (laterDate == null) ||
        (initialDate.compareTo(laterDate) < 0);
}
/**
 * Return true if validator is attached to entity object
 * level at runtime.
 */
private boolean validatorAttachedAtEntityLevel(JboValidatorContext ctx) {
    return ctx.getOldValue() instanceof EntityImpl;
}
// NOTE: Getter/Setter Methods omitted
private String description;
private String initialDateAttrName;
private String laterDateAttrName;
}

```

For easier reuse of your custom validation rules, you would typically package them into a JAR file for reference by applications that make use of the rules.

### 38.9.2 Adding a Design Time Bean Customizer for Your Rule

Since a validation rule class is a bean, you can implement a standard JavaBean customizer class to improve the design time experience of setting the bean properties. In the example of the `DateMustComeAfter` rule (in [Example 38-19](#)), the two properties that the developers must configure are the `initialDateAttrName` and `laterDateAttrName` properties.

[Figure 38-3](#) illustrates using JDeveloper's visual designer for Swing to create a `DateMustComeAfterRuleCustomizer` using a `JPanel` with a titled border containing two `JLabel` prompts and two `JComboBox` controls for the dropdown lists. The code in the class populates the dropdown lists with the names of the `Date`-valued attributes of the current entity object being edited in the IDE. This will allow a developer who adds a `DateMustComeAfterRule` validation to their entity object to easily pick which date attributes should be used for the starting and ending dates for validation.

**Figure 38-3** Using JDeveloper's Swing Visual Designer to Create a Validation Rule Customizer

To associate a customizer with your `DateMustComeAfterRule` Java Bean, you follow the standard practice of creating a `BeanInfo` class. As shown in [Example 38–20](#), the `DateMustComeAfterRuleBeanInfo` returns a `BeanDescriptor` that associates the customizer class with the `DateMustComeAfter` bean class.

You would typically package your customizer class and this bean info in a separate JAR file for design-time-only use.

**Example 38–20 BeanInfo to Associate a Customizer with a Custom Validation Rule**

```
package oracle.fodemo...frameworkExt.rules;
import java.beans.BeanDescriptor;
import java.beans.SimpleBeanInfo;
public class DateMustComeAfterRuleBeanInfo extends SimpleBeanInfo {
    public BeanDescriptor getBeanDescriptor() {
        return new BeanDescriptor(DateMustComeAfterRule.class,
                                DateMustComeAfterRuleCustomizer.class);
    }
}
```

### 38.9.3 Registering and Using a Custom Rule in JDeveloper

After you've created a custom validation rule, you can add it to the project or application level in the JDeveloper IDE so that other developers can use the rule declaratively.

**To register a custom validation rule in a project containing entity objects:**

1. In the Application Navigator, right-click the desired project, and choose **Project Properties** from the context menu.
2. In the Project Properties dialog, expand **Business Components**, and select **Registered Rules**.
3. On the Registered Rules page, click **Add**.
4. In the Register Validation Rule dialog, browse to find the validation rule you have created (such as the one created in [Section 38.9.1, "How to Create a Custom Validation Rule"](#)), and click **OK**.

**To register a custom validator at the IDE level:**

1. From the **Tools** menu, choose **Preferences**.
2. From the **Business Components > Register Rules** page, you can add a one or more validation rules.

When adding a validation rule, provide the fully-qualified name of the validation rule class, and supply a validation rule name that will appear in JDeveloper's list of available validators.

## 38.10 Creating New History Types

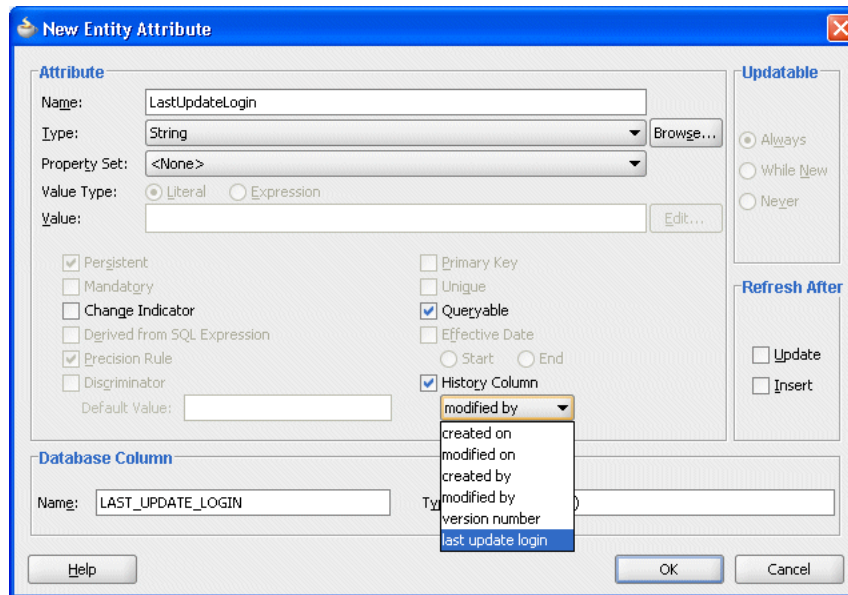

History types are used to track data specific to a point in time. JDeveloper ships with a number of history types, but you can also create your own. For more information on the standard history types and how to use them, see [Section 4.10.12, "How to Track Created and Modified Dates Using the History Column."](#)

### 38.10.1 How to Create New History Types

You are not limited to the history types provided, you can add or remove custom history types using the History Types page in the Preferences dialog, and then write custom Java code to implement the desired behavior. The code to handle custom history types should be written in your application-wide entity base class for reuse.

Figure 38–5 shows a custom type called `last_update_login` with type Id of 11. Assume that `last_update_login` is a foreign key in the `FND_LOGINS` table.

**Figure 38–4 New History Types in the New Entity Attribute Dialog**

**To create a custom history type:**

1. From the **Tools** menu, choose **Preferences**.
2. In the Preferences dialog, expand **Business Components**, and click **History Types**.
3. On the History Types page, click **New**.
4. In the Create History Type dialog, enter a string value for the name (spaces are allowed) and a numerical Id.

The **Type Id** must be an integer between 11 and 126. The numerical values 0-10 are reserved for internal use. The display string is displayed in the **History Column** dropdown list the next time you use the Edit Attribute dialog.

**Figure 38–5** Creating New History Types

5. Open the `EntityImpl.java` file and add a definition similar to the one in [Example 38–21](#).

**Example 38–21** History Type Definition

```
private static final byte LASTUPDATELOGIN_HISTORY_TYPE = 11;
```

6. Override the `getHistoryContextForAttribute(AttributeDefImpl attr)` method in the `EntityImpl` base class with code similar to [Example 38–22](#).

**Example 38–22** Overriding `getHistoryContextForAttribute()`

```
@Override
protected Object getHistoryContextForAttribute(AttributeDefImpl attr) {
    if (attr.getHistoryKind() == LASTUPDATELOGIN_HISTORY_TYPE) {
        // Custom History type logic goes here
    }
    else {
        return super.getHistoryContextForAttribute(attr);
    }
}
```

**38.10.2** How to Remove a History Type

Because they are typically used for auditing values over the life of an application, it is rare that you would want to remove a history type. However, in the event that you need to do so, perform the following tasks:

1. Remove the history type from the JDeveloper history types list in the Preferences dialog.
2. Remove any custom code you implemented to support the history type in the base `EntityImpl.getHistoryContextForAttribute` method.

3. Remove all usages of the history type in the entity attribute metadata. Any attribute that you have defined to use this history type must be edited.

**To remove a history type from the JDeveloper history types list:**

1. From the **Tools** menu, choose **Preferences**.
2. In the Preferences dialog, expand **Business Components**, and click **History Types**.
3. On the History Types page, select the history type that you want to remove and click **Delete**.

---

## Advanced View Object Techniques

This chapter describes advanced techniques you can use while designing and working with ADF view objects in an ADF Business Components data model project.

This chapter includes the following sections:

- [Section 39.1, "Advanced View Object Concepts and Features"](#)
- [Section 39.2, "Tuning Your View Objects for Best Performance"](#)
- [Section 39.3, "Generating Custom Java Classes for a View Object"](#)
- [Section 39.4, "Working Programmatically with Multiple Named View Criteria"](#)
- [Section 39.5, "Performing In-Memory Sorting and Filtering of Row Sets"](#)
- [Section 39.6, "Using View Objects to Work with Multiple Row Types"](#)
- [Section 39.7, "Reading and Writing XML"](#)
- [Section 39.8, "Using Programmatic View Objects for Alternative Data Sources"](#)
- [Section 39.9, "Creating a View Object with Multiple Updatable Entities"](#)
- [Section 39.10, "Programmatically Creating View Definitions and View Objects"](#)
- [Section 39.11, "Declaratively Preventing Insert, Update, and Delete"](#)

### 39.1 Advanced View Object Concepts and Features

This section describes a number of interesting view object concepts and features that have not been discussed in previous chapters.

---

---

**Note:** To experiment with the examples in this chapter, use the `AdvancedViewObjectsExamples` workspace in the `StandaloneExamples` module of the Fusion Order Demo application, as described in [Section 2.4.5, "Standalone Applications in the AdvancedViewObjectExamples Application Workspace."](#) For information about how to obtain and install the Fusion Order Demo, see [Section 2.2, "Setting Up the Fusion Order Demo Application."](#)

---

---

#### 39.1.1 Limiting the View Object Max Fetch Size to Fetch the First n Rows

The default maximum fetch size of a view object is minus one (-1), which indicates there should be no limit to the number of rows that can be fetched. Keep in mind that by default, rows are fetched as needed, so -1 does not imply a view object will

necessarily fetch all the rows. It simply means that if you attempt to iterate through all the rows in the query result, you will get them all.

However, you might want to put an upper bound on the maximum number of rows that a view object will retrieve. You can use the following settings:

- You can configure a global threshold for all view objects queries using the **Row Fetch Limit** property on the Business Components page of the overview editor for the `adf-config.xml` file. You can locate the file in the Application Resources pane by expanding the **Descriptors-ADF META-INF** folder.

**Note:** Since **Row Fetch Limit** specifies a global threshold for all query operations in the application (including iterator binding property **RowCountThreshold** used to determine an estimated row count for the iterator result set), using this property means you can avoid changing settings for individual query operations where that operation's default behavior allows all rows to be fetched. If you do specify a fetch limit for individual view objects, the **Row Fetch Limit** setting will be ignored in those cases.

- You can configure a local threshold for specific view object queries using the **Max Fetch Size** with the **Only up to row number** field selected in the Tuning section of the General page of the overview editor for the view object.

**Tip:** If you want to set the global threshold for query operations using **Row Fetch Limit** and you still need to allow specific view object queries to return all available rows, then you can set the **Max Fetch Size** with the **Only up to row number** field for those view objects to a very large number.

For example, if you write a query containing an `ORDER BY` clause and only want to return the first  $n$  rows to display the "Top-N" entries in a page, you can use the overview editor for the view object to specify a value for the **Only up to row number** field in the Tuning section of the General page. For example, to fetch only the first five rows, you would enter "5" in this field. This is equivalent to calling the `setMaxFetchSize()` method on your view object to set the maximum fetch size to 5. The view object will stop fetching rows when it hits the maximum fetch size. Often you will combine this technique with specifying a **Query Optimizer Hint** of `FIRST_ROWS` also on the Tuning section of the General page of the overview editor. This gives a hint to the database that you want to retrieve the first rows as quickly as possible, rather than trying to optimize the retrieval of all rows.

### 39.1.2 Maintaining New Row Consistency in View Objects Based on the Same Entity

When multiple instances of entity-based view objects in an application module are based on the same underlying entity object, a new row created in one of them can be automatically added (without having to re-query) to the row sets of the others to keep your user interface consistent or simply to consistently reflect new rows in different application pages for a pending transaction. Consider the Fusion Order Demo application's `orderSummary.jspx` page that displays a customer's list of orders. If the customer goes to create a new order, this task is performed through a different view object and handled by a custom application module method. Using this view object new row consistency feature, the newly created order automatically appears in the customer's list of open orders on the `orderSummary.jspx` page without having to re-query the database.

For historical reasons, this capability is known as the *view link consistency* feature because in prior releases of Oracle Application Development Framework (Oracle ADF) the addition of new rows to other relevant row sets only was supported for detail view

object instances in a view link based on an association. Now this view link consistency feature works for any view objects for which it is enabled, regardless of whether they are involved in a view link or not.

### 39.1.2.1 What Happens at Runtime When View Link Consistency is Enabled

Consider two entity-based view objects `OrdersViewSummary` and `OrdersView` both based on the same underlying `Orders` entity object. When a new row is created in a row set for one of these view objects (like `OrdersView`) and the row's primary key is set, any of the *other* row sets for view objects based on the same `Orders` entity object (like `OrdersViewSummary`) receive an event indicating a new row has been created. If their view link consistency flag is enabled, then a copy of the new row is inserted into their row set as well.

### 39.1.2.2 How to Change the Default View Link Consistency Setting

You can use the Edit Business Components Configuration dialog to control the default setting for the view link consistency feature using the `jbo.viewlink.consistent` configuration parameter, as shown in [Figure 39-1](#).

**Figure 39-1** `jbo.viewlink.consistent` Property Setting

To display the configuration editor, right-click the application module in the Application Navigator and choose **Configurations**. Then, in the Manage Configurations dialog, select the configuration and click **Edit**. In the Edit Business Components Configuration dialog, select the Properties tab. The default setting for this parameter is the word "DEFAULT" which has the following meaning. If your view object has:

- A single entity usage, view link consistency is enabled
- Multiple entity usages, and:
  - If all secondary entity usages are marked as contributing reference information, then view link consistency is enabled

- If any secondary entity usage marked as **not** being a reference view link consistency is disabled.

You can globally disable this feature by setting the `jbo.viewlink.consistent` to the value `false` in your configuration. Conversely, you could globally enable this feature by setting `jbo.viewlink.consistent` to the value `true`, but Oracle does **not** recommend doing this. Doing so would force view link consistency to be set on for view objects with secondary entity usages that are not marked as a reference which presently do not support the view link consistency feature well.

To set the feature programmatically, use the `setAssociationConsistent()` API on any `RowSet`. When you call this method on a view object, it affects its default row set.

### 39.1.2.3 How to Use a RowMatch to Qualify Which New, Unposted Rows Get Added to a Row Set

If a view object has view link consistency enabled, any new row created by another view object based on the same entity object is added to its row set. By default the mechanism adds new rows in an unqualified way. If your view object has a design-time `WHERE` clause that queries only a certain subset of rows, you can apply a `RowMatch` object to your view object to perform the same filtering in-memory. The filtering expression of the `RowMatch` object you specify prevents new rows from being added that wouldn't make sense to appear in that view object.

For example, an `OrdersByStatus` view object might include a design time `WHERE` clause like this:

```
WHERE /* ... */ AND STATUS LIKE NVL(:StatusCode, '%')
```

Its custom Java class overrides the `create()` method as shown in [Example 39-1](#) to force view link consistency to be enabled. It also applies a `RowMatch` object whose filtering expression matches rows whose `Status` attribute matches the value of the `:StatusCode` named bind variable (or matches any row if `:StatusCode = '%'`). This `RowMatch` filter is used by the view link consistency mechanism to qualify the row that is a candidate to add to the row set. If the row qualifies by the `RowMatch`, it is added. Otherwise, it is not.

#### **Example 39-1** Providing a Custom RowMatch to Control Which New Rows are Added

```
// In OrdersByStatusImpl.java
protected void create() {
    super.create();
    setAssociationConsistent(true);
    setRowMatch(new RowMatch("Status = :StatusCode or :StatusCode = '%'"));
}
```

See [Section 39.5.4, "Performing In-Memory Filtering with RowMatch"](#) for more information on creating and using a `RowMatch` object. For a list of supported SQL operators see [Table 39-2](#). For a list of supported SQL function, see [Table 39-3](#).

---

**Note:** If the `RowMatch` facility does not provide enough control, you can override the view object's `rowQualifies()` method to implement a custom filtering solution. Your code can determine whether a new row qualifies to be added by the view link consistency mechanism or not.

---

### 39.1.2.4 What You May Need to Know About the Dynamic WHERE Clause and View Link Consistency

If you call `setWhereClause()` on a view object to set a dynamic WHERE clause, the view link consistency feature is disabled on that view object. If you have provided an appropriate custom `RowMatch` object to qualify new rows for adding to the row set, you can call `setAssociationConsistent(true)` after `setWhereClause()` to reenable view link consistency.

If a row set has view link consistency enabled, then new rows added due to creation by other row sets are added to the bottom of the row set.

If a row set has view link consistency enabled, then when you call the `executeQuery()` method, any qualifying new, unposted rows are added to the top of the row set before the queried rows from the database are added.

## 39.1.3 Understanding View Link Accessors Versus Data Model View Link Instances

View objects support two different styles of master-detail coordination:

- View link *instances* for data model master-detail coordination, as described in [Section 39.1.3.1, "Enabling a Dynamic Detail Row Set with Active Master-Detail Coordination."](#)
- View link *accessor* attributes for programmatically accessing detail row sets on demand, as described in [Section 39.1.3.2, "Accessing a Stable Detail Row Set Using View Link Accessor Attributes."](#)
- You can combine both styles, as described in [Section 39.1.3.3, "Accessor Attributes Create Distinct Row Sets Based on an Internal View Object."](#)

### 39.1.3.1 Enabling a Dynamic Detail Row Set with Active Master-Detail Coordination

When you add a view link instance to your application module's data model, you connect two specific view object instances. The use of the view link instance indicates that you want active master-detail coordination between the two. At runtime the view link instance in the data model facilitates the eventing that enables this coordination. Whenever the current row is changed on the master view object instance, an event causes the detail view object to be refreshed by automatically invoking `executeQuery()` with a new set of bind parameters for the new current row in the master view object.

A key feature of this data model master-detail is that the master and detail view object instances are stable objects to which client user interfaces can establish bindings. When the current row changes in the master — instead of producing a *new* detail view object instance — the existing detail view object instance updates its default row set to contain the set of rows related to the new current master row. In addition, the user interface binding objects receive events that allow the display to update to show the detail view object's refreshed row set.

Another key feature that is exclusive to data model hierarchy is that a detail view object instance can have multiple master view object instances. For example, an `PaymentOptions` view object instance may be a detail of *both* a `Customers` and a `Orders` view object instance. Whenever the current row in *either* the `Customers` or `Orders` view object instance changes, the default row set of the detail `PaymentOptions` view object instance is refreshed to include the row of payment information for the current customer and the current order. See [Section 39.1.6, "Setting Up a Data Model with Multiple Masters"](#) for details on setting up a detail view object instance with multiple-masters.

### 39.1.3.2 Accessing a Stable Detail Row Set Using View Link Accessor Attributes

When you need to programmatically access the detail row set related to a view object row by virtue of a view link, you can use the view link accessor attribute. You specify the finder name of the view link accessor attribute from the overview editor for the view link. Click the **Edit** icon in the Accessors section of the Relationship page and in the Edit View Link Properties dialog, edit the name of the view link accessor attribute.

[Example 39–2](#) shows the XML for the view link that defines the `_findername` value of the `<Attr>` element.

#### Example 39–2 View Link Accessor Attribute Name

```
<ViewLinkDefEnd
  Name="Orders"
  Cardinality="1"
  Owner="devguide.advanced.multiplemasters.Orders"
  Source="true">
  <AttrArray Name="Attributes">
    <Item Value="devguide.advanced.multiplemasters.Orders.PaymentOptionId"/>
  </AttrArray>
  <DesignTime>
    <Attr Name="_minCardinality" Value="1"/>
    <Attr Name="_isUpdateable" Value="true"/>
    <Attr Name="_finderName" Value="Orders"/>
  </DesignTime>
</ViewLinkDefEnd>
```

Assuming you've named your accessor attribute `AccessorAttrName`, you can access the detail row set using the generic `getAttribute()` API like:

```
RowSet detail = (RowSet)currentRow.getAttribute("AccessorAttrName");
```

If you've generated a custom view row class for the master view object and exposed the getter method for the view link accessor attribute on the client view row interface, you can write strongly-typed code to access the detail row set like this:

```
RowSet detail = (RowSet)currentRow.getAccessorAttrName();
```

Unlike the data model master-detail, programmatic access of view link accessor attributes does not require a detail view object instance in the application module's data model. Each time you invoke the view link accessor attribute, it returns a `RowSet` containing the set of detail rows related to the master row on which you invoke it.

Using the view link accessor attribute, the detail data rows are stable. As long as the attribute value(s) involved in the view link definition in the master row remain unchanged, the detail data rows will not change. Changing of the current row in the master does not affect the detail row set which is "attached" to a given master row. For this reason, in addition to being useful for general programmatic access of detail rows, view link accessor attributes are appropriate for UI objects like the tree control, where data for each master node in a tree needs to retain its distinct set of detail rows.

### 39.1.3.3 Accessor Attributes Create Distinct Row Sets Based on an Internal View Object

When you *combine* the use of data model master-detail with programmatic access of detail row sets using view link accessor, it is even more important to understand that they are distinct mechanisms. For example, imagine that you:

- Define `PersonsVO` and `OrdersVO` view objects

- Define a view link between them, naming the view link accessor `PersonsToOrders`
- Add instances of them to an application module's data model named `master` (of type `PersonsVO`) and `detail` (of type `OrdersVO`) coordinated actively by a view link instance.

If you find a person in the `master` view object instance, the `detail` view object instance updates as expected to show the corresponding orders. At this point, if you invoke a custom method that programmatically accesses the `PersonsToOrders` view link accessor attribute of the current `PersonsVO` row, you get a `RowSet` containing the set of `OrdersVO` rows. You might reasonably expect this programmatically accessed `RowSet` to have come from the `detail` view object instance in the data model, but this is not the case.

The `RowSet` returned by a view link accessor always originates from an *internally created* view object instance, not one you that added to the data model. This internal view object instance is created as needed and added with a system-defined name to the root application module.

The principal reason a distinct, internally-created view object instance is used is to guarantee that it remains unaffected by developer-related changes to their own view objects instances in the data model. For example, if the view row were to use the detail view object in the data model for view link accessor `RowSet`, the resulting row set could be inadvertently affected when the developer dynamically:

1. Adds a `WHERE` clause with new named bind parameters

If such a view object instance were used for the view link accessor result, unexpected results or an error could ensue because the dynamically-added `WHERE` clause bind parameter values have not been supplied for the view link accessor's `RowSet`: they were only supplied for the default row set of the detail view object instance in the data model.

2. Adds an additional master view object instance for the detail view object instance in the data model.

In this scenario, the semantics of the accessor would be changed. Instead of the accessor returning `OrdersVO` rows for the current `PersonsVO` row, it could all of a sudden start returning *only* the `OrdersVO` rows for the current `PersonsVO` that were created by a current logged in customer, for example.

3. Removes the detail view object instance or its containing application module instance.

In this scenario, all rows in the programmatically-accessed detail `RowSet` would become invalid.

Furthermore, Oracle ADF needs to distinguish between the data model master-detail and view link accessor row sets for certain operations. For example, when you create a new row in a detail view object, the framework automatically populates the attributes involved in the view link with corresponding values of the master. In the data model master-detail case, it gets these values from the current row(s) of the possibly multiple master view object instances in the data model. In the case of creating a new row in a `RowSet` returned by a view link accessor, it populates these values from the master row on which the accessor was called.

### 39.1.4 Presenting and Scrolling Data a Page at a Time Using the Range

To present and scroll through data a page at a time, you can configure a view object to manage for you an appropriately-sized range of rows. The range facility allows a client

to easily display and update a subset of the rows in a row set, as well as easily scroll to subsequent pages, *n* rows at a time. You call `setRangeSize()` to define how many rows of data should appear on each page. The default range size is one (1) row. A range size of minus one (-1) indicates the range should include all rows in the row set.

---

---

**Note:** When using the ADF Model layer's declarative data binding, the iterator binding in the page definition has a `RangeSize` property. At runtime, the iterator binding invokes the `setRangeSize()` method on its corresponding row set iterator, passing the value of this `RangeSize` property. The ADF design time by default sets this `RangeSize` property to 10 rows for most iterator bindings. An exception is the range size specified for a List binding to supply the set of valid values for a UI component like a dropdown list. In this case, the default range size is minus one (-1) to allow the range to include all rows in the row set.

---

---

When you set a range size greater than one, you control the row set paging behavior using the iterator mode. The two iterator mode flags you can pass to the `setIterMode()` method are:

- `RowIterator.ITER_MODE_LAST_PAGE_PARTIAL`

In this mode, the last page of rows may contain fewer rows than the range size. For example, if you set the range size to 10 and your row set contains 23 rows, the third page of rows will contain only three rows. This is the style that works best for Fusion web applications.

- `RowIterator.ITER_MODE_LAST_PAGE_FULL`

In this mode, the last page of rows is kept full, possibly including rows at the top of the page that had appeared at the bottom of the previous page. For example, if you set the range size to 10 and your row set contains 23 rows, the third page of rows will contain 10 rows, the first seven of which appeared as the last seven rows of page two. This is the style that works best for desktop-fidelity applications using Swing.

### 39.1.5 Efficiently Scrolling Through Large Result Sets Using Range Paging

As a general rule, for highest performance, Oracle recommends building your application in a way that avoids giving the end user the opportunity to scroll through very large query results. To enforce this recommendation, call the `getEstimatedRowCount()` method on a view object to determine how many rows would be returned by the user's query *before* actually executing the query and allowing the user to proceed. If the estimated row count is unreasonably large, your application can demand that the end-user provide additional search criteria.

However, when you *must* work with very large result sets, typically over 100 rows, you can use the view object's access mode called "range paging" to improve performance. The feature allows your applications to page back and forth through data, a range of rows at a time, in a way that is more efficient for large data sets than the default "scrollable" access mode.

The range paging access mode is typically used for paging through read-only row sets, and often is used with read-only view objects. You allow the user to find the row they are looking for by paging through a large row set with range paging access mode, then you use the `Key` of that row to find the selected row in a different view object for editing.

Range paging for view objects supports a standard access mode and a variation of the standard access mode that combines the benefits of range paging and result set scrolling with a minimum number of visits to the database. These modes for the view object range paging feature include:

- `RANGE_PAGING`, standard access mode fetches the number of rows specified by a range size. In this mode, the number of rows that may be scrolled without requerying the database is determined by a range size that you set. The default is to fetch a single row, but it is expected that you will set a range size equal to the number of rows you want to be able to display to the user before they scroll to the next result set. The application requeries the database each time a row outside of the range is accessed by the end user. Thus, scrolling backward and forward through the row set will requery the database. For clarification about this database-centric paging strategy, see [Section 39.1.5.1, "Understanding How to Oracle Supports "TOP-N" Queries."](#)
- `RANGE_PAGING_INCR`, incremental access mode gives the UI designer more flexibility for the number of rows to display at a time while keeping database queries to a minimum. In this mode, the UI incrementally displays the result set from the memory cache and thus supports scrolling within a single database query. The number of rows that the end user can scroll through in a single query is determined by the range size and a range paging cache factor that you set. For example, suppose that you set the range size to 4 and the cache factor to 5. Then, the maximum number of rows to cache in memory will be  $4 \times 5 = 20$ . For further explanation of the caching behavior, see [Section 39.1.5.4, "What Happens When View Rows are Cached When Using Range Paging."](#)

---

**Caution:** Additionally, the view object supports a `RANGE_PAGING_AUTO_POST` access mode to accommodate the inserting and deleting of rows from the row set. This mode behaves like the `RANGE_PAGING` mode, except that it eagerly calls `postChanges()` on the database transaction whenever any changes are made to the row set. However, this mode is typically not appropriate for use in Fusion web applications unless you can guarantee that the transaction will definitely be committed or rolled-back during the same HTTP request. Failure to heed this advice can lead to strange results in an environment where both application modules and database connections can be pooled and shared serially by multiple different clients.

---

### 39.1.5.1 Understanding How to Oracle Supports "TOP-N" Queries

The Oracle database supports a feature called a "Top-N" query to efficiently return the first *n* ordered rows in a query. For example, if you have a query like:

```
SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
```

If you want to retrieve the top 5 employees by salary, you can write a query like:

```
SELECT * FROM (
  SELECT X.*, ROWNUM AS RN FROM (
    SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
  ) X
) WHERE RN <= 5
```

which gives you results like:

```
EMPNO ENAME      SAL    RN
```

```

-----
7839 KING      5000  1
7788 SCOTT     3000  2
7902 FORD      3000  3
7566 JONES     2975  4
7698 BLAKE     2850  5

```

The feature is not only limited to retrieving the first  $n$  rows in order. By adjusting the criteria in the outermost `WHERE` clause you can efficiently retrieve any range of rows in the query's sorted order. For example, to retrieve rows 6 through 10 you could alter the query this way:

```

SELECT * FROM (
  SELECT X.*,ROWNUM AS RN FROM (
    SELECT EMPNO,ENAME,SAL FROM EMP ORDER BY SAL DESC
  ) X
) WHERE RN BETWEEN 6 AND 10

```

Generalizing this idea, if you want to see page number  $P$  of the query results, where each page contains  $R$  rows, then you would write a query like:

```

SELECT * FROM (
  SELECT X.*,ROWNUM AS RN FROM (
    SELECT EMPNO,ENAME,SAL FROM EMP ORDER BY SAL DESC
  ) X
) WHERE RN BETWEEN ((:P - 1) * :R) + 1 AND (:P) * :R

```

As the result set you consider grows larger and larger, it becomes more and more efficient to use this technique to page through the rows. Rather than retrieving hundreds or thousands of rows over the network from the database, only to display ten of them on the page, instead you can produce a clever query to retrieve only the  $R$  rows on page number  $P$  from the database. No more than a handful of rows at a time needs to be returned over the network when you adopt this strategy.

To implement this database-centric paging strategy in your application, you could handcraft the clever query yourself and write code to manage the appropriate values of the `:R` and `:P` bind variables. Alternatively, you can use the view object's range paging access mode, which implements it automatically for you.

### 39.1.5.2 How to Enable Range Paging for a View Object

You can use the Tuning panel of the overview editor for the view object to set the access mode to either standard range paging or incremental range paging. The **Range Paging Cache Factor** field is only editable when you select **Range Paging Incremental**. [Figure 39–2](#) shows the view object's **Access Mode** set to **Range Paging** (standard mode) with the default range size of 1. To understand the row set caching behavior of both access modes, see [Section 39.1.5.4, "What Happens When View Rows are Cached When Using Range Paging."](#)

**Figure 39–2 Access Mode in the Overview Editor for the View Object**

Package: oracle.fodemo.storefront.account.queries

Extends: <None>

Property Set: <None>

Business Components Project: [StoreFrontService](#)

**Tuning**

Enter tuning parameters for this View, to control SQL execution and how data is fetched from the database.

**Retrieve from the Database**

All Rows  Only up to row number

in Batches of:

As Needed  All at Once

At Most One Row

No Rows (i.e. used only for inserting new rows)

Query Optimizer Hint:

e.g FIRST\_ROWS, ALL\_ROWS, etc.

Fill Last Page of Rows when Paging through Rowset

Passivate State (e.g. Current Row, Bind Values, etc.)

Including All Transient Values

Retain View Link Accessor Rowset

Access Mode:

Range Size:

Range Paging Cache Factor:

To programmatically enable standard range paging for your view object, first call `setRangeSize()` to define the number of rows per page, then call the following method with the desired mode:

```
yourViewObject.setAccessMode(RowSet.RANGE_PAGING | RANGE_PAGING_INCR);
```

If you set `RANGE_PAGING_INCR`, then you must also call the following method to set the cache factor for your defined range size:

```
yourViewObject.setRangePagingCacheFactor(int f);
```

### 39.1.5.3 What Happens When You Enable Range Paging

When a view object's access mode is set to `RANGE_PAGING`, the view object takes its default query like:

```
SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
```

and automatically "wraps" it to produce a Top-N query.

For best performance, the statement uses a combination of greater than and less than conditions instead of the `BETWEEN` operator, but the logical outcome is the same as the Top-N wrapping query you saw above. The actual query produced to wrap a base query of:

```
SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
```

looks like this:

```
SELECT * FROM (
  SELECT /*+ FIRST_ROWS */ IQ.*, ROWNUM AS Z_R_N FROM (
    SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
  ) IQ WHERE ROWNUM < :0)
WHERE Z_R_N > :1
```

The two bind variables are bound as follows:

- :1 index of the first row in the current page
- :0 is bound to the last row in the current page

#### 39.1.5.4 What Happens When View Rows are Cached When Using Range Paging

When a view object operates in `RANGE_PAGING` access mode, it only keeps the current range (or "page") of rows in memory in the view row cache at a time. That is, if you are paging through results ten at a time, then on the first page, you'll have rows 1 through 10 in the view row cache. When you navigate to page two, you'll have rows 11 through 20 in the cache. This also can help make sure for large row sets that you don't end up with tons of rows cached just because you want to preserve the ability to scroll backwards and forwards.

When a view object operates in `RANGE_PAGING_INCR` access mode, the cache factor determines the number of rows to cache in memory for a specific range size. For example, suppose the range size is set to 4 and cache factor to 5. Then, the memory will keep at most  $4 \times 5 = 20$  rows in its collection. In this example, when the range is refreshed for the first time, the memory will have just four rows even though the range paging query is bound to retrieve rows 0 to 19 (for a total of twenty rows). When the range is scrolled past the fourth row, more rows will be read in from the current result set. This will continue until all twenty rows from the query result are read. If the user's action causes the next set of rows to be retrieve, the query will be re-executed with the new row number bind values. The exact row number bind values are determined by the new range-start and the number of rows that can be retained from the cache. For example, suppose all twenty rows have been filled up and the user asks to move the range-start to 18 (0-based). This means that memory can retain row 18 and row 19 and will need two more rows to fill the range. The query is re-executed for rows 20 and 21.

#### 39.1.5.5 How to Scroll to a Given Page Number Using Range Paging

When a view object operates in `RANGE_PAGING` access mode, to scroll to page number *n* call its `scrollToRangePage()` method, passing *n* as the parameter value.

#### 39.1.5.6 Estimating the Number of Pages in the Row Set Using Range Paging

When a view object operates in `RANGE_PAGING` access mode, you can access an estimate of the total number of pages the entire query result would produce using the `getEstimatedRangePageCount()` method.

#### 39.1.5.7 Understanding the Tradeoffs of Using a Range Paging Mode

You might ask yourself, "Why wouldn't I *always* want to use `RANGE_PAGING` or `RANGE_PAGING_INCR` mode?" The answer is that using range paging potentially causes more overall queries to be executed as you are navigating forward and backward through your view object rows. You would want to avoid using `RANGE_PAGING` mode in these situations:

- You plan to read all the rows in the row set immediately (for example, to populate a dropdown list).

In this case your range size would be set to -1 and there really is only a single "page" of all rows, so range paging does not add value.

- You need to page back and forth through a small-sized row set.

If you have 100 rows or fewer, and are paging through them 10 at a time, with `RANGE_PAGING` mode you will execute a query each time you go forward and backward to a new page. Otherwise, in the default scrollable mode, you will cache the view object rows as you read them in, and paging backwards through the previous pages will not re-execute queries to show those already-seen rows. Alternatively, you can use `RANGE_PAGING_INCR` mode to allow scrolling through in-memory results based on a row set cache factor that you determine.

In the case of a very large (or unpredictably large) row set, the trade off of potentially doing a few more queries — each of which only returns up to the `RangeSize` number of rows from the database — is more efficient than trying to cache all of the previously-viewed rows. This is especially true if you allow the user to jump to an arbitrary page in the list of results. Doing so in default, scrollable mode requires fetching and caching all of the rows between the current page and the page the users jumps to. In `RANGE_PAGING` mode, it will ask the database just for the rows on that page. Then, if the user jumps back to a page of rows that they have already visited, in `RANGE_PAGING` mode, those rows get re-queried again since only the current page of rows is held in memory in this mode. The incremental range paging access mode `RANGE_PAGING_INCR` combines aspects of both standard range paging and scrollable access mode since it allows the application to cache more rows in memory and permits the user to jump to any combination of those rows without needing to requery.

### 39.1.6 Setting Up a Data Model with Multiple Masters

When useful, you can set up your data model to have multiple master view object instances for the same detail view object instance. Consider view objects named `Customers`, `Orders`, and `PaymentOptions` with view links defined between:

- `Customers` and `PaymentOptions`
- `Orders` and `PaymentOptions`

---

---

**Note:** The examples in this section are not based on the Fusion Order Demo application. They currently refer to the `MultipleMasters` project in the `AdvancedViewObjectExamples` workspace, available as noted at the beginning of this chapter for download.

---

---

[Figure 39-3](#) shows what the data model panel looks like when you've configured both `Customers` and `Orders` view object instances to be masters of the same `PaymentOptions` view object instance.

**Figure 39–3 Multiple Master View Object Instances for the Same Detail**

To set up the data model as shown in [Figure 39–3](#) open the overview editor for the application module and follow these steps in the Data Model Components section of the Data Model page:

1. Add an instance of the `Customers` view object to the data model.  
Assume you name it `Customers`.
2. Add an instance of the `Orders` view object to the data model  
Assume you name it `Orders`.
3. Select the `Customers` view object instance in the **Data Model** list
4. In the **Available View Objects** list, select the `PaymentOptions` view object indented beneath the `Customers` view object and enter the view object instance name of `PaymentOptions` in the **New Instance Name** field. Click **>** to shuttle it into data model as a detail of the existing `Customers` view object instance.
5. Select the `Orders` view object instance in the **Data Model** list
6. In the **Available View Objects** list, select the `PaymentOptions` view object indented beneath the `Orders` view object and enter the view object instance name of `PaymentOptions` in the **New Instance Name** field. Click **>** to shuttle it into data model as a detail of the existing `Orders` view object instance.  
  
An alert will appear: **An instance of a View Object with the name `PaymentOptions` has already been used in the data model. Would you like to use the same instance?**
7. Click **Yes** to confirm you want the `PaymentOptions` view object instance to *also* be the detail of the `Orders` view object instance.

### 39.1.7 Understanding When You Can Use Partial Keys with `findByKey()`

View objects based on multiple entity usages support the ability to find view rows by specifying a partially populated key. A partial key is a multi-attribute `Key` object with some of its attributes set to `null`. However, there are strict rules about what kinds of partial keys can be used to perform the `findByKey()`.

If a view object is based on  $n$  entity usages, where  $n > 1$ , then the view row key is by default comprised of all of the primary key attributes from *all* of the participating entity usages. Only the ones from the *first* entity object are *required* to participate in the view row key, but by default all of them do.

If you allow the key attributes from some *secondary* entity usages to remain as key attributes at the view row level, then you should leave *all* of the attributes that form

the primary key for that entity object as part of the view row key. Assuming you have left the one or more key attributes in the view row for  $m$  of the  $n$  entity usages, where ( $m \leq n$ ), then you can use `findByKey()` to find rows based on any subset of these  $m$  entity usages. Each entity usage for which you provide values in the `Key` object, requires that you must provide non-null values for *all* of the attributes in that entity's primary key.

You have to follow this rule because when a view object is based on at least one or more entity usages, its `findByKey()` method finds rows by delegating to the `findByPrimaryKey()` method on the entity definition corresponding to the first entity usage whose attributes in the view row key are non-null. The entity definition's `findByPrimaryKey()` method requires all key attributes for any given entity object to be non-null in order to find the entity row in the cache.

As a concrete example, imagine that you have a `OrderInfoVO` view object with a `OrderEO` entity object as its primary entity usage, and an `AddressEO` entity as secondary reference entity usage. Furthermore, assume that you leave the **Key Attribute** property of *both* of the following view row attributes set to `true`:

- `OrderId` — primary key for the `OrderEO` entity
- `AddressId` — primary key for the `AddressEO` entity

The view row key will therefore be the (`OrderId`, `AddressId`) combination. When you do a `findByKey()`, you can provide a `Key` object that provides:

- A completely specified key for the underlying `OrderEO` entity
 

```
Key k = new Key(new Object[]{new Number(200), null});
```
- A completely specified key for the underlying `AddressEO` entity
 

```
Key k = new Key(new Object[]{null, new Number(118)});
```
- A completely specified key for both entities
 

```
Key k = new Key(new Object[]{new Number(200), new Number(118)});
```

When a valid partial key is specified, the `findByKey()` method can return multiple rows as a result, treating the missing entity usage attributes in the `Key` object as a wildcard.

### 39.1.8 Creating Dynamic Attributes to Store UI State

You can add one or more dynamic attributes to a view object at runtime using the `addDynamicAttribute()` method. Dynamic attributes can hold any serializable object as their value. Typically, you will consider using dynamic attributes when writing generic framework extension code that requires storing some additional per-row transient state to implement a feature you want to add to the framework in a global, generic way.

### 39.1.9 Working with Multiple Row Sets and Row Set Iterators

While you typically work with a view object's *default* row set, you can call the `createRowSet()` method on the `ViewObject` interface to create secondary, named row sets based on the same view object's query. One situation where this could make sense is when your view object's SQL query contains named bind variables. Since each `RowSet` object stores its own copy of bind variable values, you could use a single view object to produce and process multiple row sets based on different combinations of bind variable values. You can find a named row set you've created using the

`findRowSet()` method. When you're done using a secondary row set, call its `closeRowSet()` method.

For any `RowSet`, while you typically work with its *default* row set iterator, you can call the `createRowSetIterator()` method of the `RowSet` interface to create secondary, named row set iterators. You can find a named row set iterator you've created using the `findRowSetIterator()` method. When you're done using a secondary row set iterator, call its `closeRowSetIterator()` method.

**Performance Tip:** When you need to perform programmatic iteration over a result set, create a secondary iterator to avoid disturbing the current row of the *default* row set iterator. For example, through the ADF Model declarative data binding layer, user interface pages in your application work with the default row set iterator of the default row set of view objects in the application module's data model. In this scenario, if you did not create a secondary row set iterator for the business logic you write to iterate over a view object's default row set, you would consequently change the current row of the *default* row set iterator used by the user interface layer.

### 39.1.10 Optimizing View Link Accessor Access By Retaining the Row Set

Each time you retrieve a view link accessor row set, by default the view object creates a new `RowSet` object to allow you to work with the rows. This does *not* imply *re-executing* the query to produce the results each time, only creating a new instance of a `RowSet` object with its default iterator reset to the "slot" before the first row. To force the row set to refresh its rows from the database, you can call its `executeQuery()` method.

You can enable caching of the view link accessor row set when you do not want the application to incur the small amount of overhead associated with creating new detail row sets. For example, because view accessor row sets remain stable as long as the master row view accessor attribute remains unchanged, it would not be necessary to recreate a new row set for UI components, like the tree control, where data for each master node in a tree needs to retain its distinct set of detail rows. The view link accessor's detail row set can also be accessed programmatically. In this case, if your application makes numerous calls to the same view link accessor attributes, you can consider caching the view link accessor row set. This style of managing master-detail coordination differs from creating view link instances in the data model, as explained in [Section 39.1.3, "Understanding View Link Accessors Versus Data Model View Link Instances."](#)

You can enable retention of the view link accessor row set using the overview editor for the view object that is the source for the view link accessor. Select **Retain View Link Accessor Row Set** in the Tuning section of the General page of the overview editor for the view object.

Alternatively, you can enable a custom Java class for your view object, override the `create()` method, and add a line after `super.create()` that calls the `setViewLinkAccessorRetained()` method passing `true` as the parameter. It affects all view link accessor attributes for that view object.

When this feature is enabled for a view object, since the view link accessor row set is not recreated each time, the current row of its default row set iterator is also retained as a side-effect. This means that your code will need to explicitly call the `reset()` method on the row set you retrieve from the view link accessor to reset the current row in its default row set iterator back to the "slot" before the first row.

Note, however, that with accessor retention enabled, your failure to call `reset()` each time before you iterate through the rows in the accessor row set can result in a subtle, hard-to-detect error in your application. For example, if you iterate over the rows in a view link accessor row set like this, for example to calculate some aggregate total:

```
RowSet rs = (RowSet)row.getAttribute("OrdersShippedToPurchaser");
while (rs.hasNext()) {
    Row r = rs.next();
    // Do something important with attributes in each row
}
```

The first time you work with the accessor row set the code will work. However, since the row set (and its default row set iterator) are retained, the second and subsequent times you access the row set the current row will already be at the end of the row set and the while loop will be skipped since `rs.hasNext()` will be `false`. Instead, with this feature enabled, write your accessor iteration code like this:

```
RowSet rs = (RowSet)row.getAttribute("OrdersShippedToPurchaser");
rs.reset(); // Reset default row set iterator to slot before first row!
while (rs.hasNext()) {
    Row r = rs.next();
    // Do something important with attributes in each row
}
```

Recall that if view link consistency is on, when the accessor is retained the new unposted rows will show up at the end of the row set. This is slightly different from when the accessor is not retained (the default), where new unposted rows will appear at the beginning of the accessor row set.

## 39.2 Tuning Your View Objects for Best Performance

You can use view objects to read rows of data, create and store rows of transient data, as well as automatically coordinate inserts, updates, and deletes made by end users with your underlying business objects. How you design and use your view objects can definitely affect their performance at runtime. This section provides guidance on configuring your view objects to get the best possible performance.

### 39.2.1 Use Bind Variables for Parameterized Queries

Whenever the `WHERE` clause of your query includes values that might change from execution to execution, you should use named bind variables. The Create View Criteria dialog that you display from the Query page of the view object overview editor makes this an easy task. Their use also protects your application against abuse through SQL injection attacks by malicious end-users. For information about defining view criteria with bind variables, see [Section 5.11.1, "How to Create Named View Criteria Declaratively."](#)

#### 39.2.1.1 Use Bind Variables to Avoid Re-parsing of Queries

Bind variables are place holders in the SQL string whose value you can easily change at runtime without altering the text of the SQL string itself. Since the query text doesn't change from execution to execution, the database can efficiently reuse the same parsed statement each time. Avoiding re-parsing of your statement alleviates the database from having to continually re-determine its query optimization plan and eliminates contention by multiple end-users on other costly database resources used during this parsing operation. This savings leads to higher runtime performance of your application. See [Section 5.10.1, "How to Add Bind Variables to a View Object Definition"](#) for details on how to use named bind variables.

### 39.2.1.2 Use Bind Variables to Prevent SQL-Injection Attacks

Using bind variables for parameterized `WHERE` clause values is especially important if their values will be supplied by *end-users* of your application. Consider the example shown in [Example 39–3](#). It adds a dynamic `WHERE` clause formed by concatenating a user-supplied parameter value into the statement.

**Example 39–3 Using String Concatenation Instead of Bind Variables is Vulnerable to SQL-Injection Attacks**

```
// EXAMPLE OF BAD PRACTICE, Do not follow this approach!
String userSuppliedValue = ... ;
yourViewObject.setWhereClause("BANK_ACCOUNT_ID = "+userSuppliedValue);
```

A user with malicious intentions — if able to learn any details about your application's underlying database schema — could supply a carefully-constructed "bank account number" as a field value or URL parameter like:

```
BANK_ACCOUNT_ID
```

When the code in [Example 39–3](#) concatenates this value into the dynamically-applied where clause, what the database sees is a query predicate like this:

```
WHERE (BANK_ACCOUNT_ID = BANK_ACCOUNT_ID)
```

This `WHERE` clause retrieves *all* bank accounts instead of just the current user's, perhaps allowing the hacker to view private information of another person's account. This technique of short-circuiting an application's `WHERE` clause by trying to supply a maliciously-constructed parameter value into a SQL statement is called a SQL injection attack. Using named bind variables instead for these situations as shown in [Example 39–4](#) prevents the vulnerability.

**Example 39–4 Use Named Bind Variables Instead of String Concatenation**

```
// Best practice using named bind variables
String userSuppliedValue = ... ;
yourViewObject.setWhereClause("BANK_ACCOUNT_ID = :BankAccountId");
yourViewObject.defineNamedWhereClauseParam("BankAccountId", null, null);
yourViewObject.setNamedWhereClauseParam("BankAccountId", userSuppliedValue);
```

If a malicious user supplies an illegal value in this case, they receive an error your application can handle instead of obtaining data they are not suppose to see.

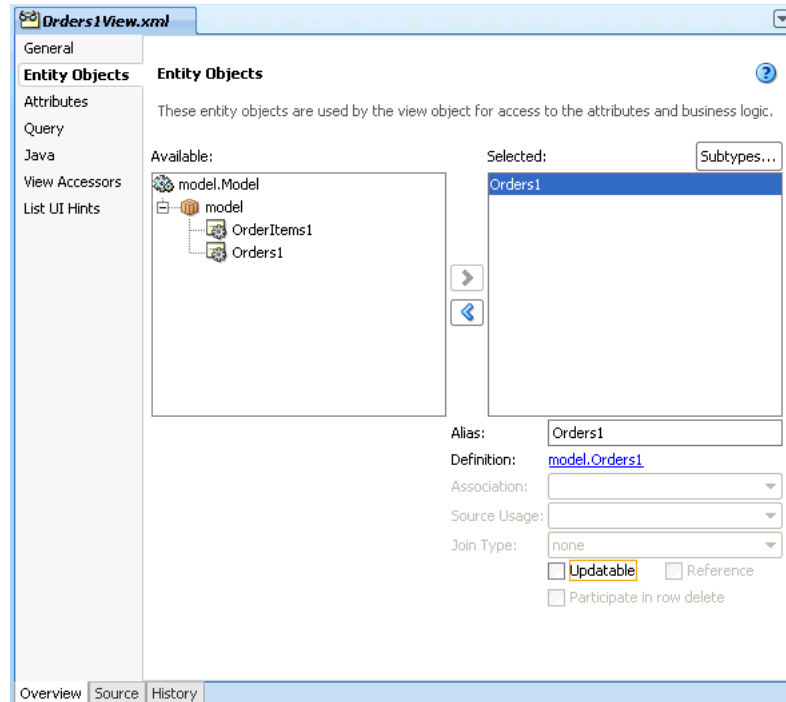

## 39.2.2 Consider Using Entity-Based View Objects for Read-Only Data

Typically view objects used for SQL-based validation purposes, as well as for displaying the list of valid selections in a dropdown list, can be read-only. You need to decide what kind of functionality your application requires and design the view object accordingly.

**Best Practice:** When you need to create a read-only view object for data lookup, you should use the entity-based view object and deselect the **Updatable** option in the Entity Objects page of the view object overview editor. The approach benefits from the design time editors which aid in generating the SQL query. The alternative of creating an expert-mode view object requires writing a SQL query. Expert mode queries are still useful for cases where Unions and Group By queries cannot be expressed using entity objects.

View objects can either be related to underlying entity objects or not. When a view object is related to one or more underlying entity objects the default behavior supports creating new rows and modifying or removing queried rows. However, the update feature can be disabled by deselecting **Updatable** in the overview editor for the entity-based view object, as shown in [Figure 39-4](#).

**Figure 39-4** Deselecting the Updatable Option for an Entity-based View Object

The alternative is to create a read-only view object and define the SQL query using **Expert Mode** in the Edit Query dialog. For the Business Components developer not comfortable with constructing a complex SQL statement, it will always be more convenient to create a non-updatable view object based on an entity object since the editor simplifies the task of creating the query. Entity-based view objects that you set to non-updatable compare favorably to read-only, expert mode-based view objects:

- There is the ability to optimize the select list at runtime to include only those attributes that are required by the user interface
- There is no significant performance degradation incurred by using the entity object to create the local cache
- The data in the view object will reflect the state of the local cache rather than need to return to the database for each read operation
- The data in the local cache will stay consistent should another view object you define need to perform an update on the non-updatable view object's base entity object.

So, while there is a small amount of runtime overhead associated with the coordination between view object rows and entity object rows (estimates show less than 5% overhead), weigh this against the ability to keep the view object definition entirely declarative and maintain a customizable view object. Expert mode-based view objects are not customizable but they can be used to perform Unions and Group By queries that cannot be expressed in entity objects. Expert mode-based view objects are

also useful in SQL-based validation queries used by the view object-based Key Exists validator.

When data is not read-only, the best (and only) choice is to create entity-based view objects. Entity-based view objects that are updatable (default behavior) are the only way to pickup entity-derived attribute default values, reflect pending changes made to relevant entity object attributes through other view objects in the same transaction, and reflect updated reference information when foreign key attribute values are changed is to use an entity-based view object.

### 39.2.3 Use SQL Tracing to Identify Ill-Performing Queries

After deciding whether your view object should be mapped to entities or not, your attention should turn to the query itself. On the Query page of the view object overview editor, click the **Edit SQL Query** icon to display the Edit Query dialog. Click the **Explain Plan** button on the Query page of the Edit Query dialog to see the query plan that the database query optimizer will use. If you see that it is doing a full table scan, you should consider adding indexes or providing a value for the **Query Optimizer Hint** field on the Tuning section of the overview editor's General page. This will let you explicitly control which query plan will be used. These facilities provide some useful tools to the developer to evaluate the query plans for individual view object SQL statements. However, their use is not a substitute for tracing the SQL of the entire application to identify poorly performing queries in the presence of a production environment's amount of data and number of end users.

You can use the Oracle database's SQL Tracing facilities to produce a complete log of all SQL statements your application performs. The approach that works in all versions of the Oracle database is to issue the command:

```
ALTER SESSION SET SQL_TRACE TRUE
```

Specifically in version 10g of Oracle, the DBA would need to grant `ALTER SESSION` privilege in order to execute this command.

This command enables tracing of the current database session and logs all SQL statements to a server-side trace file until you either enter `ALTER SESSION SET SQL_TRACE FALSE` or close the connection. To simplify enabling this option to trace your Fusion web applications, override the `afterConnect()` method of your application module (or custom application module framework extension class) to conditionally perform the `ALTER SESSION` command to enable SQL tracing based on the presence of a Java system property as shown in [Example 39-5](#).

#### **Example 39-5** Conditionally Enabling SQL Tracing in an Application Module

```
// In YourCustomApplicationModuleImpl.java
protected void afterConnect() {
    super.afterConnect();
    if (System.getProperty("enableTrace") != null) {
        getDBTransaction().executeCommand("ALTER SESSION SET SQL_TRACE TRUE");
    }
}
```

After producing a trace file, you use the `TKPROF` utility supplied with the database to format the information and to better understand information about each query executed like:

- The number of times it was (re)parsed
- The number of times it was executed

- How many round-trips were made between application server and the database
- Various quantitative measurements of query execution time

Using these techniques, you can decide which additional indexes might be required to speed up particular queries your application performs, or which queries could be changed to improve their query optimization plan. For details about working with the TKPROF utility, see sections "Understanding SQL Trace and TKPROF" and "Using the SQL Trace Facility and TKPROF" in the *Oracle Database Performance Tuning Guide*.

---

**Note:** The Oracle database provides the `DBMS_MONITOR` package that further simplifies SQL tracing and integrates it with Oracle Enterprise Manager for visually monitoring the most frequently performed query statements your applications perform.

---

### 39.2.4 Consider the Appropriate Tuning Settings for Every View Object

The Tuning section on the General page of the view object overview editor lets you set various options that can dramatically effect your query's performance. [Figure 39–5](#) shows the default options that the new view object defines.

**Figure 39–5 View Object Default Tuning Options**

The screenshot displays the 'View Object Overview Editor' for a 'View Object' named 'CustomerAddressVO'. The interface is divided into a left-hand navigation pane and a main content area. The navigation pane includes 'General', 'Entity Objects', 'Attributes', 'Query', 'Java', 'View Accessors', and 'List UI Hints'. The main content area is titled 'View Object' and contains a description: 'View objects are for joining, filtering, projecting, and sorting your business data for the specific needs of a given application task.' Below this, the 'Name' is 'CustomerAddressVO', 'Package' is 'oracle.fodemo.storefront.account.queries', 'Extends' is '<None>', and 'Property Set' is '<None>'. The 'Business Components Project' is 'StoreFrontService'. The 'Tuning' section is expanded, showing options for 'Retrieve from the Database'. The 'All Rows' radio button is selected, with 'Only up to row number' set to '10' and 'in Batches of' set to '1'. The 'As Needed' radio button is also selected, with 'All at Once', 'At Most One Row', and 'No Rows (i.e. used only for inserting new rows)' options unselected. A 'Query Optimizer Hint' field is empty, with a note 'e.g FIRST\_ROWS, ALL\_ROWS, etc.'. Below these are four checked checkboxes: 'Fill Last Page of Rows when Paging through Rowset', 'Passivate State (e.g. Current Row, Bind Values, etc.)', 'Including All Transient Values', and 'Retain View Link Accessor Rowset'. The 'Access Mode' is set to 'Scrollable' in a dropdown menu. The 'Range Size' is set to '1' and the 'Range Paging Cache Factor' is empty.

### 39.2.4.1 Set the Database Retrieval Options Appropriately

The **Retrieve from the Database** group box, controls how the view object retrieves rows from the database server. The options for the fetch mode are **All Rows**, **Only Up To Row Number**, **At Most One Row**, and **No Rows**. Most view objects will stick with the default **All Rows** option, which will be retrieved **As Needed** (default) or **All at Once** depending on which option you choose.

---

---

**Note:** The **All at Once** option does not enforce a single database round trip to fetch the rows specified by the view object query. The **As Needed** and **All at Once** options work in conjunction with the value of **in Batches of** (also known as fetch size) to determine the number of round trips. For best database access performance, you should consider changing the fetch size as described in [Section 39.2.4.2](#), "[Consider Whether Fetching One Row at a Time is Appropriate](#)."

---

---

The **As Needed** option ensures that an `executeQuery()` operation on the view object initially retrieves only as many rows as necessary to fill the first page of a display, whose number of rows is set based on the view object's range size. If you use **As Needed**, then you will require only as many database round trips as necessary to deliver the number of rows specified by the initial range size. Whereas, if you use **All at Once**, then the application will perform as many round trips as necessary to deliver all the rows based on the value of **in Batches of** (fetch size) and the number of rows identified by the query.

For view objects whose `WHERE` clause expects to retrieve a *single* row, set the option to **At Most One Row** for best performance. This way, the view object knows you don't expect any more rows and will skip its normal test for that situation. Finally, if you use the view object only for creating new rows, set the option to **No Rows** so no query will ever be performed.

### 39.2.4.2 Consider Whether Fetching One Row at a Time is Appropriate

The fetch size controls how many rows will be returned in each round trip to the database. By default, the framework will fetch rows in batches of one row at a time. If you are fetching any more than one row, you will gain efficiency by setting this **in Batches of** value.

However the higher the number, the larger the client-side buffer required, so avoid setting this number arbitrarily high. If you are displaying results  $n$  rows at a time in the user interface, it's good to set the fetch size to at least  $n+1$  so that each page of results can be retrieved in a single round trip to the database.

---

---

**Caution:** Unless your query *really* fetches just one row, leaving the *default* fetch size of one (1) in the **in Batches of** field on the Tuning section of the General page of the view object overview editor is a recipe for bad performance due to many unnecessary round trips between the application server and the database. Oracle strongly recommends considering the appropriate value for each view object's fetch size.

---

---

### 39.2.4.3 Specify a Query Optimizer Hint if Necessary

The **Query Optimizer Hint** field allows you to specify an optional hint to the Oracle query optimizer to influence what execution plan it will use. You can set this hint in the Tuning page of the overview editor for the view object, as shown in [Figure 39-5](#).

At runtime, the hint you provide is added immediately after the `SELECT` keyword in the query, wrapped by the special comment syntax `/*+ YOUR_HINT */`. Two common optimizer hints are:

- `FIRST_ROWS` — to hint that you want the first rows as quickly as possible
- `ALL_ROWS` — to hint that you want all rows as quickly as possible

There are many other optimizer hints that are beyond the scope of this manual to document. Reference the Oracle database reference manuals for more information on available hints.

### 39.2.5 Creating View Objects at Design Time

It's important to understand the overhead associated with creating view objects at runtime. Avoid the temptation to do this without a compelling business requirement. For example, if your application issues a query against a table whose name you know at design time and if the list of columns to retrieve is also fixed, then create a view object at design time. When you do this, your SQL statements are neatly encapsulated, can be easily explained and tuned during development, and incur no runtime overhead to discover the structure and data types of the resulting rows.

In contrast, when you use the `createViewObjectFromQueryStmt()` API on the `ApplicationModule` interface at runtime, your query is buried in code, it's more complicated to proactively tune your SQL, and you pay a performance penalty each time the view object is created. Since the SQL query statement for a dynamically-created view object could theoretically be different each time a new instance is created using this API, an extra database round trip is required to discover the "shape" of the query results on-the-fly. Only create queries dynamically if you *cannot* know the name of the table to query until runtime. Most other needs can be addressed using a design-time created view object in combination with runtime API's to set bind variables in a fixed where clause, or to add an additional `WHERE` clause (with optional bind variables) at runtime.

### 39.2.6 Use Forward Only Mode to Avoid Caching View Rows

Often you will write code that programmatically iterates through the results of a view object. A typical situation will be custom validation code that must process multiple rows of query results to determine whether an attribute or an entity is valid or not. In these cases, if you intend to read each row in the row set a single time and never require scrolling backward or re-iterating the row set a subsequent time, then you can use "forward only" mode to avoid caching the retrieved rows. To enable forward only mode, call `setForwardOnly(true)` on the view object.

---

---

**Note:** Using a read-only view object (with no entity usages) in forward-only mode with an appropriately tuned fetch size is the most efficient way to programmatically read data.

---

---

You can also use forward-only mode to avoid caching rows when inserting, updating, or deleting data as long as you never scroll backward through the row set and never call `reset()` to set the iterator back to the first row. Forward only mode only works with a range size of one (1).

## 39.3 Generating Custom Java Classes for a View Object

As you've seen, all of the basic querying functionality of a view object can be achieved without using custom Java code. Clients can retrieve and iterate through the data of any SQL query without resorting to any custom code on the view object developer's part. In short, for many read-only view objects, once you have defined the SQL statement, you're done. However, it's important to understand how to enable custom Java generation for a view object when your needs might require it. For example, reasons you might write code in a custom Java class include:

- To add validation methods (although Groovy Script expressions can provide this support without needing Java)
- To add custom logic
- To augment built-in behavior

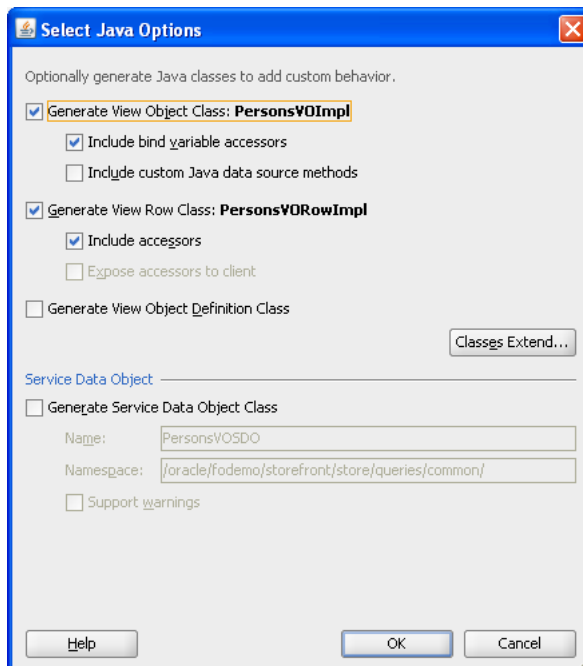

[Appendix E, "Most Commonly Used ADF Business Components Methods"](#) provides a quick reference to the most common code that you will typically write, use, and override in your custom view object and view row classes.

### 39.3.1 How To Generate Custom Classes

To enable the generation of custom Java classes for a view object, use the **Java** page of the view object overview editor. As shown in [Figure 39–6](#), there are three optional Java classes that can be related to a view object. The first two in the list are the most commonly used:

- *View object class*, which represents the component that performs the query
- *View row class*, which represents each row in the query result

**Figure 39–6** View Object Custom Java Generation Options

### 39.3.1.1 Generating Bind Variable Accessors

When you enable the generation of a custom view object class, if you also select the **Bind Variable Accessors** checkbox, then JDeveloper generates getter and setter methods in your view object class. Since the `Users` view object had three named bind variables (`TheName`, `LowUserId`, and `HighUserId`), the custom `PersonsImpl.java` view object class would have corresponding methods like this:

```
public String getTheName() {...}
public void setTheName(String value){...}
public Number getHighUserId(){...}
public void setHighUserId(Number value) {...}
public Number getLowUserId() {...}
public void setLowUserId(Number value) {...}
```

These methods allow you to set a bind variable with compile-time type-checking to ensure you are setting a value of the appropriate type. That is, instead of writing a line like this to set the value of the `LowUserId`:

```
vo.setNamedWhereClauseParam("LowUserId",new Number(150));
```

You can write the code like:

```
vo.setLowUserId(new Number(150));
```

You can see that with the latter approach, the Java compiler would catch a typographical error had you accidentally typed `setLowUserName` instead of `setLowUserId`:

```
// spelling name wrong gives compile error
vo.setLowUserName(new Number(150));
```

Or if you were to incorrectly pass a value of the wrong data type, like "ABC" instead of Number value:

```
// passing String where number expected gives compile error
vo.setLowUserId("ABC");
```

*Without* the generated bind variable accessors, an incorrect line of code like the following cannot be caught by the compiler:

```
// Both variable name and value wrong, but compiler cannot catch it
vo.setNamedWhereClauseParam("LowUserName", "ABC");
```

It contains both an incorrectly spelled bind variable name, as well as a bind variable value of the wrong datatype. If you use the generic APIs on the `ViewObject` interface, errors of this sort will raise exceptions at runtime instead of being caught at compile time.

### 39.3.1.2 Generating View Row Attribute Accessors

When you enable the generation of a custom view row class, if you also select the **Accessors** checkbox, then JDeveloper generates getter and setter methods for each attribute in the view row. For example, for the `Persons` view object, the corresponding custom `PersonsRowImpl.java` class might have methods like this generated in it:

```
public Number getPersonId() {...}
public void setPersonId(Number value) {...}
public String getEmail() {...}
public void setEmail(String value) {...}
public String getFirstName() {...}
```

```
public void setFirstName(String value) {...}
public String getLastName() {...}
public void setLastName(String value) {...}
```

These methods allow you to work with the row data with compile-time checking of the correct datatype usage. That is, instead of writing a line like this one that gets the value of the `PersonId` attribute:

```
Number personId = (Number)row.getAttribute("PersonId");
```

you can write the code like:

```
Number personId = row.getPersonId();
```

You can see that with the latter approach, the Java compiler would catch a typographical error had you accidentally typed `PersonIdentifier` instead of `PersonId`:

```
// spelling name wrong gives compile error
Number personId = row.getPersonIdentifier();
```

*Without* the generated view row accessor methods, an incorrect line of code like the following cannot be caught by the compiler:

```
// Both attribute name and type cast are wrong, but compiler cannot catch it
String personId = (String)row.getAttribute("PersonIdentifier");
```

It contains both an incorrectly spelled attribute name, as well as an incorrectly-typed cast of the `getAttribute()` return value. Using the generic APIs on the `Row` interface, errors of this kind will raise exceptions at runtime instead of being caught at compile time.

### 39.3.1.3 Exposing View Row Accessors to Clients

When enabling the generation of a custom view row class, if you choose to generate the view row attribute accessor, you can also optionally select the **Expose Accessor to the Client** checkbox. This causes an additional custom row interface to be generated which application clients can use to access custom methods on the row without depending directly on the implementation class.

**Best Practice:** When you create client code for business components, you should use business service interfaces rather than concrete classes. Using the interface instead of the implementation class, ensures that client code does not need to change when your server-side implementation does. For more details working with client code, see in [Section 3.5.9, "Custom Interface Support for Client-Accessible Components."](#)

For example, in the case of the `Persons` view object, exposing the accessors to the client will generate a custom row interface named `PersonsRow`. This interface is created in the `common` subpackage of the package in which the view object resides. Having the row interface allows clients to write code that accesses the attributes of query results in a strongly typed manner. [Example 39-6](#) shows a `TestClient3` sample client program that casts the results of the `next()` method to the `PersonsRow` interface so that it can call accessors like `getPersonId()` and `getEmail()`.

#### **Example 39-6 Simple Example of Using Client Row Interface with Accessors**

```
package devguide.examples.readonlyvo.client;
```

```

import devguide.examples.readonlyvo.queries.common.PersonsRow;
import oracle.jbo.*;
import oracle.jbo.client.Configuration;
import oracle.jbo.domain.Number;

public class TestClient3 {
    public static void main(String[] args) {
        String amDef = "devguide.examples.PersonService";
        String config = "PersonServiceLocal";
        ApplicationModule am =
            Configuration.createRootApplicationModule(amDef, config);
        ViewObject vo = am.findViewObject("PersonList");
        vo.executeQuery();
        while (vo.hasNext()) {
            // Cast next() to a strongly-typed PersonsRow interface
            PersonsRow curPerson = (PersonsRow)vo.next();
            Number personId = curPerson.getPersonId();
            String email = curPerson.getEmail();
            System.out.println(personId+ " " + email);
        }
        Configuration.releaseRootApplicationModule(am, true);
    }
}

```

### 39.3.1.4 Configuring Default Java Generation Preferences

You've seen how to generate custom Java classes for your view objects when you need to customize their runtime behavior, or if you simply prefer to have strongly typed access to bind variables or view row attributes.

To change the default settings that control how JDeveloper generates Java classes, choose **Tools | Preferences** and open the **Business Components** page. The settings you choose will apply to all future business components you create.

Oracle recommends that developers getting started with ADF Business Components set their preference to generate no custom Java classes by default. As you run into specific needs, you can enable just the bit of custom Java you need for that one component. Over time, you'll discover which set of defaults works best for you.

## 39.3.2 What Happens When You Generate Custom Classes

When you choose to generate one or more custom Java classes, JDeveloper creates the Java file(s) you've indicated.

For example, in the case of a view object named `devguide.examples.Persons`, the default names for its custom Java files will be `PersonsImpl.java` for the view object class and `PersonsRowImpl.java` for the view row class. Both files get created in the same `./devguide/examples` directory as the component's XML component definition file.

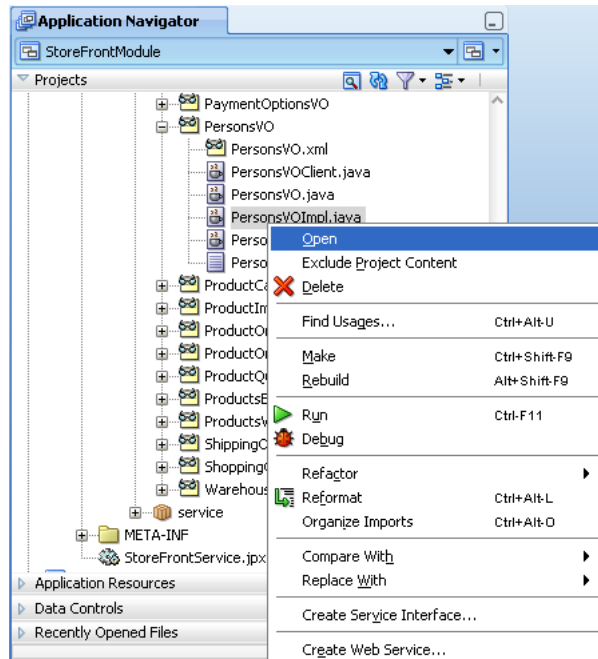

The Java generation options for the view object continue to be reflected on the Java page on subsequent visits to the view object overview editor. Just as with the XML definition file, JDeveloper keeps the generated code in your custom Java classes up to date with any changes you make in the editor. If later you decide you didn't require a custom Java file for any reason, unchecking the relevant options in the Java page causes the custom Java files to be removed.

### 39.3.2.1 Seeing and Navigating to Custom Java Files

As shown in [Figure 39–7](#), when you've enabled generation of custom Java classes, they also appear under the node for the view object. When you need to see or work with the source code for a custom Java file, there are two ways to open the file in the source editor:

- Choose **Open** in the context menu as shown in [Figure 39–7](#)
- With the Java file node selected in the Application Navigator, double-click a node in the Structure window

**Figure 39–7** Seeing and Navigating to Custom Java Classes for a View Object

## 39.3.3 What You May Need to Know About Custom Classes

This section provides additional information to help you use custom Java classes.

### 39.3.3.1 About the Framework Base Classes for a View Object

When you use an "XML-only" view object, at runtime its functionality is provided by the default ADF Business Components implementation classes. Each custom Java class that gets generated will automatically extend the appropriate ADF Business Components base class so that your code inherits the default behavior and can easily add or customize it. A view object class will extend `ViewObjectImpl`, while the view row class will extend `ViewRowImpl` (both in the `oracle.jbo.server` package).

### 39.3.3.2 You Can Safely Add Code to the Custom Component File

Based perhaps on previous negative experiences, some developers are hesitant to add their own code to generated Java source files. Each custom Java source code file that JDeveloper creates and maintains for you includes the following comment at the top of the file to clarify that it is safe to add your own custom code to this file:

```
// -----
// --- File generated by Oracle ADF Business Components Design Time.
// --- Custom code may be added to this class.
```

```
// --- Warning: Do not modify method signatures of generated methods.
// -----
```

JDeveloper does not blindly regenerate the file when you click the **OK** or **Apply** button in the component dialogs. Instead, it performs a smart update to the methods that it needs to maintain, leaving your own custom code intact.

### 39.3.3.3 Attribute Indexes and InvokeAccessor Generated Code

The view object is designed to function either in an XML-only mode or using a combination of an XML component definition and a custom Java class. Since attribute values are not stored in private member fields of a view row class, such a class is not present in the XML-only situation. Instead, in addition to a name, attributes are also assigned a numerical index in the view object's XML component definition, on a zero-based, sequential order of the `<ViewAttribute>` and association-related `<ViewLinkAccessor>` tags in that file. At runtime, the attribute values in an view row are stored in a structure that is managed by the base `ViewRowImpl` class, indexed by the attribute's numerical position in the view object's attribute list.

For the most part this private implementation detail is unimportant. However, when you enable a custom Java class for your view row, this implementation detail is related to some of the generated code that JDeveloper automatically maintains in your view row class, and you may want to understand what that code is used for. For example, in the custom Java class for the `Users` view row, [Example 39-7](#) shows that each attribute or view link accessor attribute has a corresponding generated integer constant. JDeveloper ensures that the values of these constants correctly reflect the ordering of the attributes in the XML component definition.

#### **Example 39-7 Attribute Constants Are Automatically Maintained in the Custom View Row Java Class**

```
public class PersonsRowImpl extends ViewRowImpl implements PersonsRow {
    public static final int PERSONID = 0;
    public static final int EMAIL = 1;
    public static final int FIRSTNAME = 2;
    public static final int LASTNAME = 3;
    public static final int PERSONTYPECODE = 4;
    public static final int PRIMARYADDRESSID = 5;
    // etc.
```

You'll also notice that the automatically maintained, strongly typed getter and setter methods in the view row class use these attribute constants like this:

```
// In devguide.examples.PersonsRowImpl class
public String getEmail() {
    return (String) getAttributeInternal(EMAIL); // <-- Attribute constant
}
public void setEmail(String value) {
    setAttributeInternal(EMAIL, value); // <-- Attribute constant
}
```

The last two aspects of the automatically maintained code related to view row attribute constants are the `getAttrInvokeAccessor()` and `setAttrInvokeAccessor()` methods. These methods optimize the performance of attribute access by numerical index, which is how generic code in the `ViewRowImpl` base class typically accesses attribute values. An example of the `getAttrInvokeAccessor()` method looks like the following from the `PersonsRowImpl.java` class. The companion `setAttrInvokeAccessor()` method looks similar.

```
// In devguide.examples.PersonsRowImpl class
protected Object getAttrInvokeAccessor(int index,AttributeDefImpl attrDef)
throws Exception {
    switch (index) {
        case PERSONID:           return getPersonId();
        case EMAIL:              return getEmail();
        case FIRSTNAME:         return getFirstName();
        case LASTNAME:          return getLastName();
        case PERSONTYPECODE:    return getPersonTypeCode();
        case PRIMARYADDRESSID:  return getPrimaryAddressId();
        default:
            return super.getAttrInvokeAccessor(index, attrDef);
    }
}
```

The rules of thumb to remember about this generated attribute-index related code are the following.

#### The Do's

- Add custom code if needed inside the strongly typed attribute getter and setter methods
- Use the view object overview editor to change the order or type of view object attributes

JDeveloper will change the Java signature of getter and setter methods, as well as the related XML component definition for you.

#### The Don'ts

- Don't modify the `getAttrInvokeAccessor()` and `setAttrInvokeAccessor()` methods
- Don't change the values of the attribute index numbers by hand

---

**Note:** If you need to manually edit the generated attribute constants, perhaps due to source control merge conflicts, you must ensure that the zero-based ordering reflects the sequential ordering of the `<ViewAttribute>` and `<ViewLinkAccessor>` tags in the corresponding view object XML component definition.

---

### 39.3.3.4 Avoid Creating Dependencies on Parent Application Module Types

Custom methods that you implement in the view object class or view object row class must not be dependent on the return type of an application module. At runtime, in specific cases, methods that execute with such a dependency may throw a `ClassCastException` because the returned application module does not match the expected type. It is therefore recommended that custom methods that you implement should not have code to get a specific application module implementation or view object implementation as shown below.

```
((MyAM) getRootApplicationModule()).getMyVO
```

Specifically, the above code fails with a `ClassCastException` in the following scenarios:

- When the ADF Business Components framework instantiates the view object in a different container application module than its defining container. While view objects are typically instantiated in the container application module that declares their view usage (XML definition), the ADF Business Components runtime does

not guarantee that the containers associated with each application module will remain fixed. Thus, if you implement methods with dependencies on the parent application module type, your methods may not execute consistently.

- When you manually nest an application module under a root application module. In this case, the nested application modules share the same `Transaction` object and there is no guarantee that the expected application module type is returned with the above code.
- When the ADF Business Components framework implementation changes with releases. For example, in previous releases, the framework created an internal root application module in order to control declarative transactions that the application defined using ADF task flows.

## 39.4 Working Programmatically with Multiple Named View Criteria

You can define *multiple* named view criteria in the overview editor for a view object and then selectively apply any combination of them to your view object at runtime as needed. For information about working with named view criteria at design time, see [Section 5.11.1, "How to Create Named View Criteria Declaratively."](#)

---

**Note:** The example in this section refers to the `MultipleViewCriteria` project in the `AdvancedViewObjectsExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

### 39.4.1 Applying One or More Named View Criteria

To apply one or more named view criteria, use the `setApplyViewCriteriaNames()` method. This method accepts a `String` array of the names of the criteria you want to apply. If you apply more than one named criteria, they are AND-ed together in the WHERE clause produced at runtime. New view criteria that you apply with the `setApplyViewCriteriaNames()` method will overwrite all previously applied view criteria. Alternatively, you can use the `setApplyViewCriteriaName()` method when you want to append a single view criteria to those that were previously applied.

When you need to apply more than one named view criteria, you can expose custom methods on the client interface of the view object to encapsulate applying combinations of the named view criteria. For example, [Example 39–8](#) shows custom methods `showMaleCustomers()`, `showFemaleStaff()`, and `showFemaleCustomers()`, each of which uses the `setApplyViewCriteriaNames()` method to apply an appropriate combination of named view criteria. Once these methods are exposed on the view object's client interface, at runtime clients can invoke these methods as needed to change the information displayed by the view object.

#### **Example 39–8 Exposing Client Methods to Enable Appropriate Named Criterias**

```
// In PersonsViewImpl.java
public void showMaleCustomers() {
    ViewCriteriaManager vcm = getViewCriteriaManager();
    ViewCriteria vc_gender = vcm.getViewCriteria("GenderIsNotFCriteria");
    ViewCriteria vc_type = vcm.getViewCriteria("IsCustomerCriteria");
    VariableValueManager vvm_gender = vc_gender.ensureVariableManager();
    VariableValueManager vvm_type = vc_type.ensureVariableManager();
```

```

        vvm_gender.setVariableValue("bv_Gender", "F");
        vvm_type.setVariableValue("bv_PersonTypeCode", "CUST");
        setApplyViewCriteriaNames(new String[]{"GenderIsNotFCriteria",
                                                "IsCustomerCriteria"});
    }

    public void showFemaleStaff() {
        ViewCriteriaManager vcm = getViewCriteriaManager();
        ViewCriteria vc_gender = vcm.getViewCriteria("GenderIsFCriteria");
        ViewCriteria vc_type = vcm.getViewCriteria("IsStaffSupplierCriteria");
        VariableValueManager vvm_gender = vc_gender.ensureVariableManager();
        VariableValueManager vvm_type = vc_type.ensureVariableManager();
        vvm_gender.setVariableValue("bv_Gender", "F");
        vvm_type.setVariableValue("bv_PersonTypeCode", "CUST");
        setApplyViewCriteriaNames(new String[]{"GenderIsFCriteria",
                                                "IsStaffSupplierCriteria"});

        executeQuery();
    }

    public void showFemaleCustomers() {
        ViewCriteriaManager vcm = getViewCriteriaManager();
        ViewCriteria vc_gender = vcm.getViewCriteria("GenderIsFCriteria");
        ViewCriteria vc_type = vcm.getViewCriteria("IsCustomerCriteria");
        VariableValueManager vvm_gender = vc_gender.ensureVariableManager();
        VariableValueManager vvm_type = vc_type.ensureVariableManager();
        vvm_gender.setVariableValue("bv_Gender", "F");
        vvm_type.setVariableValue("bv_PersonTypeCode", "CUST");
        setApplyViewCriteriaNames(new String[]{"GenderIsFCriteria",
                                                "IsCustomerCriteria"});

        executeQuery();
    }

```

### 39.4.2 Removing All Applied Named View Criteria

To remove any currently applied named view criteria, use `setApplyViewCriteriaNames(null)`. For example, you could add the `showAll()` method in [Example 39-9](#) to the `Users` view object and expose it on the client interface. This would allow clients to return to an unfiltered view of the data when needed.

Do not remove any design time view criteria because the row level bind variable values may already be applied on the row set. To help ensure this, named view criteria that get defined for a view accessor in the design time, will be applied as "required" view criteria on the view object instance so that it does not get removed by the view criteria's life cycle methods.

#### **Example 39-9 Removing All Applied Named View Criteria**

```

// In UsersImpl.java
public void showAll() {
    setApplyViewCriteriaNames(null);
    executeQuery();
}

```

---

---

**Note:** The `setApplyViewCriteriaas(null)` removes all applied view criteria, but allows you to later reapply any combination of them. In contrast, the `clearViewCriteriaas()` method *deletes* all named view criteria. After calling `clearViewCriteriaas()` you would have to use `putViewCriteriaas()` again to define new named criteria before you could apply them.

---

---

### 39.4.3 Using the Named Criteria at Runtime

At runtime, your application can invoke different client methods on a single view object interface to return different filtered sets of data. [Example 39–10](#) shows the interesting lines of a `TestClient` class that works with the `Persons` view object described above. The `showResults()` method is a helper method that iterates over the rows in the view object to display some attributes.

**Example 39–10 Test Client Code Working with Named View Criteria**

```
// In TestClientMultipleViewCriteriaas.java
PersonsView vo = (PersonsView)am.findViewObject("PersonsView");
vo.showMaleCustomers();
showResults(vo,"After applying view criterias for male customers");
vo.applyViewCriteriaas(null);
vo.showFemaleStaff();
showResults(vo,"After applying view criterias for female staff");
vo.showFemaleCustomers();
showResults(vo,"After applying view criterias for female customers");
vo.showAll();
vo.showResults(vo,"After clearing all view criterias");
```

Running the `TestClient` program produces output as follows:

```
---After applying view criterias for male customers ---
Daniel Faviet [CUST, M]
John Chen [CUST, M]
Ismael Sciarra [CUST, M]
Jose Manuel Urman [CUST, M]
Luis Popp [CUST, M]
Den Raphaely [CUST, M]
Alexander Khoo [CUST, M]
Sigal Tobias [CUST, M]
Guy Himuro [CUST, M]
Matthew Weiss [CUST, M]
Adam Fripp [CUST, M]
Payam Kaufling [CUST, M]
Kevin Mourgos [CUST, M]
James Landry [CUST, M]
Steven Markle [CUST, M]
...
---After applying view criterias for female staff ---
Neena Kochhar [STAFF, F]
Valli Pataballa [STAFF, F]
Diana Lorentz [STAFF, F]
Terra Bralick [SUPP, F]
Rachel Berman [SUPP, F]
Claudia Benghiat [SUPP, F]
Sharon Hemant [SUPP, F]
Alison Chen [SUPP, F]
Alex Duckers [SUPP, F]
```

```

Katrina Han [SUPP, F]
---After applying view criterias for female customers ---
Nancy Greenberg [CUST, F]
Shelli Baida [CUST, F]
Karen Colmenares [CUST, F]
Shanta Vollman [CUST, F]
Julia Nayer [CUST, F]
Irene Mikkilineni [CUST, F]
Laura Bissot [CUST, F]
---After clearing all view criterias ---
Steven King [STAFF, M]
Neena Kochhar [STAFF, F]
Lex De Haan [STAFF, M]
Alexander Hunold [STAFF, M]
Bruce Ernst [STAFF, M]
David Austin [STAFF, M]
Valli Pataballa [STAFF, F]
Diana Lorentz [STAFF, F]
Nancy Greenberg [CUST, F]
...

```

## 39.5 Performing In-Memory Sorting and Filtering of Row Sets

By default a view object performs its query against the database to retrieve the rows in its resulting row set. However, you can also use view objects to perform in-memory searches and sorting to avoid unnecessary trips to the database.

---

---

**Note:** The example in this section refers to the InMemoryOperations project in the AdvancedViewObjectsExamples application workspace in the StandaloneExamples module of the Fusion Order Demo application.

---

---

### 39.5.1 Understanding the View Object's SQL Mode

The view object's SQL mode controls the source used to retrieve rows to populate its row set. The `setQueryMode()` allows you to control which mode, or combination of modes, are used:

- `ViewObject.QUERY_MODE_SCAN_DATABASE_TABLES`  
This is the default mode that retrieves results from the database.
- `ViewObject.QUERY_MODE_SCAN_VIEW_ROWS`  
This mode uses rows already in the row set as the source, allowing you to progressively refine the row set's contents through in-memory filtering.
- `ViewObject.QUERY_MODE_SCAN_ENTITY_ROWS`  
This mode, valid only for entity-based view objects, uses the entity rows presently in the entity cache as the source to produce results based on the contents of the cache.

You can use the modes individually, or combine them using Java's logical OR operator ( $X \mid Y$ ). For example, to create a view object that queries the entity cache for unposted new entity rows, as well as the database for existing rows, you could write code like:

```
setQueryMode(ViewObject.QUERY_MODE_SCAN_DATABASE_TABLES |
             ViewObject.QUERY_MODE_SCAN_ENTITY_ROWS)
```

If you combine the SQL modes, the view object automatically handles skipping of duplicate rows. In addition, there is an implied order to the results that are found:

1. Scan view rows (if specified)
2. Scan entity cache (if specified)
3. Scan database tables (if specified) by issuing a SQL query

If you call the `setQueryMode()` method to change the SQL mode, your new setting takes effect the next time you call the `executeQuery()` method.

## 39.5.2 Sorting View Object Rows In Memory

To sort the rows in a view object at runtime, you can use the `setSortBy()` method to control the sort order or you can set the view object property `PROP_ALWAYS_USE_SORT` to `true` to allow the system to handle in-memory sorting by default.

When you want to control the sort order, you pass a sort expression that looks like a SQL `ORDER BY` clause. However, instead of referencing the column names of the table, you use the view object's attribute names. For example, for a view object containing attributes named `Customer` and `DaysOpen`, you could sort the view object first by `Customer` descending, then by `DaysOpen` by calling:

```
setSortBy("Customer desc, DaysOpen");
```

Alternatively, you can use the *zero-based* attribute index position in the sorting clause like this:

```
setSortBy("3 desc, 2");
```

After calling the `setSortBy()` method, the rows will be sorted the next time you call the `executeQuery()` method. The view object translates this sorting clause into an appropriate format to use for ordering the rows depending on the SQL mode of the view object. If you use the default SQL mode, the `SortBy` clause is translated into an appropriate `ORDER BY` clause and used as part of the SQL statement sent to the database. If you use either of the in-memory SQL modes, then the `SortBy` clause is translated into one or more `SortCriteria` objects for use in performing the in-memory sort.

---

---

**Note:** While SQL `ORDER BY` expressions treat column names in a case-insensitive way, the attribute names in a `SortBy` expression are *case-sensitive*.

---

---

### 39.5.2.1 Combining `setSortBy` and `setQueryMode` for In-Memory Sorting

You can perform an in-memory sort on the rows produced by a read-only view object using the `setSortBy()` and `setQueryMode()` methods. [Example 39-11](#) shows the interesting lines of code from the `TestClientSetSortBy` class that uses `setSortBy()` and `setQueryMode()` to perform an in-memory sort on the rows produced by a read-only view object `ClosedOrders`.

#### **Example 39-11 Combining `setSortBy` and `setQueryMode` for In-Memory Sorting**

```
// In TestClientSetSortBy.java
am.getTransaction().executeCommand("ALTER SESSION SET SQL_TRACE TRUE");
```

```

ViewObject vo = am.findViewObject("ClosedOrders");
vo.executeQuery();
showRows(vo,"Initial database results");
vo.setSortBy("Customer desc");
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_VIEW_ROWS);
vo.executeQuery();
showRows(vo,"After in-memory sorting by Customer desc");
vo.setSortBy("Customer desc, DaysOpen");
vo.executeQuery();
showRows(vo,"After in-memory sorting by Customer desc, DaysOpen");

```

Running the example produces the results:

```

--- Initial database results ---
106,Ice machine not working,1,mhartste
103,Washing machine leaks,4,ngreenbe
105,Air in dryer not hot,4,jmurman
109,Freezer is not cold,4,jwhalen
:
--- After in-memory sorting by Customer desc ---
100,I have noticed that every time I do a...,9,dfaviet
101,Agitator does not work,8,sbaida
103,Washing machine leaks,4,ngreenbe
105,Air in dryer not hot,4,jmurman
:
--- After in-memory sorting by Customer desc, DaysOpen ---
100,I have noticed that every time I do a...,9,dfaviet
101,Agitator does not work,8,sbaida
105,Air in dryer not hot,4,jmurman
109,Freezer is not cold,4,jwhalen
:

```

The first line in [Example 39-11](#) containing the `executeCommand()` call issues the `ALTER SESSION SET SQL TRACE` command to enable SQL tracing for the current database session. This causes the Oracle database to log every SQL statement performed to a server-side trace file. It records information about the text of each SQL statement, including how many times the database parsed the statement and how many round-trips the client made to fetch batches of rows while retrieving the query result.

---

---

**Note:** You might need a DBA to grant permission to the FOD account to perform the `ALTER SESSION` command to do the tracing of SQL output.

---

---

Once you've produced a trace file, you can use the `TKPROF` utility that comes with the database to format the file:

```
tkprof xe_ora_3916.trc trace.prf
```

For details about working with the `TKPROF` utility, see sections "Understanding SQL Trace and `TKPROF`" and "Using the SQL Trace Facility and `TKPROF`" in the *Oracle Database Performance Tuning Guide*.

This will produce a `trace.prf` file containing the interesting information shown in [Example 39-12](#) about the SQL statement performed by the `ClosedOrders` view object. You can see that after initially querying six rows of data in a single `execute` and fetch from the database, the two subsequent sorts of those results did not cause any further executions. Since the code set the SQL mode to `ViewObject.QUERY_MODE_`

SCAN\_VIEW\_ROWS the `setSortBy()` followed by the `executeQuery()` performed the sort in memory.

### Example 39–12 TKPROF Output of a Trace File Confirming Sort Was Done In Memory

```
*****
SELECT * FROM (select o.order_id,
    case
      when length(o.giftwrap_message) > 5 then
        rtrim(substr(o.giftwrap_message,1,5))||'...'
      else o.giftwrap_message
    end as giftwrap_message,
    ceil(
      (select trunc(max(creation_date))
        from order_histories
        where order_id = or.order_id)
      - trunc(o.order_date)
    ) as days_open,
    p.email as customer
from orders o, persons p
 where o.customer_id = p.person_id
   and order status code = 'COMPLETE')

call      count      cpu  elapsed disk  query  current    rows
-----  -
Parse          1     0.00    0.00   0      0         0         0
Execute        1     0.00    0.00   0      0         0         0
Fetch          1     0.00    0.00   0     22         0         6
-----  -
total          3     0.00    0.00   0     22         0         6
*****
```

#### 39.5.2.2 Simplified In-Memory Sorting

Should you not require control over the way that rows are sorted in memory, the view object interface provides the `PROP_ALWAYS_USE_SORT` field that enforces sorting when you change the view object query mode to use in-memory rows as the source. Set the view object property to specify default in-memory sorting after you set the query mode:

```
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_ENTITY_ROWS);
vo.setProperty(ViewObject.PROP_ALWAYS_USE_SORT, "true");
```

#### 39.5.2.3 Extensibility Points for In-Memory Sorting

Should you need to customize the way that rows are sorted in memory, you have the following two means at your disposal:

1. You can override the method:

```
public void sortRows(Row[] rows)
```

This method performs the actual in-memory sorting of rows. By overriding this method you can plug in an alternative sorting approach if needed.

2. You can override the method:

```
public Comparator getRowComparator()
```

The default implementation of this method returns an `oracle.jbo.RowComparator`. `RowComparator` invokes the `compareTo()`

method to compare two data values. These methods/objects can be overridden to provide custom compare routines.

### 39.5.3 Performing In-Memory Filtering with View Criteria

To filter the contents of a row set using `ViewCriteria`, you can call:

- `applyViewCriteria()` or `setApplyViewCriteriaNames()` followed by `executeQuery()` to produce a new, filtered row set.
- `findByViewCriteria()` to retrieve a new row set to process programmatically without changing the contents of the original row set.

Both of these approaches can be used against the database or to perform in-memory filtering, or both, depending on the view criteria mode. You set the criteria mode using the `setCriteriaMode()` method on the `ViewCriteria` object, to which you can pass either of the following integer flags, or the logical OR of both:

- `ViewCriteria.CRITERIA_MODE_QUERY`
- `ViewCriteria.CRITERIA_MODE_CACHE`

When used for in-memory filtering with view criteria, the operators supported are shown in [Table 39–1](#). You can group subexpressions with parenthesis and use the AND and OR operators between subexpressions.

**Table 39–1 SQL Operators Supported By In-Memory Filtering with View Criteria**

Operator	Operation
<code>=, &gt;, &lt;, &lt;=, &gt;=, &lt;&gt;, LIKE, BETWEEN, IN</code>	Comparison
<code>NOT</code>	Logical negation
<code>AND</code>	Conjunction
<code>OR</code>	Disjunction

[Example 39–13](#) shows the interesting lines from a `TestClientFindByViewCriteria` class that uses the two features described above both against the database and in-memory. It uses a `CustomerList` view object instance and performs the following basic steps:

1. Queries customers from the database with a last name starting with a 'C', producing the output:
 

```
--- Initial database results with applied view criteria ---
John Chen
Emerson Clabe
Karen Colmenares
```
2. Subsets the results from step 1 in memory to only those with a first name starting with 'J'. It does this by adding a second view criteria row to the view criteria and setting the conjunction to use "AND". This produces the output:
 

```
--- After augmenting view criteria and applying in-memory ---
John Chen
```
3. Sets the conjunction back to OR and re-applies the criteria to the database to query customers with last name like 'J%' or first name like 'C%'. This produces the output:
 

```
--- After changing view criteria and applying to database again ---
John Chen
```

```

Jose Manuel Urman
Emerson Clabe
Karen Colmenares
Jennifer Whalen

```

4. Defines a new criteria to find customers in-memory with first or last name that contain a letter 'o'
5. Uses `findByViewCriteria()` to produce new row set instead of subsetting, producing the output:

```

--- Rows returned from in-memory findByViewCriteria ---
John Chen
Jose Manuel Urman
Emerson Clabe
Karen Colmenares

```

6. Shows that original row set hasn't changed when `findByViewCriteria()` was used, producing the output:

```

--- Note findByViewCriteria didn't change rows in the view ---
John Chen
Jose Manuel Urman
Emerson Clabe
Karen Colmenares
Jennifer Whalen

```

### **Example 39–13 Performing Database and In-Memory Filtering with View Criteria**

```

// In TestClientFindByViewCriteria.java
ViewObject vo = am.findViewObject("CustomerList");
// 1. Show customers with a last name starting with a 'M'
ViewCriteria vc = vo.createViewCriteria();
ViewCriteriaRow vcr1 = vc.createViewCriteriaRow();
vcr1.setAttribute("LastName", "LIKE 'M%'");
vo.applyViewCriteria(vc);
vo.executeQuery();
vc.add(vcr1);
vo.executeQuery();
showRows(vo, "Initial database results with applied view criteria");
// 2. Subset results in memory to those with first name starting with 'S'
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_VIEW_ROWS);
ViewCriteriaRow vcr2 = vc.createViewCriteriaRow();
vcr2.setAttribute("FirstName", "LIKE 'S%'");
vcr2.setConjunction(ViewCriteriaRow.VCROW_CONJ_AND);
vc.setCriteriaMode(ViewCriteria.CRITERIA_MODE_CACHE);
vc.add(vcr2);
vo.executeQuery();
showRows(vo, "After augmenting view criteria and applying in-memory");
// 3. Set conjunction back to OR and re-apply to database query to find
// customers with last name like 'H%' or first name like 'S%'
vc.setCriteriaMode(ViewCriteria.CRITERIA_MODE_QUERY);
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_DATABASE_TABLES);
vcr2.setConjunction(ViewCriteriaRow.VCROW_CONJ_OR);
vo.executeQuery();
showRows(vo, "After changing view criteria and applying to database again");
// 4. Define new criteria to find customers with first or last name like '%o%'
ViewCriteria nameContainsO = vo.createViewCriteria();
ViewCriteriaRow lastContainsO = nameContainsO.createViewCriteriaRow();
lastContainsO.setAttribute("LastName", "LIKE '%o%'");
ViewCriteriaRow firstContainsO = nameContainsO.createViewCriteriaRow();

```

```

firstContains0.setAttribute("FirstName", "LIKE '%o%'");
nameContains0.add(firstContains0);
nameContains0.add(lastContains0);
// 5. Use findByViewCriteria() to produce new rowset instead of subsetting
nameContains0.setCriteriaMode(ViewCriteria.CRITERIA_MODE_CACHE);
RowSet rs = (RowSet)vo.findByViewCriteria(nameContains0,
                                         -1,ViewObject.QUERY_MODE_SCAN_VIEW_ROWS);
showRows(rs,"Rows returned from in-memory findByViewCriteria");
// 6. Show that original rowset hasn't changed
showRows(vo,"Note findByViewCriteria didn't change rows in the view");

```

### 39.5.4 Performing In-Memory Filtering with RowMatch

The RowMatch object provides an even more convenient way to express in-memory filtering conditions. You create a RowMatch object by passing a query predicate expression to the constructor like this:

```

RowMatch rm =
    new RowMatch("LastName = 'Popp' or (FirstName like 'A%' and LastName like 'K%')")
;

```

As you do with the SortBy clause, you phrase the RowMatch expression in terms of the view object attribute names, using the supported operators shown in Table 39–2. You can group subexpressions with parenthesis and use the AND and OR operators between subexpressions.

**Table 39–2 SQL Operators Supported By In-Memory Filtering with RowMatch**

Operator	Operation
=, >, <, <=, >=, <>, LIKE, BETWEEN, IN	Comparison
NOT	Logical negation  Note that logical negation operations NOT IN are not supported by the RowMatch expression.  To negate the IN operator, use this construction instead (note the use of brackets): NOT (EmpID IN ( 'VP', 'PU' ))
AND	Conjunction
OR	Disjunction

You can also use a limited set of SQL functions in the RowMatch expression, as shown in Table 39–3.

**Table 39–3 SQL Functions Supported By In-Memory Filtering with RowMatch**

Operator	Operation
UPPER	Converts all letters in a string to uppercase.
TO_CHAR	Converts a number or date to a string.
TO_DATE	Converts a character string to a date format.
TO_TIMESTAMP	Converts a string to timestamp.

---

---

**Note:** While SQL query predicates treat column names in a case-insensitive way, the attribute names in a `RowMatch` expression are case-sensitive.

---

---

### 39.5.4.1 Applying a RowMatch to a View Object

To apply a `RowMatch` to your view object, call the `setRowMatch()` method. In contrast to a `ViewCriteria`, the `RowMatch` is only used for *in-memory* filtering, so there is no "match mode" to set. You can use a `RowMatch` on view objects in any supported SQL mode, and you will see the results of applying it the next time you call the `executeQuery()` method.

When you apply a `RowMatch` to a view object, the `RowMatch` expression can reference the view object's named bind variables using the same `:VarName` notation that you would use in a SQL statement. For example, if a view object had a named bind variable named `StatusCode`, you could apply a `RowMatch` to it with an expression like:

```
Status = :StatusCode or :StatusCode = '%'
```

[Example 39-14](#) shows the interesting lines of a `TestClientRowMatch` class that illustrate the `RowMatch` in action. The `CustomerList` view object used in the example has a transient `Boolean` attribute named `Selected`. The code performs the following basic steps:

1. Queries the full customer list, producing the output:

```
--- Initial database results ---
Neena Kochhar [null]
Lex De Haan [null]
Nancy Greenberg [null]
:
```

2. Marks odd-numbered rows selected by setting the `Selected` attribute of odd rows to `Boolean.TRUE`, producing the output:

```
--- After marking odd rows selected ---
Neena Kochhar [null]
Lex De Haan [true]
Nancy Greenberg [null]
Daniel Faviat [true]
John Chen [null]
Ismael Sciarra [true]
:
```

3. Uses a `RowMatch` to subset the row set to contain only the select rows, that is, those with `Selected = true`. This produces the output:

```
--- After in-memory filtering on only selected rows ---
Lex De Haan [true]
Daniel Faviat [true]
Ismael Sciarra [true]
Luis Popp [true]
:
```

4. Further subsets the row set using a more complicated `RowMatch` expression, producing the output:

```
--- After in-memory filtering with more complex expression ---
Lex De Haan [true]
```

```
Luis Popp [true]
```

#### **Example 39–14 Performing In-Memory Filtering with RowMatch**

```
// In TestClientRowMatch.java
// 1. Query the full customer list
ViewObject vo = am.findViewObject("CustomerList");
vo.executeQuery();
showRows(vo,"Initial database results");
// 2. Mark odd-numbered rows selected by setting Selected = Boolean.TRUE
markOddRowsAsSelected(vo);
showRows(vo,"After marking odd rows selected");
// 3. Use a RowMatch to subset row set to only those with Selected = true
RowMatch rm = new RowMatch("Selected = true");
vo.setRowMatch(rm);
// Note: Only need to set SQL mode when not defined at design time
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_VIEW_ROWS);
vo.executeQuery();
showRows(vo, "After in-memory filtering on only selected rows");
// 5. Further subset rowset using more complicated RowMatch expression
rm = new RowMatch("LastName = 'Popp' "+
    "or (FirstName like 'A%' and LastName like 'K%')");
vo.setRowMatch(rm);
vo.executeQuery();
showRows(vo,"After in-memory filtering with more complex expression");
// 5. Remove RowMatch, set query mode back to database, requery to see full list
vo.setRowMatch(null);
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_DATABASE_TABLES);
vo.executeQuery();
showRows(vo,"After re-querying to see a full list again");
```

#### **39.5.4.2 Using RowMatch to Test an Individual Row**

In addition to using a `RowMatch` to filter a row set, you can also use its `rowQualifies()` method to test whether any individual row matches the criteria it encapsulates. For example:

```
RowMatch rowMatch = new RowMatch("CountryId = 'US'");
if (rowMatch.rowQualifies(row)) {
    System.out.println("Customer is from the United States ");
}
```

#### **39.5.4.3 How a RowMatch Affects Rows Fetched from the Database**

Once you apply a `RowMatch`, if the view object's SQL mode is set to retrieve rows from the database, when you call `executeQuery()` the `RowMatch` is applied to rows as they are fetched. If a fetched row does not qualify, it is not added to the rowset.

Unlike a SQL `WHERE` clause, a `RowMatch` can evaluate expressions involving transient view object attributes and not-yet-posted attribute values. This can be useful to filter queried rows based on `RowMatch` expressions involving transient view row attributes whose values are calculated in Java. This interesting aspect should be used with care, however, if your application needs to process a large rowset. Oracle recommends using database-level filtering to retrieve the smallest-possible rowset first, and then using `RowMatch` as appropriate to subset that list in memory.

## **39.6 Using View Objects to Work with Multiple Row Types**

Sometimes you will create a view object to work with entity rows of a single type like `Supplier`, which perhaps includes `Supplier`-specific attributes. At other times you

may want to query and update rows based on an entity object inheritance hierarchy in the same row set. For example, in the same row set, you might work with attributes that are common to the inheritance hierarchy of *Persons*, *Supplier*, and *Staff* entity objects.

---

**Note:** To experiment with the example described in this section, use the same `InheritanceAndPolymorphicQueries` project in the `AdvancedEntityExamples` workspace used in [Section 38.7, "Using Inheritance in Your Business Domain Layer."](#)

---

### 39.6.1 Working with Polymorphic Entity Usages

A *polymorphic* entity usage is one that references a base entity object in an inheritance hierarchy and is configured to handle *subtypes* of that entity as well. [Figure 39–8](#) shows the results of using a view object with a polymorphic entity usage. The entity-based `PersonList` view object has the `Persons` entity object as its primary entity usage. The view object partitions each row retrieved from the database into an entity row with attributes specific to the various subtypes of `Persons`. It creates the appropriate entity row subtype based on consulting the value of the discriminator attribute. For example, if the `PersonList` query retrieves one row for customer `ngreenbe`, one row for staff `sking`, and one row for supplier `ahunold`, the underlying entity row parts would be as shown in the figure.

**Figure 39–8** View Object with a Polymorphic Entity Usage Handles Entity Subtypes

### 39.6.2 How To Create a View Object with a Polymorphic Entity Usage

The view object that you create with a polymorphic entity usage may inherit one or more of the attributes of the base entity object and the subtype entities. Attributes that you select from the entity objects will be overridden by the view object attribute definitions. When an entity-based view object references an entity object with a discriminator attribute, then `JDeveloper` enforces that the discriminator attribute is included in the query (in addition to the primary key attribute).

#### Before you begin:

Create the base entity object from which the polymorphic entity usages will inherit, as described in [Section 4.2.2, "How to Create Single Entity Objects Using the Create Entity Wizard."](#)

Extend the base entity object to create the polymorphic entity usages and specify the discriminator attribute upon which the entity row subtype will be based, as described in [Section 4.10.14, "How to Set the Discriminator Attribute for Entity Object Inheritance Hierarchies."](#)

Create an entity-based view object from the base entity object and select the attributes that are common to the subtype view objects that you will create for each polymorphic entity usage. The base view object will be used to create the subtype view objects. For details about creating an entity-based view object, see [Section 5.2.1, "How to Create an Entity-Based View Object."](#)

**To create a view object with a polymorphic entity usage:**

1. In the Application Navigator, under the user interface project, right-click your application and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **View Object**, and click **OK**.
3. In the Create View Object wizard, name the view object and next to the **Extends** field, click **Browse**.

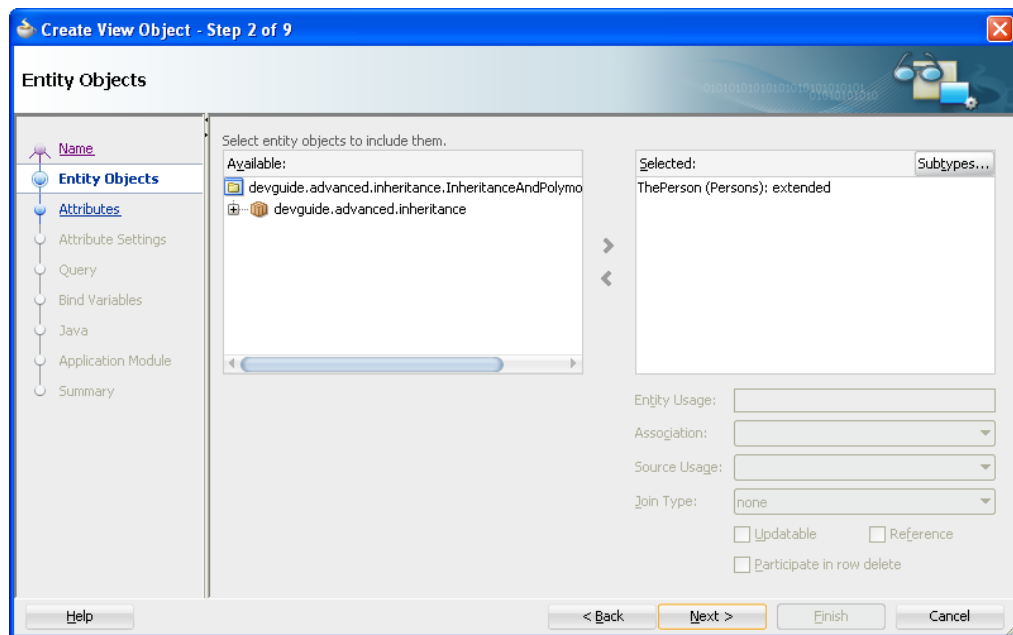

For example, the data model project might define a base `Persons` entity object in order to support the creation of view objects with polymorphic entity usages for the `Supplier` and `Staff` subtype entity objects. When you create the view object for each polymorphic entity usage, you might create one view object named `SupplierList` and another view object named `StaffList`.

4. In the Select Parent dialog, select the entity-based view object that you created from the base entity object and click **OK**.

For example, when you create the view object `PersonList` for the base entity object `Persons`, you would select `PersonList` as the view object to extend.

5. In the Create View Object wizard, click **Next** and note that the base entity object already appears in the **Selected** list and is labeled **Extended**, as shown in [Figure 39–9](#).

**Figure 39–9 View Object with a Base Entity Selection**

6. On the Entity Objects page of the Create View Object wizard, select the base entity object in the **Selected** list and click **Subtypes**.

- In the **Select Subtypes** dialog, shuttle the desired entity subtypes you want to allow from the **Available** to the **Selected** list, and click **OK**.

For example, for the `StaffList` view object you would select the entity subtype `Staff`, as shown in [Figure 39–10](#).

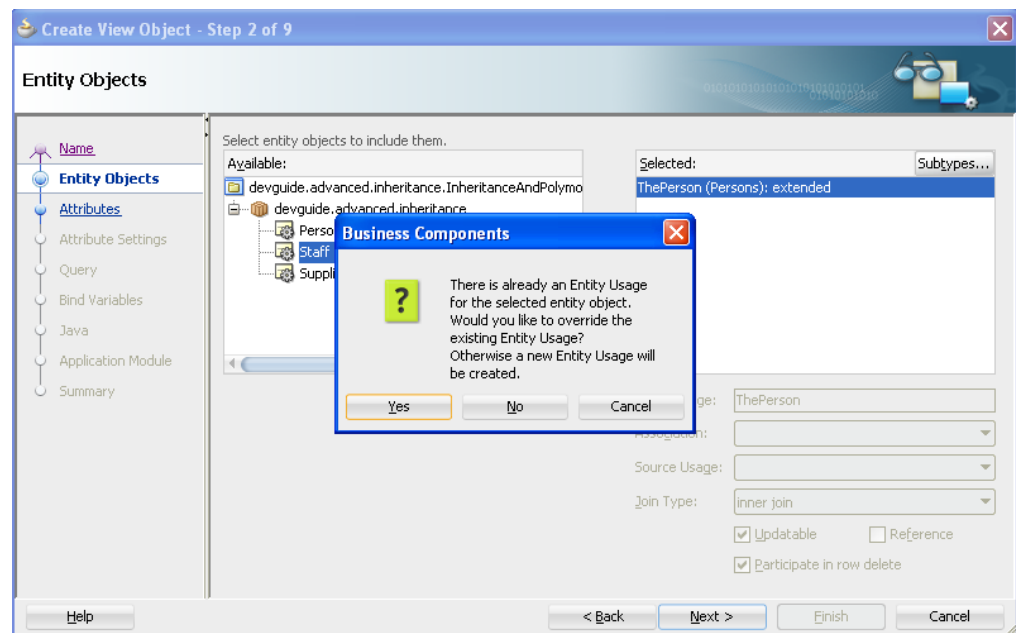

**Figure 39–10 View Object with a Entity Subtype Selection**

- In the Business Components dialog, click **OK** to override the entity usage for your view object.

The Business Components dialog warns you that you will override the attributes of the base entity usage with the entity subtype, as shown in [Figure 39–11](#).

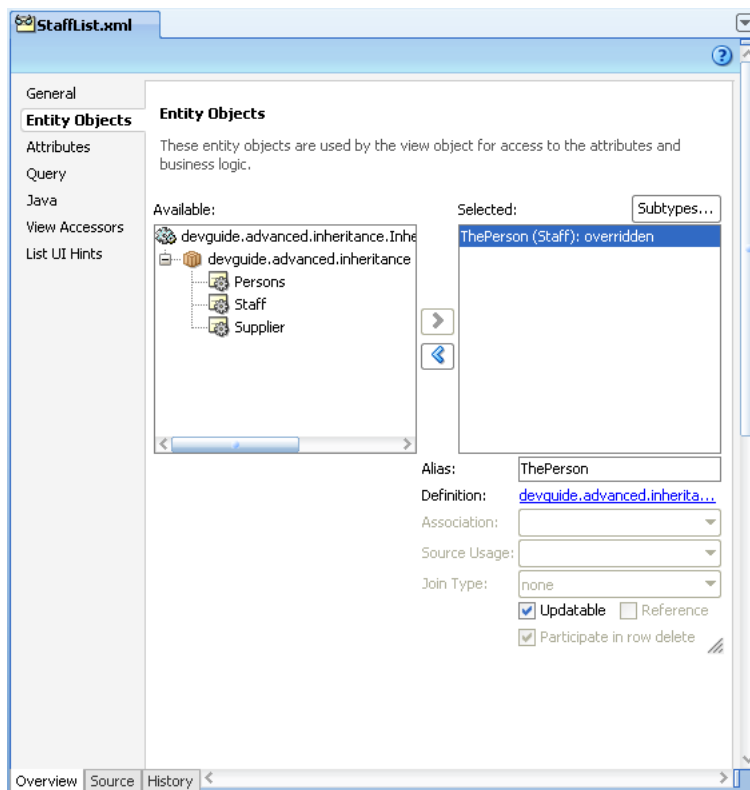

**Figure 39–11 View Object with a Polymorphic Entity Subtype Selection**

9. On the Entity Objects page of the Create View Object wizard, click **Next** and on the Attributes page of the wizard shuttle desired attributes from the base entity object to the **Selected** list.
10. Complete the wizard and click **Finish**.

The Entity Objects page of the overview editor identifies the selected entity object with the entity subtype override. For example, the overview editor for the `StaffList` view object identifies the overridden entity object `ThePerson (Staff): overridden` with the subtype in parenthesis, as shown in [Figure 39–12](#).

**Figure 39–12 View Object Editor Shows Entity Subtype is Overridden**

11. Repeat this procedure to create view objects for additional polymorphic entity usages that you created for the base entity object.

### 39.6.3 What Happens When You Create a View Object with a Polymorphic Entity Usage

When you create an entity-based view object with a polymorphic entity usage, JDeveloper adds information about the allowed entity subtypes to the view object's XML component definition. For example, when creating the `PersonList` view object above, the names of the allowed subtype entity objects are recorded in an `<AttrArray>` tag like this:

```
<ViewObject Name="PersonList" ... >
  <EntityUsage Name="ThePerson"
    Entity="devguide.advanced.inheritance.Persons" >
  </EntityUsage>
  ...
  <AttrArray Name="EntityImports">
    <Item Value="devguide.advanced.inheritance.Staff" />
  </AttrArray>
</ViewObject>
```

```

        <Item Value="devguide.advanced.inheritance.Supplier" />
    </AttrArray>
    <!-- etc. -->
</ViewObject>

```

## 39.6.4 What You May Need to Know About Entity Usages

This section provides additional information to help you work with polymorphic entity usages.

### 39.6.4.1 Your Query Must Limit Rows to Expected Entity Subtypes

If your view object expects to work with only a *subset* of the available entity subtypes in a hierarchy, you need to include an appropriate `WHERE` clause that limits the query to only return rows whose discriminator column matches the expected entity types.

### 39.6.4.2 Exposing Selected Entity Methods in View Rows Using Delegation

By design, clients do not work directly with entity objects. Instead, they work indirectly with entity objects through the view rows of an appropriate view object that presents a relevant set of information related to the task at hand. Just as a view object can expose a particular set of the underlying *attributes* of one or more entity objects related to the task at hand, it can also expose a selected set of *methods* from those entities. You accomplish this by enabling a custom view row Java class and writing a method in the view row class that:

- Accesses the appropriate underlying entity row using the generated entity accessor in the view row, and
- Invokes a method on it

For example, assume that the `Persons` entity object contains a `performPersonFeature()` method in its `PersonsImpl` class. To expose this method to clients on the `PersonsList` view row, you can enable a custom view row Java class and write the method shown in [Example 39-15](#). JDeveloper generates an entity accessor method in the view row class for each participating entity usage based on the entity usage *alias* name. Since the alias for the `Persons` entity in the `PersonsList` view object is "ThePerson", it generates a `getThePerson()` method to return the entity row part related to that entity usage.

#### **Example 39-15 Exposing Selected Entity Object Methods on View Rows Through Delegation**

```

// In PersonListRowImpl.java
public void performPersonFeature() {
    getThePerson().performPersonFeature();
}

```

The code in the view row's `performPersonFeature()` method uses this `getThePerson()` method to access the underlying `PersonImpl` entity row class and then invokes *its* `performPersonFeature()` method. This style of coding is known as *delegation*, where a view row method delegates the implementation of one of *its* methods to a corresponding method on an underlying entity object. When delegation is used in a view row with a polymorphic entity usage, the delegated method call is handled by appropriate underlying entity row subtype. This means that if the `PersonsImpl`, `StaffImpl`, and `SupplierImpl` classes implement the `performPersonFeature()` method in a different way, the appropriate implementation is used depending on the entity subtype for the current row.

After exposing this method on the client row interface, client programs can use the custom row interface to invoke custom business functionality on a particular view row. [Example 39–16](#) shows the interesting lines of code from a `TestEntityPolymorphism` class. It iterates over all the rows in the `PersonList` view object instance, casts each one to the custom `PersonListRow` interface, and invokes the `performPersonFeature()` method.

**Example 39–16 Invoking a View Row Method That Delegates to an Entity Object**

```
PersonList personlist = (PersonList)am.findViewObject("PersonList");
personlist.executeQuery();
while (personlist.hasNext()) {
    PersonListRow person = (PersonListRow)personlist.next();
    System.out.print(person.getEmail()+"->");
    person.performPersonFeature();
}
```

Running the client code in [Example 39–16](#) produces the following output:

```
austin->## performPersonFeature as Supplier
hbaer->## performPersonFeature as Person
:
sking->## performPersonFeature as Staff
:
```

Rows related to `Persons` entities display a message confirming that the `performPersonFeature()` method in the `PersonsImpl` class was used. Rows related to `Supplier` and `Staff` entities display a different message, highlighting the different implementations that the respective `SupplierImpl` and `StaffImpl` classes have for the inherited `performPersonFeature()` method.

### 39.6.4.3 Creating New Rows With the Desired Entity Subtype

In a view object with a polymorphic entity usage, when you create a new view row it contains a new entity row part whose type matches the base entity usage. To create a new view row with one of the entity *subtypes* instead, use the `createAndInitRow()` method. [Example 39–17](#) shows two custom methods in the `PersonList` view object's Java class that use `createAndInitRow()` to allow a client to create new rows having entity rows either of `Staff` or `Supplier` subtypes. To use the `createAndInitRow()`, as shown in the example, create an instance of the `NameValuePairs` object and set it to have an appropriate value for the discriminator attribute. Then, pass that `NameValuePairs` to the `createAndInitRow()` method to create a new view row with the appropriate entity row subtype, based on the value of the discriminator attribute you passed in.

**Example 39–17 Exposing Custom Methods to Create New Rows with Entity Subtypes**

```
// In PersonListImpl.java
public PersonListRow createStaffRow() {
    NameValuePairs nvp = new NameValuePairs();
    nvp.setAttribute("PersonTypeCode", "STAFF");
    return (PersonListRow)createAndInitRow(nvp);
}
public PersonListRow createSupplierRow() {
    NameValuePairs nvp = new NameValuePairs();
    nvp.setAttribute("PersonTypeCode", "SUPP");
    return (PersonListRow)createAndInitRow(nvp);
}
```

If you expose methods like this on the view object's custom interface, then at runtime, a client can call them to create new view rows with appropriate entity subtypes.

[Example 39–18](#) shows the interesting lines relevant to this functionality from a `TestEntityPolymorphism` class. First, it uses the `createRow()`, `createStaffRow()`, and `createSupplierRow()` methods to create three new view rows. Then, it invokes the `performPersonFeature()` method from the `PersonListRow` custom interface on each of the new rows.

As expected, each row handles the method in a way that is specific to the subtype of entity row related to it, producing the results:

```
## performPersonFeature as Person
## performPersonFeature as Staff
## performPersonFeature as Supplier
```

**Example 39–18 Creating New View Rows with Different Entity Subtypes**

```
// In TestEntityPolymorphism.java
PersonListRow newPerson = (PersonListRow)Personlist.createRow();
PersonListRow newStaff = Personlist.createStaffRow();
PersonListRow newSupplier = Personlist.createSupplierRow();
newPerson.performPersonFeature();
newStaff.performPersonFeature();
newSupplier.performPersonFeature();
```

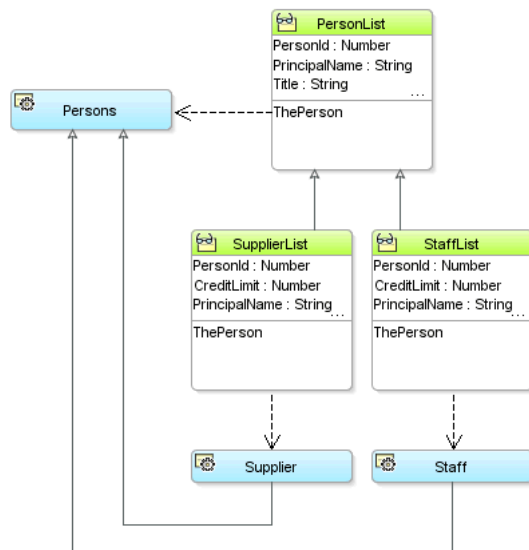

### 39.6.5 Working with Polymorphic View Rows

In the example shown in [Section 39.6, "Using View Objects to Work with Multiple Row Types,"](#) the polymorphism occurs "behind the scenes" at the entity object level. Since the client code works with all view rows using the same `PersonListRow` interface, it cannot distinguish between rows based on a `Staff` entity object from those based on a `Persons` entity object. The code works with all view rows using the same set of view row attributes and methods common to all types of underlying entity subtypes.

If you configure a view object to support polymorphic view rows, then the client can work with different types of view rows using a view row interface specific to the type of row it is. By doing this, the client can access view attributes or invoke view row methods that are specific to a given subtype as needed. [Figure 39–13](#) illustrates the hierarchy of view objects that enables this feature for the `PersonList` example considered above. `SupplierList` and `StaffList` are view objects that extend the base `PersonList` view object. Notice that each one includes an additional attribute specific to the subtype of `Person` they have as their entity usage. `SupplierList` includes an additional `ContractExpires` attribute, while `StaffList` includes the additional `DiscountEligible` attribute. When configured for view row polymorphism as described in the next section, a client can work with the results of the `PersonList` view object using:

- `PersonListRow` interface for view rows related to persons
- `SupplierListRow` interface for view rows related to suppliers
- `StaffListRow` interface for view rows related to staff

As you'll see, this allows the client to access the additional attributes and view row methods that are specific to a given subtype of view row.

**Figure 39–13 Hierarchy of View Object Subtypes Enables View Row Polymorphism**

### 39.6.6 How to Create a View Object with Polymorphic View Rows

To create a view object with polymorphic view rows, follow these steps:

1. In the Application Navigator, double-click the view object that you want to be the base.

In the example above, the `PersonList` view object is the base.

2. In the overview editor, click the **Attributes** navigation tab and select a discriminator attribute for the view row, and click the **Edit selected attribute(s)** button.
3. In the Edit Attribute dialog, give the discriminator attribute a default value and check the **Discriminator** checkbox to mark the attribute as the one that distinguishes which view row interface to use.

You must supply a value for the **Value** field that matches the attribute value for which you expect the base view object's view row interface to be used. For example, in the `PersonList` view object, you would mark the `PersonTypeCode` attribute as the discriminator attribute and supply a default value of "person".

4. Enable a custom view row class for the base view object, and expose at least one method on the client row interface. This can be one or all of the view row attribute accessor methods, as well as any custom view row methods.
5. Create a new view object that *extends* the base view object

In the example above, `SupplierList` extends the base `PersonList` view object.

6. Enable a custom view row class for the extended view object.  
If appropriate, add additional custom view row methods or override custom view row methods inherited from the parent view object's row class.
7. Supply a *distinct* value for the discriminator attribute in the extended view object.  
The `SupplierList` view object provides the value of "SUPP" for the `PersonTypeCode` discriminator attribute.

8. Repeat steps 4-6 to add additional extended view objects as needed.

For example, the `StaffList` view object is a second one that extends `PersonList`. It supplies the value "STAFF" for the `PersonTypeCode` discriminator attribute.

After setting up the view object hierarchy, you need to define the list of view object subtypes that participate in the view row polymorphism. To accomplish this, do the following:

1. Add an instance of each type of view object in the hierarchy to the data model of an application module.

For example, the `PersonModule` application module in the example has instances of `PersonList`, `SupplierList`, and `StaffList` view objects.

2. In the overview editor for the application module, click the **Data Model** navigation tab and click the **Subtypes** button.
3. In the **Subtypes** dialog that appears, shuttle the desired view object subtypes that you want to participate in view row polymorphism from the **Available** to the **Selected** list, and click **OK**.

### 39.6.7 What You May Need to Know About Polymorphic View Rows

This section provides additional information to help you work with polymorphic view rows.

#### 39.6.7.1 Selecting Subtype-Specific Attributes in Extended View Objects

When you create an extended view object, it inherits the entity usage of its parent. If the parent view object's entity usage is based on an entity object with subtypes in your domain layer, you may want your extended view object to work with one of these subtypes instead of the inherited parent entity usage type. Two reasons you might want to do this are:

1. To select attributes that are *specific* to the entity subtype
2. To be able to write view row methods that delegate to methods *specific* to the entity subtype

In order to do this, you need to override the inherited entity usage to refer to the desired entity subtype. To do this, perform these steps in the overview editor for your extended view object:

1. In the Application Navigator, double-click the view object.
2. In the overview editor, click the **Entity Objects** navigation tab and verify that you are working with an extended entity usage.

For example, when creating the `SupplierList` view object that extends the `PersonList` view object, the entity usage with the alias `ThePerson` will initially display in the **Selected** list as: **ThePerson(Person): extended**. The type of the entity usage is in parenthesis, and the "extended" label confirms that the entity usage is currently inherited from its parent.

3. Select the desired entity *subtype* in the **Available** list that you want to override the inherited one. It must be a subtype entity of the existing entity usage's type.

For example, you would select the `Supplier` entity object in the **Available** list to override the inherited entity usage based on the `Persons` entity type.

4. Click > to shuttle it to the **Selected** list

5. Acknowledge the alert that appears, confirming that you want to override the existing, inherited entity usage.

When you have performed these steps, the **Selected** list updates to reflect the overridden entity usage. For example, for the `SupplierList` view object, after overriding the `Persons`-based entity usage with the `Supplier` entity subtype, it updates to show: **ThePerson (Supplier): overridden.**

After overriding the entity usage to be related to an entity subtype, you can then use the **Attributes** tab of the editor to select additional attributes that are specific to the subtype. For example, the `SupplierList` view object includes the additional attribute named `ContractExpires` that is specific to the `Supplier` entity object.

### 39.6.7.2 Delegating to Subtype-Specific Methods After Overriding the Entity Usage

After overriding the entity usage in an extended view object to reference a subtype entity, you can write view row methods that delegate to methods specific to the subtype entity class. [Example 39–19](#) shows the code for a `performSupplierFeature()` method in the custom view row class for the `SupplierList` view object. It casts the return value from the `getThePerson()` entity row accessor to the subtype `SupplierImpl`, and then invokes the `performSupplierFeature()` method that is specific to `Supplier` entity objects.

#### **Example 39–19 View Row Method Delegating to Method in Subtype Entity**

```
// In SupplierListRowImpl.java
public void performSupplierFeature() {
    SupplierImpl supplier = (SupplierImpl) getThePerson();
    supplier.performSupplierFeature();
}
```

---

---

**Note:** You need to perform the explicit cast to the entity subtype here because `JDeveloper` does not yet take advantage of the JDK feature called covariant return types that would allow a subclass like `SupplierListRowImpl` to override a method like `getThePerson()` and change its return type.

---

---

### 39.6.7.3 Working with Different View Row Interface Types in Client Code

[Example 39–20](#) shows the interesting lines of code from a `TestViewRowPolymorphism` class that performs the following steps:

1. Iterates over the rows in the `PersonList` view object.  
For each row in the loop, it uses Java's `instanceof` operator to test whether the current row is an instance of the `StaffListRow` or the `SupplierListRow`.
2. If the row is a `StaffListRow`, then cast it to this more specific type and:
  - Call the `performStaffFeature()` method specific to the `StaffListRow` interface, and
  - Access the value of the `DiscountEligible` attribute that is specific to the `StaffList` view object.
3. If the row is a `SupplierListRow`, then cast it to this more specific type and:
  - Call the `performSupplierFeature()` method specific to the `SupplierListRow` interface, and

- Access the value of the `ContractExpires` attribute that is specific to the `SupplierList` view object.

#### 4. Otherwise, just call a method on the `PersonListRow`

#### **Example 39–20 Using View Row Polymorphism in Client Code**

```
// In TestViewRowPolymorphism.java
ViewObject vo = am.findViewObject("PersonList");
vo.executeQuery();
// 1. Iterate over the rows in the PersonList view object
while (vo.hasNext()) {
    PersonListRow Person = (PersonListRow)vo.next();
    System.out.print(Person.getEmail()+"->");
    if (Person instanceof StaffListRow) {
        // 2. If the row is a StaffListRow, cast it
        StaffListRow mgr = (StaffListRow)Person;
        mgr.performStaffFeature();
        System.out.println("Discount Status: "+staff.getDiscountEligible());
    }
    else if (Person instanceof SupplierListRow) {
        // 3. If the row is a SupplierListRow, cast it
        SupplierListRow tech = (SupplierListRow)Person;
        supplier.performSupplierFeature();
        System.out.println("Contract expires: "+tech.getContractExpires());
    }
    else {
        // 4. Otherwise, just call a method on the PersonListRow
        Person.performPersonFeature();
    }
}
```

Running the code in [Example 39–20](#) produces the following output:

```
daustin->## performSupplierFeature called
Contract expires: 2006-05-09
hbaer->## performPersonFeature as Person
:
sking->## performStaffFeature called
Discount Status: Y
:
```

This illustrates that by using the view row polymorphism feature the client was able to distinguish between view rows of different types and access methods and attributes specific to each subtype of view row.

#### **39.6.7.4 Polymorphic Entity Usage and Polymorphic View Rows Usages**

You can work with either type of polymorphism, or you can combine the two.

While often even more useful when used *together*, the view row polymorphism and the polymorphic entity usage features are distinct and can be used separately. In particular, the view row polymorphism feature can be used for read-only view objects, as well as for entity-based view objects. When you combine both mechanisms, you can have both the entity row part being polymorphic, as well as the view row type.

Note to use view row polymorphism with either view objects or entity objects, you must configure the discriminator attribute property separately for each. This is necessary because read-only view objects contain no related entity usages from which to infer the discriminator information.

In summary, to use view row polymorphism:

1. Configure an attribute to be the discriminator at the view object level in the root view object in an inheritance hierarchy.
2. Have a hierarchy of inherited view objects each of which provides a distinct value for the "Default Value" property of that view object level discriminator attribute.
3. List the subclassed view objects in this hierarchy in the application module's list of Subtypes.

Whereas, to create a view object with a polymorphic entity usage:

1. Configure an attribute to be the discriminator at the entity object level in the root entity object in an inheritance hierarchy.
2. Have a hierarchy of inherited entity objects, each of which overrides and provides a distinct value for the "Default Value" property of that entity object level discriminator attribute.
3. List the subclassed entity objects in a view object's list of Subtypes.

## 39.7 Reading and Writing XML

The Extensible Markup Language (XML) standard from the Worldwide Web Consortium (W3C) defines a language-neutral approach for electronic data exchange. Its rigorous set of rules enables the structure inherent in data to be easily encoded and unambiguously interpreted using human-readable text documents.

View objects support the ability to write these XML documents based on their queried data. View objects also support the ability to read XML documents in order to apply changes to data including inserts, updates, and deletes. When you've introduced view links, this XML capability supports reading and writing multi-level nested information for master-detail hierarchies of any complexity. While the XML produced and consumed by view objects follows a canonical format, you can combine the view object's XML features with XML Stylesheet Language Transformations (XSLT) to easily convert between this canonical XML format and any format you need to work with.

---

---

**Note:** The example in this section refers to the `ReadingAndWritingXML` project in the `AdvancedViewObjectsExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

### 39.7.1 How to Produce XML for Queried Data

To produce XML from a view object, use the `writeXML()` method. It offers two ways to control the XML produced:

1. For precise control over the XML produced, you can specify a view object attribute map indicating which attributes should appear, including which view link accessor attributes should be accessed for nested, detail information:

```
Node writeXML(long options, HashMap voAttrMap)
```

2. To producing XML that includes all attributes, you can simply specify a depth-level that indicates how many levels of view link accessor attributes should be traversed to produce the result:

```
Node writeXML(int depthCount, long options)
```

The `options` parameter is a integer flag field that can be set to one of the following bit flags:

- `XMLInterface.XML_OPT_ALL_ROWS`  
Includes all rows in the view object's row set in the XML.
- `XMLInterface.XML_OPT_LIMIT_RANGE`  
Includes only the rows in the current range in the XML.

Using the logical OR operation, you can combine either of the above flags with the `XMLInterface.XML_OPT_ASSOC_CONSISTENT` flag when you want to include new, unposted rows in the current transaction in the XML output.

Both versions of the `writeXML()` method accept an optional third argument which is an XSLT stylesheet that, if supplied, is used to transform the XML output before returning it.

## 39.7.2 What Happens When You Produce XML

When you produce XML using `writeXML()`, the view object begins by creating a wrapping XML element whose default name matches the name of the view object definition. For example, for a `Persons` view object in the `devguide.advanced.xml.queries` package, the XML produces will be wrapped in an outermost `<Persons>` tag.

Then, it converts the attribute data for the appropriate rows into XML elements. By default, each row's data is wrapped in an row element whose name is the name of the view object with the `Row` suffix. For example, each row of data from a view object named `Persons` is wrapped in an `<PersonsRow>` element. The elements representing the attribute data for each row appear as nested children inside this row element.

If any of the attributes is a view link accessor attribute, and if the parameters passed to `writeXML()` enable it, the view object will include the data for the detail rowset returned by the view link accessor. This nested data is wrapped by an element whose name is determined by the name of the view link accessor attribute. The return value of the `writeXML()` method is an object that implements the standard W3C `Node` interface, representing the root element of the generated XML.

---

---

**Note:** The `writeXML()` method uses view link accessor attributes to programmatically access detail collections. It does not require adding view link instances in the data model.

---

---

For example, to produce an XML element for all rows of a `Persons` view object instance, and following view link accessors as many levels deep as exists, [Example 39–21](#) shows the code required.

### **Example 39–21** Generating XML for All Rows of a View Object to All View Link Levels

```
ViewObject vo = am.findViewObject("PersonsView");
printXML(vo.writeXML(-1,XMLInterface.XML_OPT_ALL_ROWS));
```

The `Persons` view object is linked to a `Orders` view object showing the orders created by that person. In turn, the `Orders` view object is linked to a `OrderItems` view object providing details on the items ordered by customers. Running the code in

[Example 39–21](#) produces the XML shown in [Example 39–22](#), reflecting the nested structure defined by the view links.

**Example 39–22 XML from a Persons View Object with Two Levels of View Linked Details**

```

...
<PersonViewRow>
  <PersonId>111</PersonId>
  <PrincipalName>ISCIARRA</PrincipalName>
  <FirstName>Ismael</FirstName>
  <LastName>Sciarra</LastName>
  <PersonTypeCode>CUST</PersonTypeCode>
  <ProvisionedFlag>N</ProvisionedFlag>

</OrdersView>
</PersonsViewRow>
...

```

### 39.7.3 What You May Need to Know About Reading and Writing XML

This section provides additional information to help you work with XML.

#### 39.7.3.1 Controlling XML Element Names

You can use the Property Inspector to change the default XML element names used in the view object's canonical XML format by setting several properties. To accomplish this, open the overview editor for the view object, then:

- Select the attribute on the Attributes page and in the Property Inspector, select the Custom Properties navigation tab and set the custom *attribute*-level property named **Xml Element** to a value *SomeOtherName* to change the XML element name used for that attribute to `<SomeOtherName>`

For example, the `Email` attribute in the `Persons` view object defines this property to change the XML element you see in [Example 39-22](#) to be `<EmailAddress>` instead of `<Email>`.

- Select the General navigation tab in the Property Inspector and set the custom *view object*-level property named **Xml Row Element** to a value *SomeOtherRowName* to change the XML element name used for that view object to `<SomeOtherRowName>`.

For example, the `Persons` view object defines this property to change the XML element name for the rows you see in [Example 39-22](#) to be `<Person>` instead of `<PersonsRow>`.

- To change the name of the element names that wrapper nested row set data from view link attribute accessors, use the View Link Properties dialog. To open the dialog, in the view link overview editor, click the **Edit accessors** icon on the Accessors section of Relationship page. Enter the desired name of the view link accessor attribute in the **Accessor Name** field.

### 39.7.3.2 Controlling Element Suppression for Null-Valued Attributes

By default, if a view row attribute is `null`, then its corresponding element is omitted from the generated XML. Select the attribute on the Attributes page of the overview editor and in the Property Inspector, select the Custom Properties navigation tab and set the custom *attribute*-level property named **Xml Explicit Null** to any value (e.g. `"true"` or `"yes"`) to cause an element to be included for the attribute if its value is null. For example, if an attribute named `AssignedDate` has this property set, then a row containing a `null` assigned date will contain a corresponding `<AssignedDate null="true"/>` element. If you want this behavior for all attributes of a view object, you can define the **Xml Explicit Null** custom property at the view object level as a shortcut for defining it on each attribute.

### 39.7.3.3 Printing or Searching the Generated XML Using XPath

Two of the most common things you might want to do with the `XMLNode` object returned from `writeXML()` are:

1. Printing the node to its serialized text representation — to send across the network or save in a file, for example
2. Searching the generated XML using W3C XPath expressions

Unfortunately, the standard W3C Document Object Model (DOM) API does not include methods for doing *either* of these useful operations. But there is hope. Since ADF Business Components uses the Oracle XML parser's implementation of the DOM, you can cast the `Node` return value from `writeXML()` to the Oracle specific classes `XMLNode` or `XMLElement` (in the `oracle.xml.parser.v2` package) to access additional useful functionality like:

- Printing the XML element to its serialized text format using the `print()` method
- Searching the XML element in memory with XPath expressions using the `selectNodes()` method
- Finding the value of an XPath expression related to the XML element using the `valueOf()` method.

[Example 39–23](#) shows the `printXML()` method in the `TestClientWriteXML`. It casts the `Node` parameter to an `XMLNode` and calls the `print()` method to dump the XML to the console.

#### **Example 39–23 Using the XMLNode's print() Method to Serialize XML**

```
// In TestClientWriteXML.java
private static void printXML(Node n) throws IOException {
    ((XMLNode)n).print(System.out);
}
```

### 39.7.3.4 Using the Attribute Map For Fine Control Over Generated XML

When you need fine control over which attributes appear in the generated XML, use the version of the `writeXML()` method that accepts a `HashMap`. [Example 39–24](#) shows the interesting lines from a `TestClientWriteXML` class that use this technique. After creating the `HashMap`, you put `String[]`-valued entries into it

containing the names of the attributes you want to include in the XML, keyed by the fully-qualified name of the view definition those attributes belong to. The example includes the `PersonId`, `Email`, `PersonTypeCode`, and `OrdersView` attributes from the `Persons` view object, and the `OrderId`, `OrderStatusCode`, and `OrderTotal` attributes from the `OrdersView` view object.

---

**Note:** For upward compatibility reasons with earlier versions of ADF Business Components the `HashMap` expected by the `writeXML()` method is the one in the `com.sun.java.util.collections` package.

---

While processing the view rows for a given view object instance:

- If an entry exists in the attribute map with a key matching the fully-qualified view definition name for that view object, then only the attributes named in the corresponding `String` array are included in the XML.

Furthermore, if the string array includes the name of a view link accessor attribute, then the nested contents of its detail row set are included in the XML. If a view link accessor attribute name does not appear in the string array, then the contents of its detail row set are not included.

- If no such entry exists in the map, then *all* attributes for that row are included in the XML.

#### **Example 39–24 Using a View Definition Attribute Map for Fine Control Over Generated XML**

```
HashMap viewDefMap = new HashMap();
viewDefMap.put("devguide.advanced.xml.queries.PersonsView",
    new String[]{"PersonId", "Email", "PersonTypeCode",
        "OrdersView" /* View link accessor attribute */
    });
viewDefMap.put("devguide.advanced.xml.queries.OrdersView",
    new String[]{"OrderId", "OrderStatusCode", "OrderTotal"});
printXML(vo.writeXML(XMLInterface.XML_OPT_ALL_ROWS, viewDefMap));
```

Running the example produces the XML shown in [Example 39–25](#), including only the exact attributes and view link accessors indicated by the supplied attribute map.

#### **Example 39–25 XML from a Users View Object Produced Using an Attribute Map**

```
<OrdersViewRow>
  <OrderId>1033</OrderId>
  <OrderDate>2009-01-30 13:59:39.0</OrderDate>
  <OrderShippedDate>2009-02-02 13:59:39.0</OrderShippedDate>
  <OrderStatusCode>COMPLETE</OrderStatusCode>
  <OrderTotal>2677.96</OrderTotal>
  <CustomerId>108</CustomerId>
  <ShipToAddressId>20</ShipToAddressId>
  <ShippingOptionId>1</ShippingOptionId>
  <PaymentOptionId>1016</PaymentOptionId>
  <DiscountId>3</DiscountId>
  <FreeShippingFlag>Y</FreeShippingFlag>
  <CustomerCollectFlag>Y</CustomerCollectFlag>
  <CollectionWarehouseId>101</CollectionWarehouseId>
  <GiftwrapFlag>N</GiftwrapFlag>
  <CreatedBy>0</CreatedBy>
  <CreationDate>2009-02-23 13:59:39.0</CreationDate>
```

```

<LastUpdatedBy>0</LastUpdatedBy>
<LastUpdateDate>2009-02-23 13:59:39.0</LastUpdateDate>
<ObjectVersionId>0</ObjectVersionId>
<OrderItemsView>
  <OrderItemsViewRow>
    <OrderId>1033</OrderId>
    <LineItemId>1</LineItemId>
    <ProductId>10</ProductId>
    <Quantity>3</Quantity>
    <UnitPrice>225.99</UnitPrice>
    <CreatedBy>0</CreatedBy>
    <CreationDate>2009-02-23 13:59:40.0</CreationDate>
    <LastUpdatedBy>0</LastUpdatedBy>
    <LastUpdateDate>2009-02-23 13:59:40.0</LastUpdateDate>
    <ObjectVersionId>0</ObjectVersionId>
  </OrderItemsViewRow>
  <OrderItemsViewRow>
    <OrderId>1033</OrderId>
    <LineItemId>2</LineItemId>
    <ProductId>1</ProductId>
    <Quantity>1</Quantity>
    <UnitPrice>1999.99</UnitPrice>
    <CreatedBy>0</CreatedBy>
    <CreationDate>2009-02-23 13:59:40.0</CreationDate>
    <LastUpdatedBy>0</LastUpdatedBy>
    <LastUpdateDate>2009-02-23 13:59:40.0</LastUpdateDate>
    <ObjectVersionId>0</ObjectVersionId>
  </OrderItemsViewRow>
</OrderItemsView>
</OrdersViewRow>
...

```

### 39.7.3.5 Use the Attribute Map Approach with Bi-Directional View Links

If your view objects are related through a view link that you have configured to be bi-directional, then you must use the `writeXML()` approach that uses the attribute map. If you were to use the `writeXML()` approach in the presence of bi-directional view links and were to supply a maximum depth of `-1` to include all levels of view links that exist, the `writeXML()` method will go into an infinite loop as it follows the bi-directional view links back and forth, generating deeply nested XML containing duplicate data until it runs out of memory. Use `writeXML()` with an attribute map instead in this situation. Only by using this approach can you control which view link accessors are included in the XML and which are not to avoid infinite recursion while generating the XML.

### 39.7.3.6 Transforming Generated XML Using an XSLT Stylesheet

When the canonical XML format produced by `writeXML()` does not meet your needs, you can supply an XSLT stylesheet as an optional argument. It will produce the XML as it would normally, but then transform that result using the supplied stylesheet before returning the final XML to the caller.

Consider the XSLT stylesheet shown in [Example 39–26](#). It is a simple transformation with a single template that matches the root element of the generated XML from [Example 39–25](#) to create a new `<CustomerEmailAddresses>` element in the result. The template uses the `<xsl:for-each>` instruction to process all `<PersonsView>` elements that contain more than one `<OrdersViewRow>` child element inside a nested `<OrdersViews>` element. For each `<PersonsView>` element that qualifies, it creates a

<Customer> element in the result whose Contact attribute is populated from the value of the <Email> child element of the <PersonsView>.

**Example 39–26 XSLT Stylesheet to Transform Generated XML Into Another Format**

```
<?xml version="1.0" encoding="windows-1252" ?>
<xsl:stylesheet version="1.0" xmlns:xsl="http://www.w3.org/1999/XSL/Transform">
  <xsl:template match="/">
    <CustomerEmailAddresses>
      <xsl:for-each
        select="/PersonsView/PersonsViewRow[count(OrdersView/OrdersViewRow) >
          1]">
        <xsl:sort select="Email"/>
        <Customer Contact="{Email}"/>
      </xsl:for-each>
    </CustomerEmailAddresses>
  </xsl:template>
</xsl:stylesheet>
```

Example 39–27 shows the interesting lines from a TestClientWriteXML class that put this XSLT stylesheet into action when calling writeXML().

**Example 39–27 Passing an XSLT Stylesheet to writeXML() to Transform the Resulting XML**

```
// In TestClientWriteXML.java
XSLStylesheet xsl = getXSLStylesheet();
printXML(vo.writeXML(XMLInterface.XML_OPT_ALL_ROWS, viewDefMap, xsl));
```

Running the code in Example 39–27 produces the transformed XML shown here:

```
<CustomerEmailAddresses>
  <Customer Contact="dfaviet"/>
  <Customer Contact="jchen"/>
  <Customer Contact="ngreenbe"/>
</CustomerEmailAddresses>
```

The getXSLStylesheet() helper method shown in Example 39–28 is also interesting to study since it illustrates how to read a resource like an XSLT stylesheet from the classpath at runtime. The code expects the Example.xml stylesheet to be in the same directory as the TestClientWriteXML class. By referencing the Class object for the TestClientWriteXML class using the .class operator, the code uses the getResource() method to get a URL to the resource. Then, it passes the URL to the newXSLStylesheet() method of the XSLProcessor class to create a new XSLStylesheet object to return. That object represents the compiled version of the XSLT stylesheet read in from the \*.xml file.

**Example 39–28 Reading an XSLT Stylesheet as a Resource from the Classpath**

```
private static XSLStylesheet getXSLStylesheet()
    throws XMLParseException, SAXException, IOException, XSLException {
    String xslurl = "Example.xml";
    URL xslURL = TestClientWriteXML.class.getResource(xslurl);
    XSLProcessor xslProc = new XSLProcessor();
    return xslProc.newXSLStylesheet(xslURL);
}
```

---

---

**Note:** When working with resources like XSLT stylesheets that you want to be included in the output directory along with your compiled Java classes and XML metadata, you can use the **Compiler** page of the **Project Properties** dialog to update the **Copy File Types to Output Directory** field to include `.xsl` in the semicolon-separated list.

---

---

### 39.7.3.7 Generating XML for a Single Row

In addition to calling `writeXML()` on a view object, you can call the same method with the same parameters and options on any `Row` as well. If the `Row` object on which you call `writeXML()` is an entity row, you can bitwise-OR the additional `XMLInterface.XML_OPT_CHANGES_ONLY` flag if you only want the changed entity attributes to appear in the XML.

## 39.7.4 How to Consume XML Documents to Apply Changes

To have a view object consume an XML document to process inserts, updates, and deletes, use the `readXML()` method:

```
void readXML(Element elem, int depthcount)
```

The canonical format expected by `readXML()` is the same as what would be produced by a call to the `writeXML()` method on the same view object. If the XML document to process does not correspond to this canonical format, you can supply an XSLT stylesheet as an optional third argument to `readXML()` to transform the incoming XML document *into* the canonical format before it is read for processing.

## 39.7.5 What Happens When You Consume XML Documents

When a view object consumes an XML document in canonical format, it processes the document to recognize row elements, their attribute element children, and any nested elements representing view link accessor attributes. It processes the document recursively to a maximum level indicated by the `depthcount` parameter. Passing `-1` for the `depthcount` to request that it process all levels of the XML document.

### 39.7.5.1 How `ViewObject.readXML()` Processes an XML Document

For each row element it recognizes, the `readXML()` method does the following:

- Identifies the related view object to process the row.
- Reads the children attribute elements to get the values of the primary key attributes for the row.
- Performs a `findByKey()` using the primary key attributes to detect whether the row already exists or not.
- If the row exists:
  - If the row element contains the marker attribute `bc4j-action="remove"`, then the existing row is deleted.
  - Otherwise, the row's attributes are updated using the values in any attribute element children of the current row element in the XML
- If the row does not exist, then a new row is created, inserted into the view object's rowset. Its attributes are populated using the values in any attribute element children of the current row element in the XML.

### 39.7.5.2 Using readXML() to Processes XML for a Single Row

The same `readXML()` method is also supported on any `Row` object. The canonical XML format it expects is the same format produced by a call to `writeXML()` on the same row. You can invoke `readXML()` method on a row to:

- Update its attribute values from XML
- Remove the row, if the `bc4j-action="remove"` marker attribute is present on the corresponding row element.
- Insert, update, or delete any nested rows via view link accessors

Consider the XML document shown in [Example 39–29](#). It is in the canonical format expected by a single row in the `PersonsView` view object. Nested inside the root `<PersonsViewRow>` element, the `<ConfirmedEmail>` attribute represents the customer's email address. The nested `<OrdersView>` element corresponds to the `Orders` view link accessor attribute and contains three `<OrdersViewRow>` elements. Each of these includes `<OrderId>` elements representing the primary key of a `OrdersView` row.

#### **Example 39–29 XML Document in Canonical Format to Insert, Update, and Delete Rows**

```
<PersonsViewRow>
  <!-- This will update Person's ConfirmedEmail attribute -->
  <PersonId>110</PersonId>
  <ConfirmedEmail>NewConfirmed</ConfirmedEmail>
  <OrdersView>
    <!-- This will be an update since it does exist -->
    <OrdersViewRow>
      <OrderId>1011</OrderId>
      <OrderStatusCode>SHIP</OrderStatusCode>
    </OrdersViewRow>
    <!-- This will be an insert since it doesn't exist -->
    <OrdersViewRow>
      <OrderId>1070</OrderId>
      <OrderStatusCode>PENDING</OrderStatusCode>
    </OrdersViewRow>
    <!-- This will be deleted -->
    <OrdersViewRow bc4j-action="remove">
      <OrderId>1026</OrderId>
    </OrdersViewRow>
  </OrdersView>
</PersonsViewRow>
```

[Example 39–30](#) shows the interesting lines of code from a `TestClientReadXML` class that applies this XML datagram to a particular row in the `PersonsView` view object. `TestClientReadXML` class performs the following basic steps:

1. Finds a target row by key (e.g. for customer "jchen").
2. Shows the XML produced for the row before changes are applied.
3. Obtains the parsed XML document with changes to apply using a helper method.
4. Reads the XML document to apply changes to the row.
5. Shows the XML with the pending changes applied.

`TestClientReadXML` class is using the `XMLInterface.XML_OPT_ASSOC_CONSISTENT` flag described in [Section 39.7.1, "How to Produce XML for Queried Data"](#) to ensure that new, unposted rows are included in the XML.

**Example 39–30 Applying Changes to an Existing Row with readXML()**

```

ViewObject vo = am.findViewObject("CustomersView");
Key k = new Key(new Object[] { 110 });
// 1. Find a target row by key (e.g. for customer "jchen")
Row jchen = vo.findByKey(k, 1)[0];
// 2. Show the XML produced for the row before changes are applied
printXML(jchen.writeXML(-1, XMLInterface.XML_OPT_ALL_ROWS));
// 3. Obtain parsed XML document with changes to apply using helper method
Element xmlToRead = getInsertUpdateDeleteXMLGram();
printXML(xmlToRead);
// 4. Read the XML document to apply changes to the row
jchen.readXML(getInsertUpdateDeleteXMLGram(), -1);
// 5. Show the XML with the pending changes applied
printXML(jchen.writeXML(-1, XMLInterface.XML_OPT_ALL_ROWS |
XMLInterface.XML_OPT_ASSOC_CONSISTENT));

```

Running the code in [Example 39–30](#) initially displays the "before" version of John Chen's information. Notice that:

- The `ConfirmedEmail` attribute has the value "JCHEN"
- The status code for order 1011 has a level of "CANCEL"
- There is an orders row for order 1026, and
- There is no orders row related to order 1070.

```

<PersonsViewRow>
  <PersonId>110</PersonId>
  <PrincipalName>JCHEN</PrincipalName>
  <FirstName>John</FirstName>
  <LastName>Chen</LastName>
  <PersonTypeCode>CUST</PersonTypeCode>
  <ProvisionedFlag>N</ProvisionedFlag>
  <PrimaryAddressId>37</PrimaryAddressId>
  <MembershipId>1</MembershipId>
  <Email>JCHEN</Email>
  <ConfirmedEmail>JCHEN</ConfirmedEmail>
  <PhoneNumber>706.555.0103</PhoneNumber>
  <DateOfBirth>1967-09-28</DateOfBirth>

    <ObjectVersionId>0</ObjectVersionId>
  </OrderItemsViewRow>
</OrderItemsView>
</OrdersViewRow>
...

```

After applying the changes from the XML document using `readXML()` to the row and printing its XML again using `writeXML()` you see that:

- The `ConfirmedEmail` is now "NewConfirmed"
- A new orders row for order 1070 got created.
- The status code for order 1011 has a level of "SHIP", and
- The orders row for order 1026 is removed

```

      <LastUpdateDate>2009-02-01 13:59:39.0</LastUpdateDate>
      <ObjectVersionId>0</ObjectVersionId>
    </OrderItemsViewRow>
  </OrderItemsView>
</OrdersViewRow>
...
```

---

---

**Note:** The example illustrated using `readXML()` to apply changes to a single row. If the XML document contained a wrapping `<PersonsView>` row, including the primary key attribute in each of its one or more nested `<PersonsViewRow>` elements, then that document could be processed using the `readXML()` method on the `PersonsView` view object for handling operations for multiple `PersonsView` rows.

---

---

## 39.8 Using Programmatic View Objects for Alternative Data Sources

By default view objects read their data from the database and automate the task of working with the Java Database Connectivity (JDBC) layer to process the database result sets. However, by overriding appropriate methods in its custom Java class, you can create a view object that programmatically retrieves data from alternative data sources like a `REF CURSOR`, an in-memory array, or a Java `*.properties` file, to name a few.

### 39.8.1 How to Create a Read-Only Programmatic View Object

To create a read-only programmatic view object, you use the Create View Object wizard.

#### To create the read-only programmatic view object:

1. In the Application Navigator, right-click the project in which you want to create the view object and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **View Object**, and click **OK**.
3. In the Create View Object wizard, in the Name page, provide a name and package for the view object. For the data source, select **Rows populated programmatically, not based on a query**.
4. In the Attributes page, click **New** one or more times to define the view object attributes your programmatic view object requires.
5. In the Attribute Settings page, adjust any setting you may need to for the attributes you defined.
6. In the Java page, select **Generate View Object Class** to enable a custom view object class (`ViewObjImpl`) to contain your code.
7. Click **Finish** to create the view object.

In your view object's custom Java class, override the methods described in [Section 39.8.3, "Key Framework Methods to Override for Programmatic View Objects"](#) to implement your custom data retrieval strategy.

### 39.8.2 How to Create an Entity-Based Programmatic View Object

To create an entity-based view object with programmatic data retrieval, create the view object in the normal way, enable a custom Java class for it, and override the methods described in the next section to implement your custom data retrieval strategy.

### 39.8.3 Key Framework Methods to Override for Programmatic View Objects

A programmatic view object typically overrides all of the following methods of the base `ViewObjectImpl` class to implement its custom strategy for retrieving data:

- `create()`

This method is called when the view object instance is created and can be used to initialize any state required by the programmatic view object. At a minimum, this overridden method will contain the following lines to ensure the programmatic view object has no trace of a SQL query related to it:

```
// Wipe out all traces of a query for this VO
getViewDef().setQuery(null);
getViewDef().setSelectClause(null);
setQuery(null);
```

- `executeQueryForCollection()`

This method is called whenever the view object's query needs to be executed (or re-executed).

- `hasNextForCollection()`

This method is called to support the `hasNext()` method on the row set iterator for a row set created from this view object. Your implementation returns `true` if you have not yet exhausted the rows to retrieve from your programmatic data source.

- `createRowFromResultSet()`

This method is called to populate each row of "fetched" data. Your implementation will call `createNewRowForCollection()` to create a new blank row and then `populateAttributeForRow()` to populate each attribute of data for the row.

- `getQueryHitCount()`

This method is called to support the `getEstimatedRowCount()` method. Your implementation returns a count, or estimated count, of the number of rows that will be retrieved by the programmatic view object's query.

- `protected void releaseUserDataForCollection()`

Your code can store and retrieve a user data context object with each row set. This method is called to allow you to release any resources that may be associated with a row set that is being closed.

Since the view object component can be related to several active row sets at runtime, many of the above framework methods receive an `Object` parameter named `qc` in which the framework will pass the collection of rows in question that your code is supposed to be filling, as well as the array of bind variable values that might affect which rows get populated into the specific collection.

You can store a user-data object with each collection of rows so your custom datasource implementation can associate any needed datasource context information. The framework provides the `setUserDataForCollection()` and `getUserDataForCollection()` methods to get and set this per-collection context information. Each time one of the overridden framework methods is called, you can use the `getUserDataForCollection()` method to retrieve the correct `ResultSet` object associated with the collection of rows the framework wants you to populate.

The examples in the following sections each override these methods to implement different kinds of programmatic view objects.

### 39.8.4 How to Create a View Object on a REF CURSOR

Sometimes your application might need to work with the results of a query that is encapsulated within a stored procedure. PL/SQL allows you to open a cursor to iterate through the results of a query, and then return a reference to this cursor to the client. This so-called `REF CURSOR` is a handle with which the client can then iterate the results of the query. This is possible even though the client never actually issued the original SQL `SELECT` statement.

---

---

**Note:** The example in this section refers to the `ViewObjectOnRefCursor` project in the `AdvancedViewObjectsExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

Declaring a PL/SQL package with a function that returns a `REF CURSOR` is straightforward. For example, your package might look like this:

```
CREATE OR REPLACE PACKAGE RefCursorExample IS
```

```

TYPE ref_cursor IS REF CURSOR;
FUNCTION get_orders_for_customer(p_email VARCHAR2) RETURN ref_cursor;
FUNCTION count_orders_for_customer(p_email VARCHAR2) RETURN NUMBER;
END RefCursorExample;

```

After defining an entity-based `OrdersForCustomer` view object with an entity usage for a `Order` entity object, go to its custom Java class `OrdersForCustomerImpl.java`. At the top of the view object class, define some constant `Strings` to hold the anonymous blocks of PL/SQL that you'll execute using `JDBC CallableStatement` objects to invoke the stored functions:

```

/*
 * Execute this block to retrieve the REF CURSOR
 */
private static final String SQL =
    "begin ? := RefCursorSample.get_orders_for_customer(?);end;";
/*
 * Execute this block to retrieve the count of orders that
 * would be returned if you executed the statement above.
 */
private static final String COUNTSQL =
    "begin ? := RefCursorSample.count_orders_for_customer(?);end;";

```

Then, override the methods of the view object as described in the following sections.

#### 39.8.4.1 The Overridden `create()` Method

The `create()` method removes all traces of a SQL query for this view object.

```

protected void create() {
    getViewDef().setQuery(null);
    getViewDef().setSelectClause(null);
    setQuery(null);
}

```

#### 39.8.4.2 The Overridden `executeQueryForCollection()` Method

The `executeQueryForCollection()` method calls a helper method `retrieveRefCursor()` to execute the stored function and return the `REF CURSOR` return value, cast as a `JDBC ResultSet`. Then, it calls the helper method `storeNewResultSet()` that uses the `setUserDataForCollection()` method to store this `ResultSet` with the collection of rows for which the framework is asking to execute the query.

```

protected void executeQueryForCollection(Object qc, Object[] params,
                                         int numUserParams) {
    storeNewResultSet(qc, retrieveRefCursor(qc, params));
    super.executeQueryForCollection(qc, params, numUserParams);
}

```

The `retrieveRefCursor()` uses the helper method described in [Section 37.4, "Invoking Stored Procedures and Functions"](#) to invoke the stored function and return the `REF CURSOR`:

```

private ResultSet retrieveRefCursor(Object qc, Object[] params) {
    ResultSet rs = (ResultSet) callStoredFunction(OracleTypes.CURSOR,
        "RefCursorExample.get_requests_for_customer(?)",
        new Object[]{getNamedBindParamValue("CustEmail", params)});
    return rs ;
}

```

### 39.8.4.3 The Overridden createRowFromResultSet() Method

For each row that the framework needs fetched from the datasource, it will invoke your overridden `createRowFromResultSet()` method. The implementation retrieves the collection-specific `ResultSet` object from the user-data context, uses the `createNewRowForCollection()` method to create a new blank row in the collection, and then use the `populateAttributeForRow()` method to populate the attribute values for each attribute defined at design time in the view object overview editor.

```
protected ViewRowImpl createRowFromResultSet(Object qc, ResultSet rs) {
    /*
     * We ignore the JDBC ResultSet passed by the framework (null anyway) and
     * use the resultset that we've stored in the query-collection-private
     * user data storage
     */
    rs = getResultSet(qc);

    /*
     * Create a new row to populate
     */
    ViewRowImpl r = createNewRowForCollection(qc);
    try {
        /*
         * Populate new row by attribute slot number for current row in Result Set
         */
        populateAttributeForRow(r,0, rs.getLong(1));
        populateAttributeForRow(r,1, rs.getString(2));
        populateAttributeForRow(r,2, rs.getString(3));
    }
    catch (SQLException s) {
        throw new JboException(s);
    }
    return r;
}
```

### 39.8.4.4 The Overridden hasNextForCollectionMethod()

The overridden implementation of the framework method `hasNextForCollection()` has the responsibility to return `true` or `false` based on whether there are more rows to fetch. When you've hit the end, you call the `setFetchCompleteForCollection()` to tell view object that this collection is done being populated.

```
protected boolean hasNextForCollection(Object qc) {
    ResultSet rs = getResultSet(qc);
    boolean nextOne = false;
    try {
        nextOne = rs.next();
        /*
         * When were at the end of the result set, mark the query collection
         * as "FetchComplete".
         */
        if (!nextOne) {
            setFetchCompleteForCollection(qc, true);
            /*
             * Close the result set, we're done with it
             */
            rs.close();
        }
    }
}
```

```

catch (SQLException s) {
    throw new JboException(s);
}
return nextOne;
}

```

#### 39.8.4.5 The Overridden `releaseUserDataForCollection()` Method

Once the collection is done with its fetch-processing, the overridden `releaseUserDataForCollection()` method gets invoked and closes the `ResultSet` cleanly so no database cursors are left open.

```

protected void releaseUserDataForCollection(Object qc, Object rs) {
    ResultSet userDataRS = getResultSet(qc);
    if (userDataRS != null) {
        try {
            userDataRS.close();
        }
        catch (SQLException s) {
            /* Ignore */
        }
    }
    super.releaseUserDataForCollection(qc, rs);
}

```

#### 39.8.4.6 The Overridden `getQueryHitCount()` Method

Lastly, in order to properly support the view object's `getEstimatedRowCount()` method, the overridden `getQueryHitCount()` method returns a count of the rows that would be retrieved if all rows were fetched from the row set. Here the code uses a `CallableStatement` to get the job done. Since the query is completely encapsulated behind the stored function API, the code also relies on the PL/SQL package to provide an implementation of the count logic as well to support this functionality.

```

public long getQueryHitCount(ViewRowSetImpl viewRowSet) {
    Object[] params = viewRowSet.getParameters(true);
    BigDecimal id = (BigDecimal)params[0];
    CallableStatement st = null;
    try {
        st = getDBTransaction().createCallableStatement(COUNTSQL,
            DBTransaction.DEFAULT);
        /*
         * Register the first bind parameter as our return value of type CURSOR
         */
        st.registerOutParameter(1,Types.NUMERIC);
        /*
         * Set the value of the 2nd bind variable to pass id as argument
         */
        if (id == null) st.setNull(2,Types.NUMERIC);
        else            st.setBigDecimal(2,id);
        st.execute();
        return st.getLong(1);
    }
    catch (SQLException s) {
        throw new JboException(s);
    }
    finally {try {st.close();} catch (SQLException s) {}}
}

```

## 39.9 Creating a View Object with Multiple Updatable Entities

---

**Note:** The example in this section refers to the `MultipleMasters` project in the `AdvancedViewObjectsExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

When you create a view object with multiple entity usages, you can enable a secondary entity usage to be updatable by selecting it in the **Selected** list of the **Entity Objects** page of the view object overview editor and:

- Deselecting the **Reference** checkbox
- Selecting the **Updatable** checkbox

If you only plan to use the view object to update or delete existing data, then this is the only step required. The user can update attributes related to any of the non-reference, updatable entity usages and the view row will delegate the changes to the appropriate underlying entity rows.

However, if you need a view object with multiple updatable entities to support creating new rows and the association between the entity objects is not a composition, then you need to write a bit of code to enable that to work correctly.

---

**Note:** You only need to write code to handle creating new rows when the association between the updatable entities is not a composition. If the association is a composition, then ADF Business Components handles this automatically.

---

When you call `createRow()` on a view object with multiple update entities, it creates new entity row parts for each updatable entity usage. Since the multiple entities in this scenario are related by an association, there are three pieces of code you might need to implement to ensure the new, associated entity rows can be saved without errors:

1. You may need to override the `postChanges()` method on entity objects involved to control the correct posting order.
2. If the primary key of the associated entity is populated by a database sequence using `DBSequence`, and if the multiple entity objects are associated but not composed, then you need to override the `postChanges()` and `refreshFKInNewContainees()` method to handle cascading the refreshed primary key value to the associated rows that were referencing the temporary value.
3. You need to override the `create()` method of the view object's custom view row class to modify the default row creation behavior to pass the context of the parent entity object to the newly-created child entity.

In [Section 38.8, "Controlling Entity Posting Order to Avoid Constraint Violations,"](#) you've already seen the code required for 1 and 2 above in an example with associated `Suppliers` and `Products` entity objects. The only thing remaining is the overridden `create()` method on the view row. Consider a `ProductAndSupplier` view object with a primary entity usage of `Product` and secondary entity usages of `Supplier` and `User`. Assume the `Product` entity usage is marked as updatable and non-reference, while the `User` entity usage is a reference entity usage.

[Example 39–31](#) shows the commented code required to correctly sequence the creation of the multiple, updatable entity row parts during a view row create operation.

**Example 39–31 Overriding View Row create() Method for Multiple Updatable Entities**

```
/**
 * By default, the framework will automatically create the new
 * underlying entity object instances that are related to this
 * view object row being created.
 *
 * We override this default view object row creation to explicitly
 * pre-populate the new (detail) ProductsImpl instance using
 * the new (master) SuppliersImpl instance. Since all entity objects
 * implement the AttributeList interface, we can directly pass the
 * new SuppliersImpl instance to the ProductsImpl create()
 * method that accepts an AttributeList.
 */
protected void create(AttributeList attributeList) {
    // The view row will already have created "blank" entity instances
    SuppliersImpl newSupplier = getSupplier();
    ProductsImpl newProduct = getProduct();
    try {
        // Let product "blank" entity instance to do programmatic defaulting
        newSupplier.create(attributeList);
        // Let product "blank" entity instance to do programmatic
        // defaulting passing in new SuppliersImpl instance so its attributes
        // are available to the EmployeeImpl's create method.
        newProduct.create(newSupplier);
    }
    catch (JboException ex) {
        newSupplier.revert();
        newProduct.revert();
        throw ex;
    }
    catch (Exception otherEx) {
        newSupplier.revert();
        newProduct.revert();
        throw new RowCreateException(true        /* EO Row? */,
                                     "Product" /* EO Name */,
                                     otherEx    /* Details */);
    }
}
```

In order for this view row class to be able to invoke the protected `create()` method on the `Suppliers` and `Products` entity objects, they need to override the `create()` method. If the view object and entity objects are in the same package, the overridden `create()` method can have protected access. Otherwise, it requires public access.

```
/**
 * Overriding this method in this class allows friendly access
 * to the create() method by other classes in this same package, like the
 * ProductsAndSuppliers view object implementation class, whose overridden
 * create() method needs to call this.
 * @param nameValuePair
 */
protected void create(AttributeList nameValuePair) {
    super.create(nameValuePair);
}
```

## 39.10 Programmatically Creating View Definitions and View Objects

The `oracle.jbo.server.ViewDefImpl` class lets you dynamically define the view definition meta-object for view object instances. The view definition describes the view object's structure.

Typically, the application creates the view definition by loading an XML file that you create using JDeveloper overview editors. When the application needs to create a view object instance, it queries the `MetaObjectManager` for the view object's view definition by the view definition name, it then finds the XML file, opens it, parses it, and constructs a view definition object in memory.

Alternatively, you can create the view definition programmatically using methods of the `ViewDefImpl` class. When you create a programmatic view definition, your application code begins with code like:

```
ViewDefImpl viewDef = new ViewDefImpl("MyViewDef");
viewDef.setFullName("sessiondef.mypackage.MyViewDef");
```

A view definition that you create must be uniquely identified by its full name, where the full name is a package-qualified name. Thus, you call `setFullName()` to pass in the package-qualified name of your view definition object (for example, `sessiondef.mypackage.MyViewDef`).

The `MyViewDef` name that you initially pass in is the short name of the view definition you create. Your application may pass the short name when an API requires a view definition name. For example, your application might request the `defName` parameter when invoking `ApplicationModule.createViewObject(String, String)`.

To create a view definition and then create a view object instance based on that definition, follow these basic steps (as illustrated in [Example 39-32](#)):

1. Create the view definition object and set the full name.
2. Define the view object SQL statement.
3. Resolve the view definition and save it into the MDS repository.
4. With the view definition, construct instance of view objects based on it.

---

**Note:** To save the view definition into the MDS repository, the `adf-config.xml` file must be appropriately configured for the saved view definition. For details about configuring the `adf-config.xml` file, see [Example 39-33](#).

---

### **Example 39-32** *Creating a View Definition Using the ViewDefImpl API*

```
/*
 * 1. Create the view definition object.
 */
ViewDefImpl v = new ViewDefImpl("DefNameForObject");

v.setFullName("sessiondef.some.unique.DefNameForObject");

/*
 * 2. Then, define the view object's SQL statement by either using a fully-
 * specified "expert-mode" SQL query.
 */
v.setQuery("select e.empno,e.ename,e.sal,e.deptno,d.dname,d.loc,"+
           "d.deptno,trunc(sysdate)+1 tomorrow_date, "+
```

```

        "e.sal + nvl(e.comm,0) total_compensation, "+
        "to_char(e.hiredate,'dd-mon-yyyy') formatted_hiredate"+
        " from emp e, dept d "+
        " where e.deptno = d.deptno (+)" +
        " order by e.ename");
v.setFullSql(true);

/*
 * Or, you can construct the SQL statement in parts like this.
 */
v.setSelectClause("e.empno,e.ename,e.sal,e.deptno,d.dname,d.loc,"+
                 "d.deptno,trunc(sysdate)+1 tomorrows_date,"+
                 "e.sal + nvl(e.comm,0) total_compensation, "+
                 "to_char(e.hiredate,'dd-mon-yyyy') formatted_hiredate");
v.setFromClause("emp e, dept d");
v.setWhereClause("e.deptno = d.deptno (+)"); v.setOrderByClause("e.ename");

/*
 * 3. Then resolve and save the view definition.
 */
v.resolveDefObject();
v.writeXMLContents();
v.saveXMLContents();

/*
 * 4. Finally, use the dynamically-created view definition to construct
 * instances of view objects based on it. myAM is an instance of
 * oracle.jbo.ApplicationModule that will parent this VO instance.
 */
ViewObject vo = myAM.createViewObject("SomeInstanceName", v.getFullName());

```

After defining a view definition, it is important to write and save the view definition into the MDS repository. If it is not properly saved, you may encounter issues when the request is redirected to a different node in a cluster because the definition cannot be loaded and accessed from the other node.

In order to save the definition, you need to define the `mds-config` element of `adf-config.xml`. For example, your `adf-config.xml` file should contain definitions similar to those shown in [Example 39-33](#).

### **Example 39-33 MDS Configuration Defines Namespaces to Save View Definition**

```

<mds-config version="11.1.1.000">
  <persistence-config>
<!-- metadata-namespaces must define /sessiondef and /persdef namespaces -->
    <metadata-namespaces>
      <namespace path="/sessiondef" metadata-store-usage="mymdsstore">
      <namespace path="/persdef" metadata-store-usage="mymdsstore">
    </metadata-namespaces>

    <metadata-store-usages>
      <metadata-store-usage id="mymdsstore" default-cust-store="true">
        <metadata-store name="fs1"
          class-name="oracle.mds.persistence.stores.file.FileMetadataStore">
<!-- metadata-path value should be the absolute dir path where you want
the metadata documents to be written -->
          <property name="metadata-path" value="/tmp">
        </metadata-store>
      </metadata-store-usage>
    </metadata-store-usages>

```

```

</persistence-config>

<cust-config>
  <match path="/">
    <customization-class name="oracle.adf.share.config.UserCC">
  </match>
</cust-config>
</mds-config>

```

If your `adf-config.xml` file already defines the `metadata-store-usage` element, then you may be able to define the two namespaces `/sessiondef` and `/persdef` so that they use that `metadata-store-usage` definition. For more information about MDS configuration entries in the `adf-config.xml` file, see [Section A-5, "Sample adf-config.xml File."](#) For more information about configuring MDS repositories, see the *Oracle Fusion Middleware Administrator's Guide*.

## 39.11 Declaratively Preventing Insert, Update, and Delete

Some 4GL tools like Oracle Forms provide declarative properties that control whether a given data collection allows inserts, updates, or deletes. While the view object does not yet support this as a built-in feature in the current release, it's easy to add this facility using a framework extension class that exploits custom metadata properties as the developer-supplied flags to control insert, update, or delete on a view object.

---

---

**Note:** The example in this section refers to the `DeclarativeBlockOperations` project in the `AdvancedViewObjectsExamples` application workspace in the `StandaloneExamples` module of the Fusion Order Demo application.

---

---

To allow developers to have control over individual view object instances, you could adopt the convention of using application module custom properties by the same name as the view object instance. For example, if an application module has view object instances named `ProductsInsertOnly`, `ProductsUpdateOnly`, `ProductsNoDelete`, and `Products`, your generic code might look for application module custom properties by these same names. If the property value contains `Insert`, then insert is enabled for that view object instance. If the property contains `Update`, then update allowed. And, similarly, if the property value contains `Delete`, then delete is allowed. You could use helper methods like this to test for these application module properties and determine whether insert, update, and delete are allowed for a given view object:

```

private boolean isInsertAllowed() {
    return isStringInAppModulePropertyNamedAfterVOInstance("Insert");
}
private boolean isUpdateAllowed() {
    return isStringInAppModulePropertyNamedAfterVOInstance("Update");
}
private boolean isDeleteAllowed() {
    return isStringInAppModulePropertyNamedAfterVOInstance("Delete");
}
private boolean isStringInAppModulePropertyNamedAfterVOInstance(String s) {
    String voInstName = getViewObject().getName();
    String propVal = (String)getApplicationModule().getProperty(voInstName);
    return propVal != null ? propVal.indexOf(s) >= 0 : true;
}

```

**Example 39–34** shows the other code required in a custom framework extension class for view rows to complete the implementation. It overrides the following methods:

- `isAttributeUpdateable()`  
To enable the user interface to disable fields in a new row if insert is not allowed or to disable fields in an existing row if update is not allowed.
- `setAttributeInternal()`  
To prevent setting attribute values in a new row if insert is not allowed or to prevent setting attributes in an existing row if update is not allowed.
- `remove()`  
To prevent remove if delete is not allowed.
- `create()`  
To prevent create if insert is not allowed.

**Example 39–34 Preventing Insert, Update, or Delete Based on Custom Properties**

```
public class CustomViewRowImpl extends ViewRowImpl {
    public boolean isAttributeUpdateable(int index) {
        if (hasEntities() &&
            ((isNewOrInitialized() && !isInsertAllowed()) ||
             (isModifiedOrUnmodified() && !isUpdateAllowed()))) {
            return false;
        }
        return super.isAttributeUpdateable(index);
    }
    protected void setAttributeInternal(int index, Object val) {
        if (hasEntities()) {
            if (isNewOrInitialized() && !isInsertAllowed())
                throw new JboException("No inserts allowed in this view");
            else if (isModifiedOrUnmodified() && !isUpdateAllowed())
                throw new JboException("No updates allowed in this view");
        }
        super.setAttributeInternal(index, val);
    }
    public void remove() {
        if (!hasEntities() || isDeleteAllowed() || isNewOrInitialized())
            super.remove();
        else
            throw new JboException("Delete not allowed in this view");
    }
    protected void create(AttributeList nvp) {
        if (isInsertAllowed()) {
            super.create(nvp);
        } else {
            throw new JboException("Insert not allowed in this view");
        }
    }
    // private helper methods omitted from this example
}
```

---

---

## Application State Management

This chapter describes the Fusion web application state management facilities and how to use them to specify the release level for ADF application modules to support stateful applications on the web.

This chapter includes the following sections:

- [Section 40.1, "Understanding Why State Management is Necessary"](#)
- [Section 40.2, "Introduction to Fusion Web Application State Management"](#)
- [Section 40.3, "Using Save For Later"](#)
- [Section 40.4, "Setting the Application Module Release Level at Runtime"](#)
- [Section 40.5, "What Model State Is Saved and When It Is Cleaned Up"](#)
- [Section 40.6, "Timing Out the HttpSession"](#)
- [Section 40.7, "Managing Custom User-Specific Information"](#)
- [Section 40.8, "Managing the State of View Objects"](#)
- [Section 40.9, "Using State Management for Middle-Tier Savepoints"](#)
- [Section 40.10, "Testing to Ensure Your Application Module is Activation-Safe"](#)
- [Section 40.11, "Keeping Pending Changes in the Middle Tier"](#)

### 40.1 Understanding Why State Management is Necessary

Most real-world business applications need to support multi-step user tasks. Modern sites tend to use a step-by-step style user interface to guide the end user through a logical sequence of pages to complete these tasks. When the task is done, the user can save or cancel everything as a unit.

#### 40.1.1 Examples of Multi-Step Tasks

In a typical search-then-edit scenario, the end user searches to find an appropriate row to update, then may open several different pages of related master/detail information to make edits before deciding to save or cancel his work. Consider another scenario where the end user wants to book a vacation online. The process may involve the end user's entering details about:

- One or more flight segments that comprise the journey
- One or more passengers taking the trip
- Seat selections and meal preferences

- One or more hotel rooms in different cities
- Car they will rent

Along the way, the user might decide to complete the transaction, save the reservation for finishing later, or abandoning the whole thing.

It's clear these scenarios involve a logical unit of work that spans multiple web pages. You've seen in previous chapters how to use JDeveloper's JSF page navigation diagram to design the page flow for these use cases, but that is only part of the puzzle. The pending changes the end user makes to business domain objects along the way — Trip, Flight, Passenger, Seat, HotelRoom, Auto, etc. — represent the in-progress state of the application for each end user. Along with this, other types of "bookkeeping" information about selections made in previous steps comprise the complete picture of the application state.

### 40.1.2 Stateless HTTP Protocol Complicates Stateful Applications

While it may be easy to imagine these multi-step scenarios, *implementing* them in web applications is complicated by the stateless nature of HTTP, the hypertext transfer protocol. [Figure 40-1](#) illustrates how an end user's visit to a site comprises a series of HTTP request/response pairs. However, HTTP affords a web server no way to distinguish one user's request from another user's, or to differentiate between a single user's first request and any subsequent requests he makes while interacting with the site. The server gets each request from any user always as if it were the first (and only) one they make.

**Figure 40-1 Web Applications Use the Stateless HTTP Protocol**

But even if you've never *implemented* your own web applications before, since you've undoubtedly *used* a web application to buy a book, plan a holiday, or even just read your email, it's clear that a solution must exist to distinguish one user from another.

### 40.1.3 How Cookies Are Used to Track a User Session

As shown in [Figure 40-2](#), the technique used to recognize an ongoing sequence of requests from the same end user over the stateless HTTP protocol involves a unique identifier called a *cookie*. A cookie is a name/value pair that is sent in the header information of each HTTP request the user makes to a site. On the initial request made by a user, the cookie is not part of the request. The server uses the *absence* of the cookie to detect the start of a user's session of interactions with the site, and it returns a unique identifier to the browser that represents this session for this user. In practice, the cookie value is a long string of letters and numbers, but for the simplicity of the illustration, assume that the unique identifier is a letter like "A" or "Z" that corresponds to different users using the site.

Web browsers support a standard way of recognizing the cookie returned by the server that allows the browser to identify the following:

- the site that sent the cookie

- how long it should remember the cookie value

On each subsequent request made by that user, until the cookie expires, the browser sends the cookie along in the header of the request. The server uses the value of the cookie to distinguish between requests made by different users.

A cookie that expires when you close your browser is known as a session cookie, while other cookies that are set to live beyond a single browser session might expire in a week, a month, or a year from when they were first created.

**Figure 40–2 Tracking State Using a Session Cookies and Server-Side Session**

Java EE-compliant web servers provide a standard server-side facility called the `HttpSession` that allows a web application to store Java objects related to a particular user's session as named attribute/value pairs. An object placed in this session `Map` on one request can be retrieved by the application while handling a subsequent request during the same session.

The session remains active while the user continues to send new requests within the timeframe configured by the `<session-timeout>` element in the `web.xml` file. The default session length is 35 minutes.

#### 40.1.4 Performance and Reliability Impact of Using `HttpSession`

The `HttpSession` facility is an ingredient in most application state management strategies, but it can present performance and reliability problems if not used judiciously. First, because the session-scope Java objects you create are held in the memory of the Java EE web server, the objects in the HTTP session are lost if the server should fail.

As shown in [Figure 40–3](#), one way to improve the reliability is to configure multiple Java EE servers in a cluster. By doing this, the Java EE application server replicates the objects in the HTTP session for each user across multiple servers in the cluster so that if one server goes down, the objects exist in the memory of the other servers in the cluster that can continue to handle the users requests. Since the cluster comprises separate servers, replicating the HTTP session contents among them involves broadcasting the changes made to HTTP session objects over the network.

**Figure 40-3 Session Replication in a Server Cluster**

You can begin to see some of the performance implications of overusing the HTTP session:

- The more active users, the more HTTP sessions will be created on the server.
- The more objects stored in each HTTP session, the more memory you will need. Note that the memory is not reclaimed when the user becomes inactive; this only happens with a session timeout or an explicit session invalidation. Session invalidations don't always happen because users don't always logout.
- In a cluster, the more objects in each HTTP session that *change*, the more network traffic will be generated to replicate the changed objects to other servers in the cluster.

At the outset, it would seem that keeping the number of objects stored in the session to a minimum addresses the problem. However, this implies leveraging an alternative mechanism for temporary storage for each user's pending application state. The most popular alternatives involve saving the application state to the database between requests or to a file of some kind on a shared file system.

Of course, this is easier said than done. A possible approach involves eagerly saving the pending changes to your underlying database tables and committing the transaction at the end of each HTTP request. But this idea has two key drawbacks:

- *Your database constraints might fail.*  
At any given step of the multi-step process, the information may only be partially complete, and this could cause errors at the database level when trying to save the changes.
- *You complicate rolling back the changes.*  
Cancelling the logical of unit of work would involve carefully deleting all of the eagerly-committed rows in possible multiple tables.

These limitations have led developers in the past to invent solutions involving a "shadow" set of database tables with no constraints and with all of the column types defined as character-based. Using such a solution becomes very complex very quickly. Ultimately, you will conclude that you need some kind of generic application state management facility to address these issues in a more generic and workable way. The solution comes in the form of ADF Business Components, which implements this for you out of the box.

## 40.2 Introduction to Fusion Web Application State Management

State management enables you to easily create web applications that support multi-step use cases without falling prey to the memory, reliability, or implementation complexity problems described in [Section 40.1, "Understanding Why State Management is Necessary."](#)

Application state management is provided at two levels, by the Save For Later feature in a task flow, and application module state management in the model layer.

Save For Later is activated at the controller layer and automatically saves a "snapshot" of the current UI and controller states, and delegates to the model layer to *passivate* (save) its state as well.

If you are not using ADF data controls, you can still use application module state management alone, but since this will save only the model state, this is an outside case for most applications.

### 40.2.1 Basic Architecture of the Save for Later Facility

Save for Later saves an incomplete transaction without enforcing validation rules or submitting the data. The end user can resume working on the same transaction later with the same data that was originally saved when the application was exited.

### 40.2.2 Basic Architecture of the Application Module State Management Facility

Your ADF Business Components-based application automatically manages the application state of each user session. This provides the simplicity of a stateful programming model that you are accustomed to in previous 4GL tools, yet implemented in a way that delivers scalability nearing that of a purely stateless application. Understanding what happens behind the scenes is essential to make the most efficient use of this important feature.

You can use application module components to implement completely stateless applications or to support a unit of work that spans multiple browser pages. [Figure 40–4](#) illustrates the basic architecture of the state management facility to support these multi-step scenarios. An application module supports *passivating* (storing) its pending transaction state to an XML document, which is stored in the database in a single, generic table, keyed by a unique passivation snapshot ID. It also supports the reverse operation of *activating* pending transaction state from one of these saved XML snapshots. This passivation and activation is performed automatically by the application module pool when needed.

**Figure 40–4 ADF Provides Generic, Database-Backed State Management**

The ADF binding context is the one object that lives in the `HttpSession` for each end user. It holds references to lightweight application module data control objects that manage acquiring an application module instance from the pool during the request (when the data control is accessed) and releasing it to the pool at the end of each request. The data control holds a reference to the ADF session cookie that identifies the user session. In particular, business domain objects created or modified in the pending transaction are *not* saved in the `HttpSession` using this approach. This minimizes both the session memory required per user and eliminates the network traffic related to session replication if the servers are configured in a cluster.

For improved reliability, serialize your session objects. Objects stored in distributed sessions need to implement the `java.io.Serializable` interface. Implementing this interface ensures the data can be transported over-the-wire to each server instance in the cluster. Use a custom method like the `addObjectToSession(String key, Serializable value)` method, instead of the default `HttpSession.setAttribute(String key, Object value)` method when adding session data. The distinction is, if you were to call the `addObjectToSession()` method with a non-serializable object, you would see a compile-time error. If you were to try to replicate a session object that had non-serializable objects placed into session with the `put()` method, you would see a runtime error and potentially, a broken user experience.

Additionally, if you have multiple application servers and you enable the optional ADF Business Components failover support (explained in [Section 40.2.2.2, "How Passivation Changes When Optional Failover Mode is Enabled"](#)), then subsequent end-user requests can be handled by any server in your server farm or cluster. The session cookie can reactivate the pending application state from the database-backed XML snapshot if required, regardless of which server handles the request.

#### 40.2.2.1 Understanding When Passivation and Activation Occurs

To better understand when the automatic passivation and activation of application module state occurs, consider the following simple case:

1. At the beginning of an HTTP request, the application module data control handles the `beginRequest` event by checking out an application module instance from the pool.

The application module pool returns an *unreferenced* instance. An unreferenced application module is one that is not currently managing the pending state for any other user session.

2. At the end of the request, the application module data control handles the `endRequest` event by checking the application module instance back into the pool in "managed state" mode.

That application module instance is now *referenced* by the data control that just used it. And the application module instance is an object that still contains pending transaction state made by the data control (that is, entity object and view object caches; updates made but not committed; and cursor states), stored in memory. As you'll see below, it's not *dedicated* to this data control, just referenced by it.

3. On a subsequent request, the same data control — identified by its `SessionCookie` — checks out an application module instance again.

Due to the "stateless with user affinity" algorithm the pool uses, you might assume that the pool returns the exact same application module instance, with the state still there in memory. (To understand this algorithm, read [Section 41.1, "Introduction to Application Module Pooling"](#) and the discussion of Referenced Pool Size in [Section 41.2.7.2, "Pool Sizing Parameters."](#))

Sometimes due to a high number of users simultaneously accessing the site, application module instances must be sequentially reused by different user sessions. In this case, the application pool must *recycle* a currently referenced application module instance for use by another session, as follows:

1. The application module data control for User A's session checks an application module instance into the application pool at the end of a request. Assume this instance is named `AM1`.
2. The application module data control for User Z's new session requests an application module instance from the pool for the first time, but there are no unreferenced instances available. The application module pool then:
  - Passivates the state of instance `AM1` to the database.
  - Resets the state of `AM1` in preparation to be used by another session.
  - Returns the `AM1` instance to User Z's data control.
3. On a subsequent request, the application module data control for User A's session requests an application module instance from the pool. The application module pool then:
  - Obtains an unreferenced instance.
    - This could be instance `AM1`, obtained by following the same steps as in (2) above, or another `AM2` instance if it had become unreferenced in the meantime.
  - Activates the appropriate pending state for User A from the database.
  - Returns the application module instance to User A's data control.

The process of passivation, activation, and recycling allows the state referenced by the data control to be preserved across requests without requiring a dedicated application module instance for each data control. Both browser users in the above scenario are carrying on an application transaction that spans multiple HTTP requests, but the end users are unaware whether the passivation and activation is occurring in the background. They just continue to see the pending changes. In the process, the

pending changes never need to be saved into the underlying application database tables until the end user is ready to commit the logical unit of work.

Note that this keeps the session memory footprint low because the only business component objects that are directly referenced by the session (and are replicable) are the data control and the session cookie.

The application module pool makes a best effort to keep an application module instance "sticky" to the current data control whose pending state it is managing. This is known as maintaining user session affinity. The best performance is achieved if a data control continues to use exactly the same application module instance on each request, since this avoids any overhead involved in reactivating the pending state from a persisted snapshot.

#### 40.2.2.2 How Passivation Changes When Optional Failover Mode is Enabled

The `jbo.dofailover` parameter controls when and how often passivation occurs. You can set this parameter in your application module configuration on the **Pooling and Scalability** tab of the Business Components Configuration dialog. When the failover feature is disabled, which it is by default, then application module pending state will only be passivated on demand when it must be. This occurs just before the pool determines it must hand out a currently-referenced application module instance to a *different* data control.

---

---

**Note:** Passivation can also occur when an application module is timed out. For more information about application pool removal algorithms (such as `jbo.ampool.timetolive`), see [Section 41.2.7.3, "Pool Cleanup Parameters."](#)

---

---

In contrast, with the failover feature turned on, the application module's pending state is passivated every time it is checked back into application module pool. This provides the most pessimistic protection against application server failure. The application module instances' state is always saved and may be activated by any application module instance at any time. Of course, this capability comes at expense of the additional overhead of eager passivation on each request.

When failover is turned on, a failure can occur when Oracle WebLogic Server is configured to forcibly release connections back into the pool. A failure of this type produces a `SQLException` (Connection has already been closed.) that is saved to the server log. The exception is not reported through the user interface. To ensure that state passivation occurs and users' changes are saved, the server administrator should set an appropriate value for the `weblogic-application.xml` deployment descriptor parameter `inactive-connection-timeout-seconds` on the `<connection-check-params>` pool params element. Setting the deployment descriptor parameter to several minutes, in most cases, should avoid forcing the inactive connection timeout and the resulting passivation failure. Adjust the setting as needed for your environment.

---

---

**Note:** When running or debugging an application that uses failover support within the JDeveloper environment, you are frequently starting and stopping the application server. The ADF failover mechanism has no way of knowing whether you stopped the server to simulate an application server failure, or whether you stopped it because you want to retest something from scratch in a fresh server instance. If you intend to do the latter, exit out of your browser before restarting the application on the server. This eliminates the chance that you will be confused by the correct functioning of the failover mechanism when you didn't intend to be testing that aspect of your application.

---

---

### 40.2.2.3 About State Management Release Levels

When a data control handles the `endRequest` notification indicating the processing for the current HTTP request has completed, it releases the application module instance by checking it back into the application module pool. The application module pool manages instances and performs state management tasks (or not) based on the *release level* you use when returning the instance to the pool.

There are three release levels used for returning an instance of an application module to a pool:

- **Managed** - This is the default level, where the application module pool prefers to keep the same application module instance for the same data control, but may release an instance if necessary.
- **Unmanaged** - No state needs to be preserved beyond the current request.
- **Reserved** - A one-to-one relationship is preserved between an application module instance and a data control.

---

---

**Caution:** In general, it is strongly recommended never to use Reserved release level. You would normally avoid using this mode because the data control to application module correlation becomes one to one, the scalability of the application reduces very sharply, and so does reliability of the application.

---

---

**40.2.2.3.1 About Managed Release Level** This is the default release level and implies that application module's state is relevant and has to be preserved for this data control to span over several HTTP requests. Managed level does not guarantee that for the next request this data control will receive the same physical application module instance, but it does guarantee that an application module with identical state will be provided so it is logically the same application module instance each time. It is important to note that the framework makes the best effort it can to provide the same instance of application module for the same data control if it is available at the moment. This is done for better performance since the same application module does not need to activate the previous state which it still has intact after servicing the same data control during previous request. However, the data control is not guaranteed to receive the same instance for all its requests and if the application module that serviced that data control during previous is busy or unavailable, then a different application module will activate this data control's state. For this reason, it is not valid to cache references to application module objects, view objects, or view rows across HTTP requests in controller-layer code.

This mode was called the "Stateful Release Mode" in previous releases of JDeveloper.

---

---

**Note:** If the `jbo.ampool.doampooling` configuration property is `false` — corresponding to your unchecking the **Enable Application Module Pooling** option in the **Pooling and Scalability** tab of the Business Components Configuration dialog — then there is effectively no pool. In this case, when the application module instance is released at the end of a request it is immediately removed. On subsequent requests made by the same user session, a new application module instance must be created to handle each user request, and pending state must be reactivated from the passivation store. Setting this property to `false` is useful to discover problems in your application logic that might occur when reactivation does occur due to unpredictable load on your system. However, the property `jbo.ampool.doampooling` set to `false` is not a supported configuration for production applications and must be set to `true` before you deploy your application. For further details, see [Section 40.10, "Testing to Ensure Your Application Module is Activation-Safe."](#)

---

---

**40.2.2.3.2 About Unmanaged Release Level** This mode implies that no state associated with this data control has to be preserved to survive beyond the current HTTP request. This level is the most efficient in performance because there is no overhead related to state management. However, you should limit its use to applications that require no state management, or to cases when state no longer needs to be preserved at this point. Usually, you can programmatically release the application module with the unmanaged level when you want to signal that the user has ended a logical unit of work.

**Performance Tip:** .The default release level is Managed, which implies that the application module's state is relevant and has to be preserved to allow the data control to span over several HTTP requests. Set release level to Unmanaged programmatically at runtime for particular pages to eliminate passivation and achieve better performance. A typical example is releasing the application module after servicing the HTTP request from a logout page.

This mode was called the "Stateless Release Mode" in previous releases of JDeveloper.

**40.2.2.3.3 About Reserved Release Level** This level guarantees that each data control will be assigned its own application module during its first request and for all subsequent requests coming from the `HttpSession` associated with this data control. This data control will always receive the same physical instance of application module. This mode exists for legacy compatibility reasons and for very rare special use cases.

An example of using Reserved level occurs when there is a pending database state across a request resulting from the `postChanges()` method or a PL/SQL stored procedure but not issuing a `commit()` or `rollback()` at the end of the request. In this case, if any other release level is used instead of Reserved, when the application module instance is recycled, a rollback is issued on the database connection associated with this application module instance and all uncommitted changes would be lost.

**Performance Tip:** If you must use Reserved level, call `setReleaseLevel()` on the data control to keep its period as short as possible. For details about changing the release level programmatically, see [Section 40.4, "Setting the Application Module Release Level at Runtime."](#)

Consequences of Reserved mode can be adverse. Reliability suffers because if for whatever reason the application module is lost, the data control will not be able to receive any other application module in its place from the pool, and so `HttpSession` gets lost as well, which is not the case for managed level.

The failover option is ignored for an application module released with Reserved release level since its use implies your application absolutely requires working with the same application module instance on each request.

#### 40.2.2.4 State Management and Subclassed Entity Objects

If your application employs subclassed entity objects, the key attribute of new entities must be prepopulated. If the key is not prepopulated, passivation and activation will fail. You can prepopulate the key attribute by overriding the `create()` method or by using the `DBSequence` type that will assign a temporary negative value to the key before the real value is fetched from the database after commit. For more information, see [Section 4.10.10, "How to Get Trigger-Assigned Primary Key Values from a Database Sequence."](#)

### 40.2.3 What You May Need to Know About Using Application Scoped Managed Beans in a Clustered Environment

JSF Application Scope beans are backed by a servlet context which can only have one instance per cluster node. Therefore, for each design time configured bean, there will be a runtime instance of the bean for each node in a cluster. Because there is no synchronization across nodes, each instance of the application running on different nodes will have separate instances of that bean with separate values. Therefore, application scoped managed beans should not be used to carry application-wide values that can be updated to be shared across all nodes in a cluster. They can, however, be used to carry constants, read-only values, or values to reflect the state of a single node within the cluster (such as the number of users on a node).

## 40.3 Using Save For Later

To enable Save For Later, you must first add Save Points to the application at points where you would like application state and data to be preserved if the end user leaves the application. You can use it to save data and state information about a region, view port, or portlet. Later, you use the Save Point Restore activity to restore application state and data associated with a Save Point.

For more information on how create and restore Save Points, see [Section 18.9, "Using Save Points in Task Flows."](#)

Save For Later can also perform implicit saves. These occur when data is saved automatically without the end user performing an explicit Save action when the user session times out or closes the browser window, for example.

For more information on how to perform an implicit save, see [Section 18.9, "Using Save Points in Task Flows."](#)

## 40.4 Setting the Application Module Release Level at Runtime

If you do not want to use the default "Managed State" release level for application modules, you can set your desired level programmatically.

### 40.4.1 How to Set Unmanaged Level

To set a data control to release its application module using the unmanaged level, call the `resetState()` method on the `DCDataControl` class (in the `oracle.adf.model.binding` package).

You can call this method any time during the request. This will cause application module not to passivate its state at all when it is released to the pool at the end of the request. Note that this method only affects the current application module instance in the current request. After this, the application module is released in unmanaged level to the pool, it becomes unreferenced and gets reset. The next time the application module is used by a client, it will be used in the managed level again by default.

---

**Note:** You can programmatically release the application module with the unmanaged level when you want to signal that the user has ended a logical unit of work. This will happen automatically when the `HTTPSession` times out, as described below.

---

### 40.4.2 How to Set Reserved Level

To set a data control to release its application module using the reserved level, call the `setReleaseLevel()` method of the `DCJboDataControl` class (in the `oracle.adf.model.bc4j` package), and pass the integer constant `ApplicationModule.RELEASE_LEVEL_RESERVED`.

When the release level for an application module has been changed to "Reserved" it will stay so for all subsequent requests until explicitly changed.

### 40.4.3 How to Set Managed Level

If you have set an application module to use reserved level, you can later set it back to use managed level by calling the `setReleaseLevel()` method of the `DCJboDataControl` class, and passing the integer constant `ApplicationModule.RELEASE_LEVEL_MANAGED`.

### 40.4.4 How to Set Release Level in a JSF Backing Bean

[Example 40–1](#) shows calling the `resetState()` method on a data control named `UserModuleDataControl` from the action method of a JSF backing bean.

**Example 40–1 Calling `resetState()` on Data Control in a JSF Backing Bean Action Method**

```
package devguide.advanced.releasestateless.controller.backing;
import devguide.advanced.releasestateless.controller.JSFUtils;
import oracle.adf.model.BindingContext;
import oracle.adf.model.binding.DCDataControl;
/**
 * JSF Backing bean for the "Example.jspx" page
 */
public class Example {
    /**
     * In an action method, call resetState() on the data control to cause
```

```

    * it to release to the pool with the "unmanaged" release level.
    * In other words, as a stateless application module.
    */
public String commandButton_action() {
    // Add event code here...
    getDataControl("UserModuleDataControl").resetState();
    return null;
}
private DCDataControl getDataControl(String name) {
    BindingContext bc =
        (BindingContext)JSFUtils.resolveExpression("#{data}");
    return bc.findDataControl(name);
}
}

```

#### 40.4.5 How to Set Release Level in an ADF PagePhaseListener

[Example 40–2](#) shows calling the `resetState()` method on a data control named `UserModuleDataControl` from the `after-prepareRender` phase of the ADF lifecycle using a custom ADF page phase-listener class. You would associate this custom class to a particular page by setting the `ControllerClass` attribute on the page's page definition to the fully-qualified name of this class.

##### **Example 40–2** *Calling `resetState()` on Data Control in a Custom `PagePhaseListener`*

```

package devguide.advanced.releasestateless.controller;
import oracle.adf.controller.v2.lifecycle.Lifecycle;
import oracle.adf.controller.v2.lifecycle.PagePhaseEvent;
import oracle.adf.controller.v2.lifecycle.PagePhaseListener;
import oracle.adf.model.binding.DCDataControl;
public class ReleaseStatelessPagePhaseListener
    implements PagePhaseListener {
    /**
     * In the "after" phase of the final "prepareRender" ADF Lifecycle
     * phase, call resetState() on the data control to cause it to release
     * to the pool with the "unmanaged" release level. In other words,
     * as a stateless application module.
     *
     * @param event ADF page phase event
     */
    public void afterPhase(PagePhaseEvent event) {
        if (event.getPhaseId() == Lifecycle.PREPARE_RENDER_ID) {
            getDataControl("UserModuleDataControl", event).resetState();
        }
    }
    // Required to implement the PagePhaseListener interface
    public void beforePhase(PagePhaseEvent event) {}
    private DCDataControl getDataControl(String name,
                                         PagePhaseEvent event) {
        return event.getLifecycleContext()
            .getBindingContext()
            .findDataControl(name);
    }
}

```

#### 40.4.6 How to Set Release Level in an ADF PageController

[Example 40–3](#) shows calling the `resetState()` method on a data control named `UserModuleDataControl` from an overridden `prepareRender()` method of a custom

ADF page controller class. You would associate this custom class to a particular page by setting the `ControllerClass` attribute on the page's page definition to the fully-qualified name of this class.

---

**Note:** You can accomplish basically the same kinds of page-specific lifecycle customization tasks using a custom `PagePhaseListener` or a custom `PageController` class. The key difference is that the `PagePhaseListener` interface can be implemented on any class, while a custom `PageController` must extend the `PageController` class in the `oracle.adf.controller.v2.lifecycle` package.

---

**Example 40–3 Calling `resetState()` on Data Control in a Custom ADF PageController**

```
package devguide.advanced.releasestateless.controller;
import oracle.adf.controller.v2.context.LifecycleContext;
import oracle.adf.controller.v2.lifecycle.PageController;
import oracle.adf.controller.v2.lifecycle.PagePhaseEvent;
import oracle.adf.model.binding.DCDataControl;
public class ReleaseStatelessPageController extends PageController {
    /**
     * After calling the super in the final prepareRender() phase
     * of the ADF Lifecycle, call resetState() on the data control
     * to cause it to release to the pool with the "unmanaged"
     * release level. In other words, as a stateless application module.
     *
     * @param lcCtx ADF lifecycle context
     */
    public void prepareRender(LifecycleContext lcCtx) {
        super.prepareRender(lcCtx);
        getDataControl("UserModuleDataControl", lcCtx).resetState();
    }
    private DCDataControl getDataControl(String name,
                                         LifecycleContext lcCtx) {
        return lcCtx.getBindingContext().findDataControl(name);
    }
}
```

#### 40.4.7 How to Set Release Level in an Custom ADF PageLifecycle

If you wanted to build a Fusion web application where every request was handled in a completely stateless way, use a global custom `PageLifecycle` class as shown in [Example 40–4](#). For details on how to configure your application to use your custom lifecycle see [Section 21.2, "The JSF and ADF Page Lifecycles."](#)

**Example 40–4 Calling `resetState()` on Data Control in a Custom ADF PageLifecycle**

```
package devguide.advanced.releasestateless.controller;
import oracle.adf.controller.faces.lifecycle.FacesPageLifecycle;
import oracle.adf.controller.v2.context.LifecycleContext;
import oracle.adf.model.binding.DCDataControl;
public class ReleaseStatelessPageLifecycle extends FacesPageLifecycle {
    /**
     * After calling the super in the final prepareRender() phase
     * of the ADF Lifecycle, call resetState() on the data control
     * to cause it to release to the pool with the "unmanaged"
     * release level. In other words, as a stateless application module.
     *
     * @param lcCtx ADF lifecycle context
     */
}
```

```

*/
public void prepareRender(LifecycleContext lcCtx) {
    super.prepareRender(lcCtx);
    getDataControl("UserModuleDataControl", lcCtx).resetState();
}
private DCDataControl getDataControl(String name,
                                     LifecycleContext lcCtx) {
    return lcCtx.getBindingContext().findDataControl(name);
}
}

```

## 40.5 What Model State Is Saved and When It Is Cleaned Up

The information saved by application model passivation is divided in two parts: transactional and non-transactional state. Transactional state is the set of updates made to entity object data – performed either directly on entity objects or on entities through view object rows – that are intended to be saved into the database. Non-transactional state comprises view object runtime settings, such as the current row index, WHERE clause, and ORDER BY clause.

### 40.5.1 State Information Saved During Passivation

The information saved as part of the application module passivation "snapshot" includes the following.

#### Transactional State

- New, modified, and deleted entities in the entity caches of the root application module for this user session's (including old/new values for modified ones).

#### Non-Transactional State

- For each active view object (both statically and dynamically created):
  - Current row indicator for each row set (typically one)
  - New rows and their positions. (New rows are treated differently than updated ones. Their index in the view object is traced as well.)
  - ViewCriteria and all related parameters such as view criteria row, etc.
  - Flag indicating whether or not a row set has been executed
  - Range start and Range size
  - Access mode
  - Fetch mode and fetch size
  - Any view object-level custom data

---

**Note:** Transient view object attributes can be saved if they are selected for passivation at design time. However, use this feature judiciously because this results in a snapshot that will grow in size with the number of rows that have been retrieved.

---

- SELECT, FROM, WHERE, and ORDER BY clause if created dynamically or changed from the View definition

---

---

**Note:** If you enable ADF Business Components runtime diagnostics, the contents of each XML state snapshot are also saved. See [Section 6.3.8, "How to Enable ADF Business Components Debug Diagnostics"](#) for information on how to enable diagnostics.

---

---

## 40.5.2 Where the Model State Is Saved

By default, passivation snapshots are saved in the database, but you can configure it to use the file system as an alternative.

### 40.5.2.1 How Database-Backed Passivation Works

The passivated XML snapshot is written to a BLOB column in a table named `PS_TXN`, using a connection specified by the `jbo.server.internal_connection` property. Each time a passivation record is saved, it is assigned a unique passivation snapshot ID based on the sequence number taken from the `PS_TXN_SEQ` sequence. The ADF session cookie held by the application module data control in the ADF binding context remembers the latest passivation snapshot ID that was created on its behalf and remembers the previous ID that was used.

### 40.5.2.2 Controlling the Schema Where the State Management Table Resides

The ADF runtime recognizes a configuration property named `jbo.server.internal_connection` that controls which database connection and schema should be used for the creation of the `PS_TXN` table and the `PS_TXN_SEQ` sequence. If you don't set the value of this configuration parameter explicitly, then the state management facility creates the temporary tables using the credentials of the current application database connection.

To keep the temporary information separate, the state management facility uses a different connection *instance* from the database connection pool, but the database credentials are the same as the current user. Since the framework creates temporary tables, and possibly a sequence if they don't already exist, the implication of not setting a value for the `jbo.server.internal_connection` is that the current database user must have `CREATE TABLE`, `CREATE INDEX` and `CREATE SEQUENCE` privileges. Since this is often not desirable, Oracle recommends always supplying an appropriate value for the `jbo.server.internal_connection` property, providing the credentials for a state management schema where table and schema be created. Valid values for the `jbo.server.internal_connection` property in your configuration are:

- A fully-qualified JDBC connection URL like:  
`jdbc:oracle:thin:username/password@host:port:SID`
- A JDBC datasource name like:  
`java:/comp/env/jdbc/YourJavaEEDataSourceName`

**Performance Tip:** When creating the `PS_TXN` table, use `securefiles` to store LOB data (the content column), and create a primary column index on the `PS_TXN` table as global, partitioned reverse key index. The `securefile` configuration delivers superior performance over the `basicfile` configuration when working with LOB data. The reverse key index helps by reducing contention that can happen when the rate of inserts is high.

### 40.5.2.3 Configuring the Type of Passivation Store

Passivated information can be stored in several places. You can control it programmatically or by configuring an option in the application module configuration. The choices are database or a file stored on local file system:

- **File**

This choice may be the fastest available, because access to the file is faster than access to the database. This choice is good if the entire middle tier is either installed on the same machine or has access to a commonly shared file system, so passivated information is accessible to all. Usually, this choice may be good for a small middle tier where one Oracle WebLogic Server domain is used. In other words this is a very suitable choice for small middle tier such as one Oracle WebLogic Server instance with all its components installed on one physical machine. The location and name of the persistent snapshot files are determined by `jbo.tmpdir` property if specified. It follows usual rules of ADF property precedence for a configuration property. If nothing else is specified, then the location is determined by `user.dir` if specified. This is a default property and the property is OS specific.

- **Database**

This is the *default* choice. While it may be a little slower than passivating to file, it is by far the most reliable choice. With passivation to file, the common problem might be that it is not accessible to Oracle WebLogic Server instances that are remotely installed. In this case, in a cluster environment, if one node goes down the other may not be able to access passivated information and then failover will not work. Another possible problem is that even if file is accessible to the remote node, the access time for the local and remote node may be very different and performance will be inconsistent. With database access, time should be about the same for all nodes.

To set the value of your choice in design time, set the property `jbo.passivationstore` to `database` or `file`. The value `null` will indicate that a connection-type-specific default should be used. This will use database passivation for Oracle or DB2, and file serialization for any others.

To set the storage programmatically use the method `setStoreForPassiveState()` of interface `oracle.jbo.ApplicationModule`. The parameter values that you can pass are:

- `PASSIVATE_TO_DATABASE`
- `PASSIVATE_TO_FILE`

## 40.5.3 Cleaning Up the Model State

Under normal circumstances, the ADF state management facility provides automatic cleanup of the passivation snapshot records.

### 40.5.3.1 Previous Snapshot Removed When Next One Taken

When a passivation record is saved to the database on behalf of a session cookie, as described above, this passivation record gets a new, unique snapshot ID. The passivation record with the previous snapshot ID used by that same session cookie is deleted as part of the same transaction. In this way, assuming no server failures, there will only ever be a single passivation snapshot record per active end-user session.

### 40.5.3.2 Passivation Snapshot Removed on Unmanaged Release

The passivation snapshot record related to a session cookie is removed when the application module is checked into the pool with the unmanaged state level. This can occur when:

- Your code specifically calls `resetState()` on the application module data control.
- Your code explicitly invalidates the `HttpSession`, for example, as part of implementing an explicit "Logout" functionality.
- The `HttpSession` times out due to exceeding the session timeout threshold for idle time and failover mode is disabled (which is the default).

In each of these cases, the application module pool also resets the application module referenced by the session cookie to be "unreferenced" again. Since no changes were ever saved into the underlying database tables, once the pending session state snapshots are removed, there remains no trace of the unfinished work the user session had completed up to that point.

### 40.5.3.3 Passivation Snapshot Retained in Failover Mode

When the failover mode is enabled, if the `HttpSession` times out due to session inactivity, then the passivation snapshot is retained so that the end user can resume work upon returning to the browser.

After a break in the action, when the end user returns to his browser and continues to use the application, it continues working as if nothing had changed. The session cookie is used to reactivate any available application module instance with the user's last pending state snapshot before handling the request. So, even though the user's next request will be processed in the context of a new `HttpSession` (perhaps even in a different application server instance), the user is unaware that this has occurred.

---

---

**Note:** If an application module was released with reserved level then the `HttpSession` times out, the user will have to go through authentication process, and all unsaved changes are lost.

---

---

## 40.5.4 Cleaning Up Temporary Storage Tables

JDeveloper provides the `adfbcpurge_statesnapshots.sql` script to help with periodically cleaning up the application module state management table. You can find this file in the `oracle_common` subdirectory of your Oracle Middleware installation directory (for example, `ORACLE_HOME\oracle_common\common\sql`).

Persistent snapshot records can accumulate over time if the server has been shutdown in an abnormal way, such as might occur during development or due to a server failure. Running the script in SQL\*Plus will create the `BC4J_CLEANUP` PL/SQL package. The two relevant procedures in this package are:

- `PROCEDURE Session_State(olderThan DATE)`

This procedure cleans-up application module session state storage for sessions older than a given date.

- `PROCEDURE Session_State(olderThan_minutes INTEGER)`

This procedure cleans-up application module session state storage for sessions older than a given number of minutes.

You can schedule periodic cleanup of your ADF temporary persistence storage by submitting an invocation of the appropriate procedure in this package as a database job.

You can use an anonymous PL/SQL block like the one shown in [Example 40–5](#) to schedule the execution of `bc4j_cleanup.session_state()` to run starting tomorrow at 2:00am and each day thereafter to cleanup sessions whose state is over 1 day (1440 minutes) old.

#### **Example 40–5 Scheduling Periodic Cleanup of the State Management Table**

```
SET SERVEROUTPUT ON
DECLARE
  jobId    BINARY_INTEGER;
  firstRun DATE;
BEGIN
  -- Start the job tomorrow at 2am
  firstRun := TO_DATE(TO_CHAR(SYSDATE+1,'DD-MON-YYYY')||' 02:00',
    'DD-MON-YYYY HH24:MI');
  -- Submit the job, indicating it should repeat once a day
  dbms_job.submit(job      => jobId,
    -- Run the ADF Purge for Session State
    -- to cleanup sessions older than 1 day (1440 minutes)
    what      => 'bc4j_cleanup.session_state(1440);',
    next_date => firstRun,
    -- When completed, automatically reschedule
    -- for 1 day later
    interval  => 'SYSDATE + 1'
  );
  dbms_output.put_line('Successfully submitted job. Job Id is '||jobId);
END;
/
```

## 40.6 Timing Out the HttpSession

Since HTTP is a stateless protocol, the server receives no implicit notice that a client has closed his browser or gone away for the weekend. Therefore any Java EE-compliant server provides a standard, configurable session timeout mechanism to allow resources tied to the HTTP session to be freed when the user has stopped performing requests. You can also programmatically force a timeout.

### 40.6.1 How to Configure the Implicit Timeout Due to User Inactivity

You configure the session timeout threshold using the `<session-timeout>` tag in the `web.xml` file. The default value is 35 minutes. When the `HttpSession` times out the `BindingContext` goes out of scope, and along with it, any data controls that might have referenced application modules released to the pool in the managed state level. The application module pool resets any of these referenced application modules and marks the instances unreferenced again.

### 40.6.2 How to Code an Explicit HttpSession Timeout

To end a user's session before the session timeout expires, you can call the `invalidate()` method on the `HttpSession` object from a backing bean in response to the user's click on a Logout button or link. This cleans up the `HttpSession` in the same way as if the session time had expired. Using JSF and ADF, after invalidating the session, you *must* perform a redirect to the next page you want to display, rather than

just doing a forward. [Example 40–6](#) shows sample code to perform this task from a Logout button.

**Example 40–6 Programatically Terminating a Session**

```
public String logoutButton_action() throws IOException{
    ExternalContext ectx = FacesContext.getCurrentInstance().getExternalContext();
    HttpServletResponse response = (HttpServletResponse)ectx.getResponse();
    HttpSession session = (HttpSession)ectx.getSession(false);
    session.invalidate();
    response.sendRedirect("Welcome.jspx");
    return null;
}
```

As with the implicit timeouts, when the HTTP session is cleaned up this way, it ends up causing any referenced application modules to be marked unreferenced.

## 40.7 Managing Custom User-Specific Information

It is fairly common practice to add custom user-defined information in the application module in the form of member variables or some custom information stored in `oracle.jbo.Session` user data hashtable. The ADF state management facility provides a mechanism to save this custom information to the passivation snapshot as well, by overriding the `passivateState()` method and the `activateState()` method in the `ApplicationModuleImpl` class.

---

---

**Note:** Similar methods are available on the `ViewObjectImpl` class and the `EntityObjectImpl` class to save custom state for those objects to the passivation snapshot as well.

---

---

### 40.7.1 How to Passivate Custom User-Specific Information

You can override `passivateState()` and `activateState()` to ensure that custom application module state information is included in the passivation/activation cycle. [Example 40–7](#) shows how this is done.

In the example, `jbo.counter` contains custom values you want to preserve across passivation and activation of the application module state. Each application module has an `oracle.jbo.Session` object associated with it that stores application module-specific session-level state. The session contains a user data hashtable where you can store transient information. For the user-specific data to "survive" across application module passivation and reactivation, you need to write code to save and restore this custom value into the application module state passivation snapshot.

**Example 40–7 Passivating and Activating Custom Information in the State Snapshot XML Document**

```
/**
 * Overridden framework method to passivate custom XML elements
 * into the pending state snapshot document
 */
public void passivateState(Document doc, Element parent) {
    // 1. Retrieve the value of the value to save
    int counterValue = getCounterValue();
    // 2. Create an XML element to contain the value
    Node node = doc.createElement(COUNTER);
    // 3. Create an XML text node to represent the value
```

```

Node cNode = doc.createTextNode(Integer.toString(counterValue));
// 4. Append the text node as a child of the element
node.appendChild(cNode);
// 5. Append the element to the parent element passed in
parent.appendChild(node);
}
/**
 * Overridden framework method to activate custom XML elements
 * into the pending state snapshot document
 */
public void activateState(Element elem) {
    super.activateState(elem);
    if (elem != null) {
        // 1. Search the element for any <jbo.counter> elements
        NodeList nl = elem.getElementsByTagName(COUNTER);
        if (nl != null) {
            // 2. If any found, loop over the nodes found
            for (int i=0, length = nl.getLength(); i < length; i++) {
                // 3. Get first child node of the <jbo.counter> element
                Node child = nl.item(i).getFirstChild();
                if (child != null) {
                    // 4. Set the counter value to the activated value
                    setCounterValue(new Integer(child.getNodeValue()).intValue()+1);
                    break;
                }
            }
        }
    }
}
}
}
/**
 * Helper Methods
 */
private int getCounterValue() {
    String counterValue = (String)getSession().getUserData().get(COUNTER);
    return counterValue == null ? 0 : Integer.parseInt(counterValue);
}
private void setCounterValue(int i) {
    getSession().getUserData().put(COUNTER, Integer.toString(i));
}
private static final String COUNTER = "jbo.counter";

```

## 40.7.2 What Happens When You Passivate Custom Information

In [Example 40-7](#), when `activateState()` is overridden, the following steps are performed:

1. Search the element for any `jbo.counter` elements.
2. If any are found, loop over the nodes found in the node list.
3. Get first child node of the `jbo.counter` element.

It should be a DOM Text node whose value is the string you saved when your `passivateState()` method above got called, representing the value of the `jbo.counter` attribute.

4. Set the counter value to the activated value from the snapshot.

When `passivateState()` is overridden, it performs the reverse job by doing the following:

1. Retrieve the value of the value to save.

2. Create an XML element to contain the value.
3. Create an XML text node to represent the value.
4. Append the text node as a child of the element.
5. Append the element to the parent element passed in.

---

---

**Note:** The API's used to manipulate nodes in an XML document are provided by the Document Object Model (DOM) interfaces in the `org.w3c.dom` package. These are part of the Java API for XML Processing (JAXP). See the Javadoc for the `Node`, `Element`, `Text`, `Document`, and `NodeList` interfaces in this package for more details.

---

---

### 40.7.3 What You May Need to Know About Activating Custom Information

The `activateState()` method is called at the end of the activation process after the view objects have been activated. Most of the time this is where you want to place the application module state activation logic. However, if your application module activation logic needs to set up custom state information before the ADF state management facility activates the view objects (for example, you might need to write custom code to allow the view objects to internally reference custom values at execution time), then the `prepareForActivation()` method in the `ApplicationModuleImpl` class would be the right place because it fires at the beginning of the activation process.

## 40.8 Managing the State of View Objects

By default, all view objects are marked as passivation-enabled, so their state will be saved. However, view objects that have transient attributes do not have those attributes passivated by default. You can change how a view object is passivated, and even which attributes are passivated, using the Tuning page of the view object overview editor.

### 40.8.1 How to Manage the State of View Objects

Each view object can be declaratively configured to be passivation-enabled or not. If a view object is not passivation enabled, then no information about it gets written in the application module passivation snapshot.

**Performance Tip:** There is no need to passivate read-only view objects since they are not intended to be updated and are easily recreated from the XML definition. This eliminates the performance overhead associated with passivation and activation and reduces the CPU usage needed to maintain the application module pool.

**To set the passivation state of a view object:**

1. In the Application Navigator, double-click a view object to open it in the overview editor.
2. On the General page, expand the **Tuning** section.
3. Select **Passivate State** to make sure the view object data is saved.

Optionally, you can select **Including All Transient Attributes** to passivate all transient attributes at this time, but see [Section 40.8.4, "What You May Need to Know About Passivating Transient View Objects"](#) for additional information.

## 40.8.2 What You May Need to Know About Passivating View Objects

The activation mechanism is designed to return your view object to the state it was in when the last passivation occurred. To ensure that, Oracle ADF stores in the state snapshot the values of any bind variables that were used for the last query execution. These bind variables are in addition to those that are set on the row set at the time of passivation. The passivated state also stores the user-supplied WHERE clause on the view object related to the row set at the time of passivation.

## 40.8.3 How to Manage the State of Transient View Objects and Attributes

Because view objects are marked as passivated by default, a transient view object — one that contains only transient attributes — is marked to be passivation enabled, but only passivates its information related to the current row and other non-transactional state.

**Performance Tip:** Transient view object attributes are not passivated by default. Due to their nature, they are usually intended to be read-only and are easily recreated. So, it often doesn't make sense to passivate their values as part of the XML snapshot. This also avoids the performance overhead associated with passivation and activation and reduces the CPU usage needed to maintain the application module pool.

### To individually set the passivation state for transient view object attributes:

1. In the Application Navigator, double-click a view object to open it in the overview editor.
2. On the Attributes page, select the transient attribute you want to passivate and click the **Edit** icon.
3. In the Edit Attribute dialog, click the **View Attribute** node.
4. Select the **Passivate** checkbox and click **OK**.

## 40.8.4 What You May Need to Know About Passivating Transient View Objects

Passivating transient view object attributes is more costly resource-wise and performance-wise, because transactional functionality is usually managed on the entity object level. Since transient view objects are not based on an entity object, this means that all updates are managed in the view object row cache and not in the entity cache. Therefore, passivating transient view objects or transient view object attributes requires special runtime handling.

Usually passivation only saves the values that have been changed, but with transient view objects passivation has to save entire row. The row will include only the view object attributes marked for passivation.

## 40.8.5 How to Use Transient View Objects to Store Session-level Global Variables

Using passivation, you can use a view object to store one or more global variables, each on a different transient attribute. When you mark a transient attribute as passivated, the ADF Business Components framework will remember the transient values across passivation and activation in high-throughput and failover scenarios. Therefore, it is an easy way to implement a session-level global value that is backed up by the state management mechanism, instead of the less-efficient HTTP Session replication. This also makes it easy to bind to controls in the UI if necessary.

There are two basic approaches to store values between invocations of different screens, one is controller-centric, and the other is model-centric.

### Implementation of the task in the ADF controller

The controller-centric approach involves storing and referencing values using attributes in the page flow scope. This approach might be appropriate if the global values do not need to be referenced internally by any implementations of ADF Business Components.

For more information about page flow scope, see [Section 14.2.4, "What You May Need to Know About Memory Scope for Task Flows."](#)

### Implementation of the task in the ADF model

The model-centric approach involves creating a transient view object, which is conceptually equivalent to a non-database block in Oracle Forms.

1. Create a new view object using the View Object Wizard, as described in [Section 5.2.1, "How to Create an Entity-Based View Object."](#)
  - On step 1 of the wizard, select the option for **Rows populated programmatically, not based on a query.**
  - On step 2, click **New** to define the transient attribute names and types the view object should contain. Make sure to set the **Updateable** option to **Always.**
  - Click **Finish** and the newly-created view object appears in the overview editor.
2. Disable any queries from being performed in the view object.
  - On the General page of the overview editor, expand the **Tuning** section, and in the **Retrieve from Database** group box, select the **No Rows** option.
3. Make sure data in the view object is not cleared out during a rollback operation. To implement this, you enable a custom Java class for the view object and override two rollback methods.
  - On the Java page of the overview editor, click the **Edit** icon in the **Java Classes** section to open the Java dialog.
  - In the Java dialog, select **Generate View Object Class** and click **OK.**
  - In the overview editor, click on the hyperlink next to the View Object Class in the **Java Classes** section to open the source editor.
  - From the **Source** menu, choose **Override Methods.**
  - In the Override Methods dialog, select the `beforeRollback()` and `afterRollback()` methods to override, and click then **OK.**
  - In both the `beforeRollback()` and `afterRollback()` methods, comment out the call to `super` in the Java code.
4. Add an instance of the transient view object to your application module's data model, as described in [Section 9.2.3.2, "Adding Master-Detail View Object Instances to an Application Module."](#)
5. Create an empty row in the view object when a new user begins using the application module.
  - Enable a Java class for your application module if you don't have one yet.

- Override the `prepareSession()` method of the application module, as described in [Section 9.11.1, "How to Override a Built-in Framework Method."](#)
- After the call to `super.prepareSession()`, add code to create a new row in the transient view object and insert it into the view object.

Now you can bind read-only and updateable UI elements to the "global" view object attributes just as with any other view object using the data control palette.

## 40.9 Using State Management for Middle-Tier Savepoints

In the database server you are likely familiar with the savepoint feature that allows a developer to rollback to a certain point within a transaction instead of rolling back the entire transaction. An application module offers the same feature but implemented in the middle tier.

---

**Best Practice:** Oracle ADF provides a declarative approach to working with savepoints, described in [Section 18.9, "Using Save Points in Task Flows."](#) Use the programmatic approach described in [Section 40.9.1, "How to Use State Management for Savepoints"](#) only if the declarative approach doesn't meet your needs.

---

### 40.9.1 How to Use State Management for Savepoints

To use state management for implementing middle-tier savepoints, you override three methods in the `oracle.jbo.ApplicationModule` interface

```
public String passivateStateForUndo(String id,byte[] clientData,int flags)
public byte[] activateStateForUndo(String id,int flags)
public boolean isValidIdForUndo(String id)
```

You can use these methods to create a stack of named snapshots and restore the pending transaction state from them by name. Keep in mind that those snapshots do not survive past duration of transaction (for example, events of commit or rollback). This feature could be used to develop complex capabilities of the application, such as the ability to undo and redo changes. Another ambitious goal that could exploit this functionality would be functionality to make the browser back and forward buttons behave in an application-specific way. Otherwise, simple uses of these methods can come quite in handy.

## 40.10 Testing to Ensure Your Application Module is Activation-Safe

If you have not *explicitly* tested that your application module functions when its pending state gets activated from a passivation snapshot, then you may encounter an unpleasant surprise in your production environment when heavy system load tests this aspect of your system for the first time.

### 40.10.1 Understanding the `jbo.ampool.doampooling` Configuration Parameter

The `jbo.ampool.doampooling` configuration property corresponds to the **Enable Application Module Pooling** option in the **Pooling and Scalability** tab of the Business Components Configuration dialog. By default, this checkbox is checked so that application module pooling is enabled. Whenever you deploy your application in a production environment the default setting of `jbo.ampool.doampooling` to `true` is the way you will run your application. But, as long as you run your application in a test environment, setting the property to `false` can play an important role in your

testing. When this property is false, there is effectively no application pool. When the application module instance is released at the end of a request it is immediately removed. On subsequent requests made by the same user session, a new application module instance must be created to handle it and the pending state of the application module must be reactivated from the passivation store.

## 40.10.2 Disabling Application Module Pooling to Test Activation

As part of your overall testing plan, you should adopt the practice of testing your application modules with the `jbo.ampool.doampooling` configuration parameter set to `false`. This setting completely disables application module pooling and forces the system to activate your application module's pending state from a passivation snapshot on *each* page request. It is an excellent way to detect problems that might occur in your production environment due to assumptions made in your custom application code.

---

---

**Caution:** It is important to reenable application module pooling after you conclude testing and are ready to deploy the application to a production environment. The configuration property `jbo.ampool.doampooling` set to `false` is not a supported configuration for production applications and must be set to `true` before deploying the application.

---

---

For example, if you have transient view object attributes you believe *should* be getting passivated, this technique allows you to test that they are working as you expect. In addition, consider situations where you might have introduced:

- Private member fields in application modules, view objects, or entity objects
- Custom user session state in the `Session` user data hashtable

Your custom code likely assumes that this custom state will be maintained across HTTP requests. As long as you test with a single user on the JDeveloper Integrated WebLogic Server, or test with a small number of users, things will appear to work fine. This is due to the "stateless with affinity" optimization of the ADF application module pool. If system load allows, the pool will continue to return the same application module instance to a user on subsequent requests. However, under heavier load, during real-world use, it may not be able to achieve this optimization and will need to resort to grabbing any available application module instance and reactivating its pending state from a passivation snapshot. If you have not correctly overridden `passivateState()` and `activateState()` (as described in [Section 40.7, "Managing Custom User-Specific Information"](#)) to save and reload your custom component state to the passivation snapshot, then your custom state will be missing (i.e. `null` or back to your default values) after this reactivation step. Testing with `jbo.ampool.doampooling` set to `false` allows you to quickly isolate these kinds of situations in your code.

## 40.11 Keeping Pending Changes in the Middle Tier

The ADF state management mechanism relies on passivation and activation to manage the state of an application module instance. Implementing this feature in a robust way is only possible if all pending changes are managed by the application module transaction in the middle tier. The most scalable strategy is to keep pending changes in middle-tier objects and not perform operations that cause pending database state to exist across HTTP requests. This allows the highest leverage of the performance

optimizations offered by the application module pool and the most robust runtime behavior for your application.

When the `jbo.doconnectionpooling` configuration parameter is set to `true` — typically in order to share a common pool of database connections across multiple application module pools — upon releasing your application module to the application module pool, its JDBC connection is released back to the database connection pool and a `ROLLBACK` will be issued on that connection. This implies that all changes which were posted but *not committed* will be lost. On the next request, when the application module is used, it will receive a JDBC connection from the pool, which may be a different JDBC connection instance from the one it used previously. Those changes that were posted to the database but not committed during the previous request are lost.

---

---

**Caution:** When the `jbo.doconnectionpooling` configuration parameter is set to `true` — typically in order to share a common pool of database connections across multiple application module pools — upon releasing your application module to the application module pool, its JDBC connection is released back to the database connection pool and a `ROLLBACK` will be issued on that connection. This implies that all changes which were posted but *not committed* will be lost. On the next request, when the application module is used, it will receive a JDBC connection from the pool, which may be a different JDBC connection instance from the one it used previously. Those changes that were posted to the database but not committed during the previous request are lost.

The `jbo.doconnectionpooling` configuration parameter is set by checking the **Disconnect Application Module Upon Release** property on the **Pooling and Scalability** tab of the Business Components Configuration dialog.

---

---

### 40.11.1 How to Set Applications to Use Optimistic Locking

Oracle recommends using optimistic locking, the default mode for web applications. Pessimistic locking should not be used for web applications as it creates pending transactional state in the database in the form of row-level locks. If pessimistic locking is set, state management will work, but the locking mode will not perform as expected. Behind the scenes, every time an application module is recycled, a rollback is issued in the JDBC connection. This releases all the locks that pessimistic locking had created.

**Performance Tip:** Always use the default mode optimistic locking for web applications. Only optimistic locking is compatible with the application module unmanaged release level mode, which allows the application module instance to be immediately released when a web page terminates. This provides the best level of performance for web applications that expect many users to access the application simultaneously.

To ensure your configuration uses optimistic locking, open the **Properties** tab of the Business Components Configuration dialog and confirm that the value of the `jbo.locking.mode` property is set to `optimistic` or `optupdate`.

---

---

**Note:** To open the Business Components Configuration dialog, right-click the application module in the Application Navigator, and choose **Configurations** from the context menu. Then, in the Manage Configurations dialog, select the configuration you want to edit and click **Edit**.

---

---

Optimistic locking (`optimistic`) issues a `SELECT FOR UPDATE` statement to lock the row, then detects whether the row has been changed by another user by comparing the change indicator attribute — or, if no change indicator is specified, the values of all the persistent attributes of the current entity as they existed when the entity object was fetched into the cache.

Optimistic update locking (`optupdate`) does not perform any locking. The `UPDATE` statement determines whether the row was updated by another user by including a `WHERE` clause that will match the existing row to update only if the attribute values are unchanged since the current entity object was fetched.

### 40.11.2 How to Avoid Clashes Using the `postChanges()` Method

The transaction-level `postChanges()` method exists to force the transaction to post unvalidated changes without committing them. This method is not recommended for use in web applications unless you can guarantee that the transaction will definitely be committed or rolled-back during the same HTTP request. Failure to heed this advice can lead to strange results in an environment where both application modules and database connections can be pooled and shared serially by multiple different clients.

### 40.11.3 How to Use the Reserved Level For Pending Database States

If for some reason you need to create a transactional state in the database in some request by invoking `postChanges()` method or by calling PL/SQL stored procedure, but you cannot issue a commit or rollback by the end of that same request, then you *must* release the application module instance with the **reserved** level from that request until a subsequent request when you either commit or rollback.

**Performance Tip:** Use as short a period of time as possible between creation of transactional state in the database and performing the concluding commit or rollback. This ensures that reserved level doesn't have to be used for a long time, as it has adverse effects on application's scalability and reliability.

Once an application module has been released with reserved level, it remains at that release level for all subsequent requests until release level is explicitly changed back to managed or unmanaged level. So, it is your responsibility to set release level back to managed level once commit or rollback has been issued.

For more information, see [Section 40.4, "Setting the Application Module Release Level at Runtime."](#)

---

---

## Tuning Application Module Pools and Connection Pools

This chapter describes how ADF Business Components application module pools work and how you can tune both application module pools and database connection pools to optimize ADF application performance.

This chapter includes the following sections:

- [Section 41.1, "Introduction to Application Module Pooling"](#)
- [Section 41.2, "Setting Pool Configuration Parameters"](#)
- [Section 41.3, "Initializing Database State and Pooling Considerations"](#)

### 41.1 Introduction to Application Module Pooling

An application module pool is a collection of application module runtime instances of the same type. To provision a number of users visiting it, an application can be configured to provide one or more application module instances from the pool to service users at runtime.

Each application module instance in a pool is shared by multiple browser clients whose typical "think time" between submitting web pages allows optimizing the number of application module components to be effectively smaller than the total number of active users working on the system. For example, twenty users visiting the website from their browser might be able to be serviced by 5 or 10 application module instances instead of having as many application module instances as you have browser users. Therefore, not only can the pool service more users than the number of application modules available, but in addition the middle tier requires less memory to service this smaller set of application modules allowing ADF applications to scale further on limited hardware resources.

Through your design-time configuration, application modules can be used to support Fusion web application scenarios that are completely stateless, or they can be used to support a unit of work that spans multiple browser pages. As a performance optimization, when an instance of an application module is returned to the pool in "managed state" mode, the pool tracks session references to the application module. The application module instance is still in the pool and available for use, but it would *prefer* to be used by the same session that was using it the last time because maintaining this "session affinity" improves performance.

So, at any one moment in time, the instances of application modules in the pool are logically partitioned into three groups, reflecting their state:

- Unconditionally *available* for use

- Available for use, but *referenced* for session affinity reuse by an active user session
- *Unavailable*, inasmuch as it's currently in use (at that very moment) by some thread in the web container.

[Section 41.2.5, "What You May Need to Know About Configuration Property Scopes"](#) describes the application module pool configuration parameters and how they affect the behavior of the pool.

## 41.1.1 Types of Pools Created When Running the Fusion Web Application

There are two kinds of pools in use when running a typical Fusion web application, Application Module pools and database connection pools. It's important to understand how many of each kind of pool your application will create.

### 41.1.1.1 Application Module Pools

Application Module components can be used at runtime in two ways:

- As an application module the client accesses directly
- As a reusable component aggregated (or "nested") inside of another application module instance

When a client accesses it directly, an application module is called a *root application module*. Clients access nested application modules *indirectly* as a part of their containing application module instance. It's possible, but not common, to use the same application module at runtime in both ways. The important point is that ADF Business Components only creates an application module pool for a *root* application module.

The basic rule is that one application module pool is created for each *root* application module used by a Fusion web application in *each* Java VM where a root application module of that type is used by the ADF Controller layer.

### 41.1.1.2 Database Connection Pools

The type of database connection pool the Fusion web application uses depends on the connection type that you configure for your application modules:

- JDBC URL (e.g. `jdbc:oracle:thin:@penguin:1521:ORCL`)
- JNDI name for a data source (e.g. `java:comp/env/jdbc/YourConnectionDS`)

If you supply a JDBC URL connection while configuring your application module — which happens when you select a JDeveloper named connection which encapsulates the JDBC URL and username information — then the ADF database connection pool will be used for managing the connection pool.

If you supply the JNDI name of a JDBC data source then the ADF database connection pool will *not* be used and the configuration parameters described below relating to the ADF database connection pool are not relevant.

---

---

**Note:** To configure the database connection pool for JDBC data sources looked-up by JNDI from your Java EE web and/or EJB container, consult the documentation for your Java EE container to understand the pooling configuration options and how to set them.

---

---

When using ADF database connection pooling, you have the following basic rule: One database connection pool is created for each unique `<JDBCURL, Username>` pair, in

each Java VM where a <JDBCURL, Username> connection is requested by a root application used by the ADF Controller layer.

## 41.1.2 Understanding Application Module and Connection Pools

The number of pools and the type of pools that your application will utilize will depend upon how the target platform is configured. For example, will there be more than one Java Virtual Machine (JVM) available to service the web requests coming from your application users and will there be more than one Oracle WebLogic Server domain? To understand how many pools of which kinds are created for an application in both a single-JVM scenario and a multiple-JVM runtime scenario, review the following assumptions:

- Your Fusion web application makes use of two application modules `HRModule` and `PayablesModule`.
- You have a `CommonLOVModule` containing a set of commonly used view objects to support list of values in your application, and that both `HRModule` and `PayablesModule` aggregate a nested instance of `CommonLOVModule` to access the common LOV view objects it contains.
- You have configured both `HRModule` and `PayablesModule` to use the same `JDeveloper` connection definition named `appuser`.
- In both `HRModule` and `PayablesModule` you have configured `jbo.passivationstore=database` (the default) and configured the ADF Business Components "internal connection" (`jbo.server.internal_connection`) used for state management persistence to have the value of a fully qualified JDBC URL that points to a *different* username than the `appuser` connection does.

### 41.1.2.1 Single Oracle WebLogic Server Domain, Single Oracle WebLogic Server Instance, Single JVM

If you deploy this application to a single Oracle WebLogic Server domain, configured with a single Oracle WebLogic Server instance, there is only a single Java VM available to service the web requests coming from your application users.

Assuming that all the users are making use of web pages that access both the `HRModule` and the `PayablesModule`, this will give:

- One application module pool for the `HRModule` root application module
- One application module pool for the `PayablesModule` root application module
- One DB connection pool for the `appuser` connection
- One DB connection pool for the JDBC URL supplied for the internal connection for state management.

This gives a total of two application module pools and two database pools in this single Java VM.

---

**Note:** There is no separate application module pool for the nested instances of the reusable `CommonLOVModule`. Instances of `CommonLOVModule` are wrapped by instances of `HRModule` and `PayablesModule` in their respective application module pools.

---

### 41.1.2.2 Multiple Oracle WebLogic Server Domains, Multiple Oracle WebLogic Server Instance, Multiple JVMs

Next consider a deployment environment involving multiple Java VMs. Assume that you have configured four different physical machines as two Oracle WebLogic Server domains, with a hardware load-balancer in front. On these four machines, each Oracle WebLogic Server instance will have a single JVM. As users of your application access the application, their requests are shared across these two Oracle WebLogic Server domains, and within each domain, across the two JVMs that its Oracle WebLogic Server instances have available.

Again assuming that all the users are making use of web pages that access both the `HRModule` and the `PayablesModule`, this will give:

- Four application module pools for `HRModule`, one in each of four JVMs.  
(1 `HRModule` root application module) x (2 Oracle WebLogic Server domains) x (2 Oracle WebLogic Server JVMs each)
- Four application module pools for `PayablesModule`, one in each of four JVMs.  
(1 `PayablesModule` root application module) x (2 Oracle WebLogic Server domains) x (2 Oracle WebLogic Server JVMs each)
- Four DB connection pools for `appuser`, one in each of four JVMs.  
(1 `appuser` DB connection pool) x (2 Oracle WebLogic Server domains) x (2 Oracle WebLogic Server JVMs each)
- Four DB connection pools for the internal connection JDBC URL, one in each of four JVMs.  
(1 internal connection JDBC URL DB connection pool) x (2 Oracle WebLogic Server domains) x (2 Oracle WebLogic Server JVMs each)

This gives a total of eight application module pools and eight DB connection pools spread across four JVMs.

As you begin to explore the configuration parameters for the application module pools in [Section 41.2.7, "What You May Need to Know About Application Module Pool Parameters,"](#) keep in mind that the parameters apply to a given application module pool for a given application module in a single JVM.

As the load balancing spreads user requests across the multiple JVMs where Oracle ADF is running, each individual application module pool in each JVM will have to support one  $n^{\text{th}}$  of the user load — where  $n$  is the number of JVMs available to service those user requests. The appropriate values of the application module and DB connection pools need to be set with the number of Java VMs in mind. The basic approach is to base sizing parameters on load testing and the results of the application module pooling statistics, then divide that total number by the  $n$  number of pools you will have based on your use of multiple application server domains and multiple Oracle WebLogic Server instances. For example, if you decide to set the minimum number of application modules in the pool to ten and you end up with five pools due to having five Oracle WebLogic Server instances servicing this application, then you would want to configure the parameter to 2 (ten divided by five), not 10 (which would only serve a given application module in a single JVM). For details about available sizing parameters, see [Table 41–2](#) and [Table 41–5](#).

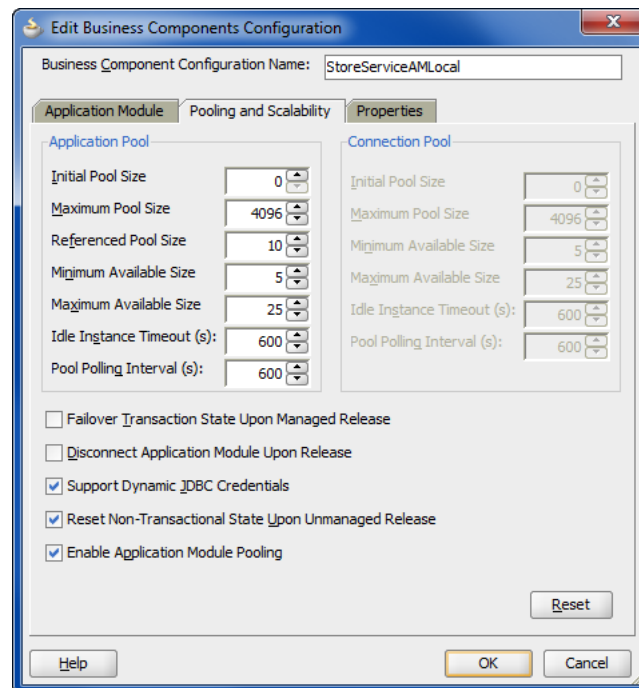

## 41.2 Setting Pool Configuration Parameters

You control the runtime behavior of an application module pool by setting appropriate configuration parameters. You can set these declaratively in an application module configuration, supply them as Java System parameters, or set them programmatically at runtime.

### 41.2.1 How to Set Configuration Properties Declaratively

The **Pooling and Scalability** tab of the Edit Business Components Configuration dialog shown in [Figure 41–1](#) is used for viewing and setting parameters.

**Figure 41–1** *Pooling and Scalability Tab of the Configuration Manager*

#### To edit your application module's pooling configuration:

1. In the Application Navigator, double-click the application module.
2. In the overview editor, click the **Configurations** navigation tab.
3. In the Configurations page, double-click the configuration you want to edit.
4. In the Edit Business Components Configuration dialog, click the **Pooling and Scalability** tab and edit the desired runtime properties and click **OK** to save the changes for your configuration.

### 41.2.2 What Happens When You Set Configuration Properties Declaratively

The values that you supply through the Configuration Manager are saved in an XML file named `bc4j.xcfg` in the `./common` subdirectory relative to the application module's XML document. All of the configurations for all of the application modules in a single Java package are saved in that same file.

For example, if you look at the `bc4j.xcfg` file in the `./src/oracle/fodemo/storefront/store/service/common` directory of the Fusion Order Demo application's `StoreFront` project, you will see the three named

configurations for its `StoreServiceAM` application module, as shown in [Example 41–1](#). In this case, The `StoreServiceAMLocal` and the `StoreServiceAMLocalWeb` configurations specify JDBC URL connections for use by the Business Component Browser. The connection details for the JDBC connections appear in the `connections.xml` file located in the `./adf/META-INF` subdirectory relative to the project directory. The third configuration `StoreFrontService` specifies a JDBC data source name and is used by the Fusion web application. This type of configuration is generated by default when you expose a service interface for the application module in the Service Interface page of the overview editor.

#### Example 41–1 Configuration Settings for the StoreService Application Module

```
<BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/configuration">
  <AppModuleConfigBag ApplicationName="oracle.fodemo.storefront.store.service.StoreServiceAM">
    <AppModuleConfig
      DeployPlatform="LOCAL"
      JDBCName="FOD"
      jbo.project="StoreFrontService"
      name="StoreServiceAMLocal"
      ApplicationName="oracle.fodemo.storefront.store.service.StoreServiceAM">
      <Database jbo.locking.mode="optimistic"/>
      <Security AppModuleJndiName="oracle.fodemo.storefront.store.service.StoreServiceAM"/>
    </AppModuleConfig>
    <AppModuleConfig
      DeployPlatform="LOCAL"
      JDBCName="FOD"
      jbo.project="StoreFrontService"
      name="StoreServiceAMLocalWeb"
      ApplicationName="oracle.fodemo.storefront.store.service.StoreServiceAM">
      <AM-Pooling jbo.ampool.initpoolsize="1"/>
      <Database jbo.locking.mode="optimistic"/>
      <Security AppModuleJndiName="oracle.fodemo.storefront.store.service.StoreServiceAM"/>
      <Custom fod.application.isssoaenabled="true"/>
    </AppModuleConfig>
    <AppModuleConfig
      name="StoreFrontService"
      ApplicationName="oracle.fodemo.storefront.store.service.StoreServiceAM"
      jbo.project="StoreFrontService"
      DeployPlatform="SI">
      <AM-Pooling jbo.ampool.resetnontransactionalstate="true"/>
      <Database jbo.SQLBuilder="ORACLE" jbo.locking.mode="optimistic"
        jbo.TypeMapEntries="Java"/>
      <Security AppModuleJndiName="oracle.fodemo.storefront.store.service.StoreServiceAM"/>
      <Custom JDBCDataSource="java:comp/env/jdbc/FODDS"/>
    </AppModuleConfig>
  </AppModuleConfigBag>
</BC4JConfig>
```

Note that attributes of child elements of the `<AppModuleConfig>` tag have names beginning with `jbo` that match the names of their ADF Business Components properties (for example, the `<Database>` tag defines the attribute `jbo.locking.mode` that corresponds to the property `jbo.locking.mode`). It's also important to understand that if a property is currently set to its runtime *default* value in the Edit Business Components Configuration dialog, then JDeveloper does *not* write the entry to the `bc4j.xcfg` file.

### 41.2.3 How to Set Configuration Properties as System Parameters

As an alternative to specifying configuration properties in the `bc4j.xcfg` file, you can also set Java VM system parameters with the same property names. These system parameters will be used *only if* a corresponding property *does not exist* in the relevant `bc4j.xcfg` file for the application module in question. In other words, configuration parameters that appear in the application module configuration take precedence over parameters of the same name supplied as Java system parameters.

You typically set Java system parameters using the `-D` command line flag to the Java VM like this:

```
java -Dproperty=value -jar yourserver.jar
```

Alternatively, your Java EE container probably has a section in its own configuration files where Java system parameters can be specified for use at Java EE container startup time.

If you adopt the technique of specifying site-specific *default* values for Oracle ADF configuration parameters as Java system parameters, you should make sure that your application's `bc4j.xcfg` files do *not* include references to these parameters unless you want to define an application-module-specific exception to these global default values.

---

---

**Caution:** The values of **Idle Instance Timeout**, **Pool Polling Interval** settings for both the **Application Pool** and the database **Connection Pool** are displayed and edited in this dialog as a number of *seconds*, but are saved to the configuration file in milliseconds. If you provide a value for any of these four parameters as a Java System parameter — or if you hand-edit the `bc4j.xcfg` file — make sure to provide these time interval values in milliseconds!

---

---

### 41.2.4 How to Programmatically Set Configuration Properties

You can set configuration properties programmatically by creating a Java class that implements the `EnvInfoProvider` interface in the `oracle.jbo.common.ampool` package. In your class, you override the `getInfo()` method and call `put()` to put values into the environment `Hashtable` passed in as shown in [Example 41-2](#).

#### **Example 41-2** Setting Environment Properties with a Custom `EnvInfoProvider`

```
package devguide.advanced.customenv.view;
import java.util.Hashtable;
import oracle.jbo.common.ampool.EnvInfoProvider;
/**
 * Custom EnvInfoProvider implementation to set
 * environment properties programmatically
 */
public class CustomEnvInfoProvider implements EnvInfoProvider {
    /**
     * Overridden framework method to set custom values in the
     * environment hashtable.
     *
     * @param string - ignore
     * @param environment Hashtable of config parameters
     * @return null - not used
     */
    public Object getInfo(String string, Object environment) {
```

```

        Hashtable envHashtable = (Hashtable)environment;
        envHashtable.put("some.property.name", "some value");
        return null;
    }
    /* Required to implement EnvInfoProvider */
    public void modifyInitialContext(Object object) {}
    /* Required to implement EnvInfoProvider */
    public int getNumOfRetries() {return 0;}
}

```

When creating an application module for a stateless or command-line-client, with the `createRootApplicationModule()` method of the `Configuration` class, you can pass the custom `EnvInfoProvider` as the optional second argument. In order to use a custom `EnvInfoProvider` in an ADF web-based application, you need to implement a custom session cookie factory class as shown in [Example 41-3](#). To use your custom session cookie factory, set the `jbo.ampool.sessioncookiefactoryclass` configuration property to the fully qualified name of your custom session cookie factory class.

**Example 41-3 Custom SessionCookieFactory to Install a Custom EnvInfoProvider**

```

package devguide.advanced.customenv.view;
import java.util.Properties;
import oracle.jbo.common.ampool.ApplicationPool;
import oracle.jbo.common.ampool.EnvInfoProvider;
import oracle.jbo.common.ampool.SessionCookie;
import oracle.jbo.http.HttpSessionCookieFactory;
/**
 * Example of custom http session cookie factory
 * to install a custom EnvInfoProvider implementation
 * for an ADF web-based application.
 */
public class CustomHttpSessionCookieFactory
    extends HttpSessionCookieFactory {
    public SessionCookie createSessionCookie(String appId,
        String sessionId,
        ApplicationPool pool,
        Properties props) {
        SessionCookie cookie =
            super.createSessionCookie(appId, sessionId, pool, props);
        EnvInfoProvider envInfoProv = new CustomEnvInfoProvider();
        cookie.setEnvInfoProvider(envInfoProv);
        return cookie;
    }
}

```

## 41.2.5 What You May Need to Know About Configuration Property Scopes

Each runtime configuration property used by ADF Business Components has a scope. The scope of each property indicates when the property's value is evaluated and whether its value is effectively shared (i.e. static) in a single Java VM, or not. The ADF Business Components `PropertyManager` class is the registry of all supported properties. It defines the property names, their default values, and their scope. This class contains a `main()` method so that you can run the class from the command line to see a list of all the configuration property information.

Assuming `JDEVHOME` is the JDeveloper installation directory, to see this list of settings for reference, do the following:

```
$ java -cp JDEVHOME/BC4J/lib/bc4jmt.jar oracle.jbo.common.PropertyManager
```

Issuing this command will send all of the ADF Business Components configuration properties to the console. It also lists a handy reference about the different levels at which you can set configuration property values and remind you of the precedence order these levels have:

```

-----
Properties loaded from following sources, in order:
1. Client environment [Provided programmatically
                      or declaratively in bc4j.xcfg]
2. Applet tags
3. -D flags (appear in System.properties)
4. bc4j.properties file (in current directory)
5. /oracle/jbo/BC4J.properties resource
6. /oracle/jbo/common.jboserver.properties resource
7. /oracle/jbo/common.Diagnostic.properties resource
8. System defined default
-----

```

You'll see each property is listed with one of the following scopes:

- **MetaObjectManager**  
Properties at this scope are initialized once per Java VM when the ADF PropertyManager is first initialized.
- **SessionImpl**  
Properties at this scope are initialized once per invocation of `ApplicationModule.prepareSession()`.
- **Configuration**  
Properties at this scope are initialized when the `ApplicationModule` pool is first created and the application module's configuration is read the first time.
- **Diagnostic**  
Properties at this scope are specific to the built-in ADF Business Components diagnostic facility.

At each of these scopes, the layered value resolution described above is performed when the properties are initialized. Whenever property values are initialized, if you have specified them in the *Client Environment* (level 1 in the resolution order) the values will take precedence over values specified as System parameters (level 3 in the resolution order).

The Client Environment is a hashtable of name/value pairs that you can either programmatically populate, or which will be automatically populated for you by the `Configuration` object when loaded, with the name/value pairs it contains in its entry in the `bc4j.xcfg` file. The implication of this is that for any properties scoped at `MetaObjectManager` level, the most reliable way to ensure that all of your application modules use the same default value for those properties is to do both of the following:

1. Make sure the property value does not appear in any of your application module's `bc4j.xcfg` file configuration name/value pair entries.
2. Set the property value using a Java system property in your runtime environment.

If, instead, you leave any `MetaObjectManager`-scoped properties in your `bc4j.xcfg` files, you will have the undesirable behavior that they will take on the value specified

in the configuration of the *first* application module whose pool gets created after the Java VM starts up.

## 41.2.6 What You May Need to Know About How Database and Application Module Pools Cooperate

How ADF application module pools use the database connection pool depends on the setting of the `jbo.doconnectionpooling` application module configuration parameter. In the Configuration Manager panel shown in [Figure 41-1](#), you set this parameter using the checkbox labelled **Disconnect Application Module Upon Release**.

---

---

**Note:** The notion of *disconnecting* the application module upon release to the pool better captures what the actual feature is doing than the related configuration parameter name (`jbo.doconnectionpooling`) does. The setting of `jbo.doconnectionpooling=false` does not mean that there is no database connection pooling happening. What it means is that the application module is not disconnected from its JDBC connection upon check in back to the application module pool.

---

---

If the default setting of `jbo.doconnectionpooling=false` is used, then when an application module instance is created in any pool it acquires a JDBC connection from the appropriate connection pool (based on the JDBC URL in the ADF case, or from the underlying JDBC data source implementation's pool in the case of a JNDI data source name). That application module instance holds onto the JDBC connection object that it acquired from the pool until the application module instance is removed from the application module pool. During its lifetime, that application module instance may service many different users, and ADF worries about issuing rollbacks on the database connection so that different users don't end up getting pending database state confused. By holding onto the JDBC connection, it allows each application module instance to keep its JDBC `PreparedStatement` objects cached and reusable across subsequent accesses by clients, thereby providing the best performance.

If `jbo.doconnectionpooling=true`, then each time a user session finishes using an application module (typically at the end of each HTTP request), the application module instance disassociates itself with the JDBC connection it was using on that request and it returns it to the JDBC connection pool. The next time that application module instance is used by a user session, it will reacquire a JDBC connection from the JDBC connection pool and use it for the span of time that application module is checked out of the application module pool (again, typically the span of one HTTP request). Since the application module instance "unplugs" itself from the JDBC connection object used to create the `PreparedStatements` it might have used during the servicing of the current HTTP request, those `PreparedStatements` are no longer usable on the next HTTP request because they are only valid in the context of the Connection object in which they were created. So, when using the connection pooling mode turned on like this, the trade-off is slightly more JDBC overhead setup each time, in return for using a smaller number of overall database connections.

The key difference is seen when many application module pools are all using the same underlying database user for their application connection.

- If 50 different application module pools each have even just a single application module instance in them, with `jbo.doconnectionpooling=false` there will be 50 JDBC application connections in use. If the application module pooling

parameters are set such that the application module pools are allowed to shrink to 0 instances after an appropriate instance idle timeout by setting `jbo.ampool.minavailablesize=0`, then when the application module is removed from its pool, it will put back the connection its holding onto.

- In contrast, if 50 different application module pools each have a single application module instance and `jbo.doconnectionpooling=true`, then the amount of JDBC connections in use will depend on how many of those application modules are *simultaneously* being used by different clients. If an application module instance is in the pool and is not currently being used by a user session, then with `jbo.doconnectionpooling=true` it will have released its JDBC connection back to the connection pool and while the application module instance is sitting there waiting for either another user to need it again, or to eventually be cleaned up by the application module pool monitor, it will not be "hanging on" to a JDBC connection.

**Performance Tip:** Leave the `jbo.doconnectionpooling` configuration parameter set to `false` for best performance without sacrificing scalability and reliability. Database connection pooling is still achieved through application module pooling. The only exception is when multiple application module pools (and therefore a large number of application module instances) share the same database, making the total available database connections the highest priority.

Highest performance is achieved by not disconnecting the application module instance from its database connection on each check in to the application module pool. Accordingly, the default setting of the `jbo.doconnectionpooling` configuration parameter is `false`. The pooling of application module instances is already an effective way to optimize resource usage, and the Oracle ADF runtime is more efficient when you do not have to disconnect application module instances from their associated JDBC connection after each release to the pool. Effectively, by pooling the application modules which are related one-to-one with a JDBC connection, you are already achieving a pooling of database connections that is optimal for most Fusion web applications.

To achieve a more ideal balance between conserving JDBC connections and keeping all application modules connected to the database, you can configure `jbo.ampool.connection_threshold`. This runtime property specifies the maximum number of connections that application modules in all application module pools combined may hold onto without releasing back to the connection pool upon checkin. Setting the maximum number of connections implies disconnecting application modules upon release is desired and automatically enables `jbo.doconnectionpooling=true`. For more details about optimizing the `jbo.doconnectionpooling` property, see [Section 41.3.2, "What You May Need to Know About Optimizing Connection Pooling."](#)

## 41.2.7 What You May Need to Know About Application Module Pool Parameters

The application module pool configuration parameters fall into three logical categories relating to pool behavior, pool sizing, and pool cleanup behavior.

### 41.2.7.1 Pool Behavior Parameters

[Table 41–1](#) lists the application module configuration parameters that affect the behavior of the application module pool.

**Table 41–1 Application Module Pool Behavior Configuration Parameters**

Pool Configuration Parameter	Description
Failover Transaction State Upon Managed Release ( <code>jbo.dofailover</code> )	<p>Specifies whether to disable or enable failover. By default, failover is disabled. To enable failover, set the parameter to <code>true</code>. When enabled, the Oracle ADF framework performs eager passivation of the pending transaction state each time an application module is released to the pool in "Managed State" mode. See <a href="#">Section 40.2.2.2, "How Passivation Changes When Optional Failover Mode is Enabled"</a> for more information.</p> <p>The failover feature is disabled by default (<code>jbo.dofailover=false</code>) as a performance optimization when there is only one web server instance configured, thus reducing the need for passivation and activation. This allows for application module affinity to a specific user session.</p> <p>For high availability, in a clustered server environment, the failover feature will auto-default to enabled (<code>jbo.dofailover=true</code>). This ensures that more application modules are readily available, thereby increasing scalability. In this mode, passivation occurs at the end of every request.</p> <p><b>Note:</b> When enabling application module state passivation, a failure can occur when Oracle WebLogic Server is configured to forcibly release connections back into the pool. A failure of this type produces a <code>SQLException</code> (Connection has already been closed.) that is saved to the server log. The exception is not reported through the user interface.</p> <p>To ensure that state passivation occurs and users' changes are saved, set an appropriate value for the <code>weblogic-application.xml</code> deployment descriptor parameter <code>inactive-connection-timeout-seconds</code> on the <code>&lt;connection-check-params&gt;</code> pool params element.</p> <p>Setting the deployment descriptor parameter to several minutes, in most cases, should avoid forcing the inactive connection timeout and the resulting passivation failure. Adjust the setting as needed for your environment.</p>
Row-Level Locking Behavior Upon Release ( <code>jbo.locking.mode</code> )	<p>Forces the application module pool not to create a pending transaction state on the database with row-level locks each time the application module is released to the pool. See <a href="#">Section 40.11.1, "How to Set Applications to Use Optimistic Locking"</a> for more information.</p> <p>Fusion web applications should leave the locking mode set to the default value <code>optimistic</code> to avoid creating the row-level locks.</p> <p>This feature is disabled when the property is set to <code>pessimistic</code>.</p>

**Table 41–1 (Cont.) Application Module Pool Behavior Configuration Parameters**

Pool Configuration Parameter	Description
Disconnect Application Module Upon Release ( <code>jbo.doconnectionpooling</code> )	<p>Forces the application module pool to release the JDBC connection used each time the application module is released to the pool. See <a href="#">Section 41.2.6, "What You May Need to Know About How Database and Application Module Pools Cooperate"</a> for more information.</p> <p>This feature is disabled by default (<code>false</code>).</p>
Disconnect Application Module Upon Reaching Maximum Connection Threshold ( <code>jbo.ampool.connection_threshold</code> )	<p>Forces application modules to hold onto their JDBC connections so they do not release back to the connection pool upon checkin until a maximum number of JDBC connections is reached for all application modules in all application module pools combined. Once the threshold is reached, connections will be released on next pool cleanup cycle starting from least recently used, available application modules.</p> <p>Setting the maximum number of connections implies disconnecting application modules upon release is desired and automatically enables <code>jbo.doconnectionpooling=true</code>. See <a href="#">Section 41.3.2, "What You May Need to Know About Optimizing Connection Pooling."</a> for more information.</p> <p>This feature is disabled by default (<code>jbo.ampool.connection_threshold=0</code>).</p> <p>Setting the threshold to a limit greater than 0, releases JDBC connections during application module pool cleanup instead of during application module checkin. To ensure JDBC connections are released efficiently, configure <code>jbo.ampool.monitorsleepinterval</code> to shorten the monitor sleep period.</p>
Transaction Memory State Upon Release ( <code>jbo.txn.disconnect_level</code> )	<p>Forces the application module, view objects and row sets to remain in memory and stay valid but allows their corresponding references to JDBC objects to be dropped. Upon activation, the framework reexecutes and synchronizes the cursor positions.</p> <p>When used in conjunction with <code>jbo.doconnectionpooling=true</code> or <code>jbo.ampool.connection_threshold</code>, improves performance and reduces the memory overhead associated with this situation. See <a href="#">Section 41.3.2, "What You May Need to Know About Optimizing Connection Pooling."</a> for more information.</p> <p>Setting <code>jbo.txn.disconnect_level=0</code>, changes the application module passivation behavior so that the view objects and their row sets are closed and removed. In this case, view objects and their row sets will be re-created and reverted to their original state upon activation.</p>

**Table 41–1 (Cont.) Application Module Pool Behavior Configuration Parameters**

Pool Configuration Parameter	Description
Enable Application Module Pooling ( <code>jbo.ampool.doampooling</code> )	<p>Enables application module pooling by default. Whenever you deploy your application in a production environment the default setting of <code>jbo.ampool.doampooling</code> set to <code>true</code> is the way you will run your application. But, as long as you run your application in a test environment, setting the property to <code>false</code> can play an important role in your testing. When this property is <code>false</code>, there is effectively no application pool. See <a href="#">Section 40.10, "Testing to Ensure Your Application Module is Activation-Safe"</a> for more information.</p> <p>This feature is enabled by default (<code>true</code>).</p>
Support Dynamic JDBC Credentials ( <code>jbo.ampool.dynamicjdbccredentials</code> )	<p>Enables additional pooling lifecycle events to allow developer-written code to change the database credentials (username/password) each time a new user session begins to use the application module.</p> <p>This feature is enabled by default (<code>true</code>), however this setting is a necessary but not sufficient condition to implement the feature. The complete implementation requires additional developer-written code.</p>
Support Dynamic JDBC Credentials ( <code>jbo.ampool.dynamicjdbccredentials</code> )	<p>Enables additional pooling lifecycle events to allow developer-written code to change the database credentials (username/password) each time a new user session begins to use the application module.</p> <p>This feature is enabled by default (<code>true</code>), however this setting is a necessary but not sufficient condition to implement the feature. The complete implementation requires additional developer-written code.</p>
Reset Non-Transactional State Upon Unmanaged Release ( <code>jbo.ampool.resetnontransactionalstate</code> )	<p>Forces the application module to reset any non-transactional state like view object runtime settings, JDBC prepared statements, bind variable values, etc. when the application module is released to the pool in unmanaged or "stateless" mode.</p> <p>This feature is enabled by default (<code>true</code>). Disabling this feature can improve performance, however since it does not clear bind variable values, your application needs to ensure that it systemically sets bind variable values correctly. Failure to do so with this feature disabled can mean one user might see data with another users bind variable values.)</p>

### 41.2.7.2 Pool Sizing Parameters

[Table 41–2](#) lists the application module configuration parameters that affect the sizing of the application module pool.

**Table 41–2 Application Module Pool Sizing Configuration Parameters**

Pool Configuration Parameter	Description
Initial Pool Size ( <code>jbo.ampool.initpoolsize</code> )	<p>The number of application module instances to created when the pool is initialized.</p> <p>The default is 0 (zero) instances. A general guideline is to configure this to 10% more than the anticipated number of concurrent application module instances required to service all users.</p> <p>Creating application module instances during initialization takes the CPU processing costs of creating application module instances during the initialization instead of on-demand when additional application module instances are required.</p>
Maximum Pool Size ( <code>jbo.ampool.maxpoolsize</code> )	<p>The maximum number of application module instances that the pool can allocate. The pool will never create more application module instances than this limit imposes.</p> <p>The default is 4096 instances. A general guideline is to configure this to 20% more than the initial pool size to allow for some additional growth. If this is set too low, then some users may see an error accessing the application if no application module instances are available.</p>
Referenced Pool Size ( <code>jbo.recyclethreshold</code> )	<p>The maximum number of application module instances in the pool that attempt to preserve session affinity for the next request made by the session which used them last before releasing them to the pool in managed-state mode.</p> <p>The referenced pool size should always be less than or equal to the maximum pool size. The default is to allow 10 available instances to try and remain "loyal" to the affinity they have with the most recent session that released them in managed state mode.</p> <p>Configure this value to maintain the application module instance's affinity to a user's session. A general guideline is to configure this to the expected number of concurrent users that perform multiple operations with short think times. If there are no users expected to use the application with short think times, then this can be configured to 0 zero to eliminate affinity.</p> <p>Maintaining this affinity as much as possible will save the CPU processing cost of needing to switch an application module instance from one user session to another.</p>

### 41.2.7.3 Pool Cleanup Parameters

A single application module pool monitor per Java VM runs in a background thread and wakes up every so often to do resource reclamation. The pool monitor uses the following two, independent strategies to identify which application module instances are candidates to be removed from the pool and reclaimed as a potential new resource.

1. The application module pool monitor removes application module instances from the pool that have not been used for more than 3600000 milliseconds (which is the default value and is exactly one hour). These unused application module instances will be reclaimed regardless of the minimum available size for the pool. To override the maximum time to live for an application module, you can set the `jbo.ampool.timetolive` parameter. However, for most Fusion web applications, you will not need to reclaim unused application module instance and can set this parameter value to -1.
2. The application module pool monitor removes application module instances that have remained idle for 600000 milliseconds (which is the default value and is exactly 10 minutes). This cleanup stops when the number of instances in the pool reaches the minimum available size. You can override the idle timeout for application module instances using the `jbo.ampool.maxinactiveage` parameter.

Table 41–3 lists the parameters that affect how resources are reclaimed when the pool monitor does one of its resource cleanup passes.

**Best Practice:** When you specify the length of time between application module pool cleanup passes, set all application modules to use the same **Pool Polling Interval** value. Since there is only a single application monitor pool monitor per Java VM, the value that will effectively be used for the application module pool monitor polling interval will be the value found in the application module configuration read by the *first* application module pool that gets created. Setting all application modules to use the same value ensures that this value is set in a predictable way.

**Table 41–3 Application Module Resource Management Configuration Parameters**

Pool Configuration Parameter	Description
Pool Polling Interval ( <code>jbo.ampool.monitorsleepinterval</code> )	<p>The length of time in milliseconds between pool resource cleanup.</p> <p>While the number of application module instances in the pool will never exceed the maximum pool size, available instances which are candidates for getting removed from the pool do not get "cleaned up" until the next time the application module pool monitor wakes up to do its job.</p> <p>The default is to have the application module pool monitor wake up every 600000 milliseconds (which is 600 seconds, or ten minutes). Configuring a lower interval results in inactive application module instances being removed more frequently to save memory. Configuring a higher interval results in less frequent resource cleanups.</p>

**Table 41–3 (Cont.) Application Module Resource Management Configuration Parameters**

Pool Configuration Parameter	Description
Maximum Available Size ( <code>jbo.ampool.maxavailablesize</code> )	<p>The ideal maximum number of available application module instances in the pool when the server is under load.</p> <p>When the pool monitor wakes up to do resource cleanup, it will try to remove available application module instances to bring the total number of available instances down to this ideal maximum. Instances that have been not been used for a period longer than the idle instance time-out will always get cleaned up at this time, then additional available instances will be removed if necessary to bring the number of available instances down to this size.</p> <p>The default maximum available size is 25 instances. Configure this to leave the maximum number of available instances desired after a resource cleanup. A lower value generally results in more application module instances being removed from the pool on a cleanup.</p> <p>While application module pool tuning allows different values for the <code>jbo.ampool.maxavailablesize</code>   <code>jbo.ampool.minavailablesize</code> parameters, in most cases it is fine to set these minimum and maximum tuning properties to the same value.</p>
Minimum Available Size ( <code>jbo.ampool.minavailablesize</code> )	<p>The minimum number of available application module instances that the pool monitor should leave in the pool during a resource cleanup operation, when the server is under light load.</p> <p>Set to 0 (zero) if you want the pool to shrink to contain no instances when all instances have been idle for longer than the idle time-out after a resource cleanup.</p> <p>The default is 5 instances.</p> <p>While application module pool tuning allows different values for the <code>jbo.ampool.minavailablesize</code>   <code>jbo.ampool.maxavailablesize</code> parameters, in most cases it is fine to set these minimum and maximum tuning properties to the same value.</p>
Idle Instance Timeout ( <code>jbo.ampool.maxinactiveage</code> )	<p>The number of milliseconds after which to consider an idle application module instance in the pool as a candidate for removal during the next resource cleanup.</p> <p>The default is 600000 milliseconds of idle time (which is 600 seconds, or ten minutes). A lower value results in more application module instances being marked as a candidate for removal at the next resource cleanup. A higher value results in fewer application module instances being marked as a candidate for removal at the next resource cleanup.</p>

**Table 41–3 (Cont.) Application Module Resource Management Configuration Parameters**

Pool Configuration Parameter	Description
Maximum Instance Time to Live ( <code>jbo.ampool.timetolive</code> )	<p>The number of milliseconds after which to consider an unused application module instance in the pool as a candidate for removal during the next resource cleanup regardless of whether it would bring the number of instances in the pool below <code>minavailablesize</code>.</p> <p>The default is 3600000 milliseconds of total time to live (which is 3600 seconds, or one hour). A lower value reduces the time an unused application module instance can exist before it must be removed at the next resource cleanup. The default value is sufficient for most applications. A higher value increases the time an application module instance can exist before it must be removed at the next cleanup.</p> <p>Alternatively, set the parameter value to -1 when you want to prevent removal of unused application modules by the application module pool monitor.</p>

## 41.2.8 What You May Need to Know About Data Source Configuration

When you specify a JDBC data source as your application module's connection type, any configuration parameters that you have configured for the database connection pool will be ignored. To configure the connection pool for your data source, you must use the means provided by your Java EE container. In the case of Oracle WebLogic Server, you configure the data source using the Oracle WebLogic Server Administration Console.

The main steps for configuring JDBC data sources are:

1. Create a data source for each data base that you want to connect to. When you create the data source, specify the configuration options to match the ones for ADF Business Components database connection pools described in [Table 41–4](#). The configuration settings that you specify will depend on your database and the capacity planning that you need anticipate for your application.

For details about configuring JDBC data sources and connection pool capacity planning, see *Oracle Fusion Middleware Configuring and Managing JDBC Data Sources for Oracle WebLogic Server*.

2. Optionally, configure transaction options for the data source.
3. Optionally, configure connection testing options for the data source.
4. Optionally, target the data source to additional servers and clusters.

For detailed procedures for each of these steps, see the topic "Configure JDBC data sources" in the Administration Console Online Help.

**Table 41–4 Equivalent Oracle WebLogic Server Data Source Parameters**

ADF Business Components Parameter	\Oracle WebLogic Server Parameter
Initial Pool Size ( <code>jbo.initpoolsize</code> )	Initial Capacity

**Table 41–4 (Cont.) Equivalent Oracle WebLogic Server Data Source Parameters**

ADF Business Components Parameter	\Oracle WebLogic Server Parameter
Maximum Pool Size (jbo.maxpoolsize)	Maximum Capacity
Pool Polling Interval (jbo.poolmonitorsleepinterval)	No equivalent for Oracle WebLogic Server.
Maximum Available Size (jbo.poolmaxavailablesize)	Maximum Capacity
Minimum Available Size (jbo.poolminavailablesize)	Maximum Capacity
Idle Instance Timeout (jbo.poolmaxinactiveage)	Shrink Frequency Seconds

## 41.2.9 What You May Need to Know About Database Connection Pool Parameters

If you are using a JDBC URL for your connection information so that the ADF database connection pool is used, then configuration parameters listed in [Table 41–5](#) can be used to tune the behavior of the database connection pool. A single "database connection pool monitor" per Java VM runs in a background thread and wakes up every so often to do resource reclamation. The parameters in [Table 41–3](#) include the ones that affect how resources are reclaimed when the pool monitor does one of its resource cleanup passes.

---

**Note:** The configuration parameters for database connection pooling have MetaObjectManager scope (described in [Section 41.2.5, "What You May Need to Know About Configuration Property Scopes"](#) earlier). This means their settings are global and will be set once when the first application module pool in your application is created. To insure the most predictable behavior, leave the values of these parameters in the **Connection Pool** section of the **Pooling and Scalability** tab at their *default* values — so that no entry for them is written into the `bc4j.xcfg` file — and to instead set the desired values for the database connection pooling tuning parameters as Java System Parameters in your Java EE container.

---

**Table 41–5 Database Connection Pool Parameters**

Pool Configuration Parameter	Description
Initial Pool Size (jbo.initpoolsize)	The number of JDBC connection instances to created when the pool is initialized The default is an initial size of 0 instances.
Maximum Pool Size (jbo.maxpoolsize)	The maximum number of JDBC connection instances that the pool can allocate. The pool will never create more JDBC connections than this imposes. The default is 4096 instances.

**Table 41–5 (Cont.) Database Connection Pool Parameters**

Pool Configuration Parameter	Description
Pool Polling Interval ( <code>jbo.poolmonitorsleepinterval</code> )	<p>The length of time in milliseconds between pool resource cleanup.</p> <p>While the number of JDBC connection instances in the pool will never exceed the maximum pool size, available instances which are candidates for getting removed from the pool do not get "cleaned up" until the next time the JDBC connection pool monitor wakes up to do its job.</p> <p>The default is 600000 milliseconds of idle time (which is 600 seconds, or ten minutes). Configuring a lower interval results in inactive connection instances being removed more frequently to save memory. Configuring a higher interval results in less frequent resource cleanups.</p>
Maximum Available Size ( <code>jbo.poolmaxavailablesize</code> )	<p>The ideal maximum number of JDBC connection instances in the pool when the server is under load.</p> <p>When the pool monitor wakes up to do resource cleanup, it will try to remove available JDBC connection instances to bring the total number of available instances down to this ideal maximum. Instances that have been not been used for a period longer than the idle instance time-out will always get cleaned up at this time, then additional available instances will be removed if necessary to bring the number of available instances down to this size. The default is an ideal maximum of 25 instances (when not under load).</p>
Minimum Available Size ( <code>jbo.poolminavailablesize</code> )	<p>The minimum number of available JDBC connection instances that the pool monitor should leave in the pool during a resource cleanup operation, when the server is under light load. Set to zero (0) if you want the pool to shrink to contain no instances when all instances have been idle for longer than the idle time-out.</p> <p>The default is to not let the minimum available size drop below 5 instances.</p>
Idle Instance Timeout ( <code>jbo.poolmaxinactiveage</code> )	<p>The number of seconds after which to consider an inactive JDBC connection instance in the pool as a candidate for removal during the next resource cleanup.</p> <p>The default is 600000 milliseconds of idle time (which is 600 seconds, or ten minutes).</p>

Notice that since the database connection pool does not implement the heuristic of session affinity, there is *no* configuration parameter for the database connection pool which controls the referenced pool size.

## 41.3 Initializing Database State and Pooling Considerations

Sometimes you may need to invoke stored procedures to initialize database state related to the current user's session. The correct place to perform this initialization is in an overridden `prepareSession()` method of your application module.

### 41.3.1 How to Set Database State Per User

The Fusion web application can set database state on a per-user basis. You typically create a database CONTEXT namespace, associate a PL/SQL procedure with it, and then use the `SYS_CONTEXT()` SQL function to reference values from the context.

For example, you can use the PL/SQL package to set and get a package-level variable that holds the name of the currently authenticated Fusion web application user as shown in [Example 41-4](#).

#### **Example 41-4** *CONTEXT\_PKG PL/SQL Package*

```
create or replace package context_pkg as
  procedure set_app_user_name(username varchar2);
  function app_user_name return varchar2;
end context_pkg;
```

Then your application can define the WHERE clause of a view object to reference the `context_pkg.app_user_name` function and query the per-user state.

To set the database state, the application module framework extension class (`AppModuleImpl.java`) defines a `callStoredProcedure()` helper method similar to the ones in [Section 37.4.2, "How to Invoke Stored Procedure with Only IN Arguments."](#) The custom application module class then extends this framework extension class and defines the `setCurrentUserInPLSQLPackage()` helper method shown in [Example 41-5](#). The helper method uses the `callStoredProcedure()` method to invoke the `context_pkg.set_app_user_name()` stored procedure, passing the value of the currently authenticated user as a parameter value.

#### **Example 41-5** *Method to Call Context\_Pkg.Set\_App\_User\_Name Stored Procedure*

```
// In CustomAppModuleImpl.java
public void setCurrentUserInPLSQLPackage() {
    String user = getUserPrincipalName();
    callStoredProcedure("context_pkg.set_app_user_name(?)", new Object[]{user});
}
```

With this helper method in place, the custom application module class then overrides the `prepareSession()` method as shown in [Example 41-6](#).

#### **Example 41-6** *Overridden afterConnect() and prepareSession() to Set Database State*

```
// In CustomAppModuleImpl.java
protected void prepareSession(Session session) {
    super.prepareSession(session);
    getLoggedInUser().retrieveUserInfoForAuthenticatedUser();
    setUserIdIntoUserDataHashtable();
    setCurrentUserInPLSQLPackage();
}
```

### 41.3.2 What You May Need to Know About Optimizing Connection Pooling

The default setting for `jbo.doconnectionpooling` is `false`. This means the application module instance hangs onto its JDBC connection while it's in the application module pool. This is the most efficient setting because the application module can keep its JDBC prepared statements open across application module checkouts/checkins. The application module instance will trigger its `prepareSession()` method each time a new user session begins using it.

If you set `jbo.doconnectionpooling` to `true`, then on each checkout of an application module from the pool, that application module pool will acquire a JDBC connection from the database connection pool and use it during the span of the current request. At the end of the request when the application module is released back to the application module pool, that application module pool releases the JDBC connection it was using back to the database connection pool.

It follows that with `jbo.doconnectionpooling` set to `true` the application module instance in the pool may have a completely different JDBC connection each time you check it out of the pool. In this situation, the `prepareSession()` method will fire each time the application module is checked out of the pool to give you a chance to reinitialize the database state.

When you set `jbo.doconnectionpooling` to `true`, the default setting for `jbo.txn.disconnect_level` ensures that all application modules, view objects and row sets remain in memory and stay valid after their corresponding references to JDBC connections are dropped. This configuration reduces the memory overhead associated with this situation where application module passivation is normally performed upon release. Instead, upon activation, the framework reexecutes and synchronizes the cursor positions.

To achieve a more ideal balance between conserving JDBC connections and keeping all application modules connected to the database, you can configure `jbo.ampool.connection_threshold` to specify the maximum number of connections that application modules in all application module pools combined may hold onto without releasing back to the connection pool upon checkin. Setting the threshold to a limit greater than 0, forces the cleanup monitor to release JDBC connections during application module pool cleanup instead of during application module checkin.

This is an important difference with application module connection threshold enabled; application modules are disconnected during pool cleanup, not during checkin. The cleanup monitor makes a best effort to disconnect application modules until the total number of JDBC connections falls below the specified threshold limit. Note that it may not be possible if there are not enough application modules in the available state. To ensure JDBC connections are released efficiently, you can configure `jbo.ampool.monitorsleepinterval` to shorten the monitor sleep period.

The configure `jbo.ampool.connection_threshold` property is not exposed by JDeveloper property editors and is intended to be configured at runtime, strictly as a Java option for Oracle WebLogic Server. For example, in your deployment environment, the system administrator may define the property as `-Djbo.ampool.connection_threshold=limit` using the startup script for Oracle WebLogic Server, such as `setWLSEnv.cmd`.

When testing your application in JDeveloper, you can specify the property as a JVM system property. For example, specify JDeveloper launch settings for JVM using the Edit Run Configuration dialog, as shown in [Figure 41-2](#). In JDeveloper, open the Edit Run Configuration dialog from the Run/Debug/Profile page of the Project Properties dialog.

**Figure 41–2 Specifying Application Module Connection Threshold as a JDeveloper Launch Setting**

## Using the Active Data Service

This chapter describes using the ADF Model layer and ADF Faces components with Active Data Service (ADS) in a Fusion web application.

This chapter includes the following sections:

- [Section 42.1, "Introduction to the Active Data Service"](#)
- [Section 42.2, "Configuring the Active Data Service"](#)
- [Section 42.3, "Configuring Components to Use the Active Data Service"](#)
- [Section 42.4, "Using the Active Data Proxy"](#)
- [Section 42.5, "Using the Active Data with a Scalar Model"](#)

### 42.1 Introduction to the Active Data Service

The Fusion technology stack includes Active Data Service (ADS), which is a server-side push framework that allows you to provide real-time data updates for ADF Faces components. You bind ADF Faces components to a data source and ADS pushes the data updates to the browser client without requiring the browser client to explicitly request it. For example, you may have a table bound to attributes of an ADF data control whose values change on the server periodically, and you want the updated values to display in the table. You can configure your application and the component so that whenever the data changes on the server, the ADF Model layer notifies the component and the component rerenders the changed data with the new value highlighted, as shown in [Figure 42-1](#).

**Figure 42-1 Table Displays Updated Data as Highlighted**

Row No	Description	Price	Detail
	Some text to describe the object v458	v455 78,000 USD	Text v464
	Some text to describing the object v463	v468 53,000 USD	Read only text v466
	Some text v460	v460 21,000 USD	Text text v460
	Text describing the object v469	v456 583,000 USD	Text v459
	Description v450	v450 1,000,000 USD	Text only v467
	A very long description that may be truncated v470	v465 1,200 USD	Read only data v465
	Description v462	v461 336,981 USD	Data text v461
	Some text v437	v449 209,000 USD	Data v326

Using ADS is an alternative to using automatic partial page rendering (PPR) to re-render data that changes on the backend as a result of business logic associated with the ADF data control bound to the ADF Faces component. Whereas automatic PPR requires sending a request to the server (typically initiated by the user), ADS enables

changed data to be pushed from the data store as the data arrives on the server. Also, in contrast to PPR, ADS makes it possible for the component to rerender only the changed data instead of the entire component. This makes ADS ideal for situations where the application needs to react to data that changes periodically.

To use this functionality, you must configure the application to use ADS. If your application services do not support ADS, then you also need to create a proxy of the service so that the components can display the data as it updates in the source.

Any ADF Faces page can use ADS. However, you can configure only the following ADF Faces components to work with active data:

- `activeCommandToolBarButton`
- `activeImage`
- `activeOutputText`
- `table`
- `tree`
- `treeTable`
- `graph`, `gauge`, `mapPointTheme`, `sunburst`, and `treemap` ADF Data Visualization components

Note that ADS does not support active data for all `graph` component types. For a list of supported graph types, see the "How to Configure Graph Components to Display Active Data" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 42.1.1 Limitations of the Active Data Service Framework

The framework for ADS has the following limitations.

- ADS does not support active data for ADF Faces components added dynamically, using PPR.
- ADS does not support active data for ADF Faces components that appear in a web page or region that gets invoked from a task flow call activity. Do not use task flow call activities with bounded task flows when active data is required.
- ADS does not support active data for every type of ADF Faces `graph` component. For a list of supported graph types, see the "How to Configure Graph Components to Display Active Data" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*
- ADS does not support active data on ADF Faces table components with filtering enabled. Once a table is filtered at runtime, active data cannot be displayed.
- ADS does not time out from user inactivity by default. To ensure that an active session is not maintained indefinitely, you can configure the `web.xml` context-parameter `oracle.adf.view.rich.poll.TIMEOUT` to specify how long ADS should run before it times out from user inactivity. For more information, see [Section 42.2.3, "How to Configure Session Timeout for Active Data Service."](#)

### 42.1.2 Active Data Service Framework

The framework for ADS contains a number of components that work together to send the active data from the source to the UI component. When a data event occurs, if the associated ADF Model layer binding is configured for active data, the Active Data

model delivers the data to the Event Manager. The Event Manager then retrieves the data and invokes the Push Service, which delivers the data to the correct component, based on how the service is configured (for more information, see [Section 42.1.3, "Data Transport Modes"](#)). The component then applies the new data pushed from the server. [Figure 42-2](#) shows the ADS framework.

**Figure 42-2 Active Data Service Framework**

In order to use the Active Data Service, you need to have a data store that publishes events when data is changed, and you need to create business services that react to those events. By default, ADF Business Components does not react to data events. The Active Data Proxy framework allows all types of data sources, including ADF Business Components, to work with ADS. It combines the `ActiveDataModel` with the JSF model, so that you need to override functionality only on this proxy rather than on both the `ActiveDataModel` and the JSF model.

The following comprise the ADS framework:

- `ActiveDataModel` interface: Abstraction of the active data model. Its responsibilities include:
  - Starting and stopping active data
  - Keeping track of the current active data event ID
  - Letting the renderer know whether the model needs active data or not.
- Event Manager: A server-side component that works with the ADF Model layer. It is responsible for the following:
  - Listening to binding events
  - Retrieving active data
  - Managing active data encoding

- Invoking the Push service to send the encoded active data
- Push service: A delivery channel that interacts with the Event Manager on the server side and with the Active Data Manager on the client side. It provides the following:
  - Establishing and maintaining the connection between the server and the client
  - Transmitting the active data over this connection from the server to the client
  - Ensuring that active data gets delivered within desired parameters and forcing component update if not
- Active Data Manager: A client-side component that distributes the active data to the correct component. Specifically, it is responsible for the following:
  - Delivering events from the server side that are coming through the channel, using an event delivery service
  - Handling multiple browser windows through a shared channel
  - Dispatching active data events to rich client components, so that the components can render the change accordingly
- Active Data Proxy: A proxy that allows all types of data sources to enable push functionality. Specifically, the proxy is responsible for the following:
  - Implementing and delegating `ActiveDataModel` functionality
  - Delegating to JSF models
  - Listening to data change events from the data source
  - Generating active data events based on the data change events

### 42.1.3 Data Transport Modes

Active data is sent to the client using data streaming (push) or one of two types of data polling. With *data streaming*, there is only one request, which stays open. When a data change event occurs, a partial response is sent (the response is not closed), the client is notified, and the associated component is updated to show the new data, as shown in [Figure 42-3](#).

**Figure 42-3 Streaming Mode**

With *data polling*, the application is configured to poll the data source at specified intervals, as shown in [Figure 42-4](#). With each request, a response is sent and closed, whether or not a data change event has occurred. If the data has changed, then the client is notified and the component is updated.

**Figure 42–4 Poll Mode**

*Long polling* is similar to streaming. When the page is rendered, a request is sent to the active channel. However, a response is not returned until there is a data change event. At that point, the connection is closed. As soon as the connection is closed, a new connection is initiated, which results in the connection being active most of the time: there are no specific intervals. Long polling results in the majority of data change events being received when they occur, because the connection is already established and ready to send a response to the client, as shown in [Figure 42–5](#).

**Figure 42–5 Long Polling Mode**

For more information, see [Section 42.2.2, "What You May Need to Know About Transport Modes."](#)

To use ADS, you need to configure your application to determine the method of data transport, as well as other performance options. You also need to configure the bindings for your components so that they can use ADS. If you are using ADF Business Components, you need to modify your model to implement the `ActiveModel` interface to register itself as the listener for active data events using the Active Data Proxy.

**Tip:** Oracle offers Oracle Business Activity Monitoring (BAM), which is a complete solution that provides the ability to create an active data store. For more information, see the *Oracle Fusion Middleware Developer's Guide for Oracle SOA Suite*.

## 42.2 Configuring the Active Data Service

You need to configure ADS to determine the data transport mode, as well as to set other configurations, such as a latency threshold and reconnect information.

---

---

**Note:** If you enable ADS but do not configure it, the ADS framework will use the default values shown in [Table 42-1](#).

---

---

## 42.2.1 How to Configure the Active Data Service

Configuration for running the Fusion web application with ADS in JDeveloper and Integrated WebLogic Server is done in the `adf-config.xml` file. For more information about the `adf-config.xml` file, including how to create one if you need to, see the "Configuration in `adf-config.xml`" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### To configure the Active Data Service:

1. In the Application Resources panel, double-click the `adf-config.xml` file.
2. Click the **Source** tab to open the file in the source editor, and create an entry for each of the elements shown in [Table 42-1](#).

**Table 42-1** ADS Configuration Elements in `adf-config.xml`

Element	Description	Default Value (in milliseconds)	Minimum Value (in milliseconds)
<code>&lt;transport&gt;</code>	The method by which data will be delivered to the client. Value values are: <ul style="list-style-type: none"> <li>■ streaming (default)</li> <li>■ polling</li> <li>■ long-polling</li> </ul> For more information, see <a href="#">Section 42.2.2, "What You May Need to Know About Transport Modes."</a>		
<code>&lt;latency threshold&gt;</code>	Latency threshold in milliseconds. Active data messages with network delays greater than this threshold will be treated as late.	10000	1000
<code>&lt;keep-alive-interval&gt;</code>	Frequency in milliseconds for sending keep-alive messages when no events are generated.	10000	5000
<code>&lt;polling-interval&gt;</code>	When <code>&lt;transport&gt;</code> set to <code>polling</code> , frequency in milliseconds of the poll request.	5000	1000
<code>&lt;max-reconnect-attempt-time&gt;</code>	Maximum period of time in milliseconds a client will attempt to reconnect the push channel to the server upon getting disconnected.	1800000 (30 minutes)	0
<code>&lt;reconnect-wait-time&gt;</code>	Time interval in milliseconds to wait between reconnect attempts.	10000	1000

**Performance Tip:** Keep the following in mind when configuring the ADS.

- Set the latency threshold to more than 1000 to avoid frequent component refreshing.
- Set the keep-alive interval and reconnect wait time to be less than the browser's keep-alive timeout.
- Set the max reconnect time to be less than your web server's session timeout.

[Example 42–1](#) shows a sample configuration that has content pushed to the client.

**Example 42–1 Sample Configuration for ADS in *adf-config.xml***

```
<?xml version="1.0" encoding="utf-8" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
  xmlns:ads="http://xmlns.oracle.com/adf/activedata/config">
  <ads:adf-activedata-config xmlns=
    "http://xmlns.oracle.com/adf/activedata/config">
    <transport>streaming</transport>
    <latency-threshold>5000</latency-threshold>
    <keep-alive-interval>10000</keep-alive-interval>
    <max-reconnect-attempt-time>90000</max-reconnect-attempt-time>
    <reconnect-wait-time>8000</reconnect-wait-time>
  </ads:adf-activedata-config>
</adf-config>
```

3. Create a properties file with an entry for the ADS configuration.
  - a. From the **Main** menu, choose **File > New**.
  - b. In the New Gallery, select **General Category** and then **File**, and click **OK**.
  - c. Name the file `adf-config.properties` and save it to the `META-INF\services` directory.
  - d. Add the following line:
 

```
http\://xmlns.oracle.com/adf/activedata/config=oracle.adfinternal.view.
faces.activedata.ActiveDataConfiguration$ActiveDataConfigCallback
```
  - e. Save and close the file.
4. Synchronize the clocks on the data server and on the application server. If these are not synchronized, then events may appear to ADS to have occurred in the future.

## 42.2.2 What You May Need to Know About Transport Modes

ADS can use one of three transport modes to deliver active data to the component: streaming, polling, or long polling.

When you configure ADS to use the streaming mode, data is pushed to the client whenever a change event is raised by the data. On the client side, after the push channel is established, if there is no activity within the time of the value for the `latency-threshold` element plus the `keep-alive-interval`, an `establish-channel-request` will be sent out repeatedly based on the value of the `reconnect-wait-time` element, until the amount of time passed reaches the value of the `max-reconnect-attempt-time` element. After that, the connection will be considered disconnected. For example, given the values in [Example 42–1](#), if there is no

activity in 15,000 milliseconds, an establish channel request will be sent out every 8,000 milliseconds for up to 90,000 milliseconds. After that, the connection will be considered disconnected.

On the server side, the server disconnects the push channel and starts a timer to clean up with a `cleanup-delay-time` when there is an empty active data message or when it fails to send out an active data message. The `cleanup-delay-time` is calculated as `max-reconnect-attempt-time + 30 * 1000 ms`. Its default value is 30 minutes.

When you configure ADS to use the polling mode, on the client side the polling request is scheduled to be sent out repeatedly after the value of the `polling-interval` element has been reached. If no response is received after the value of the `max-reconnect-attempt-time` has elapsed, the connection is treated as disconnected and no more requests will be sent. After receiving a polling response, if the time the response has taken is greater than the `polling-interval` element, the service sends the next request out right away. If it is less, the next request will be sent as scheduled.

For the server side, the session ends after the polling response is returned. At that point, a timer with a `cleanup-delay-time` is set up to trigger cleanup. If a new request comes in before the timer fires, the old timer is canceled, and new timer is created.

When you configure ADS to use the long polling mode, requests are made as they are in streaming mode; however, as soon as the connection is treated as disconnected, a new connection is initiated. The result is a significant reduction in latency.

[Table 42-2](#) compares the three different modes.

**Table 42-2 Comparison of Streaming, Polling, and Long-Polling Modes**

	Streaming	Polling	Long-Polling
<b>Latency</b>	Very good. Directly after an event occurs on the server side, a partial response is sent to the client. If there is another event, immediately, it is also sent as a partial response. There is almost no latency with this approach.	Poor, depending on the polling interval. If the polling interval is short (for example, 0.5 seconds), it will slow down the network because the connections are repeatedly opened. It is also expensive on the client- and server-side resources.	Good. However, when there is a new event immediately after a response has been closed, there is some latency until the new data appears on the client side. On average, this is not a problem.

**Table 42–2 (Cont.) Comparison of Streaming, Polling, and Long-Polling Modes**

	<b>Streaming</b>	<b>Polling</b>	<b>Long-Polling</b>
<b>HTTP Proxy</b>	Poor.  For some older servers, because the response is never released, when a proxy is sitting between client and server, it is possible that the proxy will buffer responses.  This is an unfortunate optimization that prevents real-time data from flowing into the browser. Long polling should be used if a proxy is used.	Good.	Good.
<b>Number of live connections</b>	Poor.  Many concurrent connections, as the stream is always live.	Good.  Connections are live only during the actual poll. Note however that if there is a high polling rate then the number of concurrent connections will also be high.	Poor.  Many concurrent connections, as the stream is almost always live.
<b>Communication channel</b>	HTTP GET  This can result in the display of a "busy" cursor or the animation of a browser's "throbber" icon.	XMLHttpRequest (XHR)  HTTP GET	XMLHttpRequest (XHR)  HTTP GET

### 42.2.3 How to Configure Session Timeout for Active Data Service

By default, applications that you configure to use ADS will not time out. In polling mode, the client periodically sends polling request to server. In long polling mode, the client sends a new polling request immediately after a polling request is returned from the server. In steaming mode, the server holds the GET request response and will indefinitely write active data to it. Due to the behavior of each data transport mode, ADS will maintain the application session active whether or not the user interacts with the application.

To prevent this situation of maintaining an active session indefinitely due to ADS, the `web.xml` configuration file contains the `oracle.adf.view.rich.poll.TIMEOUT` context-parameter, which specifies how long ADS should run before it times out from user inactivity. The ADS client is considered eligible to time out if there is no keyboard or mouse activity. The default timeout period is set at ten minutes. So if the user remains inactive for ten minutes, that is, does not use the keyboard or mouse, then ADS will stop polling or will abort its connection with server, and from that point on, the application participates in the standard server-side session timeout. For example, if the server-side session timeout is 65 minutes, and the polling timeout parameter is set

to 15 minutes, then it is expected that the session should expire when the user is inactive for more than 80 minutes.

You can override this timeout setting for a specific web page using the ADF Faces poll component `timeout` attribute. The poll component allows you to deliver a heartbeat to the server to prevent users from being timed out of their session for specific pages. For more information about the `oracle.adf.view.rich.poll.TIMEOUT` context-parameter and individual web pages, see the "Using Polling Events to Update Pages" section of *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

**Before you begin:**

It may be helpful to have an understanding of the ADS configuration choices. For more information, see [Section 42.2, "Configuring the Active Data Service."](#)

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see [Section 42.1, "Introduction to the Active Data Service."](#)

**To configure the Active Data Service to timeout after session becomes inactive:**

1. In the Application Navigator, in the user interface project, expand the **Web Content** and **WEB-INF** nodes, and then double-click **web.xml**.
2. In the overview editor for the `web.xml` file, click the **Application** navigation tab and in the Context Initialization Parameters section, click the **Create** icon to add the polling timeout parameter as follows:

**Name:** Enter the context parameter `oracle.adf.view.rich.poll.TIMEOUT`.

**Value:** Enter the amount of time in milliseconds after which all pages configured to use active data will time out and ADS will stop. To disable ADF time out due to user inactivity, enter `-1`. The default value for ADS to timeout is `600000` milliseconds (ten minutes).

## 42.3 Configuring Components to Use the Active Data Service

How you configure components to use ADS depends on whether or not you must use the Active Data proxy. If your application uses a data store that publishes events when data is changed, and your business services react to those events (for example, if your application uses BAM), then you do not need to use the Active Data proxy.

If your business services do not react to those events (for example, if your application uses ADF Business Components), then you must use the Active Data proxy and follow different procedures for configuring your components.

---

**Note:** If your business service requires the use of the Active Data proxy, then you can only use the following components with active data:

- table
  - tree
  - treeTable
  - DVT graph, gauge, mapPointTheme, sunburst, and treemap components. Note that ADS does not support active data for all graph component types. For a list of supported graph types, see the "How to Configure Graph Components to Display Active Data" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- 

### 42.3.1 How to Configure Components to Use the Active Data Service Without the Active Data Proxy

To use ADS without the proxy, you need to set a value on the binding element in the corresponding page definition file.

**To configure a component to display active data without the Active Data proxy:**

1. Drop a component onto a JSF page.
2. If you are using an ADF bound tree or tree table, you need to ensure the following:
  - The binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
  - The binding rule contains a single attribute.
  - The table does not use filtering.
  - The tree component's `nodeStamp` facet contains a single `outputText` tag and contains no other tags, as described in [Section 42.3.3, "What You May Need to Know About Displaying Active Data in ADF Trees."](#)
3. Open the page's associated page definition file.
4. In the Structure window for the page definition file, select the node that represents the attribute binding for the component. In the Property Inspector, set the `ChangeEventPolicy` attribute to **Push**.

**Tip:** You can use the `statusIndicator` component to indicate the server state. For more information, see the "Displaying Application Status Using Icons" section of the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

### 42.3.2 How to Configure Components to Use the Active Data Service with the Active Data Proxy

To use ADS with the proxy, you need bind the value of your component to decorator class that will use the proxy. For more information about this class, see [Section 42.4, "Using the Active Data Proxy."](#) to set a value on the binding element in the corresponding page definition file.

**To configure a component to display active data with the Active Data proxy:**

1. Drop a component onto a JSF page.
2. Change the value attribute to be bound to a decorator class that you will create for use with the proxy. For more information, see [Section 42.4, "Using the Active Data Proxy."](#)

If you are using an ADF bound tree or tree table, you need to ensure the following:

- The binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
- The binding rule contains a single attribute.
- The table does not use filtering.
- The tree component's `nodeStamp` facet contains a single `outputText` tag and contains no other tags, as described in [Section 42.3.3, "What You May Need to Know About Displaying Active Data in ADF Trees."](#)

### 42.3.3 What You May Need to Know About Displaying Active Data in ADF Trees

When you create an ADF Faces tree (or tree table) component, you configure a `nodeStamp` facet, which is a holder for the component used to display the data for each node of the tree. Each node is rendered (stamped) once, repeatedly for all nodes.

Because of this stamping behavior, only certain types of components are supported as children inside an ADF Faces tree component. When the tree component is not bound to an active data source, all components that have no behavior are supported. However, when you configure the tree to use ADS, only the `outputText` component is supported inside of the `nodeStamp` facet, as shown in [Example 42–2](#). The `nodeStamp` facet must not contain any other tags. So, for example, active data will not work if you add `panelGroupLayout` tags to the `nodeStamp` facets of a tree configured to use ADS.

**Example 42–2 Tree Configured to Use ADS Must Contain outputText Component**

```
<f:facet name="nodeStamp">
  <af:outputText value="#{row.str2}"/>
</f:facet>
```

### 42.3.4 What Happens at Runtime: How Components Render When Bound to Active Data

After you configure your application and the component for ADS, whenever the data changes on the server, the component is notified and rerenders with only the changed data. In contrast, a component not configured for either active data or automatic PPR will need to be explicitly refreshed after a data change occurs. The explicit refresh will refetch all data that is visible on the client, including data that has not changed. Consequently, this will force the entire component to rerender. Additionally, when the component is bound to an active data source (with active data policy "Push"), the component rerenders with the new value highlighted.

### 42.3.5 What You May Need to Know About ADS and Google Chrome

When the Fusion web application runs in the Google Chrome web browser and a user presses Ctrl+N (or Ctrl+T) to open a new window (or tab) and then copies the URL from the original window into the new window, active data in the original window will stop streaming. According to the Google Chrome process model, the new browser

window will be created in a separate process and both windows will share the same HTTP session. However, because browser windows that are created in two separate processes cannot communicate with each other, ADS will become out of sync between the client and server and will stop streaming. As a workaround, to allow active data in multiple Google Chrome windows, before copying the URL from the original window into the new window users must press Ctrl-Shift-N to open the browser window in incognito mode (private browsing). Because Ctrl-Shift-N opens the window in a separate process and a separate HTTP session, ADS will not attempt to synchronize between the windows and streaming will be unaffected.

## 42.4 Using the Active Data Proxy

You use the active data proxy when your business services do not react to data events. If you want your components to update based on events passed into ADF Business Components, then you need to use the Active Data Proxy.

**Tip:** If your application uses BAM for the business service, then you do not need to use the Active Data Proxy.

---

**Note:** If your business service requires the use of the Active Data Proxy, then you can only use the following components with active data:

- table
  - tree
  - treeTable
  - DVT graph, gauge, mapPointTheme, sunburst, and treemap components. Note that ADS does not support active data for all graph component types. For a list of supported graph types, see the "How to Configure Graph Components to Display Active Data" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.
- 

You need to create a Java class that subclasses one of the following decorator classes:

- `ActiveCollectionModelDecorator` class
- `ActiveDataModelDecorator` class (for use with graphs)
- `ActiveGeoMapDataModelDecorator` class
- `ActiveGaugeDataModelDecorator` class

These classes are wrapper classes that delegate the active data functionality to a default implementation of `ActiveDataModel`. The `ActiveDataModel` class listens for data change events and interacts with the Event Manager. Specifically, it does the following:

- Starts and stops the active data and the `ActiveDataModel` object, and registers and unregisters listeners to the data source.
- Wraps the JSF model interface. For example, the `ActiveCollectionModelDecorator` class wraps the `CollectionModel` class.
- Generates active data events based on data change events from the data source.

- Manages listeners from the Event Manager and pushes active data events to the Event Manager.

You need to implement methods on this Java class that registers itself as the listener of the active data source and gets the model to which the data is being sent.

---

---

**Note:** The Active Data framework does not support complicated business logic or transformations that require the ADF runtime context, such as a user profile or security. For example, the framework cannot convert an ADF context locale-dependent value and return a locale-specific value.

As an example of complicated business logic, say you have logic that allows a user to move an order from `open` status to `pending`. This change results in an `update` event, which should cause the order to be removed from a data object called "Open Orders." The framework cannot handle this event type transformation based on business logic. Instead, you need to have your data source handle this before publishing the data change event.

---

---

#### **Before you begin:**

Implement the logic to fire the active data events asynchronously from the data source. For example, this logic might be a business process that updates the database, or a JMS client that gets notified from JMS.

#### **To use the active data service:**

1. Create a Java class that extends the decorator class appropriate for your component. [Example 42-3](#) shows a class created for a table.

#### **Example 42-3 Extend the Decorator Class**

```
package view;

import oracle.adf.view.rich.model.ActiveCollectionModelDecorator;

/**
 * This code wraps the existing collection model in the page and implements the
 * ActiveDataModel interface to enable ADS for the existing page.
 */
public class DeptModel
    extends ActiveCollectionModelDecorator
{
}
```

2. Implement the method that returns the model. [Example 42-4](#) shows an implementation of the `getCollectionModel()` method that relies on expression language (EL) to avoid needing to typecast to an internal class. The method returns the `DepartmentsView1` collection from the binding container.

#### **Example 42-4 Return the Model**

```
public CollectionModel getCollectionModel()
{
    if (_model == null)
    {
        FacesContext fc = FacesContext.getCurrentInstance();
        Application app = fc.getApplication();
```

```

ExpressionFactory elFactory = app.getExpressionFactory();
ELContext el = fc.getELContext();

// This is EL to avoid typecasting to an Internal class.
ValueExpression ve = elFactory.createValueExpression(el,
    "#{bindings.DepartmentsView1.collectionModel}", Object.class);

// Now GET the collectionModel
_model = (CollectionModel)ve.getValue(el);
}
return _model;
}

```

3. Create an inner class that is your own implementation of an `ActiveDataModel` class, which the decorator can use to start and stop the active data and connect and disconnect from the data source. This class should also use the `changeCount` API to maintain data read consistency, as shown in [Example 42-5](#). For more information, see [Section 42.4.1, "What You May Need to Know About Read Consistency."](#)

**Example 42-5 Connect to the Data Source**

```

public class MyActiveDataModel extends BaseActiveDataModel
{
    protected void startActiveData(Collection<Object> rowKeys,
        int startChangeCount)
    {
        _listenerCount.incrementAndGet();
        if (_listenerCount.get() == 1)
        {
            System.out.println("start up");

            Runnable dataChanger = new Runnable()
            {
                public void run()
                {
                    System.out.println("MyThread starting.");
                    try
                    {
                        Thread.sleep(2000);
                        System.out.println("thread running");
                        triggerDataChange(MyActiveDataModel.this);
                    }
                    catch (Exception exc)
                    {
                        System.out.println("MyThread exceptioned out.");
                    }
                    System.out.println("MyThread terminating.");
                }
            };
            Thread newThrd = new Thread(dataChanger);
            newThrd.start();
        }
    }

    protected void stopActiveData(Collection<Object> rowKeys)
    {
        _listenerCount.decrementAndGet();
        if (_listenerCount.get() == 0)
        {

```

```
        System.out.println("tear down");
    }
}

public int getCurrentChangeCount()
{
    return _currEventId.get();
}

public void bumpChangeCount()
{
    _currEventId.incrementAndGet();
}

public void dataChanged(ActiveDataUpdateEvent event)
{
    fireActiveDataUpdate(event);
}

private final AtomicInteger _listenerCount = new AtomicInteger(0);
private final AtomicInteger _currEventId = new AtomicInteger();
}
```

4. Implement the method that will return the `ActiveDataModel` class, as shown in [Example 42-6](#).

**Example 42-6 Return the ActiveDataModel**

```
public ActiveDataModel getActiveDataModel()
{
    return _activeDataModel;
}
```

5. Create a method that creates application-specific events that can be used to insert or update data on the active model.

[Example 42-7](#) shows the `triggerDataChange()` method, which uses the active model (an instance of `MyActiveDataModel`) to create `ActiveDataUpdateEvent` objects to insert and update data.

**Example 42-7 Create Event Objects to Update Model**

```
public void triggerDataChange(MyActiveDataModel l)
    throws Exception
{

    // do an update on dept 1
    l.bumpChangeCount();
    ActiveDataUpdateEvent event =
        ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.UPDATE,
                                                    l.getCurrentChangeCount(),
                                                    JboActiveDataEventUtil.convertKeyPath(new Object[]
                { new Long(1), new Integer(0) })), null, new String[]
                { "name" }, new Object[]
                { "Name Pushed" });

    l.dataChanged(event);
}
```

```

try
{
    Thread.sleep(2000);
}
catch (InterruptedException ie)
{
    ie.printStackTrace();
}
// insert dept 99

l.bumpChangeCount();
event =
    ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.INSERT_AFTER,
                                                    l.getCurrentChangeCount(),
                                                    JboActiveDataEventUtil.convertKeyPath(new Object[]
                { new Long(99), new Integer(0) })),
            JboActiveDataEventUtil.convertKeyPath(null), new String[]
                { "addr1", "name" }, new Object[]
                { "Addr Inserted", "Name Inserted" });
l.dataChanged(event);

try
{
    Thread.sleep(2000);
}
catch (InterruptedException ie)
{
    ie.printStackTrace();
}

// delete dept 10

l.bumpChangeCount();
event =
    ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.REMOVE,
                                                    l.getCurrentChangeCount(),
                                                    JboActiveDataEventUtil.convertKeyPath(new Object[]
                { new Long(9), new Integer(0) })), null, null, null);
l.dataChanged(event);

try
{
    Thread.sleep(2000);
}
catch (InterruptedException ie)
{
    ie.printStackTrace();
}

// refresh the entire table

l.bumpChangeCount();
event =
    ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.REFRESH,
                                                    l.getCurrentChangeCount(),
                                                    null, null, null,
                                                    null);
l.dataChanged(event);

```

```
    }  
  
    private MyActiveDataModel _activeDataModel = new MyActiveDataModel();  
  
    private CollectionModel _model = null;  
  
}
```

### 42.4.1 What You May Need to Know About Read Consistency

Using active data means that your component has two sources of data: the active data feed and the standard data fetch. Because of this, you must make sure your application maintains read consistency.

For example, say your page contains a table and that table has active data enabled. The table has two methods of delivery from which it updates its data: normal table data fetch and active data push. Say the back end data changes from `foo` to `bar` to `fred`. For each of these changes, an active data event is fired. If the table is refreshed *before* those events hit the browser, the table will display `fred` because standard data fetch will always get the latest data. But then, because the active data event might take longer, some time *after* the refresh the data change event would cause `foo` to arrive at the browser, and so the table would update to display `foo` instead of `fred` for a period of time. Therefore, you must implement a way to maintain the read consistency.

To achieve read consistency, the `ActiveDataModel` has the concept of a *change count*, which effectively timestamps the data. Both data fetch and active data push need to maintain this `changeCount` object by monotonically increasing the count, so that if any data returned has a lower `changeCount`, the active data event can throw it away. [Example 42-7](#) shows how you can use your implementation of the `ActiveDataModel` class to maintain read consistency.

## 42.5 Using the Active Data with a Scalar Model

ADF components that display collection-based data can be configured to work with ADS and require no extra setup in the view layer. However, imagine that your JSPX page uses an `activeOutputText` component to display new counts based on a Java timer. In this case, you will replace the model layer with scalar or "flat" data that you display from a Java Bean.

To implement the scalar model, follow these basic steps (as illustrated in the [Example 42-8](#)):

1. Use the `ActiveModelContext` API to register the bean with ADS so the bean (a scalar model) imitates an actual model.
2. Implement a custom mechanism to push the data to the view layer.

#### **Example 42-8 Implement the Scalar Model in the Java Bean**

```
package oracle.adfdemo.view.feature.rich;  
  
import java.util.Collection;  
import java.util.Timer;  
import java.util.TimerTask;  
import java.util.concurrent.atomic.AtomicInteger;
```

```

import oracle.adf.view.rich.activedata.ActiveModelContext;
import oracle.adf.view.rich.activedata.BaseActiveDataModel;
import oracle.adf.view.rich.event.ActiveDataEntry;
import oracle.adf.view.rich.event.ActiveDataUpdateEvent;

import oracle.adfinternal.view.faces.activedata.ActiveDataEventUtil;

public class CounterBean extends BaseActiveDataModel
// Example using a Java timer to create new counts
{
    public CounterBean()
    {
        timer.schedule(new UpdateTask(), 2000, 2000);
    }

    public String getState()
    {
        // 1. Use the ActiveModelContext API to register the scalar model key path for
        // the "state" attribute.
        ActiveModelContext context = ActiveModelContext.getActiveModelContext();
        Object[] keyPath = new String[0];
        context.addActiveModelInfo(this, keyPath, "state");

        return String.valueOf(counter);
    }

    // Not needed. We do not need to connect to a (real) active data source.
    protected void startActiveData(Collection<Object> rowKeys, int
        startChangeCount) {}

    // Not needed. We do not need to connect to a (real) active data source.
    protected void stopActiveData(Collection<Object> rowKeys) {}

    public int getCurrentChangeCount()
    {
        return counter.get();
    }

    protected class UpdateTask extends TimerTask
    {
        public void run()
        {
            counter.incrementAndGet();

            // 2. Use ActiveDataEventUtil to create an event object to update the model.
            ActiveDataUpdateEvent event =
                ActiveDataEventUtil.buildActiveDataUpdateEvent(
                    ActiveDataEntry.ChangeType.UPDATE,
                    counter.get(),
                    new String[0],
                    null,
                    new String[] { "state" },
                    new Object[] { counter.get() });
            fireActiveDataUpdate(event);
        }
    }

    private static final Timer timer = new Timer();
    private final AtomicInteger counter = new AtomicInteger(0);

```

After you create the bean, register the bean as a managed bean in the `faces-config.xml` file (as illustrated for `counterBean` in [Example 42-9](#)):

**Example 42-9 Register the Managed Bean**

```
...
<managed-bean>
  <managed-bean-name>counterBean</managed-bean-name>
  <managed-bean-class>
    oracle.adfdemo.view.feature.rich.CounterBean
  </managed-bean-class>
  <managed-bean-scope>session</managed-bean-scope>
</managed-bean>
```

Once the bean is registered, you can use ADS to stream the data to the view layer. Your ADF Faces component use expression language to receive the pushed data (as illustrated by the `activeOutputText` component `value` attribute in [Example 42-10](#)):

**Example 42-10 Display the Active Data**

```
...
<f:view>
  <af:document title="Active Data Visual Design Demo"
    binding="#{templateBindings.documentComponent}"
    smallIconSource="#{aboutBean.smallIconSource}"
    largeIconSource="#{aboutBean.largeIconSource}" theme="dark"
    id="d1">
    <af:pageTemplate id="dmoTpl" viewId="#{templates.componentTemplate}">
      <f:attribute name="tagName" value="Active Data Visual Design"/>
      <f:attribute name="demoKind" value="visualDesign"/>
      <f:attribute name="customEditorPresent" value="true"/>
      <f:facet name="center">
        <af:panelGroupLayout layout="scroll">
          <af:activeOutputText
            value="#{counterBean.state}"
            inlineStyle=
              "color:brown;
              font-size:100px;
              font-weight:bold;
              text-align:center;"
          />
        </af:panelGroupLayout>
      </f:facet>
    </af:pageTemplate>
  </af:document>
</f:view>
```

## Oracle ADF XML Files

This appendix provides a reference for the Oracle ADF metadata files that you create in your data model and user interface projects. You may use this information when you want to edit the contents of the metadata these files define.

This appendix includes the following sections:

- [Section A.1, "Introduction to the ADF Metadata Files"](#)
- [Section A.2, "ADF File Overview Diagram"](#)
- [Section A.3, "ADF File Syntax Diagram"](#)
- [Section A.4, "adfm.xml"](#)
- [Section A.5, "modelProjectName.jpx"](#)
- [Section A.6, "bc4j.xcfg"](#)
- [Section A.7, "DataBindings.cpx"](#)
- [Section A.8, "pageNamePageDef.xml"](#)
- [Section A.9, "adfc-config.xml"](#)
- [Section A.10, "task-flow-definition.xml"](#)
- [Section A.11, "adf-config.xml"](#)
- [Section A.12, "adf-settings.xml"](#)
- [Section A.13, "web.xml"](#)
- [Section A.14, "logging.xml"](#)

### A.1 Introduction to the ADF Metadata Files

Metadata files in the Oracle Fusion web application are structured XML files used by the application to:

- Specify the parameters, methods, and return values available to your application's Oracle ADF data control usages
- Create objects in the Oracle ADF binding context and define the runtime behavior of those objects
- Define configuration information about the UI components in JSF and ADF Faces
- Define application configuration information for the Java EE application server

In the case of ADF bindings, you can use the binding-specific editors to customize the runtime properties of the binding objects. You can open a binding editor when you

display the Structure window for a page definition file and choose **Properties** from the context menu.

Additionally, you can view and edit the contents of any metadata file in JDeveloper's XML editor. The easiest way to work with these file is through the Structure window and Property Inspector. In the Structure window, you can select an element and in the Property Inspector, you can define attribute values for the element, often by choosing among dropdown menu choices. Use this reference to learn the choices you can select in the case of the Oracle ADF-specific elements.

## A.2 ADF File Overview Diagram

The relationship between the Oracle ADF metadata files defines dependencies between the model data and the user interface projects. The dependencies are defined as file references within XML elements of the files.

Figure A-1 illustrates the hierarchical relationship of the XML metadata files that you might work with in a Fusion web application that uses an ADF Business Components application module as a service interface to JSF web pages.

**Figure A-1 Oracle ADF File Hierarchy Overview for the Fusion Web Application**

### A.2.1 Oracle ADF Data Control Files

In an ADF Business Components application, the data control implementation files are contained within the application. The application module and view object XML component descriptor files provide the references for the data control. These files, in conjunction with the `bc4j.xcfg` file, provide the necessary information for the data control.

An application that uses ADF Business Components in one project and a non-ADF Business Components data control in another project may have a `DataControls.dcx` file, as well as supporting `<sessionbeaname>.xml` and `<beaname>.xml` files.

## A.2.2 Oracle ADF Data Binding Files

These standard XML configuration files for a Fusion web application appear in your user interface project:

- `adfm.xml`: This file lists the `DataBindings.cpx` file that is available in the current project.  
See [Section A.4, "adfm.xml"](#) for more information.
- `DataBindings.cpx`: This file contains the page map, page definitions references, and data control references. The file is created the first time you create a data binding for a UI component (either from the Structure window or from the Data Controls Panel). The `DataBindings.cpx` file defines the Oracle ADF binding context for the entire application. The binding context provides access to the bindings and data controls across the entire application. The `DataBindings.cpx` file also contains references to the `<pagename>PageDef.xml` files that define the metadata for the Oracle ADF bindings in each web page.

For more information, see [Section A.7, "DataBindings.cpx"](#).

- `<pagename>PageDef.xml`: This is the page definition XML file. It associates web page UI components with data, or data controls. JDeveloper creates this file each time you design a new web page using the Data Controls Panel or Structure window. These XML files contain the metadata used to create the bindings that populate the data in the web page's UI components. For every web page that refers to an ADF binding, there must be a corresponding page definition file with binding definitions.

For more information, see [Section A.8, "pageNamePageDef.xml"](#).

## A.2.3 Web Configuration Files

These standard XML configuration files required for a JSF application appear in your user interface project:

- `web.xml`: Part of the application's configuration is determined by the contents of its Java EE application deployment descriptor, `web.xml`. The `web.xml` file defines everything about your application that a server needs to know. The file plays a role in configuring the Oracle ADF data binding by setting up the `ADFBindingFilter`. Additional runtime settings include servlet runtime and initialization parameters, custom tag library location, and security settings.

For more information about ADF data binding and JSF configuration options, see [Section A.13, "web.xml"](#).

An ADF Faces application typically uses its own set of configuration files in addition to `web.xml`. For more information, see the "Configuration in `trinidad-config.xml`" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

- `adfc-config.xml`: The configuration file for an ADF unbounded task flow. The configuration file contains metadata about the activities and control flows

contained in the unbounded task flow. The default name for this file is `adfc-config.xml`, but an end user can change the name.

For more information, see [Section A.9, "adfc-config.xml"](#).

- `task-flow-definition.xml`: The configuration file for an ADF bounded task flow. The configuration file contains metadata about the activities and control flows contained in the bounded task flow. The default name for this file can be `task-flow-definition.xml` or whatever an end user specifies in the **Create ADF Task Flow** dialog. The same application can contain multiple task flow definition files.

For more information, see [Section A.10, "task-flow-definition.xml"](#).

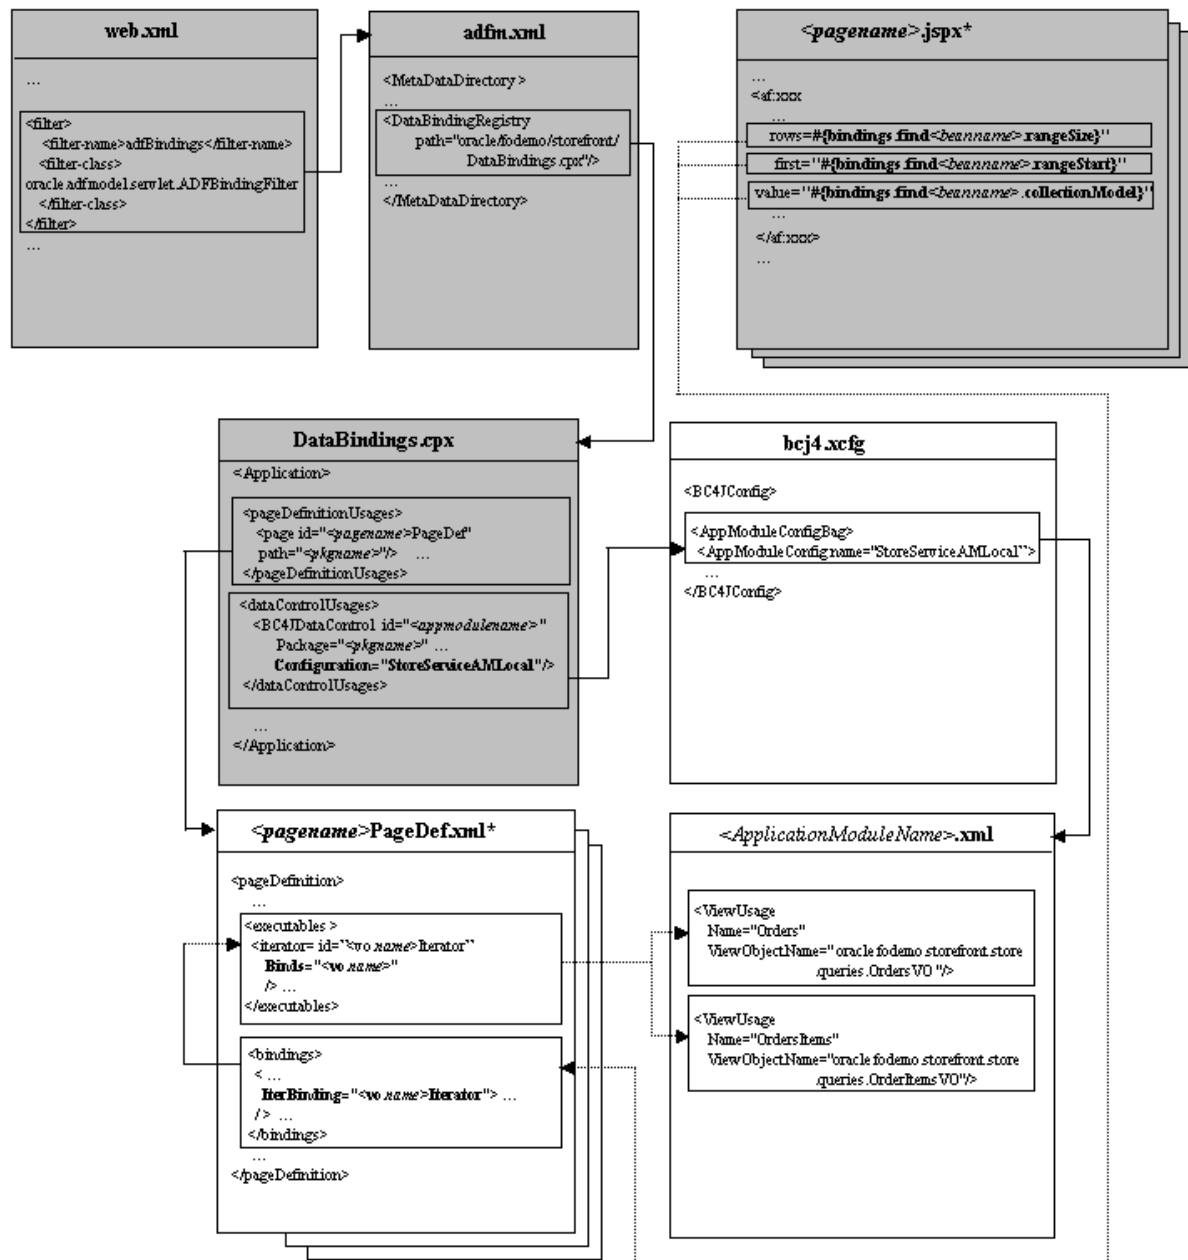

## A.3 ADF File Syntax Diagram

[Figure A-2](#) illustrates the hierarchical relationship of the XML metadata files that you might work with in a web application that uses an ADF application module as a service interface to ADF Business Components. At runtime, the objects created from these files interact in this sequence:

1. When the first request for an ADF databound web page occurs, the servlet registers the Oracle ADF servlet filter `ADFBindingFilter` named in the `web.xml` file.
2. The binding filter creates an empty binding context.
3. When a page is rendered, the binding filter asks the binding context to load a corresponding `PageDef.xml` for the page.
4. The binding context creates the binding container by loading the `<page>` file as referenced by the `<pagemap>` element in the `DataBindings.cpx` file.
5. The `adfm.xml` file loads the `DataBindings.cpx` contents and finds the right `PageDef.xml` based on the `<pagemap>` element reference to the `<pageDefinitionUsage>` element.
6. The binding container's `prepareModel` phase prepares and refreshes all relevant executables (most are marked `deferred` by default).
7. An iterator binding gets executed by referencing the named method on the data control found through the data control factory named in the case of ADF Business Components in the `bc4j.xcfg` file.
8. The binding container also creates the bindings defined in the `<bindings>` section of the `pagenamePageDef.xml` file for the mapped web page.
9. The web page references to ADF bindings through EL using the expression `{bindings}` are resolved by accessing the binding container of the page.
10. The page pulls the available data from the bindings in the binding container.

Figure A-2 Oracle ADF File Hierarchy and Syntax Diagram for an ADF BC-based Web Application

■ Presentation layer

□ ADF BC and Oracle ADF Model layer

## A.4 adfm.xml

The `adfm.xml` file contains the classpath-relative paths for the `.cpx`, `.dcx`, `.jspx`, and `.xcfg` files in each design time project that is included in the runtime deployed application. The `adfm.xml` file operates as a dynamically maintained "Registry of

Registries" that is used to quickly find all .cpx, .dcx, .jspx, and .xcfg files (which are themselves registries of metadata).

The file registry is used extensively by the ADF Library resource catalog browsing implementations, by the ADF model layer design time, and at runtime during merge and discovery.

When a developer creates a binding on a page, JDeveloper adds metadata files (for example, page definitions) in the project source tree. The `adfm.xml` file then notes the location of each.

When a project is built, the `adfm.xml` file is put in `project-root/adfmsrc/META-INF/adfm.xml`. The project-level archive deployment profiles locate the file at `META-INF/adfm.xml`.

At runtime, the application classpath is scanned to build the list of .cpx files that comprise the application. The application then loads each .cpx as needed to create the binding context. For details about the ADF model layer usage, see [Section 12.3.2, "What Happens When You Use the Data Controls Panel"](#).

Four types of sub registries are recorded by the `adfm.xml` file:

- `DataBindingRegistry (.cpx)`
- `DataControlRegistry (.dcx)`
- `BusinessComponentServiceRegistry (.xcfg)`
- `BusinessComponentProjectRegistry (.jspx)`

## A.5 modelProjectName.jpx

The .jspx file contains configuration information that JDeveloper uses in the design time to allow you to create the data model project with ADF Business Components. It also contains metadata that defines how a shared application module is used at runtime. Because the shared application module can be accessed by any data model project in the same Fusion web application, JDeveloper maintains the scope of the shared application module in the ADF Business Components project configuration file.

This file is saved in the `src` directory of the project. For example, if you look at the `StoreFrontService.jpx` file in the `./src/model` subdirectory of the Fusion Order Demo application's `StoreFrontService` project, you will see the `SharedLookupService` application module's usage definition. For details about the shared application module usage, see [Section 10.2.2, "What Happens When You Define a Shared Application Module"](#).

[Example A-2](#) displays a sample default .jspx file.

### Example A-1 Sample .jspx File

```
<JboProject
  xmlns="http://xmlns.oracle.com/bc4j"
  Name="StoreFrontService"
  Version="11.1.1.49.73"
  SeparateXMLFiles="true"
  PackageName="">
  <DesignTime>

</JboProject>

```

## A.6 bc4j.xcfg

The `bc4j.xcfg` file contains metadata information about application module names, the database connection used by the application module, and the runtime parameters the user has configured for the application module.

The `bc4j.xcfg` file is located in the `./common` subdirectory relative to the application module's XML component definition. All of the configurations for all of the application modules in a single Java package are saved in that same file. For example, if you look at the `bc4j.xcfg` file in the `./classes/oracle/fodemo/storefront/store/service/common` directory of the Fusion Order Demo application's `StoreFront` project, you will see the three named configurations for its `StoreServiceAM` application module. For details about editing the configurations, see [Section 9.3.4, "How to Change Your Application Module's Runtime Configuration"](#) and [Section 41.2, "Setting Pool Configuration Parameters"](#).

[Example A–2](#) displays a sample `bc4j.xcfg` file from the Fusion Order Demo application.

### Example A–2 Sample bc4j.xcfg File

```

<BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/configuration">
  <AppModuleConfigBag ApplicationName="oracle.fodemo.storefront.store.service.StoreServiceAM">
    <AppModuleConfig
      DeployPlatform="LOCAL"
      JDBCName="FOD"
      jbo.project="StoreFrontService"
      name="StoreServiceAMLocal"
      ApplicationName="oracle.fodemo.storefront.store.service.StoreServiceAM">
      <Database jbo.locking.mode="optimistic" />
      <Security AppModuleJndiName="oracle.fodemo.storefront.store.service.StoreServiceAM" />
    </AppModuleConfig>
  </AppModuleConfigBag>
</BC4JConfig>

```

```

<AppModuleConfig
  DeployPlatform="LOCAL"

  jbo.project="StoreFrontService"
  DeployPlatform="SI">
  <AM-Pooling jbo.ampool.resetnontransactionalstate="true"/>
  <Database jbo.SQLBuilder="ORACLE" jbo.locking.mode="optimistic"
    jbo.TypeMapEntries="Java"/>
  <Security AppModuleJndiName="oracle.fodemo.storefront.store.service.StoreServiceAM"/>
  <Custom JDBCDataSource="java:comp/env/jdbc/FODDS"/>
</AppModuleConfig>
</AppModuleConfigBag>
</BC4JConfig>

```

## A.7 DataBindings.cpx

The `DataBindings.cpx` file is created in the user interface project the first time you drop a data control usage onto a web page in the visual editor. The `DataBindings.cpx` file defines the Oracle ADF binding context for the entire application and provides the metadata from which the Oracle ADF binding objects are created at runtime. It is used extensively by the ADF Library Resource Palette browsing implementations, and also by the `.cpx` and `.dcx` design time and runtime merge and discovery. When you insert a databound UI component into your document, the page will contain binding expressions that access the Oracle ADF binding objects at runtime.

If you are familiar with building Fusion web applications in earlier releases of JDeveloper, you'll notice that the `.cpx` file no longer contains all the information copied from the `DataControls.dcx` file, but only a reference to it. If you need to make changes to the `.cpx` file, you must edit the `DataControls.dcx` file.

The `DataBindings.cpx` file appears in the `/src` directory of the user interface project. When you double-click the file node, the binding context description appears in the XML source editor. (To edit the binding context parameters, use the Property Inspector and select the desired parameter in the Structure window.)

### A.7.1 DataBindings.cpx Syntax

The top level element of the `DataBindings.cpx` file is `<DataControlConfigs>`:

```

<?xml version = '1.0' encoding = 'UTF-8'?>
<BC4JConfig version="11.0" xmlns="http://xmlns.oracle.com/bc4j/configuration">

```

where the XML namespace attribute (`xmlns`) specifies the URI to which the data controls bind at runtime. Only the package name is editable; all other attributes should have the values shown.

Figure A-3 displays the child element hierarchy of the `<DataControlConfigs>` element. Note that each business service for which you have created a data control will have its own `<dataControlUsages>` definition.

**Figure A-3 Schema for the Structure Definition of the DataBindings.cpx File**

The child elements have the following usages:

- `<definitionFactories>` registers a factory class to create the ADF binding objects associated with a particular namespace at runtime. The factory class is specific to the namespace associated with the type of ADF binding (for instance, a task flow binding).
- `<pageMap>` maps all user interface URLs and the corresponding page definition usage name. This map is used at runtime to map a URL to its page definition.
- `<pageDefinitionUsages>` maps a page definition usage (`BindingContainer` instance) name to the corresponding page definition. The `id` attribute represents the usage ID. The `path` attribute represents the full path to the page definition.
- `<dataControlUsages>` declares a list of data control usages (shortnames) and corresponding path to the data control definition entries in the `.dcx` or `.xcfg` file.

Table A-1 describes the attributes of the `DataBindings.cpx` elements.

**Table A-1 Attributes of the DataBindings.cpx File Elements**

Element Syntax	Attributes	Attribute Description
<code>&lt;definitionFactories&gt;</code> <code>&lt;factory/&gt;</code> <code>&lt;/definitionFactories&gt;</code>	<code>nameSpace</code>	A URI. Identifies the location of the executable elements in the page definition usage.
	<code>className</code>	The fully qualified class name. Identifies the location of the factory class that creates the page definition usage objects.
<code>&lt;pageMap&gt;</code> <code>&lt;page /&gt;</code> <code>&lt;/pageMap&gt;</code>	<code>path</code>	The full directory path. Identifies the location of the user interface page.

**Table A-1 (Cont.) Attributes of the DataBindings.cpx File Elements**

Element Syntax	Attributes	Attribute Description
	usageId	A unique qualifier. Names the page definition ID that appears in the ADF page definition file. The ADF binding servlet looks at the incoming URL requests and checks that the bindings variable is pointing to the ADF page definition associated with the URL of the incoming HTTP request.
<pageDefinitionUsages> <page/> </pageDefinitionUsages>	id	A unique qualifier. References the page definition ID that appears in the ADF page definition file.
	path	The fully qualified package name. Identifies the location of the user interface page's ADF page definition file.
<dataControlUsages> <dc.../> </dataControlUsages>	id	A unique qualifier. Identifies the data control usage as is defined in the DataControls.dcx file.
	path	The fully qualified package name. Identifies the location of the data control.

## A.7.2 DataBindings.cpx Sample

[Example A-3](#) shows the syntax for the DataBindings.cpx file in the Fusion Order Demo application.

The ADF executable definition factory (factory element) is named by a className attribute and is associated with a namespace. At runtime, the factory class creates the executable definition objects that leads to the creation of the binding objects for the ADF binding container associated with a particular page definition. The factory locates the page definition through two DataBindings.cpx file elements: the pageMap element that maps the page URL to the page definition ID (usageId attribute) assigned at design time and the pageDefinitionUsages element that maps the ID to the location of the page definition from the project or project classpath.

Additionally, the ADF Business Components data control (BC4JDataControl element) is named by the id attribute. The combination of the Package attribute and the Configuration attribute is used to locate the bc4j.xcfg file in the ./common subdirectory of the indicated package. The configuration contains the information of the application module name and all the runtime parameters the user has configured.

### Example A-3 Sample DataBindings.cpx File

```
<Application xmlns="http://xmlns.oracle.com/adfm/application"
  version="11.1.1.44.61" id="DataBindings" SeparateXMLFiles="false"
  Package="oracle.fodemo.storefront" ClientType="Generic"
  ErrorHandlerClass="oracle.fodemo.frmwkext.FODCustomErrorHandler">
  <definitionFactories>
    <factory namespace="http://xmlns.oracle.com/adf/controller/binding"
      className="oracle.adf.controller.internal.binding.
        TaskFlowBindingDefFactoryImpl"/>
    <factory namespace="http://xmlns.oracle.com/adfm/dvt"
      className="oracle.adfinternal.view.faces.dvt.model.binding.
        FacesBindingFactory"/>
  </definitionFactories>
  <pageMap>
    <page path="/home.jspx" usageId="homePageDef"/>
  </pageMap>
</Application>
```

```

...
</pageMap>
<pageDefinitionUsages>
  <page id="homePageDef"
    path="oracle.fodemo.storefront.pageDefs.homePageDef"/>
...
</pageDefinitionUsages>
<dataControlUsages>
  <BC4JDataControl id="StoreServiceAMDataControl"
    Package="oracle.fodemo.storefront.store.service"
    FactoryClass="oracle.adf.model.bc4j.DataControlFactoryImpl"
    SupportsTransactions="true" SupportsFindMode="true"
    SupportsRangesize="true" SupportsResetState="true"
    SupportsSortCollection="true"
    Configuration="StoreServiceAMLocalWeb" syncMode="Immediate"
    xmlns="http://xmlns.oracle.com/adfm/datacontrol"/>
...
</dataControlUsages>
</Application>

```

## A.8 pageNamePageDef.xml

The `pageNamePageDef.xml` files are created each time you insert a databound component into a web page using the Data Controls Palette or Structure window. These XML files define the Oracle ADF binding container for each web page in the application. The binding container provides access to the bindings within the page. You will have one XML file for each databound web page.

---

**Caution:** The `DataBindings.cpx` file maps JSF pages to their corresponding page definition files. If you change the name of a page definition file or a JSF page, JDeveloper does *not* automatically refactor the `DataBindings.cpx` file. You must manually update the page mapping in the `DataBindings.cpx` file.

---

The `PageDef.xml` file appears in the `/src/view` directory of the user interface project. The Application Navigator displays the file in the view package of the Application Sources node. When you double-click the file node, the page description appears in the XML source editor. To edit the page description parameters, use the Property Inspector and select the desired parameter in the Structure window.

For more information, see [Chapter 12.6, "Working with Page Definition Files"](#).

There are important differences in how the page definitions are generated for methods that return a single value and a collection.

### A.8.1 PageDef.xml Syntax

The top-level element of the `PageDef.xml` file is `<pageDefinition>`:

```

<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uiamodel"
  version="10.1.3.35.83" id="<pagename>PageDef"
  Package="oracle.fod.view.pageDefs">

```

where the XML namespace attribute (`xmlns`) specifies the URI to which the ADF binding container binds at runtime. Only the package name is editable; all other attributes should have the values shown.

[Example A-4](#) displays the child element hierarchy of the `<pageDefinition>` element. Note that each business service for which you have created a data control will have its own `<AdapterDataControl>` definition.

**Example A-4 PageDef.xml Element Hierarchy**

```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition>
  <parameters>
    ...
  </parameters>
  <executables>
    ...
  </executables>
  <bindings>
    ...
  </bindings>
</pageDefinition>
```

The child elements have the following usages:

- `<parameters>` defines page-level parameters that are EL accessible. These parameters store information local to the web page request and may be accessed in the binding expressions.
- `<executables>` defines the list of items (methods, view objects, and accessors) to execute during the `prepareModel` phase of the ADF page lifecycle. Methods to be executed are defined by `<methodIterator>`. The lifecycle performs the execute in the sequence listed in the `<executables>` section. Whether or not the method or operation is executed depends on its `refresh` or `refreshCondition` attribute value. Built-in operations on the data control are defined by:
  - `<page>` - definition for a nested page definition (binding container)
  - `<iterator>` - definition to a named collection in `DataControls`
  - `<accessorIterator>` - definition to get an accessor in a data control hierarchy
  - `<methodIterator>` - definition to get to an iterator returned by an invoked method defined by a `methodAction` in the same file
  - `<variableIterator>` - internal iterator that contains variables declared for the binding container
  - `<invokeAction>` - definition of which method to invoke as an executable

---

**Note:** Only use `invokeAction` when your application does not use the ADF Controller module from the Fusion web application technology stack. If your application uses the ADF Controller module, Oracle recommends that you use a task flow method call activity, as described in [Section 15.5, "Using Method Call Activities."](#)

---

- `<bindings>` refers to an entry in `<executables>` to get to the collection from which bindings extract/submit attribute level data.

[Table A-2](#) describes the attributes of the top-level `<pageDefinition>` element.

**Table A-2 Attributes of the PageDef.xml File <pageDefinition> Element**

Element Syntax	Attributes	Attribute Description
<pageDefinition>	ControllerClass	Fully qualified class name to create when controller requests a PageController object for this bindingContainer.
	EnableTokenValidation	Enables currency validation for this bindingContainer when a postback occurs. This is to confirm that the web tier state matches the state that particular page was rendered with.
	FindMode	FindMode is for legacy (10.1.2) use only and indicates whether this bindingContainer should start out in findMode when initially prepared.
	MsgBundleClass	Fully qualified package name. Identifies the class which contains translation strings for any bindings.
	SkipValidation	Determines if data validation occurs. The supported values are: <ul style="list-style-type: none"> <li>■ true: skips data validation. Note that client-side binding level attribute validation still occurs. For example, validates non-null and type conversion errors.</li> <li>■ false: validates all rows for all data controls referenced in the current page. This is the default value.</li> <li>■ skipDataControls: validates the current rows of iterator bindings modified in the current page.</li> <li>■ custom: set to custom if your application implements an instance of the <code>oracle.binding.BindingContainerValidator</code> interface and references it through an EL expression entry named <code>CustomValidator</code> in the binding container.</li> </ul> <p>Setting a value for this attribute can be useful if you want to skip data validation on, for example, a train component. For more information see the "How to Create the Train Model" section of the <i>Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework</i></p>
	Viewable	An EL expression that should resolve at runtime to whether this binding and the associated component should be rendered or not.

Table A-3 describes the attributes of the child element of <parameters>.

**Table A-3 Attributes of the PageDef.xml File <parameters> Element**

Element Syntax	Attributes	Attribute Description
<parameter>	evaluate	Specifies when the parameter should be evaluated: <code>eachUse</code> , <code>firstUse</code> , or <code>inPrepareModel</code> .
	id	Unique identifier. May be referenced by ADF bindings.
	option	Specifies the usage of the parameter within the binding container: <ul style="list-style-type: none"> <li>▪ <code>Final</code> specifies that this parameter cannot be passed in by a usage of this binding container. It must use the default value in the definition.</li> <li>▪ <code>Optional</code> specifies that the parameter value need not be provided.</li> <li>▪ <code>Mandatory</code> specifies that the parameter value must be provided at runtime using Java or an EL expression. Failure to provide a value for a mandatory parameter or binding leads to an exception being thrown during binding validation.</li> </ul>
	readonly	Specifies whether the parameter value may be modified or not. Set to <code>true</code> when you do not want the application to modify the parameter value.
	value	A default value, which can be an EL expression.

[Table A-4](#) describes the attributes of the PageDef.xml <executables> elements.

**Table A-4 Attributes of the PageDef.xml File <executables> Element**

Element Syntax	Attributes	Attribute Description
<accessorIterator>	Accessor	Specifies any other accessor defined by this binding.
	Binds	Specifies the view or action to which the iterator is bound.
	BeanClass	Identifies the Java type of beans in the associated iterator or collection.
	CacheResults	If <code>true</code> , manages the data collection between requests.
	ChangeEventRate	Specifies the rate of events when a component is wired to data via this iterator and is in polling event mode.
	DataControl	Interprets and returns the collection referred to by this iterator binding.
	id	Unique identifier. May be referenced by any ADF value binding.
	MasterBinding	Reference to the <code>methodIterator</code> (or iterator) that binds the data collection that serves as the master to the accessor iterator's detail collection.
	ObjectType	Used for ADF Business Components only. A boolean value determines whether the collection is an object type or not.

**Table A-4 (Cont.) Attributes of the PageDef.xml File <executables> Element**

Element Syntax	Attributes	Attribute Description
	RangeSize	Specifies the number of data objects in a range to fetch from the bound collection. The range defines a window you can use to access a subset of the data objects in the collection. Typically, when you create a component by dragging an object from the Data Controls panel, the range size is set to 25. Use RangeSize when you want to work with an entire set or when you want to limit the number of data objects to display in the page. Note that the values -1 and 0 have specific meaning: the value -1 returns all available objects from the collection, while the value 0 will return the same number of objects as the collection uses to retrieve from its data source. If the RangeSize attribute is not specified at all, all available objects are returned.
	Refresh	<p>Determines when and whether the executable should be invoked. Set one of the following properties as required:</p> <ul style="list-style-type: none"> <li>▪ <code>always</code> - causes the executable to be invoked each time the binding container is prepared. This will occur when the page is displayed and when the user submits changes, or when the application posts back to the page.</li> <li>▪ <code>deferred</code> (default for ADF faces applications) - refresh occurs when another binding requires or refers to this executable. Since refreshing an executable may be a performance concern, you can set the refresh to occur only if <code>deferred</code> is used in a binding that is being rendered.</li> <li>▪ <code>&lt;default&gt;</code> - Always set to <code>Deferred</code> by default.</li> <li>▪ <code>ifNeeded</code> (default for all view technologies other than ADF Faces) - whenever the framework needs to refresh the executable because it has not been refreshed to this point. For example, when you have an accessor hierarchy such that a detail is listed first in the page definition, the master could be refreshed twice (once for the detail and again for the master's iterator). Using <code>ifNeeded</code> gives the mean to avoid duplicate refreshes. This is the default behavior for executables.</li> <li>▪ <code>never</code> - when the application itself will call refresh on the executable during one of the controller phases and does not want the framework to refresh it at all.</li> <li>▪ <code>prepareModel</code> - causes the executable to be invoked each time the page's binding container is prepared.</li> <li>▪ <code>prepareModelIfNeeded</code> - causes the executable to be invoked during the <code>prepareModel</code> phase if this executable has not been refreshed to this point. See also <code>ifNeeded</code> above.</li> <li>▪ <code>renderModel</code> - causes the executable to be invoked each time the page is rendered.</li> <li>▪ <code>renderModelIfNeeded</code> - causes the executable to be invoked during the page's <code>renderModel</code> phase on the condition that it is needed. See also <code>ifNeeded</code> above.</li> <li>▪ <code>refreshAfter</code> - Use to handle dependencies between executables. For example, you can set the condition so that this executable refreshes after another executable.</li> </ul>

**Table A-4 (Cont.) Attributes of the PageDef.xml File <executables> Element**

Element Syntax	Attributes	Attribute Description
	RefreshCondition	An EL expression that when resolved, determines when and whether the executable should be invoked. For example, <code>{!bindings.findAllServiceRequestIter.findModel}</code> resolves the value of the <code>findModel</code> on the iterator in the ADF binding context <code>AllServiceRequest</code> . Hint: Use the Property Inspector to create expressions from the available objects of the binding context ( <code>bindings</code> namespace) or binding context ( <code>data</code> namespace), JSF managed beans, and JSP objects.
	RefreshAfter	Specifies the condition after which the page should be refreshed.
	RowCountThreshold	Specify a value to determine if a result set returns the number of rows you specify as a value. If you set <code>RowCountThreshold</code> to 0, the iterator returns the estimated row count in the result set by executing the count query. If you set <code>RowCountThreshold</code> to less than 0, the iterator does not execute the count query.  Set <code>RowCountThreshold</code> to a value greater than 0 if you want the iterator to execute the count query with the maximum value equal to the value you specify for <code>RowCountThreshold</code> . If the estimated row count is less than the value of <code>RowCountThreshold</code> , return the number of rows in the estimated row count. If the estimated row count is greater than the value of <code>RowCountThreshold</code> , return -1.
	Sortable	Specifies whether the iterator is sortable or not.
<invokeAction>		Only use <invokeAction> when your application does not use the ADF Controller module from the Fusion web application technology stack. Oracle recommends that you use a task flow method call activity, as described in <a href="#">Section 15.5, "Using Method Call Activities,"</a> if your application uses the ADF Controller module.

**Table A-4 (Cont.) Attributes of the PageDef.xml File <executables> Element**

Element Syntax	Attributes	Attribute Description
	Binds	<p>Determines the action to invoke. This may be on any <code>actionBinding</code>. Additionally, in the case, of the EJB session facade data control, you may bind to the finder method exposed by the data control. Built-in actions supported by the EJB session facade data control include:</p> <ul style="list-style-type: none"> <li>■ <code>Execute</code> executes the bound action defined by the data collection.</li> <li>■ <code>Find</code> retrieves a data object from a collection.</li> <li>■ <code>First</code> navigates to the first data object in the data collection range.</li> <li>■ <code>Last</code> navigates to the first data object in the data collection range.</li> <li>■ <code>Next</code> navigates to the first data object in the data collection range. If the current range position is already on the last data object, then no action is performed.</li> <li>■ <code>Previous</code> navigates to the first data object in the data collection range. If the current position is already on the first data object, then no action is performed.</li> <li>■ <code>setCurrentRowWithKey</code> passes the row key as a <code>String</code> converted from the value specified by the input field. The row key is used to set the currency of the data object in the bound data collection. When passing the key, the URL for the form will not display the row key value. You may use this operation when the data collection defines a multipart attribute key.</li> <li>■ <code>setCurrentRowWithKeyValue</code> is used as above, but when you want to use a primary key value instead of the stringified key.</li> </ul>
	id	Unique identifier. May be referenced by any ADF action binding.
	Refresh	See Refresh for <accessorIterator>.
	RefreshCondition	See RefreshCondition for <accessorIterator>.
<iterator> and <methodIterator>	BeanClass	Identifies the Java type of beans in the associated iterator or collection.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. Not used in current JDeveloper release.
	Binds	See Binds for <invokeAction>.
	CacheResults	See CacheResults for <accessorIterator>.
	ChangeEventRate	Specifies the rate of events when a component is wired to data via this iterator and is in polling event mode.
	DataControl	Name of the <code>DataControl</code> usage in the <code>bindingContext (.cpx)</code> which this iterator is associated with.
	DefClass	Used internally by ADF.
	id	Unique identifier. May be referenced by any ADF value binding.

**Table A-4 (Cont.) Attributes of the PageDef.xml File <executables> Element**

Element Syntax	Attributes	Attribute Description
	ObjectType	Not used by EJB session facade data control (used by ADF Business Components only).
	RangeSize	See RangeSize for <accessorIterator>.
	Refresh	See Refresh for <accessorIterator>.
	RefreshAfter	Specifies the condition after which the page should be refreshed.
	RefreshCondition	See RefreshCondition for <accessorIterator>.
	RowCountThreshold	See RowCountThreshold for <accessorIterator>.
<page> and <variableIterator>	id	Unique identifier. In the case of <page>, refers to nested page or region that is included in this page. In the case of the <variableIterator> executable, the identifier may be referenced by any ADF value binding.
	ChangeEventRate	Specifies the rate of events when a component is wired to data via this iterator and is in polling event mode.
	path	Used by <page> executable only. Advanced, a fully qualified path that may reference another page's binding container.
	Refresh	See Refresh for <accessorIterator>.
	RefreshAfter	Specifies the condition after which the page should be refreshed.
	RefreshCondition	See RefreshCondition for <accessorIterator>.

Table A-5 describes the attributes of the PageDef.xml <bindings> element.

**Table A-5 Attributes of the PageDef.xml File <bindings> Element**

Element Syntax	Attributes	Attribute Description
<action>	Action	Fully qualified package name. Identifies the class for which the data control is created. In the case of the EJB session facade, this is the session bean.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	DataControl	Name of the DataControl usage in the bindingContext (.cpx) which this iteratorBinding or actionBinding is associated with.
	Execute	Used by default when you drop an operation from the Data Controls Panel in the automatically configured ActionListener property. It results in executing the action binding's operation at runtime.
	InstanceName	Specifies the instance name for the action.
	IterBinding	Specifies the iteratorBinding instance in this bindingContainer to which this binding is associated.
	Outcome	Use if you want to use the result of a method action binding (once converted to a String) as a JSF navigation outcome name.

**Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element**

Element Syntax	Attributes	Attribute Description
<attributeValues>	ApplyValidation	Set to true by default. When true, <code>controlBinding</code> executes validators defined on the binding. You can set to false in the case of ADF Business Components, when running in local mode and the same validators are already defined on the corresponding attribute.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	ChangeEventPolicy	Specifies the event strategy for the component when run with ADS (Active Data Services). Can be specified as push poll ppr none
	ControlClass	Used internally by ADF.
	CustomInputHandler	This is the class name for a <code>oracle.jbo.uicli.binding.JUCtrlValueHandler</code> implementation that is used to process the <code>inputValue</code> for a given value binding.
	DefClass	Used internally by ADF.
	id	Unique identifier. May be referenced by any ADF action binding.
	IterBinding	Refers to the <code>iteratorBinding</code> instance in this <code>bindingContainer</code> to which this binding is associated.
	NullValueId	Refers to the entry in the message bundle for this <code>bindingContainer</code> that contains the <code>String</code> to indicate the null value in a list display.
	<button>	ApplyValidation
BindingClass		This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
BoolVal		Identifies whether the value at the zero index in the static value list in this boolean list binding represents true or false.
ControlClass		Used internally by ADF.
CustomInputHandler		This is the class name for a <code>oracle.jbo.uicli.binding.JUCtrlValueHandler</code> implementation that is used to process the <code>inputValue</code> for a given value binding.
DefClass		Used internally by ADF.
id		Unique identifier. May be referenced by any ADF action binding.

**Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element**

Element Syntax	Attributes	Attribute Description
	IterBinding	Refers to the <code>iteratorBinding</code> instance in this <code>bindingContainer</code> to which this binding is associated.
	ListIter	Refers to the <code>iteratorBinding</code> that is associated with the source list of this <code>listBinding</code> .
	ListOperMode	Determines whether this list binding is for navigation, contains a static list of values or is an LOV type list.
	NullValueFlag	Describes whether this list binding has a null value and, if so, whether it should be displayed at the beginning or the end of the list.
	NullValueId	Refers to the entry in the message bundle for this <code>bindingContainer</code> that contains the <code>String</code> to indicate the null value in a list display.
<ganttDataMap>		Maps the data binding XML for an ADF Faces gantt component.
<gaugeDataMap>		Maps the data binding XML for an ADF Faces gauge component.
<graph>	ApplyValidation	Set to true by default. When true, <code>controlBinding</code> executes validators defined on the binding. You can set to false in the case of ADF Business Components, when running in local mode and when the same validators are already defined on the corresponding attribute.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	BoolVal	Identifies whether the value at the zero index in the static value list in this boolean list binding represents true or false.
	ChildAccessorName	The name of the accessor to invoke to get the next level of nodes for a given hierarchical node type in a tree.
	ControlClass	Used internally by ADF.
	CustomInputHandler	This is the class name for a <code>oracle.jbo.uicli.binding.JUCtrlValueHandler</code> implementation that is used to process the <code>inputValue</code> for a given value binding.
	DefClass	Used internally by ADF.
	GraphPropertiesFile Name	An XML file that specifies the type of graph to use, for example, pie chart or bar graph. This XML file can be used to customize the visual properties of the graph. It contains graph attributes such as title, subtitle, footnote, graph type, legend area, and plot area. The default filename is <code>BIGraphDef.xml</code> .
	GroupLabel	For master-detail forms, specifies the attribute that will be used to group data.
	id	Unique identifier. May be referenced by any ADF action binding.
	IterBinding	Refers to the <code>iteratorBinding</code> instance in this <code>bindingContainer</code> to which this binding is associated.

**Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element**

Element Syntax	Attributes	Attribute Description
	NullValueId	Refers to the entry in the message bundle for this <code>bindingContainer</code> that contains the <code>String</code> to indicate the null value in a list display.
	SeriesLabel	Defines the attribute, based on which data will be clubbed.
	SeriesType	Determines whether graph is for <code>Single View(SINGLE_SERIES)</code> , or for <code>MASTER_DETAIL</code> .
<graphDataMap>		Wraps the data binding XML for an ADF Faces graph component.
<list>	ApplyValidation	Set to <code>true</code> by default. When <code>true</code> , <code>controlBinding</code> executes validators defined on the binding. You can set to <code>false</code> in the case of ADF Business Components, when running in local mode and when the same validators are already defined on the corresponding attribute.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	ControlClass	Used internally by ADF.
	CustomInputHandler	This is the class name for a <code>oracle.jbo.uicli.binding.JUCtrlValueHandler</code> implementation that is used to process the <code>inputValue</code> for a given value binding.
	DefClass	Used internally by ADF.
	id	Unique identifier. May be referenced by any ADF action binding.
	IterBinding	Refers to the <code>iteratorBinding</code> instance in this <code>bindingContainer</code> to which this binding is associated.
	ListIter	Refers to the <code>iteratorBinding</code> that is associated with the source list of this <code>listBinding</code> .
	ListOperMode	Determines whether this list binding is for navigation, contains a static list of values, or is an LOV type list.
	MRUCount	Specifies the number of items to display in a choice list when you want to provide a shortcut for the end-user to display their most recent selections. For example, a form might display a choice list of supplier ID values to drive a purchase order form. In this case, you can allow users to select from a list of their most recently view suppliers, where the number of supplier choices is determined by the count you enter. The default for the choice list is to display all values for the attribute and is specified by the count 0 (zero)."
	MRUId	Specifies the <code>String</code> that will be the discriminator line for the MRU list.
	NullValueFlag	Describes whether this list binding has a null value and, if so, whether it should be displayed at the beginning of the list or the end.
	NullValueId	Refers to the entry in the message bundle for this <code>bindingContainer</code> that contains the <code>String</code> to indicate the null value in a list display.

**Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element**

Element Syntax	Attributes	Attribute Description
	StaticList	Defines a static list of values that will be rendered in the bound list component.
<mapThemeDataMap>		Wraps the data binding XML for an ADF Data Visualization geographic map component.
<methodAction>	Action	Fully qualified package name. Identifies the class for which the data control is created. In the case of the EJB session facade, this is the session bean.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	ClassName	This is the class to which the method being invoked belongs.
	DataControl	Name of the DataControl usage in the bindingContext (.cpx) which this iteratorBinding or actionBinding is associated with.
	DefClass	Used internally by ADF.
	id	Unique identifier. May be referenced by any ADF action binding.
	InstanceName	A dot-separated EL path to a Java object instance on which the associated method is to be invoked.
	IsLocalObjectReference	Set to true if the instanceName contains an EL path relative to this bindingContainer.
	IsViewObjectMethod	Set to true if the instanceName contains an instance path relative to the associated data control's application module.
	MethodName	Indicates the name of the operation on the given instance or class that needs to be invoked for this methodActionBinding.
	RequiresUpdateModel	Whether this action requires that the model be updated before the action is to be invoked.
	ReturnName	The EL path of the result returned by the associated method.
<pivotTableDataMap>		Wraps the data binding XML for an ADF Faces pivot table component.
<table> and <tree>	ApplyValidation	Set to true by default. When true, controlBinding executes validators defined on the binding. You can set to false in the case of ADF Business Components, when running in local mode and when the same validators are already defined on the corresponding attribute.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	CollectionModel	Accesses the CollectionModel object, the data model that is used by ADF table components. A table's value is bound to the CollectionModel attribute. The table wraps the result set from the iterator binding in a CollectionModel object. The CollectionModel attribute allows each item in the collection to be available within the table component using the var attribute.

**Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element**

Element Syntax	Attributes	Attribute Description
	ControlClass	Used internally for testing purposes.
	CustomInputHandler	This is the class name for a <code>oracle.jbo.uicli.binding.JUCtrlValueHandler</code> implementation that is used to process the <code>inputValue</code> for a given value binding.
	DefClass	Used internally by ADF.
	DiscrValue	Indicates the discriminator value for a hierarchical type binding (type definition for a tree node). This value is used to determine whether a given row in a collection being rendered in a polymorphic tree binding should be rendered using the containing hierarchical type binding.
	id	Unique identifier. May be referenced by any ADF action binding.
	IterBinding	Refers to the <code>iteratorBinding</code> instance in this <code>bindingContainer</code> to which this binding is associated.
	TreeModel	The data model used by ADF Tree components. <code>TreeModel</code> extends <code>CollectionModel</code> to add support for container rows. Rows in the <code>TreeModel</code> may (recursively) contain other rows.

## A.9 adfc-config.xml

The default name for an ADF unbounded task flow's XML source file is `adfc-config.xml`. Each Fusion web application optionally contains a single ADF unbounded task flow. The `adfc_config.xml` file contains activities, control flow rules, and managed beans interacting to allow a user to complete a task.

The `adfc-config.xml` file is located in the `/public_html/WEB-INF` directory relative to the ADF application's user interface project.

For more information, see [Section 14.1.2.1, "Unbounded Task Flows"](#).

## A.10 task-flow-definition.xml

The XML source file for an ADF bounded task flow is called a *task flow definition*. The name for this source file is taken from the value specified in the **Task Flow ID** field of the Create ADF Task Flow wizard. By default, JDeveloper proposes the following filename when you invoke the Create ADF Task Flow wizard:

`task-flow-definition.xml`. A Fusion web application can contain one or more ADF bounded task flows. Each bounded task flow has its own task flow definition source file. For more information about bounded task flows, see [Section 14.1.2.2, "Bounded Task Flows"](#).

## A.11 adf-config.xml

JDeveloper generates the `adf-config.xml` file when you create an application using the Fusion Web Application (ADF) template. It stores the file in the following directory:

```
application_root\.\adf\META-INF
```

The `adf-config.xml` file specifies application-level settings that are usually determined at deployment and are often changed at runtime. You can use a deployment profile to specify settings that are used at application deploy time. You can change some of the settings at runtime using Oracle Enterprise Manager.

Changing settings in the `adf-config.xml` file allow you to, for example, enable or disable the validation of ADF Controller metadata. Another example is where you need to replicate memory scope if you deploy your Fusion web application in a clustered environment.

You can also change settings in the `adf-config.xml` file to manage the caching of resource bundles where your application uses EL expressions to retrieve strings at runtime from resource bundles. The properties that you can configure to do this are:

- `initial-size`  
Specifies the initial number of resource bundles that your application can cache. The default value is 100.
- `max-size`  
Specifies the maximum number of resource bundles that your application can cache. The default value is 100.
- `load-factor`  
The default value is 0.75.
- `expire-time`  
The default value is 43200 seconds (12 hours).

You specify these properties as attribute values of the `<resource-bundle-cache>` element in the `adf-config.xml` file. [Example A-5](#) demonstrates how you might configure these values for your application in the `adf-config.xml` file.

As an alternative to configuring the caching of resource bundles in the `adf-config.xml` file, you can specify the resource bundle caching properties as parameters for the Java Virtual Machine (JVM). If you specify the properties as parameters for the JVM, the changes apply to all applications managed by the JVM. For this reason, we recommend that you configure the resource bundle caching properties in the `adf-config.xml` file for your application. Use the following property names if you decide to specify the resource bundle caching properties as parameters for the JVM:

- `resource-bundle-cache-initial-size`
- `resource-bundle-cache-max-size`
- `resource-bundle-cache-load-factor`
- `resource-bundle-cache-expire-time`

At runtime, the Fusion web application loads the `adf-config.xml` file from the `META-INF` directory. If the Fusion web application finds more than one `adf-config.xml` file, it stops loading the file and logs a warning.

The following tasks also modify or require you to modify the `adf-config.xml` file:

- **Creating task flows**  
By default, the ADF Controller uses a user session level cache to store the application's unbounded task flow metadata. This enables support for user specific seeded customization or design time at runtime customization of

unbounded task flow metadata in your application. Clear the **Allow Unbounded Task Flow Customizations** checkbox in the Controller page of the `adf-config.xml`'s file overview editor to disable this behavior and set the value of the `<allow-unbounded-task-flow-customizations>` element to `false`. You can still have customizations of the unbounded task flow metadata in your application. However, these customizations are shared by all users of the application. For more information about customizations, see [Chapter 34, "Customizing Applications with MDS."](#) For more information about task flows, see [Chapter 14, "Getting Started with ADF Task Flows."](#)

- Enabling implicit save points  
For more information, see [Section 18.9.7, "How to Enable Implicit Save Points"](#).
- Minimize the number of active root view ports in an application by specifying a value for the `<max-root-view-ports>` property. For more information, see [Section 18.10, "Minimizing the Number of Active Root View Ports in an Application."](#)
- Persisting saved searches in MDS  
For more information, see [Section 27.2.3, "How to Persist Saved Searches into MDS"](#).
- Configure ADF Business Components global settings  
For more information, see [Section 39.1.1, "Limiting the View Object Max Fetch Size to Fetch the First n Rows"](#) and see [Section 3.3.1, "Choosing a Connection, SQL Flavor, and Type Map."](#)
- Enabling ADF Security  
For more information, see [Section 30.3.2, "What Happens When You Enable ADF Security"](#).
- Enabling seeded customizations  
For more information, [Section 34.2.4, "How to Enable Seeded Customizations for View Projects"](#) and [Section 34.2.5, "How to Enable Seeded Customizations in Existing Pages"](#).
- Configuring change persistence  
For more information, see [Section 35.2.1, "How to Enable User Customizations"](#).
- Enabling user customizations  
For more information, see [Section 35.2.2, "What Happens When You Enable User Customizations"](#).

[Example A-5](#) shows extracts from the Fusion Order Demo application's `adf-config.xml` file.

```

```
</adf-config>
```

## A.12 adf-settings.xml

The `adf-settings.xml` file holds project-level and library-level settings such as ADF Faces help providers and ADF Controller phase listeners.

The configuration settings for `adf-settings.xml` are fixed and cannot be changed during or after application deployment. There can be multiple `adf-settings.xml` files in an application. The users of `adf-settings.xml` files are responsible for merging the contents of their configuration.

The following tasks modify or require you to modify the `adf-settings.xml` file:

- Registering a phase listener  
For more information, see [Section 21.4.2, "How to Register a Listener Globally"](#).
- Creating help for ADF Faces components  
For more information, see the "Displaying Help for Components" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

For information about how to create and edit the `adf-settings.xml` file, see the "How to Configure for ADF Faces in `adf-settings.xml`" section in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

[Example A–6](#) shows a sample `adf-setting.xml` file with settings configured for a phase listener and a help provider.

### Example A–6 Sample `adf-settings.xml` File

```
<?xml version="1.0" encoding="windows-1252" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config">
  <adfc-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
    <lifecycle>
      <phase-listener>
        <listener-id>FODPhaseListener</listener-id>
        <class>oracle.fodemo.storefront.listeners.FODPhaseListener</class>
      </phase-listener>
    </lifecycle>
    <help-provider prefix="MYAPP">
      <help-provider-class>oracle.fodemo.storefront.MyHelpProvider</help-provider-class>
      <property>
        <property-name>myCustomProperty</property-name>
        <value>someValue</value>
      </property>
    </help-provider>
  </adfc-controller-config>
</adf-config>
```

## A.13 web.xml

Oracle ADF has specific configuration settings for the standard `web.xml` deployment descriptor file.

When you create a project in JDeveloper that uses JSF technology, a starter `web.xml` file with default settings is created for you in the `/WEB-INF` folder. To edit the file, double-click **web.xml** in the Application Navigator to open it in the XML editor.

The following must be configured in `web.xml` for all applications that use JSF and ADF Faces:

- JSF servlet and mapping: The servlet `javax.faces.webapp.FacesServlet` that manages the request-processing lifecycle for web applications utilizing JSF to construct the user interface.
- ADF Faces filter and mapping: A servlet filter to ensure that ADF Faces is properly initialized by establishing a `AdfFacesContext` object. This filter also processes file uploads.
- ADF resource servlet and mapping: A servlet to serve up web application resources (images, style sheets, JavaScript libraries) by delegating to a `ResourceLoader`.

The JSF servlet and mapping configuration settings are automatically added to the starter `web.xml` file when you first create a JSF project. When you insert an ADF Faces component into a JSF page for the first time, JDeveloper automatically inserts the configuration settings for ADF Faces filter and mapping, and resource servlet and mapping.

For more information, see the "ADF Faces Configuration" appendix in the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework*.

## A.14 logging.xml

ADF Logger is a diagnostic tool that you can use in JDeveloper to capture runtime traces messages when you debug an application. You configure the use of this tool by editing the `logging.xml` file.

For more information about the `logging.xml` file and using the ADF Logger, see [Section 31.5, "Using the ADF Logger"](#).

## Oracle ADF Binding Properties

This appendix provides a reference for the properties of the ADF bindings.

[Table B-1](#) shows the properties that you can use in EL expressions to access values of the ADF binding objects at runtime. The properties appear in alphabetical order.

**Table B-1** *EL Properties of Oracle ADF Bindings*

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
actionEnabled	Use operationEnabled instead.	n/a	yes	n/a	n/a	n/a	n/a	n/a
allRowsInRange	Returns an array of the current set of rows from the associated collection. Calls getAllRowsInRange () on the RowSetIterator object.	yes	n/a	n/a	n/a	n/a	n/a	n/a
attributeDef	Returns the attribute definition for the first attribute with which the binding is associated.	n/a	n/a	yes	yes	yes	n/a	n/a
attributeDefs	Returns the attribute definitions for all the attributes to which the binding is associated.	n/a	n/a	yes	yes	yes	n/a	n/a
attributeValue	Returns an unformatted and typed (appropriate Java type) value in the current row, for the attribute to which the control binding is bound. Note that this property is not visible in the EL expression builder dialog.	n/a	n/a	yes	yes	yes	n/a	n/a
attributeValues	Returns the value of all the attributes to which the binding is associated in an ordered array. Returns an array of unformatted and typed (appropriate Java type) values in the current row for all the attributes to which the control binding is bound. Note that this property is not visible in the EL expression builder dialog.	n/a	n/a	yes	yes	yes	n/a	n/a

**Table B-1 (Cont.) EL Properties of Oracle ADF Bindings**

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
bindings	Returns a new binding for each cell or attribute exposed under the rows of a tree node binding.	no	no	no	no	no	no	yes
children	Returns the child nodes of a tree node binding.	n/a	n/a	n/a	n/a	n/a	n/a	yes
currentRow	Returns the current row on an action binding bound to an iterator (for example, built-in navigation actions).	n/a	yes	n/a	n/a	n/a	n/a	n/a
dataControl	Returns the iterator's associated data provider.	yes	n/a	n/a	n/a	n/a	n/a	n/a
displayData	<p>Returns a list of map elements. Each map entry contains the following elements:</p> <ul style="list-style-type: none"> <li>▪ selected: A boolean true if the current entry should be selected.</li> <li>▪ index: The index value of the current entry.</li> <li>▪ prompt: A string value that may be used to render the entry in the UI.</li> <li>▪ displayValues: An ordered list of display attribute values for all display attributes in the list binding.</li> </ul> <p>Note that this property is not visible in the EL expression builder dialog.</p>	n/a	n/a	n/a	n/a	yes	n/a	n/a
displayHint	Returns the display hint for the first attribute to which the binding is associated. The hint identifies whether the attribute should be displayed or not. For more information, see <code>oracle.jbo.AttributeHints.displayHint</code> . Note that this property is not visible in the EL expression builder dialog.	n/a	n/a	n/a	n/a	yes	n/a	n/a

**Table B-1 (Cont.) EL Properties of Oracle ADF Bindings**

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
displayHints	<p>Returns a list of name-value pairs for UI hints for all display attributes to which the binding is associated. The map contains the following elements:</p> <ul style="list-style-type: none"> <li>▪ label: The label to display for the current attribute.</li> <li>▪ tooltip: The tooltip to display for the current attribute.</li> <li>▪ displayHint: The display hint for the current attribute.</li> <li>▪ displayHeight: The height in lines for the current attribute.</li> <li>▪ displayWidth: The width in characters for the current attribute.</li> <li>▪ controlType: The control type hint for the current attribute.</li> <li>▪ format: The format to be used for the current attribute.</li> </ul> <p>Note that this property is not visible in the EL expression builder dialog.</p>	n/a	n/a	n/a	yes	yes	n/a	n/a
enabled	Use the operationEnabled property.	n/a	n/a	n/a	n/a	n/a	n/a	n/a
enabledString	Returns disabled if the action binding is not ready to be invoked. Otherwise, returns an empty string (" ").	n/a	yes	n/a	n/a	n/a	n/a	n/a
error	Returns any exception that was cached while updating the associated attribute value for a value binding or when invoking an operation bound by an operation binding.	yes	yes	yes	yes	yes	yes	yes
estimatedRowCount	Returns the maximum row count of the rows in the collection with which this iterator binding is associated	yes	n/a	n/a	n/a	n/a	yes	yes
findMode	Returns true if the iterator is currently operating in find mode. Otherwise, returns false.	yes	n/a	n/a	n/a	n/a	n/a	n/a
fullName	Returns the fully qualified name of the binding object in the Oracle ADF binding context.	yes	yes	yes	yes	yes	yes	yes

**Table B-1 (Cont.) EL Properties of Oracle ADF Bindings**

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
hints	Returns the value of the UI hint indicated for the binding. See <code>displayHints</code> for the list of UI hint keywords.	yes	yes	yes	yes	yes	yes	yes
inputValue	Returns the value of the first attribute to which the binding is associated. If the binding was used to set the value on the attribute and the set operation failed, this method returns the invalid value that was being set.	n/a	n/a	yes	yes	yes	yes	yes
iteratorBinding	Returns the iterator binding that provides access to the data collection.	n/a	yes	yes	yes	yes	yes	yes
label	Returns the label (if supplied by control hints) for the first attribute of the binding.	n/a	n/a	yes	yes	yes	n/a	n/a
labels	Returns a map of labels (if supplied by control hints) keyed by attribute name for all attributes to which the binding is associated. Note that this property is not visible in the EL expression builder dialog.	n/a	n/a	yes	yes	yes	yes	n/a
labelSet	Returns an ordered set of labels for all the attributes to which the binding is associated. Note that this property is not visible in the EL expression builder dialog.	n/a	n/a	yes	yes	yes	yes	n/a
mandatory	Returns whether the first attribute to which the binding is associated is required.	n/a	n/a	yes	yes	yes	n/a	n/a
name	Returns the name of the binding object in the context of the binding container to which it is registered. Note this property is not visible in the EL expression builder dialog.	yes	yes	yes	yes	yes	yes	yes
operationEnabled	Returns <code>true</code> or <code>false</code> , depending on the state of the action binding. For example, the action binding may be enabled ( <code>true</code> ) or disabled ( <code>false</code> ) based on the currency (as determined, for example, when the user clicks the First, Next, Previous, Last navigation buttons).	n/a	yes	n/a	n/a	n/a	n/a	n/a

**Table B-1 (Cont.) EL Properties of Oracle ADF Bindings**

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
rangeSet	<p>Returns a list of map elements over the range of rows from the associated iterator binding. The elements in this list are wrapper objects over the indexed row in the range that restricts access to the attributes to which the binding is bound. The properties returned on the reference object are:</p> <ul style="list-style-type: none"> <li>▪ index: The range index of the row this reference is pointing to.</li> <li>▪ key: The key of the row this reference is pointing to.</li> <li>▪ keyStr: The string format of the key of the row this reference is pointing to.</li> <li>▪ currencyString: The current indexed row as a string. Returns "*" if the current entry belongs to the current row; otherwise, returns ". This property is useful in JSP applications to display the current row.</li> <li>▪ attributeValues: The array of applicable attribute values from the row.</li> </ul> <p>You may also access an attribute value by name on a range set like <code>rangeSet.dname</code> if <code>dname</code> is a bound attribute in the range binding.</p>	n/a	n/a	n/a	n/a	n/a	yes	yes
rangeSize	Returns the range size of the ADF iterator binding's row set. This allows you to determine the number of data objects to bind from the data source.	yes	n/a	n/a	n/a	n/a	yes	yes
rangeStart	Returns the absolute index in a collection of the first row in range. See the javadoc for <code>oracle.jbo.RowSetIterator.getRangeStart()</code> .	yes	n/a	n/a	n/a	n/a	yes	yes
result	Returns the result of a method that is bound and invoked by a method action binding.	n/a	yes	n/a	n/a	n/a	n/a	n/a
rootNodeBinding	Returns the root node of a tree binding.	n/a	n/a	n/a	n/a	n/a	n/a	yes

---

**Table B-1 (Cont.) EL Properties of Oracle ADF Bindings**

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
selectedValue	Returns the value corresponding to the current selected index in the list or button binding.	n/a	n/a	n/a	yes	yes	n/a	n/a
tooltip	Returns the tooltip hint for the first attribute to which the binding is associated.	n/a	n/a	yes	yes	yes	n/a	n/a
updateable	Returns <code>true</code> if the first attribute to which the binding is associated is updateable. Otherwise, returns <code>false</code> .	n/a	n/a	yes	yes	yes	n/a	n/a

## Oracle ADF Permission Grants

This appendix lists the security-aware components of Oracle Application Development Framework (Oracle ADF) and the actions that their `Permission` implementation classes define.

[Table C-1](#) shows the ADF components and their permission grants that you can define to create ADF security policies. You add grants to the policy store using the overview editor for ADF security policies. A permission grant specifies the fully qualified permission class name, the fully qualified resource name, the action that can be performed against the resource, and the application role target of the grant. When you enable ADF security to enforce permission checking, the operations supported by ADF components will be inaccessible to users who do not possess sufficient access rights as defined by grants to their application role.

For complete details about defining ADF security policies in Fusion web applications, see [Chapter 30, "Enabling ADF Security in a Fusion Web Application."](#)

---

---

**Note:** JDeveloper displays grantable actions for Fusion web applications including actions for the Oracle WebCenter Portal: Framework. WebCenter Portal: Framework supports creating personalizable web pages. For details about securing WebCenter Portal: Framework applications, see the *Oracle Fusion Middleware Developer's Guide for Oracle WebCenter Portal*.

---

---

**Table C-1 ADF Security Permission Grants**

ADF Component	Grantable Action	Corresponding Implementation
ADF bounded task flow	View	The view action controls who can read and execute a bounded task flow. Pages that the user accesses within the process of executing a bounded task flow will not be individually security checked and will run under the permission of the task flow.  In this release, this is the only task flow action supported by Fusion web applications without Oracle WebCenter Portal: Framework.
	Customize	Reserved for future use. This action is not checked at runtime.
	Grant	Reserved for future use. This action is not checked at runtime.
	Personalize	Reserved for future use. This action is not checked at runtime.

**Table C-1 (Cont.) ADF Security Permission Grants**

ADF Component	Grantable Action	Corresponding Implementation
ADF page definition	View	<p>The <code>View</code> action controls who can view the page. Page-level security is checked for pages that have an associated page definition binding file <i>only</i> if the page is accessed in the process of an unbounded task flow. There is a one-to-one relationship between the page definition file and the web page it secures.</p> <p>In this release, this is the only page definition action supported by Fusion web applications without Oracle WebCenter Portal: Framework.</p>
	Customize	The <code>Customize</code> action controls who can make implicit changes (such as minimize/restore, delete, or move) to a WebCenter Portal customizable component (in a Panel Customizable or Show Detail Frame) contained in a page of a custom application (one enabled to use Oracle WebCenter Portal's Composer) or a WebCenter Portal: Framework application.
	Edit	The <code>Edit</code> action controls who can invoke Oracle WebCenter Portal's Composer and who can make changes to the page using Oracle WebCenter Portal's Composer. Additionally, this action combines <code>personalize</code> and <code>customize</code> actions. This means that the <code>Edit</code> action also controls who can make implicit changes to a WebCenter Portal customizable component (in a Panel Customizable or Show Detail Frame) contained in a page with the <code>edit</code> permission grant.
	Grant	The <code>Grant</code> action confers the rights specified by all WebCenter-specific actions combined; it is equivalent to granting all other actions. It also controls who can make grants to other users and who can change security settings on the page using Oracle WebCenter Portal's Composer.
	Personalize	The <code>Personalize</code> action controls who can make implicit changes (such as minimize/restore, delete, or move) to a WebCenter Portal customizable component (in a Panel Customizable or Show Detail Frame) contained in a page of a custom application (one enabled to use Oracle WebCenter Portal's Composer) or a WebCenter Portal: Framework application.
ADF Business Components entity objects	read	The <code>read</code> action controls who can view a row of the bound collection.
	update	The <code>update</code> action controls who can update any attribute of the bound collection.
	delete	The <code>delete</code> action controls who can delete a row from the bound collection. This action corresponds to the entity object <code>removeCurrentRow</code> operation.
ADF Business Components attributes of entity objects	update	The <code>update</code> action controls who can update a specific attribute of the bound collection.

---

# ADF Equivalents of Common Oracle Forms Triggers

This appendix provides a quick summary of how basic tasks performed with the most common Oracle Forms triggers are accomplished using Oracle ADF.

This appendix includes the following sections:

- [Section D.1, "Validation and Defaulting \(Business Logic\)"](#)
- [Section D.2, "Query Processing"](#)
- [Section D.3, "Database Connection"](#)
- [Section D.4, "Transaction "Post" Processing \(Record Cache\)"](#)
- [Section D.5, "Error Handling"](#)

## D.1 Validation and Defaulting (Business Logic)

**Table D-1 ADF Equivalents for Oracle Forms Validation and Defaulting Triggers**

Forms Trigger	ADF Equivalent
WHEN-VALIDATE-RECORD Execute validation code at the record level	In the custom <code>EntityImpl</code> class for your entity object, write a public method returning a <code>boolean</code> type with a method name like <code>validateXXXX()</code> and have it return <code>true</code> if the validation succeeds or <code>false</code> if the validation fails. Then, add a Method validator for this validation method to your entity object at the entity level. When doing that, you can associate a validation failure message with the rule.
WHEN-VALIDATE-ITEM Execute validation code at the field level	In the custom <code>EntityImpl</code> class for your entity object, write a public method returning a <code>boolean</code> type and accepting a single argument of the same data type as your attribute, having a method name like <code>validateXXXX()</code> . Have it return <code>true</code> if the validation succeeds or <code>false</code> if the validation fails. Then, add a Method validator for this validation method to the entity object at the attribute level for the appropriate attribute. When doing that, you can associate a validation failure message with the rule.
WHEN-DATABASE-RECORD Execute code when a row in the data block is marked for insert or update	Override the <code>addToTransactionManager()</code> method of your entity object. Write code after calling the <code>super</code> .

**Table D-1 (Cont.) ADF Equivalents for Oracle Forms Validation and Defaulting Triggers**

Forms Trigger	ADF Equivalent
<p>WHEN-CREATE-RECORD</p> <p>Execute code to populate complex default values when a new record in the data block is created, without changing the modification status of the record</p>	<p>Override the <code>create()</code> method of your entity object and after calling the super, use appropriate <code>setAttribute()</code> methods to set default values for attributes as necessary.</p> <p>To immediately set a primary key attribute to the value of a sequence, construct an instance of the <code>SequenceImpl</code> helper class and call its <code>getSequenceNumber()</code> method to get the next sequence number. Assign this value to your primary key attribute.</p> <p>If you want to wait to assign the sequence number until the new record is saved, but still without using a database trigger, you can use this technique in an overridden <code>prepareForDML()</code> method in your entity object.</p> <p>If instead you want to assign the primary key from a sequence using your own <code>BEFOREINSERTFOREACHROW</code> database trigger, then use the special data type called <code>DBSequence</code> for your primary key attribute instead of the regular <code>Number</code> type.</p>
<p>WHEN-REMOVE-RECORD</p> <p>Execute code whenever a row is removed from the data block</p>	<p>Override the <code>remove()</code> method of your entity object and write code either before or after calling the super.</p>

## D.2 Query Processing

**Table D-2 ADF Equivalents for Oracle Forms Query Processing Triggers**

Forms Trigger	ADF Equivalent
<p>PRE-QUERY</p> <p>Execute logic before executing a query in a data block, typically to set up values for Query-by-Example criteria in the "example record"</p>	<p>Override the <code>executeQueryForCollection()</code> method on your view object class and write code before calling the super.</p>
<p>ON-COUNT</p> <p>Override default behavior to count the query hits for a data block</p>	<p>Override the <code>getQueryHitCount()</code> method in your view object and do something instead of calling the super.</p>
<p>POST-QUERY</p> <p>Execute logic after retrieving each row from the data source for a data block.</p>	<p>Generally instead of using a <code>POST-QUERY</code> style technique to fetch descriptions from other tables based on foreign key values in the current row, in ADF it's more efficient to build a view object that has multiple participating entity objects, joining in all the information you need in the query from the main table, as well as any auxiliary or lookup-value tables. This way, in a single roundtrip to the database you get all the information you need. If you still need a per-fetched-row trigger like <code>POST-QUERY</code>, override the <code>createInstanceFromResultSet()</code> method in your view object class.</p>
<p>ON-LOCK</p> <p>Override default behavior to attempt to acquire a lock on the current row in the data block</p>	<p>Override the <code>lock()</code> method in your entity object class and do something instead of calling the super.</p>

## D.3 Database Connection

**Table D-3 ADF Equivalents for Oracle Forms Database Connection Triggers**

Forms Trigger	ADF Equivalent
POST-LOGON Execute logic after logging into the database	Override the <code>afterConnect()</code> method on your custom application module. Since application module instances can stay connected while serving different logical client sessions, you can override the <code>prepareSession()</code> method, which is fired after initial login, as well as after any time the application module is accessed by a user that was different from the one that accessed it last time.
PRE-LOGOUT Execute logic before logging out of the database	Override the <code>beforeDisconnect()</code> method on your custom application module class.

## D.4 Transaction "Post" Processing (Record Cache)

**Table D-4 ADF Equivalents for Oracle Forms Transactional Triggers**

Forms Trigger	ADF Equivalent
PRE-COMMIT Execute code before commencing processing of the changed rows in all data blocks in the transaction	Override the <code>commit()</code> method in a custom <code>DBTransactionImpl</code> class and write code before calling the super.  <b>Note:</b> For an overview of creating and using a custom <code>DBTransaction</code> implementation, see <a href="#">Section 37.7.5.1, "Creating a Custom Database Transaction Framework Extension Class."</a>
PRE-INSERT Execute code before a new row in the data block is inserted into the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_INSERT</code> , then write code <i>before</i> calling the super.
ON-INSERT Override default processing for inserting a new row into the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_INSERT</code> , then write code <i>instead of</i> calling the super.
POST-INSERT Execute code after new row in the data block is inserted into the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_INSERT</code> , then write code <i>after</i> calling the super.
PRE-DELETE Execute code before a row removed from the data block is deleted from the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_DELETE</code> , then write code <i>before</i> calling the super.
ON-DELETE Override default processing for deleting a row removed from the data block from the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_DELETE</code> , then write code <i>instead of</i> calling the super.

**Table D-4 (Cont.) ADF Equivalents for Oracle Forms Transactional Triggers**

Forms Trigger	ADF Equivalent
POST-DELETE Execute code after a row removed from the data block is deleted from the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_DELETE</code> , then write code <i>after</i> calling the <code>super</code> .
PRE-UPDATE Execute code before a row changed in the data block is updated in the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_UPDATE</code> , then write code <i>before</i> calling the <code>super</code> .
ON-UPDATE Override default processing for updating a row changed in the data block from the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_UPDATE</code> , then write code <i>instead of</i> calling the <code>super</code> .
POST-UPDATE Execute code after a row changed in the data block is updated in the database during "post" processing	Override the <code>doDML()</code> method in your entity class, and if the <code>operation</code> equals <code>DML_UPDATE</code> , then write code <i>after</i> calling the <code>super</code> .
POST-FORMS-COMMIT Execute code after Forms has "posted" all necessary rows to the database, but before issuing the data commit to end the transaction	If you want a single block of code for the whole transaction, you can override the <code>doCommit()</code> method in a custom <code>DBTransactionImpl</code> object and write code before calling the <code>super</code> .  To execute entity-specific code before commit for each affected entity in the transaction, override the <code>beforeCommit()</code> method on your entity object, and write code there.
POST-DATABASE-COMMIT Execute code after database transaction has been committed	Override the <code>commit()</code> method in a custom <code>DBTransactionImpl</code> class, and write code <i>after</i> calling the <code>super</code> .

## D.5 Error Handling

**Table D-5 ADF Equivalents for Oracle Forms Error Handling Triggers**

Forms Trigger	ADF Equivalent
ON-ERROR Override default behavior for handling an error	Install a custom error handler ( <code>DCErrorHandler</code> ) on the ADF <code>BindingContext</code> . For details, see <a href="#">Section 28.10, "Customizing Error Handling."</a>

---

---

# Most Commonly Used ADF Business Components Methods

This appendix lists the most commonly used methods in the interfaces and classes of the ADF Business Components layer of Oracle Application Development Framework (Oracle ADF).

This appendix contains the following sections:

- [Section E.1, "Most Commonly Used Methods in the Client Tier"](#)
- [Section E.2, "Most Commonly Used Methods in the Business Service Tier"](#)

## E.1 Most Commonly Used Methods in the Client Tier

All of the interfaces described in this section are designed for use by client-layer code and are part of the `oracle.jbo.*` package.

This section provides a summary of the most frequently called, written, and overridden methods for the key ADF Business Components interfaces.

---

---

**Note:** The corresponding implementation classes for these `oracle.jbo.*` interfaces are intentionally designed to *not* be directly accessed by client code. [Section E.2, "Most Commonly Used Methods in the Business Service Tier"](#) shows that the implementation classes reside in the `oracle.jbo.server.*` package and generally have the suffix `Impl` in their name to help remind you not to use them in your client-layer code.

---

---

### E.1.1 ApplicationModule Interface

An application module is a business service component that acts as a transactional container for other ADF components and coordinates *with* them to implement a number of Java EE design patterns important to business application developers. These design pattern implementations enable your client code to work easily with updatable collections of value objects, based on fast-lane reader SQL queries that retrieve only the data needed by the client, in the way the client wants to view it. Changes made to these value objects are automatically coordinated with your persistent business domain objects in the business service tier to enforce business rules consistently and save changes back to the database. [Table E-1](#) describes the operations that you can perform on an application module using the `ApplicationModule` interface.

---

---

**Note:** For the complete list of design patterns that ADF Business Components implements, see [Appendix F, "ADF Business Components Java EE Design Pattern Catalog."](#)

---

---

**Table E-1 ApplicationModule Interface**

If you want to...	Call this ApplicationModule interface method
Access an existing view object instance using the assigned instance name (for example, <code>MyVOInstanceName</code> )	<code>findViewObject()</code>
Create a new view object instance from an existing definition	<code>createViewObject()</code>
Create a new view object instance from a SQL Statement	<code>createViewObjectFromQueryStmnt()</code>
	<p><b>Notes:</b></p> <p>This incurs runtime overhead to describe the "shape" of the dynamic query's <code>SELECT</code> list. Use this method only when you cannot know the <code>SELECT</code> list for the query at design time. Furthermore, if you are creating the dynamic query based on some kind of custom runtime repository, you can follow the steps to create (both read-only and updatable) dynamic view objects without the runtime-describe overhead, as described in <a href="#">Section 39.9, "Creating a View Object with Multiple Updatable Entities."</a> If only the <code>WHERE</code> needs to be dynamic, create the view object at design time, then set the <code>WHERE</code> clause dynamically as needed using <code>ViewObject</code> APIs.</p>
Access a nested application module instance by name	<code>findApplicationModule()</code>
Create a new nested application module instance from an existing definition	<code>createApplicationModule()</code>
Find a view object instance in a nested application module using a dot-notated name (for example, <code>MyNestedAMInstanceName.OneOfItsVONames</code> )	<p><code>findViewObject()</code></p> <p><b>Notes:</b></p> <p>You can use this method to find an instance of a view object belonging to a nested application module in a single method call. This way you do not need to first call <code>findApplicationModule()</code> to find the nested application module, before calling <code>findViewObject()</code> on that nested application module.</p>
Access the current transaction object	<code>getTransaction()</code>

In addition to generic application module access, Oracle JDeveloper can generate a custom `YourApplicationModuleName` interface containing service-level custom methods that you've chosen to expose to the client. You use the **Client Interface** page of the Edit Application Module dialog to select the methods that you want to appear in your client interface.

## E.1.2 Transaction Interface

The `Transaction` interface exposes methods allowing the client to manage pending changes in the current transaction. [Table E-2](#) describes the operations that you can perform on the transaction using the `Transaction` interface.

**Table E-2 Transaction Interface**

If you want to...	Call this Transaction interface method
Commit pending changes	<code>commit()</code>
Roll back pending changes	<code>rollback()</code>
Execute a one-time database command or block of PL/SQL	<code>executeCommand()</code> <b>Notes:</b> Do not use this command with methods that require retrieving OUT parameters and that will be executed more than once, or that could benefit from using bind variables. Instead, expose a custom method on your application module.
Validate all pending invalid changes in the transaction	<code>validate()</code>
Change the default locking mode	<code>setLockingMode()</code> <b>Notes:</b> You can set the locking mode in your configuration by setting the property <code>jbo.locking.mode</code> to one of the four supported values: <code>none</code> , <code>optimistic</code> , <code>pessimistic</code> , <code>optupdate</code> . If you don't explicitly set the locking mode, it will default to <code>optimistic</code> . For Fusion web applications, use <code>optimistic</code> or <code>optupdate</code> modes.
Decide whether to use bundled exception reporting mode or not	<code>setBundledExceptionMode()</code> <b>Notes:</b> ADF Controller layer support sets this parameter to <code>true</code> automatically for Fusion web applications.
Decide whether entity caches will be cleared upon a successful commit of the transaction	<code>setClearCacheOnCommit()</code> <b>Notes:</b> Default is <code>false</code> .
Decide whether entity caches will be cleared upon a rollback of the transaction	<code>setClearCacheOnRollback()</code> <b>Notes:</b> Default is <code>true</code> .
Clear the entity cache for a specific entity object	<code>clearEntityCache()</code>

## E.1.3 ViewObject Interface

A view object is a component that encapsulates a database query and simplifies working with the row set of results it produces. You use view objects to project, filter, join, or sort business data using SQL from one or more tables to cast the data into exactly the format that the user should see on the page or panel. You can create "master-detail" hierarchies of any depth or complexity by connecting view objects together using view links. View objects can produce read-only query results, or when

associated with one or more entity objects at design time, can be fully updatable. Updatable view objects can support insertion, modification, and deletion of rows in the result collection, with automatic delegation to the correct business domain objects.

Every view object contains a "default row set" for simplifying the 90 percent of use cases where you work with a single row set of results for the view object's query. A view object implements all the methods on the `RowSet` interface by delegating them to this default `RowSet`. That means you can invoke any `RowSet` methods on any view object as well.

Every view object implements the `StructureDef` interface to provide information about the number and types of attributes in a row of its row sets. So you can call `StructureDef` methods directly on any view object.

[Table E-3](#) describes the operations that you can perform on a view object using the `ViewObject` interface

**Table E-3 ViewObject Interface**

If you want to...	Call this ViewObject interface method
Set an additional runtime <code>WHERE</code> clause on the row set	<code>setWhereClause()</code>  <b>Notes:</b> This <code>WHERE</code> clause augments any <code>WHERE</code> clause specified at design time in the base view object. It does not replace it.
Set a dynamic <code>ORDER BY</code> clause	<code>setOrderByClause()</code>
Create a Query-by-Example criteria collection	<code>createViewCriteria()</code>  <b>Notes:</b> You then create one or more <code>ViewCriteriaRow</code> objects using the <code>createViewCriteriaRow()</code> method on the <code>ViewCriteria</code> object you created. Then you <code>add()</code> these view criteria rows to the view criteria collection and apply the criteria using the <code>applyViewCriteria()</code> method.
Apply a Query-by-Example criteria collection	<code>applyViewCriteria()</code>
Set a query optimizer hint	<code>setQueryOptimizerHint()</code>
Access the attribute definitions for the key attributes in the view object	<code>getKeyAttributeDefs()</code>
Add a dynamic attribute to rows in this view object's row sets	<code>addDynamicAttribute()</code>
Clear all row sets produced by a view object	<code>clearCache()</code>
Remove a view object instance and its resources	<code>remove()</code>
Set an upper limit on the number of rows that the view object will attempt to fetch from the database	<code>setMaxFetchSize()</code>  <b>Notes:</b> Default is -1, which means to impose no limit on how many rows would be retrieved from the database if you iterated through them all. By default, as you iterate through them, they are fetched lazily.

In addition to generic `ViewObject` access, `JDeveloper` can generate you a custom `YourViewObjectName` interface containing view object-level custom methods that

you've chosen to expose to the client. You use the **Client Interface** page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

## E.1.4 RowSet Interface

A row set is an object that contains a set of rows, typically produced by executing a view object's query.

Every RowSet aggregates a "default row set iterator" for simplifying the 90 percent of use cases where you need only a single iterator over the row set. A RowSet object implements all the methods on the RowSetIterator interface by delegating them to this default RowSetIterator. This means you can invoke any RowSetIterator method on any RowSet object (or view object, since it implements RowSet, as well for its default RowSet).

Table E-4 describes the operations that you can perform on a row set using the RowSet interface.

**Table E-4 RowSet Interface**

If you want to...	Call this RowSet interface method
Set a WHERE clause bind variable value	setWhereClauseParams () <b>Notes:</b> Bind variable ordinal positions are zero-based.
Avoid view object row caching if data is being read only once	setForwardOnly ()
Force a row set's query to be (re)executed (in the case of exclusive view object instances) or potentially executed (in the case of shared view object instances)	executeQuery () <b>Notes:</b> The behavior of this method differs depending on whether the view object belongs to a shared application module or not. When reexecuting the query for an exclusive view object (not an instance of a shared module), a new query collection is created. Before executing the query for a shared view object instance, a check is performed to determine whether the results already exist. Already cached results will be reused for the shared view object instance instead of reexecuting the query. If you want to ensure that the results for a shared view object instance are refreshed, you can invoke the forceExecuteQueryOfSharedVO () method. However, if at the time of invoking force execute a user is iterating over the collection of a shared view object instance, then the behavior is undefined and exceptions may result.
Estimate the number of rows in a view object's query result	getEstimatedRowCount ()
Produce an XML document for rows in a view object row set	writeXML ()
Process all rows from an incoming XML document	readXML ()

**Table E-4 (Cont.) RowSet Interface**

<b>If you want to...</b>	<b>Call this RowSet interface method</b>
Set whether a row set will automatically see new rows based on the same entity object created through other row sets	<code>setAssociationConsistent()</code>
Create a secondary iterator to use for programmatic iteration	<code>createRowSetIterator()</code>
	<p><b>Notes:</b></p> <p>If you plan to find and use the secondary iterator by name later, then pass in a string name as the argument; otherwise, pass <code>null</code> for the name and make sure to close the iterator when done iterating by calling its <code>closeRowSetIterator()</code> method.</p>

### E.1.5 RowSetIterator Interface

A row set iterator is an iterator over the rows in a row set. By default it allows you to iterate both forward and backward through the rows. Table E-5 describes the operations that you can perform on a row set using the RowSetIterator interface.

**Table E-5 RowSetIterator Interface**

<b>If you want to...</b>	<b>Call this RowSetIterator interface method</b>
Get the first row of the iterator's row set	<code>first()</code>
Test whether there are more rows to iterate	<code>hasNext()</code>
Get the next row of an iterator's row set	<code>next()</code>
Find a row in this iterator's row set with a given key value	<code>findByKey()</code>
	<p><b>Notes:</b></p> <p>It's important that the <code>Key</code> object that you pass to <code>findByKey</code> be created using the <i>exact</i> same data types as the attributes that comprise the key of the rows in the view object you're working with.</p>
Create a new row to populate for insertion	<code>createRow()</code>
	<p><b>Notes:</b></p> <p>The new row will already have default values set for attributes which either have a static default value supplied at the entity object or view object level, or if the values have been populated in an overridden <code>create()</code> method of the underlying entity object(s).</p>
Create a view row with an initial set of foreign key and/or discriminator attribute values	<code>createAndInitRow()</code>
	<p><b>Notes:</b></p> <p>You use this method when working with view objects that can return one of a "family" of entity object subtypes. By passing in the correct discriminator attribute value in the call to create the row, the framework can create you the correct matching entity object subtype underneath.</p>

**Table E-5 (Cont.) RowSetIterator Interface**

<b>If you want to...</b>	<b>Call this RowSetIterator interface method</b>
Insert a new row into the iterator's row set	<code>insertRow()</code>  <b>Notes:</b> It's a good habit to always immediately insert a newly created row into the rowset. That way you will avoid a common gotcha of creating the row but forgetting to insert it into the rowset.
Get the last row of the iterator's row set	<code>last()</code>
Get the previous row of the iterator's row set	<code>previous()</code>
Reset the current row pointer to the slot before the first row	<code>reset()</code>
Close an iterator when done iterating	<code>closeRowSetIterator()</code>
Set a given row to be the current row	<code>setCurrentRow()</code>
Remove the current row	<code>removeCurrentRow()</code>
Remove the current row to later insert it at a different location in the same iterator	<code>removeCurrentRowAndRetain()</code>
Remove the current row from the current collection but do not remove it from the transaction.	<code>removeCurrentRowFromCollection()</code>
Set/change the number of rows in the range (a "page" of rows the user can see)	<code>setRangeSize()</code>
Scroll to view the <i>n</i> th page of rows (1-based)	<code>scrollToRangePage()</code>
Scroll to view the range of rows starting with row number <i>n</i>	<code>scrollRangeTo()</code>
Set row number <i>n</i> in the range to be the current row	<code>setCurrentRowAtRangeIndex()</code>
Get all rows in the range as a row array	<code>getAllRowsInRange()</code>

## E.1.6 Row Interface

A row is generic value object. It contains attributes appropriate in name and Java type for the view object that it is related to. [Table E-6](#) describes the operations that you can perform on a view object row using the `Row` interface.

**Table E-6 Row Interface**

<b>If you want to...</b>	<b>Call this Row interface method</b>
Get the value of an attribute by name	<code>getAttribute()</code>
Set the value of an attribute by name	<code>setAttribute()</code>
Produce an XML document for a single row	<code>writeXML()</code>
Eagerly validate a row	<code>validate()</code>
Read row attribute values from XML	<code>readXML()</code>
Remove the row	<code>remove()</code>
Flag a newly created row as temporary (until updated again)	<code>setNewRowState(Row.STATUS_INITIALIZED)</code>

**Table E-6 (Cont.) Row Interface**

If you want to...	Call this Row interface method
Retrieve the attribute structure definition information for a row	<code>getStructureDef()</code>
Get the Key object for a row	<code>getKey()</code>

In addition to generic Row access, JDeveloper can generate a custom *YourViewObjectNameRow* interface containing your type-safe attribute getter and setter methods, as well as any desired row-level custom methods that you've chosen to expose to the client. You use the **Client Row Interface** page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

## E.1.7 StructureDef Interface

The `StructureDef` interface provides access to runtime metadata about the structure of a Row object.

In addition, for convenience every view object implements the `StructureDef` interface as well, providing access to metadata about the attributes in the resulting view rows that its query will produce.

[Table E-7](#) describes the operations that you can perform on a view object row using the `StructureDef` interface.

**Table E-7 StructureDef Interface**

If you want to...	Call this StructureDef interface method
Access attribute definitions for all attributes in the view object row	<code>getAttributeDefs()</code>
Find an attribute definition by name	<code>findAttributeDef()</code>
Get attribute definition by index	<code>getAttributeDef()</code>
Get number of attributes in a row	<code>getAttributeCount()</code>

## E.1.8 AttributeDef Interface

The `AttributeDef` interface provides attribute definition information for any attribute of a view object row or entity object instance like attribute name, Java type, and SQL type. It also provides access to custom attribute-specific metadata properties that can be inspected by generic code you write, as well as UI hints that can assist in rendering an appropriate user interface display for the attribute and its value.

[Table E-8](#) describes the operations that you can perform on an attribute using the `AttributeDef` interface.

**Table E-8 AttributeDef Interface**

If you want to...	Call this AttributeDef interface method
Get the Java type of the attribute	<code>getJavaType()</code>
Get the SQL type of the attribute	<code>getSQLType()</code>
	<b>Notes:</b>
	The <code>int</code> value corresponds to constants in the JDBC class <code>java.sql.Types</code> .

**Table E-8 (Cont.) AttributeDef Interface**

<b>If you want to...</b>	<b>Call this AttributeDef interface method</b>
Determine the kind of attribute	<code>getAttributeKind()</code>
	<b>Notes:</b> A simple attribute is one that returns one of the constants <code>ATTR_PERSISTENT</code> , <code>ATTR_SQL_DERIVED</code> , <code>ATTR_TRANSIENT</code> , <code>ATTR_DYNAMIC</code> , <code>ATTR_ENTITY_DERIVED</code> . If the attribute is a 1-to-1 or many-to-1 association/viewlink accessor, it returns <code>ATTR_ASSOCIATED_ROW</code> . If the attribute is a 1-to-many or many-to-many association/viewlink accessor, it returns <code>ATTR_ASSOCIATED_ROWITERATOR</code>
Get the Java type of elements contained in an Array-valued attribute	<code>getElemJavaType()</code>
Get the SQL type of elements contained in an Array-valued attribute	<code>getElemSQLType()</code>
Get the name of the attribute	<code>getName()</code>
Get the index position of the attribute	<code>getIndex()</code>
Get the precision of a numeric attribute or the maximum length of a string attribute	<code>getPrecision()</code>
Get the scale of a numeric attribute	<code>getScale()</code>
Get the underlying column name corresponding to the attribute	<code>getColumnNameForQuery()</code>
Get attribute-specific custom property values	<code>getProperty()</code> , <code>getProperties()</code>
Get the UI <code>AttributeHints</code> object for the attribute	<code>getUIHelper()</code>
Test whether the attribute is mandatory	<code>isMandatory()</code>
Test whether the attribute is querable	<code>isQueryable()</code>
Test whether the attribute is part of the primary key for the row	<code>isPrimaryKey()</code>

### E.1.9 AttributeHints Interface

The `AttributeHints` interface exposes UI hint information that you can use to render an appropriate user interface display for the attribute and its value. [Table E-9](#) describes the operations that you can perform on an attribute using the `AttributeHints` interface.

**Table E-9 AttributeHints Interface**

<b>If you want to...</b>	<b>Call this AttributeHints interface method</b>
Get the UI label for the attribute	<code>getLabel()</code>
Get the tooltip for the attribute	<code>getTooltip()</code>
Get the formatted value of the attribute, using any format mask supplied	<code>getFormattedAttribute()</code>

**Table E-9 (Cont.) AttributeHints Interface**

If you want to...	Call this AttributeHints interface method
Get the display hint for the attribute	<code>getDisplayHint()</code>
	<b>Notes:</b> The display hint will have a string value of either <code>Display</code> or <code>Hide</code> .
Get the preferred control type for the attribute	<code>getControlType()</code>
Parse a formatted string value using any format mask supplied for the attribute	<code>parseFormattedAttribute()</code>

## E.2 Most Commonly Used Methods in the Business Service Tier

The implementation classes corresponding to the `oracle.jbo.*` interfaces, as described in [Section E.1, "Most Commonly Used Methods in the Client Tier,"](#) are intentionally designed to *not* be directly accessed by client code. They reside in a different package named `oracle.jbo.server.*` and have the `Impl` suffix in their name to help remind you not to use them in your client-layer code.

In your business service tier implementation code, you can use any of the same methods that are available to clients, but in addition you can also:

- Safely cast any `oracle.jbo.*` interface to its `oracle.jbo.server.*` package implementation class and use any methods on that `Impl` class as well.
- Override any of the `public` or `protected` methods for the base framework implementation classes and write custom code in your component subclass before or after calling `super.methodName()` to augment or change the default functionality.

This section provides a summary of the most frequently called, written, and overridden methods for the key ADF Business Components classes.

### E.2.1 Controlling Custom Java Files for Your Components

Before examining the specifics of individual classes, it's important to understand how you can control which custom Java files each of your components will use. When you don't need a customized subclass for a given component, you can just let the base framework class handle the implementation at runtime.

Each business component you create comprises a single XML component descriptor, and zero or more related custom Java implementation files. Each component that supports Java customization has a Java page in its component overview editor in the JDeveloper IDE. By selecting or deselecting the different Java classes, you control which ones will be created for your component. If none of the classes is specified, then your component will be an XML-only component, which simply uses the base framework class as its Java implementation. Otherwise, tick the checkbox of the related Java classes for the current component that you need to customize. JDeveloper will create a custom *subclass* of the framework base class in which you can add your code.

---

**Note:** You can set up global IDE preferences for the Java classes to be generated by default for each ADF business component type by choosing **Tools > Preferences > Business Components** and ticking the checkboxes to indicate what you want your defaults to be.

---

A best practice is to *always* generate entity object and view row classes, even if you don't require any custom code in them other than the automatically generated getter and setter methods. These getter and setter methods offer you compile-time type checking that prevents errors surfacing at runtime in response to an attribute having been set to an incorrect kind of value.

## E.2.2 ApplicationModuleImpl Class

The `ApplicationModuleImpl` class is the base class for application module components. Since the application module is the ADF component used to implement a business service, think of the application module class as the place where you can write your service-level application logic. The application module coordinates with view object instances to support updatable collections of value objects that are automatically "wired" to business domain objects. The business domain objects are implemented as ADF entity objects.

### E.2.2.1 Methods You Typically Call on ApplicationModuleImpl

[Table E-10](#) describes the operations that you can perform on an application module using the `ApplicationModuleImpl` class.

**Table E-10** *Methods You Typically Call on ApplicationModuleImpl*

If you want to...	Call this method of the <code>ApplicationModuleImpl</code> class
Perform any of the common application module operations from inside your class, which can also be done from the client	For a list of these methods, see <a href="#">Section E.1.1</a> , " <a href="#">ApplicationModule Interface</a> ."
Access a view object instance that you added to the application module's data model at design time	<code>getViewObjectName()</code> <b>Notes:</b> JDeveloper generates this type-safe view object instance getter method for you to reflect each view object instance in the application module's design time data model.
Access the current <code>DBTransaction</code> object	<code>getDBTransaction()</code>
Access a nested application module instance that you added to the application module at design time	<code>getAppModuleName()</code> <b>Notes:</b> JDeveloper generates this type-safe application module instance getter method for you to reflect each nested application module instance added to the current application module at design time.

### E.2.2.2 Methods You Typically Write in Your Custom ApplicationModuleImpl Subclass

[Table E-11](#) describes the operations that you can perform on an application module using your custom `ApplicationModuleImpl` class.

**Table E–11 Methods You Typically Write in Your Custom ApplicationModuleImpl Subclass**

If you want to...	Write a method like this in your custom ApplicationModuleImpl class
Invoke a database stored procedure	<p><code>someCustomMethod()</code></p> <p><b>Notes:</b></p> <p>Use the appropriate method on the DBTransaction interface to create a JDBC PreparedStatement. If the stored procedure has OUT parameters, then create a CallableStatement instead.</p> <p>For sample code that demonstrates encapsulating a call to a PL/SQL stored procedure inside your application module, see <a href="#">Section 37.4, "Invoking Stored Procedures and Functions."</a></p>
Expose custom business service methods on your application module	<p><code>someCustomMethod()</code></p> <p><b>Notes:</b></p> <p>Select the method name on the <b>Client Interface</b> page of the Edit Application Module dialog to expose it for client access if required.</p>

JDeveloper can generate a custom *YourApplicationModuleName* interface containing service-level custom methods that you've chosen to expose to the client. You can use the **Client Interface** page of the Edit Application Module dialog to select the methods that you want to appear in your client interface.

### E.2.2.3 Methods You Typically Override in Your Custom ApplicationModuleImpl Subclass

Table E–12 describes the operations that you can override on an application module using your custom ApplicationModuleImpl class.

**Table E–12 Methods You Typically Override in Your Custom ApplicationModuleImpl Subclass**

If you want to...	Override this method in your custom ApplicationModuleImpl class
Perform custom setup code the first time an application module is created and each subsequent time it gets used by a different client session.	<p><code>prepareSession()</code></p> <p><b>Notes:</b></p> <p>This is the method you'd use to set up per-client context info for the current user in order to use Oracle's Virtual Private Database (VPD) features. It can also be used to set other kinds of PL/SQL package global variables, whose values might be client-specific, on which other stored procedures might rely.</p> <p>This method is also useful to perform setup code that is specific to a given view object <i>instance</i> in the application module. If instead of the view object setup code being instance-specific, you want it to be initialized for every instance ever created of that view object component, then put the setup logic in an overridden <code>create()</code> method in your ViewObjectImpl subclass instead.</p>

**Table E–12 (Cont.) Methods You Typically Override in Your Custom ApplicationModuleImpl Subclass**

<b>If you want to...</b>	<b>Override this method in your custom ApplicationModuleImpl class</b>
Perform custom setup code after the application module's transaction is associated with a database connection from the connection pool	<p><code>afterConnect()</code></p> <p><b>Notes:</b></p> <p>Can be a useful place to write a line of code that uses <code>getDBTransaction().executeCommand()</code> to perform an <code>ALTER SESSION SET SQL TRACE TRUE</code> to enable database SQL trace logging for the current application connection. These logs can then be processed with the TKPROF utility to study the SQL statements being performed and the query optimizer plans that are getting used.</p> <p>For details about the TKPROF utility, see the "Understanding SQL Trace and TKPROF" section in the <i>Oracle Database Performance Tuning Guide</i>.</p>
Perform custom setup code before the application module's transaction releases its database connection back to the database connection pool	<p><code>beforeDisconnect()</code></p> <p><b>Notes:</b></p> <p>If you have set <code>jbo.doconnectionpooling</code> to <code>true</code>, then the connection is released to the database connection pool each time the application module is returned to the application module pool.</p>
Write custom application module state to the state management XML snapshot	<code>passivateState()</code>
Read and restore custom application module state from the state management XML snapshot	<code>activateState()</code>

## E.2.3 DBTransactionImpl2 Class

The `DBTransactionImpl2` class — which extends the base `DBTransactionImpl` class, and is constructed by the `DatabaseTransactionFactory` class — is the base class that implements the `DBTransaction` interface, representing the unit of pending work in the current transaction.

### E.2.3.1 Methods You Typically Call on DBTransaction

[Table E–13](#) describes the operations that you can perform on a transaction using the `DBTransaction` class.

**Table E–13 Methods You Typically Call on DBTransaction**

<b>If you want to...</b>	<b>Call this method on the DBTransaction class</b>
Commit the transaction	<code>commit()</code>
Roll back the transaction	<code>rollback()</code>
Eagerly validate any pending invalid changes in the transaction	<code>validate()</code>
Create a JDBC <code>PreparedStatement</code> using the transaction's <code>Connection</code> object	<code>createPreparedStatement()</code>

**Table E-13 (Cont.) Methods You Typically Call on DBTransaction**

<b>If you want to...</b>	<b>Call this method on the DBTransaction class</b>
Create a JDBC CallableStatement using the transaction's Connection object	<code>createCallableStatement()</code>
Create a JDBC Statement using the transaction's Connection object	<code>createStatement()</code>
Add a warning to the transaction's warning list	<code>addWarning()</code>

### E.2.3.2 Methods You Typically Override in Your Custom DBTransactionImpl2 Subclass

Table E-14 describes the operations that you can perform on a transaction using your custom DBTransactionImpl2 subclass.

**Table E-14 Methods You Typically Override in Your Custom DBTransactionImpl2 Subclass**

<b>If you want to...</b>	<b>Override this method in your custom DBTransactionImpl2 class</b>
Perform custom code before or after the transaction commit operation	<code>commit()</code>
Perform custom code before or after the transaction rollback operation	<code>rollback()</code>

In order for your custom DBTransactionImpl2 subclass to be used at runtime, there are you must follow these steps:

1. Create a custom subclass of DatabaseTransactionFactory that overrides the create method to return an instance of your custom DBTransactionImpl2 subclass like this:

```
package com.yourcompany.adfextensions;
import oracle.jbo.server.DBTransactionImpl2;
import oracle.jbo.server.DatabaseTransactionFactory;
import com.yourcompany.adfextensions.CustomDBTransactionImpl;
public class CustomDatabaseTransactionFactory
    extends DatabaseTransactionFactory {
    /**
     * Return an instance of our custom CustomDBTransactionImpl class
     * instead of the default implementation.
     *
     * @return An instance of our custom DBTransactionImpl2 implementation.
     */
    public DBTransactionImpl2 create() {
        return new CustomDBTransactionImpl();
    }
}
```

2. Tell the framework to use your custom transaction factory class by setting the value of the TransactionFactory configuration property to the fully qualified class name of your custom transaction factory. As with other configuration properties, if not supplied in the configuration XML file, it can be provided alternatively as a Java system parameter of the same name.

## E.2.4 EntityImpl Class

The `EntityImpl` class is the base class for entity objects, which encapsulate the data, validation rules, and business behavior for your business domain objects.

### E.2.4.1 Methods You Typically Call on EntityImpl

Table E-15 describes the operations that you can perform on an entity object using the `EntityImpl` class.

**Table E-15** *Methods You Typically Call on EntityImpl*

If you want to...	Call this method in the EntityImpl class
Get the value of an attribute	<code>getAttributeName()</code>  <b>Notes:</b> This code-generated getter method calls <code>getAttributeInternal()</code> , but provides compile-time type checking.
Set the value of an attribute	<code>setAttributeName()</code>  <b>Notes:</b> This code-generated setter method calls <code>setAttributeInternal()</code> , but provides compile-time type checking.
Get the value of an attribute by name	<code>getAttributeInternal()</code>
Set the value of an attribute by name	<code>setAttributeInternal()</code>
Eagerly perform entity object validation	<code>validate()</code>
Refresh the entity from the database	<code>refresh()</code>
Populate the value of an attribute without <i>marking</i> it as being changed, but sending <i>notification</i> of its being changed so that the UI refreshes the value on the screen/page	<code>populateAttributeAsChanged()</code>
Access the Definition object for an entity	<code>getDefinitionObject()</code>
Get the Key object for an entity	<code>getKey()</code>
Determine the state of the entity instance, irrespective of whether it has already been posted (but not yet committed) in the current transaction	<code>getEntityState()</code>  <b>Notes:</b> This method will return one of the constants <code>STATUS_UNMODIFIED</code> , <code>STATUS_INITIALIZED</code> , <code>STATUS_NEW</code> , <code>STATUS_MODIFIED</code> , <code>STATUS_DELETED</code> , or <code>STATUS_DEAD</code> , indicating the status of the entity instance in the current transaction.
Determine the state of the entity instance	<code>getPostState()</code>  <b>Notes:</b> This method is typically relevant only if you are programmatically using the <code>postChanges()</code> method to post but not yet commit, entity changes to the database and need to detect the state of an entity with regard to its posting state.
Get the value originally read from the database for a given attribute	<code>getPostedAttribute()</code>

**Table E-15 (Cont.) Methods You Typically Call on EntityImpl**

<b>If you want to...</b>	<b>Call this method in the EntityImpl class</b>
Eagerly lock the database row for an entity instance	<code>lock()</code>

### E.2.4.2 Methods You Typically Write in Your Custom EntityImpl Subclass

Table E-16 describes the operations that you can perform on an entity object using your custom `EntityImpl` subclass.

**Table E-16 Methods You Typically Write in Your Custom EntityImpl Subclass**

<b>If you want to...</b>	<b>Write a method like this in your custom EntityImpl subclass</b>
Perform attribute-specific validation	<pre>public boolean validateSomething(AttrTypevalue)</pre> <p><b>Notes:</b> Register the attribute validator method by adding a <code>MethodValidator</code> rule on the correct attribute in the <b>Validation</b> page of the Edit Entity Object dialog.</p>
Perform entity-level validation	<pre>public boolean validateSomething()</pre> <p><b>Notes:</b> Register the entity-level validator method by adding a <code>MethodValidator</code> rule on the entity in the <b>Validation</b> panel of the Edit Entity Object dialog.</p>
Calculate the value of a transient attribute	Add your calculation code to the generated <code>getAttributeName()</code> method.

### E.2.4.3 Methods You Typically Override in Your Custom EntityImpl Subclass

Table E-17 describes the operations that you can override on an entity object using your custom `EntityImpl` subclass.

**Table E-17 Methods You Typically Override in Your Custom EntityImpl Subclass**

<b>If you want to...</b>	<b>Override this method in your EntityImpl subclass</b>
Set calculated default attribute values, including programmatically populating the primary key attribute value of a new entity instance	<pre>create()</pre> <p><b>Notes:</b> After calling <code>super.create()</code>, call the appropriate <code>setAttrName()</code> method(s) to set the default values for the attributes.</p>
Modify attribute values before changes are posted to the database	<pre>prepareForDML()</pre>
Augment or change the standard <code>INSERT</code> , <code>UPDATE</code> , or <code>DELETE</code> DML operation that the framework will perform on your entity object's behalf to the database	<pre>doDML()</pre> <p><b>Notes:</b> This method checks the value of the operation flag to the constants <code>DML_INSERT</code>, <code>DML_UPDATE</code>, or <code>DML_DELETE</code> to test what DML operation is being performed.</p>

**Table E-17 (Cont.) Methods You Typically Override in Your Custom EntityImpl Subclass**

If you want to...	Override this method in your EntityImpl subclass
Perform complex, SQL-based validation after all entity instances have been posted to the database but before those changes are committed	<code>beforeCommit()</code>
Insure that a related, newly-created, parent entity gets posted to the database <i>before</i> the current child entity on which it depends	<code>postChanges()</code> <b>Notes:</b> If the parent entity is related to this child entity via a composition association, then the framework already handles posting the changes automatically. If they are only associated (but not composed), then you need to override <code>postChanges()</code> to force a newly created parent entity to post before the current, dependent child entity. For an example of the code you typically write in your overridden <code>postChanges()</code> method to accomplish this, see <a href="#">Section 38.8.3, "Overriding postChanges() to Control Post Order."</a>

---

**Note:** It is possible to write attribute-level validation code directly inside the appropriate `setAttributeName` method of your `EntityImpl` class; however, adopting the `MethodValidator` approach suggested in [Table E-16](#) conveniently places all the validations in effect on the **Validation Rules** page of the overview editor for the attributes of the entity object.

---

---

**WARNING:** It is also possible to override the `validateEntity()` method to write entity-level validation code; however, if you want to maintain the benefits of the ADF bundled exception mode — where the framework collects and reports a *maximal* set of validation errors back to the client user interface — use the `MethodValidator` approach suggested in [Table E-16](#). This allows the framework to automatically collect all of your exceptions that your validation methods throw without your having to understand the bundled exception implementation mechanism. Overriding the `validateEntity()` method directly shifts the responsibility onto your *own* code to correctly catch and bundle the exceptions that Oracle ADF would have caught by default, which is non-trivial and a chore to remember and hand-code each time.

---

## E.2.5 EntityDefImpl Class

The `EntityDefImpl` class is a singleton, shared metadata object for all entity objects of a given type in a single Java VM. It defines the structure of the entity instances and provides methods to create new entity instances and find existing instances by their primary key.

### E.2.5.1 Methods You Typically Call on EntityDefImpl

Table E-18 describes the operations that you can perform on an entity object using the EntityDefImpl class.

**Table E-18 Methods You Typically Call on EntityDefImpl**

If you want to...	Call this method in the EntityDefImpl class
Find an entity object of a given type by its primary key	<code>findByPrimaryKey()</code> <b>Notes:</b> For a tip about getting <code>findByPrimaryKey()</code> to find entity instances of subtype entities as well, see <a href="#">Section 38.7.4.2, "Finding Subtype Entities by Primary Key."</a>
Access the current DBTransaction object	<code>getDBTransaction()</code>
Find any EntityDefImpl object by its fully qualified name	<code>findDefObject()</code> (static method)
Retrieve the value of an entity object's custom property	<code>getProperty(), getProperties()</code>
Set the value of an entity object's custom property	<code>setProperty()</code>
Create a new instance of an entity object	<code>createInstance2()</code> <b>Notes:</b> Alternatively, you can expose custom <code>createXXX()</code> methods with your own expected signatures in that same custom EntityDefImpl subclass. See <a href="#">Section E.2.5.2, "Methods You Typically Write in Your Custom EntityDefImpl Class"</a> for details.
Iterate over the entity instances in the cache of this entity type	<code>getAllEntityInstancesIterator()</code>
Access an array list of entity definition objects for entities that extend the current one.	<code>getExtendedDefObjects()</code>

### E.2.5.2 Methods You Typically Write in Your Custom EntityDefImpl Class

Table E-19 describes the operations that you can perform on an entity object using your custom EntityDefImpl class.

**Table E-19 Methods You Typically Write on EntityDefImpl**

If you want to...	Write a method like this in your custom EntityDefImpl class
Allow other classes to create an entity instance with an initial type-safe set of attribute values or setup information	<code>createXXXX(Type1arg1, ..., TypeNargN)</code> <b>Notes:</b> Internally, using this method would create and populate an instance of a NameValuePair object (which implements AttributeList) and call the protected method <code>createInstance()</code> , passing that NameValuePair object. Make sure that the method is <code>public</code> if other classes need to be able to call it.

### E.2.5.3 Methods You Typically Override in Your Custom EntityDefImpl

Table E–20 describes the operations that you can perform on an entity object using the `EntityDefImpl` class.

**Table E–20** *Methods You Typically Override on EntityDefImpl*

If you want to...	Override this method in your custom EntityDefImpl class
Perform custom metadata initialization when this singleton metaobject is loaded	<code>createDef()</code>
Avoid using the <code>RETURNING INTO</code> clause to support refresh-on-insert or refresh-on-update attributes	<code>isUseReturningClause()</code> <b>Notes:</b> Set this method to return <code>false</code> to disable the use of <code>RETURNING INTO</code> , necessary sometimes when your entity object is based on a view with <code>INSTEAD OF</code> triggers that don't support <code>RETURNING INTO</code> at the database level.
Control whether the <code>UPDATE</code> statements issued for this entity update only changed columns or for all columns	<code>isUpdateChangedColumns()</code> <b>Notes:</b> Defaults to <code>true</code> .
Find any <code>EntityDefImpl</code> object by its fully qualified name	<code>findDefObject()</code> <b>Notes:</b> Static method.
Set the value of an entity object's custom property	<code>setProperty()</code>
Allow other classes to create a new instance of an entity object without doing so implicitly via a view object	<code>createInstance()</code> <b>Notes:</b> If you don't write a custom create method as noted in Section E.2.5.2, "Methods You Typically Write in Your Custom EntityDefImpl Class", you'll need to override this method and widen the visibility from <code>protected</code> to <code>public</code> to allow other classes to construct an entity instance.

## E.2.6 ViewObjectImpl Class

The `ViewObjectImpl` class is the base class for view objects.

### E.2.6.1 Methods You Typically Call on ViewObjectImpl

Table E–21 describes the operations that you can perform on a view object using the `ViewObjectImpl` class.

**Table E–21** *Methods You Typically Call on ViewObjectImpl*

If you want to...	Call this method in the ViewObjectImpl class
Perform any of the common view object, row set, or row set iterator operations from inside your class, which can also be done from the client	For more information about operations at the view object, row set, or row set iterator-level, see Section E.1.3, "ViewObject Interface," Section E.1.4, "RowSet Interface," and Section E.1.5, "RowSetIterator Interface."

**Table E–21 (Cont.) Methods You Typically Call on ViewObjectImpl**

If you want to...	Call this method in the ViewObjectImpl class
Set an additional runtime WHERE clause on the default row set	setWhereClause()
Define a named bind parameter	defineNamedWhereClauseParam()
Remove a named bind parameter	removeNamedWhereClauseParam()
Set bind variable values on the default row set by name	setNamedWhereClauseParam() <b>Notes:</b> Only works when you have formally defined named bind variables on your view object.
Set bind variable values on the default row set	setWhereClauseParams() <b>Notes:</b> Use this method for view objects with binding style of "Oracle Positional" or "JDBC Positional" when you have not formally defined named bind variables.
Retrieve a subset of rows in a view object's row set based on evaluating an in-memory filter expression	getFilteredRows()
Retrieve a subset of rows in the current range of a view object's row set based on evaluating an in-memory filter expression	getFilteredRowsInRange()
Set the number of rows that will be fetched from the database per roundtrip for this view object	setFetchSize() <b>Notes:</b> The default fetch size is a single row at a time. This is definitely not optimal if your view object intends to retrieve many rows, so you should either set the fetch size higher at design time on the <b>Tuning</b> page of the Edit View Object dialog, or set it at runtime using this method.
Force a row set's query to be (re)executed specifically on a lookup view object instance in a shared application module	forceExecuteQueryOfSharedVO() <b>Notes:</b> Reexecuting the query forces a new query collection and will prevent the application module cache from being used. You should only use this method when you are sure that you are accessing the shared application module during setup and not during runtime. This method when used during normal runtime may have unintended side-effects that disrupt the navigation of users accessing the collection concurrently. If you want to refresh the collection from the cache without creating a new query collection, call executeQuery() instead.

**E.2.6.2 Methods You Typically Write in Your Custom ViewObjectImpl Subclass**

Table E–22 describes the operations that you can perform on a view object using your custom ViewObjectImpl subclass.

**Table E–22 Methods You Typically Write in Your Custom ViewObjectImpl Subclass**

If you want to...	Write a method like this in your custom ViewObjectImpl subclass
Provide clients with type-safe methods to set bind variable values without exposing positional details of the bind variables themselves	<pre data-bbox="954 300 1365 352">someMethodName (Type1arg1, . . . , TypeNargN)</pre> <p data-bbox="954 365 1430 510"><b>Notes:</b> Internally, this method would call the <code>setWhereClauseParams ()</code> method to set the correct bind variables with the values provided in the type-safe method arguments.</p>

JDeveloper can generate a custom *YourViewObjectName* interface containing view object custom methods that you've chosen to expose to the client. You can use the **Client Interface** page of the Edit View Object to select the methods that you want to appear in your client interface.

### E.2.6.3 Methods You Typically Override in Your Custom ViewObjectImpl Subclass

Table E–23 describes the operations that you can perform on a view object using your custom ViewObjectImpl subclass.

**Table E–23 Methods You Typically Override in Your Custom ViewObjectImpl Subclass**

If you want to...	Override this method in your custom ViewObjectImpl subclass
Initialize custom view object class members (not row attributes) when the view object instance is created for the first time	<pre data-bbox="954 978 1065 1003">create ()</pre> <p data-bbox="954 1016 1438 1415"><b>Notes:</b> This method is useful to perform set up logic that is applicable to every instance of a view object that will ever get created, in the context of any application module.  If instead of <i>generic</i> view object setup logic, you need to perform logic specific to a given view object <i>instance</i> in an application module, then override the <code>prepareSession ()</code> method of your application module's <code>ApplicationModuleImpl</code> subclass and perform the logic there after calling <code>findViewObject ()</code> to find the view object instance whose properties you want to set.</p>
Write custom view object instance state to the state management XML snapshot	<pre data-bbox="954 1436 1179 1461">passivateState ()</pre>
Read and restore custom view object instance state from the state management XML snapshot	<pre data-bbox="954 1509 1166 1535">activateState ()</pre>

**Table E–23 (Cont.) Methods You Typically Override in Your Custom ViewObjectImpl**

If you want to...	Override this method in your custom ViewObjectImpl subclass
Customize the execution of the view object query to utilize an alternative data source	<code>executeQueryForCollection()</code> <b>Notes:</b> By default view objects read their data from the database and automate the task of working with the JDBC layer to process the database result sets. However, by overriding appropriate methods in its custom Java class, you can create a view object that programmatically retrieves data from alternative data sources, as described in <a href="#">Section 39.8, "Using Programmatic View Objects for Alternative Data Sources."</a>
Customize the programmatic view object to utilize an alternative data source and determine whether the query collection has more rows to fetch from the query execution	<code>hasNextForCollection()</code>
Customize the programmatic view object to utilize an alternative data source and populate each row of the retrieved data	<code>createRowFromResultSet()</code>
Customize the programmatic view object to utilize an alternative data source and return a count of the number of rows that will be retrieved	<code>getQueryHitCount()</code>
Customize the programmatic view object to utilize an alternative data source and release any resources that may be associated with a row set that is being closed	<code>releaseUserDataForCollection()</code>
Change or augment the way that the ViewCriteria collection of ViewCriteriaRows is converted into a Query-by-Example WHERE clause	<code>getViewCriteriaClause()</code>

## E.2.7 ViewRowImpl Class

The ViewRowImpl class is the base class for view row objects.

### E.2.7.1 Methods You Typically Call on ViewRowImpl

[Table E–24](#) describes the operations that you can perform on a view object row using your custom ViewRowImpl class.

**Table E–24 Methods You Typically Call on ViewRowImpl**

If you want to...	Call this method in your custom ViewRowImpl class
Perform any of the common view row operations from inside your class, which can also be done from the client	For more information about the row-level operations, see <a href="#">Section E.1.6, "Row Interface."</a>
Get the value of an attribute	<code>getAttrName()</code>
Set the value of an attribute	<code>setAttrName()</code>

**Table E–24 (Cont.) Methods You Typically Call on ViewRowImpl**

If you want to...	Call this method in your custom ViewRowImpl class
Access the underlying entity instance to which this view row is delegating attribute storage	<code>getEntityUsageAliasName()</code> <b>Notes:</b> You can change the name of the entity usage alias name on the <b>Entity Objects</b> page of the Edit View Object dialog.

### E.2.7.2 Methods You Typically Write in Your Custom ViewRowImpl Class

Table E–25 describes the operations that you can perform on a view object row using your custom `ViewRowImpl` class.

**Table E–25 Methods You Typically Write on ViewRowImpl**

If you want to...	Write a method like this in your custom ViewRowImpl class
Calculate the value of a view object-level transient attribute	<code>getAttrName()</code> <b>Notes:</b> JDeveloper generates the skeleton of the method for you, but you need to write the custom calculation logic inside the method body.
Perform custom processing of the setting of a view row attribute	<code>setAttrName()</code> <b>Notes:</b> JDeveloper generates the skeleton of the method for you, but you need to write the custom logic inside the method body if required.
Determine the updateability of an attribute in a conditional way	<code>isAttributeUpdateable()</code>
Expose logical operations on the current row, optionally callable by clients	<code>doSomething()</code> <b>Notes:</b> Often these view-row-level custom methods simply turn around and delegate to a method call on the underlying entity object related to the current row.

JDeveloper can generate a custom `YourViewObjectNameRow` interface containing view row custom methods that you've chosen to expose to the client. You can use the **Client Row Interface** page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

### E.2.7.3 Methods You Typically Override in Your Custom ViewRowImpl Subclass

Table E–26 describes the operations that you can perform on a view object row using your custom `ViewRowImpl` subclass.

**Table E-26 Methods You Typically Override in Your Custom ViewRowImpl Subclass**

If you want to...	Write a method like this in your ViewRowImpl subclass
Determine the updateability of an attribute in a conditional way	isAttributeUpdateable()

## E.2.8 Setting Up Your Own Layer of Framework Base Classes

Before you begin to develop application-specific business components, you can create a layer of classes that extend all of the ADF Business Components framework base implementation classes described in this appendix. An example of a customized framework base class for application module components might look like this:

```
package com.yourcompany.adfextensions;
import oracle.jbo.server.ApplicationModuleImpl;
public class CustomApplicationModuleImpl extends ApplicationModuleImpl {
    /*
     * We might not yet have any custom code to put here yet, but
     * the first time we need to add a generic feature that all of
     * our company's application modules need, we will be very happy
     * that we thought ahead to leave ourselves a convenient place
     * in our class hierarchy to add it so that all of the application
     * modules we have created will instantly benefit by that new feature,
     * behavior change, or even perhaps, bug workaround.
     */
}
```

A common set of customized framework base classes in a package name of your own choosing like `com.yourcompany.adfextensions`, each importing the `oracle.jbo.server.*` package, would consist of the following classes:

- `public class CustomEntityImpl extends EntityImpl`
- `public class CustomEntityDefImpl extends EntityDefImpl`
- `public class CustomViewObjectImpl extends ViewObjectImpl`
- `public class CustomViewRowImpl extends ViewRowImpl`
- `public class CustomApplicationModuleImpl extends ApplicationModuleImpl`
- `public class CustomDBTransactionImpl extends DBTransactionImpl2`
- `public class CustomDatabaseTransactionFactory extends DatabaseTransactionFactory`

For completeness, you may also want to create customized framework classes for the following classes as well:

- `public class CustomViewDefImpl extends ViewDefImpl`
- `public class CustomEntityCache extends EntityCache`
- `public class CustomApplicationModuleDefImpl extends ApplicationModuleDefImpl`

Overriding anything in these classes would be a fairly rare requirement.

---

---

# ADF Business Components Java EE Design Pattern Catalog

This appendix summarizes the Java Platform, Enterprise Edition (Java EE) design patterns that the ADF Business Components layer implements for you.

By using Oracle Application Development Framework (Oracle ADF) business components building-blocks and related design time extensions to JDeveloper, you get a prescriptive architecture for building richly functional and cleanly layered Java EE business services with great performance.

[Table F-1](#) provides a brief overview of the numerous design patterns that the ADF Business Components layer implements for you. Some are the familiar patterns from Sun's Java EE BluePrints and some are design patterns that ADF Business Components adds to the list. For details about Java EE BluePrints, see the BluePrints page at the Oracle Technology Network web site at <http://www.oracle.com/technetwork/java/index-jsp-136701.html>.

**Table F-1 Java EE Design Patterns Implemented by ADF Business Components**

Pattern Name and Description	How ADF Business Components Implements It
<p><b>Model/View/Controller</b></p> <p>Cleanly separates the roles of data and presentation, allowing multiple types of client displays to work with the same business information.</p>	<p>The ADF application module provides a generic implementation of a Model/View/Controller "application object" that simplifies exposing the application data model for any application or service, and facilitates declaratively specifying the boundaries of a logical unit of work. Additional UI-centric frameworks and tag libraries provided in JDeveloper help you implement the view and controller layers.</p>
<p><b>Interface / Implementation Separation</b></p> <p>Cleanly separates the API or Interface for components from their implementation class.</p>	<p>ADF Business Components enforces a logical separation of client-tier accessible functionality (via interfaces) and its business tier implementation. JDeveloper handles the creation of custom interfaces and client proxy classes automatically.</p>
<p><b>Service Locator</b></p> <p>Abstracts the technical details of locating a service so that the client can use it more easily.</p>	<p>ADF application modules are looked up using a simple configuration object which hides the low-level details of finding the service instance behind the scenes. For Fusion web applications, it also hides the implementation of the application module pool usage, a lightweight pool of service components that improves application scalability.</p>

**Table F-1 (Cont.) Java EE Design Patterns Implemented by ADF Business Components**

<b>Pattern Name and Description</b>	<b>How ADF Business Components Implements It</b>
<p><b>Inversion of Control</b></p> <p>A containing component orchestrates the lifecycle of the components it contains, invoking specific methods that you can override at the appropriate times, so as to be able to focus more on what the code should do, instead of when it should be executed.</p>	<p>ADF components contain a number of easy-to-override methods that the framework invokes as needed during the course of application processing.</p>
<p><b>Dependency Injection</b></p> <p>Simplifies application code, and increases configuration flexibility by deferring component configuration and assembly to the container.</p>	<p>ADF Business Components configures all its components from externalized XML metadata definition files. At runtime, the framework automatically injects dependent objects like view object instances into your application module service component and entity objects into your view rows, implementing lazy loading. It supports runtime factory substitution of components by any customized subclass of that component to simplify onsite application customization scenarios. Much of the ADF Business Components functionality is implemented via dynamic injection of validator and listener subscriptions that coordinate the framework interactions depending on what declarative features have been configured for each component in their XML metadata.</p>
<p><b>Active Record</b></p> <p>Avoids the complexity of "anything to anything" object/relational mapping, by providing an object that wraps a row in a database table or view, encapsulates the database access, and adds domain logic on that data.</p>	<p>ADF entity objects handle the database mapping functionality you use most frequently, including inheritance, association, and composition support, so you don't have to focus on object/relational mapping. They also provide a place to encapsulate both declarative business rules and one-off programmatic business domain.</p>
<p><b>Data Access Objects</b></p> <p>Prevents unnecessary marshalling overhead by implementing dependent objects as lightweight, persistent classes instead of each as an individual enterprise bean. Isolates persistence details into a single, easy-to-maintain class.</p>	<p>ADF view objects automate the implementation of data access for reading data using SQL statements. ADF entity objects automate persistent storage of lightweight business entities. ADF view objects and entity objects cooperate to provide a sophisticated, performant data access objects layer, where any data queried through a view object can optionally be made fully updatable without requiring that you write any "application plumbing" code.</p>
<p><b>Session Facade</b></p> <p>Prevents inefficient client access of entity beans and inadvertent exposure of sensitive business information by wrapping entity beans with a session bean.</p>	<p>ADF application modules are designed to implement a coarse-grained "service facade" architecture in any of their supported deployment modes. When deployed as a service interface, they provide an implementation of the Session Facade pattern automatically.</p>

**Table F-1 (Cont.) Java EE Design Patterns Implemented by ADF Business Components**

<b>Pattern Name and Description</b>	<b>How ADF Business Components Implements It</b>
<p><b>Value Object</b></p> <p>Prevents unnecessary network roundtrips by creating one-off "transport" objects to group a set of related attributes needed by a client program.</p>	<p>ADF Business Components provides an implementation of a generic Row object, which is a metadata-driven container of any number and kind of attributes that need to be accessed by a client. The developer can work with the generic Row interface and do late-bound <code>getAttribute("Price")</code> and <code>setAttribute("Quantity")</code> calls, or optionally generate early-bound row interfaces like <code>OverdueOrdersRow</code>, to enable type-safe method calls like <code>getPrice()</code> and <code>setQuantity()</code>. Smarter than just a simple "bag 'o attributes", the ADF Row object can be introspected at runtime to describe the number, names, and types of the attributes in the row, enabling sophisticated, generic solutions to be implemented.</p>
<p><b>Page-by-Page Iterator</b></p> <p>Prevents sending unnecessary data to the client by breaking a large collection into page-sized "chunks" for display.</p>	<p>ADF Business Components provides an implementation of a generic RowSet interface which manages result sets produced by executing view object SQL queries. The RowSet interface allows you to set a desired page size, for example 10 rows, and page up and down through the query results in these page-sized chunks. Since data is retrieved lazily, only data the user actually visits will ever be retrieved from the database on the backend, and in the client tier the number of rows in the page can be returned over the network in a single roundtrip.</p>
<p><b>Fast-Lane Reader</b></p> <p>Prevents unnecessary overhead for read-only data by accessing JDBC APIs directly. This allows an application to retrieve only the attributes that need to be displayed, instead of finding all of the attributes by primary key when only a few are required by the client. Typically, implementations of this pattern sacrifice data consistency for performance, since queries performed at the raw JDBC level do not "see" pending changes made to business information represented by enterprise beans.</p>	<p>ADF view objects read data directly from the database for best performance; however, they give you a choice regarding data consistency. If updateability and/or consistency with pending changes is desired, you need only associate your view object with the appropriate entity objects whose business data is being presented. If consistency is not a concern, view objects can simply perform the query with no additional overhead. In either case, you never have to write JDBC data access code. You need only provide appropriate SQL statements in XML descriptors.</p>
<p><b>(Bean) Factory</b></p> <p>Allows runtime instantiation and configuration of an appropriate subclass of a given interface or superclass based on externally configurable information.</p>	<p>All ADF component instantiation is done based on XML configuration metadata through factory classes allowing runtime substitution of specialized components to facilitate application customization.</p>
<p><b>Entity Facade</b></p> <p>Provides a restricted view of data and behavior of one or more business entities.</p>	<p>ADF view objects can surface any set of attributes and methods from any combination of one or more underlying entity objects to furnish the client with a single, logical value object to work with.</p>

---

**Table F-1 (Cont.) Java EE Design Patterns Implemented by ADF Business Components**

<b>Pattern Name and Description</b>	<b>How ADF Business Components Implements It</b>
<p><b>Value Messenger</b></p> <p>Keeps client value object attributes in sync with the middle-tier business entity information that they represent in a bidirectional fashion.</p>	<p>The ADF Business Components value object implementation coordinates with a client-side value object cache to batch attribute changes to the EJB tier and receive batch attribute updates which occur as a result of middle-tier business logic. The ADF Value Messenger implementation is designed to not require any kind of asynchronous messaging to achieve this effect.</p>
<p><b>Continuations</b></p> <p>Gives you the simplicity and productivity of a stateful programming model with the scalability of a stateless web solution.</p>	<p>ADF Business Components application module pooling and state management functionality combine to deliver this value-add. Application module pooling eliminates the need to dedicate application server tier resources to individual users and supports a "stateless with user affinity" optimization that you can tune.</p>

---

# Performing Common Oracle Forms Tasks in Oracle ADF

This appendix describes how some common Oracle Forms tasks are implemented in Oracle ADF. In Oracle Forms, you do some tasks in the data block, and others in the UI. For this reason, the appendix is divided into two sections: tasks that relate to data, and tasks that relate to the UI.

This appendix includes the following sections:

- [Section G.1, "Performing Tasks Related to Data"](#)
- [Section G.2, "Performing Tasks Related to the User Interface"](#)

## G.1 Performing Tasks Related to Data

In Oracle Forms, tasks that relate solely to data are performed in the data block. In Oracle ADF, these tasks are done on the business components that persist data (entity objects) and on the objects that query data (view objects).

### G.1.1 How to Retrieve Lookup Display Values for Foreign Keys

In Oracle Forms, an editable table often has foreign key lookup columns to other tables. The user-friendly display values corresponding to the foreign key column values exist in related tables. You often need to present these related display values to the user.

In Oracle Forms, this was a complicated task that required adding nondatabase items to the data block, adding a block-level `POST-QUERY` trigger to the data block, and writing a SQL select statement for each foreign key attribute. Additionally, if the user changed the data, you needed to sync the foreign key values with an item-level `WHEN-VALIDATE-ITEM` trigger. This process is much easier in Oracle ADF.

#### Implementation of the task in Oracle ADF

1. Create a view object that includes the following:
  - The main, editable entity object as the primary entity usage
  - Secondary "reference" entity usages for the one or more associated entities whose underlying tables contain the display text

For more information, see [Section 5.5.1, "How to Create Joins for Entity-Based View Objects."](#)

2. Select the desired attributes (at least the display text) from the secondary entity usages as described in [Section 5.5.2, "How to Select Additional Attributes from Reference Entity Usages."](#)

At runtime, the data for the main entity and all related lookup display fields is retrieved from the database in a single join.

If the user can change the data, no additional steps are required. If the user changes the value of a foreign key attribute, the reference information is automatically retrieved for the new, related row in the associated table.

## G.1.2 How to Get the Sysdate from the Database

In Oracle Forms, when you wanted to get the current date and time, you retrieved the `sysdate` from the database. In Oracle ADF, you also have the option of getting the system date using a Java method or a Groovy expression.

### Implementation of the task in Oracle ADF

To get the system date from the database, you can use the following Groovy expression at the entity level:

```
DBTransaction.currentDbTime
```

---

---

**Note:** The `DBTransaction` reference is for entity-level Groovy expressions only.

---

---

If you want to assign a default value to an attribute using this Groovy expression, see [Section 4.10.7, "How to Define a Default Value Using a Groovy Expression."](#)

To get the system date from Java, you call the `getCurrentDate()` method. For more information, see [Section 8.10, "Accessing the Current Date and Time."](#)

## G.1.3 How to Implement an Isolation Mode That Is Not Read Consistent

In Oracle Forms, you might have been concerned with *read consistency*, that is, the ability of the database to deliver the state of the data at the time the SQL statement was issued.

### Implementation of the task in Oracle ADF

If you use an entity-based view object, the query sees the changes currently in progress by the current user's session in the pending transaction. This is the default behavior, and the most accurate.

If instead, you want a snapshot of the data on the database without considering the pending changes made by the current user, you can use a read-only view object and reexecute the query to see the latest committed database values. For more information on read-only view objects, see [Section 5.2.3, "How to Create an Expert Mode, Read-Only View Object."](#)

## G.1.4 How to Implement Calculated Fields

Calculated fields are often used to show the sum of two values, but they could also be used for the concatenated value of two or more fields, or the result of a method call.

### Implementation of the task in Oracle ADF

Calculated attributes are usually not stored in the database, as their values can easily be obtained programmatically. Attributes that are used in the middle tier, but that are not stored in the database are called *transient attributes*. Transient attributes can be defined at the entity object level or the view object level.

If a transient attribute will be used by more than one view object that might be based on an entity object, then define the attribute at the entity object level. Otherwise, define the transient attribute at the view object level for a particular view object.

To define transient attributes at the entity object level, see [Section 4.14, "Adding Transient and Calculated Attributes to an Entity Object."](#) To define transient attributes at the view object level, see [Section 5.15, "Adding Calculated and Transient Attributes to a View Object."](#)

## G.1.5 How to Implement Mirrored Items

In Oracle Forms, you may be used to using mirrored items to show two or more fields that share identical values.

### Implementation of the task in Oracle ADF

There is no need to have mirrored items in Oracle ADF, because the UI and data are separated. The same view object can appear on any number of pages, so you don't need to create mirrored items that have the same value. Likewise, a form could have the same field represented in more than one place and it would not have to be mirrored.

## G.1.6 How to Use Database Columns of Type CLOB or BLOB

If you are used to working with standard database types, you may be wondering how to use the CLOB and BLOB types in Oracle ADF.

### Implementation of the task in Oracle ADF

In Oracle ADF, use the built-in data types `ClobDomain` or `BlobDomain`. These are automatically created when you reverse-engineer entity objects or view objects from existing tables with these column types. ADF Business Components also supports data types for Intermedia column types: `OrdImage`, `OrdAudio`, `OrdDoc`, and `OrdVideo`. For more information, see [Section 4.10.1, "How to Set Database and Java Data Types for an Entity Object Attribute."](#)

## G.2 Performing Tasks Related to the User Interface

In Oracle ADF, common UI-related tasks (such as master-detail screens, popup list of values, and page layout) are handled quite differently than they were in Oracle Forms. This section describes how to perform some common Oracle Forms tasks that relate to the UI with Oracle ADF.

### G.2.1 How to Lay Out a Page

Oracle Forms is based on an absolute pixel or point-based layout, as compared to the container-based approach of JSF, and the Layout Manager approach in ADF Swing.

### **Implementation of the task in Oracle ADF**

See the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework* for information on how to lay out a page in Oracle ADF.

## **G.2.2 How to Stack Canvases**

In Oracle Forms, stacked canvases were often used to hide and display areas of the screen.

### **Implementation of the task in Oracle ADF**

The analog of stacked canvases in Oracle ADF is panels (layout containers) with the rendered property set to `true` or `false`. See the *Oracle Fusion Middleware Web User Interface Developer's Guide for Oracle Application Development Framework* for more information.

## **G.2.3 How to Implement a Master-Detail Screen**

Master-detail relationships in Oracle ADF are coordinated through a view link. A view link is conceptually similar to a Oracle Forms *relation*.

### **Implementation of the task in Oracle ADF**

For information on how create view links, see [Section 5.6, "Working with Multiple Tables in a Master-Detail Hierarchy."](#) Once you have established a relationship between two view objects with a view link, see [Section 5.6.4, "How to Enable Active Master-Detail Coordination in the Data Model."](#)

## **G.2.4 How to Implement an Enter Query Screen**

In Oracle Forms, another common task was creating an *enter query screen*. That is, a screen that starts in Find mode.

### **Implementation of the task in Oracle ADF**

In Oracle ADF, this accomplished with a search form. Complete information on how to create a search form is covered in [Chapter 27, "Creating ADF Databound Search Forms."](#) In particular, you may want to look at [Section 27.3.1, "How to Set Search Form Properties on the View Criteria."](#)

## **G.2.5 How to Implement an Updatable Multi-Record Table**

In Oracle Forms, you may be used to creating tables where you can edit and insert many records at the same time. This can be slightly more complicated when using a JSF page in Oracle ADF, because the operations to edit an existing record and to create a new record are not the same.

### **Implementation of the task in Oracle ADF**

In Oracle ADF, this is done using an input table. To create an input table, see [Section 23.4, "Creating an Input Table."](#)

## **G.2.6 How to Create a Popup List of Values**

In Oracle Forms, it was simple to create a list of values (LOV) object and then associate that object with a field in a declarative manner. This LOV would display a popup window and provide the following capabilities:

- Selection of modal values
- Query area at the top of the LOV dialog
- Display of multiple columns
- Automatic reduction of LOV contents, possibly based on the contents of the field that launched the LOV
- Automatic selection of the list value when only one value matches the value in the field when the LOV function is invoked
- Validation of the field value based on the values cached by the LOV
- Automatic popup of the LOV if the field contents are not valid

#### **Implementation of the task in Oracle ADF**

To implement a popup list in Oracle ADF, you configure one of the view object's attributes to be of LOV type, and select **Input Text with List of Values** as the style for its UI hint. For a description of how to do this, see [Section 5.13, "Working with List of Values \(LOV\) in View Object Attributes."](#)

### **G.2.7 How to Implement a Dropdown List as a List of Values**

In Oracle Forms, you could create a list of values (LOV) object and then associate that object with a field in a declarative manner. In Oracle ADF, you can implement an LOV (lookup-value) screen with a search item, usable for a lookup field with many possible values.

#### **Implementation of the task in Oracle ADF**

To implement a dropdown list in Oracle ADF, you configure one of the view object's attributes to be of LOV type, and select **Input Text with List of Values** as the style for its UI hint. For a description of how to do this, see [Section 5.13, "Working with List of Values \(LOV\) in View Object Attributes."](#)

### **G.2.8 How to Implement a Dropdown List with Values from Another Table**

In Oracle Forms, you could create a list of values (LOV) object and then associate that object with a field in a declarative manner. In Oracle ADF, you can implement a dropdown list with string values from a different table. These string values populate the field with an id code that is valid input in the table that the screen is based on.

#### **Implementation of the task in Oracle ADF**

To implement a dropdown list of this type in Oracle ADF, you configure one of the view object's attributes to be of LOV type, and select **Choice List** as the style for its UI hint. For a description of how to do this, see [Section 5.13, "Working with List of Values \(LOV\) in View Object Attributes."](#)

### **G.2.9 How to Implement Immediate Locking**

In Oracle ADF, you can lock a record in the database at the first moment it is obvious that the user is going to change a specific record.

#### **Implementation of the task in Oracle ADF**

Immediate row locking can be configured in ADF Business Components, although it is not the default and is typically not used in web application scenarios. For web applications, use the default configuration setting

`jbo.locking.mode=optimistic`. For more information, see [Section 40.11.1, "How to Set Applications to Use Optimistic Locking."](#)

## G.2.10 How to Throw an Error When a Record Is Locked

When a record has been locked by a user, it's helpful to throw an error to let other users know that the record is not currently updatable.

### Implementation of the task in Oracle ADF

Locking rows and throwing an exception if the row is already locked is built-in ADF Business Components functionality. There are a couple of different ways that you can handle the error message, depending on whether you want a static error message or a custom message with information about the current row.

- To throw a static message, register a custom message bundle in your ADF Business Components project to substitute the default `RowAlreadyLockedException`'s error message with something more meaningful or user-friendly.
- To throw a message that contains information about the row, override the `lock()` method on the entity object, using a try/catch block to catch the `RowAlreadyLocked` exception. After you catch the exception, you can throw an error message that might contain more specific information about the current row.

# Data Controls in Oracle ADF Fusion Web Applications

This appendix describes the various types of data controls available for Oracle ADF Fusion Web Applications. It also presents a brief comparison of how data access features are implemented for each type of data control.

This appendix includes the following sections:

- [Section H.1, "Introduction to Data Controls"](#)
- [Section H.2, "Data Control Feature Implementation Comparison"](#)
- [Section H.3, "Data Control Objects"](#)

## H.1 Introduction to Data Controls

A data control is essentially a bridge that makes data from a source available to the user interface in an ADF Fusion Web Application. You can use the objects in the data control to create databound user interface components.

The most commonly used types of data controls include the following:

- ADF Business Components Data Control

This type of data control is generated by JDeveloper when you create an application module in your ADF Business Components application.

For more information, see [Section 12.3, "Using the Data Controls Panel."](#)

- JavaBean Data Control

This type of data control obtains the structure of the data from POJOs (plain, old Java objects).

To create a JavaBean data control, right-click a Java class file (in the Application Navigator), and choose Create Data Control.

For information about the data control objects available in a JavaBean data control, see [Section H.3, "Data Control Objects."](#)

- EJB Data Control

The EJB data control is essentially the same as the JavaBean data control, except that it uses features inherent in the EJB architecture to obtain the structure of the data.

You can create an EJB data control from the New Gallery. Expand the **Business Tier** node, select **Data Controls**, choose **EJB Data Control**, and click **OK**.

For information about the data control objects available in an EJB data control, see the *Oracle Fusion Middleware Java EE Developer's Guide for Oracle Application Development Framework*.

- URL Service Data Control

A URL service data control lets you access and consume the data stream from a specified URL. This type of data control is not updateable.

You can create a URL Service data control from the New Gallery. Expand the **Business Tier** node, select **Data Controls**, choose **URL Service Data Control**, and click **OK**.

For information about the data control objects available in a URL Service data control, see [Section H.3, "Data Control Objects."](#)

- Web Service Data Control

A Web Service data control obtains the structure of the data from the WSDL for a web service.

You can create a Web Service data control from the New Gallery. Expand the **Business Tier** node, select **Data Controls**, choose **Web Service Data Control**, and click **OK**.

For more information, see [Section 13.3, "Creating Web Service Data Controls."](#)

- JMX Data Control

A JMX data control obtains the structure of the JMX MBeans from an MBean Server.

You can create a JMX data control from the New Gallery. Expand the **Business Tier** node, select **Data Controls**, choose **JMX Data Control**, and click **OK**. For more information about creating a JMX data control, see the online help for the Create JMX Data Control wizard.

Before you can create a JMX data control, you must first have a JMX connection. For more information about JMX connections, see the online help for the Create JMX Connection dialog.

For information about the data control objects available in a JMX data control, see [Section H.3, "Data Control Objects."](#)

- Placeholder Data Control

A placeholder data control is a special type of data control that doesn't require a traditional data structure. As the name implies, it is a placeholder that can be used during UI development, and then replaced with the real data control when it becomes available.

You can create a Placeholder data control from the New Gallery. Expand the **Business Tier** node, select **Data Controls**, choose **Placeholder Data Control**, and click **OK**.

For more information, see [Chapter 29, "Designing a Page Using Placeholder Data Controls."](#)

## H.2 Data Control Feature Implementation Comparison

The type of data control that you choose to use will impact how you implement data access features. [Table H-1](#) provides a comparison of how you implement some commonly used data access features for each type of data control.

**Table H–1 Comparison of Feature Implementation in Data Controls**

	<b>ADF Business Components data control</b>	<b>JavaBean data control</b>	<b>EJB data control</b>	<b>Web Services data control</b>	<b>URL Service data control</b>	<b>JMX data control</b>	<b>Placeholder data control</b>
af:Query	declarative	declarative	declarative	implemented programmatically	not available	not available	not available
af:quickQuery	declarative	declarative	declarative	implemented programmatically	not available	not available	not available
af:inputCombo ListOfValues	declarative	declarative	declarative	implemented programmatically	not available	not available	declarative
af:Calendar	declarative	implemented programmatically	implemented programmatically	implemented programmatically	not available	not available	not available
af:Media	declarative	implemented programmatically	implemented programmatically	implemented programmatically	not available	not available	not available

The features that are listed in the table as "implemented programmatically" can be implemented using the necessary Java classes required to implement a business model that can be used by the specific data-entry component. For more information, refer to the Javadoc for the appropriate classes.

### H.3 Data Control Objects

In the Data Controls panel, each data control object is represented by an icon. [Table H–2](#) describes what each icon represents, where it appears in the Data Controls panel hierarchy, and what components it can be used to create.

You can design a databound user interface by dragging an item from the Data Controls panel and dropping it on a page as a specific UI component.

The objects described in [Table H–2](#) are applicable to the JavaBean data control, the EJB data control, the JMX data control, the URL Service data control, unless otherwise noted. For information about the data control objects available in the other types of data controls, refer to the documentation for desired type of data control as listed in [Section H.1, "Introduction to Data Controls"](#)

**Table H-2 Data Controls Panel Icons and Object Hierarchy for JavaBeans, EJBs, and URLs**

Icon	Name	Description	Used to Create...
	Data Control	<p>Represents a data control. You cannot use the data control itself to create UI components, but you can use the child objects listed under the data control. There may be more than one data control, each representing a logical grouping of data functions.</p> <p>Typically, there is one data control for a given source (bean, EJB, or URL). However, you may have additional data controls that were created for other types of objects (for example, application modules or web services).</p>	Serves as a container for the other objects. Not used to create anything.
	Create Method	<p>Represents a built-in method that creates a new instance of an object in a data collection using the new Java constructor call. Create method icons are located in a node named after the data collection to which they belong. These data collection nodes are located in the <b>Constructors</b> node under the data control. The <b>Attributes</b> node, which appears as a child under a create method, contains all the attributes of the data collection. If the collection contains an attribute from another collection (called a <i>foreign key</i> in relational databases), that attribute is represented by an accessor return icon. In this case, the accessor returns a single object.</p> <p>This object is not available in a URL Service data control. Because the URL Service data control is not updateable, there is no instance of an object that can be created.</p> <p>This object is not available in the JMX data control.</p>	Creation forms.
	Method	<p>Represents a custom method on the data control that may accept parameters, perform some action or business logic, and return data or data collections. If the method is a <code>get</code> method of a map and returns a data collection, a method return icon appears as a child under it. If a method requires a parameter, a folder appears under the method, which lists the required parameters.</p> <p>The URL Service data control exposes only one method <code>loadData()</code> which retrieves the contents of the URL.</p>	UI actions such as buttons or links.
	Method Return	<p>Represents a data collection that is returned by a custom method. A method return appears as a child under the method that returns it. The objects that appear as children under a method return may be attributes of the collection, accessor returns that represent collections related to the parent collection, other methods that perform actions related to the parent collection, and operations that can be performed on the parent collection.</p>	Forms, tables, trees, and range navigation components.

**Table H-2 (Cont.) Data Controls Panel Icons and Object Hierarchy for JavaBeans, EJBs, and URLs**

Icon	Name	Description	Used to Create...
	Accessor Return	<p>Represents an object returned by a bean-style accessor method on the business service. An accessor method is used when the objects returned are JavaBeans. Accessor returns appear as children under method returns, other accessor returns, or in the <b>Attributes</b> node under built-in create methods. Accessor returns are objects that are related to the current object in the parent collection. This relationship is usually based on a common unique attribute in both objects. For example, if a method returns a collection of users, an accessor return that is a child of that collection might be a collection of service requests that are assigned to a particular user. In ADF, the relationship between parent and child collections is called a master-detail relationship. For more information about master-detail objects, see <a href="#">Chapter 24, "Displaying Master-Detail Data."</a></p> <p>Accessor returns can be either collections or single objects. For example, if a method returns a collection of service requests, one accessor return under that method might be a collection of service history details for the current service request, while another accessor return might be a single user assigned to the current service request. By default, when data controls are created from session beans over POJOs, the names of accessors that return collections end in <code>Collection</code> (for example, <code>OrderCollection</code>). The UI components available from the Data Controls panel context menu differ depending on whether the accessor return is a collection or a single object.</p> <p>The children under an accessor return may be attributes of the collection or object, other accessor returns, custom methods that return a value from the collection or object, and operations that can be performed on the collection or object. The accessor returns under a built-in create method are always a single object and never have any children.</p>	<p>For collections: Forms, tables, trees, range navigation components, and master-detail widgets.</p> <p>For single objects: Forms, master-detail widgets, and selection lists.</p> <p>For single objects under a constructor: selection lists only.</p>
	Attribute	<p>Represents a discrete data element in an object. Attributes appear as children under method returns or accessor returns.</p>	<p>Label, text field, and selection list components.</p>
	Operation	<p>Represents a built-in data control operation that performs actions on the parent object. If an operation requires a parameter, a folder appears under the method, which lists the required parameters. Data control operations are located in an <b>Operations</b> node under method returns or accessor returns and under the root data control node. The operations that are children of a particular method or accessor return operate on that return object only, while operations under the data control node operate on all the objects represented by the data control.</p> <p>Because the URL Service data control is not updateable, only retrieval and navigation operations are available.</p>	<p>UI actions such as buttons or links.</p>
	Parameter	<p>Represents a parameter value that is declared by the method or operation under which it appears. Parameters appear in a folder under a method or operation.</p> <p>The parameter for a URL Service data control is the parameter that a user passes in the URL. These show up as a parameters to the <code>loadData()</code> method when the URL Service data control is created. For example, say you create a data control to the URL <code>http://www.example.org?id=##param##</code>. On the Data Controls panel, you would see that the <code>loadData()</code> method has one parameter with the name <code>param</code>. The value supplied to this parameter is substituted in the URL when the invocation occurs.</p>	<p>Label, text, and selection list components.</p>

---

---

# Glossary

## **action binding**

A binding for command components, such as buttons or links, to built-in or custom methods on the [data control](#), or to built-in collection-level operations (such as, Create, Delete, Next, or Previous). An action binding object encapsulates the details of how to invoke a method and what parameters (if any) the method is expecting.

## **activity**

A piece of work that is performed when an ADF Controller [task flow](#) runs, for example, a method call or view.

## **ADF**

See [Oracle ADF](#).

## **ADF binding filter**

A servlet filter that ADF web applications use to preprocess any HTTP requests that may require access to the binding context.

## **ADF Business Components**

A framework that simplifies the development, delivery, and customization of business applications for the Java 2 Platform. You use ADF Business Components to define associations between [entity objects](#), [view objects](#), and [application modules](#) to reflect the foreign keys present in the underlying tables.

## **ADF Controller layer**

A mechanism that provides an enhanced navigation and state management model on top of JSF. This mechanism declaratively defines navigation using control flow rules.

## **ADF Faces Rich Client (RC)**

A set of standard JSF components that include built-in Ajax functionality.

## **ADF Model layer**

A layer that implements service abstraction called the [data control](#).

## **application module**

A transactional component that UI clients use to work with application data. It defines an updatable data model and top-level procedures and functions (called *service methods*) related to a logical unit of work. This unit of work is related to an end-user task.

**binding context**

A container object that holds a list of available [data controls](#) and data binding objects. The `DataBindings.cpx` files define the binding context for the application. See also [data control](#).

**bounded task flow**

A specialized form of ADF Controller task flow that has a single entry point and zero or more exit points. It contains its own set of private, [control flow](#) rules, activities, and managed beans. A bounded task flow allows reuse, parameters, transaction management, and reentry. When dropped on a page, it becomes a [region](#).

**control flow**

An ADF Controller activity that enables navigation between other activities in an ADF task flow. The control flow links one [activity](#) to another in a [task flow](#).

**data control**

XML configuration files that describe a service. At design time, visual tools like JDeveloper can leverage that metadata to UI component to be declaratively bound to an operation or data collection.

**Data Controls panel**

A panel in JDeveloper that lists all the [data controls](#) that have been created for the application's business services and exposes all the collections (row sets of data objects), methods, and built-in operations that are available for binding to UI components.

**entity object**

An object that represents a row in a database table and that simplifies modifying its data by handling all data manipulation language operations for you. Entity objects are [ADF Business Components](#) that provide the mapping to underlying data structures.

**invoke action**

An action that binds to a method that invokes the operations or methods defined in an action or a method action binding during any phase of the page lifecycle. See also [action binding](#).

**iterator binding**

A binding to an iterator that iterates over view object collections. There is one iterator binding for each collection used on the page. All of the value bindings on the page must refer to an iterator binding in order for the component values to be populated with data at runtime.

Contrast with [variable iterator](#) and [method iterator](#).

**list of values (LOV)**

See [LOV](#).

**LOV**

Input components that allow a user to enter values by picking from a list that is generated by a query

**MDS**

An application server and Oracle relational database that keep metadata in these areas: a file-based repository data, dictionary tables (accessed by built-in functions) and a

---

metadata registry. One of the primary uses of MDS is to store customizations and persisted personalization for Oracle applications

**method iterator**

A binding to an iterator that iterates over the collections returned by custom methods in the data control. An iterator binding that is always related to a method [action binding](#) object. The method action binding encapsulates the details about how to invoke the method and what parameters the method is expecting. The method action binding is itself bound to the method iterator, which provides the data.

**Oracle ADF**

An end-to-end application framework that builds on Java Platform, Enterprise Edition standards and open-source technologies to simplify and accelerate implementing service-oriented applications.

**Oracle Application Development Framework (Oracle ADF)**

See [Oracle ADF](#).

**Oracle Metadata Services (MDS)**

See [MDS](#).

**page definition file**

A file that defines the binding objects that populate the data in UI components at runtime. For every page that has ADF bindings, there must be a corresponding page definition file that defines the binding objects used by that page.

**region**

An ADF Controller UI component whose content is based on a [task flow](#) definition. When first rendered, the region's content is that of the first view activity in a task flow. See also [activity](#).

**task flow**

A set of ADF Controller activities, [control flow](#) rules and managed beans that interact to allow a user to complete a task.

**unbounded task flow**

A set of activities, ADF [control flow](#) rules, and managed beans that interact to allow a user to complete a task. An unbounded task flow has a single point of entry.

**value binding**

A binding used by ADF view UI components that display data. Value bindings range from the most basic variety that work with a simple text field to more sophisticated list and tree bindings that support the additional needs of list, table, and tree UI controls.

**value iterator**

An ADF Model iterator pointing to a collection that contains only one data object whose attributes are the binding container variable. Contrast with [method iterator](#) and [value iterator](#) iterator.

**variable iterator**

A binding to an iterator that exposes all the variables in the binding container to the other bindings. While there is an iterator binding for each collection, there is only one

variable iterator binding for all variables used on the page. Contrast with [method iterator](#) and [value iterator](#) iterator.

**view accessor**

An ADF Business Components object that points from an entity object attribute (or [view object](#)) to a destination view object or shared view instance in the same application workspace. The view accessor returns a row set that by default contains all the rows from the destination view object.

**view object**

An ADF Business Components object that represents a SQL query and simplifies working with its results. The SQL language is used to join, project, filter, sort, and aggregate data into the shape required by the end-user task being represented in the user interface.
