The `adf-config.xml` file is updated when you create the version release names. This file appears in the Applications window in the Application Resources panel, under the **Descriptors** and **ADF META-INF** nodes. The `connections.xml` file in the same folder is created when you first create the ADF Business Components.

How to Edit the ADF REST Resource Definition

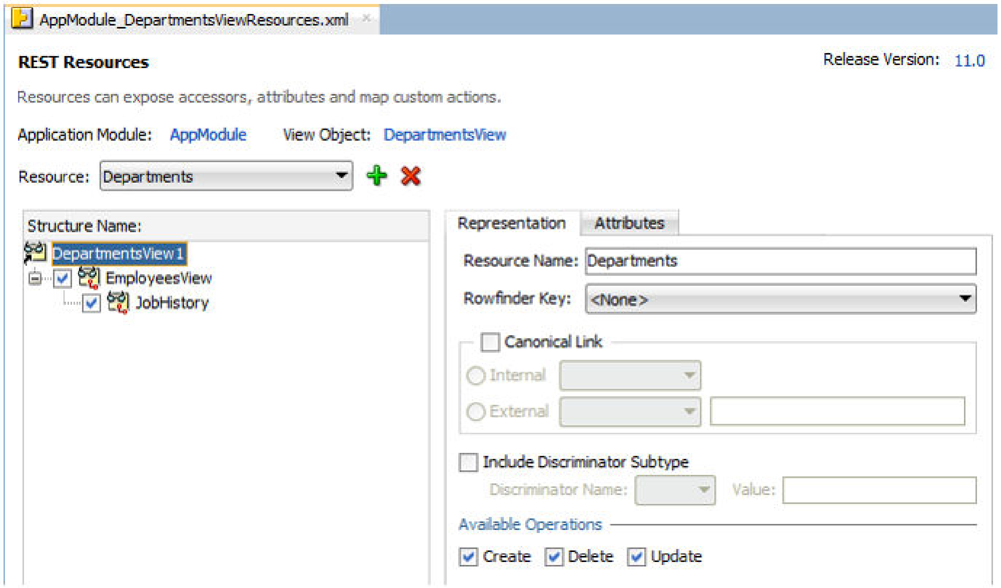
After you add an ADF REST resource definition to the ADF Model project, the REST section of the application module overview editor displays the names of the resources you have created. You can open the REST resource definition in its own editor by clicking the resource name in the list (as shown in Figure 16-2).

The overview editor for REST resources displays the options for editing the structure of the resource. From the standpoint of the RESTful web service, the REST resource structure determines the available data that may be invoked by REST calls at runtime.

At design time, you can edit the REST resource definition to select only the resources that you want to expose from the view object hierarchy backing the resource. When you first create a REST resource, you are required to select a view object exposed by the data model of the application module to back the resource. This original view object selection defines the root resource of the REST resource. You may optionally expose additional child view objects if present.

For example, the left side of the REST resource editor shown in Figure 16-5 displays the default structure of the resource, `Departments`. The resource structure appears as a tree with the root node representing the root resource (in this case `DepartmentsView1`). The leaf nodes of the tree represent child resources. In this example, the `Departments` resource is comprised of a root resource `DepartmentsView1` and various child resources, including `Employees` and `JobHistory`. Because the `DepartmentsView1`, `Employees`, and `JobHistory` resources are related as view instances in the data model, they appear in the hierarchy. You use the checkboxes beside leaf nodes to add and remove child resources from the resource structure.

Figure 16-5 Overview Editor Displays Resource Structure



AppModule_DepartmentsViewResources.xml

REST Resources

Release Version: 11.0

Resources can expose accessors, attributes and map custom actions.

Application Module: AppModule View Object: DepartmentsView

Resource: Departments

Available Operations
☑ Create ☑ Delete ☑ Update

> **Note:**
>
> The right side of the REST resource editor displays the available options corresponding to the node selections that you make in the **Structure** tree.

Table 16-1 summarizes the nodes of the resource structure tree:

Table 16-1 Nodes of the Resource Structure Tree

Node	Description	Editing Options
Root resource node:  Structure Name: DepartmentsView1 ☑ Employees	Represents the view object instance that backs the root resource selection.	The backing view object instance of the root resource cannot be altered or removed. You may select this node to select options on the root resource. For details about these options, see Customizing the ADF REST Resource Representation and Methods.
Child resource node:  Structure Name: DepartmentsView1 ☑ Employees	Represents a view link accessor used in the data model to define master-details relationships defined for the view object instance that backs the root resource selection. Note: Child nodes are not displayed when the view object instance of the root resource is not included in a master-detail relationship.	Child resources are disabled by default. Select the checkbox to expose a child resource in the resource representation. To remove a child resource from the resource representation, deselect the checkbox. You may select a child resource node to select options on the child resource. For details about these options, see Customizing the ADF REST Resource Representation and Methods.

Before you begin:

It may be helpful to have an understanding of how ADF REST supports application modules and enables web service clients to access rows of data and perform service operations. See About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. See Additional Functionality for RESTful Web Services.

You will need to complete this task:

- Create the desired REST resource, as described in Creating ADF REST Resources Using the Application Module.

To edit the ADF REST resource structure:

1. In the Applications window, double-click the resource definition file that defines the ADF REST resource you want to edit.
2. In the overview editor, make the desired selections.

   Press **F1** to view the JDeveloper Help Center topic for the overview editor.
3. Choose **File** and then **Save All** to save the changes on this resource.

JDeveloper saves your changes in the resource definition file for the resource, as described in What Happens When You Create REST Resources in the ADF Business Components Project.

How to Expose Child Resources in the ADF REST Resource

Child resources may be exposed in the ADF REST resource when the application module data model specifies one or more hierarchical, master-detail relationships. For each master-detail relationship in the data model, the ADF Business Components Model project must define a view link accessor that names the related parent and child view objects, thereby nesting the child or detail view object instance within the parent or master view object instance.

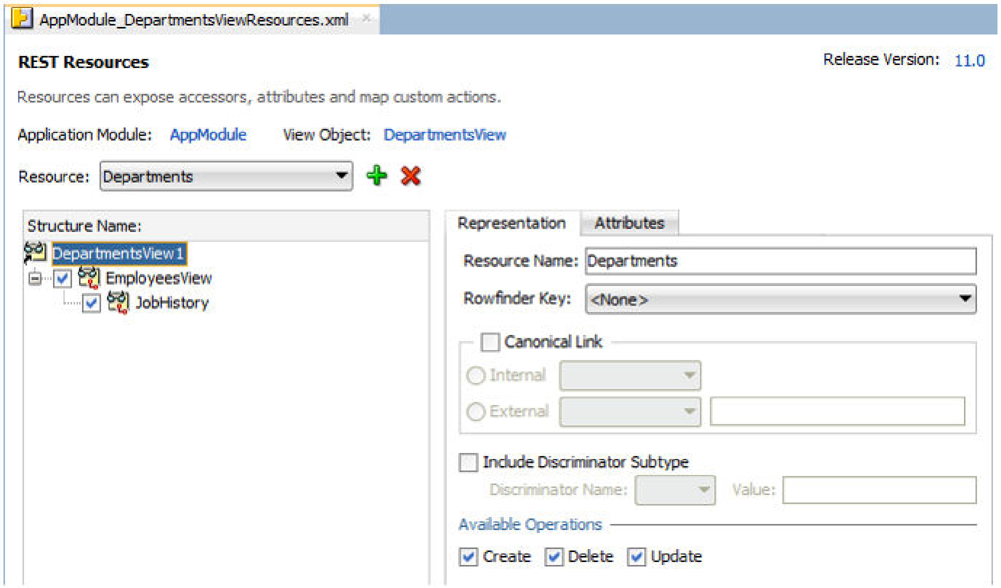
At runtime, a REST resource that exposes nested view instances supports returning collections for the master and detail in a single roundtrip. Thus, exposing child resources at design-time is useful for service clients with the requirement to manipulate master-detail data.

In JDeveloper, the overview editor for REST resources displays master-detail relationships as a resource structure tree with child resources displayed as leaf nodes of the root resource. For example, Figure 16-6 shows the `Departments` resource in the overview editor with the following nested resource structure:

- `DepartmentsView1` is the master view instance and backs the root resource.
- `Employees` is a detail view instance, nested below `DepartmentsView1` and the checkbox for the tree node appears selected, indicating the `Departments` resource exposes the child resource.
- `JobHistory` is another detail view instance, nested below `EmployeesView` and the checkbox for the tree node appears selected, indicating the `Departments` resource exposes the child resource.

By default, JDeveloper creates the REST resource based on the selected backing view instance, but does not include child resources. In the resource structure tree, child resources appear unselected by default to indicate that these resources are not exposed. You may expose or hide child resources, by selecting or unselecting its checkbox.

Figure 16-6 Child Resources Enabled in the Overview Editor



AppModule_DepartmentsViewResources.xml

REST Resources

Release Version: 11.0

Resources can expose accessors, attributes and map custom actions.

Application Module: AppModule View Object: DepartmentsView

Discriminator Name: Value:

Available Operations

☑ Create ☑ Delete ☑ Update

> **Note:**
>
> By default, child resources are not exposed and must be selected in the overview editor to expose them in the resource.

Before you begin:

It may be helpful to have an understanding of how ADF REST supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete this task:

- Create the desired REST resource, as described in Creating ADF REST Resources Using the Application Module.

To expose nested resources:

1. In the Applications window, double-click the resource definition file that defines the ADF REST resource you want to edit.
2. In the overview editor for the REST resource, expand the **Structure** tree and select the checkbox of any child resource of the root resource.

   By default, child resource nodes appear unselected in the **Structure** tree, which indicates that nested resources are unexposed in the resource.

If the data model does not define a master-detail hierarchy for the backing view instance of the root resource, then no child resource node will appear in the **Structure** tree. For more information about **Structure** nodes, see Table 16-1.

3. Select the checkbox of another child resource in the **Structure** tree to enable its nested resource on the resource.

What You May Need to Know About Optimizing Child Resource Database Queries

REST requests where M-1 or 1-1 child resources render as nested objects can result in a high number of database queries, based on the number of resource items. For example, child Department resources rendered for an Employee object result in a database roundtrip for each employee. However, if the REST nested object request is made and the ADF REST framework discovers a M-1 or 1-1 child relationship involving the child's primary key under the following additional conditions, then lookup of child resources is optimized by finding a row in the view object's entity cache. If these conditions do not exist, a database query will be performed for the row fetches.

To ensure that the primary key lookup is used to improve the execution time for fetching a one-side view link, nested entity-backed view objects must meet the following conditions:

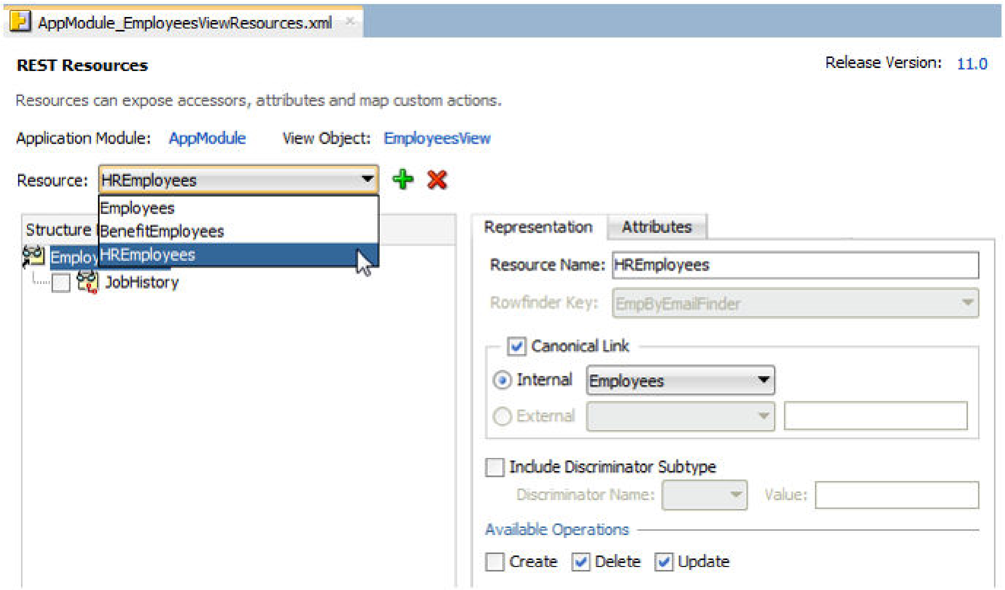
- The view object has an entity reference to a child view object and includes the attributes that the child resource exposes. For example, the employee's department name or manager name.
- The view link must be based on an association.
- The association attributes for the other side are primary keys.
- The association does not have any custom where clauses.
- The view object for the other side does not have any custom where clauses or applied database-only view criteria.

How to Add and Remove Resources Based on the Same View Instance

In JDeveloper, you can use the overview editor for REST resources to define multiple resources for the same view instance. You might add a resource when a single resource definition does not support all of the use cases of your service client. After you add a resource you will be able to modify the operations, list of attributes, and other items of the resource structure to support the desired use cases. Because each resource you define represents a unique resource collection to the service client, resource names should reflect the differences.

The overview editor for REST resources displays the list of resources you add in the **Resource** dropdown. For example, Figure 16-7 shows the `Employees` resource and the `EmployeesAllAttrs` resource in the overview editor for the same backing view object `EmployeesView`.

Figure 16-7 Resource List Supports Multiple Resource in the REST Resource Definition



AppModule_EmployeesViewResources.xml

REST Resources

Release Version: 11.0

Resources can expose accessors, attributes and map custom actions.

Application Module: AppModule View Object: EmployeesView

Resource: HREmployees

Discriminator Name: Value:

Available Operations

□ Create ☑ Delete ☑ Update

> **Note:**
>
> JDeveloper lets you remove resource definitions that have been added in the overview editor for REST resources. However, the empty definition file will appear in the Applications window.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete this task:

- Create the REST resource for which you want to add or remove a resource, as described in Creating ADF REST Resources Using the Application Module.

To add and remove resources in the overview editor:

1. In the Applications window, double-click the resource definition file that defines the ADF REST resource for which you want to add or remove resources.
2. In the overview editor for the REST resource, choose the resource from the **Resource** dropdown and then click **Delete Resource** to delete a resource that has already been defined for the view object.

If you delete the root resource definition using **Delete Resource**, the resource is deleted, but the empty definition file will appear in the Applications window.

3. In the overview editor for the REST resource, to add a resource that you will create for the view object, click **Add Resource**.
4. In the Add Resource for View Object dialog, enter the **Resource Name** of the REST resource collection that you want to add for the selected root view instance and then click **OK**.
5. In the overview editor for the REST resource, select the new resource from the **Resource** dropdown to edit its resource definition:
   a. Add and remove child resources defined by view link accessors. For details, see How to Edit the ADF REST Resource Definition.
   b. Add and remove attributes. For details, see How to Hide and Expose Attributes in the ADF REST Resource.
   c. Modify access to standard operations defined by HTTP methods, canonical links, row finder filters, and subtype view usages. For details, see Customizing the ADF REST Resource Representation and Methods.

How to Hide a Resource from the Catalog Describe

You can hide a top-level resource from the ADF REST catalog describe by setting the `Visibility` attribute within the `ServiceConfiguration` tag in the resource definition as shown in the following code example.

```
<tree..>
  <ServiceConfiguration Visibility="unlisted"/>
   ...
</tree>
```

You can set the `Visibility` attribute to `unlisted` or `public`. You can use the `include` query parameter to include the description of resources of a certain visibility. For more information, see Retrieving the Catalog Describe Based on Resource Visibility Declaration.

How to Rename the ADF REST Resource

During development of ADF REST resources you may use the overview editor for REST resources to change the name of a resource in the resource definition file. Because service clients use the resource names to interact with the desired REST resource collections, it is important that you finalize the names of ADF REST resources before deploying the service to a production environment.

When you need to change the name of an ADF REST resource *after* deployment, this is best handled by creating an entirely new version of the resource, as described How to Version the ADF REST Resource.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete this task:

- Create the REST resource, as described in Creating ADF REST Resources Using the Application Module.

To rename a resource before production deployment:

1. In the Applications window, double-click the resource definition file that defines the ADF REST resource you want to rename.
2. In the overview editor for the REST resource, choose the desired resource from the **Resource** dropdown.

   If you have not created additional resources on the resource definition file, the list displays the original resource created for the backing view object.
3. Click the **Representation** tab of the overview editor and enter the new name in the **Resource Name** field.

What You May Need to Know About Naming ADF REST Resources

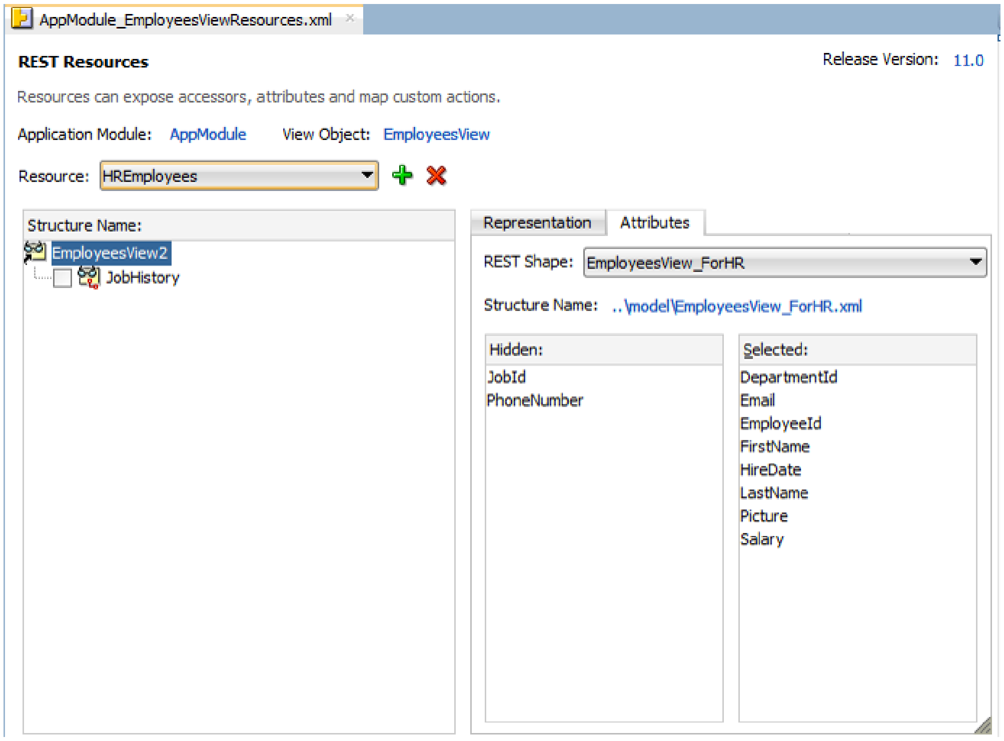
The REST resource name is the way service clients identify and interact with exposed resource collections. REST resource names typically identify the view object the consuming client is to access. As such, REST resource names are nouns, not verbs.

How to Hide and Expose Attributes in the ADF REST Resource

In JDeveloper, you can use the overview editor for REST resources to define multiple resources for the same view instance. You might add a resource when a single resource definition does not support all of the use cases of your service client. After you add a resource, you can modify the list of exposed attributes, and other items of the resource structure, as needed to support the desired use cases.

The overview editor for REST resources displays the list of exposed attributes in the **Attributes** tab. The list is populated by a REST service shape selection that you define on the view object backing the root resource. For example, Figure 16-8 shows the service shape definition `EmployeesView_ForHR` that exposes all but two of the attributes for the `EmployeesView` view object.

Figure 16-8 Attributes Exposed By REST Service Shape Definition Selection



AppModule_EmployeesViewResources.xml

REST Resources

Release Version: 11.0

Resources can expose accessors, attributes and map custom actions.

Application Module: AppModule View Object: EmployeesView

Resource: HREmployees

Structure Name:

- EmployeesView2
  - □ JobHistory

Representation | Attributes

REST Shape: EmployeesView_ForHR

Structure Name: ..\model\EmployeesView_ForHR.xml

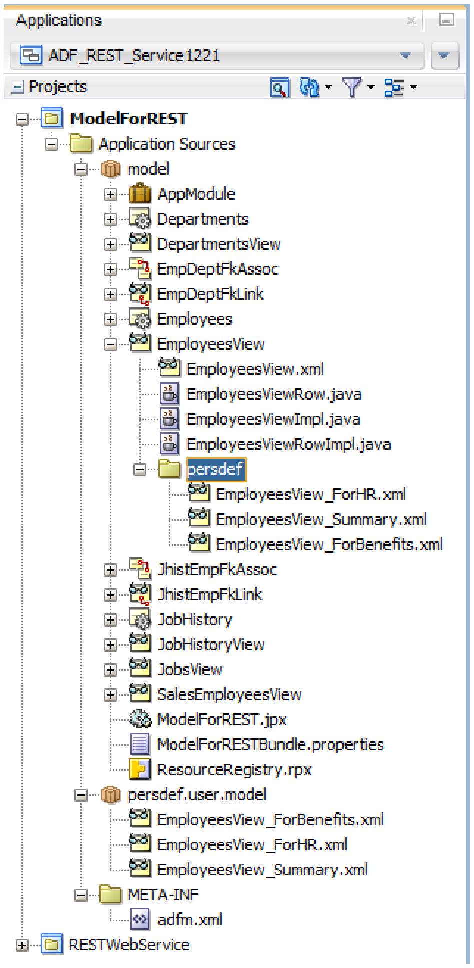
Hidden:	Selected:
JobId	DepartmentId
PhoneNumber	Email
	EmployeeId
	FirstName
	HireDate
	LastName
	Picture
	Salary

Note:

You do not directly modify the list of exposed attributes in the overview editor for REST resources. Rather, you must create service shape definitions on the backing view object, and you then apply the desired **REST Shape** definition to the current **Resource** dropdown selection.

To support the use cases of service clients, you can define as many service shape definitions for each view object as required. The Applications window displays service shape definitions that you create for the view object in the **persdef** folder under the view object node. For example, Figure 16-9 shows two service shape definition files **EmployeesView_forHR.xml** and **EmployeesView_ForBenefits.xml** beneath the **EmployeesView** view object.

Figure 16-9 REST Service Shape Definition Files in the Applications Window



Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete this task:

- Create the REST resource, as described in Creating ADF REST Resources Using the Application Module.

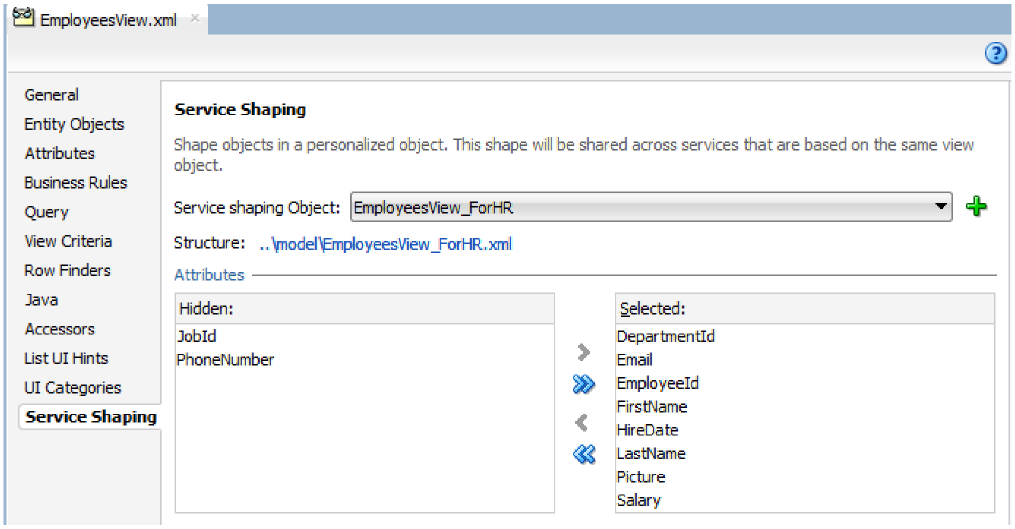
To apply a REST service shape definition to a REST resource:

1. In the Applications window, double-click the resource definition file that defines the ADF REST resource you want to edit.
2. In the overview editor for the REST resource, click the **View Object** link.
3. In the overview editor for the view object, click the **Service Shape** navigation tab.

4. In the Service Shaping page, click the **Create Service Shaping Object** button and then in the Create Service Shape dialog, enter a suffix name to uniquely identify the service shape definition.

   The suffix you enter forms the name of the service shape definition file. For example, the suffix `ForHR` is added to the view object `EmployeesView` to form the service shape definition name `EmployeesView_ForHR`, as shown in Figure 16-10.

Figure 16-10 View Object Service Shape Definition Defines Available Attributes



EmployeesView.xml

Service Shaping

Shape objects in a personalized object. This shape will be shared across services that are based on the same view object.

Service shaping Object: EmployeesView_ForHR

Structure: ..\model\EmployeesView_ForHR.xml

Attributes

Hidden:	Selected:
JobId	DepartmentId
PhoneNumber	Email
	EmployeeId
	FirstName
	HireDate
	LastName
	Picture
	Salary

5. In the Service Shaping page, use the shuttle buttons to alter the list of **Hidden** and **Selected** attributes and save the view object definition.

   When you alter the service shape in the overview editor for REST resources, JDeveloper updates the service shape definition file for the view object. The resource structure of any ADF REST resource that references the service shape will be updated as well.

6. In the overview editor for the REST resource, select the desired resource from the **Resource** dropdown.

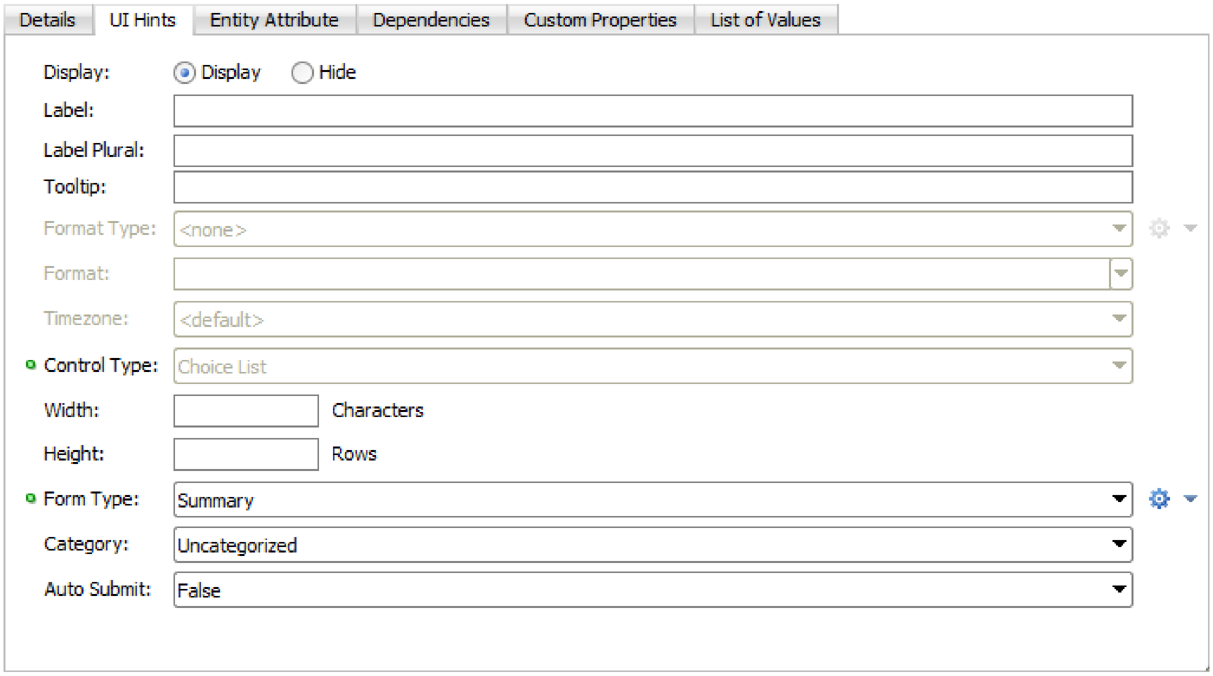
7. Click the **Attributes** tab of the overview editor, and then select the **Service Shaping Object** that defines the list of attributes that you want to expose.

What You May Need to Know About ADF REST Attribute Hints

In JDeveloper, you can use the overview editor to set ADF REST attribute hints.

Setting the attribute hints effects the REST service describe payload. They appear as attribute properties in the `json` payload.

Figure 16-11   UI Hints Editor



Display: ● Display ○ Hide

Label:

Label Plural:

Tooltip:

Format Type: <none>

Format:

Timezone: <default>

Control Type: Choice List

Width: Characters

Height: Rows

Form Type: Summary

Category: Uncategorized

Auto Submit: False

As Figure 16-11 shows, in the overview editor for the view object, you can set UI Hints for the attributes. If you set the `Form Type` property to `Summary`, the `includeInCompactView=true` hint will be surfaced on the attribute. After you have set the `From Type` hint for the attribute, it will suggest as a hint to metadata driven UIs to include the attribute in a compact view.

How to Control the ADF REST Response Payload Fields

The fields returned in a response payload for a GET request are limited by using the `?fields` URL parameter. If you do not specify the `?fields` URL parameter, it might result in a response of larger size. You can control the fields that are returned in the response payload by setting the `Form Type` hint of an attribute either to `Detail` or `Summary`. The default value is `Detail`.

When you set the `Form Type` hint of an attribute to `Summary`, the `includeInCompactView=true` hint will be surfaced on the attribute. See What You May Need to Know About ADF REST Attribute Hints.

You can use the `prefer` HTTP header either to return all the fields in the response payload or only the most common fields by using one of the following `return` options:

- **minimal**: returns only a minimal response to a successful request. This option returns only those attributes in the payload for which `includeInCompactView=true` is set. The minimal response is at the discretion of the server.
- **representation**: returns the current state of the resources in the response to a successful request. This option returns all the fields irrespective of the attributes set. A POST or PATCH request with `return=representation` will return all fields.

```
Content-Type: application/vnd.oracle.adf.resourceitem+json
Prefer: return=representation/minimal
```

What You May Need to Know About Response Payload When a Shape is Defined on a Resource

When you define a compact shape to a REST resource and do not specify `?fields` in the URL, then only those attributes for which the `Form Type` hint is set to `Summary` are returned in the payload.

For example, if you define a REST service shape on a root or child resource, only the fields that support `Form Type=summary` in the REST service shape are returned when you do not specify the `?fields` parameter.

The response payload for a REST resource is controlled at the resource level only if a resource has the `EnableCompactview=view` configuration property set.

```
<tree IterBinding="EmpIter" id="employees" AccessorFolder="Always">
    <ServiceConfiguration EnableCompactView="true"/>
<nodeDefinition .../>
</tree>
```

A REST client can expand or contract the default set of fields by using the + and - operators in the fields parameter.

The following example returns the PhoneNumber field in the response in addition to all fields in the default shape.

```
/employees?fields=+PhoneNumber
```

The following example returns all the fields in the default shape in response, except the email field.

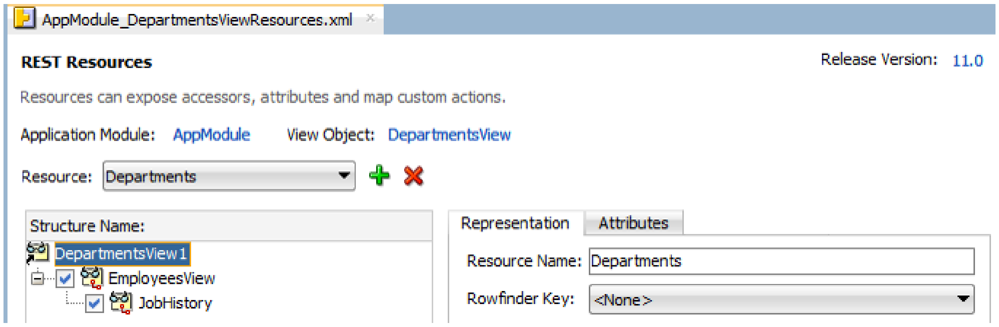
```
/employees?fields=-Email
```

Use the `Prefer` REST HTTP header to toggle between full set of fields and the default set. See How to Control the ADF REST Response Payload Fields.

What You May Need to Know About Modifying the ADF REST Resource Structure

As shown in Figure 16-12, after you create the resource and assign a version identifier, the overview editor for the REST resource displays the version in the top, right corner of the editor to help you identify which version you are editing.

Figure 16-12   REST Resource Editor Displays Version



Release Version: 11.0

Resources can expose accessors, attributes and map custom actions.

Application Module: AppModule   View Object: DepartmentsView

Resource: Departments

Resource Name: Departments

Rowfinder Key: <None>

Changes that you make to ADF REST resources during the development cycle can be made without the need to version the resource. However, once you have deployed the RESTful web service, service clients that access the ADF REST resources rely on the stability of the resource collection to satisfy their use cases.

Over time, as use cases change or the backing view objects of the REST resources change, you may need to modify the resource structure of already deployed resources. At that time, modifications to existing ADF REST resources may become backward-incompatible with the deployed REST service and may necessitate creating a new version identifier and ADF REST resource for that version. For details about when to version the REST resource, see What You May Need to Know About Versioning ADF REST Resources.

JDeveloper lets you manage resource versions in the Release Versions page of the overview editor for the `adf-config.xml` file in the ADF META-INF folder. For details about how to create a new version of ADF REST resources, see Versioning the ADF REST Resource.

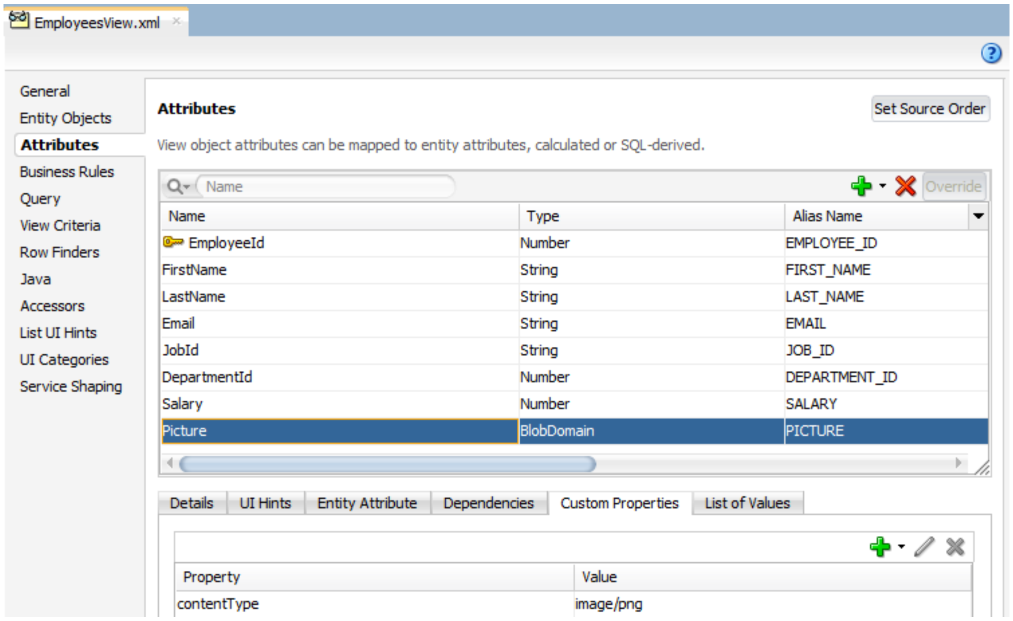
What You May Need to Know About ADF REST Resources and LOB Attributes

A resource that exposes a BLOB or CLOB type attribute will be accessible at runtime as streaming media. By default, the view object attribute will be handled by the ADF REST runtime using the generic content type `application/octet-stream`. When you want to support a specific content type, you can configure the special property `contentType` as a custom property of the LOB-type attribute. For example, when working with PNG image files, the following content type can be configured at design time.

- **Custom Property**: `contentType`
- **Value**: `image/png`

As Figure 16-13 shows, the custom property `contentType` has been added to the view object definition for the `Picture` attribute in the overview editor for the view object.

Figure 16-13 Custom Content Type Configured for LOB Attributes



Attributes

View object attributes can be mapped to entity attributes, calculated or SQL-derived.

Name	Type	Alias Name
EmployeeId	Number	EMPLOYEE_ID
FirstName	String	FIRST_NAME
LastName	String	LAST_NAME
Email	String	EMAIL
JobId	String	JOB_ID
DepartmentId	Number	DEPARTMENT_ID
Salary	Number	SALARY
Picture	BlobDomain	PICTURE

Property	Value
contentType	image/png

As Figure 16-14 shows, in the overview editor for the view object, you can set UI Hints for the attributes. If you set the **Form Type** hint to `Summary`, the `includeInCompactView=true` hint will be surfaced on the attribute. After you have set the **Form Type** hint for the attribute, it will suggest as a hint to metadata driven UIs to include the attribute in a compact view.

What You May Need to Know About LOV Accessors in the ADF REST Resource

A list of value (LOV) attribute is any attribute of a view object that relies on another view object as its data source. Typically, the data source view object specifies a fixed list of possible values for the LOV-enabled attribute. When you explicitly define an LOV-enabled attribute on a view object, ADF Business Components defines an LOV view accessor that the ADF REST runtime will automatically expose in the ADF REST resource as a LOV child resource. Thus, at runtime when an LOV-enable attribute is detected on a resource, service clients may invoke LOV view accessors to obtain the data source of an LOV-enabled attribute and present selection choices to the end user.

Note that the LOV attribute must not rely on an LOV view accessor that references an entity object attribute. Only LOV view accessors based on a view object attribute will be visible to the REST service. At runtime, ADF REST knows nothing about attributes and links defined at the level of entity objects and will return an HTTP error code 500 when the resource contains an LOV attribute defined by an LOV view accessor that references an entity object attribute.

> **Note:**
>
> By default, LOV accessor resources are exposed on resources and are not displayed in the structure tree of the resource overview editor. For details about creating LOV-enabled attributes, see Working with List of Values (LOV) in View Object Attributes.

What You May Need to Know About Mandatory Attributes in the ADF REST Resource

A mandatory attribute is any attribute of a view object that must be supplied in a query and if not supplied, will trigger a validation error at runtime. The ADF REST resource describe identifies whether or not an attribute is mandatory using the property `“mandatory”: true` or `“mandatory”:false`. The mandatory property of the resource describe is based on the view object attribute metadata specified at design time. When the attribute is set as mandatory and the setting is determined at runtime, using a Groovy expression to evaluate to `true` or `false`, then the describe will return `“isMandatoryConditional”:true` in the attribute properties list.

What You May Need to Know About Case Sensitivity in Resource Collection Query Operations

The ADF REST framework supports case insensitive search when using a `q` query parameter to filter search results. The flag named `restV1QueryCaseSensitive` in the `adf-config.xml` file can be set to `false` if you want to perform case insensitive search. The default value of the flag is `true` which implies case sensitive search.

Customizing the ADF REST Resource Representation

JDeveloper allows you to edit the ADF REST resource definition. You can enable HTTP actions, expose a row finder, enable a canonical resource link for nodes of the tree, expose subtype view objects in the resource, and configure the resource cache duration.

You use the overview editor for the ADF REST resource to edit the ADF REST resource definition. For example, selections that you make in the resource structure tree let you enable HTTP actions, expose a row finder, and enable a canonical resource link for each node of the tree.

The customization choices that you make for REST resources in your ADF Model project ultimately affect the ability of service clients to interact with these resources at runtime. Therefore it is important to understand the requirements of the service client use cases to support the desired ADF REST runtime features though the various design time customizations described in this section.

For details about the ADF REST runtime, see Consuming ADF RESTful Web Services.

> **Note:**
>
> Custom properties defined for a resource attribute are included in the describe. However, custom properties whose name begins with `INTERNAL`, `internal`, or __ (double underscore), are hidden from the describe.

How to Expose Canonical Resources in the ADF REST Resource

The ADF REST resource representation limits the attributes returned in a runtime response to the attributes queried by the resource's backing view object. When defining the view object query at design time, it is therefore important to expose only the attributes required to support specific use cases of the service client. However, in order to allow the service client to navigate from the partial REST resource representation to the full representation of the same data, you can configure a link to a canonical resource.

Typically, the canonical resource is considered as the source of truth and therefore specifies the full representation of a given data source. An example of a canonical resource, can be illustrated by the `employees` resource with a link to a resource that describes a `manager` instance. In this scenario, where typical use cases may require only the manager name, the non-canonical `manager` resource includes only the name attribute. And, for cases where the name is not sufficient to identify the manager, the non-canonical resource may link to a canonical resource that exposes all attributes of the `manager` instance, including name, id, department, hire date, and so on. Thus, the canonical resource and the non-canonical resource exist as follows:

- Non-canonical resources and the canonical resource expose different representations of the same data source.
- Non-canonical resources expose only a representation of the data source needed to support service client use cases and are therefore a partial representation.

- Non-canonical resources include a link to its canonical, full representation when defined.

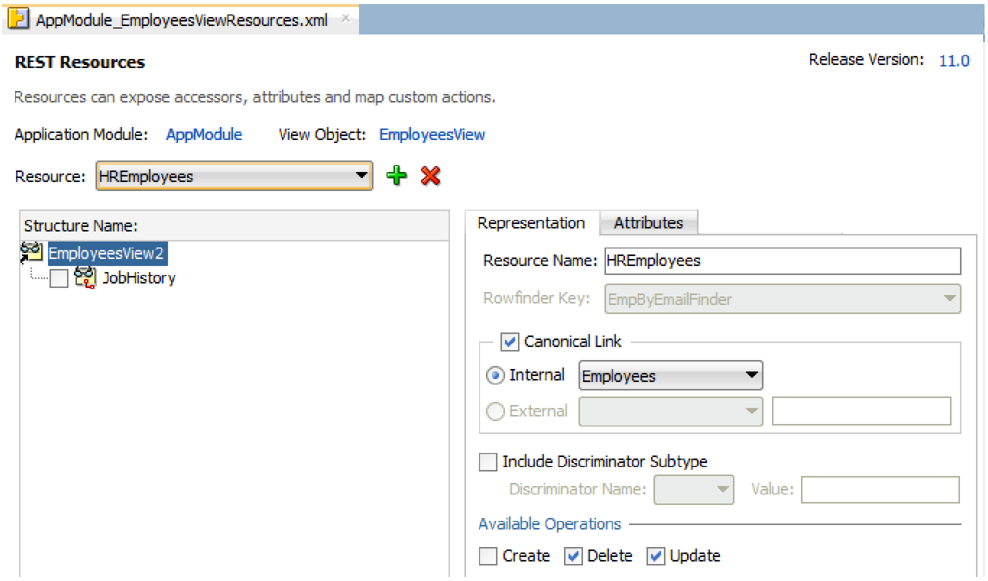
In the overview editor for the resource, for each resource node in the resource structure tree, you may choose a canonical resource from an existing REST resource defined by the ADF Model project or you may choose an external resource defined by an existing URL connection in the `connections.xml` file of the application.

The internal canonical resource that you can select in the overview editor for REST resources, must meet the following criteria:

1. Your ADF Model project must define a view object that accesses the same data source backing the existing, partial representation resource. The view object may or may not be entity-based.
2. The view object must query a superset of available attributes queried by the non-canonical resources.
3. The superset representation view object must be specified as a view instance on the data model of the application module.

Figure 16-15 shows the `EmployeesView` root resource node selection in the overview editor and the Resource dropdown selection `HREmployees`, with the internal canonical resource `Employees` enabled. In this case, the database table specified by each backing view object is the same for both the `HREmployees` and the `Employees` resource. In this example, `Employees` is the canonical resource and contains all attributes from the backing view object whereas the `HREmployees` resource is backed by the same view object but queries only the attributes required to support a specific use case.

Figure 16-15 Canonical Resource Enabled in the Overview Editor



AppModule_EmployeesViewResources.xml

REST Resources

Release Version: 11.0

Resources can expose accessors, attributes and map custom actions.

☑ Canonical Link
● Internal Employees
○ External

□ Include Discriminator Subtype
Discriminator Name: Value:

Available Operations
□ Create ☑ Delete ☑ Update

> **Note:**
>
> A resource (resource_partial) can only select another resource as canonical (resource_full) as long as the resource_full contains all the attributes that resource_partial exposes.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete these tasks:

- Create the desired REST resource, as described in Creating ADF REST Resources Using the Application Module.
- When you want the REST resource's canonical link to expose an internal canonical resource, create a view object definition that queries the superset of available attributes from the data source (must be the same data source as the non-canonical REST resource) and expose that view object in the data model, then create a resource for the internal canonical resource. For details about creating a resource, see How to Create ADF REST Resources from View Object Instances.
- When you want the REST resource's canonical link to expose an external canonical resource, create a URL connection in the application connection file (`connections.xml`), as described in the “Create URL Connection Dialog” topic in the JDeveloper Online Help.

To expose a canonical resource link:

1. In the Applications window, double-click the resource definition file that defines the ADF REST resource you want to edit.
2. In the overview editor for the REST resource, choose the desired resource from the **Resource** dropdown, expand the **Structure** tree and select the node for which you want to define a canonical resource link.

   You can define a canonical link for each resource node in the resource tree. For more information about **Structure** nodes, see Table 16-1.
3. With the resource node selected in the **Structure** tree, click the **Representation** tab of the overview editor, and then select **Canonical Link**.

   If you do not want to expose a canonical resource for the current resource accessor node selection, deselect **Canonical Link**.
4. In the **Canonical Link** section, select whether the canonical resource is **Internal** or **External** and choose the desired resource from the dropdown list to represent the canonical version of the resource.

The dropdown list for internal resources is populated by the resources that you added to the current resource; these are resources that are internal to the application and must be based on the same data source as the current resource.

The dropdown list for external resources is populated by URL connections that you have defined for the application and registered in the application connection file (`connections.xml`).

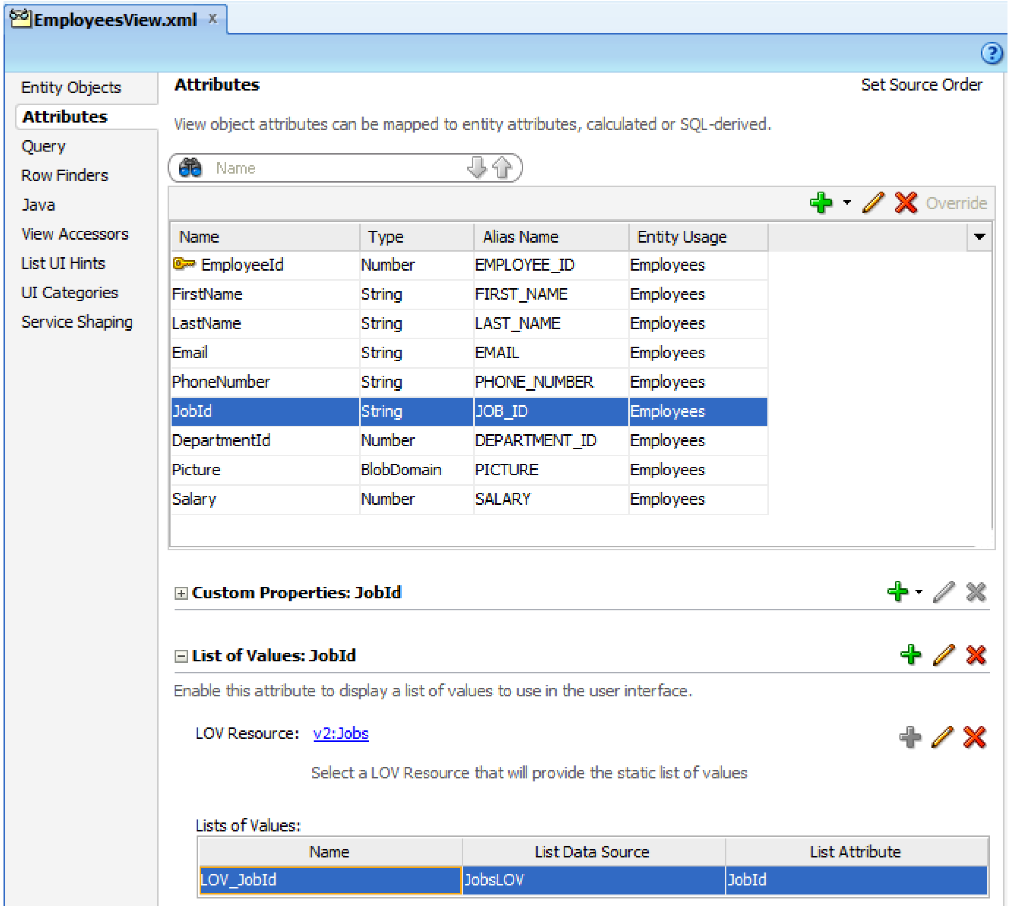
How to Support Create Operations on ADF REST Resources with LOV Attributes

When you want the ADF REST resource to support resource operations that require a list of values (LOV) without a row context to populate the list, you must create a LOV resource. For example, a service client may invoke a resource item create operation on the REST resource, in which case no row context will be available for the LOV list. In this situation, the LOV resource does not exist as a child resource and must instead be accessed at runtime by the service client independent from resource items that they attempt to create.

> **Note:**
>
> No design time changes are required to support resources with LOV-enabled attributes when the service client needs to access *existing* resource items. It is only necessary to create an LOV resource at design time when you want to enable service clients to create new resource items and the resource item is backed by an LOV-enabled attribute. In the case of existing resource items, the resource item provides a row context within the resource collection that allows the ADF REST runtime to automatically generate LOV links as a child resource. For more information about LOV child resources, see What You May Need to Know About LOV Accessors in the ADF REST Resource.

In JDeveloper, you use the overview editor for view objects to create LOV definitions for individual attributes in the Attributes page of the editor. The same page is used to define the static LOV resource. For example, Figure 16-16 shows the `EmployeesView` view object and the LOV-enabled attribute `JobId` in the overview editor for the view object backing the `Employees` resource. The static LOV resource is identified by the specific ADF REST resource that it supports: in this case, `v2` (the internal version identifier of the `Jobs` resource). Below the static LOV resource is the LOV definition used by the LOV-enabled attribute of the view object.

Figure 16-16 Static LOV Resource Supports Create Operations on the REST Resource



Attributes

View object attributes can be mapped to entity attributes, calculated or SQL-derived.

Name	Type	Alias Name	Entity Usage
EmployeeId	Number	EMPLOYEE_ID	Employees
FirstName	String	FIRST_NAME	Employees
LastName	String	LAST_NAME	Employees
Email	String	EMAIL	Employees
PhoneNumber	String	PHONE_NUMBER	Employees
JobId	String	JOB_ID	Employees
DepartmentId	Number	DEPARTMENT_ID	Employees
Picture	BlobDomain	PICTURE	Employees
Salary	Number	SALARY	Employees

⊞ Custom Properties: JobId

⊟ List of Values: JobId

Enable this attribute to display a list of values to use in the user interface.

LOV Resource: v2:Jobs

Select a LOV Resource that will provide the static list of values

Lists of Values:

Name	List Data Source	List Attribute
LOV_JobId	JobsLOV	JobId

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete this task:

- Enable an LOV for the attribute of the view object, as described in Creating ADF REST Resources Using the Application Module.
- Create the REST resource for the view object with the LOV-enabled attribute for which you want to expose a create operation, as described in Creating ADF REST Resources Using the Application Module.

> **Caution:**
>
> When the view object defines an LOV resource, the view object service shape definition must not hide attributes that are required by the LOV-enabled attribute's LOV definition. Required LOV attributes include attributes mapped to the LOV data source, as well as LOV display attributes. For more information about service shaping and ADF REST resources, see How to Hide and Expose Attributes in the ADF REST Resource.

To define a static LOV resource for use with ADF REST resources:

1. In the Applications window, double-click the resource definition file that defines the ADF REST resource you want to edit.
2. In the overview editor for the REST resource, click the **View Object** link.
3. In the overview editor for the view object, click the **Attributes** navigation tab.
4. In the Attributes page, expand the LOV section and click the **Create LOV Resource on Attribute** button.
5. In the Create LOV Resource dialog, select the **Release Version** identifier, select the **Resource Name** for the ADF REST resource that exposes the LOV-enabled attribute, and then select the defining resource from the resource structure tree.

   The **Resource Name** list is populated by the ADF REST resource definitions in the Model project. The REST resource you select must have the same view object definition as the view object that defines the LOV attributes data source. For example, when creating an `Employees` resource, the `EmployeesView` view object defines an LOV attribute `JobsId`. In the Create LOV Resource editor, you would select the ADF REST resource `Jobs` and the root resource `JobsView1` from the `Jobs` resources resource structure tree, as shown in Figure 16-17.

6. Click **OK** to save the LOV resource definition.

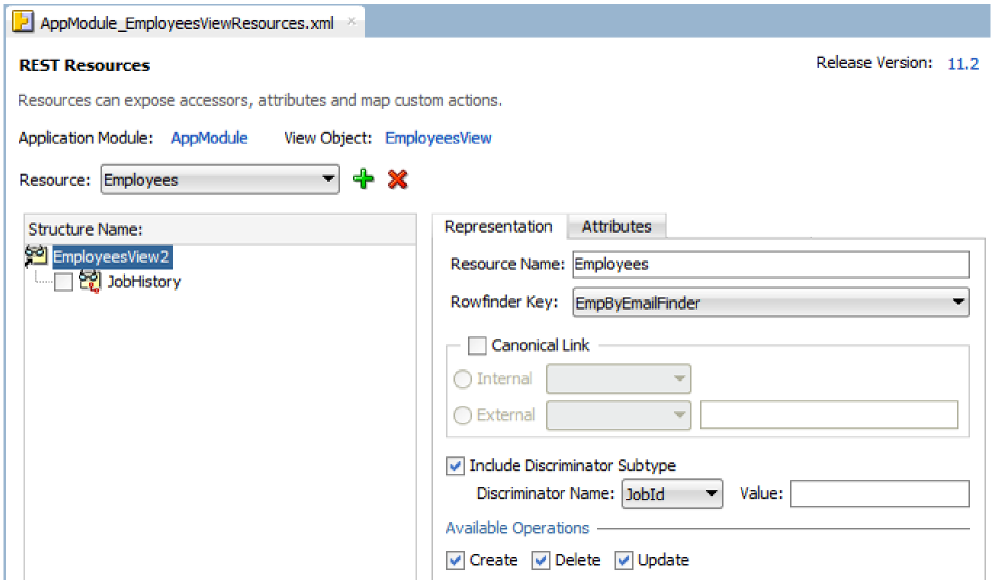
How to Enable Row Finder Keys in the ADF REST Resource

When you do not want service clients to be able to query resources using the primary key for the resource (often a numeric value), the business components developer can create a row finder that specifies a row finder key based on a view object attribute with values that can be uniquely identified by name. One such example may find employees by the first letters of the email attribute.

When a row finder has been explicitly defined on the view object named in the ADF REST resource, the overview editor for the ADF REST resource gives you the option to enable the row finder to filter the resource collection. Row finders are not enabled by default; you must the select the row finder key by name to apply it the current node selection in the resource structure.

In JDeveloper, the overview editor for ADF REST resources displays the list of available row finders in the **Rowfinder Key** dropdown. The list is populated by the row finders that have been defined on the view object definition backing the node selection in the resource structure tree. For example, Figure 16-18 shows the `EmpByEmailFinder` row finder key where `Employees` is the node defining the view instance with the row finder `EmpByEmailFinder`.

Figure 16-18 Row Finder Key Enabled on the Root of the ADF REST Resource



AppModule_EmployeesViewResources.xml

REST Resources

Release Version: 11.2

Resources can expose accessors, attributes and map custom actions.

□ Canonical Link
- ○ Internal
- ○ External

☑ Include Discriminator Subtype

Discriminator Name: JobId Value:

Available Operations

☑ Create ☑ Delete ☑ Update

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete these tasks:

- Create the desired REST resource, as described in Creating ADF REST Resources Using the Application Module.
- Create the application module data model that contains the view object instances that you want the REST resource to expose, as described in How to Create an Application Module.
- Create the row finders on the view instances that you want the REST resource to expose, as described in Working with Row Finders.

To expose row finder filters:

1. In the Applications window, double-click the resource definition file that defines the ADF REST resource you want to edit.
2. In the overview editor for the REST resource, choose the desired resource from the **Resource** dropdown, expand the **Structure** tree and select the resource node for which you want to expose a row finder.

   If the data model does not define a master-detail hierarchy for the backing view instance of the root resource, then no view link accessor node will appear in the **Structure** tree. For more information about **Structure** nodes, see Table 16-1.

3. Click the **Representation** tab of the overview editor, and then, in the **Rowfinder key**, select the row finder on the current **Structure** tree selection.

   The **Rowfinder key** dropdown may appear disabled if the resource enables a canonical link and the canonical resource itself enables a row finder key. The overview editor for ADF REST resources will disable the row finder key field and automatically reflect the row finder key on the partial resource, as described in What You May Need to Know About Row Finders in ADF REST Resource Requests.

4. Optionally, click **Canonical Link** when you want the row finder selection to filter the canonical resource representing the current node selection.

   If you enable a canonical link, you must also select an internal or external source for the canonical resource.

5. Select another node in the **Structure** tree to expose another row finder.

What You May Need to Know About Configuring LOV Resources for Row Finders

When you want service clients to be able to query resources using a LOV resource, the business components developer can create a finder that specifies a finder key based on a view object attribute with a finder value that can be uniquely identified by name. A link between a regular resource and an LOV resource is configured using the resource description. You must configure a resource that has the LOV definition in order to use the LOV resource. Nested resources are exposed in an order to represent some cascading LOVs that follow a tree structure.

For example, consider there are LOVs for `State` and `City` named `LOV_City` and `LOV_State`. `LOV_City` filters the value that is already selected in `State`. Let us assume there is a resource named `Cities` that has all possible cities in the countries grouped by `State`. The `LOV_City` must filter the Cities resource with a State value already selected. For that you need to define a `Cities` view object with a finder with the value `ByStateFinder` that accepts a parameter `State`. The LOV URL would be `/Cities?finder=ByStateFinder;stateVar={State}`, where State points to the `State` attribute in the address object that has the master LOV.

The following view object definition shows the metadata for the view object that provides the LOV source for the cities and states example.

```
<ViewAttribute
  Name="City"
  IsNotNull="true"
  PrecisionRule="true"
  EntityAttrName="CityName"
  EntityUsage="Address"
  AliasName="CITYNAME"
  LOVName="LOV_City">
  <Properties>
    <SchemaBasedProperties>
      <LOVResource name="Cities" finder="ByStateFinder"/>
    </SchemaBasedProperties>
  </Properties>
</ViewAttribute>
<ViewAttribute
```

```
  Name="State"
  IsNotNull="true"
  PrecisionRule="true"
  EntityAttrName="StateCode"
  EntityUsage="Address"
  AliasName="STATECODE"
  LOVName="LOV_State">
  <Properties>
    <SchemaBasedProperties>
      <LOVResource name="States"/>
    </SchemaBasedProperties>
  </Properties>
</ViewAttribute>
```

In the above example, the cascading LOV is being handled by the LOV with a finder class.

Note that the custom property `LOVResource` identifies the source of that the LOV resource uses for its data. The property name `LOVResource` is specific to ADF REST framework version 5 and later and serves to distinguish the parametrized row finder URL usage to obtain the LOV list from the usage associated with earlier framework versions, where the LOV list URL does not use a row finder. The view object metadata for the LOV source attribute identifies framework versions 1 though 4 by using the property name `ResourceLOV`.

The resource describe associated for these two usages also differs. Compare the static LOV resource associated with the regular view object-backed resource with framework version 5 enabled (attribute metadata property identified as `LOVResource`) to the same resource describe with framework version 4 enabled (attribute metadata property identified as `ResourceLOV`).

Here is the describe with version 5 enabled. The `LOVResource` is added to the `lov` element section of the regular resource (`Address`) and the `childRefForCreate` property identifies the URL name that appears in the `item - links` element section .

```
{
  "Resources" : {
    "Address" : {
      "discrColumnType" : false,
      "attributes" : [ {

          "name" : "Cities",
          "kind" : "collection"
        }, {
...
```

What You May Need to Know About Row Finders in ADF REST Resource Requests

At runtime, an ADF REST resource with a row finder key enabled must be accessed in the service client by the row finder key attribute. The row finder supports returning a collection or instance for the row finder-enabled resource using only the row finder key attribute. Thus, service clients may access REST resources without requiring knowledge of database primary key values to end users. For example, compare these two GET requests to retrieve a specific employee in the Employees resource collection:

No row finder:

```
http://localhost:7101/RESTSample_App/rest/11.1/Employees/101
```

With row finder

```
http://localhost:7101/RESTSample_App/rest/11.1/Employees/NSMITH
```

The first URL, with no row finder key defined, requires the ID of the employee to locate the employee resource item. The second URL uses the row finder key value (employee's email address) in the resource path. Once the row finder key has been enabled on the resource at design time, service clients may access the resource by row finder key values using links generated in the request payload by the ADF REST runtime.

You can optionally apply the row finder to a canonical resource that your ADF REST resource defines. If a canonical resource with row finder key is defined on the ADF REST resource with a row finder key enabled, then both sides must be defined by the same key structure. The key attributes must be of the same type and in the same sequence. When you create a canonical resource with a row finder key and then create a partial resource with a canonical link, the overview editor for ADF REST resources will disable the row finder key field and automatically reflect the row finder key on the partial resource. For details about canonical resources, see How to Expose Canonical Resources in the ADF REST Resource.

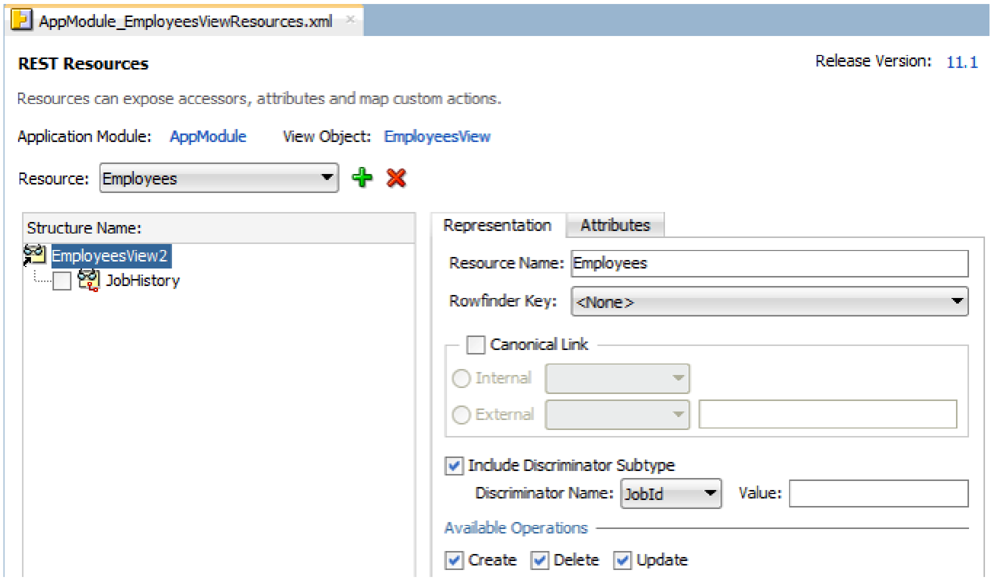
How to Expose Subtype View Objects in the ADF REST Resource

A subtype view object is a view object that extends a base view object in an inheritance hierarchy. The subtype view object inherits its list of attributes from the base view object and contributes its own attributes that are specific to the subtype. Such subtype view objects are called polymorphic view objects. At runtime, polymorphic view objects define subtype view rows comprised of attributes from the base view object and attributes from the defining subtype view object.

In order to query subtype view rows, the subtype view object must specify a discriminator attribute that determines the specific type. For example, an `EmployeesView` base view object with a discriminator attribute `JobId` may instantiate subtype view rows based on the available jobs (Accountant, Sale Representative, and so on), where the attributes of subtype view rows are determined by the specified job ID value. For example, a Sales Representative with the job ID `SA_REP` might contribute the subtype view row attribute `CommissionPct`, whereas the subtype view rows for the other job types would omit this attribute.

The overview editor for REST resources lets you expose subtype view objects for each node of the Structure tree when the view object backing the node defines a discriminator attribute. For example, Figure 16-7 shows the `Employees` resource and the `EmployeesView2` resource node selected in the overview editor. The backing view object `EmployeesView` defines the discriminator attribute `JobId` and the subtype view object `SalesEmployeeView` defines the subtype `SA_REP`. The editor exposes the `SalesEmployeesView` subtype view object by enabling **Include Discriminator Subtype**, specifying the **Discriminator Name** and omitting the discriminator attribute value. Omitting the `JobId` discriminator attribute value ensures that subtype attributes will be returned in service client requests for `Employees` based on the `JobId` value of the requested employee.

Figure 16-19 Defining a Discriminator Attribute in the REST Resource Definition



AppModule_EmployeesViewResources.xml

☑ Include Discriminator Subtype

Discriminator Name: JobId Value:

Available Operations

☑ Create ☑ Delete ☑ Update

> **Note:**
>
> Discriminator attributes are defined on the backing view object and support subtype view rows. Subtype view objects are not exposed in the design time as ADF REST resources. The subtype definition is specified on the application module and by the ADF REST runtime.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand how view objects support subtype view rows. For more information, see Working with Polymorphic View Rows.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete these tasks:

- Create the polymorphic view objects, as described in How to Create a View Object with Polymorphic View Rows.
- Create the REST resource for which you want to add or remove a resource, as described in Creating ADF REST Resources Using the Application Module.

To expose subtype view rows in the resource definition:

1. In the Applications window, double-click the resource definition file that defines the ADF REST resource you want to edit.
2. In the overview editor for the REST resource, choose the desired resource from the **Resource** dropdown, expand the **Structure** tree and select the resource node for which you want to expose a subtype view object.

   If the data model does not define a master-detail hierarchy for the backing view instance of the root resource, then no view link accessor node will appear in the **Structure** tree. For more information about **Structure** nodes, see Table 16-1.
3. Click the **Representation** tab of the overview editor, and then, select **Include Discriminator Subtype** to enable subtype view rows on the current **Structure** tree selection.
4. Select the subtype discriminator attribute from the **Discriminator Name** dropdown and omit the value that defines the desired subtype view rows when the subtype view object defines the subtype discriminator attribute value.

   The **Discriminator Name** dropdown is populated by the discriminator attribute definition of the backing view object. For example, an `EmployeesView` view object might define the discriminator attribute `JobId` attribute as the discriminator attribute with a subtype view object `SaleEmployeesView`. In most cases, the subtype view object will define the subtype discriminator attribute value, and you can leave the attribute value empty in the resource definition. For example, where the subtype view object `SalesEmployeesView` defines `SA_REP` (Sales Representative) as the `JobId` discriminator attribute value, a request made for the `Employees` resource will contain the subtype attributes based on the employee's job ID and not by the subtype defined by the resource. Defining the discriminator attribute subtype value in the resource forces the resource items to the same type.

How to Expose Standard HTTP Actions in the ADF REST Resource

Standard data manipulation operations that you expose on the ADF REST resource correspond to actions on the backing view instance of the resource. At runtime, the service client invokes these operations as HTTP actions on the RESTful web service.

Table 16-2 lists the standard operations that are exposed by default in the overview editor for the REST resource. You can expose a different set of operations by deselecting operations from the list for each resource selection you make in the resource tree. Note that the GET method is always exposed for a resource.

Table 16-2 Standard View Instance Data Manipulation Operations

Operation Selection	HTTP Method Name	Operation Description
Create	POST	Creates an ADF Business Components view row or view row set.
Create and **Update** (combined equals Upsert)	POST	Merges payload content with the REST resource using a POST method in combination with a header `Upsert-Mode` set to true. Creates the REST resource if the REST resource does not exist. Merges the payload content with the REST resource if this REST resource exists.

Table 16-2   (Cont.) Standard View Instance Data Manipulation Operations

Operation Selection	HTTP Method Name	Operation Description
Update	PATCH	Updates the specified items of an ADF Business Components view row. The view row must exist for this operation to succeed.
Delete	DELETE	Deletes an ADF Business Components view row or view row set.
not applicable	GET	Reads an ADF Business Components view row or view row set. Note that this operation is available by default when you create a resource.

> **Note:**
>
> Note that Oracle has deprecated the functionality for executing HTTP PUT methods on ADF REST resource requests. In the current release, the describe for ADF REST resources continues to display PUT actions when the backing view object has the Update operation enabled (the operation enables both PUT and PATCH methods); however, ADF REST service clients should avoid making PUT requests (replace all items of the view row) as this functionality will be desupported in a future release.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete this task:

- Create the desired REST resource, as described in Creating ADF REST Resources Using the Application Module.

To expose HTTP actions:

1. In the Applications window, double-click the resource definition file that defines the ADF REST resource you want to edit.
2. In overview editor for the REST resource, choose the desired resource from the **Resource** dropdown, expand the **Structure** tree and select the resource accessor node that you want to edit.

   You can expose operations for root resources and child resources. For more information about **Structure** nodes, see Table 16-1.

3. Click the **Representation** tab of the overview editor, and then, in the **Available Operations** section, select the operations to expose for the current **Structure** tree selection.
4. Select another node in the **Structure** tree to expose operations on another resource accessor in the resource structure.

What You May Need to Know About Optimizing ADF REST Resource Get Operations

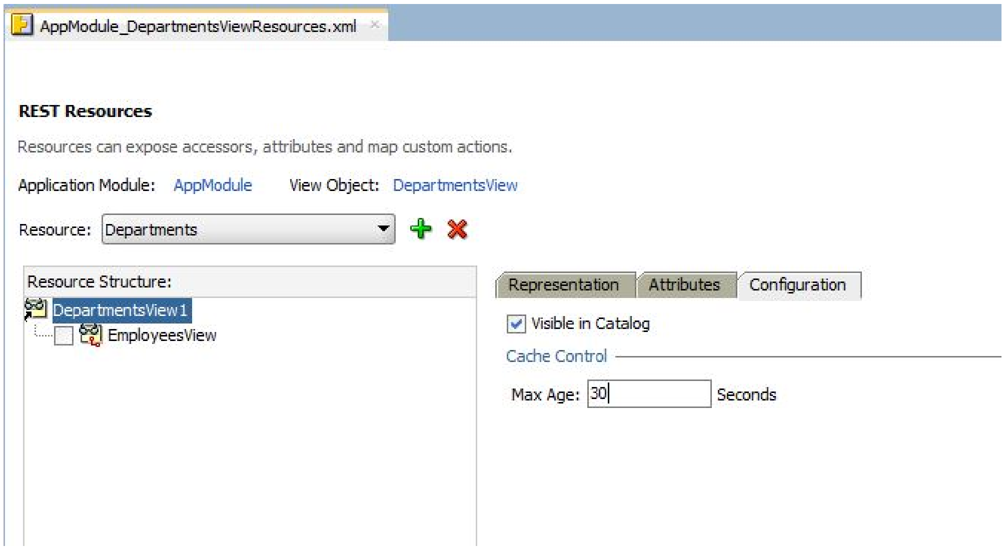
All ADF REST resources support read operations by service clients. To support efficient read operations (HTTP GET requests), the backing view object definition of ADF REST resources should define access mode set to support paging of the collection in an HTTP Request payload. For more information about range paging, see How to Enable Range Paging for a View Object.

How to Control Caching of ADF REST Resources

When you want fine control over the cache duration of ADF REST resource payload resulting from an ADF REST resource request, you can configure cache control in seconds on the root of the resource in the REST resource overview editor. At runtime, the cache setting can help to avoid intermediate proxies to cache/store the resource payload in the HTTP response.

In JDeveloper, the overview editor for REST resources displays the resource cache control setting in the **Configurations** tab for the root node of the resource. When this setting is made on the root resource, it overrides the application-level cache setting that may be configured in the `web.xml` file. For example, the following figure shows the cache maximum age set to 30 seconds on the root of the Departments resource. The option **Visible in Catalog** if selected enables the cache setting to appear in the describe for ADF REST resource requests.

Figure 16-20 Cache Maximum in Seconds Set on the Root of the REST Resource



AppModule_DepartmentsViewResources.xml

REST Resources

Resources can expose accessors, attributes and map custom actions.

Application Module: AppModule   View Object: DepartmentsView

Resource: Departments

Resource Structure:
- ☑ DepartmentsView1
  - □ EmployeesView

☑ Visible in Catalog

Cache Control

Max Age: 30 Seconds

From release 12.1.1.4.0, REST framework supports additional configuration options for `Cache-Control`. See Header Field Definitions - Cache Control. You can specify these additional configuration options in the source editor. When you specify one of the valid values, then that `Cache-Control` header will be added in the payload response.

The valid values are:

- **Cacheability**: indicates if a response can be cached or not. Valid values are: `public`, `private`, and `no-cache`.
  The value `public` cache indicates that the response can be cached by any cache irrespective of the cache status. This value is useful for requests that include an `authorization` header, because requests with authorization header prevents a shared cache from caching the response.

  The value `no-cache` does not mean not to cache the response, but instructs the browser to re-validate before returning the response.
- **NoStore**: indicates that the response should not be cached irrespective of the cacheability setting. It is a boolean flag with values `true` and `false`. When set to `true`, `no-store` is added to the `Cache-Control` header in the response, separated by comma if other settings are present.
- **Revalidation**: indicates that the response must be revalidated if a cache is configured to return a stale response. If you configure `MaxAge` to `0`, the response becomes stale immediately, thus forcing the cache to revalidate every time. Valid value is `must-revalidate`.

See, What You May Need to Know About the Cache-Control Header.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete this task:

- Create the REST resource for the view object, as described in Creating ADF REST Resources Using the Application Module.

To configure the cache control maximum age setting:

1. In the Applications window, double-click the resource definition file that defines the ADF REST resource you want to edit.
2. In the overview editor for the REST resource, choose the desired resource from the **Resource** dropdown and then, in the **Structure** tree, select the root resource node.

   For more information about **Structure** nodes, see Table 16-1.
3. Click the **Configuration** tab of the overview editor, and then, click **Visible in Catalog** when you want the describe to show the cache control setting. For **Max Age** enter the maximum age of the payload cache in seconds.

This tab is not displayed for child resource nodes that you select in the **Structure** tree.

What You May Need to Know About the Cache-Control Header

The following table lists few example use cases that REST framework supports with selected subset of options in any valid combination. The developer can choose any combination to generate the desired `Cache-Control` header in the response.

Cache-Control Value	Category	Explanation	Example

`<CacheControl>`
`<Cacheability>no-cache</Cacheability>`
`<NoStore>true</NoStore>`
`<Revalidation>must-revalidate</Revalidation>`
`</CacheControl>`
	Sensitive data	Response is not cached.	Bank account info

`<CacheControl>`
`<Cacheability>public</Cacheability>`
`<MaxAge>30</MaxAge>`
`</CacheControl>`
	Public shared data	Response can be cached by browser and any intermediary caches for up to the specified number of seconds.	LOV. For example country codes

`<CacheControl>`
`<Cacheability>private</Cacheability>`
`<MaxAge>30</MaxAge>`
`</CacheControl>`
	Private data	Response can be cached by the client's browser only for up to the specified number of seconds.	Order history

For example, the following service configuration is defined on `DeptAM_DeptVOResources.xml`:

```
<tree IterBinding="DeptIter" id="departments" AccessorFolder="Always">
  <ServiceConfiguration>
    <CacheControl>
      <Cacheability>private</Cacheability>
      <MaxAge>600</MaxAge>
    </CacheControl>
  </ServiceConfiguration>
  <nodeDefinition .../>
</tree>
```

Any requests against the departments resource have the following `Cache-Control` header:

REQUEST

```
GET http://example.com/demoApi/resources/1.0/departments
```

RESPONSE

```
200 OK
Cache-Control: private,
max-age=600
{
  ...
```

How to Control the Format of the ADF REST Response

You can use REST-Pretty-Print header to remove extra whitespace in the response payload. You can set this attribute for describe and GET, PATCH, and POST payload responses. You must set this property in the adf-config.xml under the startup Properties element.

```
<adf-adfm-config xmlns="http://xmlns.oracle.com/adfm/config">
    <startup>
      <Properties>
        <adf-property name="ORACLE.BC.REST.PRETTYPRINTJSON" value="true"/>
      </Properties>
    </startup>
</adf-adfm-config>
```

In the case of describe, this header reduces the size of the response by nearly 50%.

Versioning the ADF REST Resource

JDeveloper allows you to version the ADF REST resource. It helps create new versions of the ADF REST resource if use cases or backing view objects of ADF REST resource change.

Changes that you make to ADF REST resources during the development cycle can be made without the need to version the resource. However, once you have deployed the RESTful web service, service clients that access the ADF REST resources rely on the stability of the resource collection to satisfy their use cases.

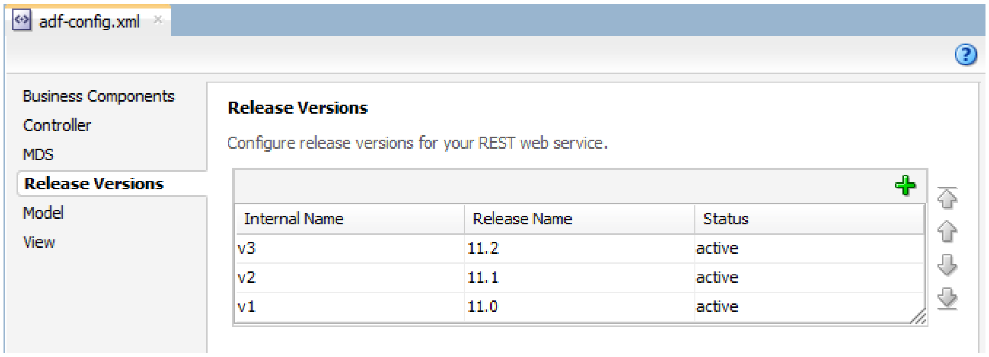
Over time, as use cases change or the backing view objects of the REST resources change, you may need to modify the resource structure of already deployed resources. At that time, modifications to existing ADF REST resources may become backward-incompatible with the deployed REST service and may necessitate creating a new version identifier and ADF REST resource for that version.

How to Version the ADF REST Resource

You use the overview editor for the adf-config.xml file to create new version identifiers and to update the lifecycle status of existing versions. Lifecycle status can be either active, deprecated, or desupported. If the service client requests a resource that does not exist for the requested version, the ADF REST runtime will fallback to a previous version with status active or deprecated

Note that the order of the release name identifiers in the release version list is significant. The ADF REST runtime recognizes the top-most release name as the most recent version. Subsequent release names below the top name in the list form a sequential list of versions. As Figure 16-21 shows, `11.0` is the first version and must appear at the bottom of the list, with subsequent versions, listed above, where `11.2` is the latest version.

Figure 16-21   Managing ADF REST Resource Versions



Release Versions

Configure release versions for your REST web service.

Internal Name	Release Name	Status
v3	11.2	active
v2	11.1	active
v1	11.0	active

> **Note:**
>
> To alter the position of a release identifier in the sequential list of versions, you can use the arrows in the Release Versions page of the overview editor to move the identifier up (more recent version) or down (previous version) in the list.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand when editing a resource may introduce backward-incompatible changes that require creating a resource with a new version. For more information, see What You May Need to Know About Versioning ADF REST Resources.

You may also find it helpful to understand how requests by service clients depend on the version identifier of the resource. For more information, see What Happens At Runtime: Invoking ADF REST Resource Versions.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

To manage ADF REST versions:

1. In the Applications window, in the Application Resources pane, expand the **Descriptors** and **ADF META-INF** nodes, and then double-click the **adf-config.xml** file.
2. In the overview editor for the `adf-config.xml` file, click the **Release Versions** navigation tab, then click the **Create New Release Version** icon button to create a new resource version identifier.

3. When you want to change the order of the versions to affect the runtime, select a version from the table and use the arrows to the right of the table to change its hierarchy in the list of versions.

   The ADF REST runtime will recognized the version at the top of the list as the most recent version of the resource.

4. Optionally, select the status to conform to the desired resource lifecycle: **active**, **desupported**, **deprecated**.

   After you create the version and assign it to REST resources, the version identifier must not be deleted from the `adf-config.xml` file. The proper way to effectively remove a version is to change its status to **desupported**.

What You May Need to Know About Versioning ADF REST Resources

The following are examples of changes to the ADF REST resource structure that should be considered backward-incompatible with already deployed RESTful web services:

- Renaming exposed attributes
- Removing or hiding previously exposed attributes
- Removing previously exposed child resources
- Disabling standard operations
- Disabling LOV view accessors or changing an LOV to a different view object

Under certain circumstances, you may modify the ADF REST structure without versioning the resource. The following changes are considered to be backward compatible and therefore do not necessitate creating a new version of the already deployed ADF REST resource.

- Exposing new attributes and the backing view object does not define the attributes as mandatory

  Note that exposing mandatory-defined attributes requires versioning the resource.
- Exposing standard operations
- Exposing new child resources
- Defining a LOV view accessor for already exposed attributes

What Happens At Runtime: Invoking ADF REST Resource Versions

Version identifiers that you specify will form the URL that the service client uses to invoke operations of the REST resource. For example, the following GET request specifies the URL parameters `11.0` and `11.1` to access two different versions of the `Departments` resource:

```
http://localhost:7101/RESTSample_App/rest/11.0/Departments
```

```
http://localhost:7101/RESTSample_App/rest/11.1/Departments
```

When you use the overview editor for the `adf-config.xml` file to update the lifecycle status of existing versions, you tag each version as either `active`, `deprecated`, or `desupported`. The status `deprecated` has no runtime impact and is provided for documentation purposes, but the status `desupported` will cause the deployed resource to become inaccessible.

Note that the order of the release name identifiers in the adf-config.xml file's release version list is significant. The ADF REST runtime recognizes the top-most release name as the most recent version. Release names below the top name in the list form a sequential list of versions. For example, the following GET request retrieves version 11.1 of the Departments resource, where 11.1 is at the top of the release versions list:

```
http://localhost:7101/RESTSample_App/rest/11.1/Departments
```

If the service client requests a resource that does not exist for the requested version, the ADF REST runtime will fallback to a previous version with status active or deprecated. Thus, if the Departments resource versions 11.0 and 11.1 exist but 11.2 does not, the request for version 11.2 will return the next more recent resource, version 11.1.

Versioning the ADF REST Runtime Framework

JDeveloper allows you to specify the default ADF REST runtime framework that you want the service client to use when processing requests on ADF REST resources. Declaring a default framework version ensures that clients interact with the appropriate level of functionality.

Oracle JDeveloper 12c releases, starting with release 12.2.1.2.0, will introduce ADF REST framework enhancements to support new runtime functionality on service clients. Whether or not your application will benefit from these enhancements depends on the use cases of your application. To support your ability to evaluate framework enhancements before exposing them to service clients, each iteration of the ADF REST framework is identified by a version number, such as version 1, 2, and 3, where version 1 is associated with your application by default. Your application can either remain at the current framework version (for example, the base framework version 1) or you can decide to opt into a newer version (for example, framework version 2) to enhance your application use cases. This ensures that the ADF REST runtime will process the request using the framework version that offers the desired level of functionality for your service clients. Being able to specify a framework version to process requests on your application, allows you to opt into those features when you are ready.

As new ADF REST runtime framework versions are introduced, you may want to update your application to make use of runtime functionality offered in a later framework. To accomplish this, the ADF REST design time allows you to associate a restFrameworkVersion property in the adf-config.xml file to define the default framework version for each version of your application's ADF REST resources. For example, you may have a resource version 11.0, which is by default associated with the base functionality of framework version 1. Then starting with Oracle JDeveloper 12.2.1.2.0 and ADF REST framework version 2, you can choose to create a new resource version 11.1 and associate it with framework version 2. Alternatively, you can opt into framework version 2 on your existing resource version instead of creating a new resource version. By specifying a default framework version that you associate with individual resource versions, you ensure that your application will expose the appropriate level of functionality to service clients.

> **Note:**
>
> Starting in JDeveloper release 12.2.1.2.0, versions 1, 2, and 3 of the ADF REST runtime framework exist, where version 1 is the base version and includes the ability to support multiple framework versions on the ADF REST service client. Starting in JDeveloper release 12.2.1.4.0, versions 4, 5, 6, and 7 also exist. For complete details about versions of the framework, see What You May Need to Know About Versioning the ADF REST Runtime Framework.

How to Version the ADF REST Runtime Framework

You use the overview editor for the `adf-config.xml` file in Source view to declare the default ADF REST framework versions for the resource versions of the ADF REST application. When the service client requests a resource, the ADF REST runtime will process the request using the declared framework version that is associated with the resource version specified on the request URL.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. See About RESTful Web Services and ADF Business Components.

You may find it helpful to understand the role of release versions that you create to manage the release iterations of your application's ADF REST resources. For more information, see Versioning the ADF REST Resource.

You may also find it helpful to understand how an ADF REST framework version may introduce backward-incompatible changes that will require creating a new resource version and declaring a default framework version for it. See What You May Need to Know About Versioning ADF the REST Framework.

You may also find it helpful to understand how the processing of requests by service clients is affected by the ADF REST framework declared for the resource version. See What Happens At Runtime: Invoking an ADF Rest Framework Version.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. See Additional Functionality for RESTful Web Services.

To declare default ADF REST framework versions:

1. In the Applications window, in the Application Resources pane, expand the **Descriptors** and **ADF META-INF** nodes, and then double-click the **adf-config.xml** file.
2. In the overview editor for the `adf-config.xml` file, click the **Release Versions** navigation tab to view the existing list of release versions that the application uses.
3. Optionally, click the **Create New Release Version** icon button to create a new resource version identifier to associate with the new framework version. For example, you may want to create a new release version when the new ADF REST framework version will introduce backward-incompatible changes to the service client and you wish to preserve the original functionality for the existing release version that you can associate with the existing framework version.

4. To specify a default framework version to process requests for the resources of a particular release version, click the **Source** tab and edit the `<version>` element to add the `restFrameworkVersion` property with a specific framework version number. Starting in JDeveloper 12.2.1.2.0, versions 1, 2, and 3 are available. Starting in JDeveloper 12.2.1.4.0, versions 4, 5, 6, and 7 are also available. Make no other changes to the XML and specifically do not change the order of the release versions, where the top-most release version defines the most recent release version.

```
<versions>
    <version name="11.2" displayName="11.2" restFrameworkVersion="3"/>
    <version name="11.1" displayName="11.1" restFrameworkVersion="2"/>
    <version name="11.0" displayName="11.0" restFrameworkVersion="1"/>
</versions>
```

   In the above example, requests for ADF REST resources named version `11.0` will use framework version `1` to process the request, while requests for resources named `11.1`, will use the functionality offered by framework version `2`, and requests for resources named `11.2`, will use the functionality offered by framework version `3` when processing the request.

What You May Need to Know About Versioning the ADF REST Framework

One reason that you may want to version the ADF REST framework for your ADF REST application is to opt into new functionality offered by a later version of the ADF REST runtime framework. Currently, Oracle offers the following framework versions.

> **Note:**
>
> Each ADF REST framework version after version 1 introduces functionality that the previous framework versions does not support. Thus, when you choose to opt into a later framework version, the REST API of your application may introduce backward incompatible changes on the service client consuming the REST API. This topic explains the changes for each framework version.

Framework Version 1

The ADF REST framework identified as version 1 is available starting with JDeveloper release 12.2.1.0.0, when ADF REST was initially introduced. This is the base version which specified a particular JSON payload format. In this release and all subsequent releases, the ability to support multiple framework version was included, by allowing the `restFrameworkVersion` property in the `adf-config.xml` file.

Version 1 is the default version that the ADF REST runtime will use to process requests for service clients when no other version is specified. Therefore, when you want to support service clients at the base level of functionality, your application does not need to declare the version using the `restFrameworkVersion` property in the `adf-config.xml` file.

Note that the query-by-example resource query syntax supported in the base framework version (version 1) is not compatible with later versions of the ADF REST framework. Beginning with version 2 of the ADF REST framework, a more advanced query syntax is offered instead.

Framework Version 2

The ADF REST runtime framework identified as version 2 is available starting with JDeveloper release 12.2.1.2.0. The purpose of this new version is to introduce an expanded query expression syntax for ADF REST requests. Version 2 of the ADF REST framework will interpret the `q` query parameter value differently than the way framework version 1 does, and therefore introduces a backward incompatible change to service clients that rely on framework version 1. Only when framework version 2 (or later) is specified for the resource request will the ADF REST runtime support the use of the expanded expression syntax to process the request.

In version 1, filtering resource collections using the `q` query parameter is limited to a query-by-example syntax, as follows.

```
GET /rest/11.0/Departments?q=Dname SA*;Loc BOSTON
```

Whereas, starting in version 2, the new advanced query syntax supports filtering resource collections using rowmatch query expressions, as follows.

```
GET /rest/11.1/Departments?q=Dname like 'SA*' or Loc = 'BOSTON'
```

> **Note:**
>
> To support both rowmatch expressions (offered in framework version 2 and later) and the query-by-example syntax (version 1 only), you would need to associate framework version 2 (or later) with a new release version identifier that you define for the REST resources in the `adf-config.xml` file. For example, in the above URL samples, you can preserve the original functionality for release version 11.0 and expose the new functionality for version 11.1. This assumes that the `adf-config.xml` file for the application has declared framework version 2 the default using the `restFrameworkVersion=″2″` property on release version `11.1`. Alternatively, if your service clients will no longer require the functionality of your current framework version, you may associate the new framework version with your existing release version identifier. Therefore, you are not required to increment the release version to make use of a new framework version.

For an explanation of the enhanced query syntax offered by rowmatch expressions, see What You May Need to Know About the Advanced Query Syntax in ADF REST Framework Version 2.

Framework Version 3

The ADF REST runtime framework identified as version 3 is available starting with JDeveloper release 12.2.1.2.0. The purpose of this version is to add support for retrieving nested child resources with payload attributes that may be used by the service client to determine whether more resource items would be returned in a subsequent ADF REST request. To support this functionality, the payload structure in framework version 3 now represents nested child resources as a resource collection, instead of an array of items, as was true in version 1 and 2. Therefore, version 3 introduces a backward incompatible change to service clients that rely on framework version 1 or version 2. If you decide to opt into version 3, you will expose functionality that allows GET operations to use the ?expand and ?fields query parameter to return a nested child resource as a resource collection with the hasMore attribute. In affect, this change supports pagination of nested child resources that would otherwise require more than one request to fetch.

When you want to add support for framework version 3 to your application, the same guidelines described for framework version 2 (see above section) apply for preserving the existing level of functionality using the restFrameworkVersion property in the adf-config.xml file.

For an example of the new payload structure for nested child resources introduced in version 3, see Fetching Nested Child Resources and Querying With Filtering Attributes (Partial Get). For details about paginating a resource collection using the hasMore attribute, see Paging a Resource Collection.

Framework Version 4

The ADF REST runtime framework identified as version 4 is available starting with JDeveloper release 12.2.1.4.0. In addition to HTTP status codes and error messages, it is possible to obtain exception details in the response when your request is enabled to use ADF REST framework version 4 and the request is made for either application/vnd.oracle.adf.error+json or application/json media types. With framework version 4, the response will be in the form an exception detail payload which provides the following benefits to the service client:

- If multiple errors occur in a single request, the details of each error are presented in a hierarchical structure.
- An application-specific error code may be present that identifies the ADF exception corresponding to each error.
- An error path may be present that identifies the location of each error in the request payload structure.

> **Note:**
>
> The exception detail may or may not present certain details, such as the application-specific error code and the request payload’s error path.

For example, compare the error response for a POST submitted with a payload that contains the following incorrectly formatted date field when framework version 3 (or earlier) is enable and when framework version 4 (or later) is enabled.

```
{    "EmpNum" : 5027,
     "EmpName" : "John",
     "EmpHireDate" : "not a date"
}
```

Standard Error Response

Without framework version 4, no response payload is generated and instead only a single error message that does not reference the request payload will be returned in the response.

```
"An instance of type oracle.jbo.domain.Date cannot be created from
string not a date. The string value must be in format YYYY-MM-
DDTHH:MI:SS.sss+hh:mm."
```

Exception Payload Error Response

With framework version 4 (or later) enabled, the following exception detail payload is generated for the response. The payload includes the usual HTTP status code and formats the details of one or more exceptions in an array structure.

```
{    "title" : "Bad Request",
    "status" : "400",
    "o:errorDetails" : [ {
     "detail" : "An instance of type oracle.jbo.domain.Date cannot be
created from string not a date.
               The string value must be in format YYYY-MM-
DDTHH:MI:SS.sss+hh:mm.",
       "o:errorCode" : "26099",
       "o:errorPath" : "/EmpHireDate"
    } ]
 }
```

Framework Version 5

The ADF REST runtime framework identified as version 5 is available starting with JDeveloper release 12.2.1.4.0. In versions 4 and earlier you might pick a nested resource as an LOV target. For example: `/rest/v1/States/California/Cities`. In versions 5 and later you use filtering to access the nested LOV resource instead, for example: `/rest/v1/Cities?finder=ByState;name=California`. With this framework version, the row context LOV URLs are no longer returned in the payload and in the describe. Only LOV resource URLs that point to top-level resources are described and included in the payloads.

See What You May Need to Know About Configuring LOV Resources for Row Finders and Retrieving LOV-Enabled Attribute Values with Framework Version 5 and Later.

This framework version 5 also provides support for request and response parameters beyond the current supported types of string, number, date, and boolean. The supported Java types include `java.util.List` and `java.util.Map`. For the ADF REST catalog describe, if the response parameter is `java.util.List`, then specify the request parameter as `array` and if the response parameter is `java.util.Map` then specify the request parameter as `object`.

```
{
  "name" : "sales",
  "parameters" : [ {
    "name" : "prices",
    "type" : "array",
    "typeProperties": {
      "itemType": "number"
    },
    "mandatory" : false
  }, {
    "name" : "quantities",
    "type" : "object",
    "typeProperties": {
      "itemType": "array",
      "typeProperties": {
        "itemType": "integer"
      }
    },
    "mandatory" : false
  } ],
  "resultType" : "object",
  "typeProperties": {
    "itemType": "number"
  },
  "method" : "POST",
  "requestType" : [ "application/vnd.oracle.adf.action+json" ],
  "responseType" : [ "application/vnd.oracle.adf.actionresult+json",
"application/json" ]
}
```

Framework Version 6

The ADF REST runtime framework identified as version 6 is available starting with JDeveloper release 12.2.1.4.0. The purpose of this framework version is to easily differentiate between the resource fields and the item context information like links and headers. A new element `@context` is introduced in this version and all the information for an item is moved under `@context` section. The `changeIndicator` value is moved to `ETag`, which is under `headers`. A new context information key is included under `@context` that contains the unique identifier of the specific resource item as a string. The `@context` section also contains warnings in the response payload for create/upsert and update actions. See Fetching a Resource with Grouped Context Information .

The new payload for a resource item in a response payload and collection response payload will be similar to the one below:

```
{
   "field1": "value1",
   "field2": "value2",
     ...
   "@context" : {
      "key" : "AB8765BCD",
      "headers" : {
         "ETag" : "ACED..."
       ...
      },
      "links": [ {
         "rel": "self",
         "href":
          ...
      } ]
      "warnings": [ {
         "detail": "Warning from overridden validateEntity method in DeptImpl :
DeptName = ABC"
      }, {
         "detail": "Attribute set with value 92 for DeptNum in Dept failed",
         "o:errorCode": "27011",
         "o:errorPath": "/DeptNum"
      }, {
        "detail": "Warning from overridden afterCommit method in DeptViewImpl"
      }, {
        "detail": "Warning from overridden afterCommit method in DeptViewImpl"
      } ]
  }
}
```

Framework Version 7

The ADF REST runtime framework identified as version 7 is available starting with JDeveloper release 12.2.1.4.0. This framework version supports top-level LOVs, and fully removes row-level LOV resource descriptions in the ADF REST describe. Framework versions earlier than framework version 5 support nested LOVs in the context of a row in the REST resource. With framework version 7 enabled, use instead static LOV resources and row finder URL links in the describe, as described in Retrieving LOV-Enabled Attribute Values with Framework Version 5 and Later.

Additionally, version 7 removes LOV links from the resource item payload links section of the response. The goal is to enforce the use of parametrized row finders as implemented by version 5 and later by removing LOV links. For example, compare this response for a resource item request made with version 7 enabled to the same request with an earlier version.

```
{
   "EmpId" : 101,
   "EmpName" : "Bob",
   "@context" : {
      "key" : "1",
      "links" : [ {
        "rel" : "self",
        "href" : "http://server/demo/rest/12.0/Employees/101",
        "name" : "Employees",
        "kind" : "item"
      }, {
        "rel" : "canonical",
        "href" : "http://server/demo/rest/12.0/Employees/101",
        "name" : "Employees",
        "kind" : "item"
      } ]
   }
}
```

Here is the same response with an earlier version with the LOV resource link returned.

```
{
   "EmpId" : 101,
   "EmpName" : "Bob",
   "@context" : {
      "key" : "1",
      "links" : [ {
        "rel" : "self",
        "href" : "http://server/demo/rest/12.0/Employees/101",
        "name" : "Employees",
        "kind" : "item"
      }, {
        "rel" : "canonical",
        "href" : "http://server/demo/rest/12.0/Employees/101",
        "name" : "Employees",
        "kind" : "item"
      }, {
        "rel" : "lov",
        "href" : "http://server/demo/rest/12.0/Employees/10/lov/
JobsLOV",
        "name" : "JobsLOV",
        "kind" : "collection"
      } ]
   }
}
```

What You May Need to Know About the Advanced Query Syntax in ADF REST Framework Version 2

The ADF REST runtime framework identified as version 2 was offered starting with JDeveloper release 12.2.1.2.0. The purpose of this framework version is to introduce an expanded query expression syntax for ADF REST requests. This version will interpret the q query parameter value differently than the way framework version 1 does, and therefore introduces a backward incompatible change to service clients that rely on framework version 1.

When you decide to opt into framework version 2 (or later), the ADF REST runtime will process fetch requests for the q query parameter using the expanded expression syntax, whereas requests using the query-by-example syntax will become invalid and will return an error. However, you may decide not to opt into the functionality offered in framework version 2 by leaving the default for your release version set to framework version 1. Or, you may preserve the base functionality by creating a new release version identifier that you associate with framework version 2, while leaving the existing release identifier in the adf-config.xml file as framework version 1.

In version 1, filtering resource collections using query parameters is limited to a query-by-example syntax, which separates expressions using a semi-colon, as follows:

```
GET /rest/11.0/Departments?q=Dname SA*;Loc BOSTON
```

Whereas, starting in version 2, a new advanced query syntax supports filtering resource collections using rowmatch expressions, as follows:

```
GET /rest/11.1/Departments?q=Dname like 'SA*' or Loc = 'BOSTON'
```

Such rowmatch expressions include the case-sensitive name of a resource item, followed by an operator and one or more operand values (depending on the operator used). The filter can be as simple as a single expression, or it can combine expressions using the and and or conjunctions with matching sets of parentheses for grouping.

Benefits of the Advanced Query Syntax Offered in Framework Version 2 and Later

The advantages of rowmatch expression include the following.

- They may use supported operators:

  DepartmentNumber = 20

  DepartmentNumber <> 20

  DepartmentNumber <= 20

  DepartmentNumber < 20

  DepartmentNumber >= 20

DepartmentNumber >20

DepartmentNumber between 20 and 40

DepartmentNumber not between 20 and 40

DepartmentNumber in (20, 30, 40)

DepartmentName like '%S%'

DepartmentName like 'RE%'

DepartmentName not like 'RE%'

Location is null

Location is not null

- They may involve multiple attributes:

  DepartmentNumber = 10 or DepartmentName like 'RESEARCH'

  DepartmentNumber > 10 and DepartmentNumber < 40

  DepartmentNumber < 20 or DepartmentNumber > 30

  (DepartmentNumber = 10 or DepartmentNumber = 30) and (DepartmentName like 'SALES')

  DepartmentNumber BETWEEN 20 and 40) and (Location like 'DAL%')

  (DepartmentNumber > 0 and DepartmentNumber < 100) and (DepartmentName <> 'SALES') and (Location not like 'NEW%')

  (DepartmentNumber = 10 or DepartmentNumber = 30) and (DepartmentName = 'ACCOUNTING' or DepartmentName = 'SALES')

  (DepartmentNumber = 10 and DepartmentName like 'ACC%') or (DepartmentNumber = 20 and DepartmentName like 'RES%')

  DepartmentName='ACCOUNTING' or (DepartmentName like 'R%' and Location like '%ALLA%')

  (DepartmentName like 'R%' and Loc like '%ALLA%') or DepartmentName='ACCOUNTING'

  (DepartmentName like 'R%' or Loc like '%ALLA%') or DepartmentName='ACCOUNTING'

  (DepartmentNumber between 20 and 40) and DepartmentNumber is not null

- They may involve attributes of nested child resources:

  Deptno > 5 and Emps.Job = 'MANAGER'

  Emps.Job = 'MANAGER' and Deptno > 5

  Deptno > 5 and (Emps.Job = 'MANAGER')

  (Emps.Job = 'MANAGER') and Deptno > 5

  (Deptno > 5) and (Emps.Job = 'MANAGER')

  (Deptno = 10 and Emps.Job = 'PRESIDENT') or (Deptno = 20 and Emps.Job = 'MANAGER')

  Deptno > 5 and Emps.Job = 'MANAGER' and Emps.Sal >= 2500

  Deptno > 5 and (Emps.Job = 'ANALYST' or Emps.Sal >= 4000)

  (Deptno > 5 and Emps.Job = 'ANALYST') or Emps.Sal >= 4000

Emps.Job = 'ANALYST' or Emps.Job = 'SALESMAN'

Deptno > 5 and (Emps.Job = 'ANALYST' or Emps.Job = 'SALESMAN')

Deptno > 5 and Emps.Job = 'MANAGER' and Emps.DirectReports.Sal >= 2000

Deptno > 5 and (Emps.Job = 'MANAGER' or Emps.DirectReports.Sal >= 2000)

Deptno > 10 and (Emps.Job = 'MANAGER' and (Loc = 'NEW YORK' or Emps.Mgr=7698))

Deptno > 10 and (Emps.Job = 'MANAGER' or (Loc = 'NEW YORK' or Emps.Mgr=7698))

Deptno > 10 and (Emps.Job = 'MANAGER' or (Loc = 'NEW YORK' or Emps.Mgr=7698)) or Deptno = 40

Deptno > 10 and (Emps.Job = 'MANAGER' or (Loc = 'NEW YORK' or Emps.Mgr=7698)) or (Deptno = 40)

Deptno > 10 and (Emps.Job = 'MANAGER' or (Emps.DirectReports.Sal > 2000 and (Emps.DirectReports.Comm = 500 or Emps.DirectReports.Deptno > 10)))

Deptno > 10 and (Emps.Job = 'MANAGER' and (Emps.DirectReports.Sal >= 2000 and (Emps.DirectReports.Comm = 500 or Emps.DirectReports.Deptno > 10)))

- They may involve the UPPER function:

  UPPER(DepartmentName) = 'RESEARCH'

  UPPER(DepartmentName) = UPPER('research')

  UPPER(DepartmentName) like 'RES%' and UPPER(Location) like 'DAL%'

  UPPER(DepartmentName) like UPPER('research')

Overview of the Advanced Query Syntax Offered in Framework Version 2 and Later

The following are some examples of rowmatch expressions.

- To test whether a value is `null` you must use the `is null` or the `is not null` keywords:

  ```
  AssignedToId is null
  ```

  ```
  AssignedToId is not null
  ```

- For equality use the = sign, and for inequality use either the `!=` or the <> operators.

  ```
  AssignedToId = 100000000089003
  ```

  ```
  Priority != 1
  ```

  ```
  Priority <> 1
  ```

  ```
  ActivityType != 'RS'
  ```

  ```
  ActivityType <> 'RS'
  ```

- For relational comparisons, use the familiar <, <=, >, or <> operators, along with `between` or `not between`.

  ```
  Priority <= 2
  ```

  ```
  Priority < 3
  ```

  ```
  Priority <> 1
  ```

```
Priority > 1
```

```
Priority >= 1
```

```
TotalLoggedHours >= 12.75
```

```
Priority between 2 and 4
```

```
Priority not between 2 and 4
```

- For string matching, you can use the `like` operator, employing the percent sign `%` as the wildcard character to obtain "starts with", "contains", or "ends with" style filtering, depending on where you place your wildcard(s):

  ```
  RecordName like 'TT-%'
  ```

  ```
  RecordName like '%-TT'
  ```

  ```
  RecordName like '%-TT-%'
  ```

- To test whether a field's value is in a list of possibilities, you can use the `in` operator:

  ```
  ActivityType in ('OC','IC','RS')
  ```

- You can combine expressions using the conjunctions `and` and `or` along with matching sets of parentheses for grouping to create more complex filters like:

  ```
  (AssignedToId is null) or ( (Priority <= 2) and (RecordName like
  'TT-99%'))
  ```

  ```
  (AssignedToId is not null) and ( (Priority <= 2) or (RecordName like
  'TT-99%'))
  ```

  When using the `between` or `in` clauses, you must surround them by parentheses when you join them with other clauses using `and` or `or` conjunctions.

What Happens At Runtime: Invoking an ADF REST Framework Version

After Oracle JDeveloper introduces a new ADF REST framework version (such as framework version 2 offered in JDeveloper release 12.2.1.2.0 and later), you may want to create a new resource version and associate it with the new framework version to ensure that service clients make use of the appropriate level of functionality.

For example, the following URL specifies resource version 11.2, where the application’s `adf-config.xml` file associates this resource version with version 2 of the ADF REST framework. Because ADF REST framework version 2 supports rowmatch filter expressions, as a result, the ADF REST runtime will process the request with the appropriate functionality and fetch the departments with names that begin with SA (for example, SALES) or have a Location of BOSTON.

```
http://server/demo/rest/11.2/Departments?q=DepartmentName like 'SA*' or
Location = 'BOSTON'
```

Note that a service client may override the default framework version and process individual requests using a specified framework version that gets passed in a custom header, `REST-Framework-Version`. In this case, the ADF REST runtime will ignore the application default framework version declaration. If the custom header is omitted on the request, then the ADF REST runtime always uses the application’s default framework version, as defined in the `adf-config.xml` file. When the application does not define a default framework version and the request on the service client omits the version header, then version 1 of the ADF REST framework is assumed. For information about processing requests using the framework versions, see Working with ADF REST Framework Versions.

The following table contrasts what happens at runtime when a request uses functionality supported (or not supported) by a particular ADF REST framework version. In particular, note the URLs that contrast the query-by-example syntax supported only in version 1 with rowmatch expressions supported in version 2 (and later). The column for the `REST-Framework-Version` header specifies whether the request passes a version header on the request. When the request includes the version header, the ADF REST runtime processes the request with the passed framework value and overrides the default `adf-config.xml` file declaration.

Table 16-3 Example Requests Processed By ADF REST Framework Versions

URI	REST-Framework-Version Header	Resolved Version	Success / Error Notes
GET /rest/11.0/Departments		1	Success. Uses default framework version for resource version 11.0.
GET /rest/11.0/Departments	1	1	Success. Uses the requested framework version, which matches the default declaration in the `adf-config.xml` file.
GET /rest/11.0/Departments	2	2	Success. Uses the requested framework version, which overrides the default declaration in the `adf-config.xml` file.
GET /rest/11.1/Departments		2	Success. Uses the default framework version for resource version 11.1.
GET /rest/11.0/Departments?q=Dname SA*;Loc BOSTON		1	Success. Uses the default framework version for resource version 11.0, which is defined as version 1. Query by example syntax is supported in framework version 1.
GET /rest/11.1/Departments?q=Dname SA*;Loc BOSTON		2	Error is returned. Uses the default framework version for resource version 11.1, which is defined a version 2. Query by example syntax is not supported in framework version 2.

Table 16-3 (Cont.) Example Requests Processed By ADF REST Framework Versions

URI	REST-Framework-Version Header	Resolved Version	Success / Error Notes
GET /rest/11.0/ Departments? q=Dname LIKE 'SA*' OR Loc = 'BOSTON'	2	2	Success. Uses the requested framework version, which overrides the default declaration in the `adf-config.xml` file. Rowmatch expressions are supported in framework version 2.
GET /rest/11.0/ Departments? q=Dname LIKE 'SA*' OR Loc = 'BOSTON'		1	Error is returned. Uses the default framework version for resource version 11.1, which is defined as version 1. Rowmatch expressions are not supported in framework version 1.
GET /rest/11.1/ Departments? q=Dname LIKE 'SA*' OR Loc = 'BOSTON'	1	1	Error is returned. Uses the requested framework version, which overrides default declaration in the `adf-config.xml` file. Rowmatch expressions are not supported in framework version 1.

Granting Client Access to the ADF REST Resource

Use the Configure ADF Security wizard and in the wizard select RESTWebService.jpr as the web project in the wizard to manage ADF REST resource security.

You can enable security for the ADF REST resources when you want to require user authentication to invoke actions on the REST request. Security is handled like all Fusion web applications and is enabled when you run the Configure ADF Security wizard and select the **RESTWebService.jpr** as the web project in the wizard. Enabling ADF Security on the web service project, means the deployed service will be inaccessible by default and users will require security grants to application roles that confer specific access permission.

Permission that you can grant to users of the RESTful web service is defined by the following classes:

- `oracle.adf.share.security.authorization.RestServicePermission` which defines the authorization grants to the standard actions defined in a REST resource.

Table 16-4 lists the actions defined by the ADF REST permission class that you may grant to your defined application roles.

Table 16-4 Secured Actions of ADF REST Resources

Grantable Action	Effect on the REST Resource
`describe`	Grants describing the collections and instances of the REST resource.
`get`	Grants returning the collection or instance for the REST resource.
`update`	Grants updating a collection or instance for the REST resource.
`delete`	Grants deleting a collection or instance for the REST resource.
`create`	Grants creating a collection or instance for the REST resource.

The general process to authorize users to invoke actions of the ADF REST resource is as follows.

1. Enable the desired standard actions on the REST resource.
2. Run the ADF Security wizard on the **RESTWebService** project.
3. Create one or more application roles and test users to test security in JDeveloper.
4. Create a resource grant for the REST resource that you associate with the desired application role.
5. Map the application roles and their resource grants to your test users.

How to Create a Resource Grant for ADF REST Resources

You can use the overview editor for security policies to create a grant that will secure operations that you have exposed on the resource. JDeveloper will match your resource type definition to the OPSS permission class `oracle.adf.share.security.authorization.RestServicePermission`, as described in Table 16-4.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. See About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see See Additional Functionality for RESTful Web Services.

You will need to complete these tasks:

- Create the desired REST resource, as described in How to Create ADF REST Resources from View Object Instances.
- Enable the standard operations that you want the REST resource to secure, as described in How to Expose Standard HTTP Actions in the ADF REST Resource.

- Run the Configure ADF Security wizard to enforce security and make the REST resource methods protected by default. In the Authentication Type page of the wizard instead of selecting **ViewController**, as described in Enabling ADF Security, select the default generated **RESTWebService** project from the **Web Project** dropdown to configure ADF Security for a ADF Business Components model project that defines the ADF REST resources.
- Create one or more test users and map them to application roles that you create for the purpose of granting resource permissions, as described in How to Associate Test Users and Application Roles.

To create the ADF REST resource grant:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, choose **ADF REST Resource** from the **Resource Type** dropdown.
3. Locate the Model project that defines the resource and add it to the **Source Project** field.
4. In the **Resources** column, select the resource.
5. In the **Granted To** column, click the **Add Grantee** icon and choose **Add Application Role** and then, in the Select Application Roles dialog, click the **Add** icon and choose the application role to receive the resource grants. For example, if you created a role `ManagerRole`, select the role and click **OK**.
6. With the role selected in the **Granted To** column, select the desired actions from the **Actions** list.

   The overview editor displays the resource grant made to the application role, as shown in Figure 16-22.

Deploying the ADF REST Resource

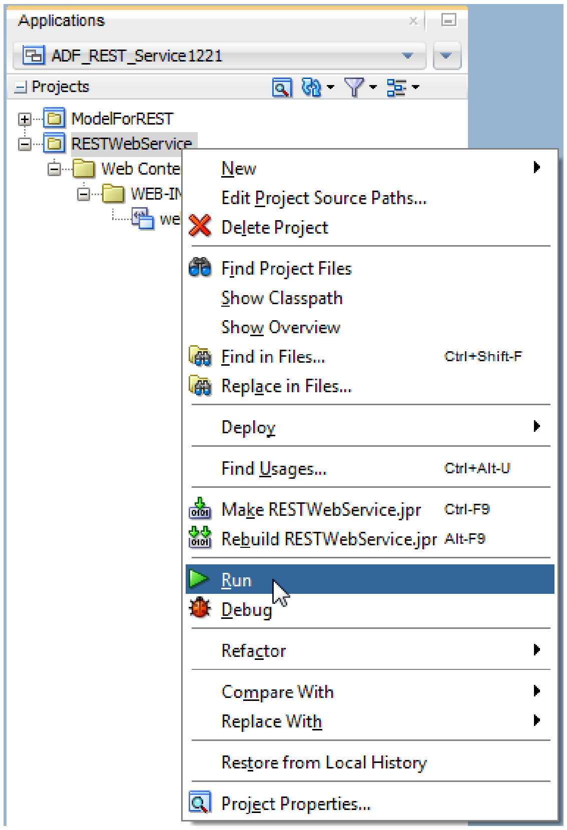
You can deploy the RESTful web service to either the Integrated Oracle WebLogic Server of JDeveloper or to the standalone Oracle WebLogic Server.

You can deploy the RESTful web service to either JDeveloper's Integrated WebLogic Server or to standalone Oracle WebLogic Server.

How to Deploy the ADF REST Resource to Integrated WebLogic Server

You can deploy the RESTful web service to JDeveloper's Integrated WebLogic Server using the default **Run** option that you select on the **RESTWebService** project, as shown in Figure 16-23.

Figure 16-23 Using the Default Run Option on RESTWebService Project



Once you have deployed the service to Integrated WebLogic Server, you can click the target URL in the Log window to access the service in the HTTP Analyzer tool in JDeveloper and to perform testing using the syntax that establishes the request (GET or POST, for example). For details about testing RESTful web services, see Testing the ADF REST Resources Using Integrated WebLogic Server.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete these tasks:

- Create the desired REST resource, as described in Creating ADF REST Resources Using the Application Module.
- Optionally, create an Integrated WebLogic Server connection and configure the default domain, as described in Working with the Default Domain. If you do not create the connection, JDeveloper will prompt you to do so.
- Optionally, edit the REST servlet's URL pattern and context root as you want it to appear in the target URL used to access the deployed RESTful web service. For more information about editing the URL pattern, see What You May Need to Know About Modifying the Target URL Used by Service Clients.

To deploy the web service to Integrated WebLogic Server:

1. In the Applications window, select the **RESTWebService** project node, right-click and choose **Run**.

   If you have not already configured Integrated WebLogic Server, JDeveloper prompts you to configure the default domain.

   JDeveloper deploys the application and starts the web service. During this time, the output from these processes is displayed in the **Running: IntegratedWebLogicServer** tab of the Log window. After the web service has started, the target URL appears at the bottom of the log, as shown in Figure 16-24.

   Figure 16-24   Log Window Displays Target URL

   
   Running: IntegratedWebLogicServer - Log

HTTP Analyzer Instances
Actions
Messages
Deployment
Running: IntegratedWebLogicServer

   ```
   DeploymentFactory Cache: Found for appId ADF_REST_ServiceApp74: weblogic.application.internal.Ea
   <oracle.adf.common> <AdfDiagnosticsJarsVersionDumpImpl> <executeDump> <Path of the jars version
   [03:28:08 PM] Application Redeployed Successfully.
   [03:28:08 PM] The following URL context root(s) were defined and can be used as a starting point
   [03:28:08 PM] http://10.245.174.187:7101/RESTDemo2
   [03:28:08 PM] Uploading jazn-data users.
   [03:28:08 PM] Creating user "testuser".
   [03:28:08 PM] Elapsed time for deployment:  7 seconds
   [03:28:08 PM] ----  Deployment finished.  ----
   Run startup time: 6840 ms.
   [Application ADF_REST_ServiceApp74 running on IntegratedWebLogicServer]

   Target URL -- http://127.0.0.1:7101/RESTDemo2/rest/
   ```

2. After you deploy the web service, in the **Running: IntegratedWebLogicServer** tab of the Log window, click the target URL to access the web service in the HTTP Analyzer and to perform testing on the deployed service in JDeveloper.

   For example, the **Running: IntegratedWebLogicServer** tab of the Log window might display the following target URL that you can click, where 7101 is the port number and what follows is the service context root and the REST servlet URL pattern:

   `http://<hostname>:7101/RESTSample_App-context-root/rest`

3. Alternatively, to display the web service using a web browser, paste the target URL the Log window into the browser address field, modify the URL to identify the ADF REST resource, and submit the HTTP Get request.

   For example, a Get request for version `11.1` of the `Departments` resource looks like this:

```
http://localhost:7101/RESTSample_App-context-root/rest/11.1/
Departments
```

Be sure to include the version number that you configured for the resource in the URL. In this example, `11.1` was configured as the version for the `Departments` resource, as shown in Figure 16-25.

Figure 16-25   Using the Browser to Make a GET REST Request

                    }
                },
              ▾ {
                    rel: "canonical",
                    href: http://127.0.0.1:7101/demo/rest/11.1/Departments/20,
                    name: "Departments",
                    kind: "item"
                },
              ▾ {
                    rel: "child",
                    href: http://127.0.0.1:7101/demo/rest/11.1/Departments/20/child
                    /EmployeesView,
                    name: "EmployeesView",
                    kind: "collection"
```

How to Configure the ADF REST Resources Deployment Profile For Standalone Oracle WebLogic Server Deployment

Before you can deploy the RESTful web service to standalone Oracle WebLogic Server, you must configure the ADF REST resources deployment profile to declare the RESTWebService project as a dependent module of the ADF REST application EAR file. This project contains a `web.xml` file and a `weblogic.xml` file that ensure access to the REST resources by service clients.

In JDeveloper, you use the Application Assembly page of the Edit EAR Deployment Profile Properties dialog to add the module dependency to the application. Then, when you deploy the ADF REST application, the two files of the selected RESTWebService project will be assembled as a WAR file in the deployed EAR file.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete these tasks:

- Create the desired REST resource, as described in Creating ADF REST Resources Using the Application Module.

To configure the deployment profile:

1. Add the RESTWebService project as a dependency for the application's EAR deployment profile:
   a. In the Applications window, select the application and then choose **Application - Application Properties** from the main menu.
   b. In the Application Properties dialog, choose **Deployment** and select the application module deployment profile and click **Edit Profile**.
   c. In the Edit EAR Deployment Profile Properties dialog, choose **Application Assembly** and expand the **RESTWebService.jpr** module and then select the project as shown in Figure 16-26 and click **OK**.

Figure 16-26 Adding a Deployment Dependency on RESTWebService Project

How to Deploy the ADF REST Resource to Standalone Oracle WebLogic Server

You can deploy the RESTful web service to standalone Oracle WebLogic Server.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete these tasks:

- Create the desired REST resource, as described in Creating ADF REST Resources Using the Application Module.
- Modify the deployment profile to add the RESTWebService project as a dependency and deploy the web service, as described in How to Configure the ADF REST Resources Deployment Profile For Standalone Oracle WebLogic Server Deployment.
- When the application uses the customization features provided by Oracle Metadata Services (MDS) framework and shaping definitions are applied to ADF REST resources, it is necessary to modify the MAR profile for the customization features, as described in What You May Need to Know About Deploying ADF REST Resources With MDS Customization Support.
- Optionally, edit the REST servlet's URL pattern and context root as you want it to appear in the target URL used to access the deployed RESTful web service. For more information about editing the URL pattern, see What You May Need to Know About Modifying the Target URL Used by Service Clients.

To deploy the web service to standalone Oracle WebLogic Server:

1. In the Applications window, select the application and then choose **Application - Deploy - *deployment_profile* to *server_name*** from the main menu.

   JDeveloper deploys the application and starts the web service. During this time, the output from these processes is displayed in the **Deployment** tab of the Log window. After the web service has started, the target URL is also displayed in the Log window.

2. After you deploying the web service, open the Deployment - Log window and click the target URL to access the web service and to perform testing on the deployed service.

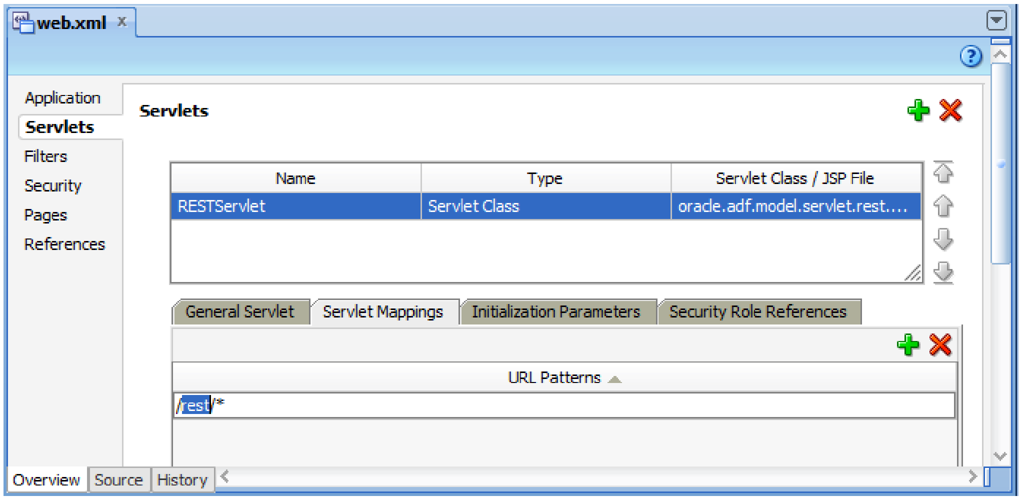
What You May Need to Know About Modifying the Target URL Used by Service Clients

You can edit the REST servlet's URL pattern as you want it to appear in the URL that service clients use to access the service. By default the servlet mapping uses `rest` in the URL pattern:

```
http://localhost:7101/RESTSample_App-context-root/rest/11.1/Departments
```

To edit the servlet mapping pattern, in the Applications window, expand the **RESTWebService** project and double-click the `web.xml` file, and then in the editor for the `web.xml` file, edit the URL pattern for the REST servlet, as shown in Figure 16-27.

Figure 16-27 Editing the URL Pattern for the REST Servlet Mapping



Name	Type	Servlet Class / JSP File
RESTServlet	Servlet Class	oracle.adf.model.servlet.rest....

URL Patterns
/rest/*

You may also edit the context root as you want it to appear in the URL to access the service. By default, the context root is based on the application name and may be shortened as desired. To edit the context root, in the Applications window, right-click the **RESTWebService** project and choose **Project Properties**, and then, in the Project Properties dialog, click **Java EE Application** and edit the **Java EE Context Root** as shown in Figure 16-28 and click **OK**.

Figure 16-28 Editing the Default Context Root on the RESTWebService Project

What You May Need to Know About Deploying ADF REST Resources With MDS Customization Support

If your Model project defines view object shaping definitions and the application supports end user customizations using features of the Oracle Metadata Services (MDS) framework, it is necessary to create a MAR profile that includes the `/persdef/` name in the `user` directory.

This is necessary because MDS customizations define the namespace path shared by the ADF REST shaping definitions:

```
<namespace path="/persdef/" metadata-store-usage="reposX"/>
```

In this case, the `adf-config.xml` file should define `deploy-target="true"` for the corresponding `metadata-store-usage` element.

For details about how to package the customized metadata, see How to Package and Deploy Customized Applications.

Testing the ADF REST Resources Using Integrated WebLogic Server

JDeveloper allows you to test an ADF REST resource deployed on the Integrated WebLogic Server. Use the HTTP Analyzer to create an HTTP request, web browser for GET requests, or cURL command line tool.

You use JDeveloper to deploy the RESTful web service to Integrated WebLogic Server and then access the ADF REST resources using the target URL generated by the deployment process. Using the generated URL, you can make requests to test the ADF REST resources of the ADF Model project.

You can use any of the following techniques to test the deployed RESTful web service by modifying the URL of the deployed service to return an expected payload:

- In the HTTP Analyzer in JDeveloper, using the **Create HTTP Request** option
- In a web browser (typically limited to GET requests)
- In the cURL command line tool from a command window

  Note that cURL is a third-party tool that you can install and configure to make REST requests using a command window.

Testing the ADF resource using the deployed RESTful web service requires knowledge of the REST API syntax enabled by the ADF REST runtime. However, you can use the instructions in this document to make a basic GET request to view a resource collection.

For example, a GET request that returns all versions of all resources looks like this:

```
http://<server>/<context-root>/rest
```

For example, a GET request that returns all resources of a specific version looks like this:

```
http://<server>/<context-root>/rest/<versionID>/describe
```

For example, a GET request that returns a specific version of a specific resource collection looks like this:

```
http://<server>/<context-root>/rest/<versionID>/<resourceName>
```

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables service clients to access rows of data and perform service operations. See About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand the ADF REST framework and the syntax for making API calls using HTTP methods. See Consuming ADF RESTful Web Services.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. See Additional Functionality for RESTful Web Services.

You will need to complete these tasks:

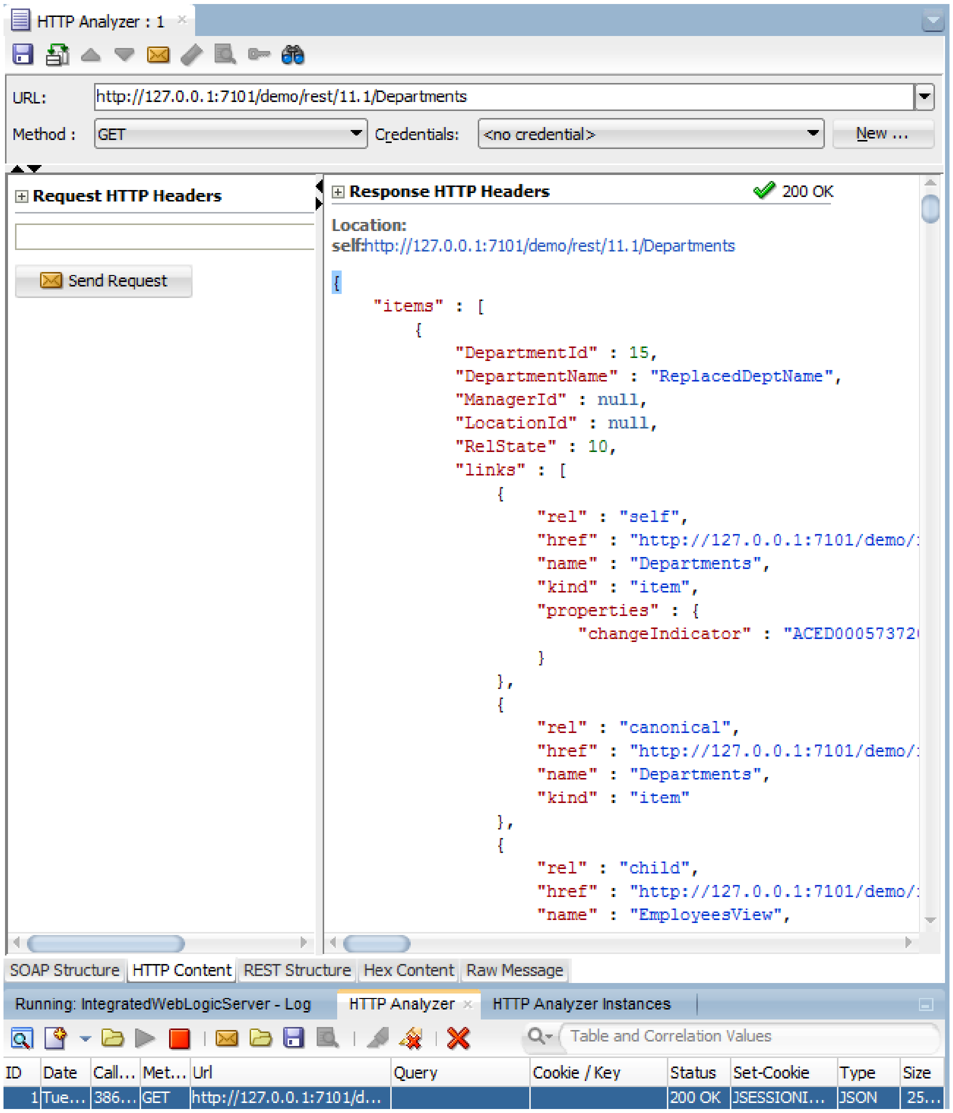
- Create the desired REST resource, as described in Creating ADF REST Resources Using the Application Module.
- Deploy the ADF REST resources to Integrated WebLogic Server, as described in How to Deploy the ADF REST Resource to Integrated WebLogic Server.
- Download the command line tool cURL when you want to use the tool to test the RESTful web service operations against REST resources.

To test the web service using HTTP GET:

1. To test using JDeveloper's HTTP Analyzer, choose **Tools - HTTP Analyzer** from the main menu, then choose **Create New HTTP Request** in the HTTP Analyzer Log window and then, in the HTTP Analyzer, select the HTTP Content tab and paste the target URL that you copied from the Log window into the **URL** field, modify the URL to identify the REST resource, then choose the desired **Method** and click **Send Request**.

   Be sure to include the version number that you configured for the resource in the URL. In this example, `11.1` is the release name version identifier used to access the `Departments` resource, as shown in Figure 16-29.

Figure 16-29   Using the HTTP Analyzer to Make a GET REST Request



URL: http://127.0.0.1:7101/demo/rest/11.1/Departments

Method : GET   Credentials: <no credential>

Location:
self:http://127.0.0.1:7101/demo/rest/11.1/Departments

```
{
    "items" : [
        {
            "DepartmentId" : 15,
            "DepartmentName" : "ReplacedDeptName",
            "ManagerId" : null,
            "LocationId" : null,
            "RelState" : 10,
            "links" : [
                {
                    "rel" : "self",
                    "href" : "http://127.0.0.1:7101/demo/:
                    "name" : "Departments",
                    "kind" : "item",
                    "properties" : {
                        "changeIndicator" : "ACED00057372
                    }
                },
                {
                    "rel" : "canonical",
                    "href" : "http://127.0.0.1:7101/demo/:
                    "name" : "Departments",
                    "kind" : "item"
                },
                {
                    "rel" : "child",
                    "href" : "http://127.0.0.1:7101/demo/:
                    "name" : "EmployeesView",
```

ID	Date	Call...	Met...	Url	Query	Cookie / Key	Status	Set-Cookie	Type	Size
1	Tue...	386...	GET	http://127.0.0.1:7101/d...			200 OK	JSESSIONI...	JSON	25...

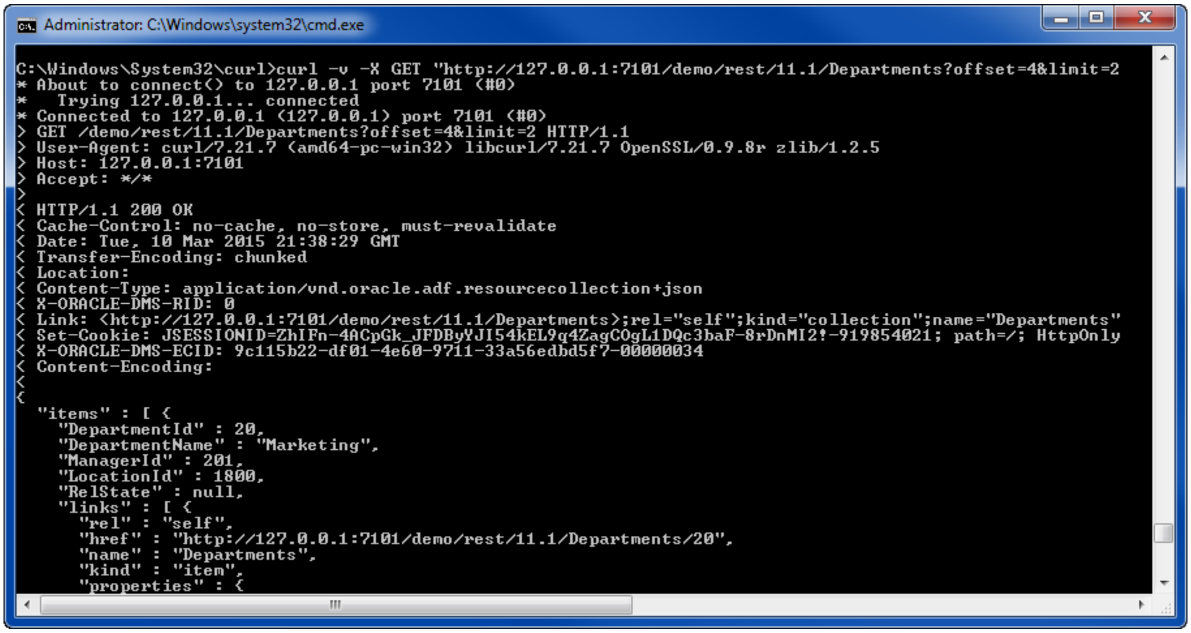
Note that the HTTP Analyzer supports SOAP, standard HTTP, and REST type requests. However, the WADL that you might normally supply to the HTTP Analyzer to define a generic RESTful web service does not support the describe format of ADF REST resources. Therefore when using the HTTP Analyzer to test the deployed ADF REST resource, you must create a new HTTP type request instead of a REST request.

2. To test using the third-party cURL command line tool, open a command prompt and enter a cURL command for the REST resource similar to the following, where `-v` is the option to see what cURL sends and `-X` is the request option:

   ```
   curl -v -X GET http://127.0.0.1:7101/RESTDemo/rest/11.1/Departments
   ```

   Be sure to include the version number that you configured for the resource in the URL. In this example, `11.1` is the release name version identifier used to access the `Departments` resource, as shown in Figure 16-30.

Figure 16-30   Using cURL to Make a REST Request



```
C:\Windows\System32\curl>curl -v -X GET "http://127.0.0.1:7101/demo/rest/11.1/Departments?offset=4&limit=2

```

17 Extending Business Components Functionality

This chapter describes techniques that you can use to incorporate custom code with all types of ADF Business Components and to extend the ADF Business Components framework behavior.

This chapter includes the following sections:

About Extending Business Components Functionality

You can extend base classes of ADF Business Components to incorporate custom code.

One of the powerful features of framework-based development is the ability to extend the base framework to change a built-in feature to behave differently or to add a new feature that can be used by all of your applications.

The base classes of the **ADF Business Components** framework may be extended to incorporate custom code with all types of components in the framework and to extend the ADF Business Components framework behavior.

When used without customization, your business component is completely defined by its XML document and it will be fully functional without custom Java code or even a Java class file for the component. If you have no need to extend the built-in functionality of a component in ADF Business Components, and no need to write any custom code to handle its built-in events, you can use the component in this XML-only fashion. However, when you do extend base classes of the ADF Business Components framework, you can still work with XML documents in JDeveloper.

Once you have created framework extension classes, any new business component you create can be based on your *customized* framework class instead of the base one. And, you can always update the definitions of existing components to use the new framework extension class as well.

Additional Functionality for Extending Business Components

You may find it helpful to understand other **Oracle ADF** features before you start working with the ADF Business Components framework. Following are links to other functionality that may be of interest.

- For details about creating a reusable library to make your framework extension layer classes easier to package, see Reusing Application Components .
- For details about using the customization features provided by Oracle Metadata Services (MDS) to create applications that can be customized and subsequently deployed by a customer, see Customizing Applications with MDS .
- For a quick reference to the most common code that you will typically write, use, and override in your custom classes, see Most Commonly Used ADF Business Components Methods.
- For API documentation related to the `oracle.jbo` package, see the following Javadoc reference document:
  - *Java API Reference for Oracle ADF Model*

Creating ADF Business Components Extension Classes

An ADF Business Components extension class augments or modifies behavior of built-in features and also allows you to provide a generic workaround for a bug.

An ADF Business Components framework extension class is a Java class you write that extends one of the framework's base classes to:

- Augment a built-in feature with additional, generic functionality
- Change how a built-in feature works, or even to
- Workaround a bug you encounter in a generic way

Before you begin to develop application-specific business components, Oracle recommends that you consider creating a complete layer of framework extension classes and set up your project-level preferences to use that layer by default. You might not have any custom code in mind to put in these framework extension classes initially, but this practice will help when customization becomes practical.

This way, substantial inconvenience can be avoided if you discover mid-project that all of your **entity objects**, for example, require a new generic feature, augmented built-in feature, or a generic bug workaround.

> **Note:**
>
> To experiment with the examples in this chapter, use the `SummitADF_Examples` workspace, as described in Running the Standalone Samples from the SummitADF_Examples Workspace. For information about how to obtain and install the Summit ADF standalone sample applications, see Setting Up the Summit Sample Applications for Oracle ADF.

How To Create a Framework Extension Class

When you need to add custom code to extend the base functionality of the ADF Business Components framework, you can enable a custom Java class for any of the key types of business components you create. You enable the generation of custom classes for a component on the Java page of its respective overview editor in JDeveloper. When you enable this option, JDeveloper creates a Java source file for a custom class related to the component whose name follows a configurable naming standard. This class, whose name is recorded in the component's XML document, provides a place where you can write the custom Java code required by that component.

To create a framework extension class:

1. Identify a project to contain the framework extension class.

   You can create it in the same project as your business service components if you believe it will only be used by components in that project. Alternatively, if you believe you might like to reuse the framework extension class across multiple Fusion web applications, create a separate model project to contain the framework extension classes.

2. Ensure that the **BC4J Runtime** library is in the project's libraries list.

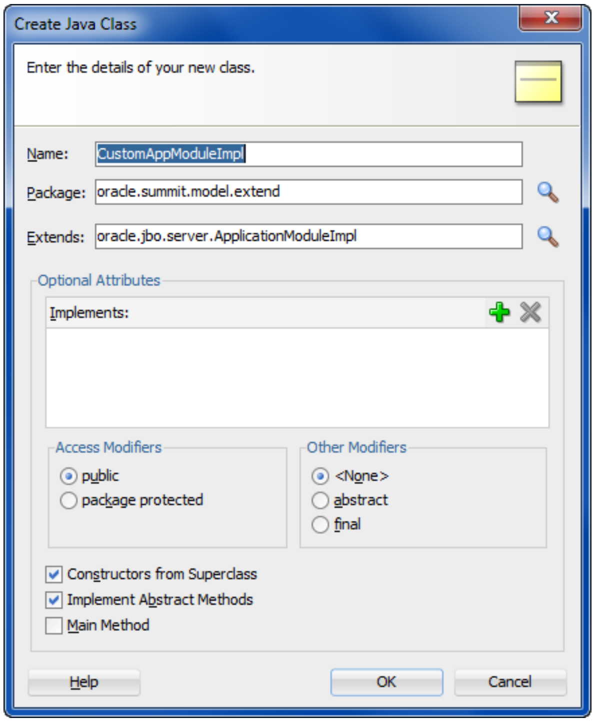
   Use the **Libraries and Classpath** page of the **Project Properties** dialog to verify this and to add the library if missing.

3. In the Applications window, right-click the project in which you want to create the extension class and choose **New** and then **Java Class**.

4. In the Create Java Class dialog, specify the appropriate framework base class from the `oracle.jbo.server` package in the **Extends** field.

   Figure 17-1 illustrates what it would look like to create a custom framework extension class named `CustomAppModuleImpl` in the `com.yourcompany.fwkext` package to customize the functionality of the base **application module** component. To quickly find the base class you're looking for, use the **Browse** button next to the **Extends** field that launches the JDeveloper **Class Browser**. Using its **Search** tab, you can type in part of the class name (including using `*` as a wildcard) to quickly subset the list of classes to find the one you're looking for.

Figure 17-1 Creating a Framework Extension Class for an Application Module



Enter the details of your new class.

Name: CustomAppModuleImpl

Package: oracle.summit.model.extend

Extends: oracle.jbo.server.ApplicationModuleImpl

Optional Attributes

Implements:

Access Modifiers

● public
○ package protected

Other Modifiers

● <None>
○ abstract
○ final

☑ Constructors from Superclass
☑ Implement Abstract Methods
□ Main Method

When you click **OK**, JDeveloper creates the custom framework extension class for you in the directory of the project's source path corresponding to the package name you've chosen.

> **Note:**
>
> Some ADF Business Component classes exist in both a server-side and a remote-client version. For example, if you use the JDeveloper **Class Browser** and type `ApplicationModuleImpl` into the **Match Class Name** field on the **Search** tab, the list will show two `ApplicationModuleImpl` classes: one in the `oracle.jbo.server` package and the other in the `oracle.jbo.client.remote` package. When creating framework extension classes, use the base ADF Business Components classes in the `oracle.jbo.server` package.

What Happens When You Create a Framework Extension Class

After creating a new framework extension class, it will not automatically be used by your application. You must decide which components in your project should make use of it. The following sections describe the available approaches for basing your business components on your own framework extension classes.

What You May Need to Know About Customizing Framework Extension Bases Classes

To make your framework extension layer classes easier to package as a reusable library, create them in a separate project from the projects that use them.

A common set of customized framework base classes in a package name of your own choosing like *com.yourcompany.fwkext*, each importing the oracle.jbo.server.* package, would consist of the following classes:

- public class CustomEntityImpl extends EntityImpl
- public class CustomEntityDefImpl extends EntityDefImpl
- public class CustomViewObjectImpl extends ViewObjectImpl
- public class CustomViewRowImpl extends ViewRowImpl
- public class CustomApplicationModuleImpl extends ApplicationModuleImpl
- public class CustomDBTransactionImpl extends DBTransactionImpl2
- public class CustomDatabaseTransactionFactoryImpl extends DatabaseTransactionFactory

For details about using the custom DBTransactionImpl2 and DatabaseTransactionFactory classes, see Configuring an Application Module to Use a Custom Database Transaction Class.

For completeness, you may also want to create customized framework classes for the following classes as well, note however that overriding anything in these classes would be a fairly rare requirement.

- public class CustomViewDefImpl extends ViewDefImpl
- public class CustomEntityCache extends EntityCache
- public class CustomApplicationModuleDefImpl extends ApplicationModuleDefImpl

How to Base a Business Component on a Framework Extension Class

You can set the base classes for any business component using the **Java** page of any ADF Business Components wizard or editor.

Before you begin:

- Create the framework extension class, as described in How To Create a Framework Extension Class.
- If you created your framework extension classes in a separate project, visit the **Dependencies** page of the Project Properties dialog for the project containing your business components and select **Build Output** to add the framework extension project as a project dependency.
- If you have packaged your framework extension classes in a Java archive (JAR) file, create a named library definition to reference its JAR file and also list that library in the library list of the project containing your business components. To create a library if missing, use the Manage Libraries dialog available from the

Tools > Manage Libraries main menu item. To verify or adjust the project's library list, use the **Libraries** page of the Project Properties dialog.

After you ensure the framework classes are available to reference, you can create the business component. Every ADF Business Components wizard and editor displays the same **Class Extends** button on the **Java** page so you can use the technique to choose your desired framework extension base class(es) both for new components or existing ones.

There is no fixed limit on how many levels of framework extension classes you create. For example, after creating a company-level CustomAppModuleImpl to use for all application modules in all Fusion web applications that your company creates, some later project team might encounter the need to further customize that framework extension class. That team could create a SomeProjectCustomAppModuleImpl class that extends the CustomAppModuleImpl and then include the project-specific custom application module code in there as shown in the following example.

```
public class SomeProjectCustomAppModuleImpl
       extends CustomAppModuleImpl {
  /*
   * Custom application module code specific to the
   * "SomeProject" project goes here.
   */
}
```

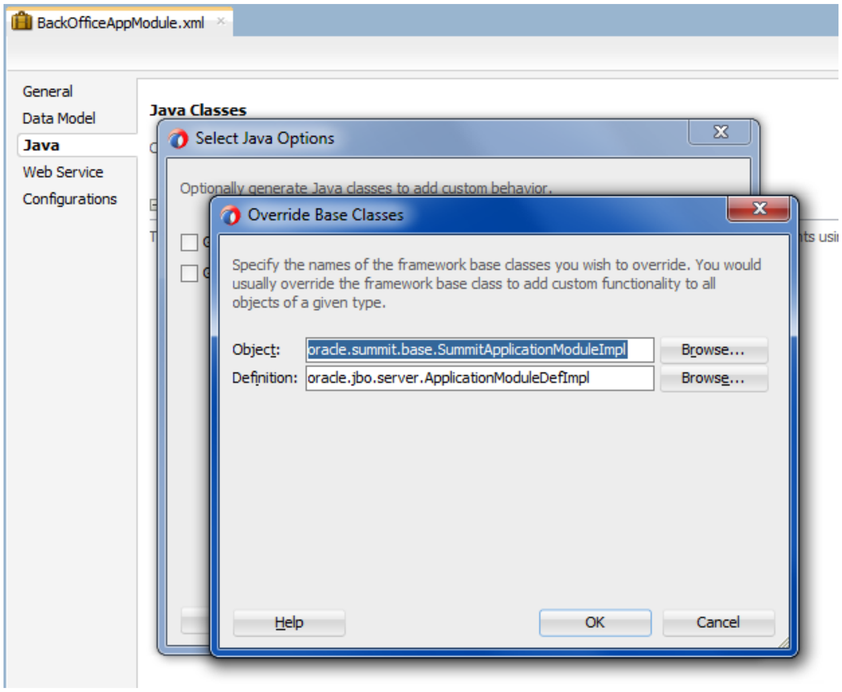
Then, any application modules created as part of the implementation of this specific project can use the SomeProjectCustomAppModuleImpl as their base class instead of the CustomAppModuleImpl.

To create a business component based on a framework extension class:

1. In the Applications window, double-click the desired component.
2. In the overview editor, click the **Java** navigation tab and then click the **Edit Java options** button.
3. In the Select Java Options dialog, click **Classes Extends**.
4. In the Override Base Classes dialog, enter the fully qualified name of the framework base classes you wish to override. You can also use the **Browse** button to use the JDeveloper Class Browser to find the classes quickly.

   When you use the Class Browser to select a custom base class for the component, the list of available classes is automatically filtered to show only classes that are appropriate. For example, when clicking **Browse** in Figure 17-2 to select an application module **Object** base class, the list will only show classes available in the current project's library list which extend the oracle.jbo.server.ApplicationModule class either directly or indirectly. If you don't see the class you're looking for, either you extended the incorrect base class or you have chosen the wrong component class name to override.

Figure 17-2 Specifying a Custom Base Class for a New Application Module



Optionally generate Java classes to add custom behavior.

Specify the names of the framework base classes you wish to override. You would usually override the framework base class to add custom functionality to all objects of a given type.

Object: oracle.summit.base.SummitApplicationModuleImpl

Definition: oracle.jbo.server.ApplicationModuleDefImpl

How to Define Framework Extension Classes for All New Components

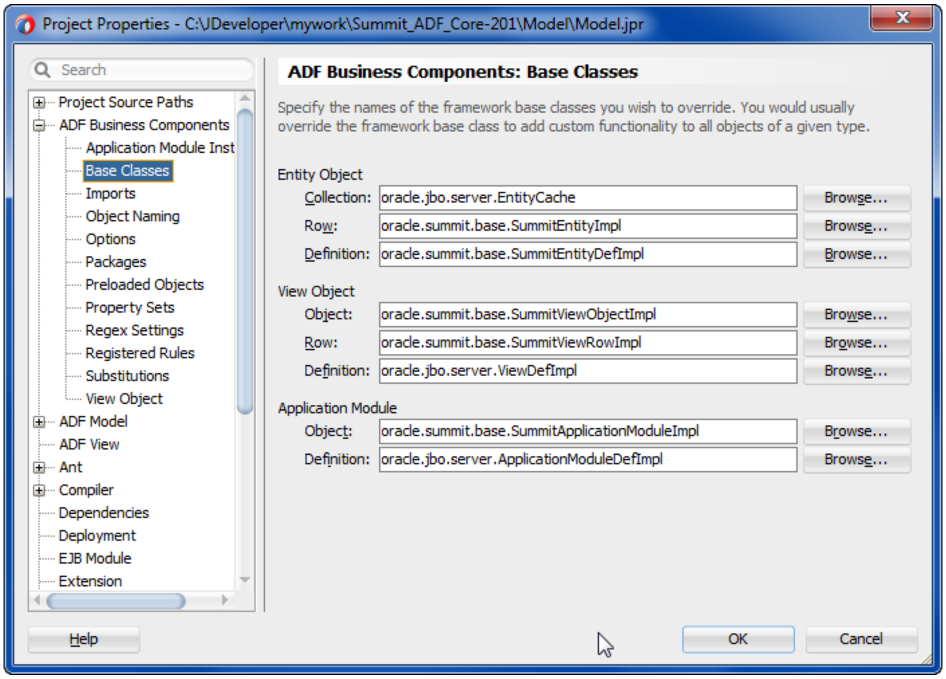
If you decide to use a specific set of framework extension classes as a standard for a given project, you can use the Project Properties dialog to define your preferred base classes for each component type. Setting these preferences for base classes does not affect any existing components in the project, but the component wizards will use the preferences for any new components created.

To define project-level preferences for framework extension classes:

1. In the Applications window, right-click the project that will contain the extension classes and choose **Project Properties**.
2. In the Project Properties dialog, expand **ADF Business Components > Base Classes** and enter the fully qualified name of the base class in the **Application Module Object** class name field.

   For example, to indicate that any new application modules created in the project should use the `CustomAppModuleImpl` class by default, enter the fully qualified name of that class in the ***componentName*** **Object** class name field as shown in Figure 17-3.

Figure 17-3 Setting Project-Level Preferences for Business Component Base Classes



Project Properties - C:\JDeveloper\mywork\Summit_ADF_Core-201\Model\Model.jpr

ADF Business Components: Base Classes

Specify the names of the framework base classes you wish to override. You would usually override the framework base class to add custom functionality to all objects of a given type.

Entity Object
Collection: oracle.jbo.server.EntityCache
Row: oracle.summit.base.SummitEntityImpl
Definition: oracle.summit.base.SummitEntityDefImpl

View Object
Object: oracle.summit.base.SummitViewObjectImpl
Row: oracle.summit.base.SummitViewRowImpl
Definition: oracle.jbo.server.ViewDefImpl

Application Module
Object: oracle.summit.base.SummitApplicationModuleImpl
Definition: oracle.jbo.server.ApplicationModuleDefImpl

How to Define Framework Extension Classes for All New Projects

When you want to apply the same base class preferences to each new project that you create in JDeveloper, you can define the preferences at a global level using the Preferences dialog. Base classes that you specify at the global level will not alter your existing projects containing business components.

To define global preferences for framework extension classes:

1. In the main menu, choose **Tools** and then **Preferences**.
2. In the Preferences dialog, expand **ADF Business Components > Base Classes** in the tree.
3. On the Business Components page, enter the fully qualified name of that class in ***componentName*** **Object** class name field.

   The page displays the same options for specifying the preferred base classes for each component type as shown in How to Define Framework Extension Classes for All New Components.

What Happens When You Base a Component on a Framework Extension Class

When a business component you create extends a custom ADF Business Components framework extension class, JDeveloper updates its XML document to reflect the custom class name you've chosen.

XML-Only Components

For example, assume you've created the YourService application module in the com.yourcompany.yourapp package, with a custom application module base class of CustomAppModuleImpl. If you have opted to leave the component as an XML-only component with no custom Java file, its XML document (YourService.xml) will look similear to the one shown in the following example. The value of the ComponentClass attribute of the AppModule tag is read at runtime to identify the Java class to use to represent the component.

```
<AppModule
   Name="YourService"
   ComponentClass="com.yourcompany.fwkext.CustomAppModuleImpl" >
  <!-- etc. -->
</AppModule>
```

Figure 17-4 illustrates how the XML-only YourService application module relates to your custom extension class. At runtime, it uses the CustomAppModuleImpl class which inherits its base behavior from the ApplicationModuleImpl class.

Figure 17-4 XML-Only Component Reference an Extended Framework Base Class

Your Company Framework Extension Code
Application-Specific Component

Components with Custom Java Classes

If your component requires a custom Java class, as you've seen in previous chapters you open the **Java** page of the component editor and check the appropriate checkbox to enable it. For example, when you enable a custom application module class for the YourServer application module, JDeveloper creates the appropriate YourServiceImpl.java class. As shown in the following example, it also updates the component's XML document to reflect the name of the custom component class.

```
<AppModule
   Name="YourService"
   ComponentClass="com.yourcompany.yourapp.YourServiceImpl" >
  <!-- etc. -->
</AppModule>
```

JDeveloper also updates the component's custom Java class to modify its extends clause to reflect the new custom framework base class, as shown in the following example.

```
package com.yourcompany.yourapp;
import com.yourcompany.fwkext.CustomAppModuleImpl;
// ---------------------------------------------------------------------
// ---    File generated by Oracle ADF Business Components Design Time.
// ---    Custom code may be added to this class.
// ---    Warning: Do not modify method signatures of generated methods.
// ---------------------------------------------------------------------
public class YourServiceImpl extends CustomAppModuleImpl {
  /**This is the default constructor (do not remove)   */
  public YourServiceImpl() {}
  // etc.
}
```

Figure 17-5 illustrates how the `YourService` application module with its custom `YourServiceImpl` class is related to your framework extension class. At runtime, it uses the `YourServiceImpl` class which inherits its base behavior from the `CustomAppModuleImpl` framework extension class which, in turn, extends the base `ApplicationModuleImpl` class.

What You May Need to Know About Updating the Extends Clause in Custom Component Java Files

If you have a business component with a custom Java class and later decide to base the component on an ADF Business Components framework extension class, use the **Class Extends** button in the Select Java Options dialog to change the component's base class. You can open the dialog from the **Java** page of the component's overview editor. Doing this updates the component's XML document to reflect the new base class, and *also* modifies the `extends` clause in the component's custom Java class.

> **Note:**
>
> If you manually update the `extends` clause without using the component editor, the component's XML document will not reflect the new inheritance and the next time you open the editor, your manually modified `extends` clause will be overwritten with what the component editor believes is the correct component base class.

How to Package Your Framework Extension Layer in a JAR File

Use the **Create Deployment Profile: JAR File** dialog to create a JAR file containing the classes in your framework extension layer. This is available in the **New Gallery** in the **General > Deployment Profiles** category.

Give the deployment profile a name like `FrameworkExtensions` and click **OK**. By default the JAR file will include all class files in the project. Since this is exactly what you want, when the **JAR Deployment Profile Properties** dialog appears, you can just click **OK** to finish.

> **Note:**
>
> Do not use the **ADF Library JAR** archive type to package your framework extension layer. You create the ADF Library JAR file when you want to package reusable components to share in the JDeveloper Resource Catalog. For details about working with business components and the ADF Library JAR archive type, see Packaging a Reusable ADF Component into an ADF Library.

Finally, to create the JAR file, right-click the project node in the Applications window and choose **Deploy** - ***YourProfileName*** - **to JAR File** on the context menu. A **Deployment** tab appears in the JDeveloper **Log window** that should display feedback like:

```
----  Deployment started.  ----    Feb 14, 2013 1:42:39 PM
Running dependency analysis...
Wrote JAR file to ...\FrameworkExtensions\deploy\FrameworkExtensions.jar
Elapsed time for deployment:  2 seconds
----  Deployment finished.  ----    Reb 14, 2013 1:42:41 PM
```

How to Create a Library Definition for Your Framework Extension JAR File

JDeveloper uses named libraries as a convenient way to organize the one or more JAR files that comprise reusable component libraries.

To define a library for your framework extensions JAR file:

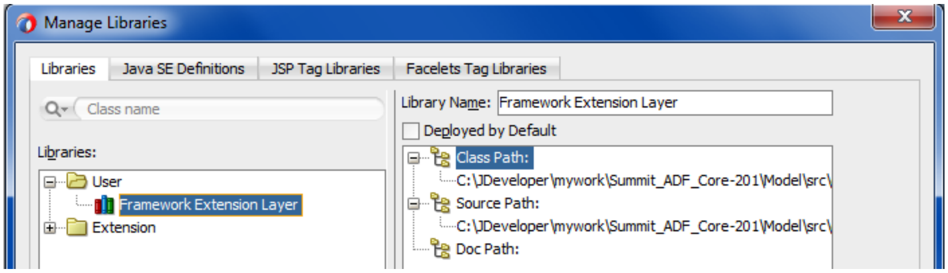
1. In the main menu, choose **Tools** and then **Manage Libraries**.

2. In the **Manage Libraries** dialog, select the **Libraries** tab and then select **User** and click **New**.
3. In the **Create Library** dialog that appears, name the library "Framework Extension Layer" and select the **Class Path** node and click **Add Entry**.
4. Use the **Select Path Entry** dialog to select the JAR file that contains the class files for the framework extension components, then click **Select**.
5. Select the **Source Path** node and click **Add Entry.**
6. Use the **Select Path Entry** dialog that appears to select the directory where the source files for the framework extension classes reside, then click **Select**.

   For example, select `..\FrameworkExtensions\src` for the JAR file `FrameworkExtensions.jar`.
7. Click **OK**.

When finished, you will see your new "Framework Extension Layer" user-defined library, as shown in Figure 17-6. You can then add this library to the library list of any project where you will be building business services, and your custom framework extension classes will be available to reference as the preferred component base classes.

Figure 17-6 New User-Defined Library for Your Framework Extensions Layer



Library Name: Framework Extension Layer

□ Deployed by Default

Class Path:
C:\JDeveloper\mywork\Summit_ADF_Core-201\Model\src\

Customizing Framework Behavior with Extension Classes

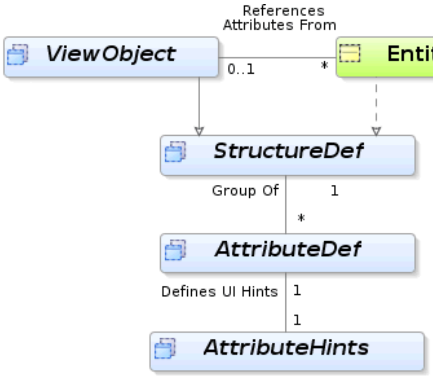
ADF Business Components framework extension code is utilized by all components of a specific type. Use ADF Business Components APIs to access component meta-data at runtime within the code, to write generic functionality.

One of the common tasks you'll perform in your framework extension classes is implementing custom application functionality. Since framework extension code is written to be used by all components of a specific type, the code you write in these classes often needs to work with component attributes in a generic way. To address this need, ADF Business Components provides API's that allow you to access component metadata at runtime. It also provides the ability to associate custom metadata properties with any component or attribute. You can write your generic framework extension code to leverage runtime metadata and custom properties to build generic functionality, which if necessary, only is used in the presence of certain custom properties.

How to Access Runtime Metadata For View Objects and Entity Objects

Figure 17-7 illustrates the three primary interfaces ADF Business Components provides for accessing runtime metadata about **view objects** and entity objects. The `ViewObject` interface extends the `StructureDef` interface. The class representing the entity definition (`EntityDefImpl`) also implements this interface. As its name implies, the `StructureDef` defines the structure and the component and provides access to a collection of `AttributeDef` objects that offer runtime metadata about each attribute in the view object row or entity row. Using an `AttributeDef`, you can access its companion `AttributeHints` object to reference hints like the display label, format mask, tooltip, etc.

Figure 17-7 Runtime Metadata Available for View Objects and Entity Objects



How to Implement Generic Functionality Using Runtime Metadata

In ViewObject Interface Methods for Working with the View Object's Default RowSet you learned that for read-only view objects the `findByKey()` method and the `setCurrentRowWithKey` builtin operation only work if you override the `create()` method on the view object to call `setManageRowsByKey(true)`. This can be a tedious detail to remember if you create a lot of read-only view objects, so it is a great candidate for automating in a framework extension class for view objects.

Assume a `FrameworkExtensions` project contains a `SummitViewObjectImpl` class that is the base class for all view objects in the application. This framework extension class for view objects extends the base `ViewObjectImpl` class and overrides the `create()` method as shown in the following example to automate this task. After calling the `super.create()` to perform the default framework functionality when a view object instance is created at runtime, the code tests whether the view object is a read-only view object with at least one attribute marked as a key attribute. If this is the case, it invokes `setManageRowsByKey(true)`.

The `isReadOnlyNonEntitySQLViewWithAtLeastOneKeyAttribute()` helper method determines whether the view object is read-only by testing the combination of the following conditions:

- `isFullSql()` is `true`

This method returns true if the view object's SQL query is completely specified by the developer, as opposed to having the select list derived automatically based on the participating entity usages.

- `getEntityDefs()` is `null`

  This method returns an array of `EntityDefImpl` objects representing the view object's entity usages. If it returns `null`, then the view object has no entity usages.

It goes on to determine whether the view object has any key attributes by looping over the `AttributeDef` array returned by the `getAttributeDefs()` method. If the `isPrimaryKey()` method returns true for any attribute definition in the list, then you know the view object has a key.

```
public class SummitViewObjectImpl extends ViewObjectImpl {
  protected void create() {
    super.create();
    if (isReadOnlyNonEntitySQLViewWithAtLeastOneKeyAttribute()) {
      setManageRowsByKey(true);
    }
  }
  boolean isReadOnlyNonEntitySQLViewWithAtLeastOneKeyAttribute() {
    if (getViewDef().isFullSql() && getEntityDefs() == null) {
      for (AttributeDef attrDef : getAttributeDefs()) {
        if (attrDef.isPrimaryKey()) {
          return true;
        }
      }
    }
    return false;
  }
  // etc.
}
```

How to Implement Generic Functionality Driven by Custom Properties

When you create application modules, view objects, and entity objects you can select the **General** navigation tab in the overview editor for these business components and expand the **Custom Properties** section to define custom metadata properties for any component. These are name/value pairs that you can use to communicate additional declarative information about the component to the generic code that you write in framework extension classes. You can use the `getProperty()` method in your code to conditionalize generic functionality based on the presence of, or the specific value of, one of these custom metadata properties.

For example, the `SummitViewObjectImpl` framework extension class overrides the view object's `insertRow()` method as shown in the following example to conditionally force a row to be inserted and to appear as the last row in the row set. If any view object extending this framework extension class defines a custom metadata property named `InsertNewRowsAtEnd`, then this generic code executes to insert new rows at the end. If a view object does not define this property, it will have the default `insertRow()` behavior.

```
public class SummitViewObjectImpl extends ViewObjectImpl {
  private static final String INSERT_NEW_ROWS_AT_END = "InsertNewRowsAtEnd";
  public void insertRow(Row row) {
    super.insertRow(row);
    if (getProperty(INSERT_NEW_ROWS_AT_END) != null) {
      row.removeAndRetain();
```

```
        last();
        next();
        getDefaultRowSet().insertRow(row);
      }
    }
    // etc.
  }
```

In addition to defining component-level custom properties, you can also define properties on view object attributes, entity object attributes, and domains. At runtime, you access them using the `getProperty()` method on the `AttributeDef` interface for a given attribute.

What You May Need to Know About the Kinds of Attributes

In addition to providing information about an attribute's name, Java type, SQL type, and many other useful pieces of information, the `AttributeDef` interface contains the `getAttributeKind()` method that you can use to determine the kind of attribute it represents. This method returns a `byte` value corresponding to one of the public constants in the `AttributeDef` interface listed in Table 17-1.

Table 17-1 Entity Object and View Object Attribute Kinds

Public `AttributeDef` Constant	Attribute Kind Description
`ATTR_PERSISTENT`	Persistent attribute
`ATTR_TRANSIENT`	Transient attribute
`ATTR_ENTITY_DERIVED`	View object attribute mapped to an entity-level transient attribute
`ATTR_SQL_DERIVED`	SQL-Calculated attribute
`ATTR_DYNAMIC`	Dynamic attribute
`ATTR_ASSOCIATED_ROWITERATOR`	Accessor attribute returning a `RowSet` of set of zero or more `Rows`
`ATTR_ASSOCIATED_ROW`	Accessor attribute returning a single `Row`

What You May Need to Know About Custom Properties

You may find it handy to programmatically set custom property values at runtime. While the `setProperty()` API to perform this function is by design not available to clients on the `ViewObject`, `ApplicationModule`, or `AttributeDef` interfaces in the `oracle.jbo` package, code that you write *inside* custom Java classes of your business components can use it.

Creating Generic Extension Interfaces

ADF Business Components allows you to create custom interfaces that all components can implement. It helps for example, to expose methods from an application module.

In addition to creating framework extension classes, you can create custom interfaces that all of your components can implement by default. The client interface is very useful for exposing methods from your application module that might be invoked by UI clients, for example. This section considers an example for an application module, however, the same functionality is possible for a custom extended view object and view row interface as well. For information about client interfaces, see Publishing Custom Service Methods to UI Clients and Working Programmatically with an Application Module's Client Interface.

Assume that you have a `CustomApplicationModuleImpl` class that extends `ApplicationModuleImpl` and that you want to expose two custom methods like this:

```
public void doFeatureOne(String arg);
public int anotherFeature(String arg);
```

Perform the following steps to create a custom extension interface `CustomApplicationModule` and have your `CustomApplicationModuleImpl` class implement it.

1. Create a custom interface that contains the methods you would like to expose globally on your application module components. For this scenario, that interface would look like this:

   ```
   package devguide.advanced.customintf.fwkext;
   /**
    * NOTE: This does not extend the
    * ====  oracle.jbo.ApplicationModule interface.
    */
   public interface CustomApplicationModule  {
     public void doFeatureOne(String arg);
     public int anotherFeature(String arg);
   }
   ```

   Notice that the interface does *not* extend the `oracle.jbo.ApplicationModule` interface.

2. Modify your `CustomApplicationModuleImpl` application module framework extension class to implement this new `CustomApplicationModule` interface.

   ```
   package devguide.advanced.customintf.fwkext;
   import oracle.jbo.server.ApplicationModuleImpl;
   public class CustomApplicationModuleImpl
          extends ApplicationModuleImpl
          implements CustomApplicationModule {
     public void doFeatureOne(String arg) {
       System.out.println(arg);
     }
     public int anotherFeature(String arg) {
       return arg == null ? 0 : arg.length();
     }
   }
   ```

3. Rebuild your project.

   The ADF Business Components overview editors will only "see" your interfaces after they have been successfully compiled.

After you have implemented your `CustomApplicationModuleImpl` class, you can create a new application module which exposes the global extension interface and is based on your custom framework extension class. For this purpose you use the overview editor for application modules.

To create a custom application module interface:

1. In the Applications window, double-click the application module for which you want to create the custom interface.

   For example, you might create a new `ProductModule` application module which exposes the global extension interface `CustomApplicationModule` and is based on the `CustomApplicationModuleImpl` framework extension class.

2. In the overview editor, select the **Java** navigation tab and then click the **Edit Java options** icon.

   The Java Classes page should show an existing Java class for the application module identified as **Application Module Class**.

   By default, JDeveloper generates the Java class for application modules you create. However, if you disabled this feature, click the **Edit Java options** button in the Java Classes section and select **Generate Application Module Class**. Click **OK** to add a Java class to the project from which you will create the custom interface.

3. In the Select Java Options dialog, click **Class Extends**.

4. In the Override Base Classes dialog, specify the name of the framework base class you want to override and click **OK**.

   For example, you might select `CustomApplicationModuleImpl` as the base class for the application module.

5. In the Java Classes page of the overview editor, expand the **Client Interface** section and click the **Edit application module client interface** button.

6. In the Edit Client Interface dialog, click the **Interfaces** button.

7. In the Select Interfaces to Extend dialog, select the desired custom application module interface from the available list and click **OK**.

   For example, you might shuttle the `CustomApplicationModule` interface to the **Selected** list to be one of the custom interfaces that clients can use with your component.

8. In the Edit Client Interfaces dialog, ensure that at least one method appears in the **Selected** list.

   > **Note:**
   >
   > You need to select at least one method in the **Selected** list in the Edit Client Interfaces dialog, even if it means redundantly selecting one of the methods on the global extension interface. Any method will do in order to get JDeveloper to generate the custom interface.

9. Click **OK**.

   The Java Classes page displays the new custom interface for the application module identified as **Application Module Client Interface**.

When you dismiss the Edit Client Interfaces dialog and return to the application module overview editor, JDeveloper generates the application module custom interface. For example, the custom interface `ProductModule` automatically extends *both* the base `ApplicationModule` interface and your `CustomApplicationModule` extension interface like this:

```
package devguide.advanced.customintf.common;
import devguide.advanced.customintf.fwkext.CustomApplicationModule;

import oracle.jbo.ApplicationModule;
// ---------------------------------------------------------------------
// ---    File generated by ADF Business Components Design Time.
// ---------------------------------------------------------------------
public interface ProductModule
       extends CustomApplicationModule, ApplicationModule {
  void doSomethingProductRelated();
}
```

Once you've done this, then client code can cast your `ProductModule` application module to a `CustomApplicationModule` interface and invoke the generic extension methods it contains in a strongly typed way.

> **Note:**
>
> The basic steps are the same for exposing methods on a `ViewObjectImpl` framework extension class, as well as for a `ViewRowImpl` extension class.

Invoking Stored Procedures and Functions

You can write custom code in the custom Java classes of ADF Business Components to invoke database stored procedures and functions.

You can write code in the custom Java classes for your business components to invoke database stored procedures and functions. Here you'll consider some simple examples based on procedures and functions in a PL/SQL package; however, using the same techniques, you also can invoke procedures and functions that are not part of a package.

Consider the PL/SQL package shown in the following example.

```
create or replace package invokestoredprocpkg as
  procedure proc_with_no_args;
  procedure proc_with_three_args(n number, d date, v varchar2);
  function  func_with_three_args(n number, d date, v varchar2) return varchar2;
  procedure proc_with_out_args(n number, d out date, v in out varchar2);
end invokestoredprocpkg;
```

The following sections explain how to invoke each of the example procedures and functions in this package.

> **Note:**
>
> The example in this section refers to the `oracle.summit.model.invokingstoredprocedure` package in the `SummitADF_Examples` application workspace.

How to Invoke Stored Procedures with No Arguments

If you need to invoke a stored procedure that takes no arguments, you can use the `executeCommand()` method on the `DBTransaction` interface (in the `oracle.jbo.server` package as shown in the following example.

```
// In InvokingStoredProcAppModuleImpl.java
public void callProcWithNoArgs() {
  getDBTransaction().executeCommand(
    "begin invokestoredprocpkg.proc_with_no_args; end;");
}
```

How to Invoke Stored Procedure with Only IN Arguments

Invoking stored procedures that accept only `IN`-mode arguments — which is the default PL/SQL parameter mode if not specified — requires using a JDBC `PreparedStatement` object. The `DBTransaction` interface provides a `createPreparedStatement()` method to create this object for you in the context of the current database connection. You could use a helper method like the one shown in the following example to simplify the job of invoking a stored procedure of this kind using a `PreparedStatement`. Importantly, by using a helper method, you can encapsulate the code that closes the JDBC `PreparedStatement` after executing it. The code performs the following basic tasks:

1. Creates a JDBC `PreparedStatement` for the statement passed in, wrapping it in a PL/SQL `begin`...`end` block.
2. Loops over values for the bind variables passed in, if any.
3. Sets the value of each bind variable in the statement.

   Notice that since JDBC bind variable API's use one-based numbering, the code adds one to the zero-based for loop index variable to account for this.
4. Executes the statement.
5. Closes the statement.

```
protected void callStoredProcedure(String stmt, Object[] bindVars) {
  PreparedStatement st = null;
  try {
    // 1. Create a JDBC PreparedStatement for
    st = getDBTransaction().createPreparedStatement("begin "+stmt+";end;",0);
    if (bindVars != null) {
      // 2. Loop over values for the bind variables passed in, if any
      for (int z = 0; z < bindVars.length; z++) {
        // 3. Set the value of each bind variable in the statement
        st.setObject(z + 1, bindVars[z]);
      }
    }
    // 4. Execute the statement
    st.executeUpdate();
  }
  catch (SQLException e) {
    throw new JboException(e);
  }
  finally {
    if (st != null) {
      try {
        // 5. Close the statement
        st.close();
      }
      catch (SQLException e) {}
    }
  }
}
```

With a helper method like this in place, calling the `proc_with_three_args` procedure shown in the previous example would look like this:

```
// In StoredProcTestModuleImpl.java
public void callProcWithThreeArgs(Number n, Date d, String v) {
  callStoredProcedure("callStoredProcedure.proc_with_three_args(?,?,?)",
                      new Object[]{n,d,v});
}
```

Notice the question marks used as JDBC bind variable placeholders for the arguments passed to the function. JDBC also supports using named bind variables, but using these simpler positional bind variables is also fine since the helper method is just setting the bind variable values positionally.

How to Invoke Stored Function with Only IN Arguments

Invoking stored functions that accept only `IN`-mode arguments requires using a JDBC `CallableStatement` object in order to access the value of the function result after executing the statement. The `DBTransaction` interface provides a `createCallableStatement()` method to create this object for you in the context of the current database connection. You could use a helper method like the one shown in the following example to simplify the job of invoking a stored function of this kind using a `CallableStatement`. The helper method encapsulates both the creation and clean up of the JDBC statement being used.

The code performs the following basic tasks:

1. Creates a JDBC `CallableStatement` for the statement passed in, wrapping it in a PL/SQL `begin`...`end` block.
2. Registers the first bind variable for the function return value.
3. Loops over values for the bind variables passed in, if any.
4. Sets the value of each user-supplied bind variable in the statement.

   Notice that since JDBC bind variable API's use one-based numbering, and since the function return value is already the first bind variable in the statement, the code adds *two* to the zero-based for loop index variable to account for these.
5. Executes the statement.
6. Returns the value of the first bind variable.
7. Closes the statement.

```
// Some constants
public static int NUMBER = Types.NUMERIC;
public static int DATE = Types.DATE;
public static int VARCHAR2 = Types.VARCHAR;

protected Object callStoredFunction(int sqlReturnType, String stmt,
                                    Object[] bindVars) {
```

```
  CallableStatement st = null;
  try {
    // 1. Create a JDBC CallabledStatement
    st = getDBTransaction().createCallableStatement(
           "begin ? := "+stmt+";end;",0);
    // 2. Register the first bind variable for the return value
    st.registerOutParameter(1, sqlReturnType);
    if (bindVars != null) {
      // 3. Loop over values for the bind variables passed in, if any
      for (int z = 0; z < bindVars.length; z++) {
        // 4. Set the value of user-supplied bind vars in the stmt
        st.setObject(z + 2, bindVars[z]);
      }
    }
    // 5. Set the value of user-supplied bind vars in the stmt
    st.executeUpdate();
    // 6. Return the value of the first bind variable
    return st.getObject(1);
  }
  catch (SQLException e) {
    throw new JboException(e);
  }
  finally {
    if (st != null) {
      try {
        // 7. Close the statement
        st.close();
      }
      catch (SQLException e) {}
    }
  }
}
```

With a helper method like this in place, calling the `func_with_three_args` procedure shown in the previous example would look like this:

```
// In InvokingStoredProcAppModuleImpl.java
public String callFuncWithThreeArgs(Number n, Date d, String v) {
  return (String)callStoredFunction(VARCHAR2,
                           "invokestoredprocpkg.func_with_three_args(?,?,?)",
                           new Object[]{n,d,v});
}
```

Notice the question marks are used as JDBC bind variable placeholders for the arguments passed to the function. JDBC also supports using named bind variables, but using these simpler positional bind variables is also fine since the helper method is just setting the bind variable values positionally.

How to Call Other Types of Stored Procedures

Calling a stored procedure or function like `invokestoredprocpkg.proc_with_out_args` that includes arguments of `OUT` or `IN OUT` mode requires using a `CallableStatement` as in the previous section, but is a little more challenging to generalize into a helper method. The following example illustrates the JDBC code necessary to invoke the `invokestoredprocpkg.proc_with_out_args` procedure.

The code performs the following basic tasks:

1. Defines a PL/SQL block for the statement to invoke.

2. Creates the `CallableStatement` for the PL/SQL block.
3. Registers the positions and types of the `OUT` parameters.
4. Sets the bind values of the `IN` parameters.
5. Executes the statement.
6. Creates a JavaBean to hold the multiple return values

   The `DateAndStringBean` class contains bean properties named `dateVal` and `stringVal`.
7. Sets the value of its `dateVal` property using the first `OUT` param.
8. Sets value of its `stringVal` property using second `OUT` param.
9. Returns the result.
10. Closes the JDBC `CallableStatement`.

```
public DateAndStringBean callProcWithOutArgs(Number n, String v) {
  CallableStatement st = null;
  try  {
    // 1. Define the PL/SQL block for the statement to invoke
    String stmt = "begin invokestoredprocpkg.proc_with_out_args(?,?,?); end;";
    // 2. Create the CallableStatement for the PL/SQL block
    st = getDBTransaction().createCallableStatement(stmt,0);
    // 3. Register the positions and types of the OUT parameters
    st.registerOutParameter(2,Types.DATE);
    st.registerOutParameter(3,Types.VARCHAR);
    // 4. Set the bind values of the IN parameters
    st.setObject(1,n);
    st.setObject(3,v);
    // 5. Execute the statement
    st.executeUpdate();
    // 6. Create a bean to hold the multiple return values
    DateAndStringBean result = new DateAndStringBean();
    // 7. Set value of dateValue property using first OUT param
    result.setDateVal(new Date(st.getDate(2)));
    // 8. Set value of stringValue property using 2nd OUT param
    result.setStringVal(st.getString(3));
    // 9. Return the result
    return result;
  } catch (SQLException e)  {
    throw new JboException(e);
  } finally  {
    if (st != null) {
      try {
        // 10. Close the JDBC CallableStatement
        st.close();
      }
      catch (SQLException e) {}
    }
  }
}
```

The `DateAndString` bean used in the previous example is a simple JavaBean with two bean properties like this:

```
package oracle.summit.model.invokingstoredprocedure;

import java.io.Serializable;
import oracle.jbo.domain.Date;

public class DateAndStringBean implements Serializable {
  Date dateVal;
  String stringVal;
  public void setDateVal(Date dateVal) {this.dateVal=dateVal;}
  public Date getDateVal() {return dateVal;}
  public void setStringVal(String stringVal) {this.stringVal=stringVal;}
  public String getStringVal() {return stringVal;}
}
```

> **Note:**
>
> In order to allow the custom method to be a legal candidate for inclusion in an application module's custom service interface (if desired), the bean needs to implement the `java.io.Serializable`. interface. Since this is a "marker" interface, this involves simply adding the `implements Serializable` keywords without needing to code the implementation of any interface methods.

Accessing the Current Database Transaction

When trying to integrate third-party code with ADF Business Components, use a helper method to access the JDBC Connection object.

Since ADF Business Components abstracts all of the lower-level database programming details for you, you typically won't need *direct* access to the JDBC `Connection` object. There is no guarantee at runtime that your application will use the exact same **application module instance** or JDBC `Connection` instance across different web page requests. Since inadvertently holding a reference to the JDBC Connection object in this type of pooled services environment can cause unpredictable behavior at runtime, by design, ADF Business Components has no direct API to obtain the JDBC `Connection`. This is an intentional attempt to discourage its direct use and inadvertent abuse.

However, on occasion it may come in handy when you're trying to integrate third-party code with ADF Business Components, so you can use a helper method like the one shown in the following example to access the connection.

```
/**
 * Put this method in your XXXImpl.java class where you need
 * to access the current JDBC connection
 */
private Connection getCurrentConnection() throws SQLException {
 /* Note that we never execute this statement, so no commit really happens */
 PreparedStatement st = getDBTransaction().createPreparedStatement("commit",1);
 Connection conn = st.getConnection();
 st.close();
 return conn;
}
```

Caution:

Never cache the JDBC connection obtained using the helper method from the above example anywhere in your own code. Instead, call the helper method for each connection to avoid inadvertently holding a reference to a JDBC connection that might be used in a later request by another user. Due to the pooled services nature of the Oracle ADF runtime environment, you must not close the reference you are holding; however, do ensure that you close your statement.

Customizing Business Components Error Messages

You can use ADF Business Components custom message bundle to provide an alternative message string for an error code. This way, you can customize in-built error messages.

You can customize any of the builtin ADF Business Components error messages by providing an alternative message string for the error code in a custom message bundle.

Note:

The example in this section refers to the `oracle.summit.model.custommessages` package in the `SummitADF_Examples` application application workspace.

How to Customize Base ADF Business Components Error Messages

Assume you want to customize the builtin error message:

```
JBO-27014: Attribute OrderFilled in SOrd is required
```

If you have requested the Oracle Application Development Framework (Oracle ADF) source code from Oracle Worldwide Support, you can look in the `CSMessageBundle.java` file in the `oracle.jbo` package to see that this error message is related to the combination of the following lines in that message bundle file:

```
public class CSMessageBundle extends CheckedListResourceBundle {
  // etc.
  public static final String EXC_VAL_ATTR_MANDATORY = "27014";
  // etc.
  private static final Object[][] sMessageStrings = {
    // etc.
    {EXC_VAL_ATTR_MANDATORY, "Attribute {2} in {1} is required"},
    // etc.
  }
}
```

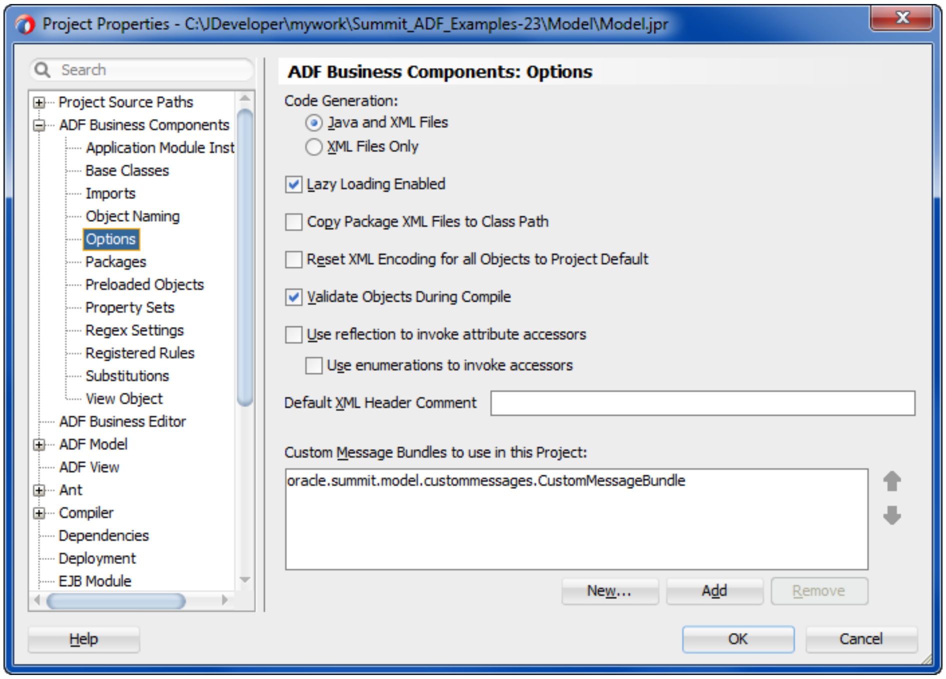
The numbered tokens `{2}` and `{1}` are error message placeholders. In this example the `{l}` is replaced at runtime with the name of the entity object and the `{2}` with the name of the attribute.

To create a custom message bundle file:

1. In the Applications window, right-click the project that you want to add the message bundle file to and choose **Project Properties**.
2. In the Project Properties dialog, select **Business Components > Options** and click **New**.
3. In the Create MessageBundle Class dialog, enter a name and package for the custom message bundle and click **OK**.

> **Note:**
>
> If the fully qualified name of your custom message bundle file does not appear in the **Custom Message Bundles to use in this Project** list, click the **Remove** button, then click the **Add** button to add the new message bundle file created. When the custom message bundle file is correctly registered, its fully qualified class name should appear in the list, as shown in Figure 17-8.

Figure 17-8 Project Properties Displays Message Resource Bundles



Project Properties - C:\JDeveloper\mywork\Summit_ADF_Examples-23\Model\Model.jpr

ADF Business Components: Options

Code Generation:
● Java and XML Files
○ XML Files Only

☑ Lazy Loading Enabled

☐ Copy Package XML Files to Class Path

☐ Reset XML Encoding for all Objects to Project Default

☑ Validate Objects During Compile

☐ Use reflection to invoke attribute accessors

☐ Use enumerations to invoke accessors

Default XML Header Comment

Custom Message Bundles to use in this Project:

oracle.summit.model.custommessages.CustomMessageBundle

4. In the Project Properties dialog, click **OK** to dismiss the **Project Properties** dialog and open the new custom message bundle class in the source editor.
5. Edit the two-dimensional `String` array in the custom message bundle class to contain any customized messages you'd like to use.

   The followig sample llustrates a custom message bundle class that overrides the error message string for the `JBO-27014` error to inform the user that a value must be provided for the named attribute. A second custom error message displays when a database constraint with the name `ORD_ORDER_FILLED_CK` is violated to inform the user of the expected Order Filled value. For more details about customizing error messages for constraints, see How to Customize Error Messages for Database Constraint Violations.

```
package oracle.summit.model.custommessages;

import java.util.ListResourceBundle;

public class CustomMessageBundle extends ListResourceBundle {
  private static final Object[][] sMessageStrings
    = new String[][] {
       {"27014","You must provide a value for {2}"},
       {"S_ORD_ORDER_FILLED_CK", "The order filled value must be Y or N"}
     };

  /* Return String Identifiers and corresponding Messages in a
   * two-dimensional array.
   */
  protected Object[][] getContents() {
    return sMessageStrings;
  }
}
```

What Happens When You Customize Base ADF Business Components Error Messages

After adding this message to your custom message bundle file, if you test the application using the Oracle ADF Model Tester and try to blank out the value of a mandatory attribute, you'll now see your custom error message instead of the default one:

```
JBO-27014: You must provide a value for Order Filled
```

You can add as many messages to the message bundle as you want. Any message whose error code key matches one of the built-in error message codes will be used at runtime instead of the default one in the `oracle.jbo.CSMessageBundle` message bundle.

How to Display Customize Error Messages as Nested Exceptions

When you customize ADF Business Components error messages, you will also need to customize the display of nested error messages. To accomplish this, you must create and register a custom error handler class.

When your business method throws an error, the ADF Model data binding layer intercepts the error and invokes the registered custom error handler class. In general, the error handler class is responsible for formatting the exception to be readable. During this process, the default error handler `DCErrorHandlerImpl` normally skips the top-level `JboException`, as this object is a wrapper over other business exceptions and does not have any business significance.

Although skipping the top-level exception is the desired behavior in the case of ADF Business Components errors, the default behavior will result in skipping the custom message you set for replacing the `SQLException`. To avoid this situation, while displaying each item in a nested exception, your custom error handler class must override `DCErrorHandlerImpl::skipException(Exception *ex*)` to decide whether to display the corresponding exception to the user in the final list or not.

Before you begin:

It may be helpful to have an understanding of application modules. For more information, see Customizing Business Components Error Messages.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Extending Business Components.

You will need to complete this task:

> Create the error message in the resource bundle, as described in How to Customize Base ADF Business Components Error Messages.

To provide custom messages for SQLExceptions in your project:

1. Create an error handler class that extends the default error handler `DCErrorHandlerImpl` interface provided by the ADF Model data binding layer.
2. In the error handler class, override the default error handler behavior for the `DCErrorHandlerImpl::skipException(Exception *ex*)` method, as shown in the following example.

   This overridden method is necessary to display each item in a nested exception, such as the ones returned for database-level error messages. You must implement logic to check for specifics exception types and, based on the business scenario, determine whether to display it in the list.
3. You can then register the custom error handler in your project's `DataBindings.cpx` file, as described in Customizing Error Handling.

The following example shows a custom implementation of the error handler that skips the `SQLIntegrityConstraintViolationException` from displaying in the error final list displayed to the user. You can choose to skip other database-level error message resulting from errors, such as unique constraint violations or foreign key constraint violations.

```
package view;

import java.sql.SQLIntegrityConstraintViolationException;

import oracle.adf.model.BindingContext;
import oracle.adf.model.RegionBinding;
import oracle.adf.model.binding.DCBindingContainer;
import oracle.adf.model.binding.DCErrorHandlerImpl;

import oracle.adf.model.binding.DCErrorMessage;

import oracle.jbo.DMLConstraintException;
import oracle.jbo.JboException;

public class CustomErrorHandler extends DCErrorHandlerImpl {

    public CustomErrorHandler() {
        super();
    }

    /**
     * If an exception is a RowValException or a TxnValException
     * and they have nested exceptions, then do not display
     * it.
     */
    @Override
    protected boolean skipException(Exception ex) {

        if (ex instanceof DMLConstraintException) {
            return false;
        } else if (ex instanceof SQLIntegrityConstraintViolationException) {
            return true;
        }
        return super.skipException(ex);
    }
)
```

How to Customize Error Messages for Database Constraint Violations

If you enforce constraints in the database, you might want to provide a custom error message in your Fusion web application to display to the end user when one of those constraints is violated. For example, assume a constraint called S_ORD_ORDER_FILLED_CK gets added to the application's S_ORD table using the following DDL statement shown in the following example.

```
alter table s_ord add (
  constraint S_ORD_ORDER_FILLED_CK
      check (ORDER_FILLED IN ('Y', 'N'))
);
```

To define a custom error message in your application, you add a message to a custom message bundle with the constraint name as the message key. The following example shows the CustomMessageBundle.java class when it defines a message with the key S_ORD_ORDER_FILLED_CK which matches the name of the database constraint name defined in previous example.

```
package oracle.summit.model.custommessages;

import java.util.ListResourceBundle;

public class CustomMessageBundle extends ListResourceBundle {
  private static final Object[][] sMessageStrings
    = new String[][] {
       {"27014","You must provide a value for {2}"},
       {"S_ORD_ORDER_FILLED_CK", "The order filled value must be Y or N"}
     };

  protected Object[][] getContents() {
    return sMessageStrings;
  }
}
```

How to Implement a Custom Constraint Error Handling Routine

If the default facility for assigning a custom message to a database constraint violation does not meet your needs, you can implement your own custom constraint error handling routine. Doing this requires creating a custom framework extension class for the ADF Business Components transaction class, which you then configure your application module to use at runtime.

Creating a Custom Database Transaction Framework Extension Class

To write a custom framework extension class for the ADF Business Components transaction, create a class like the `CustomDBTransactionImpl` shown in the following example. This example overrides the transaction object's `postChanges()` method to wrap the call to `super.postChanges()` with a `try/catch` block in order to perform custom processing on any `DMLConstraintException` errors that might be thrown. In this simple example, the only custom processing being performed is a call to `ex.setExceptions(null)` to clear out any nested detail exceptions that the `DMLConstraintException` might have. Instead of this, you could perform any other kind of custom exception processing required by your application, including throwing a *custom* exception, provided your custom exception extends `JboException` directly or indirectly.

```
package oracle.summit.model.custommessages;

import oracle.jbo.DMLConstraintException;
import oracle.jbo.server.DBTransactionImpl2;
import oracle.jbo.server.TransactionEvent;

public class CustomDBTransactionImpl  extends DBTransactionImpl2 {
  public void postChanges(TransactionEvent te) {
    try {
      super.postChanges(te);
    }
    /*
     * Catch the DML constraint exception
     * and perform custom error handling here
     */
    catch (DMLConstraintException ex) {
      ex.setExceptions(null);
      throw ex;
    }
  }
}
```

Configuring an Application Module to Use a Custom Database Transaction Class

In order for your application module to use a custom database transaction class at runtime, you must:

1. Provide a custom implementation of the `DatabaseTransactionFactory` class that overrides the `create()` method to return an instance of the customized transaction class.
2. Configure the value of the `TransactionFactory` property to be the fully qualified name of this custom transaction factory class.

The following example shows a custom database transaction factory class that does this. It returns a new instance of the `CustomDBTransactionImpl` class when the framework calls the `create()` method on the database transaction factory.

```
package oracle.summit.model.custommessages;

import oracle.jbo.server.DBTransactionImpl2;
import oracle.jbo.server.DatabaseTransactionFactory;
```

```
public class CustomDatabaseTransactionFactory
                     extends DatabaseTransactionFactory {
  public CustomDatabaseTransactionFactory() {
  }
  /**
   * Return an instance of our custom CustomDBTransactionImpl class
   * instead of the default implementation.
   *
   * @return instance of custom CustomDBTransactionImpl implementation.
   */
  public DBTransactionImpl2 create() {
    return new CustomDBTransactionImpl();
  }
}
```

To complete the job, use the Properties tab of the overview editor for application module configurations (on the `bc4j.xcfg` file) to assign the value `oracle.summit.model.custommessages.CustomDatabaseTransactionFactory` to the `TransactionFactory` property. To display the application module configuration overview editor, double-click the application module in the Applications window and, in the overview editor, select the **Configurations** navigation tab. Then, in the Configurations page of the overview editor, click the configuration hyperlink. In the application module configuration overview editor, select the **Properties** tab and click **Add Property** to select the following property from the Add Property dialog and click **OK**.

- `TransactionFactory`

Then, in the **Properties** list enter the value for the `TransactionFactory` property:

- `TransactionFactory` = `oracle.summit.model.custommessages.CustomDatabaseTransactionFactory`

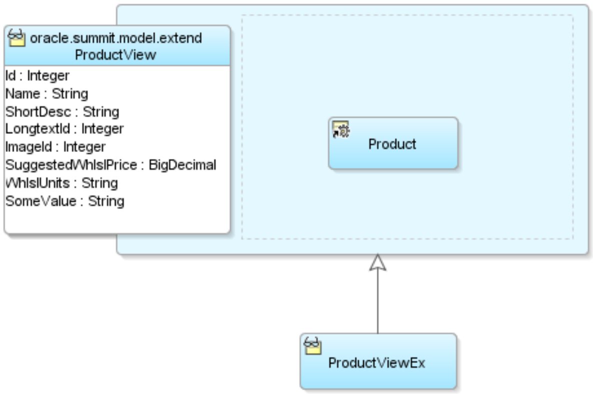
When you run the application using this configuration, your custom transaction class will be used.

Creating Extended Components Using Inheritance

ADF Business Components supports inheritance. It allows you to create a new business component by extending an existing one, which inherits all properties of the original, and thence customize the new one.

Whenever you create a new business component, if necessary, you can extend an existing one to create a customized version of the original. As shown in Figure 17-9, the `ProductViewEx` view object extends the `ProductView` view object to add a bind variable named `bv_ProductName` and to customize the `WHERE` clause to reference that bind variable.

Figure 17-9 ADF Business Components Can Extend Another Component



While the figure shows a view object example, this component inheritance facility is available for all component types. When one component extends another, the extended component inherits all of the metadata and behavior from the parent it extends. In the extended component, you can add new features or customize existing features of its parent component both through metadata and Java code.

> **Note:**
>
> The example in this section refers to the `oracle.summit.model.extend` package in the `SummitADF_Examples` application workspace.

How To Create a Component That Extends Another

To create an extended component, use the component wizard in the **New Gallery** for the type of component you want to create. For example, to create an extended view object, you use the Create View Object wizard. On the **Name** page of the wizard — in addition to specifying a name and a package for the new component — provide the fully qualified name of the component that you want to extend in the **Extends** field. To pick the component name from a list, use the **Browse** button next to the **Extends** field. Then, continue to create the extended component in the normal way using the remaining panels of the wizard.

How To Extend a Component After Creation

After you define an extended component, JDeveloper lets you change the parent component from which an extended component inherits. You can use the overview editor for the component to accomplish this.

To change the parent component after creation:

1. In the Applications window, double-click the component.
2. In the overview editor, click the **General** navigation tab and then click the **Refactor object extends** button next to the **Extends** field.

3. In the Select Parent dialog, choose the desired component to extend from the package list and click **OK**.

To change the extended component to not inherit from any parent, select the **None** checkbox in the Select Parent dialog. This has the same effect as if you deleted the component and re-created to accomplish this.

What Happens When You Create a Component That Extends Another

Business components that you create in an ADF Business Component data model project are comprised of an XML document and an optional Java class. When you create a component that extends another, JDeveloper reflects this component inheritance in both the XML document and in any generated Java code for the extended component.

Attributes in an Extended Component Inherited from the Parent Component

When you create an extended component, the extended component inherits the attributes and attribute properties of the parent component. This connection is maintained because the inherited attributes are not defined in the extended component, they are simply passed through from the parent component. Therefore, if after creating an extended component you subsequently modify an attribute in the parent component, the extended component's attribute reflects that modification.

For example, say you create a `ProductViewEx` extended view object that extends a `ProductView` view object. Then you decide to set the **Display** UI hint for the `ShortDesc` attribute to **Hide** in the `ProductView` parent view object. When you do this, the `ShortDesc` attribute is hidden in the `ProductViewEx` extended view object as well.

However, if you override an attribute in the extended object, this connection is severed because the overridden attribute is redefined in the extended object. This allows you to make a change in an extended object without impacting the parent object or any other objects derived from that parent object. Note that the override applies only to the selected attribute, the other inherited attributes are unaffected.

For example, say you have a `ProductView` view object and two extended view objects, `ProductViewEx1` and `ProductViewEx2`. After setting the **Display** UI hint for the `ShortDesc` attribute to **Hide** in the `ProductView` parent view object, you decide to set it to **Show** in the `ProductViewEx1` extended view object. When you override `ShortDesc` in `ProductViewEx1` and set the **Display** UI hint to **Show**, the change is only reflected in the `ProductViewEx1` extended view object, not in the `ProductViewEx2` extended view object or the `ProductView` parent view object.

Attributes Added to the Extended Component's XML Descriptor

JDeveloper notes the name of the parent component in the new component's XML document by adding an `Extends` attribute to the root component element. Any new declarative features you add or any aspects of the parent component's definition you've overridden appear in the extended component's XML document. In contrast, metadata that is purely inherited from the parent component is not repeated for the extended component.

The following example shows what the `ProductViewEx.xml` XML document for the `ProductViewEx` view object looks like. Notice the `Extends` attribute on the `ViewObject` element, the `Variable` element related to the additional bind variable added in the extended view object, and the overridden value of the Where attribute for the WHERE clause that was modified to reference the theProductName bind variable.

```
<ViewObject
  xmlns="http://xmlns.oracle.com/bc4j"
  Name="ProductViewEx"
  InheritPersonalization="true"
  BindingStyle="OracleName"
  CustomQuery="false"
  ComponentClass="oracle.summit.model.extend.ProductViewExImpl"
  RowClass="oracle.summit.model.extend.ProductViewExRowImpl"
  RowInterface="oracle.summit.model.extend.common.ProductViewExRow"
  ClientRowProxyName="oracle.summit.model.extend.client.ProductViewExRowClient"
  ComponentInterface="oracle.summit.model.extend.common.ProductViewEx"
  ClientProxyName="oracle.summit.model.extend.client.ProductViewExClient"
  Extends="oracle.summit.model.extend.ProductView"
  Where="UPPER(PRODUCT_NAME) LIKE UPPER(:theProductName)||'%'"
...
  <Variable
     Name="bv_ProductName"
     Kind="where"
     Type="java.lang.String"/>
...
</ViewObject>
```

Java Classes Generated for an Extended Component

If you enable custom Java code for an extended component, JDeveloper automatically generates the Java classes to extend the respective Java classes of its parent component. In this way, the extended component can override any aspect of the parent component's programmatic behavior as necessary. If the parent component is an XML-only component with no custom Java class of its own, the extended component's Java class extends whatever base Java class the parent would use at runtime. This could be the default ADF Business Components framework class in the oracle.jbo.server package, or could be your own framework extension class if you have specified that in the **Extends** dialog of the parent component.

In addition, if the extended component is an application module or view object and you enable client interfaces on it, JDeveloper automatically generates the extended component's client interfaces to extend the respective client interfaces of the parent component. If the respective client interface of the parent component does not exist, then the extended component's client interface directly extends the appropriate base ADF Business Components interface in the oracle.jbo package.

What You May Need to Know About Extending Components

Parent Classes and Interfaces for Extended Components

Since an extended component is a customized version of its parent, code you write that works with the *parent* component's Java classes or its client interfaces works without incident for either the parent component *or* any customized version of that parent component.

For example, assume you have a base ProductView view object with custom Java classes and client interfaces like:

- class `ProductViewImpl`
- row class `ProductViewRowImpl`
- client interface `ProductView`
- row client interface `ProductViewRow`

If you create a `ProductViewEx` view object that extends `ProductView`, then you can use the base component's classes and interface to work both with `ProductView` and `ProductViewEx`.

The following example illustrates a test client program that works with the `ProductView`, `ProductViewRow`, `ProductViewEx`, and `ProductViewExRow` client interfaces. A few interesting things to note about the example are the following:

1. You can use parent `ProductView` interface for working with the `ProductViewEx` view object that extends it.
2. Alternatively, you can cast an instance of the `ProductViewEx` view object to its own more specific `ProductViewEx` client interface.
3. You can test if row `ProductViewRow` is actually an instance of the more specific `ProductViewExRow` before casting it and invoking a method specific to the `ProductViewExRow` interface.

```
package oracle.summit.model.extend;

import oracle.jbo.ApplicationModule;
import oracle.jbo.AttributeDef;
import oracle.jbo.Row;
import oracle.jbo.StructureDef;
import oracle.jbo.ValidationException;
import oracle.jbo.ViewObject;
import oracle.jbo.client.Configuration;

import oracle.summit.model.extend.common.ProductView;
import oracle.summit.model.extend.common.ProductViewEx;
import oracle.summit.model.extend.common.ProductViewExRow;
import oracle.summit.model.extend.common.ProductViewRow;

public class TestClient {
    public static void main(String[] args) {
    String        amDef = "oracle.summit.model.extend.AppModule";
    String        config = "AppModuleLocal";
    ApplicationModule am =
                         Configuration.createRootApplicationModule(amDef,config);
    ProductView products = (ProductView)am.findViewObject("ProductView1");
    products.executeQuery();
    ProductViewRow product = (ProductViewRow)products.first();
    printAllAttributes(products,product);
    testSomethingOnProductsRow(product);
    products = (ProductView)am.findViewObject("ProductViewEx1");
    ProductViewEx productsByName = (ProductViewEx)products;
    productsByName.setbv_ProductName("bunny");
    productsByName.executeQuery();
    product = (ProductViewRow)productsByName.first();
    printAllAttributes(productsByName,product);
    testSomethingOnProductsRow(product);
    am.getTransaction().rollback();
    Configuration.releaseRootApplicationModule(am,true);
```

```
  }
  private static void testSomethingOnProductsRow(ProductViewRow product) {
    try {
      if (product instanceof ProductViewExRow) {
        ProductViewExRow productByName = (ProductViewExRow)product;
        productByName.someExtraFeature("Test");
      }
      product.setName("Q");
      System.out.println("Setting the Name attribute to 'Q' succeeded.");
    }
    catch (ValidationException v) {
      System.out.println(v.getLocalizedMessage());
    }
  }
  private static void printAllAttributes(ViewObject vo, Row r) {
    String viewObjName = vo.getName();
    System.out.println("Printing attribute for a row in VO '"+
                       viewObjName+"'");
    StructureDef def = r.getStructureDef();
    StringBuilder sb = new StringBuilder();
    int numAttrs = def.getAttributeCount();
    AttributeDef[] attrDefs = def.getAttributeDefs();
    for (int z = 0; z < numAttrs; z++) {
      Object value = r.getAttribute(z);
      sb.append(z > 0 ? "  " : "")
        .append(attrDefs[z].getName())
        .append("=")
        .append(value == null ? "<null>" : value)
        .append(z < numAttrs - 1 ? "\n" : "");
    }
    System.out.println(sb.toString());
  }
}
```

Running the test client produces the following results.

```
Printing attribute for a row in VO 'ProductView1'
Id=10011
  Name=Bunny Boot
  ShortDesc=Beginners ski boot
  LongtextId=518
  ImageId=1001
  SuggestedWhlslPrice=150
  WhlslUnits=<null>
  SomeValue=I am from the Product Impl Class
Setting the Name attribute to 'Q' succeeded.
```

Note:

In this example, `ProductView` is an entity-based view object based on the `Product` entity object. The `Product` entity object includes a transient `SomeValue` attribute that returns the string "I am from the Product Impl class". You'll learn more about why this was included in the example in Substituting Extended Components in a Delivered Application.

Generated Classes for Extended Components

When you create an extended component, the **Class Extends** button on the Java page of the extended component's wizard is disabled. Additionally, in the application module editor's Java page, when you click **Edit java options**, the **Class Extends** button in the Java dialog appears disabled. This is due to the fact that JDeveloper automatically extends the appropriate class of its parent component, so it does not make sense to allow you to select a different class.

Business Component Types

Entity Objects
When you create an extended entity object, you can introduce new attributes, new associations, new validators, and new custom code. You can override certain declarative aspects of existing attributes as well as overriding any method from the parent component's class. You may not remove from the extended entity object any attributes that the base class defines from the extended entity object.

View Objects
When you create an extended view object, you can introduce new attributes, new **view links**, new bind variables, and new custom code. You can override certain declarative aspects of existing attributes as well as overriding any method from the parent component's class. You may not remove from the extended view object any attributes that the base class defines.

Application Modules
When you create an extended application module, you can introduce new view object instances or new nested application module instance and new custom code. You can also override any method from the parent component's class from the extended view object.

New Attributes in an Extended Component

If you add new attributes in an extended entity object or view object, the attribute index numbers are computed relative to the parent component. For example, consider the `ProductView` view object mentioned in Parent Classes and Interfaces for Extended Components. If you enable a custom view row class, it might have attribute index constants defined in the `ProductViewRowImpl.java` class like this:

```
public class ProductViewRowImpl extends SummitViewRowImpl
                             implements ProductViewRow {

  /**
   * AttributesEnum: generated enum for identifying attributes and accessors.
   * Do not modify.
   */
  public enum AttributesEnum {...}

  public static final int ID = AttributesEnum.Id.index();
  public static final int NAME = AttributesEnum.Name.index();
  public static final int SHORTDESC = AttributesEnum.ShortDesc.index();
  public static final int LONGTEXTID = AttributesEnum.LongtextId.index();
  public static final int IMAGEID = AttributesEnum.ImageId.index();
  public static final int SUGGESTEDWHLSLPRICE =
                              AttributesEnum.SuggestedWhlslPrice.index();
  public static final int WHLSLUNITS = AttributesEnum.WhlslUnits.index();
  public static final int SOMEVALUE = AttributesEnum.SomeValue.index();
  //etc.
}
```

When you create an extended view object like `ProductViewEx`, if that view object adds an additional attribute like `SomeExtraAttr` and has a custom view row class enabled, then its attribute constants will be computed relative to the maximum value of the attribute constants in the parent component:

```
public class ProductViewExRowImpl extends ProductViewRowImpl
                                   implements ProductViewExRow {

  public static final int MAXUSAGECONST = 1;

  public enum AttributesEnum {
      SomeExtraAttr {
          public Object get(ProductViewExRowImpl obj) {
              return obj.getSomeExtraAttr();
          }

          public void put(ProductViewExRowImpl obj, Object value) {
              obj.setAttributeInternal(index(), value);
          }
      }

      private static AttributesEnum[] vals = null;
      private static int firstIndex =
          ViewDefImpl.getMaxAttrConst("oracle.summit.model.extend.ProductView");

      public abstract Object get(ProductViewExRowImpl object);

      public abstract void put(ProductViewExRowImpl object, Object value);

      public int index() {
          return AttributesEnum.firstIndex() + ordinal();
      }

      public static int firstIndex() {
          return firstIndex;
      }

      public static int count() {
          return AttributesEnum.firstIndex() +
                                 AttributesEnum.staticValues().length;
      }

      public static AttributesEnum[] staticValues() {
          if (vals == null) {
              vals = AttributesEnum.values();
          }
          return vals;
      }
  }
  public static final int SOMEEXTRAATTR = AttributesEnum.SomeExtraAttr.index();
...
}
```

Substituting Extended Components in a Delivered Application

ADF Business Components supports application customization without needing to have access to the application’s source code. It completely negates maintenance expenses and human errors involved in customizations.

If you deliver packaged applications that can require on-site customization for each potential client of your solution, ADF Business Components offers a useful feature to simplify that task.

> **Note:**
>
> The example in this section refers to the `ExtendedProject` project in the `SummitADF_Examples` application workspace.

All too often, on-site application customization is performed by making direct changes to the source code of the delivered application. This approach demonstrates its weaknesses whenever you deliver patches or new feature releases of your original application to your clients. Any customizations they had been applied to the base application's source code need to be painstakingly reapplied to the patched or updated version of the base application. Not only does this render the application customization a costly, ongoing maintenance expense, it can introduce subtle bugs due to human errors that occur when reapplying previous customizations to new releases.

ADF Business Components offers a superior, component-based approach to support application customization that doesn't require changing — or even having access to — the base application's source code. To customize your delivered application, your customers can:

1. Import one or more packages of components from the base application into a new project.
2. Create new components to effect the application customization, extending appropriate parent components from the base application as necessary.
3. Define a list of global component substitutions, naming their customized components to substitute for your base application's appropriate parent components.

When the customer runs your delivered application with a global component substitution list defined, their customized application components are used by your delivered application without changing any of its code. When you deliver a patched or updated version of the original application, their component customizations apply to the updated version the next time they restart the application without needing to reapply any customizations.

How To Substitute an Extended Component

To define global component substitutions, use the Project Properties dialog in the project where you have created extended components based on the imported components from the base application.

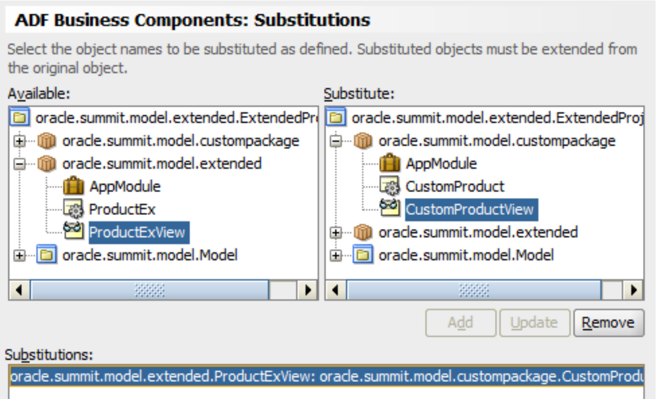
> **Note:**
>
> You can only substitute a component in the base application with an extended component that inherits directly or indirectly from the base one.

To substitute an extended component:

1. In the Applications window, right-click the project that you want to add the extended component to and choose **Project Properties**.
2. In the Project Properties dialog, select **ADF Business Components > Substitutions** and select the base application's component in the **Available** list.
3. In the **Substitute** list, select the customized, extended component to substitute .
4. Click **Add**.

   For example, assume that you have created the view object `CustomizedProduct` in a package that extends the base view object `Products`. To substitute the `CustomizedProducts` view object for the legacy `Products` view object, you would select these view objects as shown in Figure 17-10 to define the component substitution.

Figure 17-10   Defining Business Component Substitutions



ADF Business Components: Substitutions

Select the object names to be substituted as defined. Substituted objects must be extended from the original object.

Available:
oracle.summit.model.extended.ExtendedPr
oracle.summit.model.custompackage
oracle.summit.model.extended
AppModule
ProductEx
ProductExView
oracle.summit.model.Model
Substitute:
oracle.summit.model.extended.ExtendedProj
oracle.summit.model.custompackage
AppModule
CustomProduct
CustomProductView
oracle.summit.model.extended
oracle.summit.model.Model
Add
Update
Remove
Substitutions:

oracle.summit.model.extended.ProductExView: oracle.summit.model.custompackage.CustomProdu

What Happens When You Substitute

When you define a list of global component substitutions in a project named *`ExtendedProject`*, the substitution list is saved in the *`ExtendedProject`*`.jpx` in the root directory of the source path.

The file will contain `Substitute` elements as shown in the following example, one for each component to be substituted.

```
<JboProject
   Name="ExtendedProject"
   SeparateXMLFiles="true"
   PackageName="oracle.summit.model.extended" >
   <Containee
      Name="custompackage"
      FullName="oracle.summit.model.custompackage"
      ObjectType="JboPackage" >
   </Containee>
   <Containee
      Name="extended"
      FullName="oracle.summit.model.extended"
      ObjectType="JboPackage" >
   </Containee>
   <AppContainee
      Name="Model"
      FullName="oracle.summit.model.Model"
      ObjectType="JboProject">
   <Substitutes>
      <Substitute
        OldName="oracle.summit.model.extended.ProductEx"
        NewName="oracle.summit.model.custompackage.CustomProduct" />
   </Substitutes>
</JboProject>
```

How to Enable the Substituted Components in the Base Application

To have the original application use the set of substituted components, define the Java system property Factory-Substitution-List and set its value to the name of the project whose *.jpx file contains the substitution list. The value should be just the project name without any *.jpr or *.jpx extension.

For example, consider a simple example that customizes the Product entity object and the ProductView view object described in Parent Classes and Interfaces for Extended Components. To perform the customization, assume you create new project named ExtendedProject that:

- Defines a library for the JAR file containing the base components
- Imports the package containing Product and ProductView
- Creates new extended components in a distinct package name called CustomizeProduct and CustomizeProductView
- Defines a component substitution list to use the extended components.

When creating the extended components, assume that you:

- Added an extra view attribute named SomeExtraAttribute to the ProductViewEx view object.
- Added a new validation rule to the CustomizedProduct entity object to enforce that the product name cannot be the letter "Q".
- Overrode the getChecksum() method in the CustomizedProduct.java class to return "**I am the CustomizedProduct Class**".

If you define the Factory-Substitution-List Java system property set to the value ExtendsAndSubstitutes, then when you run the exact same test client class described in Parent Classes and Interfaces for Extended Components the output of the sample will change to reflect the use of the substituted components.

Part III

Using the ADF Model Layer

This part describes tasks that developers can perform in the ADF Model layer of the Fusion web application.

Part III contains the following chapters:

18
Using ADF Model in a Fusion Web Application

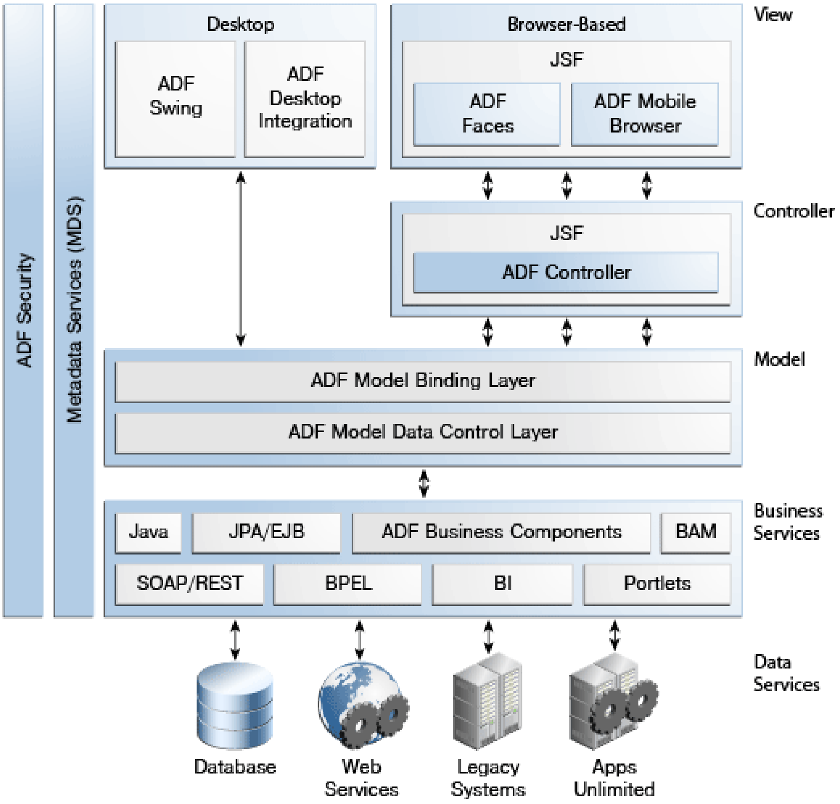
This chapter describes JDeveloper tools that you use to create databound pages from data modeled with ADF Business Components, using ADF data controls in a Fusion web application. Specifically, it describes how an ADF application module data model and ADF Business Components client interface methods appear at design time for drag and drop data binding. It also describes how they are accessible at runtime by the ADF Model data binding layer using ADF data controls.
This chapter includes the following sections:

About Using ADF Model in a Fusion Web Application

ADF Model is build on model-view-controller design where all the components are separated. This supports the development of Fusion Web application in a more structured way.
ADF Model implements concepts that enable decoupling the user interface technology from the business service implementation: **data controls** and declarative **ADF bindings**.

ADF Model builds upon the MVC (model-view-controller) design pattern, in which the code for the application's data model, visual interface, and application flow are all cleanly separated. As illustrated in Figure 18-1, ADF Model provides a layer of abstraction over the business services that typically serve as an application's model layer. For more information on how ADF Model fits in with the MVC architecture, see "Abstraction of the Application's Model Layer" in *Understanding Oracle Application Development Framework*.

Figure 18-1 ADF Model within the ADF Architecture



About ADF Data Controls

ADF Data Controls contains the functionality of the application module and created automatically when you create an application module.
ADF data controls abstract the implementation technology of a business service by using standard metadata interfaces to describe the service's operations and data collections, including information about the properties, methods, and types involved. In an application that uses **ADF Business Components**, a data control is automatically created when you create an **application module**, and it contains all the functionality of the application module. Developers can then use the representation of the data control displayed in JDeveloper's Data Controls panel to create UI components that are automatically bound to the application module. At runtime, the ADF Model layer reads the information describing the data controls and bindings from the appropriate XML files and then implements the two-way connection between the user interface and the business service.

When you create an ADF Business Component application module and add **view objects** to the data model for that application module, a data control is created for you automatically.

You can also create data controls based on different types of business services, such as EJB session beans, plain Java objects, and web services. For information on working with these kinds of data controls, see Using ADF Data Controls in *Developing Applications with Oracle ADF Data Controls*.

> **Note:**
>
> Using the ADF Model layer to perform business service access ensures that the view and the business service stay in sync. For example, while you could call a method on an application module by class-casting the data control reference to the **application module instance** and then calling the method directly, doing so would bypass the model layer and it would then become unaware of any changes.

About JSF Data Binding

You can use simple expression language to reference an object in JSF, on which the ADF bindings are based, which makes it easy to build a dynamic data-driven user interface..
ADF declarative bindings are based on JSF data binding. In JSF, you use a simple **expression language** (called EL) to bind to the information you want to present and/or modify. Example expressions look like `#{userInfoBean.principalName}` to reference a particular user's name, or `#{userInfoBean.principalName eq 'SKING'}` to evaluate whether a user's name is SKING or not. At runtime, a generic expression evaluator returns the `String` and `boolean` value of these respective expressions, automating access to the individual objects and their properties without requiring code.

At runtime, the value of certain JSF UI components is determined by the `value` attribute. While a component can have static text as its value, typically the `value` attribute will contain a binding that is an EL expression that the runtime infrastructure evaluates to determine what data to display. For example, an `outputText` component that displays the name of the currently logged-in user might have its `value` attribute set to the expression `#{userInfoBean.principalName}`. Since any attribute of a component can be assigned a value using an EL expression, it's easy to build dynamic, data-driven user interfaces. For example, you could hide a component when a user is not logged in by using a boolean-valued expression like `#{userInfoBean.prinicpalName !=null}` in the UI component's `rendered` attribute. If there is no principal name in the current instantiation of the `userInfoBean`, the `rendered` attribute evaluates to `false` and the component disappears from the page.

About ADF Data Binding

You can design a page by dragging and dropping ADF data controls as UI component on a page with little knowledge of code.. The code and objects that are needed to bind the component to data control are automatically created by JDeveloper.
ADF data binding extends JSF data binding by enabling you to bind to ADF data controls declaratively. In a typical JSF application, you would create objects like the `userInfoBean` object as a managed bean. The JSF runtime manages instantiating these beans on demand when any EL expression references them for the first time. However, in an application that uses ADF Model, instead of binding the UI component attributes to properties or methods on managed beans, JDeveloper automatically binds the UI component attributes to ADF Model, which uses XML configuration files that drive generic data binding features.

ADF declarative bindings abstract the details of accessing data from data collections in a data control and of invoking its operations. There are three basic kinds of declarative binding objects:

- Executable bindings: Included in executable bindings are iterator bindings, which simplify the building of user interfaces that allow scrolling and paging through collections of data and drilling-down from summary to detail information. Executable bindings also include bindings that allow searching and nesting a series of pages within another page, as well as bindings that cause operations to occur immediately.
- Value bindings: Used by UI components that display data. Value bindings range from the most basic variety that work with a simple text field to more sophisticated list and tree bindings that support the additional needs of list, table, and tree UI controls.
- Action bindings: Used by UI components like hyperlinks or buttons to invoke built-in or custom operations on data collections or a data control without writing code.

The group of bindings supporting the UI components on a page are described in a page-specific XML file called the **page definition file**. The ADF Model layer uses this file at runtime to instantiate the page's bindings. These bindings are held in a request-scoped map called the **binding container**, accessible during each page request using the EL expression `#{bindings}`. This expression always evaluates to the binding container for the current page.

> **Tip:**
>
> The current binding container is also available from `AdfContext` for programmatic access.

You can design a databound user interface by dragging an item from the Data Controls panel and dropping it on a page as a specific UI component. When you use data controls to create a UI component, JDeveloper automatically creates the various code and objects needed to bind the component to the data control you selected.

Additional Functionality for ADF Model Layer

ADF Model provides a different layer of configuration with different functionalities, which are helpful in creating a Fusion Web Application with ease.
You may find it helpful to understand other **Oracle ADF** features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- ADF model and data binding rely on the business layer. In most cases, you will be working with representations of your view objects. For more information, see Defining SQL Queries Using View Objects. You may also want to be familiar with advanced functionality discussed in Tuning View Object Performance.
- You can use the ADF Model layer to create your view pages. After reading this chapter for the basic information on how data binding in the view layer works, you should refer to the chapters in Creating a Databound Web User Interface for information about using data binding to create specific view functionality.
- For information about how ADF Model works with the page lifecycle, see Understanding the Fusion Page Lifecycle .

- For a complete list of configuration parameters that affect the model layer, see DataBindings.cpx and pageNamePageDef.xml.
- For a complete list of binding properties, see Oracle ADF Binding Properties.

Exposing Application Modules with ADF Data Controls

In ADF, the application module components directly implement the interfaces to optimize the interaction between business components and data in the application by binding the objects for data collections. Because of the optimized interaction, the bindings work directly with the application module instances.
When you create an application module, a data control is created for the objects that you have added to the application module's data model.

> **Note:**
>
> You can also create data controls for other kinds of business services. See Using ADF Data Controls in *Developing Applications with Oracle ADF Data Controls*.

Importantly, the application module component directly implements interfaces that binding objects expected for data collections, built-in operations, and service methods. This optimized interaction allows the bindings to work *directly* with the application module instances in its data model in the following ways:

- Iterator bindings directly bind to the default **row set iterator** of the default row set of any view object instance. The row set iterator manages the current object and current range information.

  > **Tip:**
  >
  > You can also use the iterator binding to bind to a secondary named row set that you have created. To bind to a secondary row set iterator, you need to use the `RSIName`. For information about the difference between the default row set and secondary row sets and how to create them, see Working with Multiple Row Sets and Row Set Iterators.

- Action bindings directly bind to either:
  - Custom methods on the data control client interface
  - Built-in operations of the application module and view objects

Figure 18-2 illustrates examples of iterator and action bindings connecting UI components with **application module data control** objects.

Figure 18-2 Bindings Connect UI Components to Data Controls

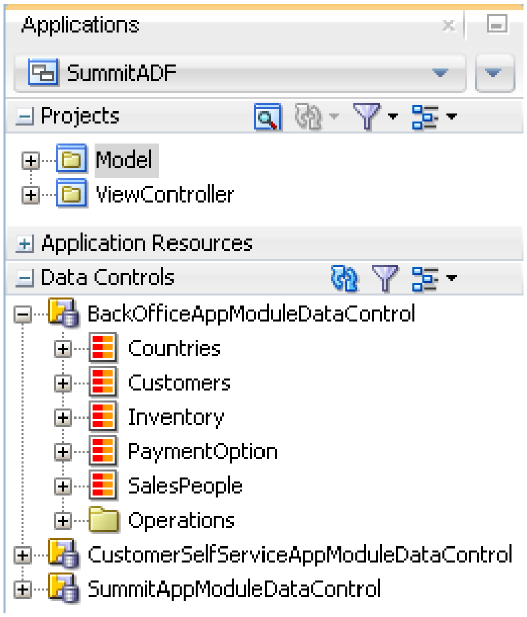
How an Application Module Data Control Appears in the Data Controls Panel

You use the Data Controls panel to create databound UI components by dragging and dropping icons from the panel onto the visual editor for a page. Figure 18-3 shows the Data Controls panel displaying the data controls for the Summit sample application for Oracle ADF.

Figure 18-3 Data Controls Panel in JDeveloper



The Data Controls panel lists all the data controls that have been created for the application's business services and exposes all the collections (row sets of data objects), methods, and built-in operations that are available for binding to UI components.

Note:

If you've configured JDeveloper to expose them, any **view link accessor** returns are also displayed. For more information, see Working with Multiple Tables in a Master-Detail Hierarchy. To view the accessor methods:

1. From the JDeveloper main menu, choose **Tools > Preferences**.
2. Select the **Data Controls Panel** node.
3. Select **Show Underlying Accessor Nodes** to activate the checkbox.

In an application that uses ADF Business Components to define the business services, each data control on the Data Controls panel represents a specific application module, and exposes the view object instances in that application's data model. The hierarchy of objects in the data control is defined by the **view links** between view objects that have specifically been added to the **application module data model**. For information about creating view objects and view links, see Defining SQL Queries Using View Objects. For information about adding view links to the data model, see How to Enable Active Master-Detail Coordination in the Data Model.

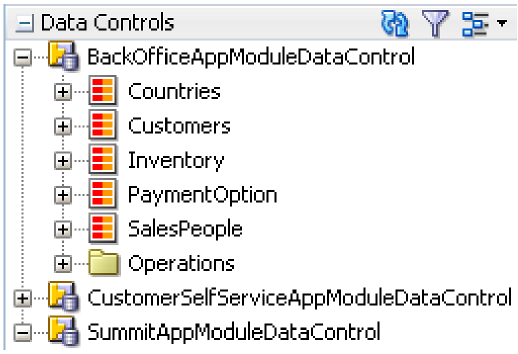
> **Tip:**
>
> You can open the overview editor for a view object by right-clicking the associated data control object and choosing **Edit Definition**.

For example, `BackOfficeAppModuleDataControl` represents the `BackOfficeAppModule` application module, which implements the part of the business service layer of the Summit ADF sample application that is available to the company's employees. The application module's data model contains numerous view object instances, including several master-detail hierarchies. The view layer of the Summit ADF sample application consists of JSF pages whose UI components are bound to data from the view object instances in `BackOfficeAppModule`'s data model, and to built-in operations and service methods on its client interface.

How the Data Model and Service Methods Appear in the Data Controls Panel

Each view object instance appears as a named data collection whose name matches the view object instance name. Figure 18-4 illustrates how the Data Controls panel displays the view object instances in `BackOfficeAppModule`'s data model. The Data Controls panel reflects the master-detail hierarchies in your application module data model by displaying detail data collections nested under their master data collection.

Figure 18-4 How the Data Model Appears in the Data Controls Panel



Data Controls
BackOfficeAppModuleDataControl
Countries
Customers
Inventory
PaymentOption
SalesPeople
Operations
CustomerSelfServiceAppModuleDataControl
SummitAppModuleDataControl

The Data Controls panel also displays any custom method on the application module's client interface as a named data control custom operation whose name matches the method name. If a method accepts arguments, they appear in a Parameters node as operation parameters nested inside the operation's node.

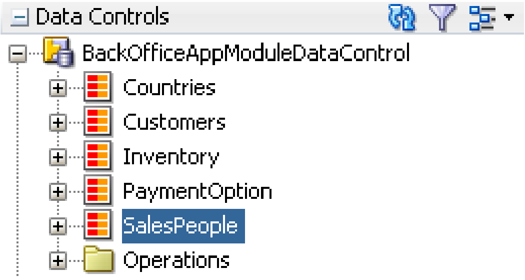
How Transaction Control Operations Appear in the Data Controls Panel

The Operations folder node of the application module data control exposes two data control built-in operations named `Commit` and `Rollback`, as shown in Figure 18-5. At runtime, when these operations are invoked by the data binding layer, they delegate to the `commit()` and `rollback()` methods of the `Transaction` object associated with the current application module instance.

Note:

In an application module with many view object instances and custom methods, you may need to scroll the Data Controls panel display to find the Operations node that is the direct child node of the data control. This node is the one that contains these built-in operations.

Figure 18-5 How Transaction Control Operations Appear in the Data Controls panel

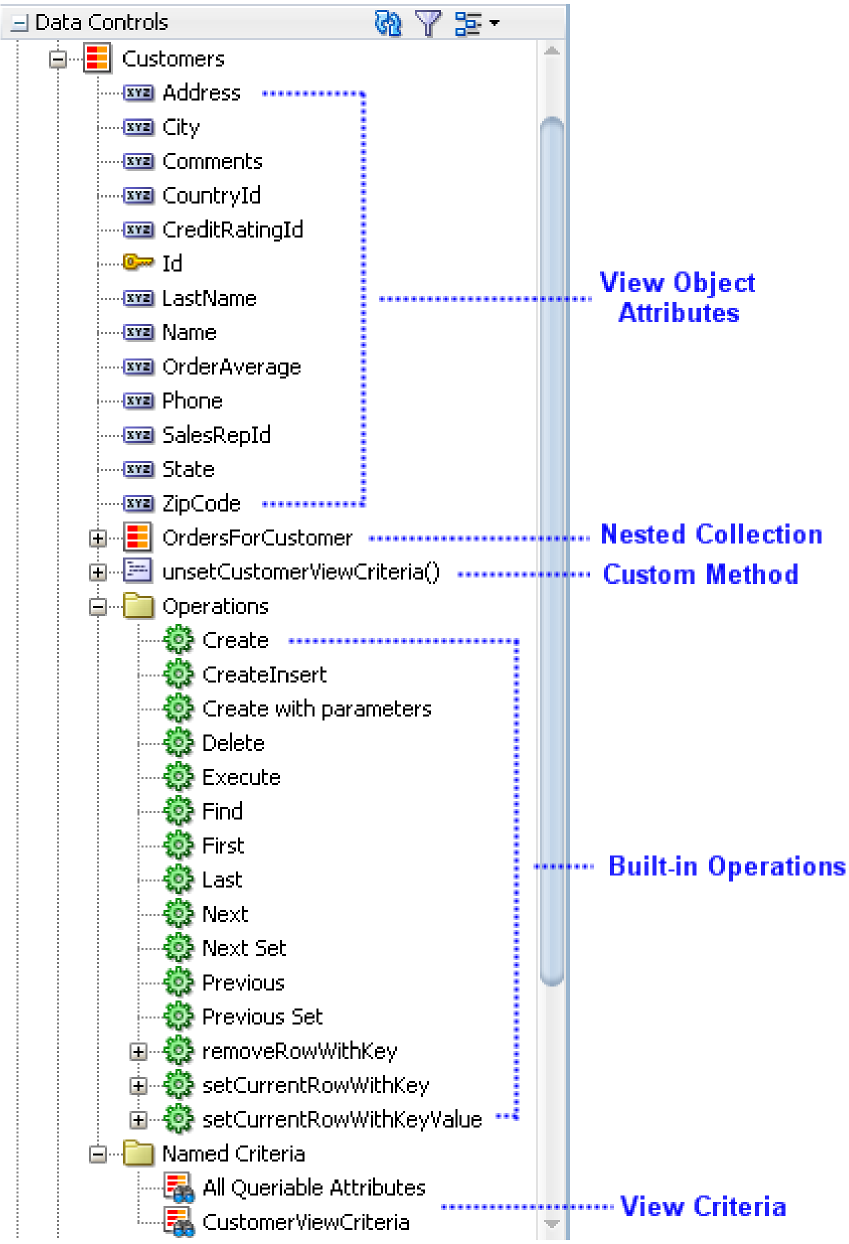


How View Objects Appear in the Data Controls Panel

The view object attributes are displayed as immediate child nodes of the corresponding data collection, as are any custom methods you've created. Figure 18-6 shows how each view object instance in the application module's data model appears in the Data Controls panel. If you have selected any custom methods to appear on the view object's client interface, they appear as custom methods immediately following the view object attributes at the same level. If the method accepts arguments, these appear in a nested Parameters node as operation parameters.

By default, implicit **view criteria** are created for each attribute that is able to be queried on a view object. They are represented by the All Queriable Attributes node under the Named Criteria node, as shown in Figure 18-6. If any named view criteria were created for the view object, they appear under the Named Criteria node. The conjunction used in the query, along with the criteria items and if applicable, any nested criteria, are shown as children. These items are used to create quick search forms, as detailed in Creating ADF Databound Search Forms .

Figure 18-6 How View Objects Appear in the Data Controls Panel



View Object Attributes

Nested Collection

Custom Method

Built-in Operations

View Criteria

As shown in Figure 18-6, the Operations node under the data collection displays all its available built-in operations. If an operation accepts one or more parameters, then those parameters appear in a nested Parameters node. At runtime, when one of these data collection operations is invoked by name by the data binding layer, the application module data control delegates the call to an appropriate method on the `ViewObject` interface to handle the built-in functionality. The built-in operations fall into three categories: operations that affect the current row, operations that refresh the data collection, and all other operations.

Operations that affect the current row:

- `Create`: Creates a new row that becomes the current row, but does not insert it.

- `CreateInsert`: Creates a new row that becomes the current row, and inserts the new blank row into the data source.
- `Create with Parameters`: Creates a new row taking parameter values. The passed parameters can supply the create-time value for the following:
  - A discriminator for a polymorphic view object
  - A composing parent's foreign key attribute needed for the creation of a polymorphic view object
  - A composed child view object row when it is not created in the context of a parent row

  For more information about polymorphic view objects, see Defining Polymorphic View Objects.
- `Delete`: Deletes the current row.
- `First`: Sets the current row to be the first row in the row set.
- `Last`: Sets the current row to be the last row in the row set.
- `Next`: Sets the row to be the next row in the row set.
- `Next Set`: Navigates forward one full set of rows.
- `Previous`: Sets the current row to be the previous row in the row set.
- `Previous Set`: Navigates backward one full set of rows.
- `setCurrentRowWithKey`: Tries to finds a row using the serialized string representation of row key passed as a parameter. If found, that row becomes the current row.
- `setCurrentRowWithKeyValue`: Tries to finds a row using the primary key attribute value passed as a parameter. If found, that row becomes the current row.

  For more information on using `setCurrentRowWithKey` and `setCurrentRowWithKeyValue`, see What You May Need to Know About Setting the Current Row in a Table.

Operations that refresh the data collection:

- `Execute`: Refreshes the data collection by executing or reexecuting the view object's query, leaving any bind parameters at their current values.
- `ExecuteWithParams`: Refreshes the data collection by first assigning new values to the named bind variables passed as parameters, then executing or reexecuting the view object's query.

> **Note:**
>
> The `executeWithParams` operation appears only for view objects that have defined one or more named bind variables at design time.

All other operations:

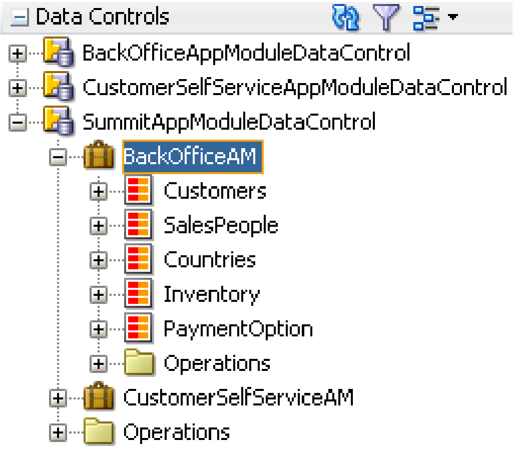
- `removeRowWithKey`: Tries to find a row using the serialized string representation of row key passed as a parameter. If found, the row is removed.

- Find: Toggles "Find Mode" on and off for the data collection.

How Nested Application Modules Appear in the Data Controls Panel

If you build composite application modules by including nested instances of other application modules, the Data Controls panel reflects this component assembly in the tree hierarchy. For example, the Summit ADF sample application contains the SummitAppModule application module, which contains nested instances of the BackOfficeAppModule and CustomerSelfServiceAppModule application modules. The nested instances are called BackOfficeAM and CustomerSelfServiceAM, respectively. As shown in Figure 18-7, there are top-level data controls for all three application modules, and the SummitAppModuleDataControl data control has subnodes for the BackOfficeAM and CustomerSelfServiceAM instances.

Figure 18-7 How Nested Application Modules Appear in the Data Controls Panel

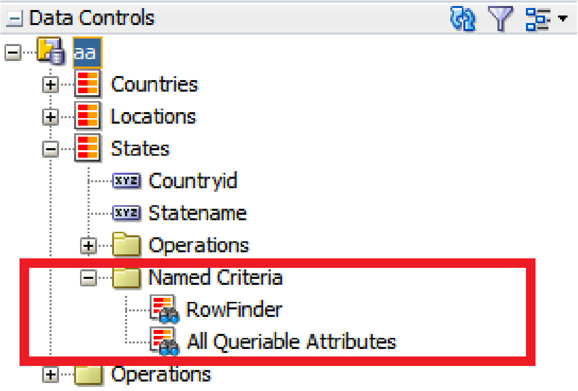


You need to be careful to perform your drag-and-drop data binding from the data control that corresponds to your intended usage. When you drop a data collection from the *top-level* BackOfficeAppModuleDataControl data control node in the panel, at runtime your page will use an instance of the BackOfficeAppModule application module acquired from a pool of BackOfficeAppModule components. When you drop a data collection from the BackOfficeAM *nested* instance of SummitAppModuleDataControl, at runtime your page will use an instance of the SummitAppModule application module acquired from a pool of SummitAppModule components. Since different types of application module data controls will have distinct transactions and database connections, inadvertently mixing and matching data collections from both a nested application module and a top-level data control will lead to unexpected runtime behavior.

How a Row Finder Appears in the Data Controls Panel

By default, any row finders that you define on a view object will appear in the Data Controls panel. At runtime, the row finder in the named criteria gets displayed as a search panel and displays only the attributes present in the named criteria and does not display any operators. The row-finder mapped attributes of a view object that the application exposes as a collection in the Data Controls panel are available in the row finder lookup operations. Figure 18-8 shows the Row Finder under Named Criteria in the Data Controls panel.

Figure 18-8 Row Finder in Data Controls Panel



When the application programmatically invokes the row finder on the view object instance, or when the end user supplies a value for a row-finder mapped attribute in the web service payload, the row finder locates the rows that match the values supplied to bind variables of the view criteria. The row finder does not alter the row set when locating matching rows.

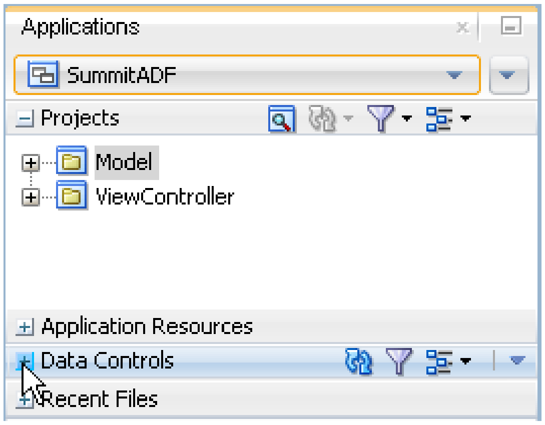
How to Open the Data Controls Panel

The Data Controls panel is a panel within the Applications window, located at the top left of JDeveloper. To view its contents, click the panel header to expand the panel. If you do not see the panel header, then the Applications window may not be displaying.

To open the Applications window and Data Controls panel:

1. From the main menu, choose **Window > Applications**.
2. To open the Data Controls accordion panel, click the expand icon in the Data Controls header, as shown in Figure 18-9.

Figure 18-9 Data Controls Panel in the Applications window



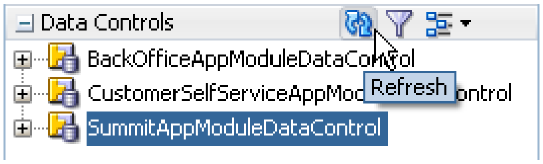
How to Refresh the Data Controls Panel

Any time changes are made to the application module or underlying services, you need to manually refresh the data control in order to view the changes.

To refresh the Data Controls panel:

Click the **Refresh** icon in the header of the Data Controls panel, as shown in Figure 18-10.

Figure 18-10 Refresh Icon on Data Controls Panel



Data Controls
BackOfficeAppModuleDataControl
CustomerSelfServiceAppMod
Refresh
ontrol
SummitAppModuleDataControl

When you click **Refresh**, the Data Controls panel looks for all available data controls, and therefore will now reflect any structural changes made to the data control.

Packaging a Data Control for Use in Another Project

You can package up data controls so that they can be used in another project. For example, one development group might be tasked with creating the services and data controls, while another development group might be tasked with creating the UI. The first group would create the services and data controls, and then package them up as an Oracle ADF Library and send it to the second group. The second group can then add the data controls to their project using the Resources window. For more information, see Reusing Application Components .

Using the Data Controls Panel

In ADF, all the components are listed in the Data Controls Panel, which helps you design a page easily. It lists the UI components, service methods, transaction control operations and also the nested application modules. All the code to bind the objects are automatically created during drag and drop operations.
You can design a databound user interface by dragging an item from the Data Controls panel and dropping it on a page as a specific UI component. When you use data controls to create a UI component, JDeveloper automatically creates the various code and objects needed to bind the component to the data control you selected.

In the Data Controls panel, each data control object is represented by a specific icon. Table 18-1 describes what each icon represents, where it appears in the Data Controls panel hierarchy, and what components it can be used to create.

Table 18-1 Data Controls Panel Icons and Object Hierarchy

Icon	Name	Description	Used to Create...
🗄	Data Control	Represents a data control. You cannot use the data control itself to create UI components, but you can use any of the child objects listed under it. Depending on how your business services were defined, there may be more than one data control. Usually, there is one data control for each application module. However, you may have additional data controls that were created for other types of business services (for example, for web services). For information about creating data controls for other business services, see Using ADF Data Controls in *Developing Applications with Oracle ADF Data Controls*.	Serves as a container for the other object and is not used to create anything.
▤	Collection	Represents a named data collection. A **data collection** represents a set of data objects (also known as a **row set**) in the data model. Each object in a data collection represents a specific structured data item (also known as a **row**) in the data model. Throughout this guide, *data collection* and *collection* are used interchangeably. For application modules, the data collection is the default row set contained in a view object instance. The name of the collection matches the view object instance name. A view link creates a **master-detail relationship** between two view objects. If you explicitly add an instance of a detail view object (resulting from a view link) to the application module data model, the collection contained in that detail view object appears as a child of the collection contained in the master view object. For information about adding detail view objects to the data model, see How to Enable Active Master-Detail Coordination in the Data Model. The children under a collection may be attributes of the collection, other collections that are related by a view link, custom methods that return a value from the collection, or built-in operations that can be performed on the collection. If you've configured JDeveloper to display view link accessor returns, then those are displayed as well.	Forms, tables, graphs, trees, range navigation components, and master-detail components. For information about using collections on a data control to create forms, see Creating a Basic Databound Page. For information about using collections to create tables, see Creating ADF Databound Tables . For information about using master-detail relationships to create UI components, see Displaying Master-Detail Data . For information about creating graphs, charts, and other visualization UI components, see Creating Databound Chart and Gauge Components.
XYZ	Attribute	Represents a discrete data element in an object (for example, an attribute in a row). Attributes appear as children under the collections or method returns to which they belong. For application module data controls, only attributes included in the corresponding view object are shown under a collection. If a view object joins one or more entity objects, that view object's collection will contain selected attributes from all of the underlying entity objects.	Label, text field, date, list of values, and selection list components. For information about using attributes to create fields on a page, see Creating Text Fields Using Data Control Attributes. For information about creating lists, see Creating Databound Selection Lists and Shuttles .

Table 18-1 (Cont.) Data Controls Panel Icons and Object Hierarchy

Icon	Name	Description	Used to Create...
▭	Structured Attribute	Represents a returned object that is neither a Java primitive type (represented as an attribute) nor a collection of any type. An example of a structured attribute would be a domain, which is a developer-created data type used to simplify application maintenance. For information about domains, see Creating Custom, Validated Data Types Using Domains.	Label, text field, date, list of values, and selection list components.
▤	Method	Represents an operation in the data control or one of its exposed structures that may accept parameters, perform some business logic and optionally return a single value, a structure, or a collection. In application module data controls, custom methods are defined in the application module itself and usually return either nothing or a single scalar value. For information about creating custom methods, see Implementing Business Services with Application Modules.	Command components For methods that accept parameters: command components and parameterized forms.
▤	Method Return	Represents an object that is returned by a custom method. The returned object can be a single value or a collection. If a custom method defined in an application module returns anything at all, it is usually a single scalar value. Application module methods do not need to return a set of data to the view layer, because displaying the latest changes to the data is handled by the view objects in the data model (For information, see What Happens at Runtime: How View Objects and Entity Objects Cooperate). However, custom methods in non-application module data controls (for example, a data control for a CSV file) can return collections to the view layer. A method return appears as a child under the method that returns it. The objects that appear as children under a method return can be attributes of the collection, other methods that perform actions related to the parent collection, or operations that can be performed on the parent collection.	The same components as for collections and attributes. When a single-value method return is dropped, the method is not invoked automatically by the framework. To invoke the method, you can drop the corresponding method as a button. If the form is part of a task flow, you can create a method activity to invoke the method. For information about executables, see Executable Binding Objects Defined in the Page Definition File.
⚙	Operation	Represents a built-in data control operation that performs actions on the parent object. Data control operations are located in an Operations node under collections or method returns, and also under the root data control node. The operations that are children of a particular collection or method return operate on those objects only, while operations under the data control node operate on all the objects in the data control. If an operation requires one or more parameters, they are listed in a Parameters node under the operation.	UI command components, such as buttons, links, and menus. For information, see Creating Command Components Using Data Control Operations, and Creating a Form to Edit an Existing Record.
🟩	Parameter	Represents a parameter value that is declared by the method or operation under which it appears. Parameters appear in the Parameters node under a method or operation.	Label, text, and selection list components.

Table 18-1 (Cont.) Data Controls Panel Icons and Object Hierarchy

Icon	Name	Description	Used to Create...
	Named criteria	Represents a query from which you can create a user search form. An All Queriable Attributes criteria is generated automatically for each accessor collection. This criteria can be used to create a search form where it is possible for the user to query based on any queriable attribute in the collection. You can create custom view criteria and add them to the Data Controls panel. See Working with Named View Criteria.	For information on creating search forms, seeCreating ADF Databound Search Forms .

How to Use the Data Controls Panel

JDeveloper provides you with a predefined set of UI components from which to choose for each data control item you can drop.

Before you begin:

It may be helpful to have an understanding of the different objects in the Data Controls panel. For more information, see Using the Data Controls Panel.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

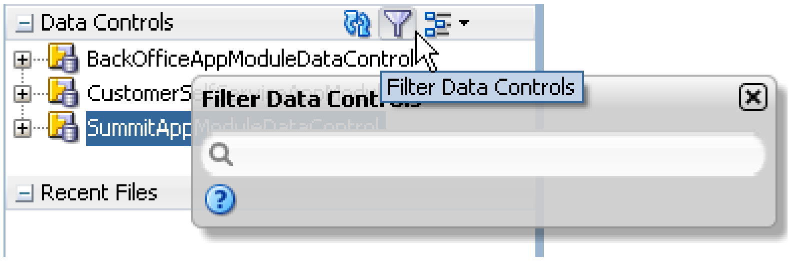
To use the Data Controls panel to create UI components:

1. Select an item in the Data Controls panel and drag it onto the visual editor for your page. For a definition of each item in the panel, see Table 18-1.

   If you need to drop an operation or method onto a method activity in a task flow, you can drag and drop it onto the activity in the task flow diagram.

   > **Tip:**
   >
   > You can use the Filter icon in the Data Controls Panel header to search for a specific item, as shown in Figure 18-11.

Figure 18-11 Filtering the Data Controls Panel

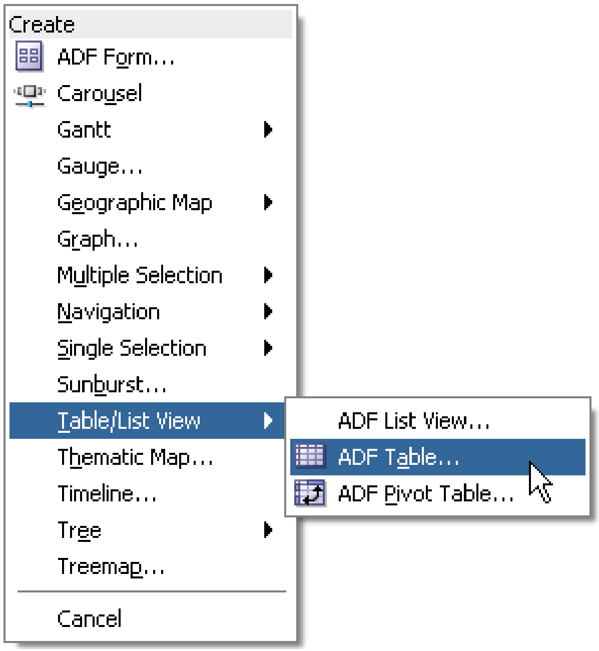


2. From the ensuing context menu, choose a UI component.

   When you drag an item from the Data Controls panel and drop it on a page, JDeveloper displays a context menu of all the default UI components available for the item you dropped. The components displayed are based on the libraries in your project.

   Figure 18-12 shows the context menu displayed when a data collection from the Data Controls panel is dropped on a page.

Figure 18-12 Data Controls Panel Context Menu

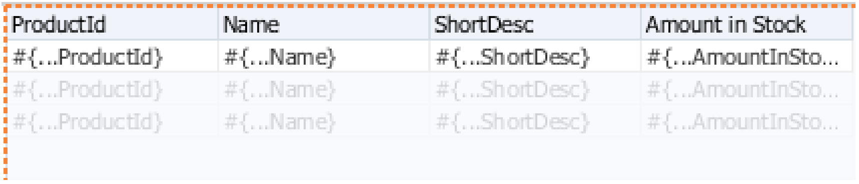


Depending on the component you select from the context menu, JDeveloper may display a dialog that enables you to define how you want the component to look. For example, if you select **Table/List View > ADF Table** from the context menu, the Create Table dialog launches. This dialog enables you to define which attributes you want to display in the table columns, what the column labels are, what types of UI components you want use for each column, and what functionality you want to include, such as row selection or column sorting. For more information about creating the various databound UI components, see the chapters in Creating a Databound Web User Interface .

The UI components selected by default are determined first by any UI control hints set on the corresponding business object. If no control hints have been set, then JDeveloper uses input components for standard forms and tables, and output components for read-only forms and tables. Components for lists are determined based on the type of list you chose when dropping the data control object.

Once you select a component, JDeveloper inserts the UI component on the page in the visual editor. For example, if you drag a collection from the Data Controls panel, choose **Table/List View > ADF Table** from the context menu, and select the read-only option, a read-only table appears in the visual editor, as shown in Figure 18-13.

Figure 18-13 Databound UI Component: ADF Read-Only Table



ProductId	Name	ShortDesc	Amount in Stock
#{...ProductId}	#{...Name}	#{...ShortDesc}	#{...AmountInSto...
#{...ProductId}	#{...Name}	#{...ShortDesc}	#{...AmountInSto...
#{...ProductId}	#{...Name}	#{...ShortDesc}	#{...AmountInSto...

By default, the UI components created when you use the Data Controls panel use ADF Faces components, are bound to attributes in the ADF data control, and may have one or more built-in features, including:

- Databound labels
- Tooltips
- Formatting
- Basic navigation buttons
- Validation, if validation rules are attached to a particular attribute. For more information, see Defining Validation and Business Rules Declaratively.

The default components are fully functional without any further modifications. However, you can modify them to suit your particular needs. Each component and its various features are discussed further in Creating a Databound Web User Interface .

> **Tip:**
>
> If you want to change the type of ADF databound component used on a page, the easiest method is to use either the visual editor or the Structure window to delete the component, and then drag and drop a new one from the Data Controls panel. When you use the visual editor or the Structure window to delete a databound component from a page, if the related binding objects in the page definition file are not referenced by any other component, JDeveloper automatically deletes those binding objects for you. Automatic deletion of binding objects will not happen if you use the source editor.

What Happens When You Use the Data Controls Panel

When an Oracle ADF web application is built using the JSF framework, it requires a few additional application object definitions to render and process a page containing ADF databound UI components. If you do not use the Data Controls panel, you will have to manually configure these various files yourself. However, when you use the Data Controls panel, JDeveloper does all of the following required steps:

- Creates a `DataBindings.cpx` file in the default package for the project (if one does not already exist), and adds an entry for the page.

  `DataBindings.cpx` files define the **binding context** for the application. The binding context is a container object that holds a list of available data controls and data binding objects. For more information, see What Happens at Runtime: How the Binding Context Works. Each `DataBindings.cpx` file maps individual pages to the binding definitions in the page definition file and registers the data controls used by those pages. For more information, see Working with the DataBindings.cpx File .

- Creates the `adfm.xml` file in the META-INF directory. This file creates a registry for the `DataBindings.cpx` file, which allows the application to locate it at runtime so that the binding context can be created.
- Registers the ADF binding filter in the `web.xml` file.

  The ADF binding filter preprocesses any HTTP requests that may require access to the binding context. For more information about the binding filter configuration, see Configuring the ADF Binding Filter.

- Adds any necessary libraries to the view project, such as the following:
  - ADF Faces Databinding Runtime
  - Oracle XML Parser v2
  - JDeveloper Runtime
  - ADF Model Runtime
  - BC4J Runtime
  - Oracle JDBC
  - Connection Manager
  - BC4J Oracle Domains
- Adds a page definition file (if one does not already exist for the page) to the page definition subpackage. The default subpackage is `view.pageDefs` in the `adfmsrc` directory.

> **Tip:**
>
> You can set the package configuration (such as name and location) in the ADF Model settings page of the Project Properties dialog (accessible by double-clicking the project node).

The page definition file (*pageName*`PageDef.xml`) defines the ADF binding container for each page in an application's view layer. The binding container provides runtime access to all the ADF binding objects for a page. In later chapters, you will see how the page definition files are used to define and edit the binding object definitions for specific UI components. For more information about the page definition file, see Working with Page Definition Files.

- Configures the page definition file, which includes adding definitions of the binding objects referenced by the page.
- Adds ADF Faces components to the JSF page.

  These prebuilt components include ADF data binding expression language (EL) expressions that reference the binding objects in the page definition file. For more information, see Creating ADF Data Binding EL Expressions.
- Adds all the libraries, files, and configuration elements required by ADF Faces components. For more information, see the "ADF Faces Configuration" appendix in *Developing Web User Interfaces with Oracle ADF Faces*.

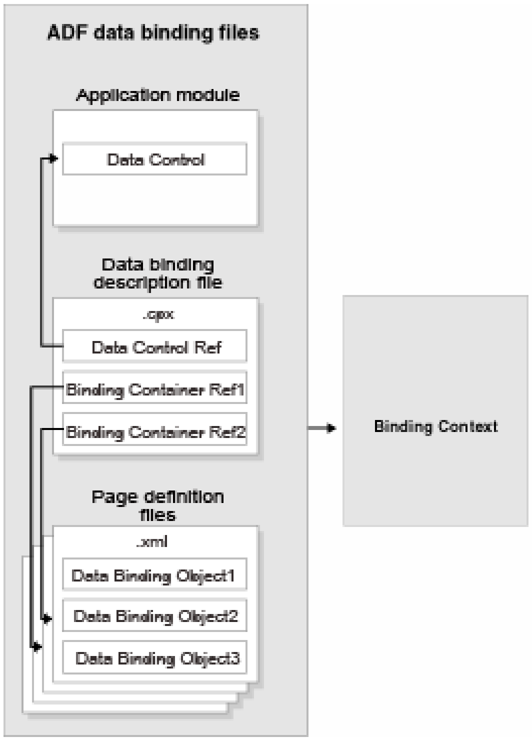
What Happens at Runtime: How the Binding Context Works

When a page contains ADF bindings, at runtime the interaction with the business services initiated from the client or controller is managed by the application through a single object known as the **binding context**. The binding context is a runtime map (named *data* and accessible through the EL expression `#{data}`) of all data controls and page definitions within the application.

The ADF lifecycle creates the Oracle ADF binding context from the application module, `DataBindings.cpx`, and page definition files, as shown in Figure 18-14. The union of all the `DataControls.dcx` files and any application modules in the workspace define the available data controls at design time, but the `DataBindings.cpx` file defines what data controls are available to the application at runtime. A `DataBindings.cpx` file lists all the data controls that are being used by pages in the application and maps the binding containers, which contain the binding objects defined in the page definition files, to web page URLs. The page definition files define the binding objects used by the application pages. There is one page definition file for each page.

The binding context does not contain real live instances of these objects. Instead, it is a map that contains references that become data control or binding container objects on demand. When the object (such as a page definition) is released from the application (for example when a task flow ends or when the binding container or data control is released at the end of the request), data controls and binding containers turn back into reference objects. For information about the ADF lifecycle, see Understanding the Fusion Page Lifecycle .

Figure 18-14   ADF File Binding Runtime Usage



> **Note:**
>
> Application module data controls also take advantage of **application module pooling**. The application module data control is a thin adapter over an application module pool that automatically acquires an available application module instance at the beginning of the request. During the current request, the application module data control holds a reference to the application module instance on behalf of the current user session. At the end of the request, the data control releases the instance back to the pool. For more information, see What Happens at Runtime: How the Application Uses Application Module Pooling and State Management.

Working with the DataBindings.cpx File

In ADF, you can find the metadata and the context for bindings in the DataBindings.cpx file. Depending on how an application is created, you can find one or multiple files. This file is available to the application at runtime.
The `DataBindings.cpx` files define the binding context for the entire application and provide the metadata from which the Oracle ADF binding objects are created at runtime. An application may have more than one `DataBindings.cpx` file if a component, for example a region, was created outside of the project and then imported. These files map individual pages to page definition files and declare which data controls are being used by the application. At runtime, only the data controls listed in the `DataBindings.cpx` files are available to the current application.

How JDeveloper Creates a DataBindings.cpx File

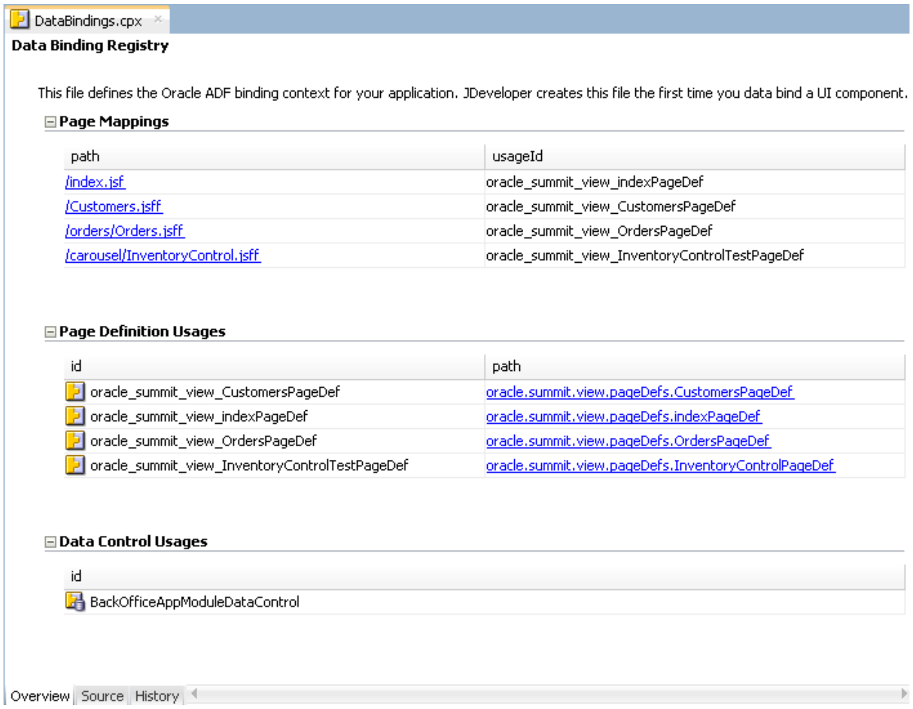
The first time you use the Data Controls panel to add a component to a page or an operation to an activity, JDeveloper automatically creates a `DataBindings.cpx` file in the default package of the view project. It resides in the `adfmsrc` directory for the project. Once the `DataBindings.cpx` file is created, JDeveloper adds an entry for the first page or task flow activity. Each subsequent time you use the Data Controls panel, JDeveloper adds an entry to the `DataBindings.cpx` for that page or activity, if one does not already exist.

> **Tip:**
>
> JDeveloper supports refactoring. That is, you can safely rename or move many of the objects referenced in the `DataBindings.cpx` file, and the references will be updated. For more information, see Refactoring a Fusion Web Application .

What Happens When JDeveloper Creates a DataBindings.cpx File

Once JDeveloper creates a `DataBindings.cpx` file, you can open it in the overview editor. Figure 18-15 shows the `DataBindings.cpx` file from the Summit ADF sample application, as viewed in the overview editor.

Figure 18-15 DataBindings.cpx File in the Overview Editor



Data Binding Registry

This file defines the Oracle ADF binding context for your application. JDeveloper creates this file the first time you data bind a UI component.

Page Mappings

path	usageId

             className="oracle.adfinternal.view.faces.dvt.model.binding.
                        FacesBindingFactory"/>
  </definitionFactories>
  <pageMap>
    <page path="/index.jsf" usageId="oracle_summit_view_indexPageDef"/>
    <page path="/Customers.jsff" usageId="oracle_summit_view_CustomersPageDef"/>
    <page path="/orders/Orders.jsff"
          usageId="oracle_summit_view_OrdersPageDef"/>
    <page path="/carousel/InventoryControl.jsff" usageId="oracle_summit_view_

InventoryControlTestPageDef"/>
  </pageMap>
  <pageDefinitionUsages>
    <page id="oracle_summit_view_CustomersPageDef"
          path="oracle.summit.view.pageDefs.CustomersPageDef"/>
    <page id="oracle_summit_view_indexPageDef"
          path="oracle.summit.view.pageDefs.indexPageDef"/>
    <page id="oracle_summit_view_OrdersPageDef"
          path="oracle.summit.view.pageDefs.OrdersPageDef"/>
    <page id="oracle_summit_view_InventoryControlTestPageDef"
          path="oracle.summit.view.pageDefs.InventoryControlPageDef"/>
  </pageDefinitionUsages>
  <dataControlUsages>
    <BC4JDataControl id="BackOfficeAppModuleDataControl"
                     Package="oracle.summit.model.services"
                     FactoryClass="oracle.adf.model.bc4j.DataControlFactoryImpl"
                     SupportsTransactions="true" SupportsFindMode="true"
                     SupportsRangesize="true" SupportsResetState="true"
                     SupportsSortCollection="true"
                     Configuration="BackOfficeAppModuleLocal"
                     syncMode="Immediate"
                     xmlns="http://xmlns.oracle.com/adfm/datacontrol"/>
  </dataControlUsages>
</Application>
```

The **Page Mappings** section of the editor maps each JSF page or task flow activity to its corresponding page definition file using an ID. The **Page Definition Usages** section maps the page definition ID to the absolute path for page definition file in the application. The **Data Control Usages** section identifies the data controls being used by the binding objects defined in the page definition files. These mappings allow the binding container to be initialized when the page is invoked.

You can use the overview editor to change the ID name for page definition files or data controls by double-clicking the current ID name and editing inline. Doing so will update all references in the application. Note, however, that JDeveloper updates only the ID name and not the file name. Be sure that you do not change a data control name to a reserved word. For more information, see How to Edit an Existing Application Module.

You can also click an element in the Structure window and then use the Properties window to change property values. For more information about the elements and attributes in the `DataBindings.cpx` file, see DataBindings.cpx.

Configuring the ADF Binding Filter

In ADF, when you add a databound object, JDeveloper automatically configures a filter which is a ADF binding filter that processes any HTTP request. This filter specifies the name of the binding objects and link filters to servlets in a web application.
The ADF binding filter is a servlet filter that is an instance of the `oracle.adf.model.servlet.ADFBindingFilter` class. ADF web applications use the ADF binding filter to preprocess any HTTP requests that may require access to the binding context. To do this, the ADF binding filter must be aware of all `DataBindings.cpx` files that exist for an application.

How JDeveloper Configures the ADF Binding Filter

The first time you add a databound component to a page using the Data Controls panel, JDeveloper automatically configures the filter for you in the application's `web.xml` file.

What Happens When JDeveloper Configures an ADF Binding Filter

To configure the binding filter, JDeveloper adds the following elements to the `web.xml` file:

- An ADF binding filter class: Specifies the name of the binding filter object, which implements the `javax.servlet.Filter` interface.

  The ADF binding filter is defined in the `web.xml` file, as shown in the following example. The `filter-name` element must contain the value `adfBindings`, and the `filter-class` element must contain the fully qualified name of the binding filter class, which is `oracle.adf.model.servlet.ADFBindingFilter`.

  ```
  <filter>
     <filter-name>adfBindings</filter-name>
     <filter-class>oracle.adf.model.servlet.ADFBindingFilter</filter-class>
  </filter>
  ```

- Filter mappings: Link filters to static resources or servlets in the web application.

  At runtime, when a mapped resource is requested, a filter is invoked. Filter mappings are defined in the `web.xml` file, as shown in the following example. The `filter-name` element must contain the value `adfBindings`.

  ```
  <filter-mapping>
    <filter-name>adfBindings</filter-name>
    <servlet-name>Faces Servlet</servlet-name>
    <dispatcher>FORWARD</dispatcher>
    <dispatcher>REQUEST</dispatcher>
  </filter-mapping>
  ```

> **Tip:**
>
> If you have multiple filters defined in the `web.xml` file, be sure to list them in the order in which you want them to run. At runtime, the filters are executed in the sequence in which they appear in the `web.xml` file.
>
> The `adfBindings` filter should appear after the Trinidad filter and before any filters that depend on the ADF context to be initialized.

What Happens at Runtime: How the ADF Binding Filter Works

At runtime, the ADF binding filter performs the following functions:

- Overrides the character encoding when the filter is initialized with the name specified as a filter parameter in the `web.xml` file. The parameter name of the filter `init-param` element is `encoding`.
- Instantiates the `ADFContext` object, which is the execution context for a Fusion web application and contains context information about ADF, including the security context and the environment class that contains the request and response object.
- Initializes the binding context for a user's HTTP session. To do this, it first loads the bindings as defined in the `DataBindings.cpx` file in the current project's `adfmsrc` directory. If the application contains `DataBindings.cpx` files that were imported from another project, those files are present in the application's class path. The filter additively loads any auxiliary `.cpx` files found in the class path of the application.
- Serializes incoming HTTP requests from the same browser (for example, from frame sets) to prevent multithreading problems.
- Notifies data control instances that they are about to receive a request, allowing them to do any necessary per-request setup.
- Notifies data control instances after the response has been sent to the client, allowing them to do any necessary per-request cleanup.

Working with Page Definition Files

In ADF, you add UI components on a page from the Data Controls panel. Then, JDeveloper creates a page definition file and adds definition for each binding object. The page definition file shows in the overview editor, which allows you to view and configure parameters, bindings and so on.
Page definition files define the binding objects that populate the data in UI components at runtime. For every page that has ADF bindings, there must be a corresponding page definition file that defines the binding objects used by that page. Page definition files provide design time access to all the ADF bindings. At runtime, the binding objects defined by a page definition file are instantiated in a binding container, which is the runtime instance of the page definition file.

Note:

When multiple windows are open to the same page, ADF Controller assigns each window its own `DataControlFrame`. This ensures that each window has its own binding container.

How JDeveloper Creates a Page Definition File

The first time you use the Data Controls panel to add a component to a page, JDeveloper automatically creates a page definition file for that page and adds definitions for each binding object referenced by the component. For each subsequent databound component you add to the page, JDeveloper automatically adds the necessary binding object definitions to the page definition file.

By default, the page definition files are located in the `view.PageDefs` package in the Application Sources node of the view project. If the corresponding JSF page is saved to a directory other than the default (`public_html`), or to a subdirectory of the default, then the page definition will also be saved to a package of the same name. For example, if you save your JSF file to the `public_html\myDirectory` directory, the page definition will be saved to the `myDirectory` package. You can change the location of the page definition files using the ADF Model Settings page of the Project Properties dialog.

JDeveloper names the page definition files using the following convention:

`pageName``PageDef.xml`

where *`pageName`* is the name of the JSF page or fragment. For example, if the JSF page is named `index.jsf`, the default page definition file name is `indexPageDef.xml`. If you organize your pages into subdirectories, JDeveloper prefixes the directory name to the page definition file name using the following convention:

`directoryName_pageName``PageDef.xml`

Tip:

Page definitions for task flows follow the same naming convention.

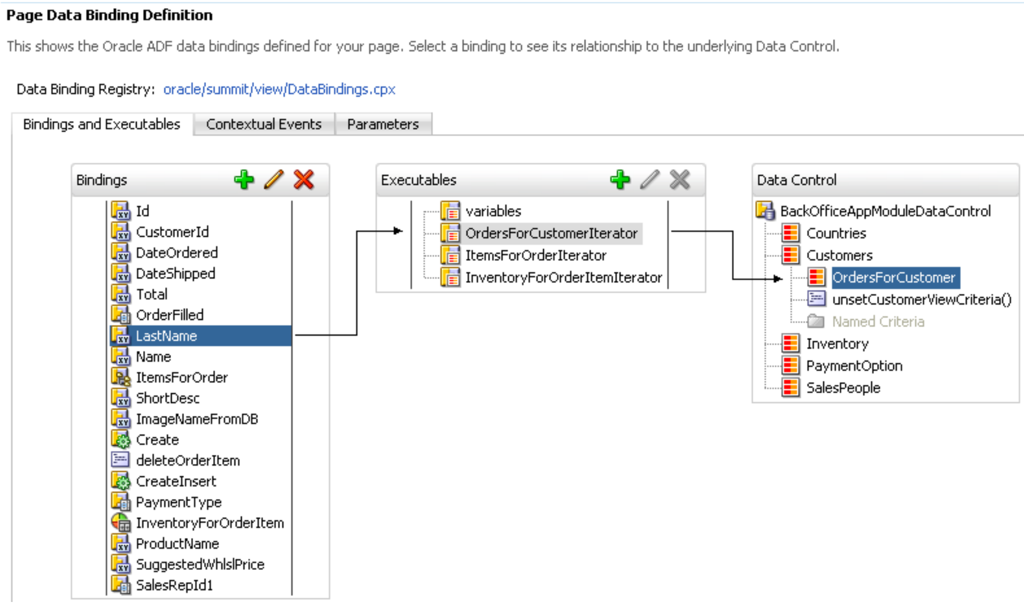
To open a page definition file, you can right-click directly on the page or activity in the visual editor, and choose **Go to Page Definition**, or for a JSF page, you can click the **Bindings** tab of the editor and click the Page Definition File link.

> **Tip:**
>
> While JDeveloper automatically creates a page definition for a JSF page when you create components using the Data Controls panel, or for a task flow when you drop an item onto an activity, it does not delete the page definition when you delete the associated JSF page or task flow activity. (This is to allow bindings to remain when they are needed without a JSF page, for example when using ADF Desktop Integration features.) If you no longer want the page definition, you need to delete the page definition and all references to it manually. Note however, that as long as a corresponding page or activity is never called, the page definition will never be used to create a binding context. It is therefore not imperative to remove any unused page definition files from your application.

What Happens When JDeveloper Creates a Page Definition File

When JDeveloper creates a page definition file, it is displayed in the overview editor. Figure 18-16 shows the page definition file in the overview editor that was created for the `Orders.jsff` page fragment in the Summit ADF sample application.

Figure 18-16 Page Definition File in the Overview Editor



Page Data Binding Definition

This shows the Oracle ADF data bindings defined for your page. Select a binding to see its relationship to the underlying Data Control.

Data Binding Registry: oracle/summit/view/DataBindings.cpx

The overview editor contains the following tabs, which allow you to view and configure bindings, contextual events, and parameters for a page:

- Bindings and Executables: The Bindings and Executables tab of the page definition overview editor shows three different types of objects: bindings, executables, and the associated data controls. (The data controls do not display unless you select a binding or executable.) For example, in Figure 18-16, you can see that the binding for the `LastName` attribute uses the `OrdersForCustomerIterator` iterator to get its value. The iterator accesses the `OrdersForCustomer` collection on the `BackOfficeAppModuleDataControl` data control. See Executable Binding Objects Defined in the Page Definition File.

By default, the model binding objects are named after the data control object that was used to create them. If a data control object is used more than once on a page, JDeveloper adds a number to the default binding object names to keep them unique. In Creating ADF Data Binding EL Expressions, you will see how the ADF data binding EL expressions reference the binding object names.

Table 18-2 shows the icons for each of the binding objects, as displayed in the overview editor (note that while parameter objects are shown in the **Parameter** section of the editor, they are also considered binding objects).

Table 18-2 Binding Object Icons

Binding Object Type	Icon	Description
Parameter		Represents a parameter binding object.
Bindings		Represents an attribute value binding object.
		Represents a list value binding object.
		Represents a tree value binding object.
		Represents a method action binding object
Bindings/ Executables		Represents an action binding object.

Table 18-2 (Cont.) Binding Object Icons

Binding Object Type	Icon	Description
Executables		Represents an iterator binding object.
		Represents a task flow executable binding object.
		Represents a search region binding object, which is used when named criteria objects are added to a page.

- Contextual Events: You can create contextual events that artifacts in an application can subscribe to. For example, you can use contextual events in a customer registration page to display the appropriate informational topic. One region in the page might contain a customer registration task flow, and the other an informational topic task flow. A contextual event can be passed from the customer registration region to the informational topic region so that the informational topic task flow can display the correct information topic. At design time, the event name, producer region, consumer region, consumer handler, and other information is stored in the event map section of the page definition file. See Using Contextual Events.
- Parameters: Parameter binding objects declare the parameters that the page evaluates at the beginning of a request. For more information about the ADF lifecycle, see Understanding the Fusion Page Lifecycle . Such parameters can also be passed through task flows, as described in Using Parameters in Task Flows.

  You can define the value of a parameter in the page definition file using static values, or EL expressions that assign a static value. The following example shows a parameter binding object that uses an EL expression to assign its value.

  ```
  <parameters>
  <parameter name="productId" value="${payLoad}"/>
  </parameters>
  ```

> **Tip:**
>
> The EL expression for the parameter values uses the dollar sign ($) because these expressions need to be resolved eagerly, so that the result is returned immediately, as the page is rendered. Most EL expressions in a JSF application use the hash sign (#), which defers the expression evaluation so that the model is prepared before the values are accessed.

When you click an item in the overview editor (or the associated node in the Structure window), you can use the Properties window to view and edit the attribute values for the item, or you can edit the XML source directly by clicking the **Source** tab. The following example shows XML code excerpts for the page definition file shown in Figure 18-16.

```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
                version="11.1.1.59.23" id="OrdersPageDef"
                Package="oracle.summit.view.pageDefs">
  <parameters/>
  <executables>
    <variableIterator id="variables"/>
    <iterator Binds="OrdersForCustomer" RangeSize="25"
              DataControl="BackOfficeAppModuleDataControl"
              id="OrdersForCustomerIterator" ChangeEventPolicy="ppr"/>
    <iterator Binds="ItemsForOrder" RangeSize="25"
              DataControl="BackOfficeAppModuleDataControl"
              id="ItemsForOrderIterator" ChangeEventPolicy="ppr"/>
    <iterator Binds="InventoryForOrderItem" RangeSize="-1"
              DataControl="BackOfficeAppModuleDataControl"
              id="InventoryForOrderItemIterator" ChangeEventPolicy="ppr"/>
  </executables>
  <bindings>
    <attributeValues IterBinding="OrdersForCustomerIterator" id="Id">
      <AttrNames>
        <Item Value="Id"/>
      </AttrNames>
    </attributeValues>
.
.
.
    <list IterBinding="OrdersForCustomerIterator" StaticList="false"
          Uses="LOV_OrderFilled" id="OrderFilled" DTSupportsMRU="false"/>
    <attributeValues IterBinding="OrdersForCustomerIterator" id="LastName">
      <AttrNames>
        <Item Value="LastName"/>
      </AttrNames>
    </attributeValues>
    <attributeValues IterBinding="OrdersForCustomerIterator" id="Name">
      <AttrNames>
        <Item Value="Name"/>
      </AttrNames>
    </attributeValues>
    <tree IterBinding="ItemsForOrderIterator" id="ItemsForOrder">
      <nodeDefinition DefName="oracle.summit.model.views.ItemVO"
                      Name="ItemsForOrder0">
        <AttrNames>
          <Item Value="ProductId"/>
          <Item Value="Name"/>
          <Item Value="Price"/>
          <Item Value="Quantity"/>
          <Item Value="ItemTotal"/>
        </AttrNames>
      </nodeDefinition>
    </tree>
.
.
.
  </bindings>
</pageDefinition>
```

In later chapters, you will see how the page definition file is used to define and edit the bindings for specific UI components. For a description of all the possible elements and attributes in the page definition file, see pageNamePageDef.xml.

Control Binding Objects Defined in the Page Definition File

There are three types of binding objects used to bind UI components to objects on the data control:

- Value: Displays data in UI components by referencing an iterator binding. Each discrete UI component on a page that will display data from the data control is bound to a value binding object. Types of value binding objects include:
  - Attribute Value: Binds text fields to a specific attribute in an object (also referred to as an **attribute binding** object.)
  - List: Binds the list items to all values of an attribute in a data collection.
  - Tree: Binds an entire table to a data collection and can also bind the root node of a tree to a data collection.
  - Button (boolean): Binds a checkbox to a boolean value for an attribute.
  - Graph: Binds a graph directly to the source data.
- Method Action: Binds command components, such as buttons or links, to custom methods on the data control. A method action binding object encapsulates the details about how to invoke a method and what parameters (if any) the method expects.
- Action: Binds command components, such as buttons or links, to built-in data control operations (such as, Commit or Rollback) or to built-in collection-level operations (such as, Create, Delete, Next, or Previous).

The following example shows an excerpt from a sample `bindings` element. Among other things, the element defines a tree binding for a table, several attribute bindings for text fields, an action binding for the `CreateInsert` built-in operation, and a list binding for a `selectOneChoice` component.

```
<bindings>
.
.
.
  <tree IterBinding="ItemsForOrderIterator" id="ItemsForOrder">
    <nodeDefinition DefName="oracle.summit.model.views.ItemVO"
                    Name="ItemsForOrder0">
      <AttrNames>
        <Item Value="ProductId"/>
        <Item Value="Name"/>
        <Item Value="Price"/>
        <Item Value="Quantity"/>
        <Item Value="ItemTotal"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
  <attributeValues IterBinding="ItemsForOrderIterator" id="ShortDesc">
    <AttrNames>
      <Item Value="ShortDesc"/>
    </AttrNames>
  </attributeValues>
  <attributeValues IterBinding="ItemsForOrderIterator" id="ImageNameFromDB"
                   ChangeEventPolicy="ppr">
    <AttrNames>
      <Item Value="ImageNameFromDB"/>
    </AttrNames>
  </attributeValues>
.
.
.
  <action IterBinding="ItemsForOrderIterator" id="CreateInsert"
          RequiresUpdateModel="true" Action="createInsertRow"/>
  <list IterBinding="OrdersForCustomerIterator" StaticList="false"
        Uses="LOV_PaymentTypeId" id="PaymentType" DTSupportsMRU="true"/>
</bindings>
```

In the example, the tree element defines the bindings for the ItemsForOrder table. The AttrNames element is used to define the columns for which values will be displayed. The IterBinding attribute references the iterator binding that manages the data to be displayed in the table. For more information, see Executable Binding Objects Defined in the Page Definition File and Iterator and Value Bindings for Tables.

The attributeValues elements define the value bindings for text fields on the page. In the example, the ShortDesc attribute binding will display the value of ShortDesc, which is defined in the AttrNames element. The IterBinding attribute references the iterator binding that manages the data to be displayed in the text field. For more information, see What Happens When You Create a Text Field .

The binding object defined in the action element encapsulates the information needed to invoke the built-in CreateInsert operation on the ItemsForOrder collection. The value of true in the RequiresUpdateModel attribute specifies that the model layer needs to be updated before the operation is executed. For more information, see What Happens When You Create Command Components Using Operations.

If this operation also raised a contextual event, an event definition would also appear. If the page contained bindings that consumed an event, the event mapping would appear. For more information, see Using Contextual Events.

The PaymentType element defines the list binding used to display the list of payment type codes by using the LOV_PaymentTypeId LOV. For more information about creating lists using LOVs on view objects, see Creating Databound Selection Lists and Shuttles .

Executable Binding Objects Defined in the Page Definition File

There are the following types of executable binding objects:

- Iterator: Binds to an iterator that iterates over view object collections. There is one iterator binding for each collection used on the page. All of the value bindings on the page must refer to an iterator binding in order for the component values to be populated with data at runtime.

When you drop a collection or an attribute of a collection on the page, an iterator binding is automatically added as an executable. Iterator binding objects bind to an underlying ADF `RowSetIterator` object, which manages the current object and current range information. The iterator binding exposes the current object and range state to the other binding objects used by the page.

By default, iterator bindings are configured so that any submitted data changes are cached until the data is committed back to the data source. When a data change is submitted, any components on the page whose bindings are associated with the iterator are refreshed to show the changed data. For more information, see What You May Need to Know About Partial Page Rendering and Iterator Bindings.

The iterator **range** represents the current set of objects to be displayed on the page. The maximum number of objects in the current range is defined in the `rangeSize` attribute of the iterator. For example, if a collection in the data control contains products and the iterator range size is 25, the first 25 products in the collection are displayed on the page. If the user scrolls down, the next set of 25 is displayed, and so on. If the user scrolls up, the previous set of 25 is displayed. If your view object uses range paging, then you can configure the iterator binding to return a set of ranges at one time. For more information, see Using Range Paging to Efficiently Scroll Through Large Result Sets.

> **Note:**
>
> If you have two pages each with an iterator binding bound to the iterator on the same view object (which you will if you drop the same collection, for example, on two different pages), then you should ensure that the `rangeSize` attribute is the same for both pages' iterator bindings. If not, the page with a smaller range size may cause the iterator to reexecute, causing unexpected results on the other page.

- Method Iterator: Binds to an iterator that iterates over the collections returned by custom methods in the data control.

  A method iterator binding is always related to a method action binding object. The method action binding encapsulates the details about how to invoke the method and what parameters (if any) the method is expecting. The method action binding is itself bound to the method iterator, which provides the data.

  You will see method iterator executable binding objects only if you drop a method return collection or an attribute of a method return collection from a custom method on the data control. If you are using only application module data controls, you will see only iterator binding objects.

- Variable Iterator: Binds to an iterator that exposes all the variables in the binding container to the other bindings. While there is an iterator binding for each collection, there is only one variable iterator binding for all variables used on the page. (The variable iterator is like an iterator pointing to a collection that contains only one data object whose attributes are the binding container variables.)

  Page variables are local to the binding container and exist only while the binding container object exists. When you use a data control method (or an operation) that requires a parameter that is to be collected from the page, JDeveloper automatically defines a variable for the parameter in the page definition file. Attribute bindings can reference the page variables.

A variable iterator can contain one of two types of variables: `variable` and `variableUsage`. A `variable` type variable is a simple value holder, while a `variableUsage` type variable is a value holder that is related to a view object's named bind parameter. Defining a variable as a `variableUsage` type allows it to inherit the default value and UI control hints from the view object named bind variable to which it is bound.

- Page: Binds to the template's page definition file (if a template is used). For more information about how this works with templates, see Using Page Templates.

> **Note:**
>
> You can also use the `page` element to bind to another page definition file. However, at runtime, only the current incoming page's (or if the rendered page is different from the incoming, the rendered page's) binding container is automatically prepared by the framework during the current request. Therefore, to successfully access a bound value in another page from the current page, you must programmatically prepare that page's binding container in the current request (for example, using a backing bean). Otherwise, the bound values in that page may not be available or valid in the current request.

- Search Region: Binds named criteria to the iterator, so that the search can be executed.
- Task Flow: Instantiates the binding container for a region's task flow.
- Multi Task Flow: Instantiates the binding container for a region's task flow from an array of task flows. This is useful when you have a page that contains an unknown number of regions, such as a `panelTabbed` component where each tab is a region, and users can add and delete tabs at runtime. For more information, see Configuring a Page To Render an Unknown Number of Regions.

At runtime, executable bindings are refreshed based on the value of their `Refresh` attribute. Refreshing an iterator binding reconnects it with its underlying `RowSetIterator` object. Before refreshing any bindings, the ADF runtime evaluates any `Refresh` and `RefreshCondition` attributes specified in the executables. The `Refresh` attribute specifies the ADF lifecycle phase within which the executable should be invoked. The `RefreshCondition` attribute specifies the conditions under which the executable should be invoked. You can specify the `RefreshCondition` value using a boolean EL expression. If you leave the `RefreshCondition` attribute blank, it evaluates to `true`.

By default, the `Refresh` value is set to `deferred`. This means the binding will not be executed unless its value is accessed (for example by an EL expression on a JSF page). Once called, it will not reexecute unless any parameter values for the binding have changed, or if the binding itself has changed.

For more information about how bindings are refreshed and how to set the `Refresh` and `RefreshCondition` attributes, see About the JSF and ADF Page Lifecycles.

The following example illustrates executable binding objects from the Summit ADF sample application.

```
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="OrdersForCustomer" RangeSize="25"
            DataControl="BackOfficeAppModuleDataControl"
            id="OrdersForCustomerIterator" ChangeEventPolicy="ppr"/>
  <iterator Binds="ItemsForOrder" RangeSize="25"
            DataControl="BackOfficeAppModuleDataControl"
            id="ItemsForOrderIterator" ChangeEventPolicy="ppr"/>
  <iterator Binds="InventoryForOrderItem" RangeSize="-1"
            DataControl="BackOfficeAppModuleDataControl"
            id="InventoryForOrderItemIterator" ChangeEventPolicy="ppr"/>
</executables>
```

In the example, the iterator binding named `OrdersForCustomerIterator` was created by dropping the `OrdersForCustomer` collection on the page as an ADF form. The iterator binding named `ItemsForOrderIterator` was created by dropping the `ItemsForOrder` collection as a table. The `InventoryForOrderItemIterator` iterator binding was created by dropping the `InventoryForOrderItem` collection as a graph.

The `OrdersForCustomer` collection has a master-detail relationship with the `ItemsForOrder` collection, so the two iterators are automatically synchronized. For more information, see What Happens at Runtime: ADF Iterator for Master-Detail Tables and Forms.

The `Binds` attribute of the `iterator` element defines the collection the iterator will iterate over. The `RangeSize` attribute defines the number of objects the iterator is to display on the page at one time. A `RangeSize` value of `-1` causes the iterator to display *all* the objects from the collection.

> **Tip:**
>
> Normally, an iterator binding's default range size is 25. However, when an iterator binding is created from the Edit List Binding dialog, the range size defaults to `-1` so that all choices display in the list, not just the first 25.

> **Performance Tip:**
>
> When you want to reduce the number of roundtrips the iterator requires to fetch the data objects from the view object in the ADF Business Components layer, you can set the `rangeSize` attribute to `-1`, and the objects will be fetched in a single round trip to the server, rather than in multiple trips as the user navigates through the objects.

Creating ADF Data Binding EL Expressions

In ADF, when you create a component, JDeveloper creates data binding expressions for every component. You can either edit these expressions or create your own expression to bind the component by using the Expression Builder.
To display data from the data model, web page UI components are bound to binding objects using JSF Expression Language (EL) expressions. These EL expressions reference a specific binding object in a binding container. At runtime, the JSF runtime

evaluates an EL expression and pulls the value from the binding object to populate the component with data when the page is displayed. If the user updates data in the UI component, the JSF runtime pushes the value back into the corresponding binding object based on the same EL expression.

> **Tip:**
>
> There may be cases when you need to use EL expressions within managed beans. For information on working with EL expressions within managed beans, see the "Creating EL Expressions" section in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create an ADF Data Binding EL Expression

When you use the Data Controls panel to create a component, the ADF data binding expressions are created for you. The expressions are added to every component attribute that will either display data from or reference properties of a binding object. Each prebuilt expression references the appropriate binding objects defined in the page definition file. You can edit these binding expressions or create your own, as long as you adhere to the basic ADF binding expression syntax. ADF data binding expressions can be added to any component attribute that you want to populate with data from a binding object.

In JSF pages, a typical ADF data binding EL expression uses the following syntax to reference any of the different types of binding objects in the binding container:

```
#{bindings.BindingObject.propertyName}
```

where:

- `bindings` is a variable that identifies that the binding object being referenced by the expression is located in the binding container of the current page. All ADF data binding EL expressions must start with the `bindings` variable.
- *`BindingObject`* is the ID, or for attributes the name, of the binding object as it is defined in the page definition file. The binding `objectID` or name is unique to that page definition file. An EL expression can reference any binding object in the page definition file, including parameters, executables, or value bindings.
- *`propertyName`* is a variable that determines the default display characteristics of each databound UI component and sets properties for the binding object at runtime. There are different binding properties for each type of binding object. For more information about binding properties, see What You May Need to Know About ADF Binding Properties.

For example, in the following expression that might appear on a JSF page:

```
#{bindings.ProductName.inputValue}
```

the `bindings` variable references a bound value in the current page's binding container. The binding object being referenced is `ProductName`, which is an attribute binding object. The binding property is `inputValue`, which returns the value of the first `ProductName` attribute.

Tip:

While the binding expressions in the page definition file can use either a dollar sign ($) or hash sign (#) prefix, the EL expressions in JSF pages can only use the hash sign (#) prefix.

As stated previously, when you use the Data Controls panel to create UI components, these expressions are built for you. However, you can also manually create them if you need to. The JDeveloper Expression Builder is a dialog that helps you build EL expressions by providing lists of binding objects defined in the page definition files, as well as other valid objects to which a UI component may be bound. It is particularly useful when creating or editing ADF databound expressions because it provides a hierarchical list of ADF binding objects and their most commonly used properties. For information about binding properties, see What You May Need to Know About ADF Binding Properties.

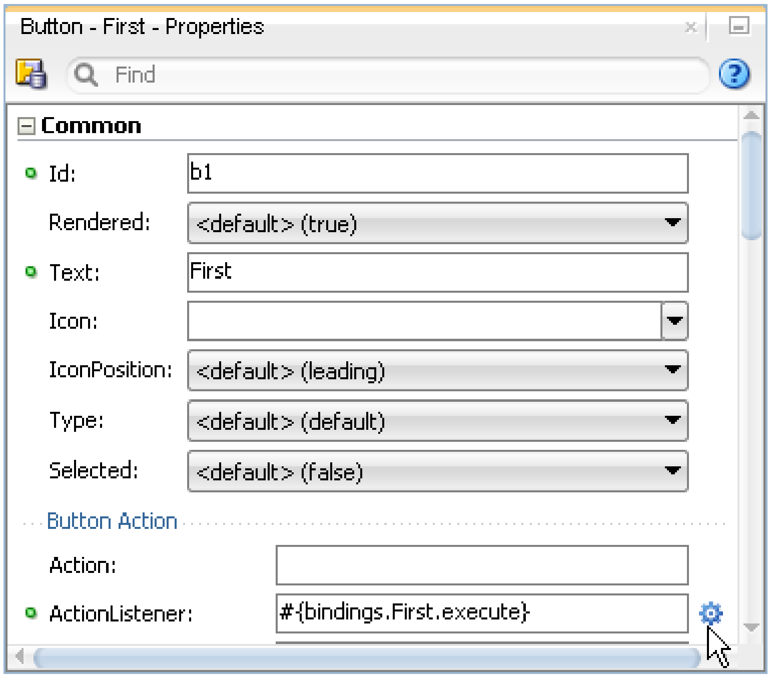
Opening the Expression Builder from the Properties Window

You can select an item in the visual editor, and then create EL expressions for specific attributes using the Properties window.

To open the Expression Builder from the Properties window:

1. Select a UI component in the Structure window or the visual editor.
2. In the Properties window, hover the mouse over the property and click the icon that appears to the right of the property, as shown in Figure 18-17.

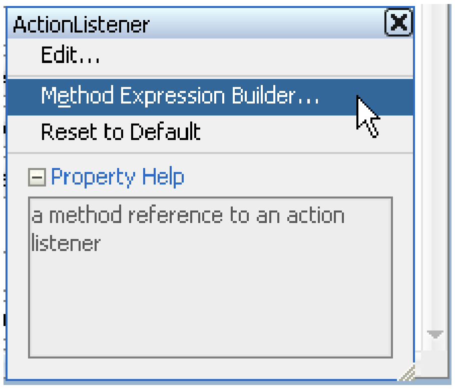
Figure 18-17 Icon for Property Menu



Id: b1
Rendered: <default> (true)
Text: First
Icon:
IconPosition: <default> (leading)
Type: <default> (default)
Selected: <default> (false)
Action:
ActionListener: #{bindings.First.execute}

3. In the popup menu, choose **Expression Builder** (or **Method Expression Builder**) as shown in Figure 18-18.

Figure 18-18 Property Menu



a method reference to an action listener

Using the Expression Builder

Once the Expression Builder is open, you can use it to create EL expressions.

Before you begin:

It may be helpful to have an understanding of how to create EL expressions when using the ADF Model layer. SeeCreating ADF Data Binding EL Expressions.

To use the Expression Builder:

1. Open the Expression Builder dialog as shown in Opening the Expression Builder from the Properties Window.
2. Use the Expression Builder to edit or create ADF binding expressions using the following features:
   - Use the **Variables** tree to select items that you want to include in the binding expression. The tree contains a hierarchical representation of the binding objects. Each icon in the tree represents various types of binding objects that you can use in an expression (see Table 18-3 for a description of each icon).

     To narrow down the tree, you can either use the dropdown filter or enter search criteria in the search field. Double-click an item in the tree to move it to the **Expression** box.
   - Use the operator buttons to add logical or mathematical operators to the expression.

> **Tip:**
>
> You can also type the expression directly in the **Expression** box.

Table 18-3 Icons Under the ADF Bindings Node of the Expression Builder

Icon	Description
	Represents the `bindings` container variable, which references the binding container of the current page. Opening the `bindings` node exposes all the binding objects for the current page.
	Represents the `data` binding variable, which references the entire binding context (created from all the `.cpx` files in the application). Opening the `data` node exposes all the page definition files in the application.
	Represents an action binding object. Opening a node that uses this icon exposes a list of valid action binding properties.
	Represents an iterator binding object. Opening a node that uses this icon exposes a list of valid iterator binding properties.
	Represents an attribute binding object. Opening a node that uses this icon exposes a list of valid attribute binding properties.
	Represents a list binding object. Opening a node that uses this icon exposes a list of valid list binding properties.
	Represents a table or tree binding object. Opening a node that uses this icon exposes a list of valid table and tree binding properties.
	Represents an ADF binding object property. For more information about ADF properties, see What You May Need to Know About ADF Binding Properties.

Table 18-3 (Cont.) Icons Under the ADF Bindings Node of the Expression Builder

Icon	Description
🟩	Represents a parameter binding object.
●	Represents a bean class.
☰	Represents a method.

What You May Need to Know About ADF Binding Properties

When you create a databound component using the Expression Builder, the EL expression might reference specific ADF binding properties. At runtime, these binding properties can define such things as the default display characteristics of a databound UI component or specific parameters for iterator bindings. The ADF binding properties are defined by Oracle APIs. For a full list of the available properties for each binding type, see Oracle ADF Binding Properties.

Values assigned to certain properties are defined in the page definition file. For example, iterator bindings have a property called `RangeSize`, which specifies the number of rows the iterator should display at one time. The value assigned to `RangeSize` is specified in the page definition file, as shown in the following example.

```
<iterator Binds="ItemsForOrder" RangeSize="25"
              DataControl="BackOfficeAppModuleDataControl"
              id="ItemsForOrderIterator" ChangeEventPolicy="ppr"/>
```

Using Simple UI First Development

In ADF, though you can use the Data Controls panel to design the page and bind objects, when your page uses declarative components, first add the UI components and then add the bindings, which can be reused as ADF Faces components.
While the Data Controls panel enables you to design and create bound components in a single drag-and-drop action, in some cases, it may be preferable to create the basic UI components first and add the bindings later. For example, if your page will use declarative components, you will first need to drop the declarative component, and then bind it to the correct ADF control. Declarative components are reusable, composite UI components that are made up of other ADF Faces components. Once imported into a project, declarative components can be dropped onto a page from the

Components window, similar to standard ADF Faces components. While the entire declarative component cannot use ADF data binding, you can use ADF data binding on the individual components that make up the declarative component, once the declarative component is dropped on the page. For more information about declarative components, see the "Using Declarative Components" section of *Developing Web User Interfaces with Oracle ADF Faces*.

> **Note:**
>
> If you know the UI components on your page will eventually use ADF data binding, but you need to develop the pages before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see Designing a Page Using Placeholder Data Controls .

When designing web pages, keep in mind that ADF bindings can be added only to certain ADF Faces tags or their equivalent JSF HTML tags. Table 18-4 lists the ADF Faces and JSF tags to which you can later add ADF bindings.

> **Tip:**
>
> To enable the use of JSF Reference Implementation UI component tags with ADF bindings, you must choose the **Include JSF HTML Widgets for JSF Databinding** option in the **ADF View Settings** of the project properties. However, using ADF Faces tags, especially with ADF bindings, provides greater functionality than does using the reference implementation JSF tags.

Table 18-4   Tags That Can Be Used for ADF Bindings

ADF Faces Tags Used in ADF Bindings	Equivalent JSF HTML Tags
Text Fields	
`af:inputText`	`h:inputText`
`af:outputText`	`h:outputText`
`af:outputLabel`	`h:outputLabel`
`af:inputDate`	n/a
Tables	
`af:table`	`h:dataTable`
Actions	
`af:button`	`h:commandButton`
`af:link`	`h:commandLink`
`af:commandMenuItem`	n/a
Selection Lists	
`af:inputListOfValues`	n/a

Table 18-4   (Cont.) Tags That Can Be Used for ADF Bindings

ADF Faces Tags Used in ADF Bindings	Equivalent JSF HTML Tags
`af:selectOneChoice`	`h:selectOneMenu`
`af:selectOneListbox`	`h:selectOneListbox`
`af:selecOneRadio`	`h:selectOneRadio`
`af:selectBooleanCheckbox`	h:selectBooleanCheckbox
Queries	
`af:query`	n/a
`af:quickQuery`	n/a
Trees	
`af:tree`	n/a
`af:treeTable`	n/a

Before adding binding to the UI components, ensure that you follow these guidelines:

- When creating the JSF page using the Create JSF JSP wizard, choose the **Do not Automatically Expose UI Components in a Managed Bean** option on the **Managed Bean** tab.

  This option turns off JDeveloper's auto-binding feature, which automatically associates every UI component in the page to a corresponding property in the backing bean for eventual programmatic manipulation. If you use the auto-binding feature, you will have to remove the managed bean bindings later, after you have added the ADF bindings. The managed bean UI component property bindings do not affect the ADF bindings, but their presence may be confusing in the JSF code. For information about managed beans, see Using a Managed Bean in a Fusion Web Application.

- Add the ADF Faces tag libraries.

  While you can add ADF bindings to JSF components, the ADF Faces components provide greater functionality, especially when combined with ADF bindings.

How to Apply ADF Model Data Binding to Existing UI Components

You apply ADF model binding to components using the Structure window.

Before you begin:

It may be helpful to have an understanding of UI first development. For more information, see Using Simple UI First Development.

You will need to complete these tasks:

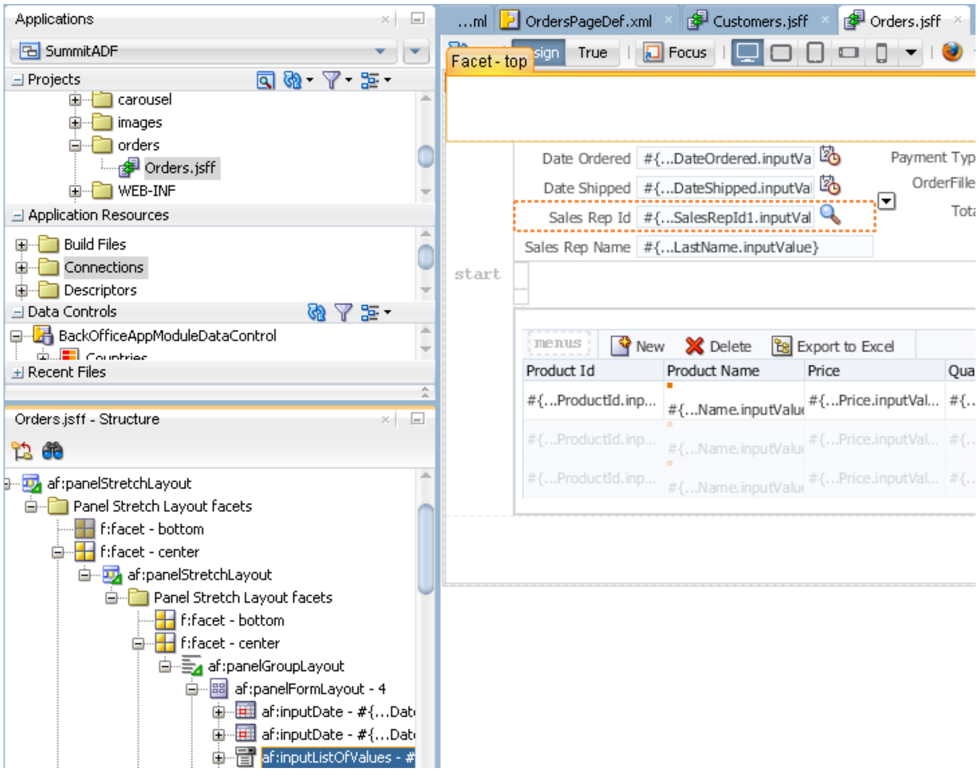
- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page, and add any components to the page.

To apply ADF Model data binding:

1. In the Design page of the visual editor, select the UI component to which you want to add ADF bindings.

   The component must be one of the tags listed in Table 18-4. When you select a component in the visual editor, JDeveloper simultaneously selects that component tag in the Structure window, as shown in Figure 18-19.

Figure 18-19 The Structure Window in JDeveloper



2. In the Structure window, right-click the UI component, and from the context menu, choose **Bind to ADF Control**.

> **Note:**
>
> Your project must already contain data controls for the **Bind to ADF Control** menu option to appear. If yours does not, you should consider using placeholder data controls, as described in Designing a Page Using Placeholder Data Controls .

3. In the Bind to ADF Control dialog, select the data control to which you want the UI component bound. JDeveloper will notify you if you choose a control that is not compatible with the selected UI component.

What Happens When You Apply ADF Model Data Binding to UI Components

When you use the Data Controls panel all of the required ADF objects are automatically created for you, as described in What Happens When You Use the Data Controls Panel.

19 Using Validation in the ADF Model Layer

This chapter describes how to use validation rules in the ADF model layer of your Oracle ADF application.

This chapter contains the following sections:

About ADF Model Layer Validation

In ADF, if you use data controls in an application that are not based on ADF Business Components, then you must use the validation rules to ensure that the data entered by user is validated.

In the model layer, ADF Model validation rules can be set for a binding's attribute on a particular page. When a user edits or enters data in a field and submits the form, the bound data is validated against any set rules and conditions. If validation fails, the application displays an error message.

Note that you don't need to add additional ADF Model validation if you have already set validation rules in the business domain layer of your entity objects. In a Fusion web application based on **ADF Business Components**, you won't need to use ADF Model validation unless you use data controls other than your **application module data control**.

ADF Model Layer Validation Use Cases and Examples

If your application uses data controls that are not based on ADF Business Components, you can use ADF Model layer validation to ensure the quality of user-entered data.

Best Practice:

Use business layer validation whenever possible. However, the following are examples of when you might need to use model layer validation:

- When your business layer does not support declarative validation.
- When you want to validate before an expensive roundtrip begins (for example, for a binding to a web service).
- When you need to validate a form created using parameters (for example, using the `executeWithParams` operation).

You can also use client-side validation for cases where you want to validate before a roundtrip to the server. For more information, see the "Adding Validation" section in *Developing Web User Interfaces with Oracle ADF Faces*.

Many of the declarative validation features available for ADF Business Components objects are also available at the model layer, should your application warrant the use of model-layer validation in addition to business-layer validation.

Additional Functionality for ADF Model Layer Validation

You may find it helpful to understand other ADF validation features before you use model layer validation. Following are links to other functionality that may be of interest.

- When you use the ADF Business Components application module data control, you do not need to use model-layer validation. Consider defining all or most of your validation rules in the centralized, reusable, and easier to maintain entity objects of your business layer. For more information, see Defining Validation and Business Rules Declaratively.
- Many of the declarative validation features available at the page level are also available at the bean level, which you would implement on the data control structure file. This can be very useful, because validation rules on the data control structure file apply to all usages of the data control. For information about implementing validation rules on the data control structure file, see the "Adding Business Logic to Data Controls" chapter in the *Developing Applications with Oracle ADF Data Controls*.

Defining Validation Rules in the ADF Model Layer

ADF provides a list of validation rules that you can use to validate binding attributes on the page definition file. You can use the Validation Rules Editor dialog to add, edit, or delete a validation rule for an attribute.
You can configure ADF Model validation for a binding's attributes on the page definition file. Validation rules in the model layer are executed for a binding's attribute on a particular page when the containing form is submitted.

You can optionally set the `skipValidation` property to `true` to bypass the ADF Model validation. You can set `skipValidation` to `skipDataControls` to validate the bound objects without validating the transaction. For example, set `skipValidation` to `skipDataControls` if you have a table action that opens a popup window to accept data entries and you want to allow the view layer to validate those entries before the commit on the table. The `skipValidation` property can be found in the Properties window after you have selected the root node of the page definition file in the Structure window.

How to Add ADF Model Layer Validation

You set ADF Model validation on the page definition file. You define the validation rule, and set an error message to display when the rule is broken.

Table 19-1 describes the ADF Model validation rules that you can configure for a binding's attributes.

Table 19-1 ADF Model Validation Rules

Validator Rule Name	Description
Compare	Compares the attribute's value with a literal value
List	Validates whether or not the value is in a list of values
Range	Validates whether or not the value is within a range of values
Length	Validates the value's character or byte size against a size and operand (such as greater than or equal to)
Regular Expression	Validates the data using Java regular expression syntax
Required	Validates whether or not a value exists for the attribute

Before you begin:

It may be helpful to have an understanding of the use of validation rules in the model layer. For more information, see Defining Validation Rules in the ADF Model Layer.

You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for ADF Model Layer Validation.

You will need to complete this task:

- Create a component on the page. The component must have binding attributes.

To create an ADF Model validation rule:

1. In the Applications window, double-click the page definition that contains the binding for which you want to create a rule.
2. In the Structure window, select the attribute, list, or table binding.
3. In the Properties window, click the **More** dropdown menu and choose **Edit Validation Rule**.
4. In the Validation Rules Editor dialog, expand the binding node, select the attribute name, and click **New**.
5. In the Add Validation Rule dialog, select a validation rule and configure the rule as needed.
6. Click the **Failure Handling** tab and configure the message to display when the rule is broken.

What Happens at Runtime: Model Validation Rules

When a user submits data, as long as the submitted value is a non-null value or a string value of at least one character, then all validators on a component are called one at a time. Because the `f:validator` tag on the component is bound to the `validator` property on the binding, any validation routines set on the model are accessed and executed.

The process then continues to the next component. If all validations are successful, the Update Model Values phase starts and a local value is used to update the model. If any validation fails, the current page is redisplayed along with an error message.

What You May Need to Know About Default Error Handling

When exceptions occur, the default behavior is to display only leaf-level errors in ADF Faces error dialogs. The default error handling mechanism for ADF Controller retrieves the list of exceptions from the page binding container and determines how to display each error. If the exception is not a `JboException`, a Faces error message is displayed with the exception message.

If the exception is a `JboException`, the error handling mechanism drills down recursively into nested exceptions, and displays a single Faces error message for each unique exception. However, if the exception has `JboWarning.HIDE_DETAIL_EXCEPTIONS_HINT`, the error handling mechanism will not drill down into nested exceptions.

Additionally, the error handling mechanism retrieves a list of binding errors for each exception and displays a Faces error message for the component associated with the binding that reported the error.

Customizing Error Handling

In ADF, you can use the ErrorHandlerClass property to set the error handler you want to use to report error or informational messages. You need not write code for error messages, but you can use the Properties windows of DataBindings.cpx file where you can set the error handler.
You can report errors using a custom error handler that extends the default `DCErrorHandlerImpl` class. You are not required to write any code to register your custom exception handler class. Instead, you select the root node of the `DataBindings.cpx` file in the Structure window, and then use the Properties window to set the `ErrorHandlerClass` property to the fully qualified name of the error handler you want it to use.

Your custom error handler can contain the following overridable methods:

- `reportException()`: Called to report any exception that occurs. It can be overridden to analyze reported exceptions.
- `getDisplayMessage()`: Returns the message that will be reported to JSF for each error that occurs. Returning `null` is the way your custom error handler signals that a given exception should not be reported to the client.
- `getDetailedDisplayMessage()`: Returns the detail portion of the message as a `String` object or HTML that will be reported to JSF for each error that occurs.

Returning `null` is the way your custom error handler signals that a given exception should not be reported to the client.

- `skipException()`: Returns a boolean depending on whether you want to display each item from the nested exception in the final error list displayed to the user. This method override lets you implement logic to check for specifics exception types and, based on the business scenario, determine whether to display it in the list.

The following example shows a custom error handler that extends the `DCErrorHandlerImpl` class and shows the override for the `skipException()` method that is needed to skip exceptions that should not appear in the list displayed to the user.

```
package view.controller.fwkext;

import java.sql.SQLIntegrityConstraintViolationException;

import java.util.ArrayList;
import java.util.List;

import oracle.adf.model.binding.DCBindingContainer;
import oracle.adf.model.binding.DCErrorHandlerImpl;

import oracle.jbo.CSMessageBundle;
import oracle.jbo.DMLConstraintException;
import oracle.jbo.JboException;

public class CustomErrorHandler extends DCErrorHandlerImpl {

   List<ExceptionMapper> exceptionMapperList = new ArrayList<ExceptionMapper>();

   public CustomErrorHandler() {
     super();
     exceptionMapperList.add(new DisableJboExceptionCodesMapper());
   }

   public void reportException(DCBindingContainer bc, Exception ex) {
     for (ExceptionMapper mapper : exceptionMapperList) {
       if (mapper.canMapException(ex)) {
         ex = mapper.mapException(ex);
       }
     }
     super.reportException(bc, ex);
   }

   /**
    * If an exception is a RowValException or a TxnValException and they
    * have nested exceptions, then do not display it. This example shows
    * an implementation that skips the SQLIntegrityConstraintViolationException
    * from displaying in the error final list displayed to the user.
    */
   @Override
   protected boolean skipException(Exception ex) {

      if (ex instanceof DMLConstraintException) {
            return false;
        } else if (ex instanceof SQLIntegrityConstraintViolationException) {
            return true;
        }
        return super.skipException(ex);
    }

}
```

Your error handler class must have a default constructor that matches the name of the custom class. For example, if you create a custom handler class `MyErrorHandler`, the exception error handler would invoke the default constructor, as shown in the following example. Following this convention allows dynamic invocation by the class name alone.

```
ErrorHandlerClass="viewcontroller.MyErrorHandler"
 public MyErrorHandler()
 {
   super();
 }
```

How to Customize the Detail Portion of a Message

If you plan to customize and use the detail portion of a message, you can create a custom error handler and implement the `getDetailedDisplayMessage` method to retrieve and process that message. The finalized message will be passed to the view layer to be integrated with other messages.

To customize the detail portion of a message:

1. Create a custom error handler class that extends the default `DCErrorHandlerImpl` class.
2. In that class, override the `getDetailedDisplayMessage` method that returns a `DCErrorMessage` object.

   The following example shows an implementation of the `getDetailedDisplayMessage` method in the custom error handler class.

   ```
   public final class MyErrorMessageHandler extends DCErrorHandlerImpl {
       public MyErrorMessageHandler (){
           super();
       }
       public DCErrorMessage getDetailedDisplayMessage(BindingContext ctx,
                                                       RegionBinding ctr,
                                                       Exception ex) {
           ...
           return new MyDCErrorMesssage(ctr, ex);
       }
   }
   ```

3. Create a custom class that implements the `DCErrorMessage` interface. The class must implement the `getHTMLText` method and the `getText` method.

   You will add code to the `getHTMLText` method to perform the actual processing, but you must also implement `getText` to satisfy the interface requirements.

4. In the `getHTMLText` implementation, add code to create and process the error message.

   `getHTMLText` of `getDetailedDisplayMessage` should return the finalized version of the error message as an HTML fragment that will be inserted into the HTML code of the page. For this reason, you should perform all necessary preprocessing on the text message before the message is returned by `getDetailedDisplayMessage`. For instance, you may want to retrieve the localized version of the message or change the right-to-left ordering of the message before it is returned.

The following example shows an implementation of this interface.

```
public final class MyDCErrorMesssage implements DCErrorMessage {
    RegionBinding m_regionBinding;
    Exception m_ex;
       public MyDCErrorMesssage(RegionBinding ctr, Exception ex) {
        super();
        this.m_regionBinding = ctr;
        this.m_ex = ex;
    }
    public String getText() {
        ...
        return "Message String";
    }
    public String getHTMLText() {
        ...
        /* Add code to process the message, including localization */
        /* and right-to-left directional requirements. */
        /* Return the message as the finalized HTML fragment.*/
        return "<html><b>error</b> message details</html>";
    }
}
```

To format the message using HTML tags, you must enclose the message within <html></html> tags, as shown in the example. Note that only the following HTML tags are allowed in error messages:

- <span>
- <b>
- <a>
- <i>
- <em>
- <br>
- <hr>
- <li>
- <ol>
- <ul>
- <p>
- <tt>
- <big>
- <small>
- <pre>

How to Display an Informational Message from a Custom Error Handler

You can use an error handler to display an informative message in response to a warning in an application using custom validation in the ADF Model layer. For applications that use model layer validation, you need to use a custom error handler at the application CPX level, for all errors and warnings.

Before you begin:

It may be helpful to have an understanding of how custom validation in the model layer works. For more information, see Customizing Error Handling.

You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for ADF Model Layer Validation.

You must also launch JDeveloper, and open the application to which you want to add the custom error handler.

To display an informational message

1. In the data model project, create a class that extends `JboWarning`. For example:

```
public class InformationalMessage extends JboWarning
{
    public static final String INFO_PROPERTY = "$InformationalMessage$INFO";
    public InformationalMessage(String message)
    {
        super(message, "", new Object[]{INFO_PROPERTY});
    }
}
```

2. In the application module implementation class, add a method and expose it as a client method. For example:

```
public void addInformationMessageTest()
  {
      addWarning
        (new InformationalMessage("Testing. This is an information
message"));
  }
```

3. In the view controller project, create a customer error handler class, as described in Customizing Error Handling.

4. Add the customer error handler you created to the data bindings file (`DataBindings.cpx`). For example:

```
<Application xmlns="http://xmlns.oracle.com/adfm/application"
             id="DataBindings" SeparateXMLFiles="false"
             Package="my.view" ClientType="Generic"
             ErrorHandlerClass="my.view.CustomErrorHandler">
  <pageMap>
    <page path="/Test.jspx" usageId="my_view_TestPageDef"/>
  </pageMap>
```

5. To test the method, you can drop the client application module method onto a `.jspx` page as a command button to invoke the information message.

   When you run the `.jspx` file and press the button, the informational message is displayed.

How to Write an Error Handler to Deal with Multiple Threads

Oracle ADF constructs an instance of the custom error handler for each `BindingContext` object that is created. Because Oracle ADF serializes simultaneous web requests from the same logical end-user session, multiple threads generally will not use the same error handler at the same time. However, to guarantee a thread-safe custom error handler, use the `setProperty()` API on `JboException`. This method stores in the exception objects themselves any hints you might need later during the phase when exceptions are translated to JSF `FacesMessage` objects for display.

20

Designing a Page Using Placeholder Data Controls

This chapter describes how to create and use placeholder data controls in an Oracle ADF application. It shows you how to create placeholder data types, including master-detail relationships. It also describes how to create and import sample data.

This chapter includes the following sections:

About Placeholder Data Controls

ADF provides placeholder data controls that you can use to support the declarative process and this does not require coding. When the real data controls are ready, you can rebind the UI components, which makes it easier when you design a complex page.

Application development is typically divided into two separate processes: technical implementation and user interface design. More often than not, they are undertaken by separate teams with very different skill sets. The two teams can work together either in a **data-first** approach or a **UI-first** approach, or with some overlap between the two. With either approach, the teams usually work together iteratively, refining the application with each cycle.

In a data-first approach, the model, or data control is built first. Then the designer creates the layout and page flow by dragging and dropping the data controls onto pages as UI components. The model data is automatically bound to the components. This approach requires the data model to be available before the designer can proceed.

In a UI-first approach, the designer creates the layout using components from the Components window. When the data controls do become available, UI components are then bound to them. With this approach, you should be able to see most of the layout and page flows to make a development evaluation. However, until the data controls are available and bound to components, the application may not fully convey the intent of its design. For instance, an application that has a **master-detail relationship** is best reviewed when there is actual data that dynamically drives that relationship.

Placeholder data controls are easy-to-create, yet fully functional, stand-in data controls that can efficiently speed up the design-development process. UI designers can use placeholder data controls to create page layouts and page flows without the need to have real data controls available. These placeholder controls can be loaded with sample data to realistically simulate application execution for design evaluations. When the real data controls are ready, the UI components can be easily rebound to complete the application.

Creating placeholder data controls is a purely declarative process and does not require coding. It does not require in-depth knowledge of the underlying model, data source technology, actual database schema, or any of the complex relationships in an actual production data control. Placeholder data controls do not require an existing data source or a database connection. You can define multiple data types with multiple attributes. You can also define nested master-detail hierarchies between data types. Placeholder data controls have the same built-in operations such as Execute, Next, and Create. An implicitly created named criteria item allows the user to create search forms as if **view objects** and **view criteria** were available.

Placeholder Data Controls Use Cases and Examples

For many complex applications, the UI design may actually drive the development of the model, or data source. In this UI-first scenario, having placeholder data controls with sample data is essential to properly model the behavior of the application. In some cases, even if production data controls are available, UI designers may opt to use placeholder data controls because of their flexibility and ease of use.

Placeholder data controls can be used in many situations. In addition to being used for design review and development, they can be used to develop realistic runtime mock-ups for usability studies, or for proof-of-concept requirements. They can be used to create demos when the data model is not yet ready.

Additional Functionality for Placeholder Data Controls

You may find it helpful to understand some data access features before you start working with placeholder data controls. Following are links to other functionality that may be of interest.

- After your initial design with placeholder data controls, when the final data controls are available, you can simply rebind the components. For more information about rebinding components, see Creating a Basic Databound Page and Creating ADF Databound Tables .
- A placeholder data type attribute can be configured to be a **list of values (LOV)**. For more information about LOVs, see Working with List of Values (LOV) in View Object Attributes.
- You can create master-detail relationships between placeholder data types, similar to the master-detail data collections in a standard data control. For more information on master-detail forms and tables, see Displaying Master-Detail Data .
- When you define placeholder data types in a master-detail hierarchy, JDeveloper creates **view links** that define that relationship. For more information about view links, see Working with Multiple Tables in a Master-Detail Hierarchy.
- Placeholder data controls can be used for the development of search forms. For more information about query search forms, see Creating ADF Databound Search Forms .
- You might want to package placeholder data controls into reusable components as ADF Library JARs. For more information about reusable components and the ADF Library, see Reusing Application Components .

Creating Placeholder Data Controls

ADF provides the menu to create Placeholder Data Controls for a project, which appears as a node in Data Controls panel with built-in operations node. You can then customize the Placeholder Data Controls, add them to your page, then rebind them to real data controls.
You add placeholder data controls to a project using the New Gallery. After the placeholder data control has been created, it appears as a node in the Data Controls panel. It has a different icon than do standard data controls. Instead of an Operations node, the placeholder data control has a Built-in Operations node. Although the Built-in Operations node contains Commit and Rollback operations, these operations do not perform commits or rollbacks because there is not an actual data source for the data.

When a data control is initially created, it does not have any data types associated with it. You will need to manually create the data types as described in section Creating Placeholder Data Types.

How to Create a Placeholder Data Control

Placeholder data controls are defined at the project level in JDeveloper. You must already have created a project before you can create placeholder data controls.

Before you begin:

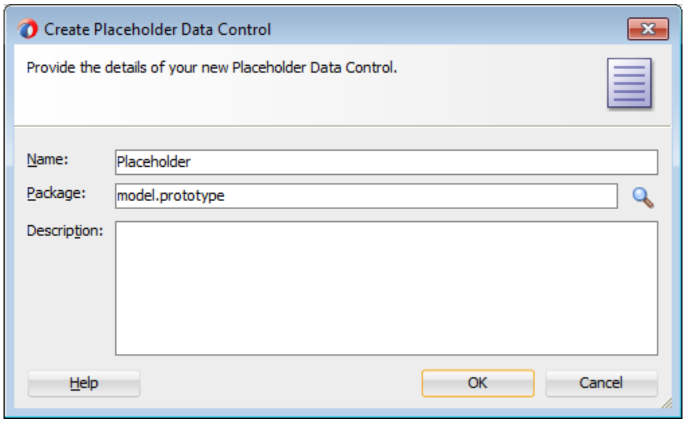
It may be helpful to have an understanding of the options you have for creating placeholder data controls. For more information, see Creating Placeholder Data Controls.

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Additional Functionality for Placeholder Data Controls.

To create a placeholder data control:

1. In the Applications window, right-click the project to which you want to add a placeholder data control and choose **New > From Gallery**.
2. In the New Gallery, expand **Business Tier**, select **Data Controls** and then **Placeholder Data Control**, and click **OK**.
3. In the Placeholder Data Control dialog, as shown in Figure 20-1, enter:
   - **Name**: The name of the placeholder data control.
   - **Package**: The package name that will be used to reference the placeholder data control.
   - **Description**: Optional description of the placeholder data control.

Figure 20-1 New Placeholder Data Control



Create Placeholder Data Control

Provide the details of your new Placeholder Data Control.

Name: Placeholder

Package: model.prototype

Description:

4. Click **OK**.

What Happens When You Create a Placeholder Data Control

When you create a placeholder data control, the package you selected to contain the data control appears under the project node in the Applications window. A data control XML file `*PlaceholderDataControl*.xml` appears under the package, where `*PlaceholderDataControl*` is the name of the placeholder data control. The following example shows a sample file called `Placeholder01.xml`, which was created when the `Placeholder01` data control was created.

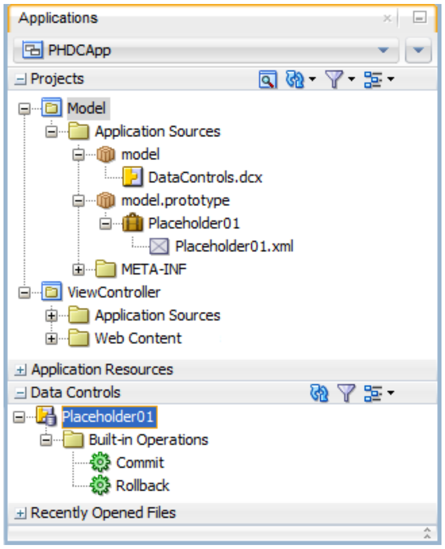
```
<?xml version='1.0' encoding='windows-1252' ?>
<AppModule
   xmlns="http://xmlns.oracle.com/placeholder"
   Name="Placeholder01" >
</AppModule>
```

JDeveloper also creates a `DataControls.dcx` file if it has not yet been defined, and adds entries for the placeholder data control, as shown in the following example.

```
<?xml version="1.0" encoding="UTF-8" ?>
<DataControlConfigs xmlns="http://xmlns.oracle.com/adfm/configuration"
                    version="12.1.2" id="DataControls"
                    Package="model">
  <PlaceholderDataControl SupportsTransactions="true" SupportsFindMode="true"
                          SupportsResetState="true" SupportsRangesize="true"
                          SupportsSortCollection="true"
                          FactoryClass=
                            "oracle.adf.model.placeholder.DataControlFactoryImpl"
                          id="Placeholder01"
                          xmlns="http://xmlns.oracle.com/adfm/datacontrol"
                          Definition="model.prototype.Placeholder01"
                          Package="model.prototype"/>
</DataControlConfigs>
```

In the Data Controls panel, the placeholder data control appears alongside other data controls in the root tree. A placeholder data control that does not yet have data types defined will have only the Commit and Rollback built-in operations available, as shown in Figure 20-2.

Figure 20-2 Applications Window and Data Controls Panel



Creating Placeholder Data Types

The placeholder data type is the data collection for the placeholder data control. ADF provides options to create the placeholder data type, add attributes from an exiting data type or from a CSV file, add sample data, and configure the placeholder data type.
A standard data control obtains its data collections and attributes from its underlying data source in the model or business service layer. For example, an **application module data control** obtains its data collections from the view objects and associated database tables.

For a placeholder data control, instead of data collections, it has placeholder data types. A **placeholder data type** is analogous to a data collection. It can be dropped onto a page to create complex components such as forms, tables, and trees. It also has a set of attributes that can be dropped onto pages as individual components such as input text, output text, and select choice. Some attributes may be defined as LOVs.

When you first create a placeholder data control, it is devoid of any data types because there are no underlying database tables for the placeholder data control to reference. You must declaratively create one or more placeholder data types. For each data type, you specify attribute names, types, default UI components, and other options. You can create multiple data types for a data control, similar to the multiple data collections in an application module.

After you have created a placeholder data type, it appears as a child node of the placeholder data control. It also has a Built-in operations node with the standard set of operations. It has a Named Criteria node that contains an All Queriable Attributes item that is analogous to the named view criteria of a view object in a standard data control. You can drag and drop the All Queriable Attributes item onto a page to create a query or quick query search form. In a standard data control, you can create multiple view criteria on a view object. Because there is no real view object in a placeholder data type, only one All Queriable Attributes item is available. For more information about query search forms, see Creating ADF Databound Search Forms .

You can create master-detail relationships between placeholder data types, similar to the master-detail data collections in a standard data control. You can drop master-detail data types onto pages to create master-detail forms and tables. For more information on master-detail forms and tables, see Displaying Master-Detail Data .

JDeveloper allows you to reuse placeholder data types created for other placeholder data controls in the same project. When you are creating a data type, you can select an option to load existing data types from another placeholder data control. If you select the **Import From: Existing Data Type** option, the attributes from the imported data type will be added to the list of attributes.

You can also select an option to import the sample data associated with the imported data type when the attributes are added.

> **Note:**
>
> Although you do not need sample data until you run the application, you should add sample data to provide a consistent design time rendering of the components.

How to Create a Placeholder Data Type

After you have created a placeholder data control, you can proceed to create data types. You define a name for the data type, and define each of its individual attributes. For each attribute, you then define its type, format, default UI component, and whether or not it should be an LOV.

In order to simplify the process of creating placeholder data types, you can select from a list of four of the most common types: `String`, `Boolean`, `Date`, and `Number`. Because placeholder attributes are typed, you can create column labels and include UI control hints in the design.

If you have a sample data file in comma-separated value (CSV) format, you can create all the attributes and load sample data using the sample data file import function. You do not need to create the attributes. JDeveloper will create them for you from the format of the CSV file, which can optionally contain a list of column headings as the first row. The attributes default to type `String`. You can manually reset each attribute to another type as required. For instructions to import sample data, see How to Import Attributes and Sample Data to a Placeholder Data Type.

Before you begin:

It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Creating Placeholder Data Types.

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Additional Functionality for Placeholder Data Controls.

Additionally, you must first create the placeholder data control, as described in How to Create a Placeholder Data Control.

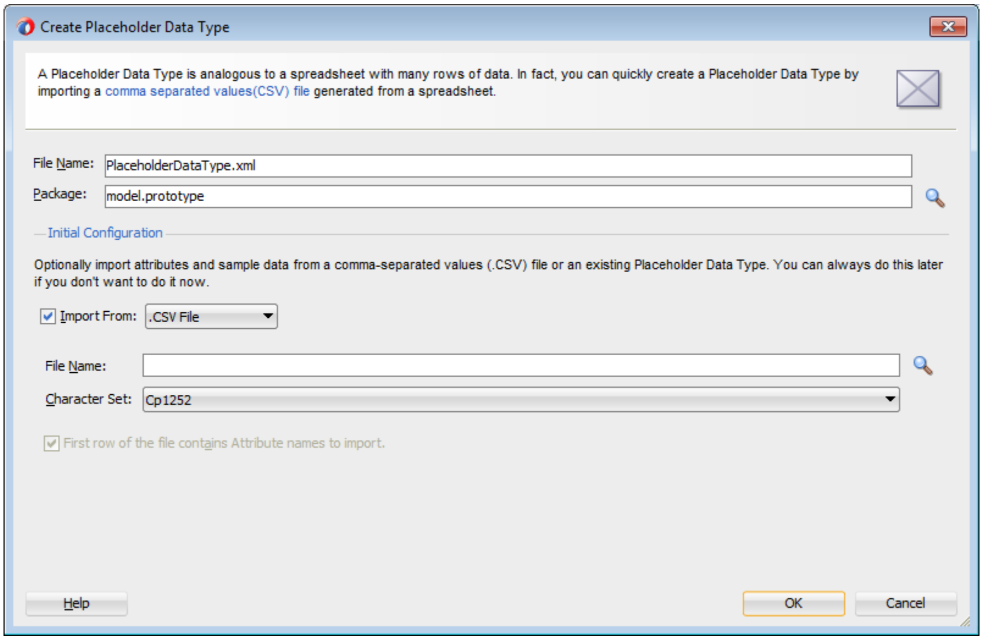
To create a placeholder data type:

1. In the Applications window, double-click the placeholder data control to which you want to add a placeholder data type.
2. In the overview editor, in the **Data Types** section, select the placeholder data control and click the **New Placeholder Data Type** icon.

   > **Note:**
   >
   > You can alternatively open the Create Placeholder Data Type dialog by right-clicking the placeholder data control in the Data Controls panel, and choosing **New Placeholder Data Type**.

   Figure 20-3 shows the Create Placeholder Data Type dialog.

   Figure 20-3 Create Placeholder Data Type Dialog



Create Placeholder Data Type

A Placeholder Data Type is analogous to a spreadsheet with many rows of data. In fact, you can quickly create a Placeholder Data Type by importing a comma separated values(CSV) file generated from a spreadsheet.

File Name: PlaceholderDataType.xml

Package: model.prototype

Initial Configuration

Optionally import attributes and sample data from a comma-separated values (.CSV) file or an existing Placeholder Data Type. You can always do this later if you don't want to do it now.

☑ Import From: .CSV File

File Name:

Character Set: Cp1252

☑ First row of the file contains Attribute names to import.

3. In the Create Placeholder Data Type dialog, enter a file name and package for the placeholder data type.
4. If you have an existing placeholder data type or a `.csv` file, from which you want to import attributes and data, select **Import From** and select either **.CSV File** or **Existing Data Type**, and then specify the options for the import.

   To import from a `.csv` file:

   a. In the **File Name** field, specify the file from which you want to import, or click the **Browse** icon to navigate to and select the file.
   b. From the **Character Set** dropdown list, select the character set that the file uses.
   c. If your file has a header row with the names of the columns, select **First row of the file contains Attribute names to import**.

   To import from an existing placeholder data type:

   a. Expand the tree to locate and select an existing placeholder data type.
   b. If the existing data type contains data that you want to import, select **Also Import Sample Data**.
5. Click **OK**.

   The placeholder data type is created and opened in the overview editor.
6. In the overview editor, click the **Attributes** navigation tab to view, add, and edit attributes for the placeholder data type.
7. Click the **Data** navigation tab to view, add, and edit sample data for the placeholder data type.

   You need sample data for runtime and for a consistent design time.

How to Add Attributes and Sample Data to a Placeholder Data Type

If you intend to run an application using the placeholder data control, you will need to add sample data to be displayed during execution. You can add sample data to the placeholder data type attributes manually or by importing the data from another placeholder data type or CSV file. Although having sample data is necessary only at runtime, you should add sample data for a consistent design time rendering of the components.

If you did not import attributes when you created your placeholder data type, you can add them using the Attributes page of the overview editor. Also, you can use the Data page of the overview editor to add sample data to be displayed during execution. Both the Attributes page and the Data page have an Import button that opens the Import Placeholder Data Type dialog, which allows you to import attributes and sample data.

Before you begin to add sample data to a placeholder data type, you should have already created a placeholder data control and a placeholder data type. If you are entering the data manually, you should have the data ready. If you are loading the data from a CSV file, you need to have the location of the file. If you are importing from another placeholder data type, you must have already created the other data type.

Manually Adding Attributes to a Placeholder Data Type

Using the Attributes page of the overview editor, you can add and configure attributes to a placeholder data type.

Before you begin:

It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Creating Placeholder Data Types.

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Additional Functionality for Placeholder Data Controls.

Additionally, you must first create the placeholder data control, as described in How to Create a Placeholder Data Control, and create the placeholder data type, as described in How to Create a Placeholder Data Type.

To manually add a placeholder data type attribute:

1. In the Applications window, double-click the placeholder data type to which you want to add attributes.

2. In the overview editor, click the **Attributes** navigation tab.
3. On the Attributes page, click the **Add** icon.
4. In the Insert View Attributes dialog, enter a name for the attribute, and click **OK**.
5. After adding attributes, select an attribute and use the fields beside the attributes list to configure the selected attribute.
   - **Name**: Enter a name for the attribute.
   - **Data Type**: Select a type for the attribute from the dropdown list. The supported types are `String`, `Boolean`, `Date`, and `Number`.
   - **Default Component**: Select a default component for the attribute from the dropdown list. For an LOV, select **Combo Box List of Values**. Then click the **Edit** icon to configure the LOV. For more information, see How to Configure a Placeholder Data Type Attribute to Be a List of Values.
   - **Default Value**: Enter the initial value for the attribute.
   - **Label**: Enter a label for the attribute. The label will be used when the component is displayed.
   - **Tooltip**: Enter text to be displayed as a tooltip for the attribute.
   - **Format Type**: This field is enabled only when the type is `Date` or `Number`. Select a format type from the dropdown list.
   - **Format**: This field is enabled only when a format mask has been defined for that format type.
   - **Display Width**: Enter the character width to be used by the control that displays this attribute.
   - **Searchable**: Select this checkbox to make the attribute searchable.

   Click the **Add** icon to add more attributes.

Adding Sample Data Manually

You can use the Sample Data page of the Edit Placeholder Data Type dialog to manually enter sample data for your placeholder data control.

Before you begin:

It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Creating Placeholder Data Types.

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Additional Functionality for Placeholder Data Controls.

Before you add sample data to a placeholder data type, you need to perform the following tasks:

- Create a placeholder data type, as described in How to Create a Placeholder Data Type.
- Have your list of sample data ready.

To add sample data to a placeholder data type manually:

1. In the Data Controls panel, right-click the placeholder data type to which you want to add sample data, and choose **Open**.

2. In the overview editor, click the **Data** navigation tab.
3. In the Data page, click the **Add** icon to add a row to the data table, and enter a value for each attribute. Repeat as necessary until you have entered adequate sample data.

How to Import Attributes and Sample Data to a Placeholder Data Type

As an alternative to manually entering attributes and sample data for a placeholder data type, you can import them in a single operation. Using the Attributes page of the overview editor, you can import attributes from an existing placeholder data type or from a `.csv` file.

A `.csv` (comma-separated values) file is a plain text file containing rows of attribute values, delimited by commas. A `.csv` file can optionally have a header row that defines the names of each attribute.

In the overview editor for a placeholder data type, both the Attributes page and the Data page have an **Import** button that opens the Import Placeholder Data Type dialog, which allows you to import attributes and sample data.

Before you begin:

It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Creating Placeholder Data Types.

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Additional Functionality for Placeholder Data Controls.

Additionally, you must first create the placeholder data control, as described in How to Create a Placeholder Data Control, and create the placeholder data type, as described in How to Create a Placeholder Data Type.

To import attributes into a placeholder data type:

1. In the Applications window, double-click the placeholder data type to which you want to add attributes.
2. In the overview editor, click the **Attributes** navigation tab.
3. If you are importing attributes as well as sample data, you must delete any existing attributes in the placeholder data type.

   If you do not remove the existing attributes, JDeveloper imports only the first columns of data for the number of defined attributes. For example, if you have two attributes defined in your data type and four columns of sample data in your CSV file, JDeveloper will import only the first two columns of data.
4. On the Attributes page, click **Import**.
5. In the Import Placeholder Data Type dialog, specify where you want to import attributes from.

   To use a `.csv` file:

   a. Select **Import from .CSV File**.
   b. In the **File Name** field, enter the full path and name of the file, or click the **Browse** icon to navigate to and select it.

c. From the **Character Set** dropdown list, select the character set represented in the specified `.csv` file.

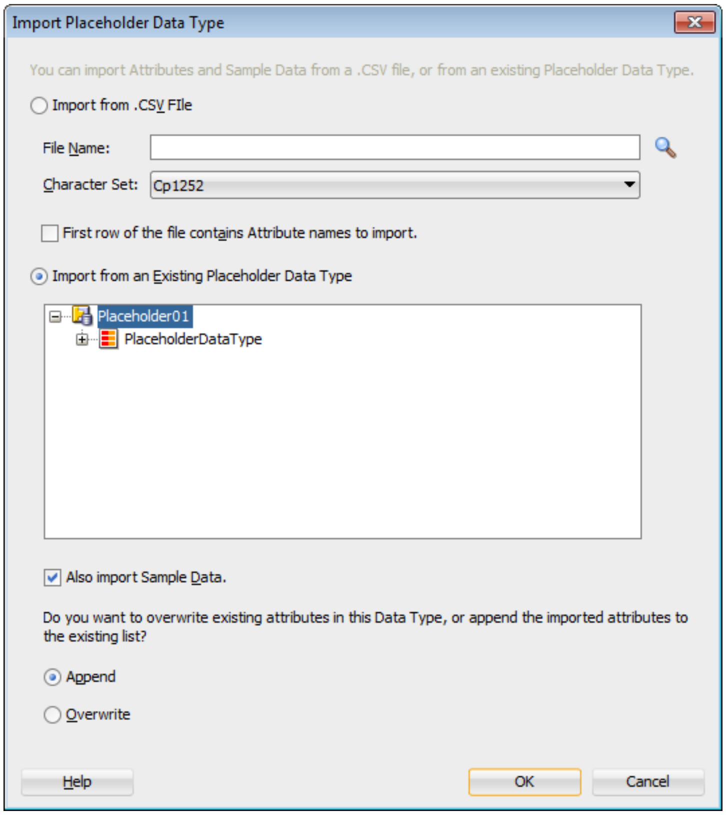
d. If the `.csv` file has a header row that contains the names of the attributes, select **First row of the file contains Attribute names to import**.

To use an existing placeholder data type:

a. Select **Import from an Existing Placeholder Data Type**.

b. Expand the available placeholder data controls displayed to see the placeholder data types they contain, and select the one you want to copy.

Figure 20-4 Import Placeholder Data Type Dialog



Import Placeholder Data Type

You can import Attributes and Sample Data from a .CSV file, or from an existing Placeholder Data Type.

○ Import from .CSV FIle

File Name:

Character Set: Cp1252

□ First row of the file contains Attribute names to import.

● Import from an Existing Placeholder Data Type

Placeholder01
PlaceholderDataType

☑ Also import Sample Data.

Do you want to overwrite existing attributes in this Data Type, or append the imported attributes to the existing list?

● Append

○ Overwrite

6. Select the **Also Import Sample Data** checkbox to load sample data from the file or existing placeholder data type.

7. Specify whether you would like to append or overwrite the attributes already defined for the placeholder data type.

   - Select **Append** to add the imported attributes to the current list of attributes in the placeholder data type
   - Select **Overwrite** to replace the current attributes with the imported attributes.

8. Click **OK**.

9. After importing attributes, you can optionally go to the Attributes page and reconfigure the attributes.

What Happens When You Add Sample Data

Placeholder sample data, whether added manually added or imported, are stored in message bundle files. The following example shows a sample message bundle with two rows of five attributes.

```
model.prototype.SupplierLocationsDataType.SL_0_0=101
model.prototype.SupplierLocationsDataType.SL_0_1=so
model.prototype.SupplierLocationsDataType.SL_0_2=Houston
model.prototype.SupplierLocationsDataType.SL_0_3=TX
model.prototype.SupplierLocationsDataType.SL_0_4=USA
model.prototype.SupplierLocationsDataType.SL_1_0=101
model.prototype.SupplierLocationsDataType.SL_1_1=dw
model.prototype.SupplierLocationsDataType.SL_1_2=Atlanta
model.prototype.SupplierLocationsDataType.SL_1_3=GA
model.prototype.SupplierLocationsDataType.SL_1_4=USA
```

What Happens When You Create a Placeholder Data Type

When you create a placeholder data type, JDeveloper creates a *PlaceholderDataType*.xml file, where *PlaceholderDataType* is the name of the placeholder data type you had specified.

The *PlaceholderDataType*.xml file has the same format as a view object XML file. It includes the name of the view object and the name and values of each placeholder attribute that was defined.

The following example shows a *PlaceholderDataType*.xml for a Supplier data type. Two attributes are declaratively defined: Supplier_Id and Supplier_Name.

```
<?xml version='1.0' encoding='windows-1252' ?>
<ViewObject
  xmlns="http://xmlns.oracle.com/placeholder"
  Name="SuppliersDataType"
  InheritPersonalization="merge"
  BindingStyle="OracleName"
  CustomQuery="true">
  <ViewAttribute
    Name="Supplier_Id"
    Type="oracle.jbo.domain.Number"/>
  <ViewAttribute
    Name="Supplier_Name"
    Type="java.lang.String"/>
</ViewObject>
```

Since a data type is similar to a data collection and is based on a view object, each data type will have a corresponding *PlaceholderDataType*.xml file.

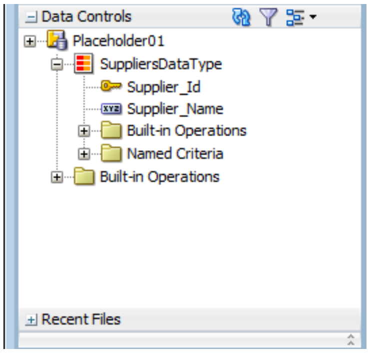
JDeveloper also adds entries for each placeholder data type to the *PlaceholderDataControl*.xml file. For example, after the Suppliers data type is created, the data control XML file includes a new ViewUsage entry for the Suppliers data type, as shown in the following example.

```
<?xml version="1.0" encoding="windows-1252" ?>
<AppModule
  xmlns="http://xmlns.oracle.com/placeholder"
  Name="Placeholder01"
  InheritPersonalization="merge">
  <ViewUsage
    Name="SuppliersDataType"
    ViewObjectName="model.prototype.SuppliersDataType"/>
</AppModule>
```

In the Data Controls panel, a placeholder data type node appears under the placeholder data control. Expanding the node reveals the presence of each of the attributes, the Built-in Operations node, and the Named Criteria node.

Figure 20-5 shows a placeholder data control as it appears in the Data Controls panel.

Figure 20-5 Data Controls Panel Showing Placeholder Data Control



How to Configure a Placeholder Data Type Attribute to Be a List of Values

A placeholder data type attribute can be configured to be a list of values (LOV). An LOV-formatted attribute binds to UI components that display dropdown lists or list picker dialogs. For more information about LOVs, see Working with List of Values (LOV) in View Object Attributes.

When you are configuring a placeholder data type attribute, you can select an option to bring up a dialog to configure that attribute to be an LOV.

If you have only one data source, you can only create a fixed LOV. To create a dynamic LOV, there must be more than one placeholder data type available to be the source.

Configuring an Attribute to Be a Fixed LOV

Before you begin, you should determine which attribute you want to be a fixed LOV and which values should be in the fixed list.

Before you begin:

It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Creating Placeholder Data Types.

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Additional Functionality for Placeholder Data Controls.

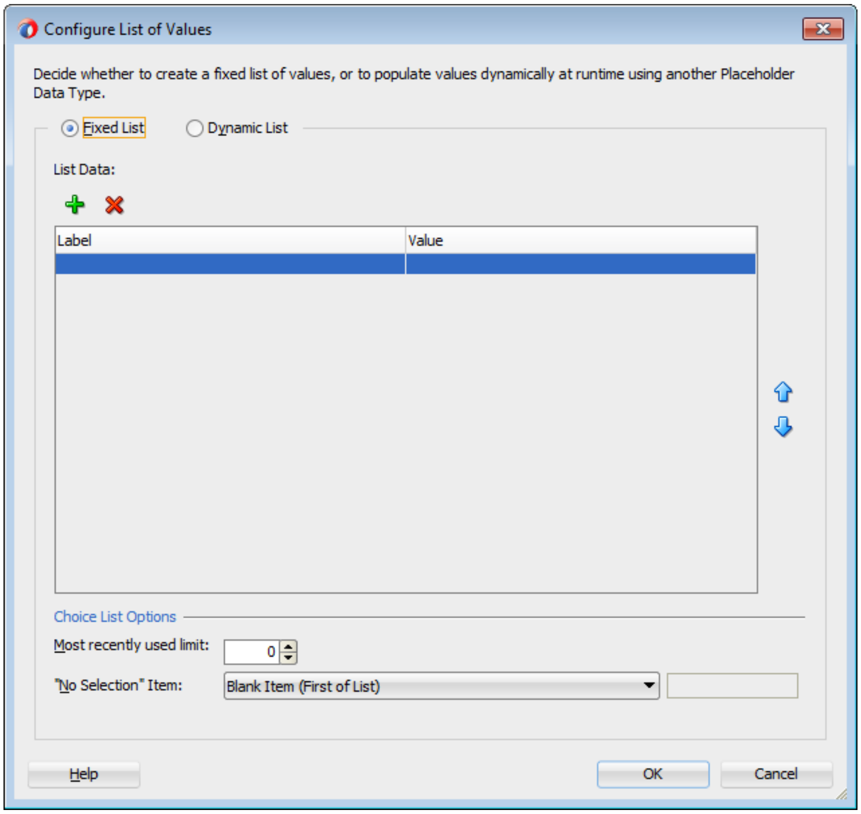
Additionally, you must have already created the placeholder data type for your placeholder data control.

To configure an attribute to be a fixed LOV:

1. In the Data Controls panel, right-click the placeholder data type and choose **Open**.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute you want to configure as an LOV.
4. Click the **Edit LOV Binding** icon next to the **Default Component** pulldown list.

   The Configure List of Values dialog appears, as shown in Figure 20-6.

Figure 20-6 Configure List of Values Dialog for a Fixed LOV



Configure List of Values

Decide whether to create a fixed list of values, or to populate values dynamically at runtime using another Placeholder Data Type.

● Fixed List ○ Dynamic List

List Data:

Label	Value

Choice List Options

Most recently used limit: 0

"No Selection" Item: Blank Item (First of List)

5. In the dialog, select **Fixed List**.
6. Click the **Add** icon to add an entry to the list of values.
7. For each entry, enter a label and a value.

   When the user selects an item from the list of values, the value entry will be entered into the input field.
8. Specify the maximum number of the most recently used items that will be displayed in the dropdown list.
9. From the **No Selection Item** dropdown list, select an option for how you want the "no selection" item to be displayed.

   For instance, selecting **Blank Item (First of List)** will display the "no selection" item as a blank at the beginning of the list.

10. Click **OK**.

Configuring an Attribute to Be a Dynamic LOV

Using a placeholder data type to serve as the source, you can configure an attribute to be a dynamic LOV.

Before you begin:

It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Creating Placeholder Data Types.

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Additional Functionality for Placeholder Data Controls.

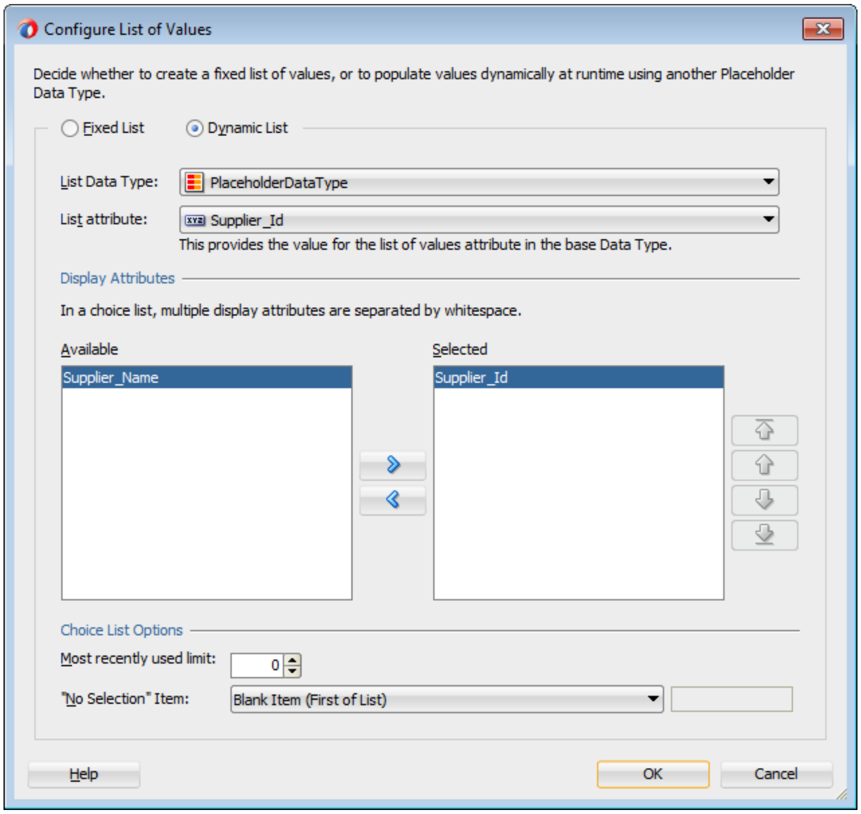
Also, you should have already created another placeholder data type to serve as the source of the dynamic LOV.

To configure an attribute to be a dynamic LOV:

1. In the Data Controls panel, right-click the placeholder data type and choose **Open**.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute you want to configure as an LOV.
4. Click the **Edit LOV Binding** icon next to the **Default Component** pulldown list.

   The Configure List of Values dialog appears, as shown in Figure 20-7.

Figure 20-7 Configure List of Values Dialog for a Dynamic LOV



Decide whether to create a fixed list of values, or to populate values dynamically at runtime using another Placeholder Data Type.

○ Fixed List ● Dynamic List

List Data Type: PlaceholderDataType

List attribute: Supplier_Id

This provides the value for the list of values attribute in the base Data Type.

Display Attributes

In a choice list, multiple display attributes are separated by whitespace.

Available: Supplier_Name

Selected: Supplier_Id

Choice List Options

Most recently used limit: 0

"No Selection" Item: Blank Item (First of List)

5. In the Configure List of Values dialog, select **Dynamic List**.
6. Select the list data type with the source attribute. You must have a source placeholder data type for this selection to be available.
7. Select the list attribute.
8. Shuttle the desired display attributes from the **Available** list to the **Selected** list.
9. Select the maximum number of the most recently used items that will be displayed in the dropdown list.
10. From the **No Selection Item** dropdown list, select an option for how you want the "no selection" item to be displayed. For example, selecting **Blank Item (First of List)** will display the "no selection" item as a blank at the beginning of the list.
11. Click **OK**.

How to Create Master-Detail Data Types

You create master-detail relationships between data types in the same way you create master-detail hierarchies between tables. In a standard data control, you can use view links to define source and target view objects that would become the master and the detail objects. For more information about master-detail relationships, see Displaying Master-Detail Data .

You first create a master data type and its attributes. Then you create a detail data type as a child of the master data type. You define the source attribute in the master data type that defines the relationship to the detail data type.

Before you begin:

It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Creating Placeholder Data Types.

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Additional Functionality for Placeholder Data Controls.

Before you create a placeholder master-detail hierarchy, you must perform the following tasks:

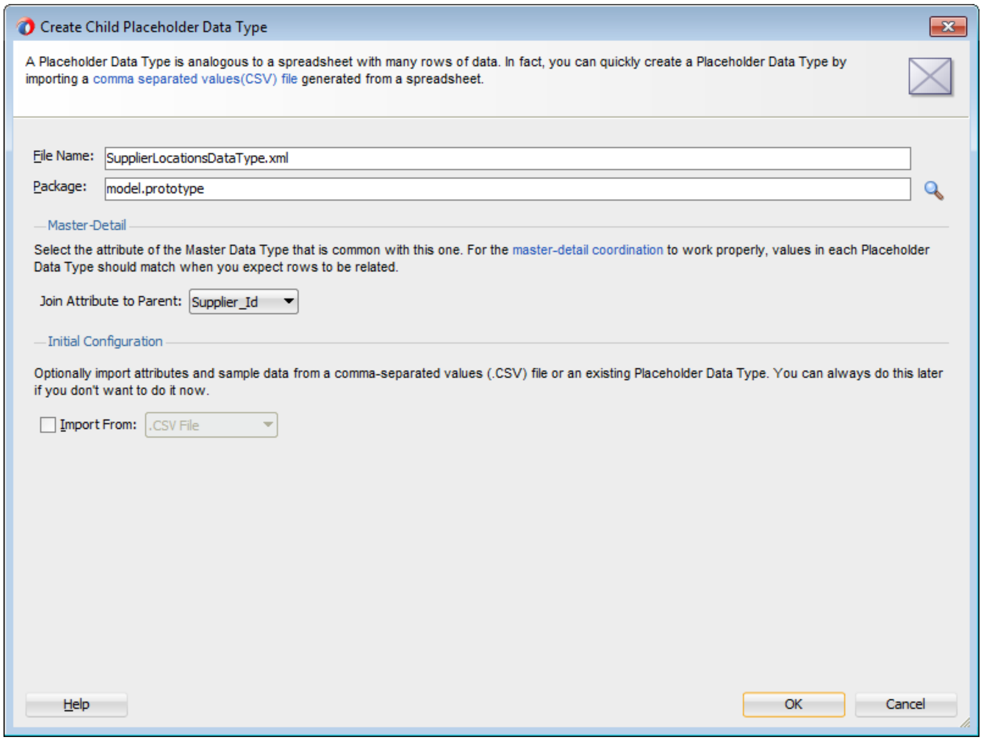
- Determine the data structure of the master data type and the data structure of the detail data type.
- Determine which attribute in the master will be the source for the detail data type.
- Create a placeholder data type to be the master, as described in How to Create a Placeholder Data Type.

To create master-detail hierarchical data types:

1. In the Data Controls panel, right-click the master placeholder data type and choose **New Child Placeholder Data Type**.

   Figure 20-8 shows the Create Placeholder Data Type dialog for entering detail data type attributes.

Figure 20-8 Create Child Placeholder Data Type Dialog



Create Child Placeholder Data Type

A Placeholder Data Type is analogous to a spreadsheet with many rows of data. In fact, you can quickly create a Placeholder Data Type by importing a comma separated values(CSV) file generated from a spreadsheet.

File Name: SupplierLocationsDataType.xml

Package: model.prototype

Master-Detail

Select the attribute of the Master Data Type that is common with this one. For the master-detail coordination to work properly, values in each Placeholder Data Type should match when you expect rows to be related.

Join Attribute to Parent: Supplier_Id

Initial Configuration

Optionally import attributes and sample data from a comma-separated values (.CSV) file or an existing Placeholder Data Type. You can always do this later if you don't want to do it now.

□ Import From: .CSV File

2. In the Create Placeholder Data Type dialog, enter a name and package for the detail data type.
3. From the **Join Attribute to Parent** dropdown list, select the attribute from the master data type that will be used to join to the new detail data type.
4. If you have an existing placeholder data type or a `.csv` file, from which you want to import attributes and data, select **Import From** and select either **.CSV File** or **Existing Data Type**, and then specify the options for the import.

   To import from a `.csv` file:

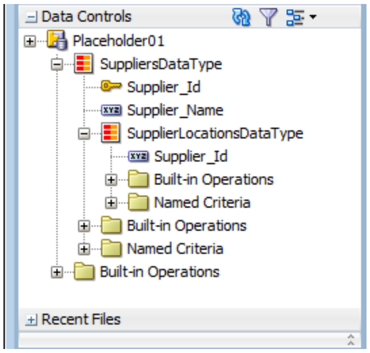
   a. In the **File Name** field, specify the file from which you want to import, or click the **Browse** icon to navigate to and select the file.
   b. From the **Character Set** dropdown list, select the character set that the file uses.
   c. If your file has a header row with the names of the columns, select **First row of the file contains Attribute names to import**.

   To import from an existing placeholder data type:

   a. Expand the tree to locate and select an existing placeholder data type.
   b. If the existing data type contains data that you want to import, select **Also Import Sample Data**.
5. Click **OK**.

The Data Controls panel displays the detail data type as a child of the master data type, as shown in Figure 20-9. If you did not import attributes, you can add them now, as described in How to Add Attributes and Sample Data to a Placeholder Data Type.

Figure 20-9   Master Detail Hierarchy in Placeholder Data Control



What Happens When You Create a Master-Detail Data Type

A master-detail relationship is implemented in the same way as is a standard master-detail relationship, using view object and view links. When you define placeholder data types in a master-detail hierarchy, JDeveloper creates a `DTLink.xml` file that contains metadata entries for view links that define that relationship. For more information about view links, see Working with Multiple Tables in a Master-Detail Hierarchy. For example, in the relationship between the master data type `SuppliersDataType` and the detail data type `SupplierLocationsDataType` associated with a key `Supplier_Id`, JDeveloper creates a `DTLink.xml` file in the form of a view link file to define that relationship, as shown in the following example.

```
<?xml version="1.0" encoding="windows-1252" ?>
<ViewLink
  xmlns="http://xmlns.oracle.com/placeholder"
  Name="DTLink"
  InheritPersonalization="merge">
  <ViewLinkDefEnd
    Name="SuppliersDataType"
    Cardinality="1"
    Source="true"
    Owner="model.prototype.SuppliersDataType">
    <AttrArray Name="Attributes">
      <Item Value="model.prototype.SuppliersDataType.Supplier_Id"/>
    </AttrArray>
  </ViewLinkDefEnd>
  <ViewLinkDefEnd
    Name="SupplierLocationsDataType"
    Cardinality="-1"
    Owner="model.prototype.SupplierLocationsDataType">
    <AttrArray Name="Attributes">
      <Item Value="model.prototype.SupplierLocationsDataType.Supplier_Id"/>
    </AttrArray>
  </ViewLinkDefEnd>
</ViewLink>
```

Using Placeholder Data Controls

You can use the placeholder data controls to create a layout, search form, or to bind components. After the real data controls are ready, you can rebind the components.

You can also package the placeholder data controls and add to ADF Library JARs and reuse them.
You use placeholder data controls in the same way you would use standard data controls. You can drag data types onto pages and use the context menus to drop the data types as forms, tables, trees, graphs, and other components. You can drop individual attributes onto pages as text, lists of values, single selections, and other components. You can use any of the built-in operations such as Create, Execute, and Next by dropping them as buttons, command links, and menu items.

You can work in several ways to take advantage of placeholder data controls:

- Build a page using the placeholder data controls and rebind to real data controls later.
- Build a page using components, bind them to placeholder data controls, and rebind to real data controls later.
- Build a page using some combination of components from the Components window, components from the placeholder data controls, and then bind or rebind to the real data controls later.

Limitations of Placeholder Data Controls

You can use placeholder data controls in your application development in many situations. For most UI design evaluations, placeholder data controls should be able to fully substitute for real data controls.

There are a few limitations:

- Because data types are not tied to an underlying data source, the Commit and Rollback operations do not perform real transactions, nor do they update the cache.
- Placeholder data controls can only be created declaratively. You cannot create custom methods like you can with a real application module or data control.
- Placeholder data controls cannot be used when there is a need either for custom data or for filtering or custom code to fetch data. Placeholder data controls will disable those operations.

Creating Layout

Use the drag-and-drop feature to create the page using the placeholder data controls, any available real data controls, and components from the Components window. If you intend to run a page or application that requires real data, enter sample data for your placeholder data types. If you have a large amount of sample data, you may be able to create CSV files from the data source and load them into the data type. You may also use spreadsheets and other tools to create CSV sample data files.

Creating a Search Form

In a standard data control, you can create view criteria on view objects to modify the query. These view criteria are also used for drag-and-drop creation of query and quick query search forms. The named view criteria items appear under the Named Criteria node for a data collection. For more information about query and quick query search forms, see Creating ADF Databound Search Forms .

For placeholder data controls, there is also a Named Criteria node under each data type node. An automatically created All Queriable Attributes item appears under this node and can be used to drag and drop onto pages to create the query or quick query search forms.

Binding Components

Instead of building the page using the data controls, for instance, if you are unsure of the shape of your data, you can lay out the page first using the Components window and later bind it to the data types, attributes, or operations of the placeholder data controls.

Rebinding Components

After the final data controls are available, you can simply rebind the components. You can select the component in the Structure window and use the context menu to open the relevant rebind dialog. You can also drag and drop the data control item onto the UI component to initiate a rebinding editor. The rebinding procedures are the same whether the component was originally bound to a placeholder data control or a standard data control.

For more information about rebinding components, see Creating a Basic Databound Page and Creating ADF Databound Tables .

Packaging Placeholder Data Controls to ADF Library JARs

A useful feature of placeholder data controls is that they allow parallel development and division of labor among developers and designers. You may be able to leverage that further by packaging placeholder data controls into reusable components as ADF Library JARs. ADF Libraries are JARs that have been packaged to contain all the necessary artifacts of an ADF component. For more information about reusable components and the ADF Library, see Reusing Application Components . You can create libraries of placeholder data controls and distribute them to multiple designers working on the same UI project. Because they are lightweight, you can even use them in place of available real data controls for the earlier phases of UI design.

21 Creating ADF REST Data Controls from ADF RESTful Web Services

This chapter describes how to create data controls for ADF RESTful web services that are based on ADF Business Components application modules.
This chapter includes the following sections:

- About Data Controls for RESTful Web Services Based on Application Modules
- Consuming Business Components as REST Resources with a REST Data Control
- Using REST Data Controls
- Configuring REST Data Controls Published by Application Modules

About Data Controls for RESTful Web Services Based on Application Modules

In ADF, using the Data Controls panel, you can create UI components to represent REST resources and methods through which you can consume the RESTful web services functionality.
ADF Business Components can be configured to publish RESTful web services. This enables you to develop applications that use such services published by other parts of the application or by a different application entirely. Therefore, when you use these services, you do not have to package the underlying business components with your application.

To simplify the consumption of RESTful web services that are based on ADF Business Components, you can use JDeveloper to create connections to these services and then generate data controls based on the resources encompassed by those connections. You can then build a client for the RESTful web service by using the Data Controls panel to create UI components to represent the REST resources and methods. You do not need to write any code to parse the web service or create a client web application that implements the service.

Though the web services exposed by application modules are based on REST principles, when you consume the services using data controls, you interact with them in much the same way that you would directly with an application module. The underlying implementation of the pages' data operations are based on REST methods, but you can build the pages with the same types of data control objects and built-in operations that you use when creating databound UI components based on application module data controls.

Though RESTful web services are stateless between requests, applications created with data controls based on RESTful web services published by application modules behave in a stateful manner. However, because the information about the state of the application is contained within the exchanged messages and not on the server, the application is stateless. User CRUD actions corresponding to HTTP methods (`GET`, `PATCH`, `POST`, and `DELETE`) are cached until the user invokes the `Commit` or `Rollback` operation, at which point the cache is cleared (and the data is committed to the data source or the changes are discarded).

> **Note:**
>
> This chapter concerns the creation of data controls that are based on RESTful web services that expose functionality developed with ADF Business Components. It is also possible to create data controls based on SOAP-based web services and RESTful web services that are not based on ADF Business Components. For more information, see "Exposing Web Services Using the ADF Model Layer" in *Developing Applications with Oracle ADF Data Controls*.

REST Web Service Data Control Use Cases and Examples

You can create a data control to consume RESTful web services that are exposed by ADF Business Components. You then use the data controls to create databound UI components on a web page to access the service's functionality.

Typically you consume such web services as a way to obtain functionality for an application without having to develop that functionality yourself. In addition, you do not need to package the base application modules directly in your application. These RESTful web services that you consume might be published by a partner, a service provider, or another development team, or they might be part of a cloud-based service.

Additional Functionality for REST Web Service Data Controls

You may find it helpful to understand other data access features before you start working with RESTful web services based on ADF Business Components. Following are links to other functionality that may be of interest.

- For further details on how ADF data controls and data binding work, see Using ADF Model in a Fusion Web Application.
- For information on designing databound user interfaces by dragging items from the Data Controls panel and dropping them on pages as UI components, see Creating a Basic Databound Page.
- For information about publishing RESTful web services based on ADF Business Components, see Creating RESTful Web Services with Application Modules.

Consuming Business Components as REST Resources with a REST Data Control

ADF provides a wizard to create an IDE connection for RESTful web services based on ADF Business Components, which is added to the Resource Window. You can then use this IDE connection in any application window to consume the RESTful web services.
The REST data control enables you to access and consume data streams from specified URIs defined by running RESTful web services that have been published

by ADF Business Components. There are two ways of creating the connections that consumes RESTful web services that are based on the ADF Business Components:

1. Create an IDE connection to the `describe` resource of the RESTful web service that has been published by the application module and then create a data control that is based on that connection.
2. Create a REST connection and the data controls together by using the Web Service Data Control wizard.

How to Create a REST Connection

You use the Create REST Connection dialog to create an IDE connection to a `describe` resource for a RESTful web service based on an ADF Business Components application module. You can access this wizard through the New Gallery or the Resources window. Any connection that you create with this wizard is added to the Resources window and can be used to create a data control in any application workspace.

Before you begin:

It may be helpful to have a general understanding of REST data controls. For more information, see Consuming Business Components as REST Resources with a REST Data Control.

You may also find it helpful to understand additional functionality that can be added using other RESTful web services features. For more information, see Additional Functionality for REST Web Service Data Controls.

> Make sure you have access to the RESTful web service that the data control will access. To use the describe feature to create a REST connection, the RESTful web service must be based on an ADF Business Components application module.

To create a REST connection:

1. From the main menu, choose **File > New > From Gallery**.
2. In the New Gallery, expand **General**, select **Connections** and then **REST Connection**, and click **OK**.
3. In the Create REST Connection dialog, enter a name for the connection.
4. Select the **IDE Connections** radio button.
5. In the **URL Endpoint** field, enter the URI for the REST resource's `describe` object.

> **Note:**
>
> This URI is composed of the host, port, resource path, and the `describe` resource. The resource path typically consists of the context root of the web service project plus the URL pattern specified in the servlet mapping in the REST project's `web.xml` file. Do include the version name and resource name, but do not include any URL parameters.
>
> For example, you can enter something like the following:
>
> ```
> http://service.example.com:7101/WebServiceProjectContextRoot/
> rest/VersionName/ResourceName/describe
> ```

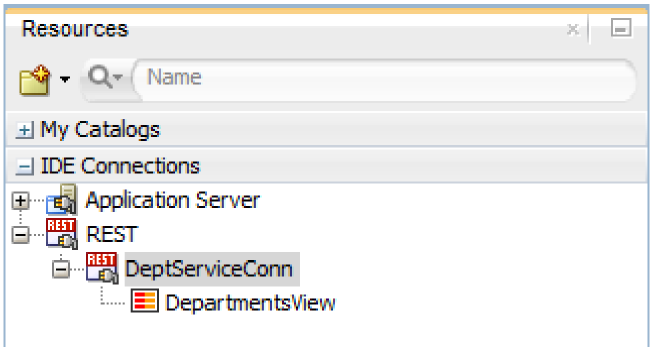
6. Select the level of authentication from the **Authentication Type** dropdown list.

   None is the default authentication type and disables authentication. Use **Digest** when security is desired. In this way, the password will be transmitted across the network as an MD5 digest of the user's password and cannot be determined by sniffing network traffic. **Basic** authentication is primarily only useful when service access over the network does not require high security.
7. If digest or basic authentication is selected, specify the user name and password required to access the web site.
8. After you have entered the name and endpoint, you can click **Test Connection** to verify the REST connection is valid.
9. Click **OK**.

What Happens When You Create a REST Connection

The REST connection is created as an IDE connection in JDeveloper and is available for use in any application that you are developing in the IDE. You can view the connection in the IDE Connections panel of the Resources window as shown in Figure 21-1.

Figure 21-1 Resources Window with a REST Connection



How to Create a Data Control From ADF REST Resources

You can create a REST data control by dragging a resource listed under a REST connection from the Resources window to the Data Controls panel. Unlike with the creation of REST data controls based on other types of RESTful web services, you do not need to go through a complex wizard to configure how the data control exposes individual resources.

Before you begin:

It may be helpful to have a general understanding of REST data controls. For more information, see Consuming Business Components as REST Resources with a REST Data Control.

You may also find it helpful to understand additional functionality that can be added using other RESTful web services features. For more information, see Additional Functionality for REST Web Service Data Controls.

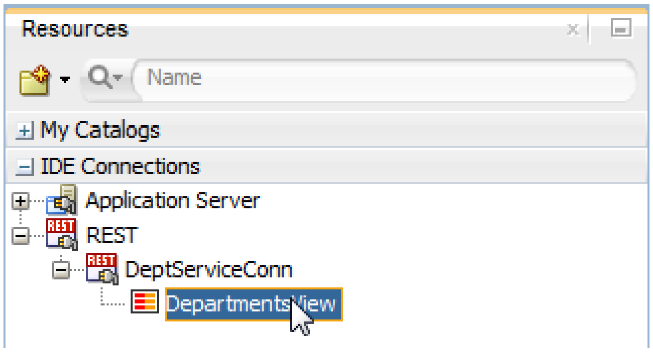
You need to complete these tasks:

- Create an application workspace and a project in that workspace. Depending on how you decide to organize your projects, you can use an existing application workspace and project or create new ones. For information on creating an application workspace, see "Creating Applications and Projects" in *Developing Applications with Oracle JDeveloper*.
- Create a REST connection as described in How to Create a REST Connection.

To create a REST data control:

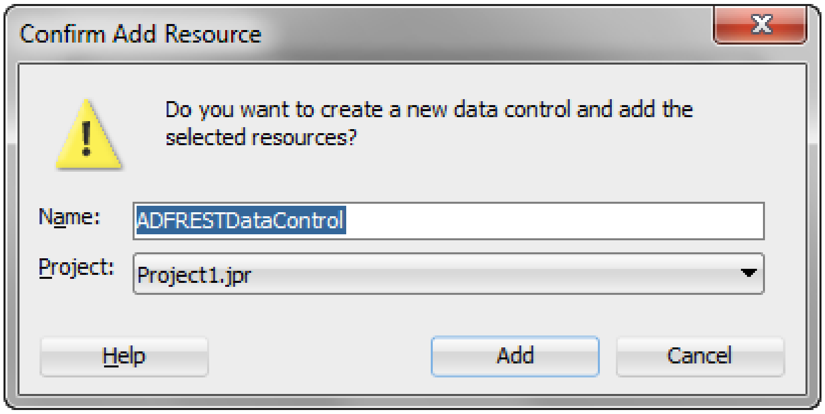
1. From the main menu, choose **Window > Resources**.
2. In the Applications window, select the node for the project where you want to create the data control.
3. In the Resources window, expand **IDE Connections** and expand the REST connection.
4. Select the resource on which you want to base the data control, as shown in Figure 21-2, and drag it to the Data Controls panel.

Figure 21-2 Resource Selected from RESTful web service Connection



5. In the Confirm Add Resource dialog as shown in Figure 21-3, select the project where you want to generate the data control and click Add.

Figure 21-3 Confirm Add Resource Dialog



Confirm Add Resource

Do you want to create a new data control and add the selected resources?

Name: ADFRESTDataControl

Project: Project1.jpr

6. Repeat steps 4 and 5 for each resource that you want to include in the data control.

How to Create an ADF Data Control Using the Web Service Data Control Wizard

You can use the Web Service Data Control wizard to create a REST connection and the **data controls** together. The REST connection you create will consume the RESTful web services that are based on the ADF Business Components. Creating a data control in this way does not require any manual configuration, because the necessary metadata is provided in the REST service's describe endpoint.

Before you begin:

It may be helpful to have an understanding of how web service data controls are used in ADF applications. For more information, see About Web Service Data Controls in ADF Applications.

It may be helpful to have an understanding of RESTful web services based on ADF Business Components. For more information, see Creating RESTful Web Services with Application Modules.

You may also find it helpful to understand additional functionality that can be added using other web services features. For more information, see Additional Functionality for Web Service Data Controls in ADF Applications.

You will need to complete these tasks:

- Create the ADF REST resource and deploy it as a RESTful web service, as described in Creating RESTful Web Services with Application Modules.

To create a REST connection and data control for a RESTful web service using the Data Control Wizard:

1. In the Applications window, right-click the project in which you want to create a web service data control and choose **New > From Gallery**.
2. In the New Gallery, select **All Items**, scroll down, select **Web Service Data Control (SOAP/REST) (Data Controls)**, and then click **OK**.
3. In the Create Web Service Data Control wizard, on the Data Source page, specify a name for the data control and select the **REST** radio button.

You can either create Describe-Based ADF Data Control or Generic Data Control with manually described features.

4. Select **Describe-Based ADF Data Control**.
5. Click the **Create a new REST connection** icon to open the Create REST Connection dialog.
6. Enter a name for the connection and a describe URI, which is the RESTful web service that is based on the ADF Business Components. Do not include any resources or parameters in the URL.

   This URI is composed of the host, port, resource path, and the describe resource. The resource path typically consists of the context root of the web service project plus the URL pattern specified in the servlet mapping in the REST project's `web.xml` file. Do include the version name and resource name, but do not include any URL parameters. For example, you can enter something like the following:

   ```
   http://service.example.com:7101/WebServiceProjectContextRoot/rest/
   VersionName/ResourceName/describe
   ```

7. Select the level of authentication from the **Authentication Type** dropdown list. **None** is the default authentication type and disables authentication. Use **Digest** when security is desired. In this way, the password will be transmitted across the network as an MD5 digest of the user's password and cannot be determined by sniffing network traffic. **Basic** authentication is primarily only useful when service access over the network does not require high security.

   > **Note:**
   >
   > In the Create REST Connection dialog, you can click **Test Connection** to verify that you can connect to the URI. However, the URI's server may be configured to not accept requests on the base URI, meaning that the test will fail. Regardless of that fact, you can click **OK** to create the connection. If you have such a base URI and would like to make sure that you can connect to the service, you can temporarily add a resource to the URL, test the connection, and then remove the resource before clicking **OK**.

8. Click **Next**.
9. On the OWSM Policies page, you can optionally set policies for the web service client as required, and click **Next**
10. Based on the web service connection that you specified, the Select Resources page displays the list of resources. You can either select all the resources to add to the data control, which is the default selection, or select a specific set of resources to add to the data control.
11. Click **Next**, and click **Finish**.

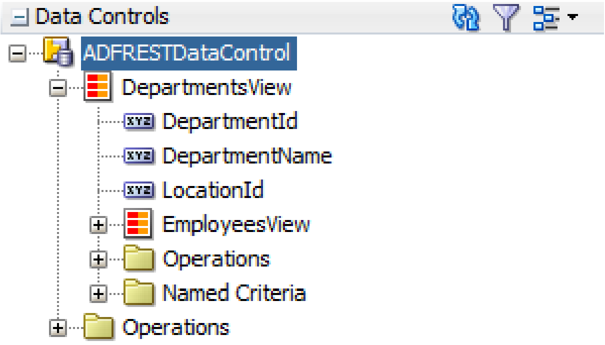
What Happens When You Create a Data Control Based on a REST Connection

When you create a data control based on a resource encompassed by a REST connection, JDeveloper creates a data control definition file (`DataControls.dcx`), opens the file in the overview editor, and displays the data control's hierarchy in the Data Controls panel.

The `DataControls.dcx` overview editor is populated with collection nodes for each resource. The Data Controls panel displays those same collection nodes in addition to subnodes for attributes and operations for those collections.

For example, Figure 21-4 shows a data control with collection object called `DepartmentsView` that corresponds with a resource exposed by the RESTful web service. Its subnodes include attributes of that collection and a nested collection, which can be used to create a list-of-values (LOV) component. In addition, it exposes a combination of data control methods and built-in data control operations that are mapped to standard REST methods.

Figure 21-4 Data Controls Panel with REST Data Control Displayed



For operations that take a parameter of a complex data type, a structured attribute node also appears.

For more information on the objects displayed in the Data Controls panel, see Using REST Data Controls.

Using REST Data Controls

Similar to other data controls, you can use the Data Controls panel for the REST data controls. You can drag an drop the components from the Data Control panel, add attributes, and configure them.
As with other kinds of data controls, you can design a databound user interface by dragging an item from the Data Controls panel and dropping it on a page as a specific UI component. For information on general use of the Data Controls panel, see How to Use the Data Controls Panel.

In the Data Controls panel, each data control object is represented by an icon. Table 21-1 describes what each icon represents, where it appears in the Data Controls panel hierarchy, and what components it can be used to create.

> **Note:**
>
> You can also create data controls based on REST web services that are not based on ADF Business Components. However, such data controls have some differences in the exposed methods and resources. For example, the `Commit` and `Rollback` operations are not exposed for REST data controls that are not based on ADF Business Components. For information on creating and using REST data controls not based on business components, see Consuming Web Services Using the ADF Model Layer in *Developing Applications with Oracle ADF Data Controls*.

Table 21-1   Data Controls Panel Icons and Object Hierarchy for REST Data Control

Icon	Name	Description	Used to Create...
	Data Control	Represents a data control. You cannot use the data control itself to create UI components, but you can use the child objects listed under the data control. There may be more than one data control, each representing a logical grouping of data functions.	Serves as a container for the other objects. Not used to create anything.

Table 21-1 (Cont.) Data Controls Panel Icons and Object Hierarchy for REST Data Control

Icon	Name	Description	Used to Create...
▤	Method	Represents any custom non-HTTP methods that are exposed as part of the web service. **Note:** When you specify a HTTP payload method, the Web Services Data Control generates a schema and displays the specified operations (GET, POST, PATCH, or DELETE) in the Data Controls panel. These payload operations are represented as Method. If a Method accepts arguments, those arguments appear in a Parameters node as parameters, nested inside the method's node. **Note:** While designing a page, you can use these payload operation methods on a form as a command button or link. When you drop an operation on a form, the operation takes the corresponding input parameters that is already dropped as input. You can then bind the form to this button.	Command components. For methods that accept parameters: command components and parameterized forms. See Using Command Components to Invoke Functionality in the View Layer.

Table 21-1 (Cont.) Data Controls Panel Icons and Object Hierarchy for REST Data Control

Icon	Name	Description	Used to Create...
	Method Return	Represents an object that is returned by a web service method. The returned object can be a single value or a collection. A method return appears as a child under the method that returns it. The objects that appear as children under a method return can be attributes of the collection, other methods that perform actions related to the parent collection, and operations that can be performed on the parent collection. When a single-value method return is dropped, the method is not invoked automatically by the framework. You should either drop the corresponding method as a button to invoke the method, or if working with task flows you can create a method activity for it. For more information about executables, see Executable Binding Objects Defined in the Page Definition File.	The same components as for collections and attributes and for query forms. For more information on query forms, see Creating ADF Databound Search Forms .
	Collection	Represents a data collection returned by an operation on the URL service. Collections appear as children under method returns, other collections, or structured attributes. The children under a collection may be attributes, other collections, custom methods, and built-in operations that can be performed on the collection.	Forms, tables, graphs, trees, range navigation components, and master-detail components. See Creating a Basic Databound Page, Creating ADF Databound Tables , Displaying Master-Detail Data , and Creating Databound Chart and Gauge Components..
	Structured Attribute	Represents a returned object that is a complex type but not a collection. For example, a structured attribute might represent a single user assigned to the current service request. **Note:** If you specify a HTTP payload method, the data control generates a schema for specified operations (GET, POST, PATCH, or DELETE) and displays the input parameters for each operation separately in the Data Controls panel. While designing a page, you can use these input parameters for the operations and can drop on a page as an editable form.	Label, text field, date, list of values, and selection list components For more information, see Creating Text Fields Using Data Control Attributes and Creating Databound Selection Lists and Shuttles ..

Table 21-1 (Cont.) Data Controls Panel Icons and Object Hierarchy for REST Data Control

Icon	Name	Description	Used to Create...
XYZ	Attribute	Represents a discrete data element in an object (for example, an attribute in a row). Attributes appear as children under the collections or method returns to which they belong.	Label, text field, and selection list components. For more information, see Creating Text Fields Using Data Control Attributes.
⚙	Operation	Represents a built-in data control operation that performs actions on the parent object. Data control operations are located in an **Operations** node under collections and under the data control's root node. The following navigation operations are supported: `First`, `Last`, `Next`, and `Previous`. `Execute` is supported for refreshing queries. Because REST data controls based on business components are transactional, any data operations that a user performs are batched together and not committed to the data source until the user issues the `Commit` operation. Likewise, the `Rollback` operation is available for the user to undo any uncommitted changes.	UI command components, such as buttons, links, and menus. See Creating Command Components Using Data Control Operations and Creating an Input Form.
🟩	Parameter	Represents a parameter value that is declared by the method under which it appears. Parameters appear in a node under a method or operation.	Label, text, and selection list components.

> **Note:**
>
> In order to use the Data Controls panel for a service based on a REST connection, the service needs to be running and accessible through the connection. Otherwise the Data Controls panel will not have the information necessary to display the structure of the service and enable you to create UI components based on those elements.

Configuring REST Data Controls Published by Application Modules

In ADF, you can use the overview editor for the DataControls.dcx file to configure the REST data controls that are based on RESTful web services. This file stores the metadata and configuration details for the data control that is specific to a resource. After you create a REST data control based on a RESTful web service that is published by an ADF Business Components application module, you can use declarative metadata to configure some aspects the default appearance and behavior of the UI components created from the data control. The things that you can configure this way include:

- Attribute default value

- UI hints for labels, tooltips, number formats, and so on
- List of Value (LOV) objects
- Validation rules

The mechanism for setting this metadata is similar to what is provided for configuring entity objects and view objects.

How to Configure a REST Data Control

You can make a data control configurable by using the overview editor for the `DataControls.dcx` file to create data control structure files that correspond to objects encompassed by the data control. You can then edit the individual data control structure files.

Before you begin:

It may be helpful to have a general understanding of data control configuration. For more information, see Configuring REST Data Controls Published by Application Modules.

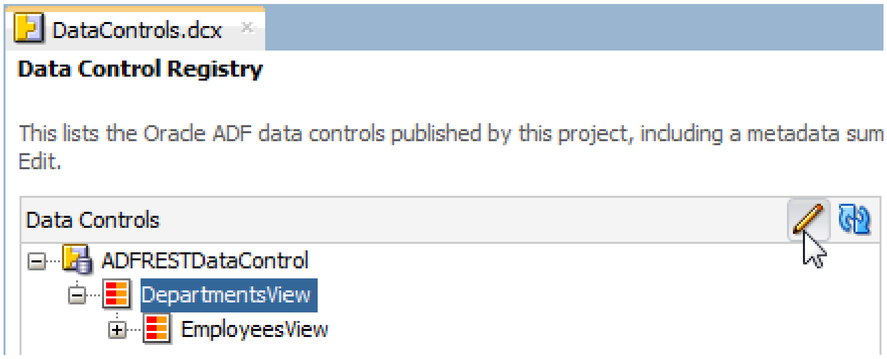
You will need to complete this task:

Create a REST data control, as described in How to Create a Data Control From ADF REST Resources.

To configure a REST data control:

1. In the Applications window, double-click **DataControls.dcx**.
2. In the overview editor, select the object that you would like to configure and click the **Edit** icon to generate a data control structure file, as shown in Figure 21-5.

Figure 21-5 Overview Editor for the DataControls.dcx File



> **Note:**
>
> To edit a REST data control, it must be based on a REST connection. If you created the REST data control from a URL connection in a previous version of JDeveloper, the connection was converted to a REST connection when you migrated the application.

3. In the overview editor of the data control structure file, make the desired modifications.

What Happens When You Edit a Data Control

When you edit a data control, JDeveloper creates a data control structure file that contains metadata for the affected collection and opens that file in the overview editor, as shown in Figure 21-6. This file stores configuration data for the data control that is specific to that resource, such as any UI hints or validators that you have specified for the data object.

Figure 21-6 Overview Editor for a Data Control Structure File

> **Note:**
>
> REST data controls based on services published by application modules also inherit some of the UI hints that the developer of those application modules may have set on the base entity objects and view objects. If you set a UI hint on the REST data control, that definition takes precedence over any conflicting ones set at the entity object or view object level.

For more information on UI hints, validation rules, and LOVs, see the following sections:

- Defining UI Hints for View Objects.
- Using the Built-in Declarative Validation Rules.
- Working with List of Values (LOV) in View Object Attributes.

What You May Need to Know About Primary Keys in REST Data Controls

Because a unique REST resource is identified by a specific resource URI rather than a data attribute, the key for a REST data control based on a service published by an application module is represented by a generated attribute called `canonical`. You can see this indicated by the key icon on the Attributes page of the overview editor for the data control structure file, as shown in Figure 21-6.

This is important to note if you want to use the `setCurrentRowWithKey` and `setCurrentRowWithKeyValue` operations. These operations require a parameter (`rowKey`) that identifies the row you want to set as current. So, rather than using the primary key of the entity object as you would when configuring an application module data control, you use the generated `canonical` attribute.

22
Consuming ADF RESTful Web Services

This chapter describes the supported HTTP methods, HTTP headers, request URL parameters, media types, and other concepts of the ADF REST runtime and the use cases that it supports for making REST API calls on resources exposed by ADF RESTful web services created for an ADF Business Components Model project. The information described in this chapter is useful to the ADF Business Components developer who wants to create RESTful web services for consumption by web service clients through a REST API.

This chapter includes the following sections:

About the ADF REST Framework

ADF provides a REST framework that supports creating and interacting with resources and ADF RESTful web services based on ADF Business Components. ADF REST framework supports the exchange of resource information by client and server during runtime.

The ADF REST framework is an ADF Model framework that allows Fusion web application developers to expose a Web API based on the REST architectural style. The framework itself does not constitute a Web API, but supports creating and interacting with resources and RESTful web services based on ADF Business Components business objects. A consequence of being RESTful, is a REST API that allows client application developers to interact with exposed business objects.

In the Fusion web application, ADF REST resources acted on by RESTful web services are backed by view object instances exposed in the data model of the ADF Business Components Model project. ADF Business Components developers working in the ADF Model project can decide on the set of attributes to expose from backing view objects, the actions to make CRUD operations available, and the view link relationships to preserve for the resulting resource.

The design-time choices made by ADF Business Components developers are captured in REST resource definition XML files. Web service client developers may interact with these resource definitions through the REST API supported by the ADF REST runtime framework. As a result, the consuming service client may invoke CRUD operations to interact with the REST resources and ADF business objects. The data is shaped by the resource's backing view object instance, with the parent-child relationships intact.

ADF REST Resource Use Cases and Examples

Any ADF Business Components developer working in the ADF Model project can publish ADF REST resources to contribute to the Fusion web application.

Specific runtime features of ADF REST framework that support the exchange of resource information by client and server include:

- Interacting with the REST resource is supported by separate JSON-based media type structures for the resource, action execution, and the results of action execution.
- Passing a custom header to specify the version of the REST API framework that will be used to process requests. The version header allows you to override the default version declaration defined by the web application. By specifying the REST API framework version, the web application developer may opt into framework enhancements made by Oracle.
- Interacting with the REST resource using standard HTTP request methods, including GET, POST, PATCH, and DELETE.
- Executing an HTTP method using an `X-HTTP-Method-Override` header using a POST request method when client restrictions prevent the use of standard HTTP methods to interact with the REST resource.
- Merging payload content with the REST resource using a POST method in combination with a header `Upsert-Mode` set to true. This action implements create if the record does not exist or update if the record exists.
- Locating a REST resource item (such as a specific employee) or resource collection (such as an collection of all employees) is supported by REST-compliant URI path names based on resource names defined in the ADF Business Components Model project.
- Obtaining a description of the REST resource, including the resource collection attributes and available actions, is supported by a specific media type and describe action.
- Obtaining a error responses in the form of a JSON payload with exception detail when ADF REST framework version 4 or later is enabled. Alternatively, with framework version 3 or earlier, error responses are in the form of a simple message string.

- Linking to a canonical REST resource is supported when a resource with a super set of updatable entities is defined. The canonical link supports alternate links for the backing view object.
- Filtering of the REST resource is supported by query string parameters on the URI specified by the client to access the specific resource.
- Encoding formats are supported on the REST resource to enable compression and decompression.
- Content streaming of BLOB and CLOB attributes exposed by the REST resource is supported by the ADF REST framework.
- Performing data consistency checks while invoking the RESTful web service is supported by the ADF REST framework. This capability uses version history in the database to enable clients to manage HTTP payloads according to updates in the resource itself.
- Passing a custom header to specify the ADF REST framework version (for example, version 2) with which the ADF REST runtime will use to process the request. The ADF REST framework version permits service clients to opt into framework enhancements made by Oracle in subsequent releases of Oracle JDeveloper.
- Authorizing users to access the REST resource is enabled by ADF Security permission grants.

Specific design time features of ADF REST framework that affect the availability of runtime functionality include:

- Registering REST resources with an application-specific resource version name (or number) to support versioning of REST resources. REST resource versions are named in the `adf-config.xml` file for the application.
- Declaring a default ADF REST framework version for individual REST resources to ensure the ADF REST runtime executes requests using functionality offered by a particular ADF REST framework version. Declaring a particular framework version allows service clients to opt into framework enhancements made by Oracle in subsequent releases of Oracle JDeveloper. The default ADF REST framework version is declared in the `adf-config.xml` file for the application. In JDeveloper starting with release 12.2.1.2.0, versions 1, 2, and 3 exist. In the release 12.2.1.4.0 and later, versions 1, 2, 3, 4, 5, 6, and 7 exist.
- Defining List of Value (LOV) attributes on the view object backing the resource to expose LOV accessor links in the URL resource path.
- Defining row finders to locate a resource using the row finder key value in the URL resource path.
- Defining view instance of the application data model using a super set of updatable attributes to expose canonical links in the URL resource path.
- Configuring change-indicator attributes on the entity object backing the resource to enable data consistency checking when making requests to access resources on the server.
- Configuring a custom content type on the BLOB or CLOB attribute of the view object backing the resource to support content streaming using a link exposed in the resource.
- Configuring security to authenticate users before allowing access to the resource.

Additional Functionality for RESTful Web Services

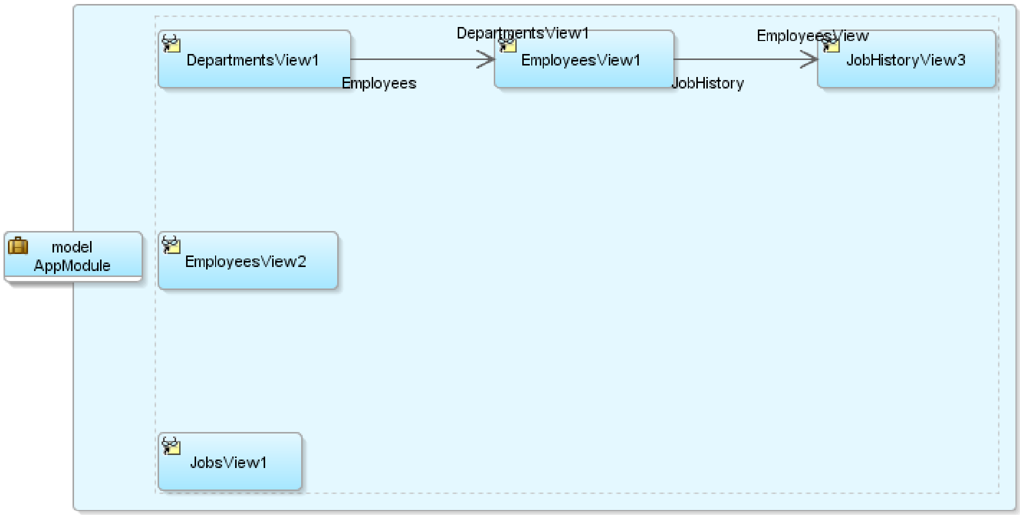
You may find it helpful to understand related Oracle ADF features before you start working with RESTful web services. Following are links to supporting functionality that may be of interest.

- For details about ADF Business Components and creating an ADF Business Components Model project, see Getting Started with ADF Business Components.
- For details about creating RESTful web services in the ADF Business Components project, including enabling LOV links, row finders, canonical resources, change indicators, custom content types for LOB attributes, and security, see Creating ADF RESTful Web Services with Application Modules.
- For details about using the ADF REST data control to design the user interface, see Creating ADF REST Data Controls from ADF RESTful Web Services.

About the Resource Samples in This Chapter

This chapter describes typical use cases for interacting with and manipulating ADF REST resources. All samples are based on DEPARTMENTS, EMPLOYEES, JOBHISTORY, and JOBS tables in the Oracle HR schema. Figure 22-1 depicts the view objects generated from these table in the ADF Business Components model project.

Figure 22-1   REST Sample Project - ADF Business Components View Instances



Sample Project Files and Data Model

As Figure 22-2 shows, the Model project and the business components it defines, includes the ADF REST resource definition files. JDeveloper also generates the **RESTWebService** project to enabling running and testing resources in JDeveloper.

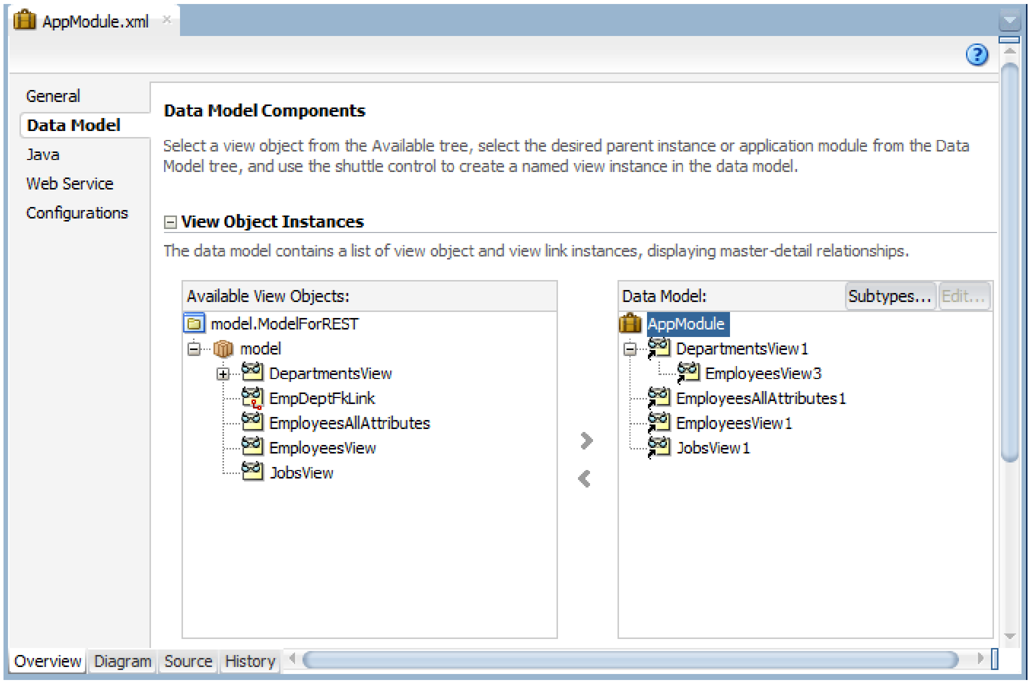
As Figure 22-3 shows, the `Departments` resource is backed by the `DepartmentsView` view object and the child resource `Employees` is enabled.

Figure 22-3   REST Sample Project - Application Module Data Model



Data Model Components

Select a view object from the Available tree, select the desired parent instance or application module from the Data Model tree, and use the shuttle control to create a named view instance in the data model.

View Object Instances

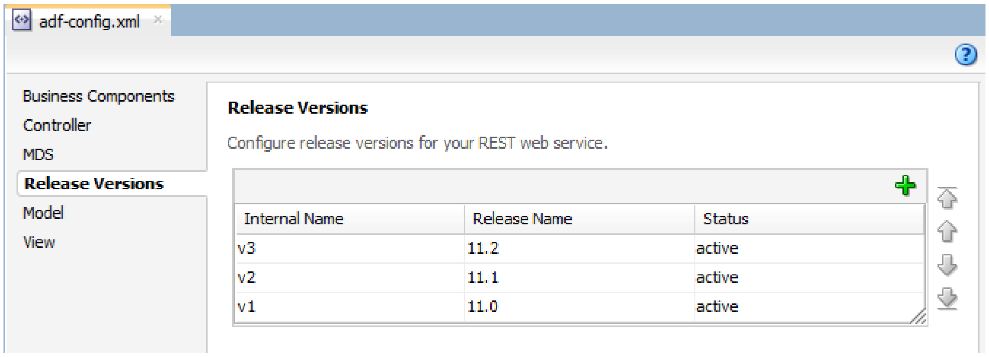
The data model contains a list of view object and view link instances, displaying master-detail relationships.

Sample Project Resources and Resource Version Identifiers

As Figure 22-4 shows, the application defines three version release names. Each ADF REST resource is assigned to one of these version identifiers and accessed at runtime by the version release name. For example, several versions of the `Employees` resource were created: one with a limited set of supported operations and another with a more complete set of operations.

Note that the order of the version identifiers determines the version sequence, with the most recent version appearing at the top of the list. In the REST samples, where multiple versions of the `Employees` resource exist, the release name `11.2` identifies the latest version.

Figure 22-4   REST Sample Project - Resource Versions



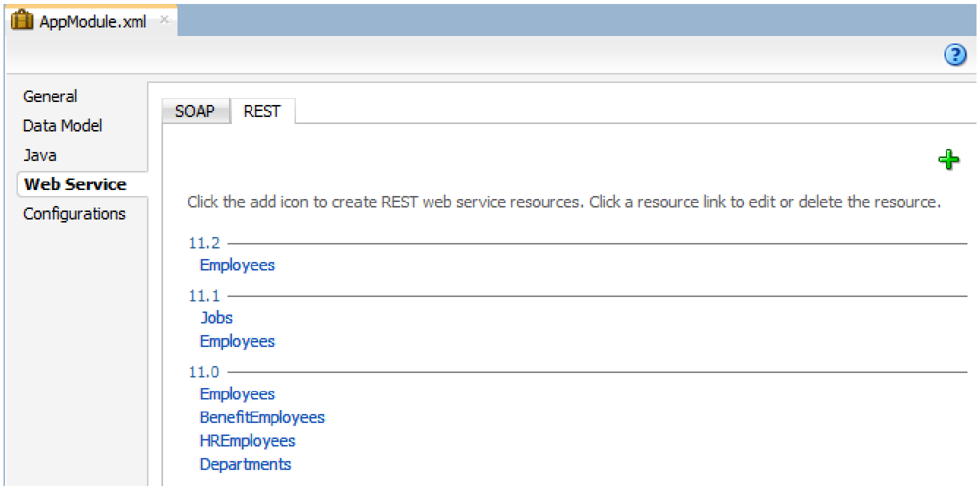
Release Versions

Configure release versions for your REST web service.

Internal Name	Release Name	Status
v3	11.2	active
v2	11.1	active
v1	11.0	active

As Figure 22-3 shows, the application module organizes the created resources by their assigned version release name. The Employees resource is originally created in version 11.0 and then revised in subsequent versions 11.1 and 11.2 with the addition of new mandatory attributes. The Jobs resource added in 11.1 supports create operations on the Employees resource with LOV-enabled attributes.

Figure 22-5 REST Sample Project - Application Module Resource Names



Click the add icon to create REST web service resources. Click a resource link to edit or delete the resource.

11.2
- Employees

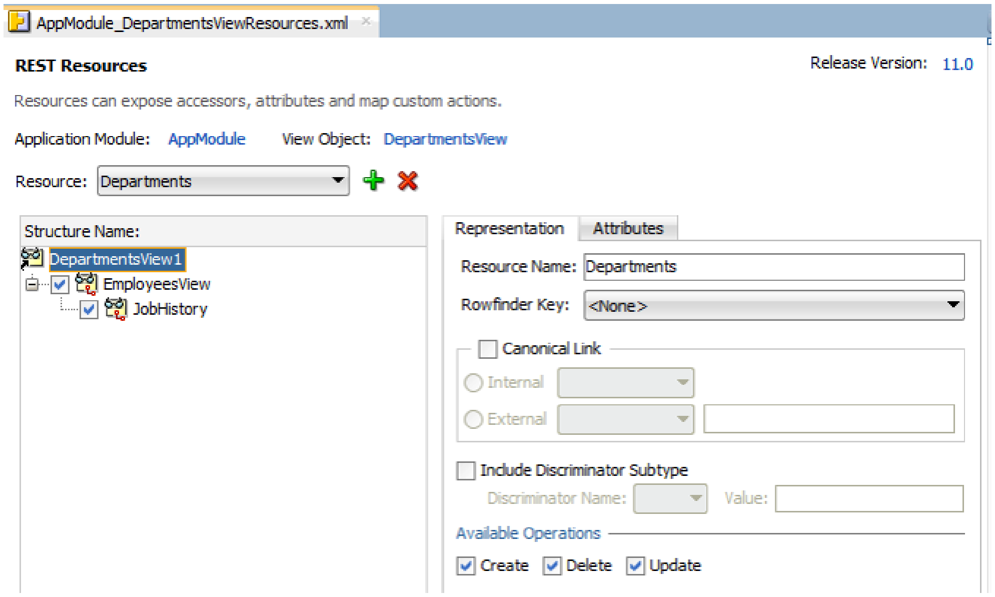
11.1
- Jobs
- Employees

11.0
- Employees
- BenefitEmployees
- HREmployees
- Departments

As Figure 22-6 shows, the Departments resource is backed by the DepartmentsView view object and the child resources Employees and JobHistory are enabled.

Note that the name of the child resource Employees is derived from the destination view instance name in the defining view link. In the sample, the destination view instance was renamed from EmployeesView1 to Employees. This supports accessing the child resource using the name Employees in the URL resource path instead of the default name EmployeesView1.

Figure 22-6 REST Sample Project - Departments Resource



REST Resources

Release Version: 11.0

Available Operations

□ Create ☑ Delete ☑ Update

As Figure 22-9 shows, version 11.1 of the Employees root resource adds functionality, including a Create operation to enable creating resource items using the Jobs resource for the LOV-enabled EmployeesView attribute JobId. At runtime, the Jobs resource will supply values for the LOV-enabled attribute JobId without requiring the context of a row. This version also enables subtype usages in the Employees resource collection, where the JobId attribute serves as the discriminator for the subtype resource. At runtime, the Employees resource displays the commission attribute for employees with the SA_REP (Sales Representative) job ID.

Entity Object and View Object Customization

AsFigure 22-11 shows, the `EmployeesView` view object defines the LOV-enabled attribute `JobId`. The LOV accessor resource returns the list of jobs by title, and presents them as choices for the corresponding job ID.

Note that JDeveloper intentionally does not expose LOV accessors in the resource definition. At runtime the ADF REST runtime automatically nests LOV accessor resources as children of the resource item's LOV-enabled attribute.

Additionally, Figure 22-11 shows support for creating a new resource item with a LOV-enabled attribute defined. The `EmployeesView` associates a specific version of an LOV accessor resource (identified as `v2:Jobs`) with the LOV-enabled attribute `JobId`. At runtime, the `Employees` resource describe exposes a link to the LOV resource. The POST request to create a resource item may be completed with the aid of the LOV resource, which relies on the view object LOV definition to return the correct values to the LOV-enabled attribute.

LOV Resource: v2:Jobs

Select a LOV Resource that will provide the static list of values

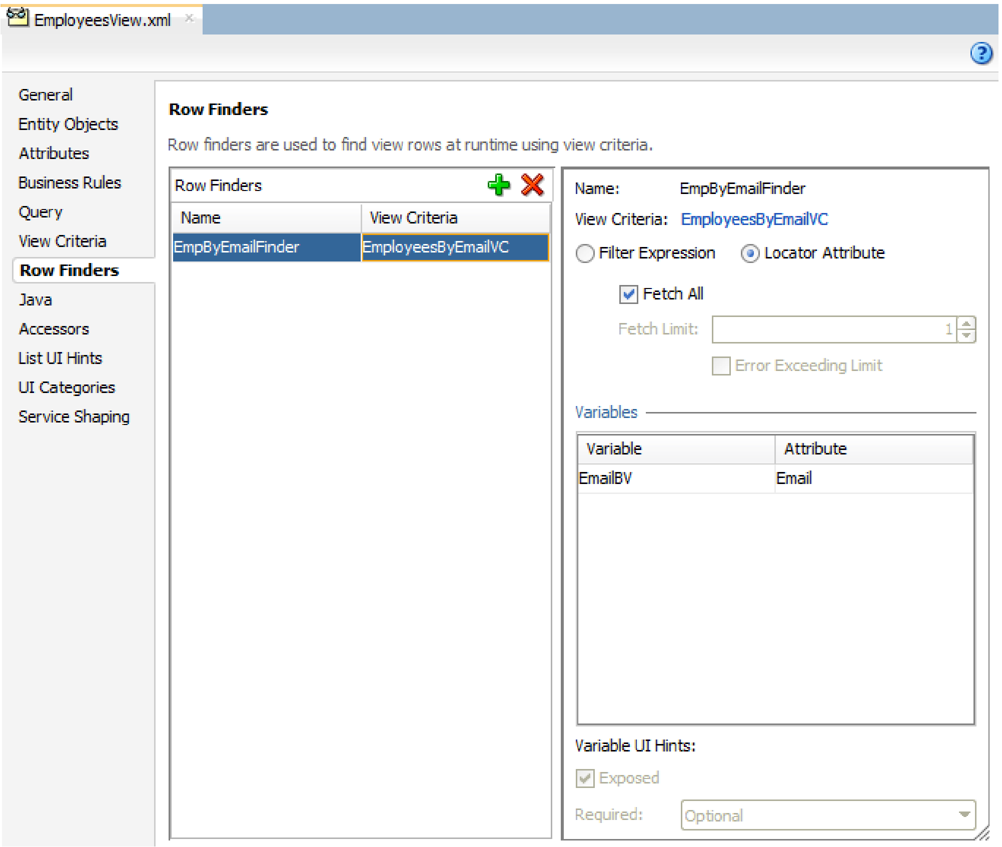
Lists of Values:

Name	List Data Source	List Attribute
LOV_JobId	JobsLOV	JobId

As Figure 22-12 shows, the `EmployeesView` view object defines the `EmpByEmailFinder` row finder. The row finder retrieves the employee using the employee's email address (`Email` attribute) instead of the employee's ID.

Note that row finders are exposed on all versions of the resource by default. However, when the row finder key attribute is defined in a particular resource definition, then it will be mandatory to use the finder name in the URL resource path. Until the row finder key is explicitly defined in the resource definition, the URL resource path will require the key attribute (`EmployeeId` in this sample).

Figure 22-12 REST Sample Project - Employees Row Finder



Row Finders

Row finders are used to find view rows at runtime using view criteria.

Row Finders

Name	View Criteria
EmpByEmailFinder	EmployeesByEmailVC

Name: EmpByEmailFinder
View Criteria: EmployeesByEmailVC
○ Filter Expression ● Locator Attribute
☑ Fetch All
Fetch Limit: 1
□ Error Exceeding Limit

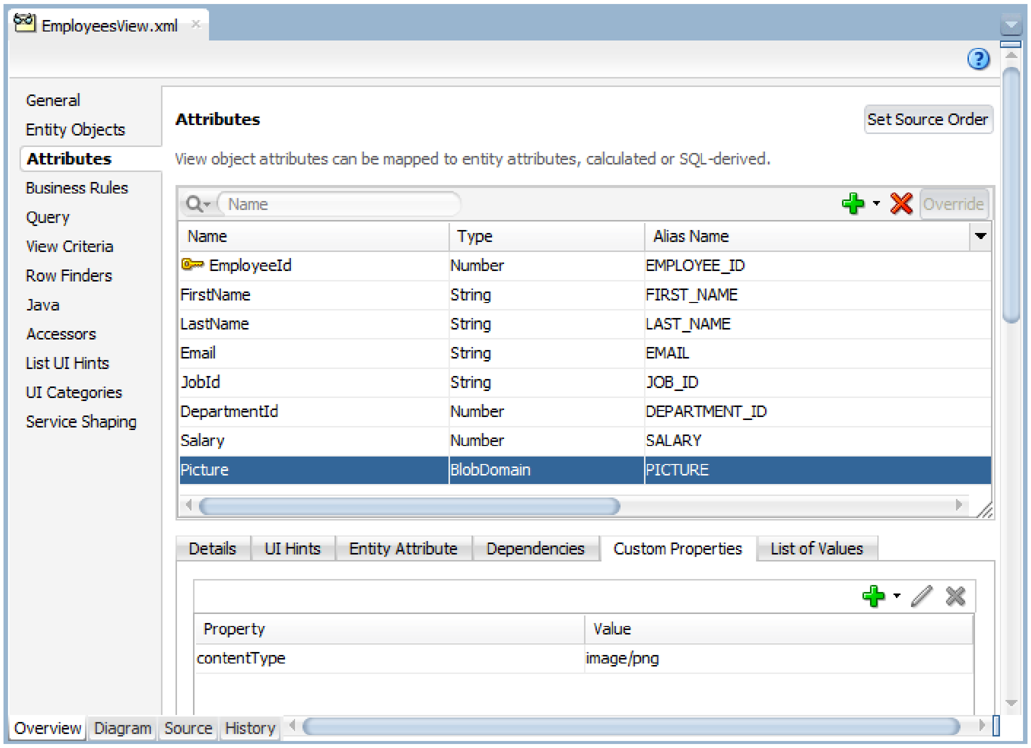
Variables

Variable	Attribute
EmailBV	Email

Variable UI Hints:
☑ Exposed
Required: Optional

As Figure 22-13 shows, the `EmployeesView` view object defines a custom content type `image/png` on the `Picture` attribute. This content type replaces the default `application/octet-stream` content type definition for the attribute and will be the expected accept type when streaming the image content.

Figure 22-13 REST Sample Project - Employees BLOB Content Type



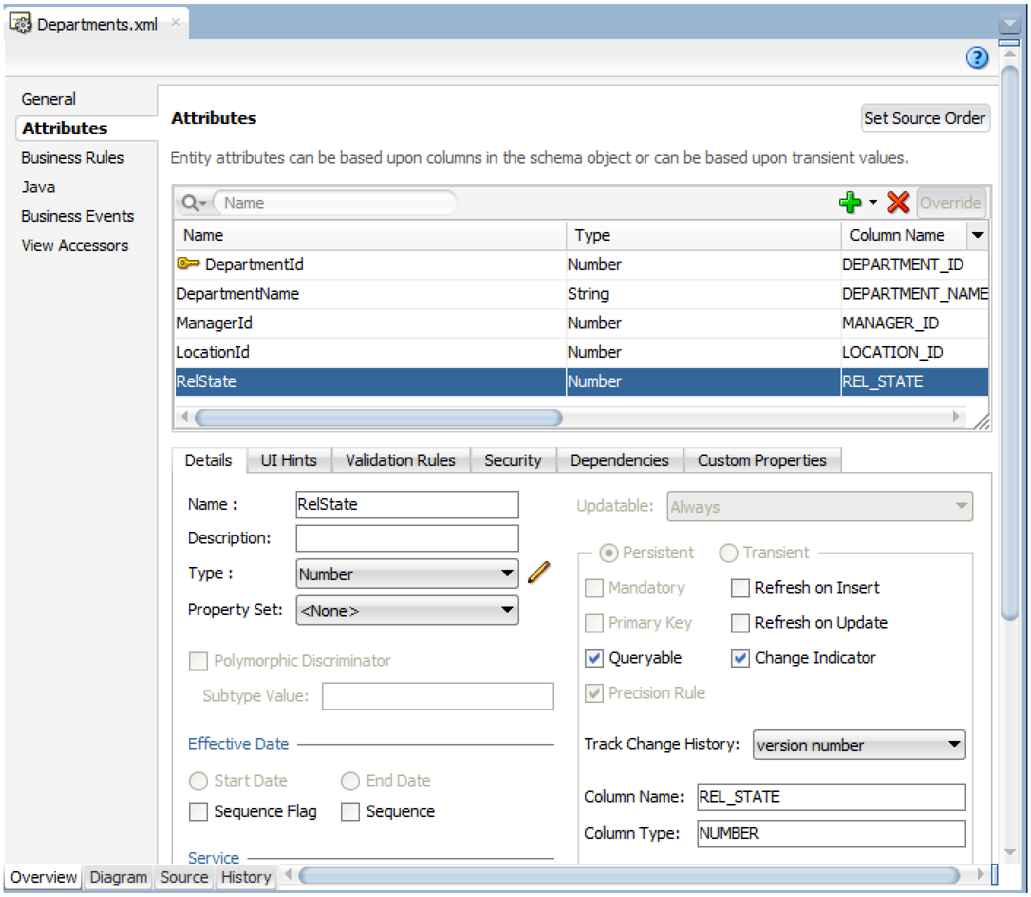
View object attributes can be mapped to entity attributes, calculated or SQL-derived.

Name	Type	Alias Name
EmployeeId	Number	EMPLOYEE_ID
FirstName	String	FIRST_NAME
LastName	String	LAST_NAME
Email	String	EMAIL
JobId	String	JOB_ID
DepartmentId	Number	DEPARTMENT_ID
Salary	Number	SALARY
Picture	BlobDomain	PICTURE

Property	Value
contentType	image/png

As Figure 22-14 shows, the `Departments` entity object defines the change-indicator attribute `RelState` to enable support for data consistency checking. The editor for the attributes has the **Change Indicator** and **History Column - version number** fields enabled to configure the change indicator.

Figure 22-14 REST Sample Project - Departments Change Indicator Attribute



Attributes

Entity attributes can be based upon columns in the schema object or can be based upon transient values.

Name	Type	Column Name
DepartmentId	Number	DEPARTMENT_ID
DepartmentName	String	DEPARTMENT_NAME
ManagerId	Number	MANAGER_ID
LocationId	Number	LOCATION_ID
RelState	Number	REL_STATE

Name : RelState

Description:

Type : Number

Property Set: <None>

□ Polymorphic Discriminator

Subtype Value:

Effective Date

○ Start Date ○ End Date

□ Sequence Flag □ Sequence

Service

Updatable: Always

● Persistent ○ Transient

□ Mandatory □ Refresh on Insert

□ Primary Key □ Refresh on Update

☑ Queryable ☑ Change Indicator

☑ Precision Rule

Track Change History: version number

Column Name: REL_STATE

Column Type: NUMBER

Understanding ADF Business Components Resources

With RESTful web services, ADF Business Components view objects are represented as a resource collection when the RESTful web service is invoked at runtime. ADF REST resources that service developers create in the ADF Business Components model project are based on view object instances that the project application module defines. For example:

- A `Departments` resource is based on a `DepartmentsVO` view instance and its accessor to an `EmployeesVO` view instance.
- An `Employees` resource is based on an `EmployeesVO` view instance.

At runtime, when an action of the RESTful web service is invoked, the payload returned by the service contains one or more resource collections, comprised of the row sets queried by the backing view objects and the individual attributes of the view object rows. The resource collections preserve the relationship of master-detail coordinating view instances.

As Table 22-1 shows, the *resource collection* is the RESTful web service payload representation of a view object instance. The *resource items* are the rows and attributes of the payload item object, which in turn correspond to view object rows.

> **Note:**
>
> The format of ADF resource collections and contained items are defined by specific ADF REST media types as JSON-encoded entities. For more details, see ADF REST Media Types.

Table 22-1 JSON Objects and ADF Business Component Representation

JSON Object	ADF Business Component
`resource collection`	View object instance comprised of one or more rows. `Departments`, `Employees` are examples of resource collections based on `DepartmentsVO` and `EmployeesVO` view instances.
`resource item`	A view object row. The specific department `10` or employee `1012` are examples of resource items from the `Departments` and `Employees` resource collections.

Retrieving the ADF REST Catalog Describe

When you invoke an HTTP GET method in RESTful web service to describe all the available resources in the resource catalog, it returns JSON objects that contain the attributes, actions, and links defined in the REST resource definitions for the web service.
The describe for the RESTful web service resource catalog allows you to identify the shape and actions allowed on an ADF RESTful web service defined for the service endpoint. By default the catalog describe request returns a JSON object that contains the information needed to understand all available public resources, including their attributes, collections, items, annotations, actions, and links.

The ADF REST framework supports the following catalog describe use cases:

- Retrieve the *full resource catalog describe*, including all resource details, such as their attributes, collections, items, annotations, actions, and links.
- Retrieve a *minimal resource catalog describe*, where the describe details will be limited to resource titles and links only and children, or nested resources, will be excluded.
- Retrieve a resource catalog describe (either full or minimal) based on resource visibility. For example, you can retrieve the describe for only public resources, only private (unlisted) resources, or both public and private resources.
- Retrieve a resource catalog describe (either full or minimal) but optionally exclude or include children resources nested within a parent resource and optionally exclude or include all resource annotations.

To retrieve the catalog describe of all the available, public resources of a specific version in the application, you append `/describe` to the version URL.

For example, the following URL returns the describe for the resource catalog of all available public resources designated as version `11.0` in the identified application:

```
http://host:port/context-root/rest/11.0/describe
```

Note:

Executing a GET request to retrieve a resource catalog describe requires the client to be in the context of a particular version. For information on how to get the version release names for the service end point, see Retrieving Resource Versions.

When you do not require an exhaustive describe that returns the full set of information for all resources in the same request, you can request a minimal describe. For example, the following URL with query parameter `metadataMode` set to `minimal` returns the describe for all parent resources but the retrieved describe information will be limited to just the titles and links of the resources:

```
http://host:port/context-root/rest/11.0/describe?metadataMode=minimal
```

Additionally, you can append URL query parameters on the request for a minimal catalog describe to retrieve specific details in the describe. For example, the following URL with appended query parameters retrieves a minimal catalog describe with all available children resources nested within their parent resources included.

```
http://host:port/context-root/rest/11.0/describe?
metadataMode=minimal&includeChildren=true
```

The following table identifies the URL query parameters the may be used with the catalog describe request. These query parameters let you control the amount of detail retrieved in the describe.

Table 22-2 Optional URL Query Parameters for Catalog Describe Requests

URL Query Parameter	Values	Description

`metadataMode`	`verbose` (default)
	`minimal`
	`list`
		Use to retrieve the description of resources with or without all details. By default, the full catalog is retrieved, performing an exhaustive describe that returns the complete set of information for all resources, including nested children resources. The full catalog describe therefore includes the following sections of information for each resource:
		title, attributes, collection, item, annotations, children, and links
		Note that annotations must be defined by the ADF REST resource developer in the application and may not be present on the resource.
		You can improve the readability of a large catalog and retrieve a shallow catalog limited to the titles and links of parent resources (does not include children resources) by appending the URL parameter `?metadataMode=minimal` to the describe request.
		If you do not want any metadata in the response but only self links, you can append `?metadataMode=list` to the describe request.
		Optionally, additional parameters may be appended to the minimal describe request to include children resources and / or resource annotations, as explained for the query parameters `showAnnotations` and `includeChildren`. For example, you can append `?metadataMode=minimal&includeChildren=true` to retrieve a minimal catalog describe with all children resources included.

`showAnnotations`	`true`, `false` (default depends on whether full or minimal catalog is retrieved)	Use to either exclude or include resource annotations, as specified in the application. The default depends on the `metadataMode` parameter value: • By default, a full catalog (`metadataMode=verbose`) describe includes annotations. To exclude resource annotations from the full catalog describe, you can append `?showAnnotations=false` on the describe request. • By default, a minimal catalog (`metadataMode=minimal`) describe excludes annotations. To include resource annotations in the minimal catalog describe, you can append `?showAnnotations=true` on the describe request. Note that annotations must be defined by the ADF REST resource developer in the application and may not be present on the resource You cannot use this parameter with `?metadataMode=list`.

Table 22-2 (Cont.) Optional URL Query Parameters for Catalog Describe Requests

URL Query Parameter	Values	Description
includeChildren	true, false (default depends on whether full or minimal catalog is retrieved)	Use to either exclude or include all available children resources nested within a parent resource. The default depends on the metadataMode parameter value: • By default, a full catalog (metadataMode=verbose) describe includes all children resources. To exclude children resources from the full catalog describe, you can append ?includeChildren=false on the describe request. • By default, a minimal catalog (metadataMode=minimal) describe excludes all children resources. To include children resources in the minimal catalog describe, you can append ?includeChildren=true on the describe request. You cannot use this parameter with ?metadataMode=list.
include	public (default), unlisted, all	Use to retrieve the description of resources of a certain visibility, as declared in the application. This URL parameter values specify including only public resources (public), only private resources (unlisted), or both types (all). By default, only resources that are public are shown in the describe. To view private resources, you must append either ?include=all or ?include=unlisted on the describe request. See How to Hide a Resource from the Catalog Describe.
resources	A comma separated list of resource collection names. Format:<resName1>,<resName2> Example: ?resources=Deparments,Employees	Use to retrieve the description of the named resources to filter resources at the catalog level.

Retrieving the Full Catalog Describe

ADF REST runtime supports describing all available resources for the application end point using a GET method and performs an exhaustive describe that returns the full set of information for all resources, including all children resources nested within parent resources.

To examine all available resources with full information included in the resource catalog:

1. Execute the resource catalog describe and locate the names of the resources in the describe. The children attribute identifies nested resources.

2. Examine these resource objects to understand the shape of each resource:
   - `attributes` specifies the list of available resource collection attributes.
   - `collection` specifies the shape of the collection and specifies `finders` for row finder, `links`, and available `actions` (including media types).
   - `item` specifies the shape of the instances of the collection and itself specifies `links` and available `actions`.
   - `children` specifies any nested resources (and itself contains `attributes`, `collection`, and `item` objects).

For example, the describe for a service with `Departments` and child `Employees` resources returns the following objects:

```
{
  "Resources" : {
    "Employees" : {
      "discrColumnType" : false,
      "attributes" : [ {
       ...
      } ],
      "collection" : {
        ...
        } ],
        "finders" : [ {
        } ]
        "links" : [ {
        } ]
        "actions" : [ {
        } ]
      },
      "item" : {
        "links" : [ {
        } ]
        "actions" : [ {
        } ]
      },
      "children" : {
        "Departments"
          ...
        } ],
      ...
      "links" : [ {
      } ]
  }
}
```

The following sample describes version `11.0` of all resources in the resource catalog. Note that the URL version parameter `11.0` may be replaced with an application-specific version identifier. For more details about specifying resource versions, see in Retrieving Resource Versions.

> **Note:**
>
> You can use the `include` query parameter to retrieve the full catalog describe with resources of a certain visibility. For example, to view both public and private resources, you can use`http://server/demo/rest/v1/describe?include=all`. You can use `all`, `unlisted`, or `public` as values for the `include` query parameter.

Request

- **URL**

  `http://server/demo/rest/11.0/describe`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.description+json`

- **Payload**

}
```

Retrieving a Minimal Catalog Describe

ADF REST runtime supports describing all available resources while retrieving a reduced amount of information for the application end point using a GET method. The reduced or minimal catalog describe helps improve the readability of the describe by limiting the resource information to resource titles, links, and available annotations.

To examine the minimal describe for all available resources in the resource catalog:

1. Execute the minimal resource catalog describe and locate the names of the resources in the describe. Note that nested resources or children resources are not shown by default.
2. Examine these resource objects `links`.

For example, the minimal describe for a service with a `Departments` resource returns the following objects:

```
{
  "Resources" : {
    "Departments" : {
      Departments,
      "links" : [ {
        "rel" : "self",
        "href" : "http://server/demo/rest/11.1/Departments/describe",
        "name" : "self",
        "kind" : "describe"
      } ]
    },
      ...
  }
}
```

By default children resources are not included in the minimal describe. Use the `includeChildren` query parameter to retrieve the minimal catalog describe with all available children resources nested within the parent resources. For example, to view children resources in the minimal describe, you can use a request like the following:

```
http://server/demo/rest/11.1/describe?
metadataMode=minimal&includeChildren=true
```

The minimal describe with the `includeChildren` query parameter set to `true` for a service with a `Departments` resource that includes a child resource `Employees` returns the following objects:

```
{
  "Resources" : {
    "Departments" : {
      Departments,
     "children" :  {
          "Employees" :  {
            "links" : [ {
              "rel" : "self",
              "href" : "http://server/demo/rest/11.1/Departments/{id}/child/
Employees/describe",
              "name" : "self",
              "kind" : "describe"
            } ]
         }
       },
      "links" : [ {
        "rel" : "self",
        "href" : "http://server/demo/rest/11.1/Departments/describe",
        "name" : "self",
        "kind" : "describe"
      } ]
    },
      ...
  }
}
```

The following sample retrieves a minimal resource catalog describe, including children resources, where the `Employees` resource is nested within the `Departments` resource and the `JobsLOV` resource is nested in the Employees resource.

Request

- **URL**

  `http://server/demo/rest/11.1/describe?`
  `metadataMode=minimal&includeChildren=true`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.description+json`

- **Payload**

```
{
  "Resources" :  {
    "Employees" :  {
        "children" :  {
          "JobsLOV" :  {
            "links" : [ {
              "rel" : "self",
              "href" : "http://server/demo/rest/11.1/Employees/{id}/child/
JobsLOV/describe",
              "name" : "self",
              "kind" : "describe"
            } ]
         }
       },
       "links" : [ {
          "rel" : "self",
          "href" : "http://server/demo/rest/11.1/Employees/describe",
          "name" : "self",
          "kind" : "describe"
        } ]
      }
    },
    "Departments" :  {
       "children" :  {
         "Employees" :  {
            "links" : [
            {
              "rel" : "self",
              "href" : "http://server/demo/rest/11.1/Departments/{id}/child/
Employees/describe",
              "name" : "self",
              "kind" : "describe"
            } ]
        }
      },
       "links" : [
        {
          "rel" : "self",
          "href" : "http://server/demo/rest/11.1/Departments/describe",
          "name" : "self",
          "kind" : "describe"
        }
      ]
    }
  }
}
```

Retrieving the Catalog Describe Based on Resource Visibility Declaration

ADF REST runtime supports describing all available resources with a URL parameter that includes resources of a certain visibility for the application end point using a GET method, optionally including those resources that the application identifies as private.

By default, only resources that are public are shown in the describe. This URL parameter can specify only public resources, only private (unlisted) resources, or both types. To view private resources, you must append either `?include=all` (both public and private resources) or `?include=unlisted` (only private resources) on the describe request.

For more information about how the application developer declares visibility in the resource definition, see How to Hide a Resource from the Catalog Describe.

To view private resources in the resource catalog:

1. Execute the resource catalog describe with the URL parameter `?include=all` or `?include=unlisted` and locate the names of the private resources in the describe.
2. Examine these resource objects to understand the shape of each resource:

The following sample retrieves a minimal resource catalog describe, including both public and private resources, where the `Locations` resource is configured as `unlisted`.

Request

- **URL**

  `http://server/demo/rest/11.1/describe?metadataMode=minimal&include=all`
- **HTTP Method**

  GET
- **Content-Type**

  none
- **Payload**

  none

Response

- **HTTP Code**

  `200`
- **Content-Type**

  `application/vnd.oracle.adf.description+json`
- **Payload**

```
{
  "Resources" :  {
     "Employees" :  {
       "links" : [
        {
           "rel" : "self",
           "href" : "http://server/demo/rest/11.1/Employees/describe",
           "name" : "self",
           "kind" : "describe"
        }
       ]
     },
     "Departments" :  {
       "links" : [
         {
           "rel" : "self",
           "href" : "http://server/demo/rest/11.1/Departments/describe",
           "name" : "self",
           "kind" : "describe"
        }
       ]
     },
     "Locations" :  {
       "links" : [
        {
          "rel" : "self",
          "href" : "http://server/demo/rest/11.1/Locations/describe",
          "name" : "self",
          "kind" : "describe"
        }
      ]
    }
  }
}
```

Retrieving the ADF REST Resource Describe

When you invoke an HTTP GET method in RESTful web service to describe a single resource, all the available resources, or the nested resources, it returns a JSON object that contains the attributes, actions, and links defined in the REST resource definition. The describe for the RESTful web service allows you to identify the shape and actions allowed on an ADF RESTful web service. It returns a JSON object that contains the attributes, actions, and links defined in the REST resource definition.

The ADF REST framework supports the following describe use cases for the service end point:

- Describe a single resource collection.
- Describe a single resource item.
- Describe a nested resource in a parent-child relationship.
- Describe two or more named resource collections.
- Describe all available resources (resource catalog). For details, see Retrieving the ADF REST Catalog Describe.

To retrieve the describe, invoke an HTTP GET with `/describe` appended to the resource URL.

> **Note:**
>
> Executing a GET request to retrieve a resource describe also requires the client to be in the context of a particular version. For information on how to get the version release names for the service end point, see Retrieving Resource Versions.

For example, the following URL returns the describe for the `Employees` resource of version `11.0` in the identified application:

```
http://host:port/context-root/rest/11.0/Employees/describe
```

To retrieve the describe of all the resources of a specific version in the application, you append `/describe` to the version URL.

For example, the following URL returns the describe for all resources of version `11.0` in the identified application:

```
http://host:port/context-root/rest/11.0/describe
```

Describing a Resource Collection

The ADF REST runtime supports describing resource collections using a GET method.

To examine a resource collection:

1. Execute the resource collection describe and locate the names of the resources in the describe.
2. Examine these resource objects to understand the shape of each resource:
   - `attributes` specifies the list of available resource collection attributes.
   - `collection` specifies the shape of the collection and specifies `finder` for row finder, `links`, and available `actions` (including media types).
   - `item` specifies the shape of the instances of the collection and itself specifies `links` and available `actions`.
   - `children` specifies any nested resources (and itself contains `attributes`, `collection`, and `item` objects).

For example, the describe for the `Departments` resource returns the following objects:

```
{
  "Resources" : {
    "Departments" : {
      "discrColumnType" : false,
      "attributes" : [ {
       ...
      } ],
      "collection" : {
        ...
        } ],
        "finders" : [ {
        } ]
        "links" : [ {
        } ]
        "actions" : [ {
        } ]
      },
      "item" : {
        "links" : [ {
        } ]
        "actions" : [ {
        } ]
      },
      "children" : {
        "Employees"
          ...
        } ],
      ...
      "links" : [ {
      } ]
  }
}
```

The following sample describes version `11.0` of the `Departments` resource.

Request

- **URL**

  `http://server/demo/rest/11.0/Departments/describe`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.description+json`

- **Payload**

```
{
  "Resources" : {

      } ]
    }
  }
}
```

Describing a Resource Item

The ADF REST runtime supports describing a resource item using a GET method.

Note that a resource item describe typically provides the same information as the collection describe. In the case of a polymorphic collection, however, a resource item describe will have more information than a resource collection describe. Consider, for example, the polymorphic collection vehicles, where the vehicles resource contains an item automobile and an item airplane. The description of vehicles will return a general shape of all vehicles, whereas, a resource item describe of an automobile will return the specific shape of that object.

To examine a resource item:

1. Execute the resource item describe and locate the names of the resources in the describe. The `children` attribute identifies nested resources.
2. Examine the resource item describe to understand its shape.
   - `attributes` specifies the list of available resource collection attributes.
   - `item` specifies `links` to the item, including defined child collections, and available `actions`.
   - `links` specifies describe links.

For example, the describe for a `Departments` resource item returns the following objects:

```
{
  "Resources" : {
    "Departments" : {
      "discrColumnType" : false,
      "attributes" : [ {
       ...
      } ],
      "item" : {
        "links" : [ {
        } ]
        "actions" : [ {
        } ]
      },
      "links" : [ {
      } ]
  }
}
```

The following sample describes version `11.0` of an instance of the `Departments` resource collection.

Note: To recursively include all children of the resource item on the requested describe, provide the query parameter `?includeChildren=true` on the describe URL.

Request

- **URL**

  `http://server/demo/rest/11.0/Departments/10/describe`
- **HTTP Method**

  GET
- **Content-Type**

  none
- **Payload**

none

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.description+json`

- **Payload**

```
{
  "Resources" : {
    "Departments" : {
      "discrColumnType" : false,
      "attributes" : [ {
        "name" : "DepartmentId",
        "type" : "integer",
        "updatable" : true,
        "mandatory" : true,
        "queryable" : true,
        "precision" : 4
      }, {

        "queryable" : true,
        "precision" : 30
      }, {
        "name" : "RelState",
        "type" : "integer",
        "updatable" : true,
        "mandatory" : false,
        "queryable" : true
      } ],
      "item" : {
        "links" : [ {
          "rel" : "child",
          "href" : "http://server/demo/rest/11.0/Departments/10/child/
Employees",
          "name" : "Employees",
          "kind" : "collection",
          "cardinality" : {
            "value" : "1 to *",
            "sourceAttributes" : "DepartmentId",
            "destinationAttributes" : "DepartmentId"
          }
        }, {
          "rel" : "self",
          "href" : "http://server/demo/rest/11.0/Departments/10",
          "name" : "self",
          "kind" : "item"
        }, {
          "rel" : "canonical",
          "href" : "http://server/demo/rest/11.0/Departments/10",
          "name" : "canonical",
          "kind" : "item"
        } ],
        "actions" : [ {
          "name" : "get",
          "method" : "GET",
          "responseType" : [ "application/json", "application/
vnd.oracle.adf.resourceitem+json" ]
        }, {
          "name" : "update",
          "method" : "PATCH",
          "requestType" : [ "application/vnd.oracle.adf.resourceitem+json" ],
          "responseType" : [ "application/json", "application/
vnd.oracle.adf.resourceitem+json" ]
        }, {
          "name" : "delete",
          "method" : "DELETE"
        } ]
      },
      "links" : [ {
        "rel" : "self",
        "href" : "http://server/demo/rest/11.0/Departments/10/describe",
        "name" : "self",
        "kind" : "describe"
      }, {
        "rel" : "canonical",
        "href" : "http://server/demo/rest/11.0/Departments/10/describe",
        "name" : "canonical",
        "kind" : "describe"
      } ]
    }
  }
}
```

Describing a Nested Resource

The ADF REST runtime supports describing an ADF REST nested resource using a GET method.

To examine nested resources in the resource catalog:

1. Execute the nested resource describe and locate the names of the resources in the describe. The `children` attribute identifies nested resources.
2. Examine these resource objects to understand the shape of each resource:
   - `attributes` specifies the list of available resource collection attributes.
   - `collection` specifies the shape of the collection and specifies `finder` for row finder, `links`, and available `actions` (including media types).
   - `item` specifies the shape of the instances of the collection and itself specifies `links` and available `actions`.
   - `children` specifies the nested resources (and itself contains `attributes`, `collection`, and `item` objects).

For example, the describe for the nested resources `Departments` and `Employees` returns the following objects:

```
{
  "Resources" : {
    "Employees" : {
      "discrColumnType" : false,
      "attributes" : [ {
       ...
```

```
   } ],
   "collection" : {
    ...
    } ],
    "finders" : [ {
    } ]
    "links" : [ {
    } ]
    "actions" : [ {
    } ]
   },
   "item" : {
    "links" : [ {
    } ]
    "actions" : [ {
    } ]
   },
   "children" : {
    "Departments"
     ...
    } ],
   ...
   "links" : [ {
   } ]
 }
}
```

The following sample (URL1) describes version `11.0` of the `Employees` resource which can be found in the context of a `Department`. The second sample (URL2), describes an item of the same nested resource `Employees`, where the ID of the employee identifies the nested resource item.

Note: To recursively include all children of the resource item on the requested describe, provide the query parameter `?includeChildren=true` on the describe URL.

Requests

- **URL 1**

  `http://server/demo/rest/11.0/Departments/10/child/Employees/describe`

- **URL 2**

  `http://server/demo/rest/11.0/Departments/10/child/Employees/200/describe`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Responses

- **HTTP Code**

  `200`

- **Content-Type**

```
application/vnd.oracle.adf.description+json
```

- **Payload 1**

    }
  }
}
```

Describing Multiple Resource Collections

REST APIs support describing two or more named resource collections.

To examine the resource collections:

1. Execute the resource collection describe with the named resources using the `resources` query parameter.
2. Locate the names of the resources in the describe.
3. Examine these resource objects to understand the shape of each resource:
   - `attributes` specifies the list of available resource collection attributes.
   - `collection` specifies the shape of the collection and specifies `finders` for row finder, `links`, and available `actions` (including media types).
   - `item` specifies the shape of the instances of the collection and itself specifies `links` and available `actions`.

- `children` specifies any nested resources (and itself contains `attributes`, `collection`, and `item` objects).

For example, the describe for the `Departments` resource returns the following objects:

```
{
  "Resources" : {
    "Departments" : {
      "discrColumnType" : false,
      "attributes" : [ {
       ...
      } ],
      "collection" : {
        ...
        } ],
        "finders" : [ {
        } ]
        "links" : [ {
        } ]
        "actions" : [ {
        } ]
      },
      "item" : {
        "links" : [ {
        } ]
        "actions" : [ {
        } ]
      },
      "children" : {
        "Employees"
          ...
        } ],
      ...
      "links" : [ {
      } ]
  }
}
```

The following sample uses the `resources` query parameter to describe version `11.0` of the `Departments` and `Employees` resources named on the request.

Request

- **URL**

  `http://server/demo/rest/11.0/Departments/describe?resources=Departments,Employees`

- **HTTP Method**

  GET

Partially Describing a Nested Resource Collection

The ADF REST runtime supports obtaining a partial describe for a nested resource using a GET method and the parameter `partialDescription` to limit the depth of the hierarchy to the next child resource only.

The `partialDescription` parameter used with a describe request ensures the response payload contains only the nested collection to a depth of one nested object in the nested parent-child hierarchy. The describe for a child of the nested parent resource is not expand and provides only a link to retrieve that partial describe for the next resource in the hierarchy.

To examine the partial describe of a nested resource collection and its child resource, if any:

1. Execute the nested resource collection describe with the `partialDescription` parameter and locate the name of the nested resource in the describe.
2. Examine these resource objects to understand the shape of the resource. Specifically examine the `children` element to identify the partial describe link for the next child resource in the resource hierarchy (to a depth of one nested resource).
   - `attributes` specifies the list of available resource collection attributes.

- `collection` specifies the shape of the collection and specifies `finder` for row finder, `links`, and available `actions` (including media types).
- `item` specifies the shape of the instances of the collection and itself specifies `links` and available `actions`.
- `children` identifies any nested resource to a depth of one object and contains a describe link with the `?partialDescription` parameter to retrieve its partial description (this child resource describe specifically does not contain the `attributes`, `collection`, and `item` objects).

For example, the partial describe for the nested `Employees` resource returns the following objects. Note that in this sample, the `Employees` collection contains the child collection `Bonus`. The partial describe request limits the depth to the nested resource and a single child of the nested resource, in this case, `Bonus`.

```
{
  "Resources" : {
    "Employees" : {
      "discrColumnType" : false,
      "attributes" : [ {
       ...
      } ],
      "collection" : {
        ...
        } ],
        "finders" : [ {
        } ]
        "links" : [ {
        } ]
        "actions" : [ {
        } ]
      },
      "item" : {
        "links" : [ {
        } ]
        "actions" : [ {
        } ]
      },
      "children" : {
        "Bonus" : {
          "$ref" : "http://server/demo/rest/12.0/Departments/describe?
partialDescription=Employees.Bonus"
        } ],
      ...
      "links" : [ {
      } ]
  }
}
```

The following sample retrieves a partial describe of version `12.0` of the nested `Employees` resource and contains a link to retrieve the partial describe for the next child in the resource hierarchy, `Bonus`.

      } ]
    }
  }
}
```

Describing a Resource Collection with Specified Fields

The ADF REST runtime supports obtaining a limited describe for resource collections using a GET method and the parameter `fields`. The `fields` parameter used with a describe request ensures the response payload contains only the specified attributes of the collection.

To examine a resource collection:

1. Execute the resource collection describe and locate the names of the resources in the describe.
2. Examine these resource objects to understand the shape of each resource:
   - `attributes` specifies the list of available resource collection attributes.
   - `collection` specifies the shape of the collection and specifies `finder` for row finder, `links`, and available `actions` (including media types).
   - `item` specifies the shape of the instances of the collection and itself specifies `links` and available `actions`.
   - `children` specifies any nested resources (and itself contains `attributes`, `collection`, and `item` objects).

For example, the describe for the `Departments` resource returns the following objects:

```
{
  "Resources" : {
    "Departments" : {
      "discrColumnType" : false,
      "attributes" : [ {
       ...
      } ],
      "collection" : {
        ...
        } ],
        "finders" : [ {
        } ]
        "links" : [ {
        } ]
        "actions" : [ {
        } ]
      },
      "item" : {
        "links" : [ {
        } ]
        "actions" : [ {
        } ]
      },
      "children" : {
        "Employees"
          ...
        } ],
      ...
      "links" : [ {
      } ]
  }
}
```

The following samples show retrieving a limited describe for version `12.0` of the `Departments` and nested `Employees` resources. The first request (URL 1) uses the `fields` parameter to retrieve a single attribute of the `Departments` resource collection. The second request (URL 2) uses the `fields` parameter and retrieves all attributes of the `Departments` resource collection by specifying the wildcard character (`*`) and then also retrieves the single `EmployeeId` attribute of the nested `Employees` child resource collection.

Request

- **URL 1**

  ```
  http://server/demo/rest/12.0/Departments/describe?
  fields=DepartmentName
  ```

  URL 2

  ```
  http://server/demo/rest/12.0/Departments/describe?
  fields=*;Employees:EmployeeId
  ```

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.description+json`

- **Payload 1**

```

            }
          }
        }
```

Using ETags in Describe Requests

ETags provide the ability for service clients to determine the metadata changes in the web server since the last time it fetched the describe. This is accomplished by returning an ETag header in the response of a describe request.

An ETag is an identifier assigned by a web server to a specific version of a REST resource describe. If the REST resource describe representation ever changes, a new and different ETag is assigned. ETags are used in the HTTP header and are unique. For more information on using ETags, see Checking for Data Consistency.

When the REST resource describe is retrieved, the web server will return the REST resource's current representation along with its corresponding ETag value, which is placed in an HTTP response header `ETag` field. For example:

```
ETag: "5265766973696F6E33"
```

The client may cache the representation, along with its ETag. If the client wants to retrieve the same describe again, it will send its previously saved copy of the ETag along with the request in a `If-None-Match` field. For example:

```
If-None-Match: "5265766973696F6E33"
```

On this subsequent request, the server compares the client's ETag with the ETag for the current version of the resource. If the ETag values match, which indicates that the resource has not changed, then the server sends a response with a `HTTP 304 Not Modified` status. This status indicates that the cached version is good for use.

The following samples describe the ETag behavior for the `employees` resource.

Example 22-1 When ETag Values Match

Request

- **URL**

  `/rest/v1/employees/describe`

- **HTTP Method**

  GET

- **If-None-Match**

  `"5265766973696F6E33"`

- **Metadata-Context**

  `label=latest`

- **Payload**

none

Response

- **HTTP Code**

  `304`

- **ETag**

  `"5265766973696F6E33"`

- **Metadata-Context**

  `label="Revision3"`

- **Payload**

  none

Example 22-2   When ETag Values Do Not Match

Request

- **URL**

  `/rest/v1/employees/describe`

- **HTTP Method**

  GET

- **If-None-Match**

  `"5265766973696F6E33"`

- **Metadata-Context**

  `label=latest`

- **Payload**

  none

Response

- **HTTP Code**

  `200`

- **ETag**

  `"5265766973696F6E34"`

- **Metadata-Context**

  `label="Revision4"`

- **Payload**

```
{
  "Resources" : {
    "employees" : {
      ...
    }
  }
}
```

> **Note:**
>
> ETags are not returned if the request metadata context is not configured to read the latest MDS label.

Retrieving Resource Versions

In ADF, you can create version identifiers for an ADF REST resource and assign lifecycle status so that you can manage and update an existing resource definition with ease.
In JDeveloper, ADF REST resource developers create version identifiers and associate these identifiers with the resources they create. The use of the version identifier allows the REST resource developer to manage updating an existing resource definition. When a resource needs to be updated with a change that is not backward compatible with the previous version, the resource developer may create a new version of the resource and assign it a unique version identifier.

The ADF REST runtime supports getting the versions defined in the application, which can include retrieving all available versions or only a specific version.

Additionally, the REST resource developer can assign a lifecycle status (`active`, `desupported`, `deprecated`) when they create or update a version identifier. Resources that have been tagged `deprecated` are handled as valid resources and that status has no runtime impact. Whereas, resources that have been tagged with the lifecycle status `desupported` will no longer be accessible by the service client and requests for desupported versions will return the following error message:

```
JBO-29151: The requested version 'x' has been desupported.
```

If the service client requests a resource that does not exist for the requested version, the ADF REST runtime will fallback to a previous version with status `active` or `deprecated`. Thus, if the `Departments` resource versions `11.0` and `11.1` exist but `11.2` does not, the request for version `11.2` will return the next more recent resource, version `11.1`.

Retrieving All Available Release Version Names

The ADF REST runtime supports retrieving the release version names defined for the service end point using a GET method.

To examine the release version names:

1. Execute the service end point describe and locate the available release version names in the describe.
2. Examine these elements to understand the order of the release versions:
   - `version` specifies the version name, as defined in the `adf-config.xml` file.
   - `isLatest` property specifies the version name of the most recent release version.
   - `predecessor-version` specifies the link to the previous release version.
   - `successor-version` specifies the link to the next latest release version.

- `current` specifies the link to the most recent release version.

3. Optionally, examine these elements to understand the version of the ADF REST framework version that will be used to process requests for a specific release version:
    - `defaultFrameworkVersion` property specifies the default ADF REST framework version that has been associated with a particular release version, as optionally defined by the ADF REST resource developer in the `adf-config.xml` file. Note that a new ADF REST framework version may introduce new functionality. Thus, associating a specific framework version with each release version ensures that service clients interact with the appropriate level of functionality. See Working with ADF REST Framework Versions.
    - `allowedFrameworkVersions` property specifies the list of ADF REST framework versions that are supported for a particular release version. Service clients may override the default framework version with any value in the list by specifying the value in the `REST-Framework-Version` header.

For example, the describe for a service end point with two release versions returns the following objects:

```
{
    "items" : [
        {
            "version" : "version_identifier_latest",
            "isLatest" : true,
            "adf:extension" : {
                    "defaultFrameworkVersion" : "framework_identifier",
                    "allowedFrameworkVersions" : [ "framework_identifier1",
"framework_identifier2", ... ]

            },
            "links" : [
                {
                    "rel" : "self",
                    ...

                },
                {
                    "rel" : "canonical",
                    ...

                },
                {
                    "rel" : "predecessor-version",
                    ...

                },
                {
                    "rel" : "describe",
                    ...

                }
            ]
        },
        {
            "version" : "version_identifier_previous",
            "adf:extension" : {
                    "defaultFrameworkVersion" : "framework_identifier",
                    "allowedFrameworkVersions" : [ "framework_identifier1",
"framework_identifier2", ... ]
            },
            "links" : [
                {
                    "rel" : "self",
                    ...
                },
                {
                    "rel" : "canonical",
                    ...
                },
                {
                    "rel" : "successor-version",
                    ...
                },
                {
                    "rel" : "describe",
                    ...
                }
            ]
        }
    ],
    "links" : [
     ...
        {
            "rel" : "current",
                    ...
        }
    ]
}
```

The following sample retrieves all available release versions defined in the resource catalog of the `demo` application. In the sample, the three release versions are `11.0`, `11.1`, and `11.2`, where `11.2` is the current (or most recent) release version. Note that links of type `predecessor-version` and `successor-version` specify the location of each release version relative to their position in the list of versions. In the sample, versions `11.0` and `11.1` are explicitly associated with ADF REST framework version `1` and release version `11.2` is associated with ADF REST framework version `3`. Note that a framework version refers to a specific version of the ADF REST framework, corresponding to a particular Oracle JDeveloper release, where a new framework version introduces new functionality.

Request

- **URL**

  `http://server/demo/rest`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response

- **HTTP Code**

`200`

- **Content-Type**

  `application/vnd.oracle.adf.description+json`

- **Payload**

```
{

Retrieving a Resource By a Specific Version

The ADF REST runtime supports retrieving a specific version of the resource using a GET method. The specific resource version is one that has been associated at design time with the resource. Release version identifiers are defined in the Release Version page of the `adf-config.xml` overview editor.

The following samples describe two versions of the `Departments` resource. The first resource describe (request 1) returns version `11.0` and the second resource describe (request 2) returns version `11.1`. The resource describe for `11.1` shows additional mandatory attributes `HireDate` and `PhoneNumber` have been defined on the resource.

Request Version 1

- **URL 1**

  `http://server/demo/rest/11.0/Departments`

```

Retrieving the ADF REST Resource

The ADF REST runtime supports the GET method on REST resources to retrieve a resource or nested resource, page a resource, filter a resource collection with a query, or sort a resource collection.
The ADF REST runtime supports the following GET method use cases:

- Fetching a resource collection.
- Fetching a paged resource collection.
- Filtering a resource payload using primary key finder parameters.
- Filtering a resource payload using query parameters.
- Fetching a resource item.
- Fetching nested child resources.
- Fetching a sorted resource collection.
- Fetching a resource collection or resource item and grouping item details under the `@context` element.

Fetching a Resource Collection

The ADF REST runtime supports fetching a resource collection using a GET method.

The following sample fetches version `11.0` of the `Departments` resource collection and five items.

Request

- **URL**

  `http://server/sample/rest/11.0/Departments`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourcecollection+json`

- **Payload**

```
{
  "items" : [ {
    "DepartmentId" : 10,
    "DepartmentName" : "Administration",
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/11.0/Departments/10",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "canonical",
      "href" : "http://server/demo/rest/11.0/Departments/10",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "child",
      "href" : "http://server/demo/rest/11.0/Departments/10/child/Employees",
      "name" : "Employees",
      "kind" : "collection"
    } ]
  }, {
    "DepartmentId" : 20,

    "name" : "Departments",
    "kind" : "collection"
  } ]
}
```

Paging a Resource Collection

The ADF REST runtime supports retrieving resource collections with row set pagination using a GET method. Paging a resource collection with the GET method is performed using the following URI query parameters:

- **limit** restricts the number of resources returned inside the resource collection. If the limit exceeds the resource count, then the framework will return all available resources. The value is the maximum number of resources to be returned.
- **offset** defines a zero-based index into the collection (where 0 is the first position). The index identifies the starting position of the resource collection. If offset exceeds the resource count, then no resources are returned.

In the following sample, where a `Departments` resource collection has five items, the first request (URL1) retrieves two items (at index 0 and 1), and because `offset` is omitted, the starting position of the response is the first item. To display another set of resource items, a second request (URL2) may be made with an `offset` of `2` to correspond to the third item and a `limit` of `2` to retrieve only two more items (at index 2 and 3), and the last request (URL3) with an `offset` of `4` returns the last item of the five item resource collection (at index 4).

Each time a new set of resource items is retrieved, the `hasMore` attribute of the response indicates whether more items may be returned from the collection. In this example, because the collection contains only five items, the response for URL3 shows `hasMore` set to `false`, indicating that the last set of items had been retrieved.

Note that when the `limit` parameter is omitted from the paging URL, the ADF REST runtime assumes a `limit` of `25` (as determined by the default `RangeSize` value on the resource's iterator binding definition). In this case, up to twenty-five items will be returned with each request. For this reason, it is a best practice when paging through a collection to always include the `limit` query parameter to ensure only the desired number of resource items are returned and not more.

Requests

- **URL 1**

  `http://server/demo/rest/11.0/Departments?limit=2`

- **URL 2**

  `http://server/demo/rest/11.0/Departments?offset=2&limit=2`

- **URL 3**

  `http://server/demo/rest/11.0/Departments?offset=4&limit=2`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Responses

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourcecollection+json`

- **Payload 1**

    }, {
      "rel" : "child",
      "href" : "http://server/demo/rest/11.0/Departments/50/child/Employees",
      "name" : "Employees",
      "kind" : "collection"
    } ]
  } ],
  "count" : 1
  "hasMore" : false,
  "limit" : 2
  "offset" : 4,
  "links" : [ {
        "rel" : "self",
        "href" : "http://server/demo/rest/11.0/Departments",
        "name" : "Departments",
        "kind" : "collection"
      } ]
    }
```

Filtering a Resource Collection with Primary Key Values

The ADF REST runtime supports fetching a resource collection using a GET method and a fixed URL that includes a finder defined by one or more primary key attributes of the resource. Every view object upon which the resource is based defines at least one primary key attribute. The ADF REST runtime supports passing primary key values in the finder query string to filter the collection.

Filtering with a primary key (PK) is performed using the **finder** query string to specify one or more primary key values. The **finder** with primary key query string parameter format is:

```
finder=PrimaryKey;<PKattr1>=<PKvalue1>,<PKattr2>=<PKvalue2>,...
```

For example, a resource collection Employees defines the primary key attribute `EmployeeId`. To filter the collection using the primary key finder for a specific employee, the finder query string may be specified as the following example shows.

```
finder=PrimaryKey;EmployeeId=101
```

When the resource is defined by a multi-part primary key, the finder allows you to pass the corresponding number of primary key values to filter the collection. For example, a resource collection Inventory might have `ProductId` and `WarehouseId` as its primary key attributes. To filter the collection using the primary key finder for a specific inventory item, both primary key values must be supplied in the finder query string as the example below shows.

```
finder=PrimaryKey;ProductId=8568,WarehouseId=45
```

The resource collection describe explains the finder and primary key attributes. To work with the primary key finder:

1. Execute the resource describe and locate the `finders` attribute in the collection element. The `name` attribute identifies the finder as `PrimaryKey`. Also locate the name of the primary key attributes under `attributes`.
2. Execute a GET with the query parameter `finder` and pass the primary key attributes using the finder name `PrimaryKey`.

For example, the Employees resources describe returns the following:

```
"collection" : {
     "rangeSize" : 24,
     "finders" : [ {
       "name" : "PrimaryKey",
       "attributes" : [ {
         "name" : "EmployeeId",
         "type" : "integer",
         "updatable" : true,
         "mandatory" : true,
         "queryable" : false
         "precision" : 4,
} ]
```

The following sample fetches the `Employees` collection specified by the finder `PrimaryKey` where the `EmployeeId` attribute value `101` is passed.

Note: To filter the collection by a non-primary key attribute, see Filtering a Resource Collection with a Row Finder.

Request

- **URL**

  ```
  http://server/demo/rest/11.1/Employees?
  finder=PrimaryKey;EmployeeId=101
  ```

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload**

  ```
  {
    "items" : [ {
      "EmployeeId" : 101,
      "FirstName" : "Neena",
      "LastName" : "Smith",
      "Email" : "NSMITH",
      "JobId" : "AD_VP",
      "DepartmentId" : 90,
      "Salary" : 2000,
      "links" : [ {
        "rel" : "self",
        "href" : "http://server/demo/rest/11.1/Employees/101",
        "name" : "Employees",
        "kind" : "item"
      }, {
        "rel" : "canonical",
        "href" : "http://server/demo/rest/11.1/Employees/101",
        "name" : "Employees",
        "kind" : "item"
      } ]
    } ],
    "count" : 1,
    "hasMore" : false,
    "limit" : 25,

  ```

```
        "name" : "Employees",
        "kind" : "collection"
      } ]
    }
```

Filtering a Resource Collection with a Query Parameter

The ADF REST runtime supports fetching a resource collection using a GET method using query parameters.

The resource collection may be queried using expressions that differ in syntax depending on the ADF REST framework version that has been registered for the ADF REST service client. For details about the ADF REST framework versions, see What You May Need to Know About Versioning the ADF REST Runtime Framework.

The following samples are based on two different versions of the `Departments` resource. The URL sample showing resource `11.0` reflects the query-by-example query parameter syntax supported only by version 1 of the ADF REST framework. While the URL sample showing resource `11.1`, reflects the rowmatch query parameter syntax supported in ADF REST framework version 2 (and later). In both framework scenarios, the samples fetch fields of the `Departments` resource collection.

> **Note:**
>
> For a REST web service request, reserved characters that appear in a query parameter value should be encoded. For example, the + character in a timestamp value must be encoded as `%2B`. Additionally, by default, resource and resource items names used in query parameter operations are case sensitive. If case insensitive filtering is desired, you may set the flag `restV1QueryCaseSensitive` in the `adf-config.xml` file to `false`. The default value of the flag is `true` which implies case sensitive filtering.

ADF REST Framework Version 2 (and later)

Starting with version 2 of the ADF REST framework, service clients may use an advanced query syntax, also known as rowmatch expressions, to fetch resources. For a complete description of the query syntax available in version 2 (and later), What You May Need to Know About the Advanced Query Syntax in ADF REST Framework Version 2.

The following sample fetches all departments with at least one employee whose salary is equal to 10000. This is an example of fetching a parent object (`Departments`) and filtering it by a child object attribute (`Employees.Salary`).

Request Example 1 Made With Framework Version 2

- **URL**

  `http://server/demo/rest/11.2/Departments?q=Employees.Salary = 10000`

- **HTTP Method**

  GET

- **Content-Type**

none

- **Payload**

  none

Response Example 1 From Framework Version 2

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourcecollection+json`

- **Payload**

```
{
  "items" : [ {
    "DepartmentId" : 70,
    "DepartmentName" : "Public Relations",
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/11.2/Departments/70",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "canonical",
      "href" : "http://server/demo/rest/11.2/Departments/70",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "child",
      "href" : "http://server/demo/rest/11.2/Departments/70/child/Employees",
      "name" : "Employees",
      "kind" : "collection"
    } ]
  }, {
    "DepartmentId" : 80,
    "DepartmentName" : "Sales",
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/11.2/Departments/820",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "canonical",
      "href" : "http://server/demo/rest/11.2/Departments/80",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "child",
      "href" : "http://server/demo/rest/11.2/Departments/80/child/Employees",
      "name" : "Employees",
      "kind" : "collection"
    } ]
  } ],
  "count" : 2,
  "hasMore" : false,
  "limit" : 25,
  "offset" : 0,
  "links" : [ {
    "rel" : "self",
      "href" : "http://server/demo/rest/11.2/Departments",
      "name" : "Departments",
      "kind" : "collection"
    } ]
  }
```

The following sample fetches all departments with the numeric ID of `10` or a department name that begins with the letter "H".

Request Example 2 Made With Framework Version 2

- **URL**

  `http://server/demo/rest/11.1/Departments?q=DepartmentId = 10 or DepartmentName like 'H*'`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response Example 2 From Framework Version 2

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourcecollection+json`

- **Payload**

```
{
  "items" : [ {
    "DepartmentId" : 10,
    "DepartmentName" : "Administration",
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/11.2/Departments/10",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "canonical",
      "href" : "http://server/demo/rest/11.2/Departments/10",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "child",
      "href" : "http://server/demo/rest/11.2/Departments/10/child/Employees",
      "name" : "Employees",
      "kind" : "collection"
    } ]
  }, {
    "DepartmentId" : 40,
    "DepartmentName" : "Human Resources",
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/11.2/Departments/40",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "canonical",
      "href" : "http://server/demo/rest/11.2/Departments/40",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "child",
      "href" : "http://server/demo/rest/11.2/Departments/40/child/Employees",
      "name" : "Employees",
      "kind" : "collection"
    } ]
  } ],
  "count" : 2,
  "hasMore" : false,
  "limit" : 25,
  "offset" : 0,
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.2/Departments",
    "name" : "Departments",
    "kind" : "collection"
  } ]
}
```

ADF REST Framework Version 1

Version 1 of the ADF REST framework supports a query-by-example syntax. No application configuration changes are required to use this syntax that is supported only in versions 1. For a description of the query syntax available in version 1 of the ADF REST framework, see GET Method Operations.

The following sample fetches departments assigned a `DepartmentId` value less than `30`.

> **Note:**
>
> In version 1 of the ADF REST framework, when you create a query with a string matching filter parameter and the string to match contains a query syntax reserved word (such as AND or OR), then the quoted string must be delimited by a space character to separate it from other parameters in the query expression. For example, the following query attempts to filter on the quoted string `‘Accounting and Finance’`. Since the string contains the reserved word AND, the string matching filter parameter requires a space before and after the single quotes to be viable in version 1.
>
> ```
> ?q=DepartmentName= 'Accounting and Finance'
> &fields=DepartmentName,Location
> ```
>
> Note that starting in framework version 2, the use of a space character is no longer required to delimit a string matching filter that contains a reserved word.

Request Made With Framework Version 1

- **URL**

`http://server/demo/rest/11.0/Departments?q=DepartmentId<30`

      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "canonical",
      "href" : "http://server/demo/rest/11.0/Departments/20",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "child",
      "href" : "http://server/demo/rest/11.0/Departments/20/child/Employees",
      "name" : "Employees",
      "kind" : "collection"
    } ]
  } ],
  "count" : 2,
  "hasMore" : false,
  "limit" : 25,
  "offset" : 0,
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.0/Departments",
    "name" : "Departments",
    "kind" : "collection"
  } ]
}
```

Fetching a Resource Item

The ADF REST runtime supports fetching an item of the resource collection using a GET method.

The following sample fetches version `11.0` of all fields of an instance of the `Departments` resource collection.

Request

- **URL**

  `http://server/demo/rest/11.0/Departments/50`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload**

```
{
  "DepartmentId" : 50,
  "DepartmentName" : "Shipping",
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.0/Departments/50",
    "name" : "Departments",
    "kind" : "item"
  }, {
    "rel" : "canonical",
    "href" : "http://server/demo/rest/11.0/Departments/50",
    "name" : "Departments",
    "kind" : "item"
  }, {
        "rel" : "child",
        "href" : "http://server/demo/rest/11.0/Departments/50/child/Employees",
        "name" : "Employees",
        "kind" : "collection"
      } ]
    }
```

Fetching Nested Child Resources

The ADF REST runtime supports retrieving nested resources using a GET method.

The payload structure of nested child resource differs depending on the ADF REST framework version that has been registered for the ADF REST service client. For details about the ADF REST framework versions, see What You May Need to Know About Versioning the ADF REST Runtime Framework.

The following samples are based on two different versions of the `Employees` resource. The URL samples showing resource `11.0` reflect a response payload structure supported by ADF REST framework versions 1 and 2. While the URL samples showing resource `11.1`, reflect the response payload structure supported in ADF REST framework version 3 (and later). In both framework scenarios, the samples fetch the `Employees` resource as a child of the `Departments` resource.

Note that the name used to identify the nested resource is determined at design time when the resource is created in the ADF Business Components model project. The default name for nested resources created in the model project is the destination view instance of the nested resource's defining view link accessor (such as `EmployeesView1` for the view link `DeptToEmpFkLink`). For this reason, it is a best practice for ADF REST resource developers to rename the resource to something more suitable as a URL parameter. In the following examples, the resource name was changed to `Employees` to follow the naming convention for the parent resource name `Departments`.

ADF REST Framework Version 3 (and later)

Starting with version 3 of the ADF REST framework, the ADF REST runtime returns a nested child resource in the response payload as a resource collection, instead of as an array of resource items. This functionality, available in framework version 3 (and later), allows service clients to make a request for additional records after determining how many items were left unfetched in the initial request. The attributes `hasMore` and `count` on the child resource indicate whether more items may be returned from the resource collection. For details about using the pagination attributes from the response payload when you opt into ADF REST framework version 3, see Paging a Resource Collection.

The following sample illustrates functionality for ADF REST framework version 3 (and later). The response payload represents the nested child resource as a resource collection, where the collection object includes the `hasMore` and `count` attributes. A link is provided should it be necessary to query the child resource for additional resource items. In this sample, items of the `Employees` child resource are fetched with a `count` of `3` in the payload. The response payload shows the `hasMore` attribute is `false`, suggesting that no items remain unfetched.

Request Made With Framework Version 3

- **URL**

  `http://server/demo/rest/11.1/Departments/50?expand=Employees`

- **HTTP Method**

  GET
- **Content-Type**

  none
- **Payload**

  none

Response From Framework Version 3

- **HTTP Code**

  `200`
- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`
- **Payload**

```
{
  "DepartmentId" : 50,
  "DepartmentName" : "Shipping",
  "Employees" : {

       }, {
         "rel" : "canonical",
         "href" : "http://server/demo/rest/11.1/Departments/50/child/
Employees/121",
         "name" : "Employees",
         "kind" : "item"
       }, {
         "rel" : "parent",
         "href" : "http://server/demo/rest/11.1/Departments/50",
         "name" : "Departments",
         "kind" : "item"
       } ]
     }, {
       ...
       } ]
     } ],
     "count" : 3,
     "hasMore" : false,
     "limit" : 25,
     "offset" : 0,
     "links" : [ {
         "rel" : "self",
         "href" : "http://server/demo/rest/11.1/Departments/50/child/
Employees",
         "name" : "Employees",
         "kind" : "collection"
     } ]
   },
   "links" : [ {
       "rel" : "self",
       "href" : "http://server/demo/rest/11.1/Departments/50",
       "name" : "Departments",
       "kind" : "item"
    }, {
       "rel" : "canonical",
       "href" : "http://server/demo/rest/11.1/Departments/50",
       "name" : "Departments",
       "kind" : "item"
    } ]
}
```

ADF REST Framework Version 1 or Version 2

Version 1 and version 2 of the ADF REST framework return the nested child resource expanded in the response payload as an array of resource items. If the resource collection being fetched is large, you may have to make several requests since the array of resource items has a limit.

The following samples illustrate functionality for ADF REST framework version 1 and version 2.

The first request sample (URL 1) retrieves a single child resource item identified by employee `120`. The URL parameter `child` identifies the relationship of the requested resource `Employees`.

The second request (URL 2) shows the use of the query parameter `expand` to ensure that all nested `Employees` resource items will be returned with `Departments` resource collection `50`.

The third request (URL 3) shows the use of accessor dot notation (for example, `Employees.JobHistory`) in combination with the query parameter `expand` to ensure that all nested `JobHistory` resource items will be returned with the `Employees` resource items for the `Departments` resource collection `80`.

Request Made With Framework Version 1 or Version 2

- **URL 1**

  `http://server/demo/rest/11.0/Departments/50/child/Employees/120`

- **URL 2**

  `http://server/demo/rest/11.0/Departments/50?expand=Employees`

- **URL 3**

  ```
  http://server/demo/rest/11.0/Departments/80?
  expand=Employees.JobHistory&onlyData=true
  ```

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response From Framework Version 1 or Version 2

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload 1**

  ```
  {
    "EmployeeId" : 120,
    "FirstName" : "Matthew",
    "LastName" : "Weiss",
    "Email" : "MWEISS",
    "JobId" : "ST_MAN",
    "DepartmentId" : 50,
    "Salary" : 8000,
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/11.0/Departments/50/child/Employees/
  120",
      "name" : "Employees",
      "kind" : "item"
    }, {
      "rel" : "canonical",
      "href" : "http://server/demo/rest/11.0/Departments/50/child/Employees/
  120",
      "name" : "Employees",
      "kind" : "item"
    }, {
      "rel" : "parent",
  ```

```
    "href" : "http://server/demo/rest/11.0/Departments/50",
    "name" : "Departments",
    "kind" : "item"
  } ]
}
```

- **Payload 2**

```

        },
       ...
    ]
}
```

Sorting a Resource Collection

The ADF REST runtime supports sorting the fetched resource collection using a GET method.

Sorting a resource collection is performed using the **orderBy** query string parameter in combination with one or more attribute names. The following optional sort order flags may be associated with each attribute:

- **asc** sorts in ascending order. (Default)
- **desc** sorts in descending order.

The **orderBy** query string parameter format is:

```
<orderBy_attribute1_name>:<(asc/desc)>, <orderBy_attribute2_name>:<(asc/
desc)>
```

Example: `attribute1:desc,attribute2`

In order to perform case-insensitive sorting on a resource collection using a GET method, the **orderBy** query string parameter must follow this format:

`upper(<orderBy_attribute1_name>):<(asc)>` or
`lower(<orderBy_attribute2_name>)`

The following sample (URL1) fetches the `Departments` collection sorted by the `DepartmentName` attribute. The second sample (URL2) fetches the child `Employees` collection sorted by the `salary` attribute. Since the sort order flag is not specified for either request sample, the response is ascending order.

Request

- **URL 1**

  `http://server/demo/rest/11.0/Departments?orderBy=DepartmentName`
- **URL 2**

  `http://server/demo/rest/11.0/Departments/50/child/Employees?orderBy=Salary`
- **HTTP Method**

  GET
- **Content-Type**

  none
- **Payload**

  none

Response

- **HTTP Code**

  `200`
- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`
- **Payload 1**

```
{
  "items" : [ {

```

Fetching a Resource with Grouped Context Information

ADF REST runtime supports fetching a resource using a GET method and retrieving the payload with resource fields and resource item context information, like links, grouped separately when your request is enabled to use ADF REST framework version 6.

Starting with version 6 of the ADF REST framework, a `@context` element is introduced in the response payload for resource requests to help you to more easily differentiate between resource fields and the context information of individual items. This element helps to organize the response payload of the GET request by grouping information together for each item.

Compared to earlier framework versions (5 and earlier), the following changes to a GET request payload result with framework version 6 or later:

- A new `@context` section appears below the list of fields of each item of the resource and contains identifying information for the item, as well as links.
- A new `key` element appears within the `@context` section and contains the unique identifier of the specific resource item as a string.
- The `links` section within the `@context` section no longer list any properties, like `changeIndicator`.

- The `changeIndicator` value is moved to `ETag`, which is under a `headers` element within the `@context` section.

The following sample fetches the `Departments` resource collection and three items with context information for each item under the `@context` element.

Collection Request Example Made With Framework Version 6

- **URL**

  `http://server/sample/rest/12.0/Departments`
- **HTTP Method**

  GET
- **Content-Type**

  none
- **Payload**

  none

Collection Response Example Made With Framework Version 6

- **HTTP Code**

  `200`
- **Content-Type**

  `application/vnd.oracle.adf.resourcecollection+json`
- **Payload**

```
{
  "items" : [ {
    "DepartmentId" : 10,
    "DepartmentName" : "Administration",
    "@context" : {
      "key" : "1",
      "headers" : {
        "ETag" : "ACED00C78"
      },
      "links" : [ {
        "rel" : "self",
        "href" : "http://server/demo/rest/12.0/Departments/10",
        "name" : "Departments",
        "kind" : "item"
      }, {
        "rel" : "canonical",
        "href" : "http://server/demo/rest/12.0/Departments/10",
        "name" : "Departments",
        "kind" : "item"
      }, {
        "rel" : "child",
        "href" : "http://server/demo/rest/12.0/Departments/10/child/
Employees",
        "name" : "Employees",
        "kind" : "collection"
      } ]
    }
  }, {
    "DepartmentId" : 20,
    "DepartmentName" : "Marketing",
    "@context" : {
      "key" : "2",
      "headers" : {
        "ETag" : "ACED00B74"
      },
      "links" : [ {
        "rel" : "self",
        "href" : "http://server/demo/rest/12.0/Departments/20",

        "kind" : "item"
      }, {
        "rel" : "canonical",
        "href" : "http://server/demo/rest/12.0/Departments/20",
        "name" : "Departments",
        "kind" : "item"
      }, {
        "rel" : "child",
        "href" : "http://server/demo/rest/12.0/Departments/20/child/
Employees",
        "name" : "Employees",
        "kind" : "collection"
      } ]
    }
  }, {
    "DepartmentId" : 30,
    "DepartmentName" : "Purchasing",
    "@context" : {
      "key" : "3",
      "headers" : {
        "ETag" : "ACED001E8"
      },
      "links" : [ {
        "rel" : "self",
        "href" : "http://server/demo/rest/12.0/Departments/30",
        "name" : "Departments",
        "kind" : "item"
      }, {
        "rel" : "canonical",
        "href" : "http://server/demo/rest/12.0/Departments/30",
        "name" : "Departments",
        "kind" : "item"
      }, {
        "rel" : "child",
        "href" : "http://server/demo/rest/12.0/Departments/30/child/
Employees",
        "name" : "Employees",
        "kind" : "collection"
      } ]
    }
  } ],
  "count" : 3,
  "hasMore" : true,
  "limit" : 25,
  "offset" : 0,
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/12.0/Departments",
    "name" : "Departments",
    "kind" : "collection"
  } ]
}
```

The following sample fetches all fields of an instance of the `Departments` resource collection with context information for each item under the `@context` element.

Item Request Example Made With Framework Version 6

- **URL**

  `http://server/demo/rest/12.0/Departments/50`
- **HTTP Method**

  GET
- **Content-Type**

  none
- **Payload**

  none

Item Response Example Made With Framework Version 6

- **HTTP Code**

  `200`
- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`
- **Payload**

```
{
  "DepartmentId" : 50,
  "DepartmentName" : "Shipping",
  "@context" : {
    "key" : "1",
    "headers" : {
      "ETag" : "ACED00G26"
    },
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/12.0/Departments/50",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "canonical",
      "href" : "http://server/demo/rest/12.0/Departments/50",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "child",
      "href" : "http://server/demo/rest/12.0/Departments/50/child/Employees",
      "name" : "Employees",
      "kind" : "collection"
    } ]
  }
}
```

Creating a Resource Item

The ADF REST runtime supports the HTTP POST method to create a resource and child resource item in the REST resource collection.

The ADF REST runtime supports the following creation use cases:

- Creating a resource item in collection.
- Creating a child resource item.

Creating a Resource Item in a Collection

The ADF REST runtime supports creating resource items on an existing resource collection using a POST method.

Before making a request with the POST method, determine whether the resource item is defined by an LOV-enabled attribute. If an LOV-enabled attribute is present and that attribute is defined as mandatory, you must first access the LOV resource on the resource collection to display the selection list to the end user. For details about how to access an LOV resource, see Retrieving LOV-Enabled Attribute Values When Creating a Resource Item.

The following sample creates a new `Departments` resource collection with a single item.

Request

- **URL**

  `http://server/demo/rest/11.0/Departments`

- **HTTP Method**

  POST

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload**

```
{
  "DepartmentId" : 15,
  "DepartmentName" : "NewDept"
}
```

Response

- **HTTP Code**

  `201`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Location**

  `http://server/demo/rest/Departments/15`

- **Payload**

```
{
  "DepartmentId" : 15,
  "DepartmentName" : "NewDept",
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.0/Departments/15",
    "name" : "Departments",
    "kind" : "item"
  }, {
    "rel" : "canonical",
    "href" : "http://server/demo/rest/11.0/Departments/15",
    "name" : "Departments",
    "kind" : "item"
  }, {
    "rel" : "child",
    "href" : "http://server/demo/rest/11.0/Departments/15/child/Employees",
    "name" : "Employees",
    "kind" : "collection"
  } ]
}
```

Creating a Child Resource Item

The ADF REST runtime supports creating ADF REST child resource items in one roundtrip using a POST method. Create will only succeed when both the parent and child do not exist.

The following samples create nested resource items. The first request sample (URL1) creates a child resource item identified by employee `999` in an existing `Departments` resource. The second request (URL2) creates the parent and child resources.

Request

- **URL 1**

  `http://server/demo/rest/11.0/Departments/15/child/Employees`

- **URL 2**

  `http://server/demo/rest/11.0/Departments`

- **HTTP Method**

  POST

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload 1**

  ```
  {
       "EmployeeId": 999,
       "FirstName": "New",
       "LastName": "Guy",
       "Email": "NGUY",
       "JobId": "SA_REP",
       "DepartmentId": 15,
       "Salary": 9999
  }
  ```

- **Payload 2**

  ```
  {
       "DepartmentId": 17,
       "DepartmentName": "NewerDept",
       "Employees": [
           {
               "EmployeeId": 99999,
               "FirstName": "Newer",
               "LastName": "Guy",
  ```

```
                "Email": "NRGUY",
                "JobId": "SA_MAN",
                "DepartmentId": 17,
                "Salary": 10001
            }
        ]
    }
```

Response

- **HTTP Code**

  201

- **Content-Type**

  application/vnd.oracle.adf.resourceitem+json

- **Location**

  http://server/demo/rest/11.0/Departments/15/child/Employees/999

- **Payload 1**

```
{
  "EmployeeId" : 999,
  "FirstName" : "New",
  "LastName" : "Guy",
  "Email" : "NGUY",
  "JobId" : "SA_REP",
  "DepartmentId" : 15,
  "Salary" : 9999,
  "links" : [ {
    "rel" : "self",

}
```

Updating a Resource Item

The ADF REST runtime supports the HTTP PATCH method to update a resource in the REST resource collection.
The ADF REST runtime supports updating resource items using a PATCH method. Update will only succeed when the row already exists.

The following sample updates `Departments` item `15`, where `DepartmentName` is changed in the request payload.

Request

- **URL**

  `http://server/demo/rest/11.0/Departments/15`

- **HTTP Method**

  PATCH

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload**

  ```
  {
    "DepartmentId" : 15,
    "DepartmentName" : "UpdatedDeptName"
  }
  ```

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload**

  ```
  {
    "DepartmentId" : 15,
    "DepartmentName" : "UpdatedDeptName",
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/11.0/Departments/15",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "canonical",
      "href" : "http://server/demo/rest/11.0/Departments/15",
      "name" : "Departments",
      "kind" : "item"
    }, {
      "rel" : "child",
      "href" : "http://server/demo/rest/11.0/Departments/15/child/Employees",
      "name" : "Employees",
      "kind" : "collection"
    } ]
  }
  ```

Updating or Creating Resource Items (Upsert)

Using a POST method with Upsert mode enabled, the ADF REST runtime supports updating resource items that exist, and if not, creating the resource items.

You use a POST method with header variable `Upsert/true` to enable the Upsert functionality that creates an ADF REST resource if this resource does not exist or updates the resource if the resource exists. You select the Create and Update checkboxes on the user interface to enable this action (Upsert). If the header variable `Upsert/true` is not provided, or is set to `Upsert/false`, then the Upsert functionality is disabled. Also, if only the Create checkbox is selected or only the Update checkbox is selected, then POST creates or updates a resource if permissions for these actions are allowed. Note that Upsert will work as intended only if both Create and Update options are enabled on the resource.

The following sample creates (through Upsert) a new Department resource item with a child Employee resource item.

Request

- **URL**

  `http://server/demoapp/rest/1.0/Departments`

- **HTTP Method**

  `POST`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **HTTP Header**

  `Upsert-Mode/true`

- **Payload**

```
{
    "Deptno": 80,
    "Dname": "ENG80",
    "Emp": [{
        "Empno": 8080,
        "Ename": "Smith",
        "Mgr": 8080
    }]
}
```

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Content Encoding**

  `Null`

- **Payload**

```
{
    "Deptno": 80,
    "Dname": "ENG80",
    "Emp": [{
        "Empno": 8080,
        "Ename": "Smith",
        "Mgr": 8080
    }]
}
```

The following sample demonstrates the update process (through Upsert). In the response payload, a Department (Dept) resource item's AltKey namely Dname is utilized. Similarly, the Employee (Emp) child resource item's Altkey namely Email is utilized. The Dname Altkey (Dname=ENG80) is used to locate and load the required

Department (Dept 80). The request then updates this Department's Location (Loc). The Email Altkey is used to locate and load the Employee child resource item (Emp 8080) and the request payload updates this Employee child resource item's Sal and Job attributes. The request payload also contains a second Employee child resource item (Emp 9080). The Ename key is used to locate this second Employee child resource item. If found, this second Employee child resource item's Sal and Job attributes get updated. If this second Employee child resource item does not exist, the request payload creates this second Employee child resource item.

Request

- **URL**

  ```
  http://server/demoapp/rest/1.0/Departments
  ```

- **HTTP Method**

  ```
  POST
  ```

- **Content-Type**

  ```
  application/vnd.oracle.adf.resourceitem+json
  ```

- **HTTP Header**

  ```
  Upsert-Mode/true
  ```

- **Payload**

  ```
  {
      "Dname": "ENG80",
      "Loc": "HQ-altkey",
      "Emp": [{
              "Email": "smith@xyz.com",
              "Sal": 8000,
              "Job": "ENGINEER1"
          },
          {
              "Empno": 9080,
              "Ename": "John",
              "Sal": 9000,
              "Job": "SALES1"
          }
      ]
  }
  ```

Response

- **HTTP Code**

  ```
  200
  ```

- **Content Type**

  ```
  application/vnd.oracle.adf.resourceitem+json
  ```

- **Content Encoding**

  ```
  Null
  ```

- **Payload**

  ```
  {
      "Deptno": 80,
      "Dname": "ENG80",
      "Loc": "HQ-altkey",
  ```

```
        "TrEmpno": null,
        "Emp": [{
                "Empno": 8080,
                "Ename": "Smith",
                "Job": "ENGINEER1",
                "Email": "smith@xyz.com",
                "Hiredate": null,
                "Sal": 8000,
                "Comm": null,
                "Deptno": 80
            },
            {
                "Empno": 9080,
                "Ename": "John",
                "Job": "SALES1",
                "Mgr": 9080,
                "Hiredate": null,
                "Sal": 9000,
                "Comm": null,
                "Deptno": 80
            }
        ]
    }
```

Deleting a Resource Item

The ADF REST runtime supports the HTTP DELETE method to delete a resource in the REST resource collection.
The ADF REST runtime supports deleting resource items using a DELETE method. The framework does not currently support deleting a resource collection.

The following sample (URL1) deletes employee ID `99999` of the `Employees` resource collection as a child of the `Departments` resource item `17`. The second request URL deletes the `Departments` resource item `17`.

Request

- **URL 1**

  `http://server/demo/rest/11.0/Departments/17/child/Employees/99999`
- **URL 2**

  `http://server/demo/rest/11.0/Departments/17`
- **HTTP Method**

  DELETE
- **Content-Type**

  none
- **Payload**

  none

Response

- **HTTP Code**

  `204`
- **Content-Type**

none

- **Payload**

  none

Checking for Data Consistency

When updating or retrieving ADF REST resource items using the HTTP method, you can check data consistency by generating an entity tag with precondition headers so that the resource item matches the server side resource state before updating or retrieving.
The ADF REST runtime supports generating an entity tag (ETag) in the response header when the requested resource has data consistency check enabled. Data consistency checking is enabled by the ADF Business Components developer who must configure a change-indicator attribute on the entity object backing the resource.

When entity change indicators are configured on the entity object backing the resource, the ADF REST runtime will assign a unique value to indicate the state of each resource on the server side. At runtime, when the row underlying the server side resource changes, Oracle ADF assigns a new state value to the ETag. The following header shows the ETag returned with a request to retrieve a `Departments` resource item.

```
HTTP/1.1 200 OK
Cache-Control: no-cache, no-store, must-revalidate
Location:
Content-Length: 1069
Content-Type: application/json
ETag: "ACED0005737203720013626163 6C6520136261636C65237200136261636C652"
Content-Encoding:
Link: <http://server/demo/rest/11.0/Departments/
10>;rel="self";kind="item";name="Departments"
```

> **Note:**
>
> Note that the ETag and data consistency checking are not automatically enabled for REST resources. To support generating ETag values, the ADF Business Components developer must configure a change-indicator enabled attribute on the entity object backing the resource to be checked. For details about configuring change indicator attributes for entity objects, see How to Protect Against Losing Simultaneously Updated Data.

The service client can use the ETag value returned in the header response of each resource item to create subsequent requests that contain precondition headers (`If-Match`/`If-None-Match`). Based on the specified ETag and the precondition, the server will evaluate the current resource state and match against the provided ETag. If the precondition is satisfied, the requested operation is executed; otherwise, a `412` error is returned. The error payload will contain the current resource in the server side and the header will also reflect the current ETag value.

To support testing ETag values, the ADF REST framework provides the following precondition header fields. Usage of these precondition fields forces the framework to compare a supplied ETag value against the ETag values of previously requested items.

- Verify that the client is providing a state (obtained from a previous resource item response) that matches the current state on the server:

  `If-Match: "<ETag value from resource item response>"`

- Verify that the client is providing a state (obtained from a previous resource item response) that does **not** match the current state on the server.

  `If-None-Match: "<ETag value from resource item response>"`

The following are typical use cases when checking for data consistency:

- Check that the resource item matches the server side resource state before updating
- Retrieve the resource item using the server side resource state when none of the requested items match any previously requested items

While these use cases involve GET and PATCH methods, the precondition header and ETag value can be used to check that any HTTP method operation will be applied to the current state of the resource.

When retrieving a resource collection, an additional custom property `changeIndicator` will appear in the response payload of resources with data consistency enabled. This property contains the current ETag value of each resource item in the requested collection. The following sample illustrates the `changeIndicator` property in the `links` section of a `Departments` resource collection. The presence of ETag values in the resource collection payload is a convenience for the service client that can reduce the number of requests to obtain the ETag from individual resource items.

Note also the presence of the `RelState` attribute in the response. This is the name of the change-indicator attribute that the ADF Business Components developer configured on the entity object to support data consistency checks. The value of the attribute reflects the number of times the state has been updated.

}
```

Checking for Data Consistency When Updating ADF REST Resource Items

The ADF REST runtime support checking for data consistency when using a PATCH method to update resource items backed by an ADF Business Components entity object with a change-indicator attribute enabled.

To check for data consistency using the ETag header and conditional header fields:

1. Query one or more resource items and, for each returned resource item, obtain the ETag value from the `changeIndicator` property in the `properties` section of the response. When querying multiple resource items, there will not be a single ETag response header. Instead, the ETag for each of the items in the response will be in the `properties` section.

```
HTTP/1.1 200 OK
Cache-Control: no-cache, no-store, must-revalidate
Location:
Content-Length: 861
Content-Type: application/json
ETag: "responseETag123"
Content-Encoding:
Link: <http://server/demo/rest/11.0/Departments/
10>;rel="self";kind="item";name="Departments"
Set-Cookie: JSESSIONID=jXvsJ1GpdkFJV5Jh0yk7D72vPZ42t8tLYDg74NRKFQzXdnsjG9vv!
1113104013; path=/; HttpOnly
X-ORACLE-DMS-ECID:
51f1ff4535af720c:-7e156247:148ec9eeb3b:-8000-00000000000001ad
X-Powered-By: Servlet/2.5 JSP/2.1

{
  "DepartmentId" : 10,
  "DepartmentName" : "Administration",
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.0/Departments/10",
    "name" : "Departments",
    "kind" : "item",
    "properties" : {
      "changeIndicator" : "responseETag123"
    }
  }, {
    "rel" : "canonical",
    "href" : "http://server/demo/rest/11.0/Departments/10",
    "name" : "Departments",
    "kind" : "item"
  }, {
    "rel" : "child",
    "href" : "http://server/demo/rest/11.0/Departments/10/child/Employees",
    "name" : "Employees",
    "kind" : "collection"
  } ]
}
```

2. Update the resource item, using a PATCH request and check for data consistency by supplying the following conditional header field:

- `If-Match: "<`*`ETag value from resource item response`*`>"` to verify that the state of a requested resource item is current with the previous resource item response.

The following sample updates the `DepartmentName` field of the Departments `10` resource item when the `If-Match` precondition test is satisfied. In the first request (Request 1), the ETag value `responseETag123` is identical to the ETag of the current `Departments 10` resource item on the server side, indicating that the state of the resource item is consistent with the server side. Consequently, the update to `DepartmentName` is allowed.

In the subsequent request (Request 2), however, the ETag supplied in the `If-Match` precondition is unchanged and no longer matches the new ETag value the server has for the `Departments 10` resource item. As a consequence of the stale ETag value used in the second request, the update fails with an HTTP code `412`, indicating the precondition test failed, and the current ETag value `responseETag567` is returned in the response header. This occurs in production web applications when multiple users simultaneously access the same resource item. For example, when user 1 and user 2 both query the same item, the item has, for example, ETag value 1. Then, if user 1 successfully updates the item with ETag value 1, and user 2 attempts to update the same item with ETag value 1, the attempt will fail.

```

Checking for Data Consistency When Retrieving ADF REST Resource Items

The ADF REST runtime supports checking for data consistency when using a GET method to retrieve resource items backed by an ADF Business Components entity object with a change-indicator attribute enabled.

To check for data consistency using the ETag header and conditional header fields:

1. Query one or more business object items and, for each returned resource item, obtain the ETag value from the `changeIndicator` property in the `properties` section of the response.

   When querying multiple business object items, there will not be a single ETag response header. In the case of ADF REST framework versions 5 and earlier, the ETag for each of the items in the response will be in the `properties` section. In the case of framework versions 6 and later, the ETag for each of the items will be in the `@context` element that serves to group all the information for an item in one section. The following sample shows the response with a framework version before version 6 enabled.

   ```
   HTTP/1.1 200 OK
   Cache-Control: no-cache, no-store, must-revalidate
   Location:
   Content-Length: 861
   Content-Type: application/json
   ETag: "responseETag123"
   Content-Encoding:
   Link: <http://server/demo/rest/11.0/Departments/
   10>;rel="self";kind="item";name="Departments"
   Set-Cookie: JSESSIONID=jXvsJ1GpdkFJV5Jh0yk7D72vPZ42t8tLYDg74NRKFQzXdnsjG9vv!
   1113104013; path=/; HttpOnly
   X-ORACLE-DMS-ECID:
   51f1ff4535af720c:-7e156247:148ec9eeb3b:-8000-00000000000001ad
   X-Powered-By: Servlet/2.5 JSP/2.1

   {
     "DepartmentId" : 10,
     "DepartmentName" : "Administration",
   ```

```
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.0/Departments/10",
    "name" : "Departments",
    "kind" : "item",
    "properties" : {
      "changeIndicator" : "ACED0005737200136A6176612E7574696C2E4"
    }
  }, {
    "rel" : "canonical",
    "href" : "http://server/demo/rest/11.0/Departments/10",
    "name" : "Departments",
    "kind" : "item"
  }, {
    "rel" : "child",
    "href" : "http://server/demo/rest/11.0/Departments/10/child/Employees",
    "name" : "Employees",
    "kind" : "collection"
  } ]
}
```

2. Query one or more business object items and check for data consistency by supplying the following conditional header field

   :

   - `If-None-Match: "`*`<ETag value from resource item response>`*`"` to verify that the state of none of the previously requested resource items is current with the resource item request.

The following sample retrieves the Departments `10` resource item when the `If-None-Match` precondition test is satisfied. In the first request (Request 1), the ETag value `responseETag123` matches the ETag of the previously requested `Departments 10` resource item on the server side, indicating that the state of the resource item is consistent with the server side. Consequently, the precondition fails and there is no need to return a newer Departments `10` resource item. The request returns with an HTTP code `304`, indicating the state on the server has not been modified.

In the subsequent request (Request 2), however, the ETag `unmatchedETagXYZ` supplied in the `If-None-Match` precondition does not exist on the server. As a consequence, the precondition succeeds and the `Departments 10` resource item is retrieved. The request returns an HTTP code `200`, indicating the state had changed, and the current (unchanged) ETag value `responseETag123` is returned in the response header.

Request 1

      "name" : "Employees",
      "kind" : "collection"
    } ]
}
```

Working with Attachments

The ADF REST runtime supports content streaming of custom content that is not contained in the payload by using a link to the content. You can create LOB content at the same time that you are creating or retrieving a resource item using the HTTP methods.
The ADF REST runtime supports content streaming for BLOB or CLOB attributes.

LOB attributes may be handled in the following ways.

- Linked to as custom content that is not contained in the payload itself.

  This is the default for BLOB and CLOB attributes and specified in the response payload using the `enclosure` link type to point to a resource that cannot be represented with the supported payload types (such as `image/png`).
- Encoded into `Base64` string format and contained in the request payload itself.

Currently, advanced features (like support for Chunked encoding) are not supported by the ADF REST runtime. Developers working on an enterprise architecture, may wish to investigate the use of specialized content management systems (such as Oracle WebCenter Content).

Instead of showing the LOB attribute in the `attribute` section, the response payload always contains an `enclosure` link to the content. The following describe for an `Employees` resource item defines the BLOB attribute `Picture` with a default `requestType` of `application/octet-stream`. The `enclosure` link for the resource item appears in the `items` section. The `actions` section identifies the operations that may be used to manipulate the content.

```
{
  "Resources" : {
    "Employees" : {
      "discrColumnType" : false,
      "attributes" : [ {
       ...
      }, {
        "name" : "Picture",
        "type" : "attachment",
        "updatable" : true,
        "mandatory" : false,
        "queryable" : false,
        "actions" : [ {
          "name" : "delete",
          "method" : "DELETE"
        }, {
          "name" : "get",
          "method" : "GET",
          "responseType" : [ "application/octet-stream" ]
        } ]
      } ],
      "item" : {
        "links" : [ {
         ...
        }, {
          "rel" : "enclosure",
          "href" : "http://server/demo/rest/11.0/Employees/101/enclosure/
Picture",
          "name" : "Picture",
          "kind" : "other"
        } ],
        "actions" : [ {
        } ]
      },
      "links" : [ {
        ...
      } ]
  }
}
```

The attribute content type of the resource item can be assigned by the ADF REST resource developer by configuring the `contentType` property as a custom property of the LOB-type attribute. For example, when working with PNG image files, the following content type can assigned in advance:

- **Custom Property**: `contentType`
- **Value**: `image/png`

In some use cases the attribute value itself is a link to some external content. When an attribute is configured this way, it is not only shown in the resource item payload but a link that points to the external content is also created. In the resource description, only the GET action will be available for the external link. You can modify the URL contained in the attribute value by making a request with an update on the resource item.

An attribute can be configured by the ADF REST resource developer to generate a link by adding the following attribute:

- **Name**: `inputHandler`
- **Value**: `oracle.adf.internal.model.rest.core.binding.inputHandler.LinkInputHandler`

Streaming Attachments Using a Resource Item Enclosure Link

The ADF REST runtime supports streaming content that cannot be contained in the payload of a resource item by using a link to the content. Supported methods on the linked content include GET and DELETE. Note that creating LOB content at the same time that you create a resource item (using a POST method) requires encoding the content as `base64`. A sample of how to embed content using `base64` can be found in Replacing LOB Content Using Base64.

To stream content from a link:

1. Retrieve the resource item and locate the `enclosure` link for the desired attribute. The `item` section defines the available links for the attribute.

   Alternatively, you can execute the resource describe to identify the enclosure link generated for resource items. In general, the resource describe contains other useful information not returned in the GET response payload, including the expected response type (`image/png`, for example) and supported actions for the attribute.

2. Execute an HTTP operation (GET or DELETE) using the link to the LOB content.

The following resource item for `Employees 101` shows the `enclosure` link for the `Picture` attribute in the `links` section.

> **Note:**
>
> The URL that you specify for `enclosure` should be the enclosure link for the image and not the URL of the image.

```
{
  "EmployeeId" : 101,
  "FirstName" : "Neena",
  "LastName" : "Smith",
  "Email" : "NSMITH",
  "JobId" : "AD_VP",
  "DepartmentId" : 90,
  "Salary" : 2000,
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.0/Employees/101",
    "name" : "Employees",
    "kind" : "item"
  }, {
    "rel" : "canonical",
    "href" : "http://server/demo/rest/11.0/Employees/101",
    "name" : "Employees",
    "kind" : "item"
  }, {
    "rel" : "lov",
    "href" : "http://server/demo/rest/11.0/Employees/101/lov/JobsLOV",
    "name" : "JobsLOV",
    "kind" : "collection"
  }, {
    "rel" : "enclosure",
    "href" : "http://server/demo/rest/11.0/Employees/101/enclosure/Picture",
    "name" : "Picture",
    "kind" : "other"
  } ]
}
```

For example, the following sample streams the PNG image associated with employee 101.

Note that by default the request type is `application/octet-stream` to support a variety of media types. If the ADF REST resource developer defined the custom property `contentType`, the specified request type appears in the resource item describe.

Request

- **URL**

  `http://server/demo/rest/11.0/Employees/101/enclosure/Picture`

- **HTTP Method**

  GET

- **Content Type**

  none

- **Payload**

  none

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `image/png`

- **Payload**

  content streamed

Replacing LOB Content Using Base64

The ADF REST runtime allows creating and updating LOB content using a JSON payload when the content is represented in `base64` string format.

For example, the following sample replaces a PNG image for employee 101. In this use case, the Picture attribute must be represented in the request payload as String encoded in base64. Because resource item 101 already exists and only the Picture attribute is being manipulated, no other attributes need to be specified.

Note that the response payload contains the enclosure link to the Picture attribute.

Request

- **URL**

  `http://server/demo/rest/11.0/Employees/101`

- **HTTP Method**

  PATCH

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload**

```
{
  "Picture" : "/9j/4AAQSkZJRgABAAEAYABgAAD//..."
}
```

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload**

```
{
  "EmployeeId" : 101,
  "FirstName" : "Neena",
  "LastName" : "Smith",
  "Email" : "NSMITH",
  "JobId" : "AD_VP",
  "DepartmentId" : 90,
  "Salary" : 2000,
  "links" : [ {
    "rel" : "lov",
    "href" : "http://server/demo/rest/11.0/Employees/101/lov/JobsLOV",
    "name" : "JobsLOV",
    "kind" : "collection"
  }, {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.0/Employees/101",
    "name" : "Employees",
    "kind" : "item"
  }, {
    "rel" : "canonical",
    "href" : "http://server/demo/rest/11.0/Employees/101",
    "name" : "Employees",
    "kind" : "item"
  }, {
    "rel" : "enclosure",
    "href" : "http://server/demo/rest/11.0/Employees/101/enclosure/Picture",
        "name" : "Picture",
        "kind" : "other"
      } ]
    }
```

Working with LOV

In ADF, you can retrieve LOV-enabled attributes when you create or retrieve existing resource items using the HTTP methods. The ADF REST runtime supports retrieving LOV-enabled attribute values when the resource item does not exist in the resource collection.
The ADF REST runtime supports the following LOV-enabled attribute use cases.

- Retrieving non-dependent LOV-enabled attribute values for a standalone LOV.

  Refer to this use case when you need to allow users to update an LOV-enabled resource item in the context of a known containing resource item.
- Retrieving nested LOV-enabled attribute values for cascading LOVs.

  Refer to this use case when you need to allow users to update a nested LOV resource item based on a dependent LOV-enabled attribute.

Note that the use case procedure changed starting with ADF REST Framework version 5. In earlier Framework versions, the REST request depended on the use case. However, starting with Framework version 5, all LOV use cases, standalone or cascading, rely on row finders URLs that you enable for static LOV resources.

Retrieving Non-Dependent LOV-Enabled Attribute Values with Framework Versions 1 Through 4

In ADF REST Framework version 4 and earlier, the runtime supports retrieving the values from LOV-enabled attributes in the context of a known containing resource item using a GET method.

In ADF REST Framework versions 4 and earlier, the resource item for an LOV-enabled attribute nests a child LOV resource URL that you can use to obtain the list of values that are based on the context of the already known containing resource item.

> **Note:**
>
> Starting with ADF REST Framework version 5, the use of row finder URLs to populate a LOV resource item is recommended. See Retrieving LOV-Enabled Attribute Values with Framework Version 5 and Later.

When you need to populate cascading LOV attribute lists, in ADF REST Framework versions 4 and earlier, see Retrieving Dependent LOV-Enabled Attribute Values with Framework Versions 1 Through 4.

In Framework version 4 and earlier, to work with LOV-enabled attributes in non-cascading lists:

1. Execute the resource describe and locate the following details about the LOV:

Under the lov description of a resource attribute, locate the childRef property to identify the child resource collection that contains the LOV choices. Note that the resource describe of a LOV child resource does not show the lov description, as the operation to retrieve LOV-enabled attribute values is not supported on LOV child resources.

The lov description contains the view object attribute mapping from the resource item to the LOV child resource collection. The attribute mapping contains one or more source attributes from the child resource whose values will be copied to the resource item when an LOV value is selected. An LOV selection could derive more values in the resource item besides the attribute displaying the LOV. In such cases, the attribute mapping will identify it as derived = true. Finally, the lov description identifies which attributes from the child resource collection could be used for displaying to end users if the results are bound to a user interface.

2. Then, look for the resource item links element and locate the link with a rel of lov and the href that identifies the corresponding LOV child resource (as specified in the resource item childRef property).

   Tip: The resource describe displays the LOV child resource as a template that is completed by supplying a specific resource item name from the resource collection. You may execute a GET to retrieve the resource collection and locate the working link for the LOV child resource that corresponds to the specific resource item.

3. Execute a GET using the LOV link and, optionally, use additional filtering to narrow down the LOV results or to exclude not needed attributes from the payload. You should always fetch the display attributes listed in the lov description. The display attribute is the attribute value that allows the end user to make an LOV value selection from a list of values that they would recognize (such as the list of job titles). The LOV definition ensures that the correct source attribute is used to update the resource item when the LOV selection is applied.

For example, the Employees resource collection describe returns the following:

```
{
  "Resources" : {
    "Employees" : {
      "discrColumnType" : false,
      "attributes" : [ {
        "name" : "EmployeeId",
        "type" : "integer",
        "updatable" : true,
        "mandatory" : true,
        "queryable" : true,
        "precision" : 6
      }, {
        "name" : "FirstName",
        "type" : "string",
        "updatable" : true,
        "mandatory" : false,
        "queryable" : true,
        "precision" : 20
      }, {
        "name" : "LastName",
        "type" : "string",
        "updatable" : true,
        "mandatory" : true,
        "queryable" : true,
        "precision" : 25
      }, {
        "name" : "Email",
        "type" : "string",
        "updatable" : true,
        "mandatory" : true,
        "queryable" : true,
        "precision" : 25
      }, {
        "name" : "JobId",
        "type" : "string",
        "updatable" : true,
        "mandatory" : true,
        "queryable" : true,
        "precision" : 10,
        "controlType" : "choice",
        "maxLength" : "10",
        "lov" : {
          "childRef" : "JobsLOV",
          "attributeMap" : [ {
            "source" : "JobId",
            "target" : "JobId"
          } ],
          "displayAttributes" : [ "JobTitle" ]
        }
     ...

      "item" : {
        "links" : [ {
          "rel" : "lov",
          "href" :
                  "http://server/demo/rest/11.0/Employees/{id}/lov/JobsLOV",
          "name" : "JobsLOV",
          "kind" : "collection"
        }, {
...
```

The following sample fetches the values for the LOV display attribute `JobTitle` from the `JobsLOV` resource collection. The query parameters `onlyData` and `fields` ensure the representation is filtered to contain only data in the response payload, where `President` and `Administration Assistant` are examples of the values of the display attribute `JobTitle`.

Request Made With Framework Version 4 or Earlier

- **URL**

  `http://server/demo/rest/11.0/Employees/101/lov/JobsLOV?onlyData=true&fields=JobTitle`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

Response Returned By Framework Version 4 or Earlier

- **HTTP Code**

```
200
```

- **Content-Type**

  ```
  application/vnd.oracle.adf.resourcecollection+json
  ```

- **Payload**

  ```
  {
    "items" : [ {
      "JobTitle" : "President"
    }, {
      "JobTitle" : "Administration Assistant"
    }, {
      "JobTitle" : "Finance Manager"
    }, {
      "JobTitle" : "Accountant"
    }, {
      "JobTitle" : "Accounting Manager"
    }, {
      "JobTitle" : "Public Accountant"
    } ],
    "count" : 6,
    "hasMore" : false,
    "limit" : 25,
    "offset" : 0,
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/11.0/Employees/101/lov/JobsLOV",
      "name" : "JobsLOV",
      "kind" : "collection"
    } ]
  }
  ```

Retrieving Dependent LOV-Enabled Attribute Values with Framework Versions 1 Through 4

In ADF REST Framework version 4 and earlier, the runtime supports retrieving LOV-enabled attribute values using a GET method when it is necessary to populate a resource item without a row context, such as when supporting dependent LOV-enabled attribute lists, also known as cascading LOVs.

In ADF REST Framework versions 1 through 4 the describe provides a static LOV URL to access the dependent list without the context of a known row, where the selection the end user makes in one LOV determines the list to display in the nested LOV. Representing two lists of States and Cities is an example of cascading LOVs, where the list to display for the Cities LOV child attribute is not know until the State LOV attribute selection has been made. In this case, the ADF REST resource developer working in the Model project defines static LOV resources that do not require a row context to enable access to the nested LOV attribute list in the resource describe. For details about creating a static LOV resource in the Model project, see How to Support Create Operations on ADF REST Resources with LOV Attributes.

When you need to populate a non-dependent LOV attribute list (a single LOV) in ADF REST Framework versions 1 through 4, see Retrieving LOV-Enabled Attribute Values for Existing Resource Items.

> **Note:**
>
> Starting with ADF REST Framework version 5, the use of row finder URLs to populate a LOV resource item is recommended. With version 5 enabled, only top-level LOV resources are supported, where the resource describe provides no URL to access nested LOV child resources. See Retrieving LOV-Enabled Attribute Values with Framework Version 5 and Later.

In Framework version 4 and earlier, to work with dependent LOV-enabled attributes:

1. Execute the resource describe and locate the following details about the LOV:

   Under the `lov` description of an attribute, locate the `lovResourcePath` property to identify the LOV resource that contains the LOV choices. Note that the resource describe of a LOV child resource does not show the `lov` description, as the operation to retrieve LOV-enabled attribute values is not supported on LOV child resources.

   The `lov` description contains the attribute mapping from the resource item to the LOV resource collection. The attribute mapping contains one or more source attributes from the LOV resource whose values will be copied to the resource item when an LOV value is selected. An LOV selection could derive more values in the resource item besides the attribute displaying the LOV. In such cases, the attribute mapping will identify it as `derived = true`. Finally, the `lov` description identifies which attributes from the LOV resource collection could be used for displaying to end users if the results are bound to a user interface.

2. Then, look for the resource collection describe `links` element and locate the link with a `rel` of `lov` and the `href` that identifies the LOV resource (as specified in the `lovResourcePath` property).

   Note the `lovResourcePath` is an array that may specify more than one LOV resource. The array supports the use case of dependent LOV-enabled attributes (also called cascading LOVs). For example, the array `"lovResourcePath" : [ "Countries", "States" ]` identifies LOV resources `Countries` and `States`, where the LOV list to display the states is dependent on the LOV selection for countries. To get the values to display for the dependent LOV attribute, you use a child link from the parent LOV resource collection as follows:

   a. Execute a GET using the LOV resource link (where `rel: lov` and `name: Countries`).

   b. The end user selects a resource item from the LOV resource collection (for example, `United States`).

   c. Execute a GET using the child link (`rel: child` and `name: States`) in the selected resource item. This will retrieve a resource collection with the list of values (states) based on the parent LOV resource (countries).

3. Execute a GET using the LOV resource link and, optionally, use additional filtering to narrow down the LOV results or to exclude not needed attributes from the payload. You should always fetch the display attributes listed in the `lov` description. The display attribute is the attribute value that allows the end user to make an LOV value selection from a list of values that they would recognize (such as the list of job titles).

4. With the cached LOV attribute values from the LOV resource, it is then possible to display the LOV display attribute in the client user interface where the end

user is expected to enter values to create a new resource item. When enters the desired values, chooses a value from the displayed LOV for the LOV-enabled attribute, and then clicks Submit, the client can execute the create request. The ADF Business Components view object attribute's LOV definition ensures that the correct source attribute is used to update the resource item when the LOV selection is applied. For details about submitting a POST request with the payload that creates a new resource item, see Creating a Resource Item in Collection.

For example, the `Employees` resource collection describe returns the following:

```
{
  "Resources" : {
    "Employees" : {
      "discrColumnType" : false,
      "attributes" : [ {
        "name" : "EmployeeId",
        "type" : "integer",
        "updatable" : true,
        "mandatory" : true,
        "queryable" : true,
        "precision" : 6
      }, {
        "name" : "FirstName",
        "type" : "string",
        "updatable" : true,
        "mandatory" : false,
        "queryable" : true,
        "precision" : 20
      }, {
        "name" : "LastName",
        "type" : "string",
        "updatable" : true,
        "mandatory" : true,
        "queryable" : true,
        "precision" : 25
      }, {
        "name" : "Email",
        "type" : "string",
        "updatable" : true,
        "mandatory" : true,
        "queryable" : true,
        "precision" : 25
      }, {
        "name" : "JobId",
        "type" : "string",
        "updatable" : true,
        "mandatory" : true,
        "queryable" : true,
        "precision" : 10,
        "controlType" : "choice",
        "maxLength" : "10",
        "lov" : {
          "childRef" : "JobsLOV",
          "attributeMap" : [ {
            "source" : "JobId",
            "target" : "JobId"
          } ],
          "displayAttributes" : [ "JobTitle" ],
          "lovResourcePath" : [ "Jobs" ]
        }
      ...
```

```
        },
        "links" : [ {
          ...
            "rel" : "lov",
            "href" : "http://server/demo/rest/11.0/Jobs",
            "name" : "Jobs",
            "kind" : "collection"
          }, {
...
```

The following sample fetches the values for the LOV display attribute `JobTitle` from the `Jobs` resource collection. The query parameters `onlyData` and `fields` ensure the representation is filtered to contain only data in the response payload, where `President` and `Administration Assistant` are examples of the values of the display attribute `JobTitle`.

Request Made With Framework Version 4 or Earlier

- **URL**

  `http://server/demo/rest/11.0/Jobs?onlyData=true&fields=JobTitle`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

Response Returned By Framework Version 4 or Earlier

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourcecollection+json`

- **Payload**

```
{
  "items" : [ {
    "JobTitle" : "President"
  }, {
    "JobTitle" : "Administration Assistant"
  }, {
    "JobTitle" : "Finance Manager"
  }, {
    "JobTitle" : "Accountant"
  }, {
    "JobTitle" : "Accounting Manager"
  }, {
    "JobTitle" : "Public Accountant"
  } ],
  "count" : 6,
  "hasMore" : false,
  "limit" : 25,
  "offset" : 0,
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.0/Jobs",
        "name" : "Jobs",
        "kind" : "collection"
      } ]
    }
```

Retrieving LOV-Enabled Attribute Values with Framework Version 5 and Later

In ADF REST Framework version 5 and later, the runtime supports retrieving values from LOV-enabled attributes using a GET method by passing in the containing resource item which may be either already known or based on a selection made at runtime in a dependent LOV attribute list.

The row finder URL supports obtaining the LOV list of a single LOV or of cascading LOVs, where the selection the end user makes in one LOV determines the list to display in the nested LOV. Representing two lists of States and Cities is an example of cascading LOVs, where the list to display for the Cities LOV child attribute is not know until the State LOV attribute selection has been made. In this case, the ADF REST resource developer working in the Model project defines static LOV resources that do not require having a row context to enable access to the nested LOV-enabled attribute list in the resource describe. For details about creating a static LOV resource in the Model project, see How to Support Create Operations on ADF REST Resources with LOV Attributes.

The row finder URL that you obtain from the resource describe and pass on a GET request allows you to submit a bind parameter value to specify the containing resource and give the LOV-enable attribute its row context. In the case of a cascading LOVs, once you have retrieved the dependent LOV attribute values, you can populate the nested LOV list by using a POST request with the retrieved values as the payload.

> **Note:**
>
> Starting with ADF REST Framework version 5, the use of row finder URLs to populate a LOV resource item is recommended. Unlike earlier versions of the framework, the use of row finder URLs in the describe supports both dependent and non-dependent LOVs. For details about working with LOVs with earlier framework versions, see instead Retrieving Non-Dependent LOV-Enabled Attribute Values with Framework Versions 1 Through 4 and Retrieving Dependent LOV-Enabled Attribute Values with Framework Versions 1 Through 4.

In Framework version 5 and later, to work with LOV row finder URLs:

1. Execute the resource describe and locate the following details about the LOV:

   Under the `lov` description of an attribute, locate the `childRefForCreate` property to identify the LOV resource that contains the LOV choices.

   The `lov` description contains the attribute mapping from the resource item to the LOV resource collection. The attribute mapping contains one or more source attributes from the LOV resource whose values will be copied to the resource item when an LOV value is selected. An LOV selection could derive more values in the resource item besides the attribute displaying the LOV. In such cases, the attribute mapping will identify it as `derived = true`. Finally, the `lov` description identifies which attributes from the LOV resource collection could be used for displaying to end users if the results are bound to a user interface.

2. Then, look for the resource item describe `links` element and locate the link with a `rel` of `lov` and the `href` for the parent LOV list.

3. Execute a GET using the LOV resource link and, optionally, use additional filtering to narrow down the LOV results or to exclude not needed attributes from the payload. You should always fetch the display attributes listed in the `lov` description. The display attribute is the attribute value that allows the end user to make an LOV value selection from a list of values that they would recognize (such as the list of states).

4. With the cached LOV attribute values from the LOV resource, it is then possible to display the LOV display attribute in the client user interface where the end user is expected to enter values to create a new resource item. When enters the desired values, chooses a value from the displayed LOV for the LOV-enabled attribute, and then clicks Submit, the client can execute the create request. The ADF Business Components view object attribute's LOV definition ensures that the correct source attribute is used to update the resource item when the LOV selection is applied. For details about submitting a POST request with the payload that creates a new resource item, see Creating a Resource Item in Collection.

5. To get the values to display for a dependent LOV attribute, use a LOV resource link (as specified in the `childRefForCreate` property) with parametrized row finder for the selected resource item. Execute a GET using the LOV resource link (`rel: lov` and `name: CityLOVForCreate`) in the selected resource item. This will retrieve a resource collection with the list of values (cities) based on the parent LOV resource (states).

For example, the `Address` resource collection describe returns the following:

```
{
  "Resources" : {
    "Address" : {
      "discrColumnType" : false,
      "attributes" : [ {
       ...
       }, {
         "name" : "City",
         "type" : "string",
         "updatable" : true,
         "mandatory" : true,
         "queryable" : true,
         "precision" : 32,
         "controlType" : "choice",
         "maxLength" : "32",
         "lov" : {
           "childRef" : "CityLOV",
           "childRefForCreate" : "CityLOVForCreate",
           "attributeMap": [ {
             "source" : "CityName",
             "target" : "City"
           }],
           "displayAttributes" : [ "CityName" ],
         }
       }, {
          "name" : "State",
          "type" : "string",
          "updatable" : true,
          "mandatory" : true,
          "queryable" : true,
          "precision" : 2,
          "controlType" : "choice",
          "maxLength" : "2",
          "lov" : {
            "childRef" : "StateLOV",
            "childRefForCreate" : "StateLOVForCreate",
            "attributeMap": [ {
              "source" : "StateCode",
              "target" : "State"
            }],
            "displayAttributes" : [ "StateCode" ],
          }
        }, {
      ...
      },
      "item" : {
        "links" : [ {
          ...
        }, {
          "rel": "lov",
          "href": "http://server/demo/rest/11.0/Address/{id}/lov/
CityLOV",
          "name": "CityLOV",
          "kind": "collection"},
        }, {
          "rel" : "lov",
          "href" : "http://server/demo/rest/11.0/Cities?
finder=ByStateFinder%3BstateVar%3D{State}",
          "name" : "CityLOVForCreate",
          "kind" : "collection"
        }, {
        }, {
          "rel": "lov",
          "href": "http://server/demo/rest/11.0/Address/{id}/lov/
StateLOV",
          "name": "StateLOV",
          "kind": "collection"},
        }, {
          "rel" : "lov",
          "href" : "http://server/demo/rest/11.0/States",
          "name" : "StateLOVForCreate",
          "kind" : "collection"
        }, {
...
```

The following sample fetches the values for the parent LOV display attribute `StateCode` from the `States` LOV resource collection. The query parameters `onlyData` and `fields` ensure the representation is filtered to contain only data in the response payload, where `CA` and `TX` are examples of the values of the display attribute `StateCode`.

LOV Request Made With Framework Version 5

- **URL**

  `http://server/demo/rest/11.0/States?onlyData=true&fields=StateCode`
- **HTTP Method**

  GET
- **Content-Type**

  none
- **Payload**

LOV Response Returned By Framework Version 5

- **HTTP Code**

  `200`
- **Content-Type**

  `application/vnd.oracle.adf.resourcecollection+json`
- **Payload**

```
{
  "items" : [ {
     "StateCode" : "CA"
  }, {
     "StateCode" : "TX"
  }, {
     "StateCode" : "MS"
  }, {
  ...
  }
 ]
}
```

Where the usage involves a cascading LOV, this sample fetches the values for the dependent LOV with the LOV display attribute `CityName` from the `Cities` LOV resource collection. The row finder takes a parameter for the state name `CA` returned in the client for the parent LOV.

Dependent LOV Request Made With Framework Version 5

- **URL**

  ```
  http://server/demo/rest/11.0/Cities?
  finder=ByStateFinder%3BstateVar%3D{State}"
  ```
- **HTTP Method**

  GET
- **Content-Type**

  none
- **Payload**

Dependent LOV Response Returned By Framework Version 5

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourcecollection+json`

- **Payload**

```
{
  "items": [{
     "Statecode": "CA",
     "Cityname": "Tracy"
  }, {
     "Statecode": "CA",
     "Cityname": "Pleasanton"
  }, {
     "Statecode": "CA",
     "Cityname": "Jackson"
  }, {
     "Statecode": "CA",
     "Cityname": "San Jose"
  }, {
  ...
  }
 ]
}
```

Working with ADF REST Framework Versions

Service clients may need to pass a different payload format to utilize a new feature or enhancement, such as the advanced query capabilities offered in version 2 of the ADF REST runtime framework. A framework version refers to a specific version of the ADF REST framework available starting in a particular Oracle JDeveloper release.

Being able to specify a framework version to process requests, allows clients to opt into those features when they are ready.

The ADF REST runtime supports the following use cases for executing requests according to specific ADF REST framework versions:

- Ability for service clients to specify a framework version that affects the processing of the payload.
- Ability for service clients to indicate the default framework version (as configured by the server) to be used.
- Ability for ADF REST resource developers to declare the default framework version for all URIs under a release version:
  - When a request does not specify a framework version, all payloads for URIs starting with `/context/<release-version>/` will assume the default framework version as declared in the `adf-config.xml` file.
  - When a request specifies a framework version, the specified framework version will be honored.

Service clients may pass the custom header REST-Framework-Version on the REST resource request to specify the framework version to use to execute the request. The ADF REST framework version passed in the version header overrides the default framework declaration defined by the application in the adf-config.xml file by the REST service developer.

When the service client passes no version header in the request, the ADF REST runtime uses the default, as defined in the adf-config.xml file. When a default framework version is not defined and no version header is passed, then the base version (version 1) of the ADF REST framework is assumed.

The framework version declaration is made by ADF REST resource developers in the adf-config.xml file for each application-specific resource version name. For example, the sample following shows resource versions 11.2, 11.1, and 11.0 with the framework versions 3, 2, and 1 declared.

```
<versions>
    <version name="11.2" displayName="11.2" restFrameworkVersion="2"/>
    <version name="11.1" displayName="11.1" lifecycle="deprecated"
restFrameworkVersion="1"/>
    <version name="11.0" displayName="11.0" lifecycle="deprecated"
restFrameworkVersion="1"/>
</versions>
```

In the above example, when the request does not pass a framework version header, resources 11.0 and 11.1 will use the old payload format, while 11.2 will use the new payload format. This ensures, in cases where a framework version is not specified in the request, existing service clients which access resources for a particular release will not be affected when the ADF REST framework introduces a new payload format; yet new service clients which access the latest resources may pick up the new payload format.

For the root resource /context, the default ADF REST framework version for the latest release will be used.

The service client may want to find out the default framework version for a particular release. To support this use case, ADF REST will return the default framework version in the resource version describe, as the following sample shows. Note that service clients may override the default framework version with another framework version identifier by specifying the value in the REST-Framework-Version header. The allowedFrameworkVersions property lists the values of the available framework versions.

```
{
    "items" : [
        {
            "version" : "11.2",
            "isLatest" : true,
            "adf:extension" : {
                    "defaultFrameworkVersion" : "2",
                    "allowedFrameworkVersions" : [ "1","2","3","4","5","6","7" ]
            },
            "links" : [
             ...
```

For details about the ADF REST framework functionality supported in each framework version, see What You May Need to Know About Versioning the ADF REST Runtime Framework.

Retrieving ADF REST Framework Versions for Resource Versions

The ADF REST runtime supports retrieving the version of the ADF REST framework associated with each application-specific release version name that the service end point defines using a GET method.

While the release versions named in the REST application are specific to the application's REST resources, framework versions designate a change in functionality of the ADF REST framework and correspond to a particular JDeveloper release. To ensure the service endpoint exposes the desired level of functionality to service clients, REST resource developers may optionally assign a framework version to each REST resource release version name in the application's `adf-config.xml` file.

> **Note:**
>
> For details about the ADF REST framework functionality supported in each framework version, see What You May Need to Know About Versioning the ADF REST Runtime Framework.

To examine the framework version assigned to the release version names that the application defines:

1. Execute the service end point describe and locate the available release version names in the describe.
2. Locate the `version` property to identify the release version.
3. Examine the associated `defaultFrameworkVersion` property to understand the version of the ADF REST framework that will be used to execute requests for the specific release version:
   - `defaultFrameworkVersion` property specifies the default ADF REST framework version that has been associated with a particular release version, as optionally defined by the ADF REST resource developer in the `adf-config.xml` file. Note that a new ADF REST framework version may introduce new functionality. Thus, associating a specific framework version with each release version ensures that service clients interact with the appropriate level of functionality. See Working with ADF REST Framework Versions.
4. If you want to override the default framework version, examine the `allowedFrameworkVersions` property to understand what versions that you may use:
   - `allowedFrameworkVersions` property identifies the list of ADF REST framework versions that are supported for a particular release version. Service clients may override the default framework version with any value in the list by specifying the value in the `REST-Framework-Version` header.

For example, the describe for a service end point with two release versions returns the following objects, where each release version has been associated with a specific ADF REST framework version:

```
{
    "items" : [
        {
            "version" : "version_identifier_latest",
            "isLatest" : true,
            "adf:extension" : {
                    "defaultFrameworkVersion" : "framework_identifier",
                    "allowedFrameworkVersions" : [ "framework_identifier1", 
"framework_identifier2", ... ]
            },
            "links" : [
                {
                    "rel" : "self",
                    ...

                },
                {
                    "rel" : "canonical",
                    ...

                },
                {
                    "rel" : "predecessor-version",
                    ...

                },
                {
                    "rel" : "describe",
                    ...

                }
            ]
        },
        {
            "version" : "version_identifier_previous",
            "adf:extension" : {
                    "defaultFrameworkVersion" : "framework_identifier",
                    "allowedFrameworkVersions" : [ "framework_identifier1", 
"framework_identifier2", ... ]
            },
            "links" : [
                {
                    "rel" : "self",
                    ...
                },
                {
                    "rel" : "canonical",
                    ...
                },
                {
                    "rel" : "successor-version",
                    ...
                },
                {
                    "rel" : "describe",
                    ...
                }
            ]
        }
    ],
    "links" : [
     ...
        {
            "rel" : "current",
                    ...
            }
        ]
}
```

The following sample retrieves all available release versions defined in the resource catalog of the `demo` application. In the sample, the three release versions are `11.0`, `11.1`, and `11.2`, where `11.2` is the current (or most recent) release version. In the sample, versions `11.0` and `11.1` are explicitly associated with ADF REST framework version `1` and release version `11.2` is associated with ADF REST framework version 2. Note that a framework version refers to a specific version of the ADF REST framework, available starting in a particular Oracle JDeveloper release.

            "name" : "current",
            "kind" : "item"
        }
    ]
}
```

Executing a Request Using the Header to Specify the Framework Version

The ADF REST runtime supports executing individual requests on the service endpoint using a custom header to affect the processing of the payload with the functionality specific to a particular ADF REST framework version. The framework version specified by the custom header overrides the default framework version declaration that may exist in the client application.

Note:

A framework version refers to a specific version of the ADF REST framework (corresponding to a particular Oracle JDeveloper release). For details about the ADF REST framework functionality supported in each framework version, see What You May Need to Know About Versioning the ADF REST Runtime Framework.

To ensure the service endpoint exposes the desired level of functionality to service clients, REST resource developers may optionally assign a default ADF REST framework version to each REST resource version named in the application’s `adf-config.xml` file. However, the service client may override the default framework version and process individual requests using a specified framework version that gets passed in a custom header. In this case, the ADF REST runtime will ignore the declared, default framework version.

To process a request using a specific ADF REST framework version, the request must pass the custom header `REST-Framework-Version` with the framework version number specified. For example, the following header specifies framework version 2 will be used to process the request that passes this version header.

```
REST-Framework-Version: 2
```

If the custom header is omitted on the request, then the ADF REST runtime uses the application’s default framework version, as defined in the `adf-config.xml` file. When the application does not define a default framework version and the request on the service client omits the version header, then the base version (version 1) of the ADF REST framework is assumed.

Executing Requests Using the Declared Default Framework Version

The ADF REST runtime supports executing all requests on the service endpoint to affect the processing of the payload with functionality specific to the declared, default version of the ADF REST framework.

Note:

A framework version refers to a specific version of the ADF REST framework (corresponding to a particular Oracle JDeveloper release). For details about the ADF REST framework functionality supported in each framework version, see What You May Need to Know About Versioning the ADF REST Runtime Framework.

To ensure the service endpoint exposes the desired level of functionality to service clients, REST resource developers may optionally assign a default ADF REST framework version to each REST resource version named in the application’s `adf-config.xml` file. Thus, when the request is made, the ADF REST runtime will process the request for the particular resource version according to the declaration in the `adf-config.xml` file.

For example, the following URL specifies resource version 11.2, where the application's adf-config.xml file associates this resource version with version 2 of the ADF REST framework. Because version 2 of the ADF REST framework supports rowmatch filter expressions, as a result, the ADF REST runtime will process the request with the appropriate functionality and fetch the departments with names that begin with SA (for example, SALES) or have a Location of BOSTON.

```
    http://server/demo/rest/11.2/Departments?q=DepartmentName like 'SA*' or
Location = 'BOSTON'
```

Note that a service client may override the default framework version and process individual requests using a specified framework version that gets passed in a custom header. In this case, the ADF REST runtime will ignore the application default. If the custom header is omitted on the request, then the ADF REST runtime always uses the application's default framework version, as defined in the adf-config.xml file. When the application does not define a default framework version and the request on the service client omits the version header, then the base version (version 1) of the ADF REST framework is assumed.

Working with Warning and Error Responses

Error responses can be obtained in the form of a JSON payload with exception details when ADF REST framework version 4 or later is enabled. Alternatively, with framework version 3 or earlier, error responses are in the form of a simple message string.

Warning responses can be obtained in the form of a JSON payload with details when ADF REST framework version 6 or later is enabled.

In addition to HTTP status codes and error messages, it is possible to obtain exception details in the response when your request is enabled to use ADF REST framework version 4 and the request is made for either application/vnd.oracle.adf.error+json or application/json media types. With framework version 4, the response will be in the form an exception detail payload which provides the following benefits to the service client:

- If multiple errors occur in a single request, the details of each error are presented in a hierarchical structure.
- An application-specific error code may be present that identifies the ADF exception corresponding to each error.
- An error path may be present that identifies the location of each error in the request payload structure.

Note:

The exception detail may or may not present certain details, such as the application-specific error code and the request payload's error path.

For example, compare the error response for a POST submitted with a payload that contains the following incorrectly formatted date field when framework version 3 (or earlier) is enable and when framework version 4 (or later) is enabled.

```
{    "EmpNum" : 5027,
     "EmpName" : "John",
     "EmpHireDate" : "not a date"
}
```

Standard Error Response, Version 3 and earlier

Without framework version 4, no response payload is generated and instead only a single error message that does not reference the request payload will be returned in the response.

```
"An instance of type oracle.jbo.domain.Date cannot be created from
string not a date. The string value must be in format YYYY-MM-
DDTHH:MI:SS.sss+hh:mm."
```

Exception Payload Error Response, Version 4 and later

With framework version 4 enabled, the following exception detail payload is generated for the response. The payload includes the usual HTTP status code and formats the details of one or more exceptions in an array structure.

```
{    "title" : "Bad Request",
    "status" : "400",
    "o:errorDetails" : [ {
     "detail" : "An instance of type oracle.jbo.domain.Date cannot be
created from string not a date.
               The string value must be in format YYYY-MM-
DDTHH:MI:SS.sss+hh:mm.",
       "o:errorCode" : "26099",
       "o:errorPath" : "/EmpHireDate"
    } ]
 }
```

Exception Payload Warning Response, Version 6 and later

With framework version 6 enabled, a warning detail payload is generated for the response similar to the following. The payload includes the usual HTTP status code and formats the details of the warning in the `@context` section for each resource item.

```
"@context" : {
    ...
    } ],
    "warnings": [ {
      "detail": "Warning from overridden validateEntity method in
DeptImpl : DeptName = ABC or DEF"
    }, {
      "detail": "Attribute set with value 50 for DeptNum in Dept
failed",
      "o:errorCode": "27011",
      "o:errorPath": "/DeptNum"
    }, {
      "detail": "Warning from overridden create method in
DeptViewDefRowImpl"
    }, {
      "detail": "Warning from overridden afterCommit method in
DeptViewImpl"
    } ]
  }
}
```

Understanding the Exception Payload Error Response

The exception detail payload will be generated for an ADF REST error response when the following conditions exist:

1. ADF REST framework version is version 4.
2. Either `application/vnd.oracle.adf.error+json` or `application/json` is an acceptable media type for the response.

The exception detail payload is a JSON object with the following structure as determined by the ADF REST framework:

```
{   "title" : "Message as per HTTP status code",
    "status" : "HTTP error code",
    "o:errorDetails" : [
     ...
        {
            "detail" : "Message of detail error",
            "o:errorCode" : "error code"
            "o:errorPath" : "JSON pointer to the location of the error
in the request payload"
        },
        ...
    ]
}
```

You opt into the exception payload as the error responses by using framework version 4 and making a request for either the `application/vnd.oracle.adf.error+json` media type or `application/json` media type.

Note that within the exception payload, `o:errorDetails` can vary as per the number and the types of errors encountered. Additionally, the error code and error path are not guaranteed to be present in the response payload and should not be relied upon by service clients.

Obtaining the Standard Error Message Response

The ADF REST runtime generates an error message that describes the validation or system error when the request is made with ADF REST framework versions 1 through 3 enabled.

Before version 4 of the ADF REST framework, the error response returns a single error message and HTTP status code. Version 4 and later allows service clients to obtain an error response with a detailed exception payload.

The following sample attempts to create the Departments object with a new department record. However, for this example the request fails because the record for the department instance already exists. The response is an error message because ADF REST framework version 4 (or later) is not enabled.

Request Example Made With Framework Version 3

- **URL**

  `http://server/demo/rest/11.2/Departments`

- **HTTP Method**

  POST

- **Accept Header**

  `application/vnd.oracle.adf.resourceitem+json,application/json`

- **Payload**

  ```
  {
      "DeptNum" : 50,
      "DeptName" : "SALES",
  }
  ```

Response Example From Framework Version 3

- **HTTP Code**

  `400`

- **Error Response**

  ```
  A department with the same name already exists. Please provide a
  different name.
  ```

Obtaining an Exception Payload Error Response

The ADF REST runtime supports obtaining exception details in the response when your request is enabled to use ADF REST framework version 4 and the request is made with an appropriate media type.

Starting with version 4 of the REST API framework, web applications may obtain an error response with a detailed exception payload.

Notice in the exception payload the `o:errorDetails` array provides the error path for where the error occurred in the request object; however, these particular details may not always be available to web applications.

The following sample attempts to create the department object with a new department item. However, for this example the request fails because the item for the department already exists.

Request Example 1 Made With Framework Version 4

- **URL**

  `http://server/demo/rest/11.2/Departments`

- **HTTP Method**

  POST

- **Accept Header**

```
application/vnd.oracle.adf.resourceitem+json,application/json
```

- **Payload**

```
{
    "DeptNum" : 50,
    "DeptName" : "SALES",
}
```

Response Example 1 From Framework Version 4

- **HTTP Code**

```
400
```

- **Content-Type**

```
application/json
```

- **Payload**

```
{
   "title" : "Bad Request",
   "status" : "400",
   "o:errorDetails" : [ {
      "detail" : "A department with the same name already exists. Please 
provide a different name.",
      "o:errorCode" : "Dept_Rule_0"
  } ]
}
```

The following sample attempts to create the department object with a new department item. However, for this example the request fails because the employee names entered exceed the number of characters allowed by the validation rule defined for the `EmpName` field.

Request Example 2 Made With Framework Version 4

- **URL**

```
http://server/demo/rest/11.1/Departments
```

- **HTTP Method**

  POST

- **Accept Header**

```
application/vnd.oracle.adf.resourceitem+json,application/
vnd.oracle.adf.error+json
```

- **Payload**

```
{
   "DeptNum" : 52,
   "DeptName" : "newDept522",
   "Employees" : [ {
        "EmpNum" : 501,
        "EmpName" : "MILLERSxxxxxxxxxxxxxxxxx"
    }, {
        "EmpNum" : 502,
        "EmpName" : "JONESPxxxxxxxxxxxxxxxxx"
      } ]
}
```

Response Example 2 From Framework Version 4

- **HTTP Code**

  `400`

- **Content-Type**

  `application/vnd.oracle.adf.error+json`

- **Payload**

```
{
   "title" : "Bad Request",
   "status" : "400",
   "o:errorDetails" : [ {
      "detail" : "Value MILLERSxxxxxxxxxxxxxxxxx for field EmpName exceeds 
the maximum length allowed.",
      "o:errorCode" : "27040",
      "o:errorPath" : "/Employees/0/EmpName"
   }, {
      "detail" : "Value JONESPxxxxxxxxxxxxxxxxx for field EmpName exceeds 
the maximum length allowed.",
      "o:errorCode" : "27040",
      "o:errorPath" : "/Employees/1/EmpName"
   } ]
}
```

The following sample attempts to perform a batch operation. However, for this example the batch operation fails for the reasons shown in the exception detail payload of the error response.

Request Example 3 Made With Framework Version 4

- **URL**

  `http://server/demo/rest/11.1`

- **HTTP Method**

  POST

- **Accept Header**

  `application/vnd.oracle.adf.batch+json,application/vnd.oracle.adf.error+json`

- **Payload**

```
{
    "parts": [
        {
            "id": "part1",
            "path": "/Employees",
            "operation": "create",
        "payload" : {
        "EmpNum" : 1299,
        "EmpJob" : "CLERK",
        "EmpMgr" : 7566,
        "EmpHireDate" : null,
        "EmpSal" : 245,
        "EmpComm" : 0,
        "EmpDeptNum" : 30
        }
        },
        {
            "id": "part2",
            "path": "/Employees",
            "operation": "create",
            "payload": {
                "EmpNum" : 7589,
        "EmpName" : "SampleEmpxxxxxxxxxxxxxxxxxx",
        "EmpJob" : "CLERK",
        "EmpMgr" : 7566,
        "EmpHireDate" : null,
        "EmpSal" : 245,
        "EmpComm" : 0,
        "EmpDeptNum" : 30
            }
        },
        {
            "id": "part3",
            "path": "/Departments",
            "operation": "create",
            "payload": {
               "DeptNum" : 52,
               "DeptName" : "newDept522",
               "Employees" : [
                   {
                       "EmpNum" : 7588,
                       "EmpName" : "SampleEmpxxxxxxxxxxxxxxxxxx",
                       "EmpJob" : "CLERK",
                       "EmpMgr" : 7566,
                       "EmpHireDate" : null,
                       "EmpSal" : 245,
                       "EmpComm" : 0,
                       "EmpDeptNum" : 30
                   }
               ]
           }
       },
    {
            "id": "part4",
            "path": "/Departments/10/child/Loc",
            "operation": "get"
        },
    {
            "id": "part5",
            "path": "/Departments?invQP=invVal",
            "operation": "get"
        },
    {
            "id": "part6",
            "path": "/Departments/54",
            "operation": "delete"
        },
    {
            "id": "part7",
            "path": "/1.0/Departments/54",
            "operation": "get"
        }
    ]
}
```

Response Example 3 From Framework Version 4

- **HTTP Code**

  400

- **Content-Type**

  `application/vnd.oracle.adf.error+json`

- **Payload**

```
{
    "title" : "Bad Request",
    "status" : "400",
    "o:errorDetails" : [ {
        "detail" : "URL request parameter invQP cannot be used in this
context.",
        "o:errorCode" : "27520"
    }, {
        "detail" : "Attribute EmpName in Emp is required.",
        "o:errorCode" : "27014",
        "o:errorPath" : "/parts/0"
    }, {
        "detail" : "Value SampleEmpxxxxxxxxxxxxxxxxxx for field EmpName
exceeds the maximum length allowed.",
        "o:errorCode" : "27040",
        "o:errorPath" : "/parts/1/payload/EmpName"
    }, {
        "detail" : "Attribute EmpName in Emp is required.",
        "o:errorCode" : "27014",
        "o:errorPath" : "/parts/1"
    }, {
        "detail" : "Value SampleEmpxxxxxxxxxxxxxxxxxx for field EmpName
exceeds the maximum length allowed.",
        "o:errorCode" : "27040",
        "o:errorPath" : "/parts/2/payload/Employees/0/EmpName"
    }, {
        "detail" : "Attribute EmpName in
AM.Dept_empWorksIn_deptToEmpQA_EmpViewDef is required.",
        "o:errorCode" : "27014",
        "o:errorPath" : "/parts/2"
    }, {
        "detail" : "Not Found",
        "o:errorCode" : "11404",
        "o:errorPath" : "/parts/3"
    } ]
}
```

Obtaining Warning Messages in the Payload Response

The ADF REST runtime supports obtaining warning details in the response when your request is enabled to use ADF REST framework version 6 and the request is made with an appropriate media type.

Starting with version 6 of the REST API framework, web applications may obtain a warning response with a response payload.

Notice in the exception payload the `o:errorPaths` element provides the error path for where the error occurred in the request object; however, these particular details depend upon validation rules set on the entity object backing the resource.

The following sample attempts to create the department object with a new department item. However, for this example the request fails because the `DeptName` for the department is specified as not allowed in the validation method of the `Departments` entity object.

Request Example 1 Made With Framework Version 6

- **URL**

  `http://server/demo/rest/12.0/Departments`

- **HTTP Method**

  POST

- **Accept Header**

  `application/vnd.oracle.adf.resourceitem+json,application/json`

- **Payload**

```
{
    "DeptNum" : 50,
    "DeptName" : "ABC",
}
```

Response Example 1 From Framework Version 6

- **HTTP Code**

  `201`

- **Content-Type**

  `application/json`

- **Payload**

```
...
  "@context" : {
    ...
  } ],
  "warnings": [ {
    "detail": "Warning from overridden validateEntity method in DeptImpl : 
DeptName = ABC or DEF"
  }, {
    "detail": "Attribute set with value 50 for DeptNum in Dept failed",
    "o:errorCode": "27011",
    "o:errorPath": "/DeptNum"
  }, {
    "detail": "Warning from overridden create method in DeptViewDefRowImpl"
  }, {
    "detail": "Warning from overridden afterCommit method in DeptViewImpl"
  } ]
 }
}
```

The following sample attempts to create the department object with a new department item. However, for this example the request fails because the employee salary entered does not meet the salary allowed by the validation rule defined for the `EmpSalary` field.

Request Example 2 Made With Framework Version 6

- **URL**

  `http://server/demo/rest/11.1/Departments`

- **HTTP Method**

  POST

- **Accept Header**

```
application/vnd.oracle.adf.resourceitem+json
```

- **Payload**

```
{
   "DeptNum" : 52,
   "DeptName" : "newDept522",
   "Employees" : [ {
        "EmpNum" : 501,
        "EmpName" : "MILLER
        "EmpSalary" : "85"
      }
   ]
}
```

Response Example 2 From Framework Version 6

- **HTTP Code**

```
200
```

- **Content-Type**

```
application/vnd.oracle.adf.error+json
```

- **Payload**

```
...
  "@context" : {
    ...
  } ],
  "warnings": [ {
    "detail": "Warning from Emp entity expressionValidator : Salary value is
< 100.",
    "o:errorCode": "ExcTooLow",
    "o:errorPath": "/Employees/10"
  }, ]
 }
}
```

Advanced Operations

You can use the HTTP methods at ADF REST runtime to perform advanced operations such as fetching a resource collection with a row finder, obtaining a count of resource items in a resource collection, querying a resource with a filter, and retrieving LOV attribute values for an existing resource item.
The ADF REST runtime supports the following advanced use cases:

- Retrieving LOV attribute values in the context of an existing resource item.
- Querying a resource with a partial get using filtering to restrict attributes.
- Fetching the resource collection with a row finder.
- Returning just the data of the resource item or resource collection.
- Returning the estimated count of resource items in a resource collection.
- Overriding the HTTP method to perform an update
- Making batch requests.

Querying With Filtering Attributes (Partial Get)

The ADF REST runtime supports retrieving a subset of fields from resource collections using a GET method.

The payload structure of nested child resource differs depending on the ADF REST framework version that has been registered for the ADF REST service client. For details about the ADF REST framework versions, see What You May Need to Know About Versioning the ADF REST Runtime Framework.

The following samples are based on two different versions of the `Employees` resource and `Departments` resource. The URL samples showing resource `11.0` reflect a response payload structure supported by ADF REST framework versions 1 and 2. While the URL samples showing resource `11.1`, reflect the response payload structure supported in ADF REST framework version 3 (and later). In both framework scenarios, the samples fetch the `Employees` resource as a child of the `Departments` resource.

> **Note:**
>
> SQL SELECT statements executed by the ADF REST resource's backing view object are based on how the view object was created. Only view objects that the ADF Business Components developer creates with declarative SQL mode enabled support optimized SQL SELECT statements formed exclusively by the list of attributes named by the query parameter `fields`. The SELECT statement executed by non-declarative view objects will contain all attributes of the view object definition. To gain this runtime optimization, it is therefore recommended that ADF Business Components developers create view objects for ADF REST resources using only declarative SQL mode.

ADF REST Framework Version 3 (and later)

Starting with version 3 of the ADF REST framework, the ADF REST runtime returns a nested child resource in the response payload as a resource collection, instead of as an array of resource items. This functionality, available in framework version 3 (and later), allows service clients to make a request for additional records after determining how many items were left unfetched in the initial request. The attributes `hasMore` and `count` on the child resource indicate whether more items may be returned from the resource collection. For details about using the pagination attributes from the response payload when you opt into ADF REST framework version 3, see Paging a Resource Collection.

The following sample illustrates functionality for ADF REST framework version 3 (and later). The response payload represents the nested child resource as a resource collection, where the collection object includes the `hasMore` and `count` attributes. A link is provided should it be necessary to query the child resource for additional resource items. In this sample, the response payload shows the `hasMore` attribute is `false`, suggesting that no items remain unfetched on the Employees child resource for either department 10 or department 20.

Request Made With Framework Version 3

- **URL**

```
http://server/demo/rest/11.1/Departments?
fields=DepartmentId;Employees:FirstName&onlyData=true
```

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response Made With Framework Version 3

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourcecollection+json`

- **Payload**

```
{
    "items" : [ {
        "DepartmentId" : 10,
        "Employees" : {
            "items" : [ {
               {
                   "FirstName" : "Jennifer"
                  }
         }  ],
         "count" : 1,
         "hasMore" : false,
         "limit" : 25,
         "offset" : 0,
         "links" : [ {
             "rel" : "self",
             "href" : "http://server/demo/rest/11.1/Departments/10/child/
Employees",
             "name" : "Employees",
             "kind" : "collection"
        }, ]
     }, {
        "DepartmentId" : 20,
            "Employees" : {
                "items" : [ {
                   {
                       "FirstName" : "Michael"
                   },
                   {
                       "FirstName" : "Pat"
                   }
         }  ],
         "count" : 2,
         "hasMore" : false,
         "limit" : 25,
         "offset" : 0,
         "links" : [ {
             "rel" : "self",
             "href" : "http://server/demo/rest/11.1/Departments/20/child/
Employees",
              "name" : "Employees",
              "kind" : "collection"
        }, ]
     }, {
      ...
    ],
    "count" : 25,
    "hasMore" : true,
    "limit" : 25,
    "offset" : 0,
    "links" : [
        {
            "rel" : "self",
            "href" : "http://server/demo/rest/11.1/Departments",
            "name" : "Departments",
            "kind" : "collection"
        }
    ]
```

ADF REST Framework Version 1 or Version 2

Version 1 and version 2 of the ADF REST framework return the nested child resource expanded in the response payload as an array of resource items. If the resource collection being fetched is large, several requests will be required to fetch all items.

The following samples fetch the attribute values for instances of the `Departments` and `Employees` collections. The query parameter `fields` ensures the response payload contains only the specified attributes. Note that a GET request may return no values for any resource in the URL that does not specify an attribute value.

The first request (URL 1) fetches the values for an instance of the `Employees` collection. The query parameter `fields` ensures the response payload contains only the specified attributes: `FirstName`, `LastName`, and `Email`.

The second request (URL 2) fetches the `DepartmentId` values for instances of the `Departments` collection and the `FirstName` value for employees of each department. The query parameter `onlyData` filters the response to hide child links.

The third request (URL 3) fetches the `DepartmentId` values for instances of the `Departments` collection, the `FirstName` value for employees of each department, and the `JobId` history for each employee. The query parameter `onlyData` again filters the response to hide child links.

Request 1 Made With Framework Version 1 or 2

- **URL 1**

  `http://server/demo/rest/11.0/Employees/101?`
  `fields=FirstName,LastName,Email`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response 1 From Framework Version 1 or 2

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload 1**

```
{
  "FirstName" : "Neena",
  "LastName" : "Smith",
  "Email" : "NSMITH",
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.0/Employees/101",
    "name" : "Employees",
    "kind" : "item"
  }, {
    "rel" : "canonical",
    "href" : "http://server/demo/rest/11.0/Employees/101",
    "name" : "Employees",
    "kind" : "item"
  }, {
    "rel" : "lov",
    "href" : "http://server/demo/rest/11.0/Employees/101/lov/JobsLOV",
    "name" : "JobsLOV",
    "kind" : "collection"
  } ]
}
```

Request 2 Made With Framework Version 1 or 2

- **URL 2**

  `http://server/demo/rest/11.0/Departments?fields=DepartmentId;Employees:FirstName&onlyData=true`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response 2 From Framework Version 1 or 2

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourcecollection+json`

- **Payload 2**

```
{
    "items" : [
        {
            "DepartmentId" : 10,
            "Employees" : [
                {
                    "FirstName" : "Jennifer"
                }
            ]
        },
        {
            "DepartmentId" : 20,
            "Employees" : [
                {
                    "FirstName" : "Michael"
                },
                {
                    "FirstName" : "Pat"
                }
            ]
        },
        {
            "DepartmentId" : 30,
            "Employees" : [
                {
                    "FirstName" : "Den"
                },
                {
                    "FirstName" : "Alexander"
                },
                {
                    "FirstName" : "Shelli"
                },
                {
                    "FirstName" : "Sigal"
                },
                {
                    "FirstName" : "Guy"
                },
                {
                    "FirstName" : "Karen"
                }
            ]
        },
        {
            "DepartmentId" : 40,
            "Employees" : [
                {
                    "FirstName" : "Susan"
                }
            ]
        },
      ...
    ],
    "count" : 25,
    "hasMore" : true,
    "limit" : 25,
    "offset" : 0,
    "links" : [
        {
            "rel" : "self",
            "href" : "http://server/demo/rest/11.0/Departments",
            "name" : "Departments",
                "kind" : "collection"
            }
        ]
```

Request 3 Made With Framework Version 1 or 2

- **URL 3**

  `http://server/demo/rest/11.0/Departments?fields=DepartmentId;Employees:FirstName;Employees.JobHistory:JobId&onlyData=true`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response 3 From Framework Version 1 or 2

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourcecollection+json`

- **Payload 3**

```
{
    "items" : [

        {
            "DepartmentId" : 10,
            "Employees" : [
                {
                    "FirstName" : "Jennifer",
                    "JobHistory" : [
                        {
                            "JobId" : "AD_ASST"
                        },
                        {
                            "JobId" : "AC_ACCOUNT"
                        }
                    ]
                }
            ]
        },
        {
            "DepartmentId" : 20,
            "Employees" : [
                {
                    "FirstName" : "Michael",
                    "JobHistory" : [
                        {
                            "JobId" : "MK_REP"
                        }
                    ]
                },
                {
                    "FirstName" : "Pat",
                    "JobHistory" : [
                        {
                            "JobId" : "AD_ASST"
                        },
                        {
                            "JobId" : "AC_ACCOUNT"
                        }
                    ]
                }
            ]
        },
        {
            "DepartmentId" : 30,
            "Employees" : [
                {
                    "FirstName" : "Den",
                    "JobHistory" : [
                        {
                            "JobId" : "ST_CLERK"
                        }
                    ]
                },
                {
                    "FirstName" : "Alexander",
                    "JobHistory" : [
                        {
                            "JobId" : "AD_ASST"
                        },
                        {
                            "JobId" : "AC_ACCOUNT"
                        }
                    ]
                },
                {
                    "FirstName" : "Shelli",
                    "JobHistory" : [
                        {
                            "JobId" : "AD_ASST"
                        },
                        {
                            "JobId" : "AC_ACCOUNT"
                        }
                    ]

            ]
          ...
    ],
    "count" : 25,
    "hasMore" : false,
    "limit" : 25,
    "offset" : 0,
    "links" : [
        {
            "rel" : "self",
            "href" : "http://server/demo/rest/11.0/Departments",
            "name" : "Departments",
            "kind" : "collection"
        }
        ]
    }
```

Filtering a Resource Collection with a Row Finder

The ADF REST runtime supports applying a row finder to fetch a resource collection using a GET method. The ADF REST resource developer defines seeded filters called row finders. The ADF REST runtime supports passing parameters into these filters and supports using the seeded filters to reduce (or filter) the collection.

Filtering with a row finder is performed using the **finder** query string to specify one or more row finder parameter values. The **finder** with row finder query string parameter format is:

```
finder=<rowfinderName>;<attr1>=<value1>,<attr2>=<value2>,...
```

Example: `finder=DeptByName;Dname=ACCOUNTING`

The resource collection describe explains the shape of a row finder. To work with the row finder:

1. Execute the resource describe and locate the `finders` attribute in the collection element. The `name` attribute identifies the row finder definition name. Also locate the name of the row finder parameter under `attributes`.
2. Execute a GET with the query parameter `finder` and pass the row finder name and parameters.

For example, the Departments resources describe returns the following:

```
"collection" : {
     "rangeSize" : 25,
     "finders" : [ {
       "name" : "EmpByEmailFinder",
       "title" : "EmployeesByEmailVC",
       "attributes" : [ {
         "name" : "Email",
         "type" : "string",
         "updatable" : true,
         "required" : "Optional",
         "queryable" : false
} ]
```

The following sample fetches the `Departments` collection specified by a row finder `EmpByEmailFinder` where the `Email` attribute value `NSMITH` is passed.

Request

- **URL**

  ```
  http://server/demo/rest/11.1/Employees?
  finder=EmpByNameFinder;Email=NSMITH
  ```

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

none

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload**

```
{
  "items" : [ {
    "EmployeeId" : 101,
    "FirstName" : "Neena",
    "LastName" : "Smith",
    "Email" : "NSMITH",
    "JobId" : "AD_VP",
    "DepartmentId" : 90,
    "Salary" : 2000,
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/11.1/Employees/101",
      "name" : "Employees",
      "kind" : "item"
    }, {
      "rel" : "canonical",
      "href" : "http://server/demo/rest/11.1/Employees/101",
      "name" : "Employees",
      "kind" : "item"
    }, {
      "rel" : "lov",
      "href" : "http://server/demo/rest/11.1/Employees/101/lov/JobsLOV",
      "name" : "JobsLOV",
      "kind" : "collection"
    } ]
  } ],
  "count" : 1,
  "hasMore" : false,
  "limit" : 25,
  "offset" : 0,
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.1/Employees",
    "name" : "Employees",
    "kind" : "collection"
  } ]
}
```

Returning Only Resource Data in a Payload

The ADF REST runtime supports retrieving only the data of resource items using a GET method of a resource collection or a resource item.

The following sample fetches the values of the `Employees` collection attributes. The query parameter `onlyData` ensures the representation is filtered to contain only data in the response payload and no links.

Request

- **URL**

  `http://server/demo/rest/11.1/Employees?onlyData=true`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload**

```
{
  "items" : [ {
    "EmployeeId" : 101,
    "FirstName" : "Neena",
    "LastName" : "Smith",
    "Email" : "NSMITH",
    "JobId" : "AD_VP",
    "DepartmentId" : 90,
    "Salary" : 2000
  }, {
    "EmployeeId" : 102,
    "FirstName" : "Lex",
    "LastName" : "De Haan",
    "Email" : "LDEHAAN",
    "JobId" : "AD_VP",
    "DepartmentId" : 90,
    "Salary" : 3000
  }, {
    "EmployeeId" : 103,
    "FirstName" : "Alexander",
    "LastName" : "Hunold",
    "Email" : "AHUNOLD",
    "JobId" : "IT_PROG",
    "DepartmentId" : 60,
    "Salary" : 4000
  }, {
    "EmployeeId" : 104,
    "FirstName" : "Bruce",
    "LastName" : "Ernst",
    "Email" : "BERNST",
    "JobId" : "IT_PROG",
    "DepartmentId" : 60,
    "Salary" : 5000
  }, {
    "EmployeeId" : 105,
    "FirstName" : "David",
    "LastName" : "Austin",
      "Email" : "DAUSTIN",
      "JobId" : "IT_PROG",
      "DepartmentId" : 60,
      "Salary" : 6000
    } ],
    "count" : 5,
    "hasMore" : true,
    "limit" : 25,
    "offset" : 0,
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/11.1/Employees",
      "name" : "Employees",
      "kind" : "collection"
    } ]
  }
```

Returning the Estimated Count of Resource Items

The ADF REST runtime supports retrieving the estimated item count in the resource collection.

The following sample estimates the total records and queries the first two items in the `Employee` collection. The query parameter `totalResults` ensures the response payload contains the `totalResults` attribute.

Request

- **URL**

  `http://server/demo/rest/11.1/Employees?totalResults=true&limit=2`

- **HTTP Method**

  GET

- **Content-Type**

  none

- **Payload**

  none

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload**

```
{
  "items" : [ {
    "EmployeeId" : 101,
    "FirstName" : "Neena",
    "LastName" : "Smith",
    "Email" : "NSMITH",
    "JobId" : "AD_VP",
    "DepartmentId" : 90,
    "Salary" : 2000,
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/11.1/Employees/NSMITH",
      "name" : "Employees",
      "kind" : "item"
    }, {
      "rel" : "canonical",
      "href" : "http://server/demo/rest/11.1/Employees/NSMITH",
      "name" : "Employees",
      "kind" : "item"
    }, {
      "rel" : "lov",
      "href" : "http://server/demo/rest/11.1/Employees/NSMITH/lov/JobsLOV",
      "name" : "JobsLOV",
      "kind" : "collection"
    } ]
  }, {
    "EmployeeId" : 102,
    "FirstName" : "Lex",
    "LastName" : "De Haan",
    "Email" : "LDEHAAN",
    "JobId" : "AD_VP",
    "DepartmentId" : 90,
    "Salary" : 3000,
    "links" : [ {
      "rel" : "self",
      "href" : "http://server/demo/rest/11.1/Employees/LDEHAAN",
      "name" : "Employees",
      "kind" : "item"
    }, {
      "rel" : "canonical",
      "href" : "http://server/demo/rest/11.1/Employees/LDEHAAN",
      "name" : "Employees",
      "kind" : "item"
    }, {
      "rel" : "lov",
      "href" : "http://server/demo/rest/11.1/Employees/LDEHAAN/lov/JobsLOV",
      "name" : "JobsLOV",
      "kind" : "collection"
    } ]
  } ],
  "totalResults" : 5,
  "count" : 2,
  "hasMore" : true,
  "limit" : 2,
  "offset" : 0,
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.1/Employees",
    "name" : "Employees",
    "kind" : "collection"
  } ]
}
```

Overriding the HTTP Method and Performing an Update

Some HTTP servers or clients do not support exposing all the methods in the HTTP specification. The ADF REST runtime allows you to use the popular POST method to carry out operations for other methods.

The following sample uses the POST method to update a `Departments` resource item by overriding the PATCH method.

Request

- **URL**

  `http://server/demo/rest/11.1/Departments/15`

- **HTTP Method**

  POST

- **X-HTTP-Method-Override**

  PATCH

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload**

```
{
  "DepartmentName": "UpdatedDept",
}
```

Response

- **HTTP Code**

  `200`

- **Content-Type**

  `application/vnd.oracle.adf.resourceitem+json`

- **Payload**

```
{
  "DepartmentId" : 15,
  "DepartmentName" : "UpdatedDept",
  "links" : [ {
    "rel" : "self",
    "href" : "http://server/demo/rest/11.1/Departments/15",
    "name" : "Departments",
    "kind" : "item"
    }
  }, {
    "rel" : "canonical",
    "href" : "http://server/demo/rest/11.1/Departments/15",
    "name" : "Departments",
    "kind" : "item"
  }, {
    "rel" : "child",
    "href" : "http://server/demo/rest/11.1/Departments/15/child/Employees",
    "name" : "Employees",
    "kind" : "collection"
  } ]
}
```

Making Batch Requests

The ADF REST runtime supports executing multiple operations in a single roundtrip using a batch request. The data is committed at the end of the request. However, if one request part in a batch request fails, then all changes are rolled back and an error response is returned.

A batch request can consist of a combination of create, update, delete, upsert, and get requests. The path parameter and the payload needs to be the same as what you use to invoke the request directly. The get method supports the same URL parameters in the batch request as a separate HTTP request.

The following sample illustrates a successful batch operation that executes operations in four parts: 1) update employee 101, 2) update employee 102, 3) update employee 103, 4) query employee 101.

Request

- **URL**

  `http://server/demo/rest/11.1`

- **HTTP Method**

  POST

- **Content-Type**

  `application/vnd.oracle.adf.batch+json`

- **Payload**

```
{
    "parts": [{
        "id": "part1",
        "path": "/Employees/101",
        "operation": "update",
        "payload": {
            "Salary": 10000
        }
    }, {
        "id": "part2",
        "path": "/Employees/102",
        "operation": "update",
        "payload": {
            "Salary": 10000
        }
    }, {
        "id": "part3",
        "path": "/Employees/103",
        "operation": "update",
        "payload": {
            "Salary": 10000
        }
    }, {
        "id": "part4",
        "path": "/Employees?q=EmployeeId%3D101",
        "operation": "get"
    }]
}
```

Response

- **HTTP Code**

  `200`

- **Content-Type**

```
application/vnd.oracle.adf.batch+json
```

- **Payload**

```
{
    "parts": [{
        "id": "part1",
        "path": "http://server/demo/rest/11.1/Employees/101",
        "operation": "update",
        "payload": {
            "EmployeeId": 101,
            "FirstName": "Neena",
            "LastName": "Smith",
            "Email": "NSMITH",
            "JobId": "AD_VP",
            "DepartmentId": 90,
            "Salary": 10000,
            "links": [{
                "rel": "self",
                "href": "http://server/demo/rest/11.1/Employees/101",
                "name": "Employees",
                "kind": "item"
            }, {
                "rel": "canonical",
                "href": "http://server/demo/rest/11.1/Employees/101",
                "name": "Employees",
                "kind": "item"
            }, {
                "rel": "lov",
                "href": "http://server/demo/rest/11.1/Employees/101/lov/
JobsLOV",
                "name": "JobsLOV",
                "kind": "collection"
            }]
        }
    }, {
        "id": "part2",
        "path": "http://server/demo/rest/11.1/Employees/102",
        "operation": "update",
        "payload": {
            "EmployeeId": 102,
            "FirstName": "Lex",
            "LastName": "De Haan",
            "Email": "LDEHAAN",
            "JobId": "AD_VP",
            "DepartmentId": 90,
            "Salary": 10000,
            "links": [{
                "rel": "self",
                "href": "http://server/demo/rest/11.1/Employees/102",
                "name": "Employees",
                "kind": "item"
            }, {
                "rel": "canonical",
                "href": "http://server/demo/rest/11.1/Employees/102",
                "name": "Employees",
                "kind": "item"
            }, {
                "rel": "lov",
                "href": "http://server/demo/rest/11.1/Employees/102/lov/
JobsLOV",
                "name": "JobsLOV",
                "kind": "collection"
            }]
        }
    }, {
        "id": "part3",
        "path": "http://server/demo/rest/11.1/Employees/103",
        "operation": "update",
        "payload": {
            "EmployeeId": 103,
            "FirstName": "Alexander",
            "LastName": "Hunold",
            "Email": "AHUNOLD",
            "JobId": "IT_PROG",
            "DepartmentId": 60,
            "Salary": 10000,
            "links": [{
                "rel": "self",

                "kind": "item"
            }, {
                "rel": "lov",
                "href": "http://server/demo/rest/11.1/Employees/101/lov/
JobsLOV",
                "name": "JobsLOV",
                "kind": "collection"
                }]
            }
        }]
    }
```

ADF REST Framework Reference

ADF REST framework supports encoding of HTTP payloads, different media types, HTTP headers, and methods, so that the communication between the server and client is seamless and secure.
The ADF REST framework supports HTTP methods, HTTP headers, request URL parameters, media types, and other concepts to enable making REST API calls on resources.

ADF REST Describe links Object Structure

`links` is a JSON object where the value is always a URL link and the link name is defined according to the `rel` of the link. The `links` object is generated for each resource collection, item, and for the resource itself.

Note that URL links in the resource describe will be generated using a template placeholder value (`{id}`) when there is not enough information to determine all parts of the URL. For example, the following child link provides a URL with the placeholder for the value of the specific Department resource:

```
"item" : {
     "links" : [ {
        "rel" : "child",
        "href" : "http://server/demo/rest/11.0/Departments/{id}/child/Employees",
        "name" : "Employees",
        "kind" : "collection",
        "cardinality" : {
          "value" : "1 to *",
          "sourceAttributes" : "DepartmentId",
          "destinationAttributes" : "DepartmentId"
        }
```

rel Attribute Values

The `rel` attribute defines the type of link relationship between the current resource and the resource which the link points to. Relationships may be specified by any of the values shown in Table 22-3.

Table 22-3 Link Relationship in ADF REST Resource Describe

Link Relationship	Description
`self`	Always generated for a resource. The `href` points to the resource itself or to the resource describe. In the `links` object, the link name is `self` for this `rel`.
`canonical`	Always generated. The `href` points to the canonical resource or to the canonical resource describe. If a canonical resource is not defined, it will have the same `href` that `self` has. In the `links` object, the link name is `canonical` for this `rel`.

Table 22-3 (Cont.) Link Relationship in ADF REST Resource Describe

Link Relationship	Description
`parent`	Always generated for a nested resource. The `href` points to the `self` link of the parent resource. In the `links` object, the link name is `parent` for this `rel`.
`child`	Generated when the resource has nested children. The `href` points to the nested collection. In the `links` object, the link name is the accessor name for this `rel`.
`lov`	Generated on a resource item for LOV-enabled (list of values) attributes. There are two types of `href`: 1.) on the `links` object of the resource item, the `href` identifies an LOV child resource (name specified in the `childRef` property of the resource item), and 2.) on the `links` object of the resource describe, the `href` identifies a LOV resource (name specified in the `lovResourcePath` property on the resource item). The first type is defined in the model project by an LOV view accessor and an LOV-enabled attribute backing the resource item. The second type is defined in the model project by an LOV resource on the LOV view accessor and the resource is associated with the LOV-enabled attribute backing the resource item.
`enclosure`	Generated for BLOB and CLOB attributes by default. This relationship indicates that the link points to a resource that cannot be represented with the supported payload types. An image, that cannot be represented in JSON, is an example of this relationship. Use the `enclosure` link (can be obtained from resource item `describe`, `get`, or `post/patch` response) to read/update/delete content.
`external`	Generated for a resource that exists outside of the framework domain.
`current`	Generated in the resource version describe when multiple resource version identifiers exist. The `href` points to the most recent version identifier, as defined by the `adf-config.xml` version definition.
`predecessor-version`	Generated in the resource version describe when multiple resource version identifiers exist. The `href` points to the previous version identifier, as defined by the `adf-config.xml` version definition.
`successor-version`	Generated in the resource version describe when multiple resource version identifiers exist. The `href` points to the next most recent version identifier, as defined by the `adf-config.xml` version definition.
`describe`	Generated in the resource version describe. The `href` points to the resource catalog describe for all resources of the same version.

href Attribute Value

The `href` attribute defines the URL to the linked resource or resource describe.

cardinality Attribute Values

The `cardinality` attribute is an optional attribute that defines the cardinality between the source resource and the destination resource. This attribute will be available only when the `rel` attribute value is `child` and the resource type is `vnd.oracle.adf.description+json`. This cardinality attribute has the following attributes.

- `value`: The value of the cardinality. Example: "`1 to *`"
- `sourceAttributes`: The attribute in the source resource used to link to the destination resource.
- `destinationAttributes`: The attribute in the destination resource used to link to the source resource.

ADF REST API Framework Versions

A framework version refers to a specific version of the ADF REST framework available starting in a particular Oracle JDeveloper release.

The ADF REST runtime supports clients to specify a framework version that affects the processing of the payload or indicate the default framework version (as configured by the server) to be used. When you specify a framework version to process requests, it allows clients to opt into those features when they are ready. For example, to support both `rowmatch` expressions (offered in framework version 2 and later) and the query-by-example syntax (version 1 only), you would need to associate framework version 2 (or later) with a new release version identifier that you define in the web application. For example, in the URL samples given below, you can preserve the original functionality for release version 11.0 and expose the new functionality for version 11.1. This assumes that web application has declared framework version 2 the default on release version 11.1. Alternatively, if your web application will no longer require the functionality of your current framework version, you may associate the new framework version with your existing release version identifier. Therefore, you are not required to increment the release version to make use of a new framework version. For details about the ADF REST framework functionality supported in each framework version, see What You May Need to Know About Versioning the ADF REST Framework.

When a request does not specify a framework version, all payloads for URIs starting with `/context/<release-version>/` will assume the default framework version as declared in the `adf-config.xml` file.

> **Note:**
>
> Each ADF REST framework version after version 1 introduces functionality that the previous framework versions does not support. Thus, when you choose to opt into a later framework version, the REST API of your application may introduce backward incompatible changes on the service client consuming the REST API. In the table below, see the Does Not Support column for backward compatibility issues.

The following table explains the changes for each framework version.

Table 22-4 ADF REST API Framework Versions

REST API Framework Version	Supports	Does Not Support	Examples
1 - Default version. Use to process requests for web applications when no other version is specified	Supports query-by-example resource query syntax Filtering resource collections using the q query parameter is limited to a query-by-example.		`GET /rest/19.0/Departments?q=Dname SA*;Loc BOSTON`
2 - You must specify the version for the request. Only then the REST API support the use of expanded expression syntax to process the request.	Supports more advanced query syntax for making REST API calls. Interprets `q` query parameter value differently than Framework version 1. Supports filtering resource collections using `rowmatch` query expressions.	Query-by-example resource query syntax is not compatible. Introduces a backward incompatible change to web application that rely on Framework version 1.	See What You May Need to Know About the Advanced Query Syntax in ADF REST Framework Version 2
3 - The payload structure represents nested child resource as a resource collection, instead of an array of items as in version 1 and 2	Supports retrieving nested child resources with payload attributes that may be used by the web application to determine whether more resource items would be returned in a subsequent REST API request. Supports pagination of nested child resource that would otherwise require more than one request to fetch. Exposes functionality that allows `GET` operations to use the `?expand` and `?fields` query parameter to return a nested child resource as a resource collection with the `hasMore` attribute	Introduces a backward incompatible change to web application that rely on Framework version 1 or 2.	See Querying With Filtering Attributes (Partial Get). Also see Obtaining the Standard Error Message Response for error response.

Table 22-4 (Cont.) ADF REST API Framework Versions

REST API Framework Version	Supports	Does Not Support	Examples
4 – Possible to obtain exception details in the response when your request is enabled to use REST API framework version 4 and the request is made for either `application/vnd.oracle.adf.error+json` or `application/json` media types.	Supports the response in the form an exception detail payload that provides the following benefits to the web application: • Presents the details of each error in a hierarchical structure if multiple errors occur in a single request. • Identifies the exception corresponding to each error by including an application specific error code. • Presents an error path that identifies the location of each error in the request payload structure.	The exception detail may or may not present certain details, such as the application-specific error code and the request payload's error path.	See Obtaining an Exception Payload Error Response.
5 - Possible to share the LOVs that may not depend on the row context to filter out records. Also possible to share the LOVs with multiple resources. LOV resources will be represented by its own top-level resource and the row context LOV URLs are no longer returned in the payload and in the describe.	Removes the dependency of LOVs to be nested inside a resource parameters in the LOV resource URL. Enhanced support for request and response parameters beyond the current supported types of string, number, date, and boolean.	Nested levels of LOV resource URL.	`GET /rest/v1/Cities?finder=ByStateFinder;stateName={State}",` See What You May Need to Know About Configuring LOV Resources for Row Finders. The supported Java types include `java.util.List` and `java.util.Map`.

Table 22-4 (Cont.) ADF REST API Framework Versions

REST API Framework Version	Supports	Does Not Support	Examples

6 - Supports differentiation between the resource fields and the item context information like links and headers. Also displays warnings in the response payload in the context section for create/upsert and update actions.	Non-attribute fields like links and headers appear within @context field in resource item response object
	links field in @context will no longer have the properties field.
	headers -> ETag has the changeIndicator value.
	key field under @context contains the unique identifier of the specific resource item as a string.
	warnings field under @context contains the validation error details when a validation rule has been enabled on a backing entity object attribute.
			...
			"@context" : {
			"key" : "AB8765BCD",
			"headers" : {
			"ETag" : "ACED..."
			...
			},
			"links": [{
			"rel": "self",
			"href":
			...
			}]
			"warnings": [{
			"detail": "Warning from overridden validateEntity method in DeptImpl : DeptName = ABC"
			}, {
			"detail": "Attribute set with value 92 for DeptNum in Dept failed",
			"o:errorCode": "27011",
			"o:errorPath": "/DeptNum"
			}, {
			"detail": "Warning from overridden afterCommit method in DeptViewImpl"
			}, {
			"detail": "Warning from overridden afterCommit method in DeptViewImpl"
			}]
			}
			}

7 - Provides an option to remove row-level LOV resource descriptions in describe and from the resource item payload links section.	Supports the use of top-level LOV resource links	Row context LOVs in the describe and payloads	

ADF REST Payload Compression Support

The HTTP payloads that are exchanged between the server and the client can be encoded. This feature is enabled when the client specifies an `Accept-Encoding: gzip` header or `Content-Encoding` header in the service request.

To disable encoding support for resources, you may set the custom property `adf.rest.enablecompression` to `false`. In JDeveloper, the property is set in the ADF configuration file (`adf-config.xml`) of the Fusion web application.

Table 22-5 describes the content-encoding tokens supported by the ADF REST framework.

Table 22-5 Supported Content-Encoding Tokens

Content-Encoding	Description
`identity`	Does not compress the payload. The behavior is the same as when the encoding is omitted.
`x-gzip` and `gzip`	Compresses the payload using the format produced by the file compression program `gzip` (GNU zip), as described in RFC 1952 [25]. This format is a `Lempel-Ziv` coding (LZ77) with a 32 bit CRC.
`deflate`	Compresses the payload with a combination of the `zlib` format defined in FRC 1950 [31] and the `deflate` compression mechanism described in RFC 1951 [29].

ADF REST Media Types

Media types, also called MIME types or content types, define the allowed resource structure of the payload exchanged between the client and server. All ADF REST media types are based on JSON. Resources accessed in client applications fall under the `application` type and `json` subtype.

The service client invoking the REST API will interact with the RESTful web service using one of the media types listed in Table 22-6. The types are defined such that the media type does not vary with the view object definition backing the resource. Note that the value of the accept header depends on the context of the invocation. Links to the JSON token structure of the ADF REST framework media types are provided in the following table.

> **Note:**
>
> As an alternative to specifying the supported media types, the service client request accept header can specify `application/json` when a superset of all supported media types may be accepted in the response.

Table 22-6 Media Types Supported by the ADF REST Framework

Media Type	Invocation Context	Description
`application/vnd.oracle.adf.resourcecollection+json`	GET method	Represents the format for all resource collections returned by the ADF REST runtime. All attributes are automatically generated by the framework. Only the content of the `items` attribute is based on the resource definition. For an example, see Describing a Resource Collection.

Table 22-6 (Cont.) Media Types Supported by the ADF REST Framework

Media Type	Invocation Context	Description
`application/vnd.oracle.adf.resourceitem+json`	GET method POST method PATCH method	Represents the format for all resource items returned by the ADF REST runtime. Also represents the format for a resource item in a POST or PATCH request payload. Only the attribute `links` is automatically generated by the framework. All the other attributes are based on the resource definition. For an example, see Describing a Resource Item.
`application/vnd.oracle.adf.actionresult+json`	POST method	Describes the result of an action execution.
`application/vnd.oracle.adf.description+json`	GET method	Describes the resource and its elements. For an example, see Describing All Available Resources. .
`application/vnd.oracle.adf.batch+json`	POST method	Describes a set of operations to be performed, where the operation consists of a set of parts and each part represents a request. The batch request is executed in one single transaction. For an example, see Making Batch Requests.
`application/vnd.oracle.adf.version+json`	GET method	Describes the result of a request to get all versions of a resource. For an example, see Retrieving All Available Version Release Names.
`application/vnd.oracle.adf.error+json`	any	Describes the exception payload error response for a request made with an error. To use this media type and obtain the exception details in an error response payload, the request must be made with ADF REST framework version 4 (or later) enabled. For an example, see Obtaining an Exception Payload Error Response.

ADF REST Data Types

ADF REST data types are mapped by the ADF REST framework between ADF REST resource items and their backing ADF Business Components entity object attributes. At runtime, the framework exposes the data type of fetched ADF REST resource items as the describe attribute `type`.

Table 22-7 shows the relationship between the ADF Business Components data types supported on entity object attributes backing the view object of ADF REST resources and the corresponding ADF REST data types that the ADF REST framework defines. In general, the framework defines the data type of an ADF REST resource item based on the SQL type of the attribute backing the resource item, with these two exceptions:

- When the backing attribute is defined as a boolean type map, then the ADF REST type will always be a boolean.
- When the backing attribute’s Java type is blob or clob, then the ADF REST type will be an attachment.

Table 22-7 Data Types Supported by the ADF REST Framework

ADF Backing Attribute	ADF REST Data Type

Where an attribute is configured with one of the following type maps:
`oracle.jbo.valuemaps.Boolean10PropertySet`
`oracle.jbo.valuemaps.BooleanTFPropertySet`
`oracle.jbo.valuemaps.BooleanYNPropertySet`
	`boolean`

Java Class: `oracle.jbo.domain.ClobDomain` or `oracle.jbo.domain.BlobDomain`	`attachment`
Java Class: `java.util.List` supported starting in ADF REST framework version 5	`array`
Java Class: `java.util.Map` supported starting in ADF REST framework version 5	`object`
SQL type: `Char`	`string`
SQL type: `Number`	`integer`
SQL type: `Number` (precision = *, scale > 0)	`number`
SQL type: `Number` (precision < 10, scale = 0)	`integer`
SQL type: `Number` (precision >= 10, scale = 0)	`integer`

SQL type: `Date`	`date` if Java type is `java.sql.Date`
	`time` if Java type is `java.sql.Time`
	`datetime` if Java type is other (not `java.sql.Date` and not `java.sql.Time`)
	The REST service accepts the YYYY-`MM-DDThh:mm:ss.s+hh:mm` or YYYY-`MM-DDThh:mm:ss.s-hh:mm` format. If you specify the time without the ":" in the second part, `s+hhmm` or `s-hhmm`, it fails.

ADF REST HTTP Codes

The ADF REST framework supports the HTTP codes listed in the following table. The specific code that is returned depends on the HTTP method invoked on the web service.

Table 22-8 HTTP Codes Supported by the ADF REST Framework

HTTP Code	Description
`200 OK`	Request successfully executed and the response has content.
`201 Created`	Resource successfully created. The response contains the created resource.
`204 No Content`	Request successfully executed and the response doesn't have content.
`304 Not Modified`	According to the provided ETag, the resource was not modified.
`400 Bad Request`	The request could not be understood by the server due to malformed syntax.

Table 22-8 (Cont.) HTTP Codes Supported by the ADF REST Framework

HTTP Code	Description
401 Unauthorized	The server is refusing to service the request because the resource of the request is secured and authentication has not yet been provided.
404 Not Found	The requested resource was not found.
406 Not Acceptable	The resource identified by the request is only capable of generating response entities which have content characteristics not acceptable according to the accept headers sent in the request.
412 Precondition failed	The resource state in the server side doesn't match the provided ETag.
415 Unsupported Media Type	The server is refusing to service the request because the entity of the request is in a format not supported by the requested resource for the requested method.
500 Internal Server Error	The server encountered an unexpected condition which prevented it from fulfilling the request.

ADF REST HTTP Headers Support

The ADF REST framework supports the HTTP headers listed in the following table.

Table 22-9 HTTP Headers Supported by the ADF REST Framework

HTTP Header Name	Description
Content-Type	Use to specify the content-type of the request/response payload. The ADF REST runtime is able to interpret (request/response) the media types, as described in ADF REST Media Types.
Content-Encoding	Use to specify the content-encoding of the request/response payload. The ADF REST runtime is able to parse a compressed request that uses the encodings, as described in ADF REST Payload Compression Support.
Accept	Use to specify the expected content-type of the response payload. The ADF REST runtime is able to interpret (request/response) the media types, as described in ADF REST Media Types.
Accept-Encoding	Use to specify the list of acceptable encoded responses. The ADF REST framework is able to generate a response using the encodings described in ADF REST Payload Compression Support.
REST-Framework-Version	Use to specify the version of the ADF REST framework to use at runtime to process the request. The ADF REST framework version passed in the version header overrides the default framework declaration defined by the application in the adf-config.xml file, as described in Working with ADF REST Framework Versions.
Location	Use to identify the URI of a newly created resource. The ADF REST framework includes the Location header in the response of a POST to create a new resource. For an example, see Creating a Resource Item in Collection.

Table 22-9 (Cont.) HTTP Headers Supported by the ADF REST Framework

HTTP Header Name	Description
`ETag`	Use to compare the state of the resource in a request with the state of resource on the server. The ADF REST framework supports the `ETag` generation for resources backed by an ADF Business Components entity object that has been configured to use an change-indicator attribute. See Checking for Data Consistency.
`If-Match`	Use to determine whether the state of the resource in a request is current with the resource on the server. This header is supported in order to execute conditional requests. See Checking for Data Consistency.
`If-None-Match`	Use to determine whether the state of the resource in a request does not match the current state on the server. This header is supported in order to execute conditional requests. See Checking for Data Consistency.
`X-HTTP-Method-Override`	Use to execute an action that is otherwise not supported by the server. This is a custom header (not defined by the HTTP specification) that contains the name of an HTTP method as its value. This value (if valid) will be used to define the HTTP method that will be used. This header will only be considered in a POST request. See Overriding the HTTP Method and Performing an Update.
`X-Requested-By`	The presence of this header is enforced for every request when the anti-CSRF mechanism is turned on. The anti-CSRF mechanism can be turned on by setting the value of the `enableAntiCSRF` ResourceServlet init parameter to `True`. This header is not enforced if the GET, OPTIONS, and HEAD methods are used. If the header cannot be found, then 400 (Bad Request) is returned.

Table 22-9 (Cont.) HTTP Headers Supported by the ADF REST Framework

<table>
<tr><th>HTTP Header Name</th><th>Description</th></tr>
<tr><td>Cache-Control</td><td>Use to avoid intermediate proxies to cache/store framework payloads. This header is configured for every HTTP response. The value, by default, turns off caching, and the framework sends the response header: no-cache, no-store, must-revalidate.
However, an application developer may override the default behavior by configuring the resource definition. The value can be set on the resource tree and the header will be set accordingly. Currently, Cache-Control can be configured only as <MaxAge>
&lt;<i>seconds</i>&gt;&lt;/MaxAge>, if set in the resource tree. The following sample of a resource definition file shows how to set the value.<pre>
<pageDefinition ...>
  <parameters/>
  <executables/>
  <bindings>
    <tree ....>
      <ServiceConfiguration>
        <CacheControl>
          <MaxAge>30</MaxAge>
        </CacheControl>
      </ServiceConfiguration>
      <nodeDefinition ../>
    </tree>
  </bindings>
</pageDefinition>
</pre>The integer value supplied within <MaxAge> is used to create the Cache-Control string like max-age=30 to specify the resource will be considered fresh for thirty seconds. This value is also set in the Cache-Control header in the response for an operation involving any resource belonging to the resource tree.
If configured on the resource definition, the Cache-Control value is also shown in the describe, per resource.</td></tr>
<tr><td>Upsert-Mode</td><td>Use Upsert-Mode:true in a request that uses POST to create a resource item if the resource item does not exist, or update a resource item if the resource item exists. Note that a POST request with Upsert-Mode:false behaves as a POST without the custom header and performs the CREATE operation exclusively.</td></tr>
<tr><td>Prefer</td><td>You can use this header to receive only those fields that are included in the compact view of the response payload. You can specify the value return=minimal to receive only those fields that are marked includeInCompactView : true in the response payload. See How to Control the ADF REST Response Payload Fields.</td></tr>
<tr><td>REST-Pretty-Print</td><td>There is a reasonable formatting in REST response resulting in a lot of white space. You can use gzip to transport a zipped up response content. See ADF REST Payload Compression Support. However, the extracted content on the client would still contain the white spaces resulting in processing time on the clients that can be reduced considerably by using this header. See How to Control the Format of the ADF REST Response.</td></tr>
</table>

Table 22-9 (Cont.) HTTP Headers Supported by the ADF REST Framework

HTTP Header Name	Description

`Metadata-Context`	A metadata revision that indicates the MDS label to be used at runtime. A metadata revision is created at the end of an event that updates mainline metadata; for example, MDS MAR deployment or unified sandbox publishing.
	If your environment is unified sandbox enabled, you must use the sandbox property in the value, which is treated as the unified sandbox ID. The Metadata-Context header is honored only if the ApplSessionFilter is the first filter that initializes ADFContext. The mode for ADFSessionOptions is always set to EDIT when this header is present.
	If you specify a revision, ADFSessionOptions will be configured according to the metadata revision.
	If you want to execute the REST service in the context of a specific metadata revision, use the following syntax. This will ensure that the execution of REST service is isolated from other metadata changes happening in the application until the REST client is ready to consume those changes.
	`Metadata-Context: revision="<metadata revision ID>"`
	If you wan to test the REST services with changes in a sandbox, use the following syntax.
	`Metadata-Context: sandbox="<unified sandbox ID>"`

ADF REST HTTP Method and Payload Support

The ADF REST framework supports operations on the following HTTP methods.

- `GET`
- `POST`
- `PATCH`
- `DELETE`

GET Method Operations

The ADF REST framework supports the following operations using a GET method with the URI as shown.

- Describe the resource collection, resource item, or resource catalog (when resource collection and resource item are omitted).

  ```
  http://server/demo/rest/{version}/[{resourceCollectionPath}|
  {resourceItemPath}]/describe
  ```

- Retrieve the resource collection representation with or without a query string parameter.

  ```
  http://server/demo/rest/{version}/{resourceCollectionPath}[?
  {queryStringParam}[&{queryStringParam}]]
  ```

- Retrieve the resource item representation with or without a query string parameter.

  ```
  http://server/demo/rest/{version}/{resourceItemPath}[?{queryStringParam}
  [&{queryStringParam}]]
  ```

- Retrieve a specific version of the resource collection or all available resources (when version identifier and resource collection are omitted).

  ```
  http://server/demo/rest/[{version}/{resourceCollectionPath}]
  ```

Request Parameters

- The GET method supports query string parameters to query, filter, page, and sort the resource representation. The supported parameters are listed in the following tables. All GET method URI parameters can be combined with any other parameter in the table, except where noted on the `expand` and `field` parameters. Note that query string parameters can only be used on resource media types. They cannot, for example, be used when describing the resource.

> **Note:**
>
> The results of the GET method or the query syntax may vary depending on the ADF REST framework version used for a client request. The following tables specify where the framework version is important to note when using query string parameters. For additional information about framework versions, see What You May Need to Know About Versioning the ADF REST Runtime Framework.

Table 22-10 Supported GET Method Query String Parameters Used Only in Resource Collections

GET URI Parameter	Value	Description
q Starting in **ADF REST framework version 2**, q supports complex rowmatch expressions.	In framework version 1, the query parameter is used in the WHERE clause and contains one or more query by example-type expressions, separated by a semi-colon. Format: `<exp1>;<exp2>` Example: `?q=Deptno>=10 and <= 30;Loc!=NY` Starting in framework 2, for richer querying support, the query parameter accepts a rowmatch expression format that identifies the specific rows to retrieve from the resource. The filter can be as simple as a single expression, or you can create more complex filters by combining expressions using the `and` and `or` conjunctions with matching sets of parentheses for grouping. For example, the following expression uses conjunction to query the resource using three different fields: `(AssignedToId is null) or ( (Priority <= 2) and (RecordName like 'TT-99%'))` If a query parameter value has a special character (like ‘;’, ‘,’, ‘=’ or similar), then the value (in the expression) should be enclosed in quotes to define a literal value. If the literal value contains quotes, then, in addition, the quotes need to be escaped, as defined by the framework version, to be viable: • Version 1 syntax encloses the literal value in double quotes (`"`) and requires a backslash (`\`) to escape double quote	The resource collection will be queried using the provided expressions. Supported operators in framework version 1 and later: • = (Equal to) • > (Greater than) • < (Less than) • >= (Greater than or equal to) • <= (Less than or equal to) • `!=` (Not equal to) framework version 1 only • `AND` (And) • `OR` (Or) • `NOT` (Not) • `LIKE` (Like) Supported operators in framework version 2 and later also include: • <> (Not equal to) • `BETWEEN` (Between) • `NOT BETWEEN` (Not between) • `IN` (In) • `NOT IN` (Not in) • `IS NULL` (Null) • `IS NOT NULL` (Not Null) Allowed special characters in framework version 1: • `"` (double quotation mark) to define a literal value for use where special characters appear in the value • `'` (single quotation mark) to define a literal value for use where reserved words appear in the value • `\` (backslash) to define an escape character to escape a double quotation mark (`"`) or single quotation mark/ apostrophe (`'`) character used within a literal value • `*` (asterisk) to define a wildcard character Allowed special characters in framework version 2 and later: • `'` (single quotation mark) to define a literal value or to define an escape character to escape a single quotation mark/apostrophe (`'`) character used within a literal value • `%` (percent) to define a wildcard character For an example of the usage supported in ADF REST framework version 1 and version 2, see Filtering a Resource Collection with a Query Parameter. For examples of rowmatch expressions, see What You May Need to Know About the Advanced Query Syntax in ADF REST Framework Version 2.

Table 22-10 (Cont.) Supported GET Method Query String Parameters Used Only in Resource Collections

GET URI Parameter	Value	Description
	characters contained in the value: `?q=NickName="\"Billy the Kid\""` - Version 2, or later, syntax encloses the literal value in single quotes (`'`) and requires a single quote to escape a single quote character contained in the value (used as an apostrophe): `?q=ListName='Bill''s list'` Additionally, in version 1, if the query parameter value contains a reserved word (such as `AND` or `OR`), then the value needs to be enclosed in single quotes (`'`) and there must be a space before and after the quoted string. For example, the string matching filter `’Accounting and Finance’` in the following query parameter expression contains the reserved word `AND`, and therefore requires a space before and after the single quotation marks to be viable in version 1 syntax: `?q=DepartmentName= 'Accounting and Finance' &fields=DepartmentName` Note that starting in framework version 2, the use of a space character is no longer required to delimit a string matching filter that contains a reserved word. For version 1, if the value contains both a special character and a reserved word, then the value needs to be enclosed in single quotes (`'`), and then enclosed again in double quotes (`"`) , along with escaping the double quotes	

Table 22-10 (Cont.) Supported GET Method Query String Parameters Used Only in Resource Collections

GET URI Parameter	Value	Description
	contained within the value with a backslash (\), and there needs to be a space before and after the twice-quoted string. For example: `?q=DepartmentName= "'\"Accounting\" and Finance'" &fields=DepartmentName` For examples of the rowmatch expression format, see What You May Need to Know About the Advanced Query Syntax in ADF REST Framework Version 2.	

Table 22-10 (Cont.) Supported GET Method Query String Parameters Used Only in Resource Collections

GET URI Parameter	Value	Description
`finder`	An expression containing the primary key attribute value definition. Format: `PrimaryKey;<PKattr1>=<PKval1>,<PKattr2>=<PKval2>,...` Example: ?`finder=PrimaryKey;EmployeeId=101` Or: An expression containing information about the row finder and its finder attributes. Format: `<rowfinderName>;<attr1>=<val1>,<attr2>=<value2>` Example: ?`finder=DeptByName;Dname=ACCOUNTING` If the finder attribute value contains any special character like ';', ',', '=' (or similar), the value must be defined as a literal and enclosed in double quotes. For example: ?`finder=EmpByName;EmpName="Jones,Bill"` If the finder attribute value is a literal value (enclosed in double quotes) and the value contains double quotation marks `"`, the contained quotation marks must be preceded by the backslash escape `\` character to be viable as a finder attribute value. For example: ?`finder=EmpByName;NickName="\"Billy the Kid\""`	The resource collection will be queried using the provided primary key and attribute values definitions. Alternatively, the resource collection will be queried using the provided row finder and attribute definitions. Finders with parameters whose type does not belong to `char`, `date`, or `number`, will be filtered out. The list of available finders (primary key finder and row finder) is provided in the describe. Allowed special characters in framework version 1 and later: • `"` (double quotation mark) to define a literal value • `\` (backslash) to define an escape character to escape a double quotation mark (`"`) character used within a literal value For a primary key finder example, see Filtering a Resource Collection with Primary Key Values. For a row finder example, see Filtering a Resource Collection with a Row Finder.

Table 22-10 (Cont.) Supported GET Method Query String Parameters Used Only in Resource Collections

GET URI Parameter	Value	Description
`totalResults`	boolean Default: `false`	The resource collection representation will include the estimated row count when `totalResults=true`. For an example, see Returning the Estimated Count of Resource Items.
`limit`	integer Default: Iterator binding `RangeSize` property in the ADF REST resource definition file.	This parameter restricts the number of resources returned inside the resource collection. If the limit exceeds the resource total results, then the framework will return the available resources. For an example, see Paging a Resource Collection.
`offset`	integer Default: 0 (the first position)	Used to define the starting position of the resource collection. If offset exceeds the resource count, then no resources are returned. For an example, see Paging a Resource Collection.

Table 22-11 Supported GET Method Query String Parameters Used in Resource Collections or Resource Items

GET URI Parameter	Value	Description
`fields` Starting in **ADF REST framework version 3 and later**, `fields` will return children resource items as a resource collection to support pagination of the collection. For more information, see What Happens at Runtime: Invoking an ADF REST Framework Version.	A simple comma separate list of resource item attributes. Format: `<attr1>,<attr2>` Example: ?`fields=Dname,DLoc` May be used on child resources. Format: *`<accessor>:<att1>,<att2>`* Example: ?`fields=Employees:FirstName,LastName` May be used on nested resources using accessor dot notation. Format: *`<accessor1>.<accessor2>:<Attr1>,<Attr2>`* Example: ?`fields=Employees.JobHistory:JobId` Or on both resources in the nested resource. Format: *`<accessor1>:<Attr1>,<Attr2>;<accessor1>.<accessor2>:<Attr1>,<Attr2>`* Example: ?`fields=Name,Location;Employees:FirstName,LastName`	This parameter filters the resource item attributes. Only the specified attributes are returned. Note that if a nested resource is queried using the accessor dot notation (`Employees.JobHistory`), then attributes may be specified on both resources. A resource in the accessor dot notation without a specified attribute will return no resource item attributes. Note this parameter cannot be combined with the `expand` parameter. If both parameters are provided, only `fields` will be considered. For examples that uses version 1 or 2 of the ADF REST framework as compared to version 3 (and later), see Querying With Filtering Attributes (Partial Get).
`onlyData`	boolean Default: `false`	The representation will be filtered in order to contain only data (no `links` objects, for example). For an example, see Returning Only Resource Data in a Payload.

Table 22-11 (Cont.) Supported GET Method Query String Parameters Used in Resource Collections or Resource Items

GET URI Parameter	Value	Description
`expand` Starting in **ADF REST framework version 3 and later**, `expand` will return children resource items as a resource collection to support pagination of the collection. For more information, see What Happens at Runtime: Invoking an ADF REST Framework Version.	Display all children. Format: `all` Display one or more child resource using a comma-separated list of accessors. Format: `<accessor1>,<accessor2>` Example: `?expand=Employees,Localizations` Display nested resources using the accessor dot notation. Format: `<accessor1>.<accessor2>` Example: `?expand=Employees.JobHistory`	When this parameter is provided, the specified children are included in the resource payload (instead of the link). Note the `expand` parameter cannot be combined with the `fields` parameter. If both parameters are provided, only `fields` will be considered. Note that if a nested resource is queried using the accessor dot notation (`Employees.JobHistory`), then the missing children will be processed implicitly. For example, `?expand=Employees.JobHistory` is the same as `?expand=Employees,Employees.JobHistory` (which will expand `Employees` and `JobHistory`). For examples that uses version 1 or 2 of the ADF REST framework as compared to version 3 (and later), see Fetching Nested Child Resources.
`dependency`	A set of dependency attributes. Format: `<attr1>=<val1>,<attr2>=<value2>` Example: `dependency=ProductId=2`	The dependencies are attributes that are set before and rolled back after generating the response. Generally, they are used to preview the effects of an attribute change as it applies to cascading LOV-enabled attributes. The dependencies attributes are always set in the resource item in question. When a child resource collection is requested and the `dependency` parameter is set, the attributes will be set in the parent resource item before generating the resource collection payload.

Table 22-11 (Cont.) Supported GET Method Query String Parameters Used in Resource Collections or Resource Items

GET URI Parameter	Value	Description

`orderBy`	A comma separated list of order-by attributes with a sort flag to specify ascending or descending order.
	Format: `<orderBy_attr1_name>[:<(asc/desc)>],<orderBy_attr2_name>[:<(asc/desc)>]`
	Example: ?`orderBy=DName:desc,DLoc`
	Default: ORDERBY attributes defined on the view object query backing the resource will be applied.
	To perform case-insensitive sorting on a resource collection, the attribute list must follow this format, using either the `upper` or `lower` flag:
	`upper(<orderBy_attr1_name>):<(asc)>`
	or
	`lower(<orderBy_attr2_name>)`
		Sorts a resource collection based on its attributes. If the `asc/desc` are not provided (or an invalid value is provided), `asc` will be used as default.
		By default, the fetched collection will be sorted in a case sensitive way unless either the `upper` or `lower` flag is specified in the order-by query request.
		For an example, see Sorting a Resource Collection.

`links`	A comma separated list of `<rel_name>`, where `<rel_name>` is a string representing the relation type of a link. Example: `self,canonical`	When a resource item or a resource collection is requested and the `links` query parameter is used, then only those links with relation types ("`rel`") matching the values in the comma-separated parameter value will be shown in the response. Note the `links` parameter cannot be combined with `onlyData` when `onlyData` has a value of `true`, as there will be no links section displayed in the payload.

Table 22-12 Supported GET Method Query String Parameters Used in Resource Catalog Describe

GET URI Parameter	Value	Description

`metadataMode`	`verbose` (default)
	`minimal`
	`list`
		Use to retrieve the description of resources with or without all details. By default, the full catalog is retrieved, performing an exhaustive describe that returns the complete set of information for all resources, including nested children resources. The full catalog describe therefore includes the following sections of information for each resource:
		title, attributes, collection, item, annotations, children, and links
		Note that annotations must be defined by the ADF REST resource developer in the application and may not be present on the resource.
		You can improve the readability of a large catalog and retrieve a shallow catalog limited to the titles and links of parent resources (does not include children resources) by appending the URL parameter `?metadataMode=minimal` to the describe request.
		If you do not want any metadata in the response but only self links, you can append `?metadataMode=list` to the describe request.
		Optionally, additional parameters may be appended to the minimal describe request to include children resources and / or resource annotations, as explained for the query parameters `showAnnotations` and `includeChildren`. For example, you can append `?metadataMode=minimal&includeChildren=true` to retrieve a minimal catalog describe with all children resources included.
		For an example, see Retrieving a Minimal Catalog Describe.

`showAnnotations`	`true`, `false` (default depends on whether full or minimal catalog is retrieved)	Use to either exclude or include resource annotations, as specified in the application. The default depends on the `metadataMode` parameter value: • By default, a full catalog (`metadataMode=verbose`) describe includes annotations. To exclude resource annotations from the full catalog describe, you can append `?showAnnotations=false` on the describe request. • By default, a minimal catalog (`metadataMode=minimal`) describe excludes annotations. To include resource annotations in the minimal catalog describe, you can append `?showAnnotations=true` on the describe request. Note that annotations must be defined by the ADF REST resource developer in the application and may not be present on the resource. You cannot use this parameter with `?metadataMode=list`.

Table 22-12 (Cont.) Supported GET Method Query String Parameters Used in Resource Catalog Describe

GET URI Parameter	Value	Description
`include`	`public` (default), `unlisted`, `all`	Use to retrieve the description of resources of a certain visibility, as declared in the application. This URL parameter values specify including only public resources (`public`), only private resources (`unlisted`), or both types (`all`). By default, only resources that are public are shown in the describe. To view private resources, you must append either `?include=all` or `?include=unlisted` on the describe request. For an example, see Retrieving the Catalog Describe Based on Resource Visibility Declaration. For information about how the application developer declares visibility in the resource definition, see How to Hide a Resource from the Catalog Describe.
`resources`	A comma separated list of resource collection names. Format:`<resName1>,<resName2>` Example: `?resources=Departments,Employees`	Use to retrieve the description of the named resources to filter resources at the catalog level.

Table 22-13 Supported GET Method Query String Parameters Used in Resource Catalog Describe or Resource Item Describe

GET URI Parameter	Value	Description
`includeChildren`	`true`, `false` (default depends on whether full or minimal catalog is retrieved)	Use to either exclude or include all available children resources nested within a parent resource. The default depends on the `metadataMode` parameter value: • By default, a full catalog (`metadataMode=verbose`) describe includes all children resources. To exclude children resources from the full catalog describe, you can append `?includeChildren=false` on the describe request. • By default, a minimal catalog (`metadataMode=minimal`) describe excludes all children resources. To include children resources in the minimal catalog describe, you can append `?includeChildren=true` on the describe request. You cannot use this parameter with `?metadataMode=list`. For a resource catalog describe example, see Retrieving a Minimal Catalog Describe. When a resource item describe is requested and `?includeChildren=true` is provided, all children will be recursively included in the describe. For an example, see Describing a Resource Item.

Query String Operators Supported by ADF REST Data Types

The following table shows the ADF REST data types and the valid operators that may be used in query parameter strings. Note that the operators BETWEEN, NOT BETWEEN, IN, NOT IN, and the wildcard character % are available only starting in ADF REST framework version 2.

Table 22-14 Operators Supported by Data Types in Query (q) Parameter Strings

ADF REST Data Type	Supported Operator

integer	• = (Equal to)
	`.../Departments?q=Deptno = 20`
	• <> (Not equal to)
	`.../Departments?q=Deptno <> 20`
	• < (Less than)
	`.../Departments?q=Deptno < 20`
	• <= (Less than or equal to)
	`.../Departments?q=Deptno <= 20`
	• > (Greater than)
	`.../Departments?q=Deptno > 30`
	• >= (Greater than or equal to)
	`.../Departments?q=Deptno >= 30`
	• `BETWEEN` (Between)
	`.../Departments?q=Deptno BETWEEN 10 AND 30`
	• `NOT BETWEEN` (Not between)
	`.../Departments?q=Deptno NOT BETWEEN 10 and 30`
	• `IN` (In)
	`.../Departments?q=Deptno IN (10, 30)`
	• `NOT IN` (Not in)
	`.../Departments?q=Deptno NOT IN (10, 30)`
	• `IS NULL` (Is null)
	`.../Departments?q=Deptno IS NULL`
	• `NOT NULL` (Not null)
	`.../Departments?q=Deptno NOT NULL`

Table 22-14 (Cont.) Operators Supported by Data Types in Query (q) Parameter Strings

ADF REST Data Type	Supported Operator

number	• = (Equal to)
	`.../Departments?q=Salary = 3120.99`
	• <> (Not equal to)
	`.../Departments?q=Salary <> 3120.99`
	• < (Less than)
	`.../Departments?q=Salary < 3120.99`
	• <= (Less than or equal to)
	`.../Departments?q=Salary <= 3120.99`
	• > (Greater than)
	`.../Departments?q=Salary > 3120.99`
	• >= (Greater than or equal to)
	`.../Departments?q=Salary >= 3120.99`
	• `BETWEEN` (Between)
	`.../Departments?q=Salary BETWEEN 2000 AND 3120.99`
	• `NOT BETWEEN` (Not between)
	`.../Departments?q=Salary NOT BETWEEN 2000 and 3120.99`
	• `IN` (In)
	`.../Departments?q=Salary IN (800, 3120.99)`
	• `NOT IN` (Not in)
	`.../Departments?q=Salary NOT IN (800, 3120.99)`
	• `IS NULL` (Is null)
	`.../Departments?q=Salary IS NULL`
	• `NOT NULL` (Not null)
	`.../Departments?q=Salary NOT NULL`

Table 22-14 (Cont.) Operators Supported by Data Types in Query (q) Parameter Strings

ADF REST Data Type	Supported Operator

string	• = (Equal to)
	`.../Departments?q=DeptName = ’SALES’`
	• <> (Not equal to)
	`.../Departments?q=DeptName <> ’SALES’`
	• `LIKE` (Like)
	`.../Departments?q=DeptName LIKE ’SA%’`
	`.../Departments?q=DeptName LIKE ’%ES’`
	`.../Departments?q=UPPER(DeptName) LIKE UPPER('%e%')`
	• `NOT LIKE` (Not like)
	`.../Departments?q=UPPER(DeptName) NOT LIKE UPPER('%c%')`
	• `IN` (In)
	`.../Departments?q=DeptName IN ('SALES', 'RESEARCH')`
	• `NOT IN` (Not in)
	`.../Departments?q=DeptName NOT IN ('SALES', 'RESEARCH')`
	• `IS NULL` (Is null)
	`.../Departments?q=DeptName IS NULL`
	• `IS NOT NULL` (Is not null)
	`.../Departments?q=DeptName IS NOT NULL`

date	• = (Equal to)
	`.../Employees?q=HireDate = ’1999-01-01’`
	• <> (Not equal to)
	`.../Employees?q=HireDate <> ’1999-01-01’`
	• < (Less than)
	`.../Employees?q=HireDate < ’1999-01-01’`
	• <= (Less than or equal to)
	`.../Employees?q=HireDate <= ’1999-01-01’`
	• > (Greater than)
	`.../Employees?q=HireDate > ’1999-01-01’`
	• >= (Greater than or equal to)
	`.../Employees?q=HireDate >= ’1999-01-01’`
	• `BETWEEN` (Between)
	`.../Employees?q=HireDate BETWEEN ’1999-01-01’ AND ’2010-01-01’`
	• `NOT BETWEEN` (Not between)
	`.../Employees?q=HireDate NOT BETWEEN ’1999-01-01’ AND ’2010-01-01’`
	• `IS NULL` (Is null)
	`.../Employees?q=HireDate IS NULL`
	• `NOT NULL` (Not null)
	`.../Employees?q=HireDate NOT NULL`

Table 22-14 (Cont.) Operators Supported by Data Types in Query (q) Parameter Strings

ADF REST Data Type	Supported Operator

time	• = (Equal to)
	`.../Employees?q=HireTime = '08:30:40'`
	• <> (Not equal to)
	`.../Employees?q=HireTime <> ’08:30:40’`
	• < (Less than)
	`.../Employees?q=HireTime < ’08:30:40’`
	• <= (Less than or equal to)
	`.../Employees?q=HireTime <= ’08:30:40’`
	• > (Greater than)
	`.../Employees?q=HireTime > ’08:30:40’`
	• >= (Greater than or equal to)
	`.../Employees?q=HireTime >= ’08:30:40’`
	• `BETWEEN` (Between)
	`.../Employees?q=HireTime BETWEEN ’04:30:00’ AND '08:30:40'`
	• `NOT BETWEEN` (Not between)
	`.../Employees?q=HireTime NOT BETWEEN ’04:30:00’ AND '08:30:40'`
	• `IS NULL` (Is null)
	`.../Employees?q=HireTime IS NULL`
	• `NOT NULL` (Not null)
	`.../Employees?q=HireTime NOT NULL`

Table 22-14 (Cont.) Operators Supported by Data Types in Query (q) Parameter Strings

ADF REST Data Type	Supported Operator

datetime
Note: Both UTC and local datetime formats are supported. The value returned is determined by the time zone configured for the VM.
	• = (Equal to)
	`.../Employees?q=HireDateTime = '1999-01-01T08:30:40Z'`
	• <> (Not equal to)
	`.../Employees?q=HireDateTime <> ’1999-01-01T08:30:40Z’`
	• < (Less than)
	`.../Employees?q=HireDateTime < ’1999-01-01T08:30:40Z’`
	• <= (Less than or equal to)
	`.../Employees?q=HireDateTime <= ’1999-01-01T08:30:40Z’`
	• > (Greater than)
	`.../Employees?q=HireDateTime > ’1999-01-01T08:30:40Z’`
	• >= (Greater than or equal to)
	`.../Employees?q=HireDateTime >= ’1999-01-01T08:30:40Z’`
	• `BETWEEN` (Between)
	`.../Employees?q=HireDateTime BETWEEN ’1999-01-01T08:30:40Z’ AND ’1999-12-01T08:30:40Z’`
	• `NOT BETWEEN` (Not between)
	`.../Employees?q=HireDateTime NOT BETWEEN ’1999-01-01T08:30:40Z’ AND ’1999-12-01T08:30:40Z’`
	• `IS NULL` (Is null)
	`.../Employees?q=HireDateTime IS NULL`
	• `NOT NULL` (Not null)
	`.../Employees?q=HireDateTime NOT NULL`

boolean	• `= ’true’` (true)
	`.../Employees?q=Active = ’true’`
	• `= ’false’` (false)
	`.../Employees?q=Active = ’false’`
	• `IS NULL` (Is null)
	`.../Employees?q=Active IS NULL`
	• `NOT NULL` (Not null)
	`.../Employees?q=Active NOT NULL`

Media Types Supported

- **Request**
  - None
- **Response**

  - `application/vnd.oracle.adf.resourcecollection+json`: When retrieving a resource collection.
  - `application/vnd.oracle.adf.resourceitem+json`: When retrieving a resource item.
  - `application/vnd.oracle.adf.description+json`: When describing a resource.
  - `application/vnd.oracle.adf.version+json`: When retrieving all available resource versions.

Use Case Samples

- Retrieving the ADF REST Resource Describe
- Querying With Filtering Attributes (Partial Get)
- Filtering a Resource Collection with a Query Parameter
- Filtering a Resource Collection with Primary Key Values
- Filtering a Resource Collection with a Row Finder
- Checking for Data Consistency When Retrieving ADF REST Resource Items
- Retrieving All Available Version Release Names
- Retrieving a Resource By a Specific Version
- Streaming Attachments Using a Resource Item Enclosure Link
- Retrieving LOV-Enabled Attribute Values for Existing Resource Items
- Returning Only Resource Data in a Payload
- Returning the Estimated Count of Resource Items

ADF REST Framework Version Overview

- What You May Need to Know About Versioning the ADF REST Framework
- What You May Need to Know About the Advanced Query Syntax in ADF REST Framework Version 2
- What Happens At Runtime: Invoking an ADF REST Framework Version

POST Method Operations

The ADF REST framework supports the following operations using a POST method with the URI as shown.

- Create a new resource.

  `http://server/demo/rest/{version}/{resourceCollectionPath}`

- Create a parent resource item and create the nested child resource collection in one roundtrip.

  `http://server/demo/rest/{version}/{resourceCollectionPath}`

- Updating or creating resource items using Upsert-Mode Header

  `http://server/demoapp/rest/{version}/{resourceCollectionPath}`

- Execute an action on a resource collection or resource item.

`http://server/demo/rest/{version}/{resourceCollectionPath}|{resourceItemPath}`

- Execute an a batch request.

  `http://server/demo/rest/{version}/{resourceCollectionPath}`

Request Parameters

- none

Media Types Supported

- **Request**
  - `application/vnd.oracle.adf.resourceitem+json`: When creating a resource or overriding the HTTP method to perform an update.
  - `application/vnd.oracle.adf.resourceitem+json`: When updating or creating a resource item using Upsert.
  - `application/vnd.oracle.adf.action+json`: When executing an action.
  - `application/vnd.oracle.adf.batch+json`: When executing a batch request.
- **Response**
  - `application/vnd.oracle.adf.resourceitem+json`: When executing an action or creating a resource.
  - `application/vnd.oracle.adf.resourceitem+json`: When updating or creating a resource item using Upsert.
  - `application/vnd.oracle.adf.actionresult+json`: When executing an action that has an object to return.
  - `application/vnd.oracle.adf.batch+json`: When executing an batch request.

Use Case Samples

- Creating a Resource Item in Collection
- Creating Child Resource Item
- Streaming Attachments Using a Resource Item Enclosure Link
- Overriding the HTTP Method and Performing an Update
- Making Batch Requests
- Updating or Creating Resource Items Using Upsert

PATCH Method Operations

The ADF REST framework supports the following operation using a PATCH method with the URI as shown.

- Updating a resource item.

  `http://server/demo/rest/{version}/{resourceItemPath}`

Request Parameters

- none

Media Types Supported

- **Request**
  - `application/vnd.oracle.adf.resourceitem+json`: The resource item to be updated.
- **Response**
  - `application/vnd.oracle.adf.resourceitem+json`: The updated resource item.

Use Case Samples

- Updating a Resource Item
- Checking for Data Consistency When Updating ADF REST Resource Items
- Replacing LOB Content Using Base64
- Overriding the HTTP Method and Performing an Update

DELETE Method

The ADF REST framework supports the following operation using a DELETE method with the URI as shown.

- Deleting a resource item.

  `http://server/demo/rest/{version}/{resourceItemPath}`

Request Parameters

- none

Media Types Supported

- **Request**
  - none
- **Response**
  - none

Use Case Samples

- Deleting a Resource Item

Part IV
Creating ADF Task Flows

This part describes the tasks developers can perform when creating ADF task flows in the Fusion web application. ADF task flows provide a modular approach for defining control flow in a Fusion web application.

Part IV contains the following chapters:

- Getting Started with ADF Task Flows
- Working with Task Flow Activities
- Using Parameters in Task Flows
- Using Task Flows as Regions
- Creating Complex Task Flows
- Using Dialogs in Your Application

23 Getting Started with ADF Task Flows

This chapter describes getting started with ADF tasks flows that you can create in your Fusion web application. In addition to describing how to create ADF task flows, key ADF task flow features such as activities, control flows, control flow rules, memory scopes, and bounded and unbounded task flows are described. The chapter also describes how to refactor, test, and run a finished task flow.
This chapter includes the following sections:

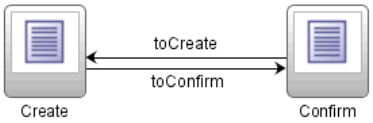
About ADF Task Flows

An ADF task flow is a graphical representation of the connectivity between the activity nodes. This method allows you to create a modular set of reusable task flows and join them through control flow cases to represent an application. The two types of task flows are, Unbounded task flow and Bounded task flow.

ADF task flows provide a modular approach for defining control flow in a Fusion web application. Instead of representing an application as a single large JSF page flow, you can break it up into a collection of reusable task flows. Each task flow contains a portion of the application's navigational graph. The nodes in the task flows are activities. An **activity node** represents a simple logical operation such as displaying a page, executing application logic, or calling another task flow. The transitions between the activities are called **control flow cases**.

Figure 23-1 shows two view activities called `Create` and `Confirm`. These view activities are similar to page nodes within a JSF page flow.

Figure 23-1 ADF Task Flow



The are two types of ADF task flow:

- Unbounded task flow: A set of activities, control flow rules, and managed beans that interact to allow a user to complete a task. The unbounded task flow consists of all activities and control flows in an application that are not included within a bounded task flow.
- Bounded task flow: A specialized form of task flow that, in contrast to the unbounded task flow, has a single entry point (an entry point is a view activity that can be directly requested by a browser) and zero or more exit points. It contains its own set of private control flow rules, activities, and managed beans. A bounded task flow allows reuse, parameters, transaction management, reentry, and can render within an ADF region in a JSF page.

  For a description of the activity types that you can add to an unbounded or bounded task flow see Working with Task Flow Activities .

  By default, JDeveloper proposes the following file name for the source file of a bounded task flow:

  ```
  task-flow-definitionN.xml
  ```

  where `N` is a number that increments each time that you create a new bounded task flow. You can choose a file name for the bounded task flow. For example, you might use `checkout-task-flow.xml` if the purpose of the bounded task flow is to allow customers to check out from a shopping application.

  The source file contains the metadata for the bounded task flow. Multiple bounded task flows can be included within the same source file using the following metadata:

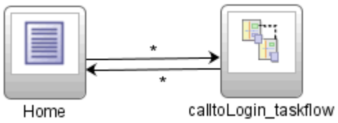
  ```
  <task-flow-definition id="TaskFlowID1">
          ...
        </task-flow-definition>
  <task-flow-definition id="TaskFlowID2">
         ...
  </task-flow-definition>
  ```

  However, as JDeveloper's visual editors show one bounded task flow per file, it makes the modification of bounded task flows easier if you do not include more than one bounded task flow within the same source file.

A typical application is a combination of the unbounded task flow and one or more bounded task flows. For example, JDeveloper, by default, creates an empty unbounded task flow (source file name is `adfc-config.xml`) when you create an application using the Fusion Web Application template. At runtime, the Fusion web application can call bounded task flows from activities that you added to the unbounded task flow.

As shown in Figure 23-2, the first activity to execute in an application is often a view activity within the unbounded task flow. A view activity represents a JSF page that displays as part of the application. The activity shown in Figure 23-2 starts with the `Home` view activity and then calls a bounded task flow. The `calltoLogin_taskFlow` activity calls a bounded task flow that enables a user to log into the application.

Figure 23-2 Unbounded Task Flow Calling a Bounded Task Flow



You can also design an application in which all application activities reside within the unbounded flow. This mimics a JSF application, but does not take advantage of bounded task flow functionality. To take full advantage of task flow functionality, use bounded task flows.

Table 23-1 describes the advantages that the control flow provided by ADF task flows offers over the control flow offered by JSF page flow. In certain scenarios you may need to use JSF page flow. For example, using phase listeners, as described in Customizing the ADF Page Lifecycle , involves using the JSF page flow's `faces-config.xml` configuration file. In general, it is not recommended that you mix JSF page flow and ADF task flows in your application.

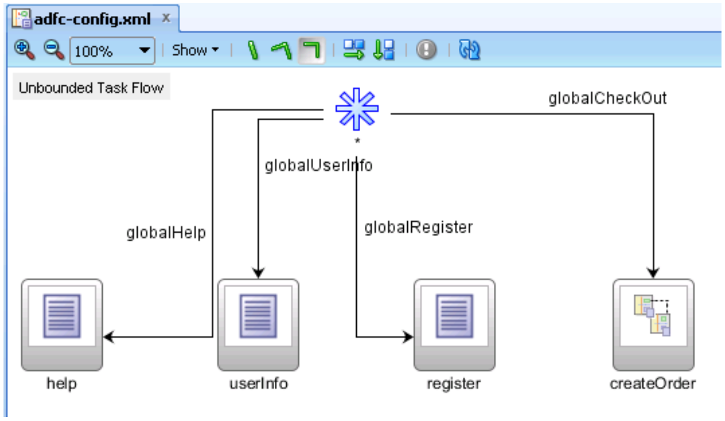
Table 23-1 ADF Task Flow Advantages

JSF Page Flow	ADF Task Flow
The entire application must be represented in a single page navigation file (`faces-config.xml`). Although you can have multiple copies of `faces-config.xml` in a project, the application loads these files as one at runtime.	The application can be broken up into a series of modular flows that call one another.
All nodes within a JSF page flow must be JSF pages. No other types of objects can exist within the JSF page flow.	You can add to the task flow diagram nodes such as views, method calls, and calls to other task flows.
Navigation is only between pages.	Navigation is between pages as well as other activities, including routers. See, see Using Router Activities.
Application fragments cannot be reused.	ADF task flows are reusable within the same or an entirely different application. After you break up your application into task flows, you may decide to reuse task flows containing common functionality. See, see Reusing Application Components .
There is no shared memory scope between multiple requests except for session scope.	Shared memory scope (for example, page flow scope) enables data to be passed between activities within the task flow. Page flow scope defines a unique storage area for each instance of a bounded task flow.

About Unbounded Task Flows

A Fusion web application always contains an **ADF unbounded task flow**, which contains the entry point or points to the application. An entry point is a view activity that can be directly requested by a browser. A Fusion web application only has one unbounded task flow. By default, the source file for the unbounded task flow is the `adfc-config.xml` file. Although you can create additional source files for unbounded task flows, the application combines all source files at runtime into the `adfc-config.xml` file. Figure 23-3 displays the diagram for an unbounded task flow from an application. This task flow contains a number of view activities that are all entry points to the application.

Figure 23-3 Unbounded Task Flow



You typically use the unbounded task flow instead of a bounded task flow if:

- You want to take advantage of ADF Controller features not offered by bounded task flows, such as bookmarkable view activities. For more information, see Bookmarking View Activities.
- The task flow will not be called by another task flow.
- The application has multiple points of entry. In Figure 23-3, the task flow can be entered through any of the pages represented by the view activity icons on the unbounded task flow.

The unbounded task flow cannot declaratively specify parameters. In addition, it cannot contain a **default activity**, an activity designated as the first to run in the unbounded task flow. This is because the unbounded task flow does not have a single point of entry. To perform any of these requires a bounded task flow.

In order to take advantage of completely declarative ADF Controller transaction and reentry support, use a bounded task flow rather than the unbounded task flow.

About Bounded Task Flows

An **ADF bounded task flow** is used to encapsulate a reusable portion of an application. A bounded task flow is similar to a Java method in that it:

- Has a single entry point
- May accept input parameters
- May generate return values
- Has its own collection of activities and control flow rules

- Has its own memory scope and managed bean lifespan (a page flow scope instance)

  For more information about memory scopes, see What You May Need to Know About Memory Scope for Task Flows.

- Can determine whether or not it has an isolated data control frame

  For more information about access to data control frames, see Sharing Data Controls Between Task Flows .

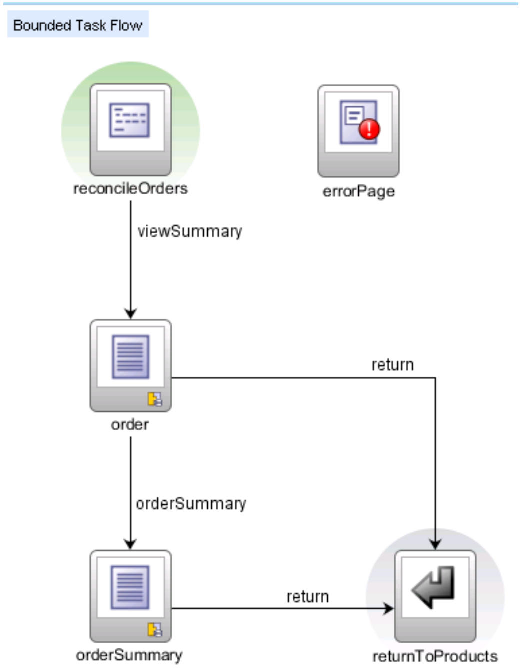
- Can define an activity as an exception handling activity

  For more information about exception handling in bounded task flows, see Handling Exceptions in Task Flows.

The `createOrder` activity in Figure 23-3 is a call to a bounded task flow. The unbounded task flow can call a bounded task flow, but cannot be called by another task flow. A bounded task flow can call another bounded task flow, which can call another and so on. There is no limit to the depth of the calls.

Figure 23-4 shows a bounded task flow.

Figure 23-4 Bounded Task Flow



The reasons for creating a bounded task flow are:

- The bounded task flow always specifies a default activity, a single point of entry that must execute immediately upon entry of the bounded task flow.

  In Figure 23-4, this is the method call activity labeled **reconcileOrders**. Because it is the default activity, the method call activity is always invoked before the bounded task flow renders the page referenced by the **order** view activity.

- It is reusable. For example, it can be included in other applications requiring a process to manage or check out orders. The bounded task flow can also be reused within the same application.
- Any managed beans you use within a bounded can be specified in page flow scope, so are isolated from the rest of the application. These managed beans (with page flow scope) are automatically released when the task flow completes.

Table 23-2 summarizes the main features of a bounded task flows.

Table 23-2 Bounded Task Flow Features

Feature	Description
Well-defined boundary	A bounded task flow consists of its own set of private control flow rules, activities, and managed beans. A caller requires no internal knowledge of page names, method calls, child bounded task flows, managed beans, and control flow rules within the bounded task flow boundary. Input parameters can be passed into the bounded task flow, and return values can be passed out on exit of the bounded task flow. Data controls can be shared between task flows.
Single point of entry	A bounded task flow has a single point of entry, a default activity that executes before all other activities in the task flow. For more information, see What You May Need to Know About the Default Activity in a Bounded Task Flow.
Page flow memory scope	You can specify page flow scope as the memory scope for passing data between activities within the bounded task flow. Page flow scope defines a unique storage area for each instance of a bounded task flow. Its lifespan is the bounded task flow, which is longer than request scope and shorter than session scope. For more information, see What You May Need to Know About Memory Scope for Task Flows.
Addressable	You can access a bounded task flow by specifying its unique identifier within the XML source file for the bounded task flow and the file name of the XML source file. For more information, see What Happens When You Add a Task Flow Call Activity .
Reuse	You can identify an entire group of activities as a single entity, a bounded task flow, and reuse the bounded task flow in another application within an ADF region. You can also reuse an existing bounded task flow simply by calling it. For example, one task flow can call another bounded task flow using a task flow call activity or a URL. In addition, you can use task flow templates to capture common behaviors for reuse across different bounded task flows. For more information, see Creating Task Flow Templates .
Parameters and return values	A caller can pass input parameters to a bounded task flow and accept return values from it. For more information, see Passing Parameters to a Bounded Task Flow. In addition, you can share data controls between bounded task flows. For more information, see Sharing Data Controls Between Task Flows .

Table 23-2 (Cont.) Bounded Task Flow Features

Feature	Description
Transaction management	A bounded task flow can represent a transactional unit of work. You can declaratively specify options on the bounded task flow that determine whether, when entering the task flow, the task flow creates a new transaction, joins an existing one or is not part of the existing transaction. For more information, see Managing Transactions in Task Flows.
Reentry	You can specify options on the bounded task flow that determine whether or not it can be reentered. For more information, see Reentering Bounded Task Flows.
On-demand loading of metadata	Bounded task flow metadata is loaded on demand when entering a bounded task flow.
Security	You can secure a bounded task flow by defining the privileges that are required for someone to use it. For more information, see Enabling ADF Security in a Fusion Web Application.

Understanding the assumptions and constraints listed in Table 23-3 will help you successfully use ADF task flows, activities and other associated ADF Controller features.

Table 23-3 ADF Controller Features Assumptions and Constraints

Feature Area	Assumption/ Constraint	Description
ADF Controller objects and diagram UI	JSF view layer	ADF Controller operates in a JSF environment. Oracle's web-based Fusion web application strategy focuses on JSF as the sole view layer technology.
ADF Controller objects and diagram UI	Dependent on Oracle ADF Faces	ADF Controller extensions are implemented on top of Oracle ADF Faces. They are dependent on the ADF Faces libraries, but ADF Controller can run against any JSF implementation, providing these libraries are present.
ADF Controller objects and diagram UI	Navigation and state management encapsulated	ADF Controller encapsulates both navigation and, to some extent, state management. JSF and the Servlet API are still available for the basic management of state at the application, session, and request levels.
ADF Controller objects and diagram UI	Model layer	ADF Model layer is used to implement the application's model layer.
ADF Controller objects and diagram UI	Dependent on MDS	ADF Controller metadata is stored in MDS. However, MDS is currently not capable of loading `faces-config.xml`. If the customization features that MDS provides are required, you should use ADF task flows exclusively in order to define managed beans and control flow rules.

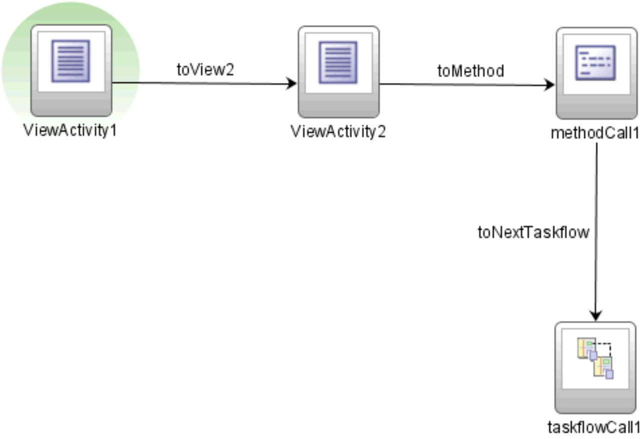
Table 23-3 (Cont.) ADF Controller Features Assumptions and Constraints

Feature Area	Assumption/ Constraint	Description
ADF Controller objects and diagram UI	No supported migration path from struts or model 1	There is no support for a migration from Struts or Model 1 to the ADF Controller. However, you can create a new bounded task flow based on selected pages in a JSF page flow. For more information, see How to Create a Task Flow from JSF Pages.
Bounded task flow	Exposed as page flow-scoped state	ADF Controller manages implementation of a page flow scoped-state. Any auto-management functions provided by the framework, such as back button support and state cleanup function, assume page flow-scoped data. In order for an application to fully implement such functions for all of its pages, the entire application should be exposed as an ADF bounded task flow, using nested bounded task flows as needed. The application should store any state requiring versioning within the page flow scope.
Bounded task flow	Transactional boundaries	The developer will use ADF bounded task flows to manage transaction boundaries.
Page flow scope	Access availability within ADF lifecycle	An application cannot attempt to access the page flow scope early in the ADF lifecycle before ADF Controller is ready to provide it. Page flow scope is not guaranteed to be available for access until after Before and After listeners have executed on the Restore View phase. ADF Controller uses before and after listeners on the Restore View phase to synchronize the server side state with the request. This is where things such as browser back-button detection and bookmark dereference are handled.
Navigation	Navigation	When using ADF Controller task flows, perform all application navigation should be performed using ADF Controller control flow rules instead of using navigation rules in `faces-config.xml`. Although ADF Controller delegates navigation handling when no matching control flow cases are found in ADF Controller metadata, not all ADF Controller functionality is guaranteed to work correctly if navigation is performed by a non-ADF Controller `NavigationHandler`.

About Control Flows

A task flow consists of activities and control flow cases that define the transitions between activities. Figure 23-5 shows a control flow rule, labeled `toView2`, that defines the transition between the `ViewActivity1` and `ViewActivity2` view activities. The `ViewActivity1` view activity displays before the `ViewActivity2` view activity when the task flow in Figure 23-5 executes.

Figure 23-5 Task Flow with Activities and Control Flow Cases

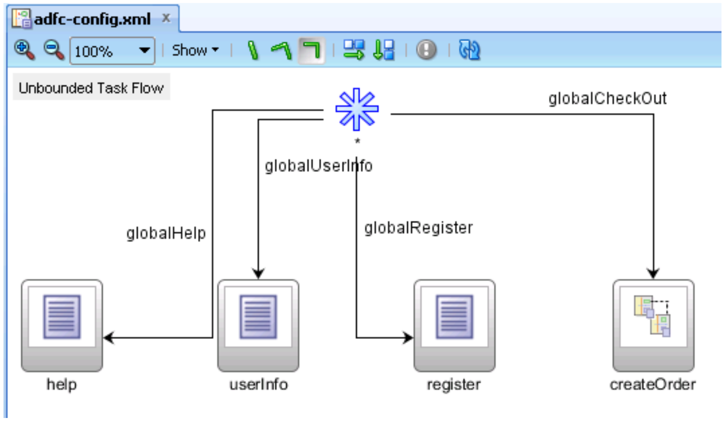


The task flow in Figure 23-5 also contains a method call activity (`methodCall1`) that invokes after the `ViewActivity2` view activity and before the `taskflowCall1` task flow call activity. In a task flow, you invoke an activity such as a method call activity before or after a page renders. Invoking a method call activity outside of a particular page can facilitate reuse because you can reuse the page in other contexts that do not require the method (for example, a different task flow). For more information about control flow rules, see Adding Control Flow Rules to Task Flows.

A wildcard control flow rule represents a control flow `from-activity-id` that contains a trailing wildcard (`foo*`) or a single wildcard character (`*`). Use the single wildcard character when you want to pass control from any activity in the task flow to the wildcard control flow rule. Alternatively, use a trailing wildcard when you want to constrain the activities that can pass control to the wildcard control flow rule.

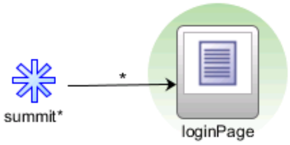
In Figure 23-6, the wildcard control flow rule contains a single wildcard character, indicating that control can pass to the activities connected to it in the task flow diagram from any activity within the task flow.

Figure 23-6   Wildcard Control Flow Rule With Single Wildcard



The trailing wildcard in Figure 23-7 indicates that control flow can pass to the `loginPage` view from any valid source activity whose `activity-id` begins with the characters `summit`.

Figure 23-7   Wildcard Control Flow Rule with Trailing Wildcard

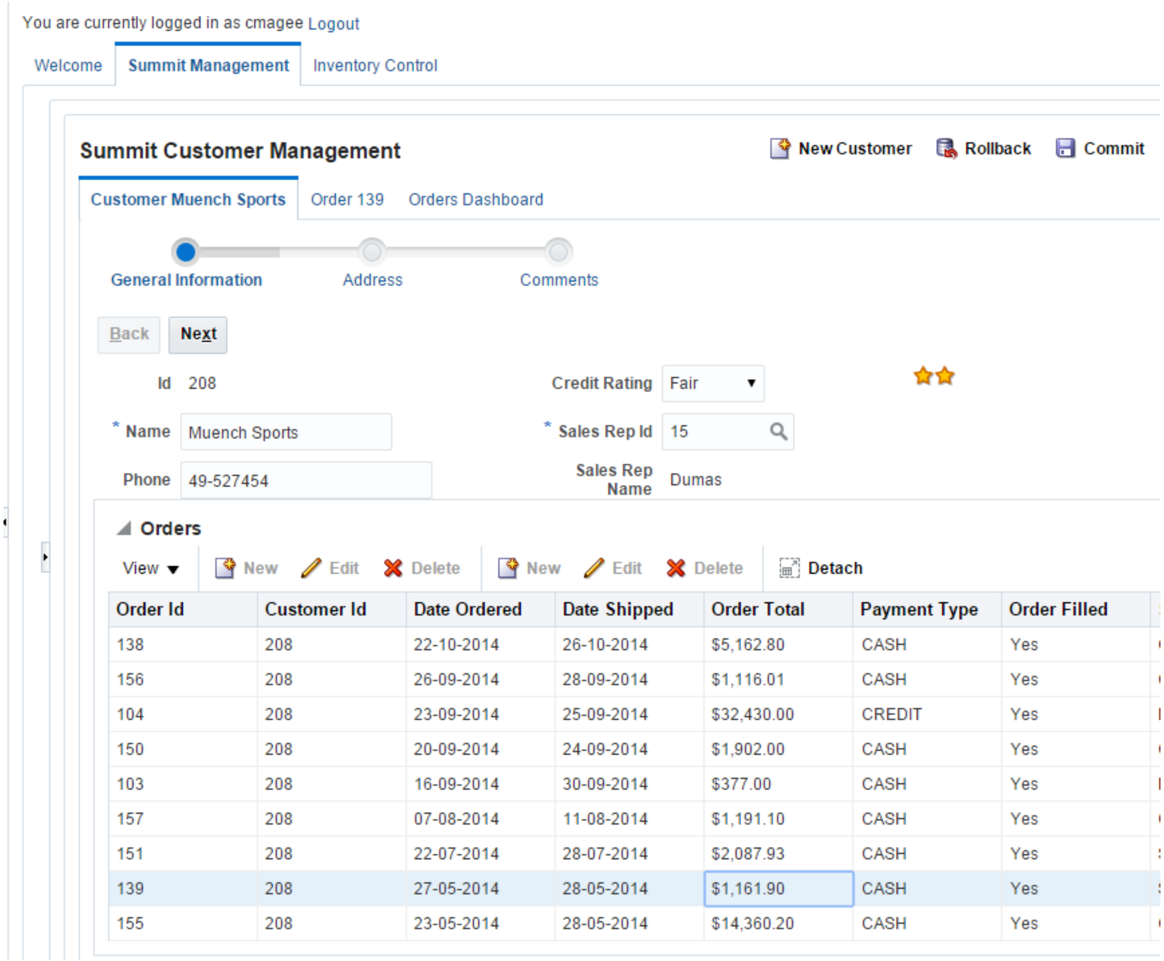


For more information about wildcard control flow rules, see How to Add a Wildcard Control Flow Rule .

ADF Task Flow Use Cases and Examples

Figure 23-8 shows a screen from the Summit sample application for ADF task flows. End users of the screen invoke a task flow that displays a list of customers. Using controls exposed on the screen, end users can also invoke a task flow that allows them to create or to edit an order.

Figure 23-8 Task Flows for Creating and Editing Data



Id	208	Credit Rating	Fair

151	208	22-07-2014	28-07-2014	$2,087.93	CASH	Yes
139	208	27-05-2014	28-05-2014	$1,161.90	CASH	Yes
155	208	23-05-2014	28-05-2014	$14,360.20	CASH	Yes

Task flows can also be used to secure your Fusion web application by reducing the number of access points that you expose to end users. For example, configure an unbounded task flow to display one page that provides navigation to the remaining pages in your application. Use bounded task flows for the remaining pages in the application. By setting the URL Invoke property of these bounded task flows to `url-invoke-disallowed`, your application has one access point (the page on the unbounded task flow). For more information about the URL Invoke property, see How to Call a Bounded Task Flow Using a URL. For more information about securing your Fusion web application, see Enabling ADF Security in a Fusion Web Application.

Additional Functionality for ADF Task Flows

You may find it helpful to understand other **Oracle ADF** features before you configure or use ADF task flows. Additionally, you may want to read about what you can do with your task flow configurations. Following are links to other functionality that may be of interest.

- Task flows can invoke managed beans. For more information about defining managed beans for use with a task flow, the supported memory scopes, and other related information, see What You May Need to Know About Memory Scope for Task Flows and Using a Managed Bean in a Fusion Web Application.

- Task flows are reusable. For more information about reusing functionality in your application, see Reusing Application Components .
- Task flows can be secured by defining the privileges that are required for someone to use it. For more information, see Enabling ADF Security in a Fusion Web Application.
- You can extend the functionality that your task flows implement by writing custom code. For example, you can write a custom exception handler that a task flow passes control to when a task flow activity raises an exception. For more information, see How to Designate Custom Code as an Exception Handler.

  Make sure when you write custom code that you do not import packages that are marked internal, as in the following example:

  ```
  import oracle.adfinternal.controller.*;
  ```

  For information about the APIs that you can use to write custom code, see the following reference documents:

  – *Java API Reference for Oracle ADF Controller*

  – *Java API Reference for Oracle ADF Faces*

Creating a Task Flow

To create an ADF task flow you must identify the activities nodes and the control flow rules between them. Also, a task flow can be created by joining multiple task flows. You can use the router activity for branching in the task flow and use the return activity to exit the task flow.

A task flow is made up of the task flow itself, plus a number of activities with control flow rules between those activities. In most cases, the majority of the activities are view activities which represent the different pages in the flow. When some method or operation needs to be called, for example before a page is rendered, you use a method call activity with a control flow case from that activity to the appropriate next activity. When you want to call another task flow, you use a task flow call activity. If the flow requires some sort of branching, you use a router activity. At the end of a bounded task flow, you use a return activity which allows the flow to exit and control is sent back to the flow that called this bounded task flow.

For more detailed information and procedures regarding the individual activities of a task flow, including the metadata created for each activity and additional configuration that you can set, see Adding Activities to a Task Flow.

How to Create a Task Flow

The processes for creating bounded and unbounded task flows are similar. The main difference is that you select the **Create as Bounded Task Flow** checkbox in the Create Task Flow dialog to create a bounded task flow.

> **Note:**
>
> When you create a project, you may not need to create the unbounded task flow for it. If **ADF Page Flow** is specified as a selected technology on the Features page of the Project Properties dialog, the new `adfc-config.xml` file is automatically created within the project. The `adfc-config.xml` file is the main source file for the unbounded task flow.

Before you begin:

It may be helpful to have an understanding of what constitutes a task flow. For more information, see Creating a Task Flow.

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for ADF Task Flows.

To create a task flow:

1. In the Applications window, right-click the project in which you want to create the task flow and choose **New** > **ADF Task Flow**.
2. In the Create Task Flow dialog, the **Create as Bounded Task Flow** checkbox is selected by default. Deselect it if you want to create to create a source file that will be incorporated into the application's unbounded task flow.

   Deselecting the checkbox automatically changes the default value in the **File Name** field. This value will be used to name the XML source file for the task flow you create. The XML source file contains metadata describing the activities and control flow rules in the task flow.

   > **Tip:**
   >
   > The default name for the unbounded task flow is `adfc-config.xml`. The default name for the source file for a bounded task flow matches the value specified in the **Task Flow ID** field.

   Because a single project can contain multiple task flows, a number may be added to the default value in the **File Name** field in order to give the source file a unique name, for example, `task-flow-definition3.xml`.
3. In the Create Task Flow dialog, the **Create with Page Fragments** checkbox is selected by default.

   Deselect this checkbox if you want the view activities that you add to the task flow to reference JSF pages that render in the main browser window as the root page. Leave the **Create with Page Fragments** checkbox selected if you want the view activities that you add to the task flow to reference page fragments files (`.jsff`) that the task flow displays in an ADF region at runtime. Note that this distinction does not apply to dialogs that you will invoke from a view activity; you may define a view activity that references either a JSF page or a page fragment file when you select **Create with Page Fragments**.
4. Click **OK**.

A diagram representing the task flow appears in the editor.

> **Tip:**
>
> You can view a thumbnail of the entire task flow diagram by clicking the diagram and then choosing **Window** > **Thumbnail** from the main menu.

After you create the task flow, you can update it using the diagram, overview, and source editors. You can also use the Structure window to update the task flow.

> **Tip:**
>
> There are other ways to create task flows, for example, by refactoring the contents of an existing task flow into a new task flow. For more information, see Refactoring to Create New Task Flows and Task Flow Templates.

5. In the ADF Task Flow page of the Components window, from the Component panel, in the Activities group, drag and drop an activity onto the diagram.

   Normally, you would start with a view activity. For more detailed procedures for adding any type of activity, see How to Add an Activity to a Task Flow.

   - If you drag a view activity onto the diagram, you can double-click it to display the wizard for the JSF page or page fragment that the task flow is configured to invoke. Use the wizard to define characteristics for the page or page fragment. For more information, see Using View Activities.

     > **Note:**
     >
     > You can also add a view activity to a task flow by dragging a page from the Applications window and dropping it on the diagram for the task flow.

   - If you drag a router activity onto the diagram, you can use the Properties window to create an expression whose evaluation determines which control flow rule to follow. For more information, see Using Router Activities.
   - If you drag a method call activity onto the diagram, you can use the Properties window to configure the method to call. For more information, see Using Method Call Activities.
   - If you drag a task flow call activity onto the diagram, you can double-click it to display the Create Bounded Task Flow dialog where you can define settings for a new bounded task flow. For more information, see Using Task Flow Call Activities.
   - If you are creating a bounded task flow, and you drag a task flow return activity onto the diagram, you can use the Properties window to configure the activity. For more information, see Using Task Flow Return Activities .
6. Create control flow cases between the activities (for more information and detailed procedures, see How to Add a Control Flow Rule to a Task Flow):

   a. In the ADF Task Flow page of the Components window, from the Component panel, in the Control Flow group, choose **Control Flow Case**.
   b. On the diagram, click a source activity, for example a view, and then click the destination activity. For example in Figure 23-14, two activities have been linked with a control flow. Both the source (`view1`) and the destination (`view2`) activities are linked.
   c. In the Properties window, expand the **General** section, and choose the outcome value using either the **From Action** attribute (if a method determines the outcome) or the **From Outcome** attribute (if the outcome can be set as a `String`).

7. If you are creating a bounded task flow, you may want to designate one of the activities as the default activity. This makes sure that this specific activity executes first whenever the bounded task flow runs. By default, JDeveloper makes the first activity you add to the task flow the default. To change to a different activity, right-click the appropriate activity in the diagram and choose **Mark Activity > Default Activity**. For more information, see What You May Need to Know About the Default Activity in a Bounded Task Flow.

What Happens When You Create a Task Flow

A new XML source file is created every time you create a new unbounded or bounded task flow. By default, the XML source file for the unbounded task flow is called `adfc-config.xml`.

As shown in the following example, `<adfc-config>` appears first as the top-level element in all ADF Controller XML source files. Bounded task flows, activities and control flow rules are defined inside the `<adfc-config>` element. Bounded task flows are identified within the source file by the `<task-flow-definition>` metadata element.

```
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2"
id="__1">
  <task-flow-definition id="task-flow-definition">
    <use-page-fragments/>
  </task-flow-definition>
</adfc-config>
```

A bounded task flow is identified by its task flow reference, which is comprised of a unique combination of identifier and document name. Example 23-1 shows a sample task flow reference within a task flow call activity.

> **Note:**
>
> If you use JDeveloper to create the bounded task flow, specify only one ID (indicating one bounded task flow) per document.

You assign both identifier and document name when you create the bounded task flow. As shown in Example 23-1, the identifier is the value in the **Task Flow ID** field. The document name is the value in the **File Name** field.

Example 23-1   Task Flow Reference

```
<adfc-config xmlns="http://xmlns.oracle.com/adf/Controller" version="1.2">
  <task-flow-definition id="task-flow-definition">
   <use-page-fragments/>
    ...
    <task-flow-call id="taskFlowCall">
      <task-flow-reference>
        <document>/WEB-INF/target-task-flow-definition.xml</document>
        <id>my-task-flow</id>
      </task-flow-reference>
    </task-flow-call>
    ...
  </task-flow-definition>
</adfc-config>
```

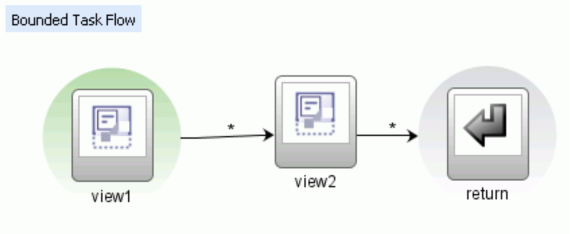
What You May Need to Know About the Default Activity in a Bounded Task Flow

The default activity is the first activity to execute in a bounded task flow. For example, the default activity always executes first when a task flow call activity passes control to the bounded task flow.

Unbounded task flows do not have default activities.

As shown in Figure 23-9, a green circle identifies the default activity in a task flow diagram.

Figure 23-9   Default Activity in a Bounded Task Flow



The first activity that you add to a new bounded task flow diagram is automatically identified as the default activity. You can also right-click any activity in the task flow diagram and choose **Mark Activity > Default Activity**. The default can be any activity type and it can be located anywhere in the control flow of the bounded task flow. To find the default activity, right-click anywhere on the task flow diagram and choose **Go to Default Activity**.

A bounded task flow can have only one default activity. If you mark a second activity as the default, the first is unmarked automatically. To unmark an activity manually, right-click the activity in the task flow diagram and choose **Unmark Activity > Default Activity**.

You should not specify a train stop in the middle of a train as a default activity. For more information, see Using Train Components in Bounded Task Flows.

Example 23-2 contains sample metadata for a default activity called `SurveyPrompt` in a bounded task flow:

Example 23-2 Default Activity Metadata in a Bounded Task Flow

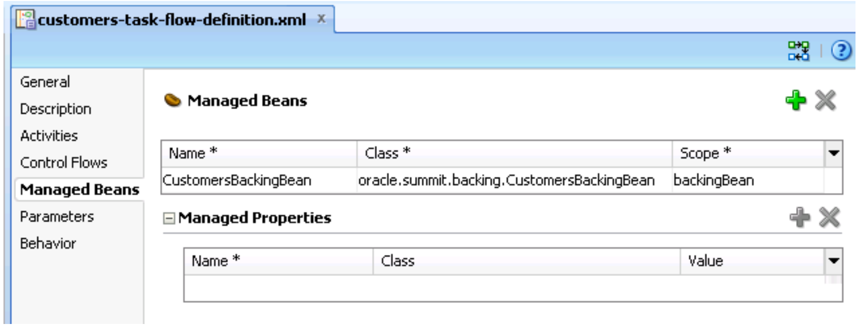
```
<task-flow-definition id="survey">
    <default-activity>SurveryPrompt</default-activity>
    <view id="SurveryPrompt">
      <page>/SurveryPrompt.jsff</page>
    </view>
    <use-page-fragments/>
</task-flow-definition>
```

What You May Need to Know About Memory Scope for Task Flows

Each task flow in your Fusion web application defines a pageFlow scope to manage state. The pageFlow scope begins when the task flow begins and ends when the task flow ends. A pageFlow scope defines a unique storage area for each instance of a task flow within an application which is used to pass data values between the activities in the task flow. When one task flow calls another, the calling task flow cannot access the called task flow's pageFlow scope. This means, for example, that a UI component on a page referenced by a task flow's view activity cannot access the pageFlow scope of another task flow even if this task flow is an ADF region embedded in the same page as the UI component.

You can define multiple managed beans with task flows. Figure 23-10 shows an example from the Summit ADF task flow sample application where a bounded task flow (`customers-task-flow-definition.xml`) references a managed bean with a backingBean scope. You can determine the scope assigned to a managed bean.

Figure 23-10 Managed Bean Registered With Task Flow



Name *	Class *	Scope *
CustomersBackingBean	oracle.summit.backing.CustomersBackingBean	backingBean

Name *	Class	Value

Table 23-4 lists available scopes for managed beans and describes when it is appropriate to use each scope in a managed bean that you define with a task flow. The table lists the scopes in order of their life span. For example, the application scope has a longer life span than the request scope. For more information about the life span of object scopes, see About Object Scope Lifecycles.

Table 23-4 Memory Scope for ADF Managed Beans

Scope	Description
application	The application scope lasts until the application stops. Values that you store in a managed bean with this scope are available to every session and every request that uses the application. Avoid using this scope in a task flow because it persists beyond the life span of the task flow.
session	The session scope begins when a user first accesses a page in the application and ends when the user's session times out due to inactivity, or when the application invalidates the session. Use this scope only for information that is relevant to the whole session, such as user or context information. Avoid using it to pass values from one task flow to another. Instead, use parameters to pass values between task flows. Using parameters gives your task flow a clear contract with other task flows that call it or are called by it. Another reason to avoid use of session scope is because it may persist beyond the life span of the task flow. Finally, if an end user opens multiple browser windows within the same session, session scoped values are shared across these browser windows. Conflicts can occur between these browser windows.
pageFlow	Choose this scope if you want the managed bean to be accessible across the activities within a task flow. A managed bean that has a pageFlow scope shares state with pages from the task flow that access it. A managed bean that has a pageFlow scope exists for the life span of the task flow.
view	Use this scope for managed bean objects that are needed only within the current view activity and not across view activities. The life span of this scope begins and ends when the current `viewId` of a view port changes. If you specify view, the application retains managed bean objects used on a page as long as the user continues to interact with the page. These objects are automatically released when the user leaves the page. Both JSF and Oracle ADF have an implementation of this scope. In a Fusion web application, when you use view scope in an EL expression, it resolves to the Oracle ADF implementation.
request	Use request scope when the managed bean does not need to persist longer than the current request.
backingBean	A backing bean is a convention to describe a managed bean that stores accessors for UI components and event handling code on a JSF page. It exists for the duration of a request and should not be used to maintain state. Use this scope if it is possible that your task flow appears in two ADF regions on the same JSF page and you want to isolate each instance of ADF region. In scenarios where you have more than one task flow, consider using a naming convention that assigns a unique name to each managed bean. Adopting this approach makes sure that you do not attempt to put two managed beans with the same name from different task flows into backingBean scope.

When you define a managed bean with a task flow, JDeveloper generates entries similar to the following in the task flow's source file:

```
<managed-bean id="__15">
    <managed-bean-name id="__16">egBackingBean</managed-bean-name>
    <managed-bean-class id="__13">oracle....egBackingBean</managed-bean-class>
    <managed-bean-scope id="__14">backingBean</managed-bean-scope>
</managed-bean>
```

The <managed-bean-scope> element holds the value for the scope of the managed bean (backingBean in the example).

When you bind a UI component to a managed bean, JDeveloper appends Scope to the scope name in the EL expression that it generates to reference the managed bean. For example, the binding attribute of a table component that references the managed bean has the following EL expression:

```
<af:table id="cartTab"
      ...
      binding="#{backingBeanScope.egBackingBean.table}"
     ...
</af:table>
```

Restrict the scope of the managed bean that you reference through a UI component's binding attribute to backingBean or request scope. Instances of UI components cannot be serialized. Objects in scopes other than backingBean and request are expected to be serializable. For this reason, you should not bind UI components to managed beans that have a scope other than backingBean or request. Note that JDeveloper defaults the binding attribute for UI components and region fragments to use the backingBean scope.

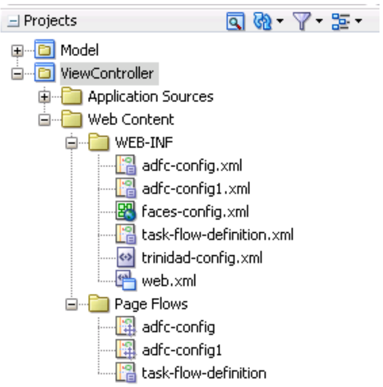
> **Note:**
>
> Write EL expressions that explicitly qualify the scope to access when writing EL expressions to access custom scopes unique to Oracle ADF (pageFlow, backingBean, and view scopes). For example, write an EL expression to access a pageFlow scope as follows:
>
> ```
> #{pageFlowScope.inpTxtBB.uiComponent}
> ```

What You May Need to Know About the Source Files for Task Flows

A single application can have multiple unbounded task flow XML source files and multiple bounded task flow XML source files. The set of files that combine to produce the unbounded task flow is referred to as the application's **ADF Controller bootstrap configuration files**. The unbounded task flow is assembled at runtime by combining one or more ADF Controller bootstrap configuration files. All activities within the bootstrap configuration files that are not contained within a bounded task flow are considered to be within the unbounded task flow.

The names of the source files within a single application must be different. The example in Figure 23-11 contains two unbounded task flows (adfc-config, adfc-config1) and a bounded task flow (task-flow-definition).

Figure 23-11 Application with Two Unbounded Task Flow XML Source Files



```
Projects
  Model
  ViewController
    Application Sources
    Web Content
      WEB-INF
        adfc-config.xml
        adfc-config1.xml
        faces-config.xml
        task-flow-definition.xml
        trinidad-config.xml
        web.xml
      Page Flows
        adfc-config
        adfc-config1
        task-flow-definition
```

Adding Activities to a Task Flow

You can modify any ADF task flow once created in the ADF application. You can add activities by dragging from the activities group from the Component panel and drop it onto the diagram.

After you create a task flow, you add activities to the task flow and configure the control flow between the activities. The Components window displays available activities and control flows. You drag and drop the activities and control flows from the Components window to the diagram for the task flow. You then configure control flow between the activities so that the task flow performs the task you want it to perform.

How to Add an Activity to a Task Flow

After you create a task flow, a task flow diagram and the Components window automatically display. The task flow diagram is a visual editor on which you can add the activities and control flows for the task flow. You can add them to the diagram by dragging them from the Components window.

Before you begin:

It may be helpful to have an understanding of what activities you can add to a task flow. For more information, see Adding Activities to a Task Flow.

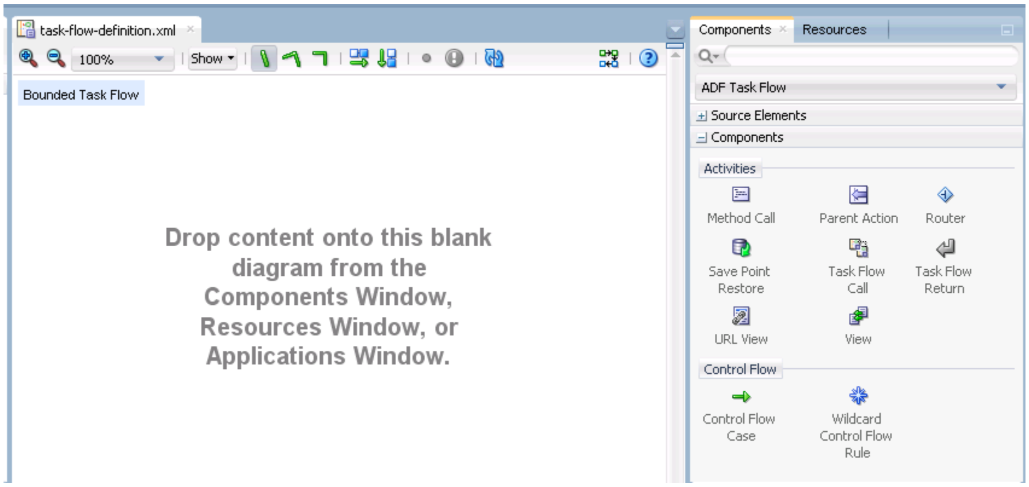
You may also find it helpful to understand functionality that can be added to task flows using other Oracle ADF features. For more information, see Additional Functionality for ADF Task Flows.

To add an activity to a task flow:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow to which you want to add an activity.

   For example, Figure 23-12 shows the editor and the Components window that automatically appears when you double-click a task flow source file (`task-flow-definition.xml`).

Figure 23-12   Task Flow Diagram



2. In the ADF Task Flow page of the Components window, from the Component panel, in the Activities group, drag and drop an activity onto the diagram.
   - If you drag a view activity onto the diagram, you can double-click it to display the wizard to create a JSF page or page fragment. For more information, see Using View Activities.
   - If you drag a task flow call activity onto the diagram, you can double-click it to display the Create Bounded Task Flow dialog where you can define settings for a new bounded task flow. For more information, see Using Task Flow Call Activities.

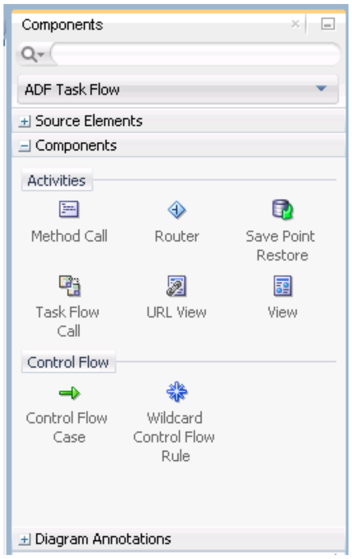
> **Tip:**
>
> Each activity you drag to the task flow diagram can display optional status icons and a tooltip that provides additional information about the activity. For example, after you drag a view activity to the task flow diagram, it may display a warning icon until you associate it with a JSF page.
>
> To turn on the icons, choose **Show** at the top of the task flow diagram, and then choose **Status** and one of the following:
>
> - **Error**: Displays when there is a problem in the task flow metadata which prevents it from running. For example, a view activity in the metadata can contain a `<bookmark>` or `<redirect>` element, but not both.
> - **Warning**: Displays when there is a problem in the task flow metadata that does not prevent the task flow from running.
> - **Incomplete**: Displays when an activity is incomplete. For example, a view activity that does not have a physical page associated with it or a task flow call that does not have a task flow reference associated with it are both considered incomplete activities. The resulting task flow metadata may prevent it from running.
>
> You can drag your mouse over a secondary icon to read a tooltip describing the icon's meaning.

What Happens When You Add an Activity to a Task Flow

As shown in Figure 23-13, the Components window contains separate sections for components and diagram annotations. The contents of the **Components** section differ slightly depending on whether you are creating a bounded or an unbounded task flow. For example, if you are creating a bounded task flow, the **Components** section contains an additional task flow return activity.

Figure 23-13 displays the activities you can add to an unbounded task flow.

Figure 23-13 Activities for an Unbounded Task Flow



Adding Control Flow Rules to Task Flows

ADF control flow rules define the path for the control to pass from one activity to another in a task flow. You can also define conditional navigation, value based navigation, or even merge multiple control flows to form a single control flow.

An ADF Controller control flow rule defines how control passes from one activity to another in a task flow. A control flow rule can contain one or more control flow cases. A control flow case identifies the activity to which control flow passes. A control case also has options that allow you to configure conditional navigation (using the `<if>` element) and/or limit navigation based on the value of the action from where the control flow originates (using the `from-action` element).

An ADF Controller control flow rules are based on JSF navigation rules, but capture additional information. JSF navigation is always between pages, whereas control flow rules describe transitions between activities. For example, a control flow rule can indicate a transition between a view activity and a subsequent method call activity. Or, it can indicate that control passes from the page (view activity) to another task flow.

The following task flow activities cannot be the source of a control flow rule:

- Save Point Restore

- Task Flow Return
- URL View

The basic structure of a control flow rule mimics a JSF navigation rule. Table 23-5 describes how metadata maps from JSF navigation rules to ADF Controller control flow rules.

Table 23-5 Mapping of JSF Navigation Rules to ADF Controller Control Flow Rules

JSF Navigation Rule	ADF Controller Control Flow Rule
Navigation Rule	Control Flow Rule
From View ID	From Activity ID
Navigation Case	Control Flow Case
From Action	From Action
From Outcome	From Outcome
If	If
To View ID	To Activity ID

When using ADF task flows, perform all application navigation using ADF Controller control flow rules instead of using JSF navigation rules in the `faces-config.xml` file. ADF Controller delegates navigation handling when it does not find a matching control flow case in its metadata. However, not all ADF Controller functionality is guaranteed to work correctly if navigation is performed by a non-ADF Controller navigation handler. For more information about how ADF Controller evaluates control flow rules, see What Happens at Runtime: How Task Flows Evaluate Control Flow Rules.

Use the task flow diagram as a starting point for creating basic control flows between activities. Later, you can edit control flow properties in the Structure window, Properties window or overview editor for the task flow diagram.

> **Tip:**
>
> You can drag and drop an activity onto an existing control flow. This splits the existing control flow into two, with the activity in the center.

How to Add a Control Flow Rule to a Task Flow

You create a control flow rule by dragging a Control Flow Case from the ADF Task Flow page of the Components window and dropping it on a source task flow activity and a target task flow activity.

Before you begin:

It may be helpful to have an understanding of what a control flow rule is. For more information, see Adding Control Flow Rules to Task Flows.

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for ADF Task Flows.

To add a control flow rule to a task flow:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow where you want to add a control flow rule.
2. In the ADF Task Flow page of the Components window, from the Component Panel, in the Control Flow group, select **Control Flow Case**.
3. On the diagram, click a source task flow activity and then click the destination task flow activity.

   In many cases, the source and destination task flow activities will be view activities. In Figure 23-14, two such task flow activities (`view1`) and (`view2`) have been linked with a control flow case.

   Figure 23-14 Control Flow Case

   
   JDeveloper adds the control flow case to the diagram. Each line that JDeveloper adds between task flow activities represents a control flow case. The arrow indicates the direction of the control flow case. The **From Outcome** element contains a value that can be matched against values specified in the `action` attribute of UI components.
4. To change the value of **From Outcome**, choose the text next to the control flow in the diagram and overwrite the default wildcard `*` character.

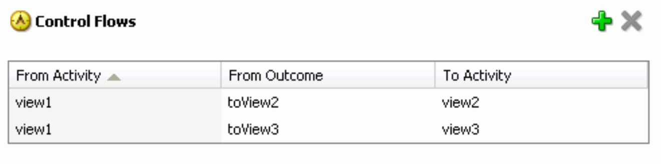
   A useful convention is to cast the control flow rule in the form `toDestination` or some other form that describes the purpose of the control flow rule. To define the control flow shown in Figure 23-14, for instance, you would overwrite the wildcard with `toView2`.
5. To change the values of **From Activity ID** (which identifies the source activity) or **To Activity ID** (which identifies the target activity), drag either end of the arrow in the diagram to a new activity.

Tip:

After you choose the control flow in the task flow diagram, you can also change its properties in the Properties window or the Structure window. The Structure window is helpful for displaying the relationship between control rules and cases.

You can also click **Control Flows** on the overview editor for the task flow diagram to add cases, as shown in Figure 23-15. To add a case, make sure that the **From Activity** (source activity) and the **To Activity** (target activity) for the rule have already been added to the task flow.

Figure 23-15 Control Flows on Overview Editor for the Task Flow



Control Flows

From Activity	From Outcome	To Activity
view1	toView2	view2
view1	toView3	view3

6. Optionally, in the Properties window expand the **Behavior** section, and write an EL expression in the **If** field that must evaluate to `true` before control can pass to the activity identified by **To Activity ID**.

How to Add a Wildcard Control Flow Rule

You can add a wildcard control flow rule to an unbounded or bounded task flow. The steps for adding it are similar to those for adding any activity to a task flow diagram.

Before you begin:

It may be helpful to have an understanding of the control flow rule options available to you. For more information, see Adding Control Flow Rules to Task Flows.

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for ADF Task Flows.

To add a wildcard control flow rule:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow where you want to add a wildcard control flow rule.
2. In the ADF Task Flow page of the Components window, from the Component panel, in the Control Flow group, drag and drop a **Wildcard Control Flow Rule** onto the diagram.
3. In the ADF Task Flow page of the Components window, from the Component panel, in the Control Flow group, select **Control Flow Case**.
4. In the task flow diagram, drag the control flow case from the wildcard control flow rule to the target activity.

   The target can be any activity type.
5. By default, the label below the wildcard control flow rule is *. This is the value for the **From Activity ID** element. To change this value, select the wildcard control

flow rule in the diagram. In the Properties window for the wildcard control flow rule, enter a new value in the **From Activity ID** field. A useful convention is to cast the wildcard control flow rule in a form that describes its purpose. For example, enter `project*`. The wildcard must be a trailing character in the new label.

> **Tip:**
>
> You can also change the **From Activity ID** value in the overview editor for the task flow diagram.

6. Optionally, in the Properties window expand the **Behavior** section, and write an EL expression in the **If** field that must evaluate to `true` before control can pass to the activity identified by **To Activity ID**.

What Happens When You Create a Control Flow Rule

Understanding the elements that define the rules in the source file for the task flow helps when creating control flow rules directly in the task flow diagram, task flow overview editor, or Structure window, or when adding them directly in the XML source file. Example 23-3 shows the general syntax of a control flow rule element in the task flow source file.

Control flow rules can consist of the following metadata:

- `control-flow-rule`: A mandatory wrapper element for control flow case elements.
- `from-activity-id`: The identifier of the activity where the control flow rule originates, for example, `source`.

  A trailing wildcard (*) character in `from-activity-id` is supported. The rule applies to all activities that match the wildcard pattern. For example, `login*` matches any logical activity ID name beginning with the literal `login`. If you specify a single wildcard character in the metadata (not a trailing wildcard), the control flow automatically converts to a wildcard control flow rule activity in the diagram. For more information, see How to Add a Wildcard Control Flow Rule .
- `control-flow-case`: A mandatory wrapper element for each case in the control flow rule. Each case defines a different control flow for the same source activity. A control flow rule must have at least one control flow case.
- `from-action`: An optional element that limits the application of the rule to outcomes from the specified action method. The action method is specified as an EL binding expression, such as `#{backing_bean.cancelButton_action}`.

  In Example 23-3, control passes to `destinationActivity` only if `outcome` is returned from `actionmethod`.

  The value in `from-action` applies only to a control flow originating from a view activity, not from any other activity types. Wildcards are not supported in `from-action`.
- `from-outcome`: Identifies a control flow case that will be followed based on a specific originating activity outcome. All possible originating activity outcomes should be accommodated with control flow cases.

  If you leave both the `from-action` and the `from-outcome` elements empty, the case applies to all outcomes not identified in any other control flow cases defined for the activity, thus creating a default case for the activity. Wildcards are not supported in from-outcome.

- to-activity-id: A mandatory element that contains the complete identifier of the activity to which the navigation is routed if the control flow case is performed. Each control flow case can specify a different to-activity-id.
- if: An optional element that accepts an EL expression as a value. If the EL expression evaluates to true at runtime, control flow passes to the activity identified by the to-activity-id element.

Example 23-3 Control Flow Rule Syntax in the Source File

```
<control-flow-rule>
    <from-activity-id>from-view-activity</from-activity-id>
  <control-flow-case>
    <from-action>actionmethod</from-action>
    <from-outcome>outcome</from-outcome>
    <to-activity-id>destinationActivity</to-activity-id>
    <if>#{myBean.someCondition}</if>
  </control-flow-case>
  <control-flow-case>
   ....
  </control_flow-case>
</control-flow-rule>
```

What Happens at Runtime: How Task Flows Evaluate Control Flow Rules

At runtime, task flows evaluate control flow rules from the most specific to the least specific match to determine the next transition between activities. Evaluation is based on the following priority, which is similar to that for JSF navigation rules:

1. from-activity-id, from-action, from-outcome
2. from-activity-id, from-outcome
3. from-activity-id

ADF Controller first searches for a match in all three elements: from-activity-id, from-action, and from-outcome. If there is no match, ADF Controller searches for a match in just the from-activity-id and from-outcome elements. Finally, ADF Controller searches for a match in the from-activity-id element alone.

If ADF Controller cannot find a control flow rule within its metadata to match a request, it allows the standard JSF navigation handler to find a match.

The unbounded task flow can have more than one ADF Controller XML source file. Because control flow rules can be defined in more than one ADF Controller XML source file, similar rules may be defined in different files. If there is a conflict in which two or more cases have the same from-activity-id, and the same from-action or from-outcome values, the last case (as listed in the adfc-config.xml, bootstrap, or bounded task flow source file) is used. If the conflict is among rules defined in different source files, the rule in the last source file to be loaded is used.

ADF Controller also implements the following interface with a number of restrictions:

```
javax.faces.application.ConfigurableNavigationHandler
```

The restrictions are:

- The Map object returned by getNavigationCases() is not modifiable. Any runtime changes to control flow rules must be made with the customization features provided with the MDS framework. For more information, see Customizing Applications with MDS .
- Do not invoke the performNavigation() method after the JSF Invoke Application phase. This is to make sure that the view ID does not change between the ADF Prepare Render phase and the JSF Render Response phase. For more information about how the JSF and ADF phases integrate in the lifecycle of a page request, see Understanding the Fusion Page Lifecycle .
- The metadata values for a task flow view activity's Bookmark and Redirect properties populate the corresponding information for the navigation case objects returned by the getNavigationCases().

Testing Task Flows

ADF task flows, as in any other application, can be tested to debug any issues or test cases to either fix the issue or to improve its performance. The task flow can be either tested and then deployed to the WebLogic Server or the test flow can be tested while the execution is in progress on the WebLogic Server without interrupting the execution. The running and debugging process is different for different types of task flows.

The procedure for running and debugging task flows differs depending on whether the task flow is bounded or unbounded, whether it contains pages or page fragments, or whether it accepts input parameters.

JDeveloper and Oracle ADF provides a number of features that facilitate your testing of the task flows that you create. Among these is the ability to set ADF declarative breakpoints on task flow activities. See How to Set and Use Task Flow Activity Breakpoints. In addition, you can also modify a task flow's metadata for an application that is currently executing in the Integrated WebLogic Server. The changes that you make to the task flow can be deployed to the application without stopping the application and redeploying it to the Integrated WebLogic Server (also known as **hot reloading**). To do this, you invoke the make command on the modified task flow (right-click the task flow and choose **Make**). This deploys the modified task flow to the application executing in the Integrated WebLogic Server. For information about hot reloading, see Reloading Oracle ADF Metadata in Integrated WebLogic Server.

The Create Default Domain dialog appears the first time you run your application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

How to Run a Bounded Task Flow That Contains Pages

You can run or debug a bounded task flow that contains view activities that are pages.

For information on running a bounded task flow that contains view activities that are page fragments, see How to Run a Bounded Task Flow That Uses Page Fragments .

Before you begin:

It may be helpful to have an understanding of the factors that affect how you test a task flow. For more information, see Testing Task Flows.

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for ADF Task Flows.

To run or debug a bounded task flow that uses pages:

- In the task flow diagram, right-click the task flow and choose either **Run** or **Debug**.
- You can also run the task flow directly by entering its URL in the browser. For example:

  ```
  http://somecompany.com/internalApp/MyApp/faces/
  adf.task-flow?adf.tfId=displayHelp&adf.tfDoc=%2FWEB-
  INF%2Fdisplayhelp.xml&topic=createPurchaseOrder
  ```

  For more information, see What You May Need to Know About Calling a Bounded Task Flow Using a URL.
- In the Applications window, expand the **WEB-INF** node, right-click the bounded task flow and choose either **Run** or **Debug**.

How to Run a Bounded Task Flow That Uses Page Fragments

Bounded task flows that use page fragments are intended to run only within an ADF region. A **page fragment** is a JSF document that renders as content in another JSF page. For more information, see About Page Fragments and ADF Regions.

Before you begin:

It may help to understand what factors affect how you test a task flow. For more information, see Testing Task Flows.

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for ADF Task Flows.

You will need to complete these tasks:

1. Create a JSF page containing a region that binds to the bounded task flow. JDeveloper automatically creates the region for you in a JSF page when you drop a bounded task flow containing page fragments on a page. For more information about creating regions, see Creating an ADF Region.
2. Create a view activity in the project's unbounded task flow that refers to the page. For more information, see How to Add an Activity to a Task Flow.

To run or debug a bounded task flow that uses page fragments:

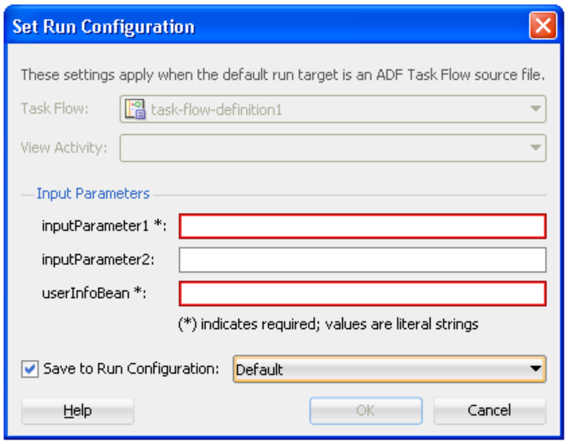
- Right-click the view activity in the Applications window or in the task flow diagram and choose **Run**.

How to Run a Bounded Task Flow That Has Parameters

Before you run a bounded task flow with parameters, you must first run a bounded task flow containing pages. For more information, see How to Run a Bounded Task Flow That Uses Page Fragments .

When you attempt to run or debug a bounded task flow with input parameters defined, the Set Run Configuration dialog appears, as shown in Figure 23-16. You enter values that you want to pass to the bounded task flow in this dialog and click **OK**. For more information about how to define input parameters for a bounded task flow, see Using Parameters in Task Flows.

Figure 23-16 Set Run Configuration dialog



Set Run Configuration

These settings apply when the default run target is an ADF Task Flow source file.

Task Flow: task-flow-definition1

View Activity:

Input Parameters

inputParameter1 *:

inputParameter2:

userInfoBean *:

(*) indicates required; values are literal strings

☑ Save to Run Configuration: Default

Before you begin:

It may be helpful to have an understanding of the factors that affect how you test a task flow. For more information, see Testing Task Flows.

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for ADF Task Flows.

To run or debug a bounded task flow that has input parameter definitions:

1. In the diagram for the bounded task flow, right-click the task flow and choose either **Run** or **Debug**.
2. In the **Input Parameters** list of the Set Run Configuration dialog, enter values that you want to be passed as input parameters to the task flow. If you do not specify a value, the input parameter is not used when calling the bounded task flow.

   Each required input parameter in the list appears with an asterisk, as shown in Figure 23-16. You must specify the parameter value as a literal string. You cannot specify an EL expression.
3. Click **OK**.

How to Run a JSF Page When Testing a Task Flow

You can run a JSF page by right-clicking the page in the Applications window and choosing **Run**. However, if the page contains navigation UI components, such as a button or link, navigation is not guaranteed to work.

Before you begin:

It may be helpful to have an understanding of the factors that affect how you test a task flow. For more information, see Testing Task Flows.

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for ADF Task Flows.

You will need to complete these tasks:

1. Create a bounded or unbounded task flow.

   For more information, see How to Create a Task Flow.

2. Add a view activity to the task flow.

   For more information, see How to Add an Activity to a Task Flow.

To run a JSF Page with fully functioning navigation:

1. In the Applications window, drag the JSF page you want to run and drop it onto the view activity in the task flow diagram.

   This associates the view activity with the JSF page.

2. In the diagram, right-click the view activity and choose **Run**.

How to Run an Unbounded Task Flow

To run or debug an unbounded task flow, you choose a specific view activity with which to start the unbounded task flow.

Before you begin:

It may be helpful to have an understanding of the factors that affect how you test a task flow. For more information, see Testing Task Flows.

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for ADF Task Flows.

To run a view activity in the unbounded task flow:

- In the task flow diagram, right-click the view activity and choose either **Run** or **Debug**.

  The unbounded task flow runs beginning with the selected view activity.

- If you have selected something other than a single view activity (or have nothing selected), you are prompted to choose one in the Set Run Configuration dialog.

How to Set a Run Configuration for a Project

A **run configuration** contains settings that determine how projects run, such as specifying the first activity to run in a task flow. You can define one or more run configurations for a project. Within a run configuration, you can designate an ADF Controller source file as the default run target. When you run the project, the source file is the first to run.

Before you begin:

It may be helpful to have an understanding of the factors that affect how you test a task flow. For more information, see Testing Task Flows.

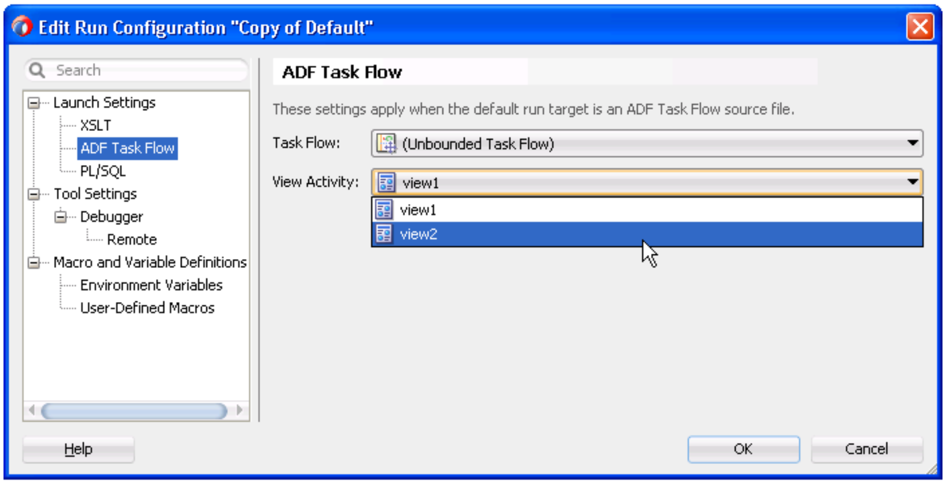
You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for ADF Task Flows.

To define a default task flow run target:

1. In the Applications window, right-click the project where you want to define a default task flow run target and choose **Project Properties**.
2. In the Project Properties dialog, select **Run/Debug** and click **New** in the Run Configurations list.
3. In the Create Run Configuration dialog, enter the name for the new run configuration.
4. If you want to base the new configuration on an existing one, choose a configuration in the **Copy Settings From** dropdown list.
5. Click **OK** to exit the Create Run Configuration dialog.
6. In the Run Configurations list, click **Edit**.
7. In the **Default Run Target** field in the Edit Run Configuration dialog, specify a source file for the task flow that should run first when you run the project.

   Once you choose a task flow, you can set a view activity (for the unbounded task flow) or input parameters (for bounded task flows).
8. In the left panel of the Edit Run Configuration dialog, click **ADF Task Flow**.
9. In the **Task Flow** dropdown list, located on the right panel, choose the task flow containing the run target.
10. If you are running the unbounded task flow, the Edit Run Configuration dialog displays the **View Activity** dropdown list where you choose the view activity that runs first in the application, as shown in Figure 23-17.

Figure 23-17 Edit Run Configuration Dialog



Edit Run Configuration "Copy of Default"

ADF Task Flow

These settings apply when the default run target is an ADF Task Flow source file.

Task Flow: (Unbounded Task Flow)

View Activity: view1

11. Click **OK**.

    The next time you run the project, the saved run configuration will be available in the **Run** > **Choose Active Run Configuration** menu.

    If you are running a bounded task flow that has been set up to accept input parameters, a dialog displays a section for specifying values for all input parameters defined for the bounded task flow. For more information, see How to Run a Bounded Task Flow That Has Parameters .

What Happens at Runtime: Testing Task Flows

The behavior that you observe when you test a task flow may depend on a number of factors. For example, if you attempt to run or debug a bounded task flow with input parameters defined, the Set Run Configuration dialog appears. Also, if it is the first time that you attempt to test an application in this installation of JDeveloper, the Create Default Domain dialog appears so that you can start a new domain in Integrated WebLogic Server.

Refactoring to Create New Task Flows and Task Flow Templates

ADF task flows allow you to create task flows and task flow templates by reusing the existing activities, JSF page flows, and JSF pages. The new bounded task flow that you extract displays in the task flow diagram.

You can convert existing activities, JSF page flows, and JSF pages into new ADF Controller components such as bounded task flows and task flow templates.

How to Extract a Bounded Task Flow from an Existing Task Flow

You can create a new bounded task flow based on activities you choose in an existing bounded or unbounded task flow.

Before you begin:

It may be helpful to have an understanding of the factors that affect how you refactor a task flow. For more information, see Refactoring to Create New Task Flows and Task Flow Templates.

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for ADF Task Flows.

To extract a bounded task flow from an existing task flow:

1. In the Applications window, expand the **WEB-INF** node and double-click the unbounded or bounded task flow containing the activities you want to extract to a new bounded task flow.
2. In the task flow diagram, select one or more activities.

   > **Tip:**
   >
   > To select multiple activities in a diagram, click the left mouse button and drag the cursor over the activities.
   >
   > You can also press the Ctrl key while selecting each activity.

3. Right-click your selection and choose **Extract Task Flow**.

4. In the Extract Bounded Task Flow dialog, enter a file name for the new bounded task flow and enter the name of the directory that stores it.

   For more information about creating a bounded task flow, see Creating a Task Flow.

What Happens When You Extract a Bounded Task from an Existing Task Flow

The new bounded task flow that you extract displays in the task flow diagram. Table 23-6 describes the properties that JDeveloper automatically sets for the new bounded task flow.

Table 23-6 Properties Updated in the New Bounded Task Flow

Property	Value
Task flow definition ID	Value you entered in the **File Name** field in the Extract Bounded Task Flow dialog.
Default activity	Determined as the destination of all incoming control flow cases. If more than one destination exists, an error is flagged and the entire operation is rolled back.
Control flow rules	Control flow cases with selected source activities are included in the new bounded task. A **source activity** is an activity from which a control flow leads. The new bounded task flow includes the following types of control flow cases: • Both the source and target activities in the control flow case were selected to create the new task flow. • Only the source activity was selected to create the new task flow. Destinations are changed to the corresponding new task flow return activities added for each outcome.

The following changes automatically occur in the originating task flow (the task flow containing the activities you selected as the basis for the new task flow):

- A new task flow call activity is added to the originating task flow. The task flow call activity calls the new bounded task flow.
- The selected activities are removed from the originating task flow.
- Existing control flow cases associated with the activities you selected are removed from the originating task flow. They are replaced with new control flow cases:
  - An incoming control flow case to the old activity is redirected to the new task flow call activity.
  - An outgoing control flow case from the old activity is redirected from the new task flow call activity.

How to Create a Task Flow from JSF Pages

You can create a new bounded task flow based on selected pages in a JSF page flow. JDeveloper converts the JSF pages that are part of a flow (that is, those that are linked by JSF navigation cases) to view activities in the new task flow.

Before you begin:

It may be helpful to have an understanding of the factors that affect how you refactor a task flow. For more information, see Refactoring to Create New Task Flows and Task Flow Templates.

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for ADF Task Flows.

To create a new task flow from selected JSF pages in a page flow:

1. In the Applications window, double-click the page flow containing the pages you want to use in the new bounded task flow.
2. In the task flow diagram, select one or more JSF pages.

   > **Tip:**
   >
   > To select multiple elements in a diagram, click the left mouse button and drag the cursor over the elements.
   >
   > You can also press the Ctrl key while selecting each element.

3. Right-click your selection and choose **Generate ADF Task Flow**.

   The Create Task Flow dialog appears, which allows you to create a new unbounded or bounded task flow.
4. In the Create Task Flow dialog, enter a file name and directory for the task flow. Clear the **Create as Bounded Task** checkbox if you want to create an unbounded task flow.

   For more information, see Creating a Task Flow.
5. Click **OK**.

How to Convert Bounded Task Flows

You can convert an existing bounded task flow to an unbounded task flow or change whether the views it contains are pages or page fragments. Table 23-7 describes the results of each conversion.

Table 23-7 Converting Bounded Task Flows

Conversion	Result
Bounded task flow to unbounded task flow	Loses all metadata not valid for unbounded task flows, such as parameter definitions and transactions.
Bounded task flow to use JSF pages	Converts page fragments associated with any view activities in the task flow to JSF pages. Old page fragments are saved if you select the **Keep Page Fragment** checkbox. New JSF page names default to the name of the old page fragment.
Bounded task flow to use page fragments	Converts all pages associated with view activities in the bounded task flow to page fragments. Old pages are saved if you select the **Keep Page** checkbox. New page fragment names default to the name of the old page

Before you begin:

It may be helpful to have an understanding of the factors that affect how you refactor a task flow. For more information, see Refactoring to Create New Task Flows and Task Flow Templates.

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for ADF Task Flows.

To convert a bounded task flow:

1. In the Applications window, expand the **WEB-INF** node and double-click the bounded task flow that you want to convert.
2. In the task flow diagram, right-click anywhere other than on an activity or a control flow.
3. Choose the appropriate menu option:
   - **Convert to Unbounded Task Flow**
   - **Convert to Task Flow with Page Fragments**
   - **Convert to Task Flow with Pages**

24

Working with Task Flow Activities

This chapter describes how to use activities in ADF task flows that you create in your Fusion web application. The chapter contains detailed information about each task flow activity type that displays in the Components window in addition to describing the properties that you can configure for each task flow activity type.
This chapter includes the following sections:

About Task Flow Activities

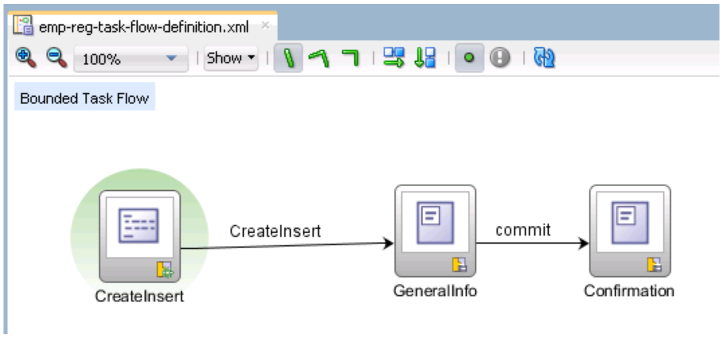
The ADF task flow activity is a module or independent set of tasks to be executed to complete a task. You can add activities to both bounded and unbounded task flows; however, certain activities can only be added to a bounded task flow.

An **activity** represents a piece of work that is performed when the task flow runs. It displays in the task flow's diagram editor as a node. You can add most activities to both bounded and unbounded task flows, although some activity types can be added only to bounded task flows.

Figure 24-1 shows the `emp-reg-task-flow-definition.xml` bounded task flow from the Summit sample application for ADF task flows. This task flow contains the following activities:

1. A method call activity that invokes a `CreateInsert` action
2. A view activity that renders a page fragment where end users can enter general information about the employee to be created
3. A view activity that renders a page fragment where a confirmation message appears if the end user successfully creates the new employee

Figure 24-1   Bounded Task Flow with Task Flow Activities



A task flow consists of activities and control flow cases that define the transitions between activities. Table 24-1 describes the types of activities and control flows you can add to a task flow by dragging and dropping from the Components window.

Table 24-1   Task Flow Activities and Control Flows

Icon	Component Name	Description
	Method Call	Invokes a method, typically a method on a managed bean. A method call activity can be placed anywhere within an application's control flow to invoke application logic based on control flow rules. See Using Method Call Activities.
	Parent Action	Allows a bounded task flow to generate outcomes that are passed to its parent view activity. Typically used for a bounded task flow running in an ADF region that needs to trigger navigation of its parent view activity. See Navigating Outside an ADF Region's Task Flow.
	Router	Evaluates an EL expression and returns an outcome based on the value of the expression. For example, a router in a credit check task flow might evaluate the return value from a previous method call and generate success, failure, or retry outcomes based on various cases. These outcomes can then be used to route control to other activities in the task flow. See Using Router Activities.
	Save Point Restore	Restores a previous persistent save point, including application state and data, in an application supporting save for later functionality. A save point captures a snapshot of the Fusion web application at a specific instance. Save point restore enables the application to restore whatever was captured when the save point was originally created. See Using Save Points in Task Flows.

Table 24-1 (Cont.) Task Flow Activities and Control Flows

Icon	Component Name	Description
	Task Flow Call	Calls a bounded task flow from the unbounded task flow or another bounded task flow. See Using Task Flow Call Activities.
↵	Task Flow Return	Identifies when a bounded task flow completes and sends control flow back to the caller. (Available for bounded task flows only). See Using Task Flow Return Activities .
	URL View	Redirects the root view port (for example, a browser page) to any URL-addressable resource, even from within the context of an ADF region. For more information see Using URL View Activities.
	View	Displays a JSF page or page fragment. Multiple view activities can represent the same page or same page fragment. See Using View Activities for more information. For more information about pages and page fragments, see Creating a Web Page.
➡	Control Flow Case	Identifies how control passes from one activity to the next in the application. See About Control Flows.
	Wildcard Control Flow Rule	Represents a control flow case that can originate from any activities whose IDs match a wildcard expression. For example, it can represent a control case `from-activity-id` containing a trailing wildcard such as `foo*`. See How to Add a Wildcard Control Flow Rule .

Table 24-2 describes the annotations (notes and attachments) you can add to a task flow.

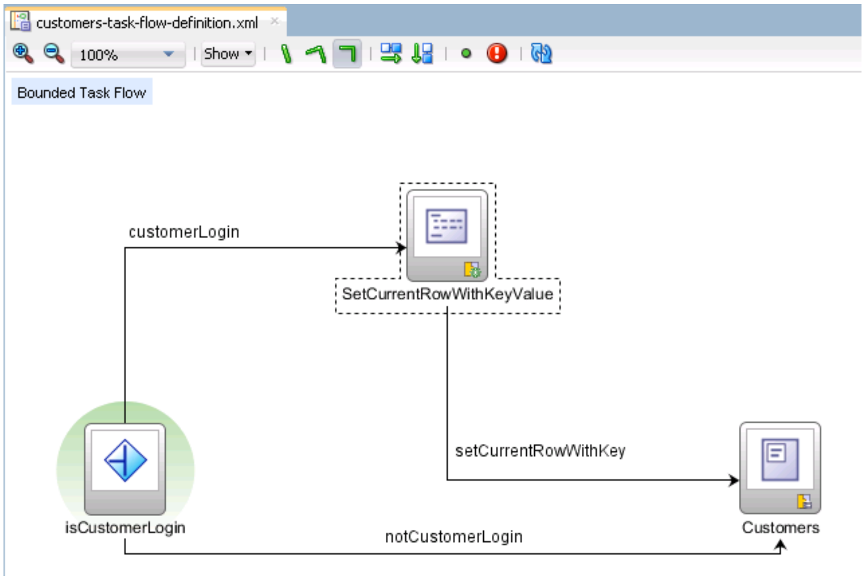
Table 24-2   Task Flow Diagram Annotations

Icon	Icon Name	Description
🟨	Note	Adds a note to the task flow diagram. You can choose the note in the diagram to add or edit text.
	Note Attachment	Attaches an existing note to an activity or a control flow case in the diagram.

Task Flow Activities Use Cases and Examples

Figure 24-2 shows the diagram for the customer task flow in the Summit ADF task flow sample application. This task flow uses a number of the activities that a bounded task flow supports in order to complete a task. For more information about the Summit ADF sample applications, see Introduction to the ADF Sample Application.

Figure 24-2   Customers Task Flow in the Summit ADF Task Flow Sample Application



Additional Functionality for Task Flow Activities

You may find it helpful to understand other **Oracle ADF** features before you configure or use task flow activities. Additionally, you may want to read about what you can do with your configured task flows. Following are links to other functionality that may be of interest.

- Task flows can invoke managed beans. For more information about managed beans, see Using a Managed Bean in a Fusion Web Application.
- Bounded task flows can be secured by defining the privileges that are required for someone to use them. For more information, see Enabling ADF Security in a Fusion Web Application.
- Bounded task flows can be packaged in ADF Library JARs. For more information, see Packaging a Reusable ADF Component into an ADF Library.
- Task flow activities can be associated with page definition files. For more information about page definition files, see Working with Page Definition Files.

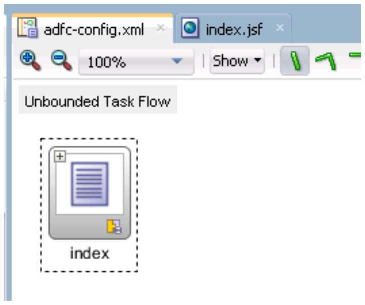
Using View Activities

The ADF task view activity allows you to display a JSF page or a page fragment. At runtime, you can transfer the control from one task flow to another. Users can bookmark a view activity within an unbounded task flow. Also, you can allow users to visit a URL by configuring a view activity.

One of the primary types of task flow activity is the view activity. A view activity displays a JSF page or page fragment. A **page fragment** is a JSF document that renders as content in another JSF page. Page fragments are typically used in bounded task flows that can be added to a JSF page as a region, as described in Creating an ADF Region.

Figure 24-3 shows the `index` view activity in the Summit ADF task flow sample application.

Figure 24-3 View Activity



> **Tip:**
>
> Click the + icon in the upper-left part of the view activity to see a thumbnail preview of the referenced page or page fragment.

XML metadata in the source file of the task flow associates a view activity with a physical JSF page or page fragment. An `id` attribute identifies the view activity.

The <page> element identifies the page or page fragment's file name. The following example shows the metadata that corresponds to the view activity in Figure 24-3:

```
<view id="index">
   <page>/index.jsf</page>
 </view>
```

The view activity ID and page name do not have to be the same.

The steps for adding a view activity to a task flow are the same as those for adding any activity to a task flow diagram. For more information, see How to Add an Activity to a Task Flow. After you add the view activity, you can double-click it to display a wizard that allows you to create a new page or page fragment. The wizard allows you to choose between one of the following two document types for the JSF page or page fragments that you create:

- Facelets

  The file extension for pages in this document type is .jsf and .jsff for page fragments.
- JSP XML

  The file extension for pages in this document type is .jspx and .jsff for page fragments.

Use one document type only in your task flows. For example, do not use the Facelets document type for view activities in one task flow and the JSP XML document type for view activities in another task flow. For more information about the document types, see Implementing the User Interface with JSF.

You also use the wizard to choose the page layout for the page or page fragment that you create. For more information about page layouts, see the "Using Quick Start Layouts" section in *Developing Web User Interfaces with Oracle ADF Faces*. In addition, you can specify whether or not to automatically expose UI components on the page or page fragment in a managed bean. For more information, see Using a Managed Bean in a Fusion Web Application.

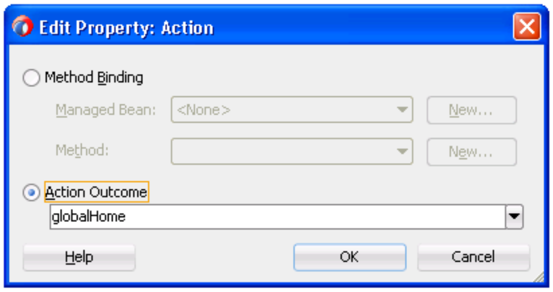
After you complete the wizard, JDeveloper automatically associates the completed page or page fragment with the view activity. As an alternative to using the wizard, you can associate a page or page fragment with a view activity by dragging an existing page or page fragment from the Applications window and dropping it on top of an existing view activity. If no view activity exists, drag a page or page fragment to any other location on the diagram. When you drop the page or page fragment, JDeveloper automatically creates a new view activity associated with the page or page fragment. During creation, a default id for the view activity is automatically generated (for example index) based on the name of the page or page fragment.

Passing Control Between View Activities

You can configure view activities in your task flow to pass control to each other at runtime. For example, to pass control from one view activity (view activity A) to a second view activity (view activity B), you could configure a command component (a button or a link) on the page associated with view activity A. Set the command component's **Action** attribute to the control flow case from-outcome that corresponds to the task flow activity that you want to invoke (for example, view activity B). At runtime, the end user initiates the control flow case by invoking the command component. You can navigate from a view activity to another activity using either a constant or dynamic value on the **Action** attribute of the UI component.

A constant value of the component's **Action** attribute is an action outcome, as shown in Figure 24-4, that always triggers the same control flow case. When an end user clicks the component, the activity specified in the control flow case is performed. There are no alternative control flows.

Figure 24-4   Edit Property Dialog



Edit Property: Action

○ Method Binding

Managed Bean: <None>

Method:

● Action Outcome

globalHome

A dynamic value of the component's **Action** attribute is bound to a managed bean or a method. The value returned by the method binding determines the next control flow case to invoke. For example, a method might verify user input on a page and return one value if the input is valid and another value if the input is invalid. Each of these different action values trigger different navigation cases, causing the application to navigate to one of two possible target pages.

You can also write an EL expression that must evaluate to `true` before control passes to the target view activity. You write the EL expression as a value for the `<if>` child element of the control flow case in the task flow. For more information, see How to Add a Control Flow Rule to a Task Flow.

How to Pass Control Between View Activities

You pass control to a view activity by specifying the value of the control flow case's `from-outcome` attribute as the value for the `action` attribute of the command component.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you configure the passing of control between view activities. For more information, see Passing Control Between View Activities.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

You will need to complete these tasks:

- Create a target view activity to receive control after an end user invokes the command component at runtime
- Create a JSF page that will host a command component for the end user to invoke at runtime

To pass control to a view activity:

1. In the Applications window, double-click the JSF page.
2. In the editor window, use one of the following options to add a UI component to the JSF page:
   - In the ADF Faces page of the Components window, from the General Controls panel, drag a navigation UI component, such as **Button** or **Link**, and drop it onto the page.
   - From the Data Controls panel, drag and drop an operation or a method onto the JSF page and, from the context menu, choose **ADF Button** or **ADF Link**.
3. In the Properties window, expand the **Common** section, and select **Edit** in the dropdown menu that you invoke from the icon that appears when you hover over the **Action** property field.
4. In the Edit Property: Action dialog, select **Action Outcome** and choose a value from the associated dropdown list.

   The list contains the control flow case already defined for the view activity associated with the page.

> **Tips:**
>
> The action attribute of the UI component can be bound either to a literal string to hard code a navigation case, or it can be bound to a method binding expression that points to a method, which takes no arguments and returns a String. It cannot be bound to any other type of EL expression.

What Happens When You Pass Control Between View Activities

The following example shows a control flow case defined in the XML source file for a bounded or unbounded task flow.

```
<control-flow-rule>
    <from-activity-id>Start</from-activity-id>
       <control-flow-case>
          <from-outcome>toOffices</from-outcome>
          <to-activity-id>WesternOffices</to-activity-id>
       </control-flow-case>
</control-flow-rule>
```

As shown in Example 24-1, a button on a JSF page associated with the Start view activity specifies toOffices as the **action** attribute. When the user clicks the button, control flow passes to the WesternOffices activity specified as the to-activity-id in the control flow metadata.

Example 24-1   Static Navigation Button Defined in a View Activity

```
<af:button text="Go" id="b1" action="toOffices">
```

Bookmarking View Activities

Bookmarking is available only for view activities within unbounded task flows.

When an end user bookmarks a page associated with a view activity, the URL that displays in the browser's address field for the view is saved as the bookmark. In most cases, this URL cannot be used to redisplay the page associated with the view. For example, the URL may contain state information that cannot be used to redisplay the page.

The bookmark URL should contain information that enables dynamic content on the page to be reproduced. For example, if an end user bookmarks a page displaying a customer's contact information, the bookmark URL needs to contain not only the page but also some identifier for the customer. This enables contact information for the same customer to display when the customer returns to the page using the bookmark.

To make sure that the URL for a page displayed in a browser can be used as a bookmark, identify the view activity associated with the page as bookmarkable.

At runtime, you can identify if a view activity within the unbounded task flow has been designated as bookmarkable using the `isViewBookmarkable()` method. The method is located off the view port context.

After you designate a view activity as bookmarkable, you can optionally specify one or more URL parameters. The value of `url-parameter` is an EL expression. The EL expression specifies where the parameters that will be included in the URL are retrieved when the bookmarkable URL is generated. The EL expression also stores a value from the URL when the bookmarkable URL is dereferenced. The `converter` option identifies a method that performs conversion and validation when parameters are passed via bookmarkable view activity URLs.

In addition, you can specify an optional method that is invoked after updating the application model with submitted URL parameter values and before rendering the view activity. You can use this method to retrieve additional information based on URL parameter key values.

The following example contains the URL syntax for a bookmarked view activity.

```
<server root>/<app_context>/faces/<view activity id>?<param name>=<param
value>&...
```

The syntax of the URL for the bookmarked view activity is:

- `<server root>`: Provided by customization at site or administrator level, for example, `http://mycompany.com/internalApp`.
- `<app context>`: The web application context root, for example, `myapp`. The context root is the base path of a web application. For example, `<app_context>` maps to the physical location of the WEB-INF node on the server.
- `faces`: The Faces servlet mapping. The value in `faces` points to the node containing the `faces-config.xml` configuration file.
- `<view activity id>`: The identifier for the bookmarked view activity, for example, `edit-customers`.
- `<param name>`: The name of the bookmarked view activity URL parameter, for example, `customer-id`.
- `<param value>`: The parameter value, derived from an EL expression, for example, `#{pageFlowScope.employee.id}`. The value of the EL expression must be capable of being represented as a string.

Example 24-2 contains a sample URL for a bookmarkable view activity in an unbounded task flow.

Example 24-2   Sample URL for Bookmarkable View Activity

```
http://mycompany.com/internalApp/MyApp/faces/edit-customers?customer-
id=1234&...
```

How to Create a Bookmarkable View Activity

To create a bookmarkable view activity, designate a view activity as bookmarkable, specify a URL parameter in the bookmark, and specify a method that is executed after the bookmark is dereferenced.

Before you begin:

It may be helpful to have an understanding of the syntax required to create a bookmarkable view activity. For more information, see Bookmarking View Activities.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

To designate a view activity as bookmarkable:

1. In the Applications window, expand the **WEB-INF** node and double-click the unbounded task flow where you want to designate a view activity as bookmarkable.
2. In the diagram for the unbounded task flow, choose the view activity that you want to designate as bookmarkable.
3. In the Properties window, expand the **Bookmark** section, and select `true` from the **Bookmark** dropdown list.
4. Enter an EL expression in the **Method** field to specify a method to invoke after ADF Controller updates the application model with the corresponding bookmark URL parameter values.
5. To add optional URL parameters to include in the URL for the bookmarked view activity, click **Add** and enter the URL parameter in the Bookmark URL Parameters list:
   - **Name**: the name for the URL parameter.
   - **Value**: A settable EL expression that, when evaluated, specifies the parameter value, for example, `#{pageFlowScope.employeeID}`. The value must be capable of being represented as a string.

     The value property is where the parameters to include in the URL are retrieved from when the bookmarkable URL is generated. In addition, parameters are stored here when the bookmarkable URL is dereferenced. If the EL expression returns `NULL`, the parameter is omitted from the bookmarked view activity URL. Example 24-2 shows how name and value are used to append a bookmark parameter to a view activity URL.
   - **Converter**: (optional) Enter a value binding for the bookmark URL parameter value, for example: `#{pageFlowScope.employee.idConverter}`.

     The object that the EL expression references must implement: `oracle.adf.controller.URLParameterConverter`

A URL parameter converter's `getAsObject()` method takes a single string value as its input parameter and returns an object of the appropriate type. ADF Controller invokes the converter method on the URL parameters before applying the parameter value to the application's model objects. Similarly, the URL parameter converter's `getAsString()` method takes an object as its input parameter and returns a string representation that is used on the URL.

In a JSF application, data values are converted and validated using the converters and validators specified with the UI components on the submitting page. In a Fusion web application using a bookmarkable URL, there is no submitting page to handle conversion and validation. Therefore, you have the option of designating a converter to use for each URL parameter.

What Happens When You Designate a View as Bookmarkable

When you designate a view activity as bookmarkable, a bookmark element is added to the metadata for the view activity, as shown in the following example. The bookmark element can optionally contain metadata specifying URL parameters and a method to execute after the bookmark is dereferenced.

```
<view id="employee-view">
  <page>/folderA/folderB/display-employee-info.jsf</page>
     <bookmark>
        <url-parameter>
          <name>employee-id</name>
          <value>#{pageFlowScope.employee.id}</value>
          <converter>#{pageFlowScope.employee.validateId}</converter>
        </url-parameter>
       <method>#{pageFlowScope.employee.queryData}</method>
     </bookmark>
</view>
```

Specifying HTTP Redirect for a View Activity

You can configure a view activity so that it redirects at runtime to a URL in response to a client request. This causes ADF Controller to create a new browser URL for the view activity. The original URL for the view activity is no longer used. You cannot configure HTTP redirect for a view activity if you have already made the view activity bookmarkable, as described in Bookmarking View Activities.

How to Specify HTTP Redirect for a View Activity

You set a view activity's `redirect` property to `true`.

Before you begin:

It may be helpful to have an understanding of the affect of setting a view activity's `redirect` property to `true`. For more information, see Specifying HTTP Redirect for a View Activity.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

To specify HTTP redirect for a view activity:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow.

2. In the task flow diagram, select the view activity.
3. In the Properties window, expand the **General** section, and in the **Redirect** dropdown list, select `true`.

What Happens When You Specify HTTP Redirect for a View Activity

The ADF Controller issues an HTTP redirect in response to a view activity request. The redirected request creates a new browser URL for the view activity. The original view URL is no longer used.

When specified, a HTTP redirect occurs in response to a client `GET` request. For a client `GET`, the `#{bindings}` EL scope is invalid until ADF Controller and ADF Model set up a new bindings context for the page. Therefore, you cannot use EL expressions, such as the following, for view activities for which you specified HTTP redirect:

```
#{bindings.foo}
```

> **Note:**
>
> If you want `http://www.mycompany.org/x.html` to instead display what is at `http://www.mycompany.org/y.html`, do not use refresh techniques such as:
>
> ```
> <META HTTP-EQUIV=REFRESH CONTENT="1; URL=http://www.example.org/
> bar">
> ```
>
> This technique could adversely affect back button behavior. If an end user clicks a browser back button, the refresh occurs again, and navigation is forward, not backward as expected.
>
> In this situation, use HTTP redirect instead.

Specifying URL Aliases for View Activities

The URL that a Fusion web application renders has a format that is generated at runtime based on the current context:

- If the view activity is in a bounded task flow, the application renders a URL in the following format:

  ```
  http://www.example.com/web-app-context-root/faces/task-flow-id/view-activity-
  ID
  ```

- If the view activity is in an unbounded task flow, the application renders a URL in the following format:

  ```
  http://www.example.com/web-app-context-root/faces/view-activity-ID
  ```

In order for end users to see a URL that may have a more meaningful name, you can specify a URL alias for a view activity. The URL alias value you specify renders instead of the default generated values. For example, in a task flow that manages data about fruit, you might have view activities to view and edit information about apples and oranges. In this scenario, your Fusion web application renders URL aliases like the following when an end user navigates to the view activity pages for apples and oranges:

```
http://www.example.com/web-app-context-root/faces/fruit/apples
http://www.example.com/web-app-context-root/faces/fruit/oranges
```

You can specify a number of different levels in URL aliases to communicate a hierarchy to end users. This means that both of the following values are valid for a view activity's URL alias:

```
/food/fruit/pineapple
/drink/juice/pineapple
```

However, the URL alias that you specify must be unique within the task flow that contains the view activity.

Specify URL aliases for view activities that render JSF pages, not JSF page fragments. This latter type of document does not render directly in the browser.

How to Specify a URL Alias for a View Activity

You specify a URL alias for a view activity by writing a value for the view activity's View-ID property (`<view-id>`).

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you specify a URL alias for a view activity. For more information, see Specifying URL Aliases for View Activities.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

You will need to complete these tasks:

- Create the view activity that renders a JSF page at runtime
- Create the JSF page that the end user views at runtime

To specify a URL alias for a view activity:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow that contains the view activity for which you want to specify a URL alias.
2. In the diagram for the task flow, select the view activity for which you want to specify a URL alias.
3. In the Properties window, expand the **General** section, and enter the URL alias value in the **View-ID** field.

   For example, enter a value in the following format:

   ```
   /food/fruit/citrus/lemons
   ```

What Happens When You Specify a URL Alias for a View Activity

JDeveloper adds the value that you specify in the **View-ID** field to the metadata for the view activity, as shown in the following example.

```
<view id="view1">
    <page>/view1.jsf</page>
    <view-id>/food/fruit/citrus/lemons</view-id>
  </view>
```

Using URL View Activities

The ADF task flow activity can display URLs and allow users to navigate to an external resource when you use the URL view activity. You can use this activity to redirect users to a location within the same application or you can redirect users to navigate to a region out of the web application.

You can use a URL view activity to redirect the root view port (for example, a browser page) to any URL-addressable resource, even from within the context of an ADF region. URL addressable resources include:

- Bounded task flows
- View activities in the unbounded task flow
- Addresses external to the current web application (for example, `http://www.oracle.com`)

To display the resource, you specify an EL expression that evaluates at runtime to generate the URL to the resource. In addition, you can specify EL expressions that, when evaluated, are added as parameters and parameter values to the URL.

A URL view activity redirects the client regardless of the view port (root view port or an ADF region) from which it is executed. The `<redirect>` element of a view activity performs in a similar way, except that it can be used only if the view activity is within the root view port. The `<redirect>` element is ignored within the context of an ADF region. See Specifying HTTP Redirect for a View Activity.

Redirecting elsewhere within the same application using URL view activities (not the `<redirect>` element) is handled similarly to back button navigation since the task flow stack is cleaned up. Redirecting out of the web application is handled like dereferencing a URL to a site external to the application.

How to Add a URL View Activity to a Task Flow

You can add a URL view activity to a bounded or unbounded task flow.

Before you begin:

It may be helpful to have an understanding of the affect of adding a URL view to the functionality of a task flow. For more information, see Using URL View Activities.

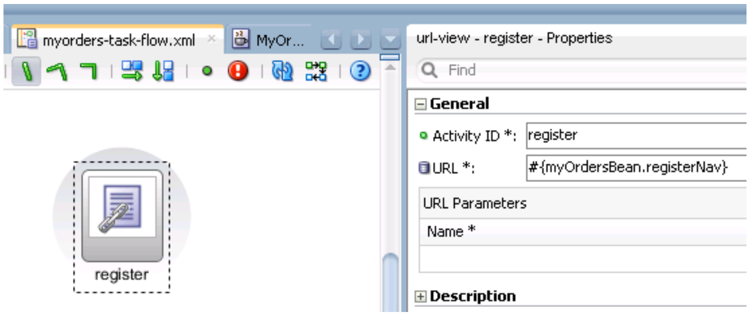
You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

To add a URL view activity to a task flow:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow to which you want to add a URL view activity.
2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a **URL View** onto the diagram.
3. In the Properties window, expand the **General** section, and enter an ID that identifies the URL view activity in the **Activity ID** field.
4. In the **URL** field, enter an EL expression that returns the URL at runtime. Click the icon that appears when you hover over the property field to use the Expression Builder if needed.

For example, Figure 24-5 shows a URL activity (**register**) in an application's `myorders-task-flow.xml` bounded task flow with an EL expression (`#{myOrdersBean.registerNav}`) that retrieves a URL at runtime.

Figure 24-5 URL View Activity



General

Activity ID *: register

URL *: #{myOrdersBean.registerNav}

URL Parameters

Name *

Description

5. Expand the **URL Parameters** section to add optional URL parameters to include in the URL:
   - **Name**: A name for the parameter.
   - **Value**: An EL expression that, when evaluated, generates the parameter value.
   - **Converter**: A settable EL expression that, when evaluated, specifies a method to perform conversion and validation when parameters are passed via bookmarkable view activity URLs. For more information, see Bookmarking View Activities.

What Happens When You Add a URL View Activity to a Task Flow

JDeveloper writes entries similar to those shown in the following example for the URL view activity in the source file of the task flow.

```
<url-view id="register">
      <url>#{myOrdersBean.registerNav}</url>
    </url-view>
```

What You May Need to Know About URL View Activities

Task flow URL view activities can be used within JSF portlets. Create the URL using one of the following options if you configure a task flow URL view activity for use within a JSF portlet:

- Invoke one of the following methods from the `ControllerContext` class in the `oracle.adf.controller` package:
  - `getLocalViewActivityURL()`
  - `getGlobalViewActivityURL()`

  Do not invoke the `encodeActionURL()` method from the `ADFPortletContainerExternalContext` class with the response from the `getLocalViewActivityURL()` or `getGlobalViewActivityURL()` methods before you invoke the `redirect()` method from the `ADFPortletContainerExternalContext` class. The `getLocalViewActivityURL()`

and `getGlobalViewActivityURL()` methods both perform the necessary encoding of the URL.

- Supply a fully qualified absolute URL.
- Supply a context path relative URL.
- Supply a URL relative to the current view.

A task flow URL view activity in a JSF portlet behaves as follows:

- If the redirect URL refers to a location in the JSF portlet application and does not contain a `queryString` parameter named `x_DirectLink` with a value of `true`, the portlet in the containing page navigates to the URL specified in the URL view activity.
- Otherwise, the client redirects to the URL specified in the URL view activity.

For more information about using a task flow's URL view activity, see Using URL View Activities.

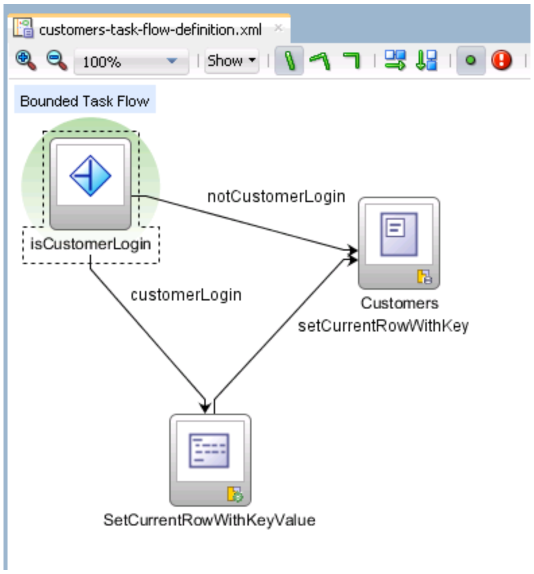
For information about the methods that you can use to get a URL, see the *Java API Reference for Oracle ADF Controller*.

Using Router Activities

While creating a task flow you may need to direct users to the activities based on the runtime evaluation of EL expressions. The ADF router activity allows you to route such controls to the appropriate activities.

Use a router activity to route control to activities based on the runtime evaluation of EL expressions. Figure 24-6 shows a router activity (**isCustomerLogin**) in the `customer-task-flow-definition.xml` task flow from the Summit ADF task flow sample application that can branch to different control flows leading from it to different activities.

Figure 24-6 Router for Alternate Control Flow Cases



Each control flow corresponds to a different router case. Each router case uses the following elements to choose the activity to which control is next routed:

- `expression`: an EL expression that evaluates to `true` or `false` at runtime.

  The router activity returns the outcome that corresponds to the EL expression that returns `true`.
- `outcome`: a value returned by the router activity if the EL expression evaluates to `true`, for example, `customerLogin`.

  If the router case `outcome` matches a `from-outcome` on a control flow case, control passes to the activity that the control flow case points to. If none of the cases for the router activity evaluate to `true`, or if no router activity cases are specified, the `outcome` specified in the router **Default Outcome** field (if any) is used.

Figure 24-6, for example, shows a router activity that passes control flow based on the evaluation of an EL expression that determines if the user is logged in and has a specific application role. If true, control passes to the SetCurrentRowWithKeyValue method call activity. Otherwise, control passes to the Customers view activity.

> **Note:**
>
> Use a router activity if your routing condition can be expressed in an EL expression.
>
> Using a router activity allows you to do more when you design the task flow that contains it. The router activity allows you to show more information about the condition on the task flow. This makes it more readable and useful to someone who looks at the diagram for your task flow.
>
> Using a router activity also makes it easier to modify your application later. For example, you may want to modify or add a routing condition later.

How to Configure Control Flow Using a Router Activity

You define a control flow by dragging a router activity from the Components window to the diagram for the task flow. You configure the Activity ID and Default Outcome properties of the router activity and add router cases to the router activity.

Before you begin:

It may be helpful to have an understanding of the properties of a router activity that can affect functionality. For more information, see Using Router Activities.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

To configure control flow using the router activity:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow where you want to configure a control flow using a router activity.
2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a **Router** activity onto the diagram.

3. In the Properties window, expand the **General** section and enter values for the following:
   - **Activity ID**: write a value that identifies the router activity in the task flow's source file.
   - **Default Outcome**: specify an activity that the router activity passes control to if no control flow cases evaluate to `true` or if no control flow case is specified.
4. Click the **Add** icon for the **Cases** section and specify values for each router case that you add:
   - **Expression**: An EL expression that evaluates to `true` or `false` at runtime.

     For example, to reference the value in an input text field of a view activity, write an EL expression similar to the following:

     ```
     #{pageFlowScope.value=='view2'}
     ```

     If this EL expression returns `true`, the router activity invokes the outcome that you specify in the **Outcome** field.
   - **Outcome**: The outcome the router activity invokes if the EL expression specified by **Expression** returns `true`.

     Create a control flow case or a wildcard control flow rule for each outcome in the diagram of your task flow. For example, for each outcome in a control flow case, make sure that there is a corresponding `from-outcome`.

What Happens When You Configure Control Flow Using a Router Activity

JDeveloper writes values to the source file of the task flow based on the values that you specify for the properties of the router activity. Example 24-3 shows the values that appear in the `customer-task-flow-definition.xml` task flow from the Summit ADF task flow sample application that branch to different control flows leading from the router activity to different activities.

At runtime, the router activity passes control to the control flow case specified by `outcome` if the EL expression returns `true`.

Example 24-3 Router Activity in the Summit ADF Task Flow Sample Application

```
<router id="isCustomerLogin">
      <case id="__4">
        <expression>#{securityContext.userInRole['Application Customer Role']}</expression>
        <outcome>customerLogin</outcome>
      </case>
      <default-outcome>notCustomerLogin</default-outcome>
    </router>
...
<control-flow-case id="__7">
        <from-outcome>customerLogin</from-outcome>
        <to-activity-id>SetCurrentRowWithKeyValue</to-activity-id>
      </control-flow-case>
```

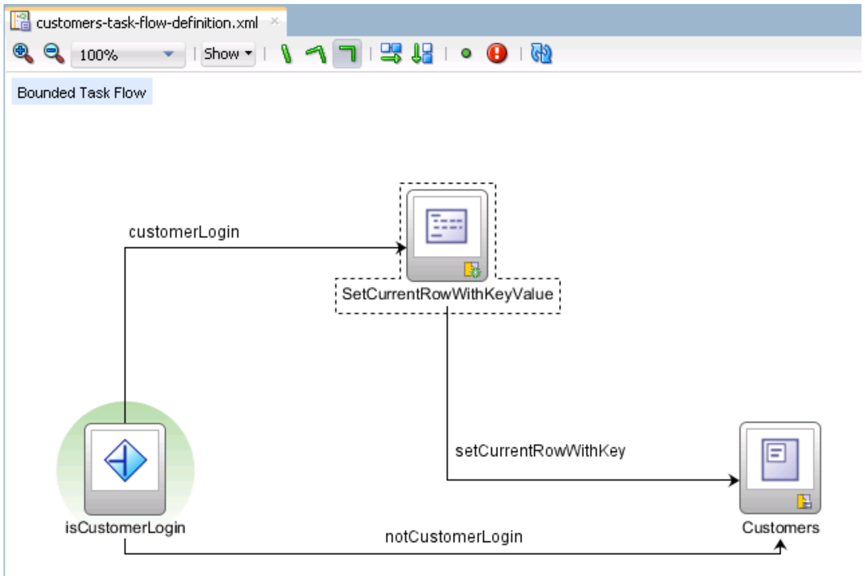
Using Method Call Activities

The ADF task flow allows you to call a custom method or invoke a built-in methods using method call activity. You can define the control flow to and from the method call activity. The method call outcome can be specified either as a fixed-outcome or as a to-string outcome.

Use a method call activity to call a custom or built-in method that invokes application logic from anywhere within an application's control flow. You can specify methods to perform tasks such as initialization before displaying a page, cleanup after exiting a page, exception handling, and so on.

Figure 24-7 shows the `customers-task-flow-definition.xml` task flow from the Summit ADF task flow sample application where the `SetCurrentRowWithKeyValue` method call activity invokes a `setCurrentRowWithKeyValues` operation from the `BackOfficeAppModuleDataControl` data control.

Figure 24-7 Method Call Activity to Set Row



You can set an outcome for the method that specifies a control flow case to pass control to after the method finishes. You can specify the outcome as either:

- `fixed-outcome`: On successful completion, the method always returns this single outcome, for example, `success`. If the method does not complete successfully, an outcome is not returned. If the method type is void, you must specify a `fixed-outcome`, not a `to-string`.
- `to-string`: If specified as `true`, the outcome is based on calling the `toString()` method on the Java object returned by the method. For example, if `toString()` returns `editBasicInfo`, navigation goes to a control flow case named `editBasicInfo`.

The following example shows the metadata for the method call activity in Figure 24-7 where the `fixed-outcome` element specifies `setCurrentRowWithKey` as the outcome to return.

```
<method-call id="SetCurrentRowWithKeyValue">
      <method>#{bindings.setCurrentRowWithKeyValue.execute}</method>
      <outcome>
        <fixed-outcome>setCurrentRowWithKey</fixed-outcome>
      </outcome>
```

For more information about control flows, see About Control Flows.

How to Add a Method Call Activity

Drag a method call activity from the Components window to the task flow diagram. You can associate the method call activity with an existing method by dropping a data control operation from the Data Controls panel directly onto the method call activity in the task flow diagram.

In the Summit ADF task flow sample application, for example, you could drag a `setCurrentRowWithKey` or `setCurrentRowWithKeyValues` operation to the diagram from the `BackOfficeAppModuleDataControl` data control in the Data Controls panel to create a method call activity that displays or selects the current row in a table.

Note:

Parameters for data control method parameters are defined in the page definition for the corresponding page rather than within ADF Controller metadata.

You can also drag methods and operations directly to the task flow diagram. A new method call activity is created automatically after you drop it on the diagram. You can specify an EL expression and other options for the method.

Tip:

To identify the method that a method call activity invokes, right-click the method call activity in the diagram of the task flow and choose **Go to Method**. JDeveloper navigates to the method that the method call activity invokes.

Before you begin:

It may be helpful to have an understanding of how the properties of a method call activity affect the functionality of a task flow. For more information, see Using Method Call Activities.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

You will need to complete this task:

Create a bounded or unbounded task flow. For more information, see Creating a Task Flow.

To add a method call activity to a task flow:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow where you want to add a method call activity.
2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a method call activity onto the diagram.

   The method call activity optionally displays a default activity ID, `methodCall`*`n`*, and a warning icon that indicates that a method EL expression has not yet been specified.

   For more information about turning on the warning icons, see How to Add an Activity to a Task Flow.
3. In the Properties window, expand the **General** section, and enter an activity ID in the **Activity ID** field if you want to change the default value.

   If you enter a new value, the new value appears under the method call activity in the diagram.
4. In the **Method** field, enter an EL expression that identifies the method to call.

   For example, enter an EL binding expression similar to the following:

   ```
   #{bindings.setCurrentRowWithKeyValue.execute}
   ```

   > **Note:**
   >
   > The `bindings` variable in the EL expression references an ADF Model binding from the current binding container. In order to specify the bindings variable, you must specify a binding container definition or page definition. For more information, see Working with Page Definition Files.

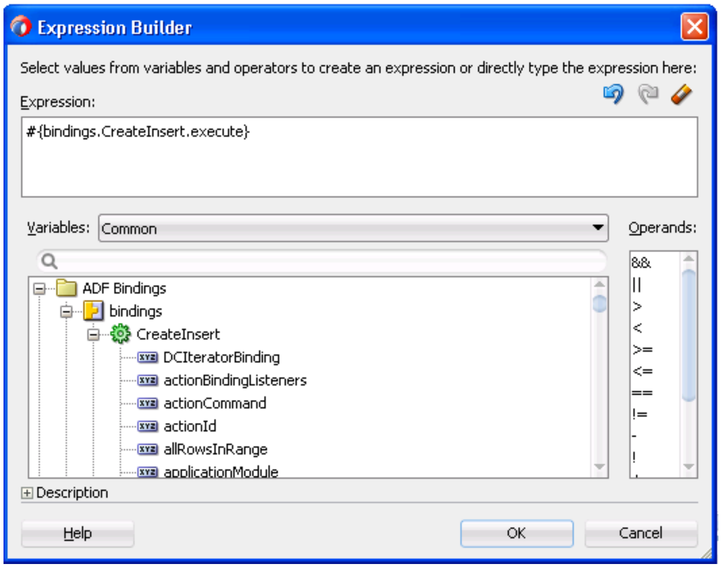
   You can also use the Expression Builder shown in Figure 24-8 to build the EL expression for the method:

   a. Choose **Method Expression Builder** from the context menu that appears when you click the icon that appears when you over the **Method** property field.

   b. In the Expression Builder dialog, navigate to the method that you want to invoke and select it.

      The Expression Builder dialog should look similar to Figure 24-8. In Figure 24-8, for example, the EL expression shown at the top of the Expression Builder references the `CreateInsert` action binding from the method call activity in the `emp-reg-task-flow-definition.xml` task flow of the Summit ADF task flow sample application.

Figure 24-8   EL Expression for Method in Expression Builder Dialog



Select values from variables and operators to create an expression or directly type the expression here:

Expression:

#{bindings.CreateInsert.execute}

Variables: Common

c. Click **OK**.

Tip:

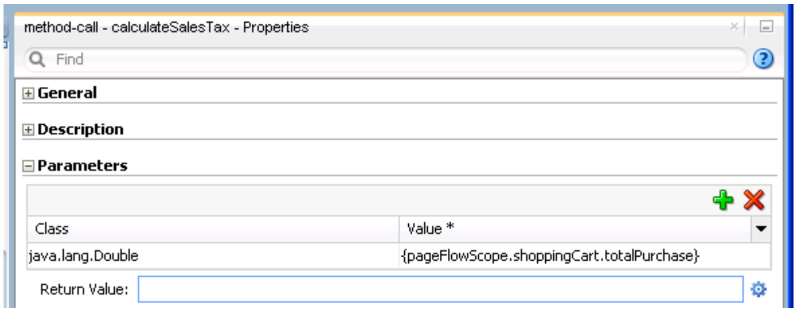
If the method call activity is going to invoke a managed bean method, double-click the method call activity in the diagram. This invokes a dialog where you can specify the managed bean method you want to invoke.

5. In the Properties window, expand the **General** section, and specify one of the following in the **Outcome** group:
   - **Fixed Outcome**: On successful completion, the method always returns this single outcome, for example, `success`. If the method does not complete successfully, an outcome is not returned. If the method type is void, you must specify a value for **Fixed Outcome** rather than for **to-string**.
   - **tostring()**: If you select **true**, the outcome is based on calling the `toString()` method on the Java object returned by the method.

How to Specify Method Parameters and Return Values

You can specify parameters and return values for a method. Figure 24-9 shows the Properties window with a single parameter defined for a method called `calculateSalesTax`. The **Value** field contains an EL expression that evaluates to the parameter value at runtime.

Figure 24-9 Method Parameters in a Method Call



Class	Value *
java.lang.Double	{pageFlowScope.shoppingCart.totalPurchase}

If parameters have not already been created by associating the method call activity to an existing method, add the parameters yourself.

Before you begin:

It may be helpful to have an understanding of how the properties of a method call activity affect the functionality of a task flow. For more information, see Using Method Call Activities.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

You will need to complete this task:

> Add a method call activity to the task flow diagram, as described in How to Add a Method Call Activity.

To add method parameters:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow that contains the method call activity to which you want to add method parameters.
2. In the task flow diagram, select the method call activity.
3. In the Properties window, expand the **Parameters** section, and click **Add** to set the following values for the parameter that you want to add:
   - **Class**: Enter the parameter class, for example, `java.lang.Double`.
   - **Value**: Enter an EL expression that retrieves the value of the parameter. For example:

     ```
     #{pageFlowScope.shoppingCart.totalPurchasePrice}
     ```
4. In the **Return Value** field, enter an EL expression that identifies where to store the method return value, for example, `#{pageFlowScope.Return}`.
5. Repeat the above steps to add additional parameters.

What Happens When You Add a Method Call Activity

After you specify parameters and return values for a method, the XML source file is updated. Example 24-4 shows the `SetCurrentRowWithKeyValue` method call activity in the `customers-task-flow-definition.xml` task flow from the Summit ADF task flow sample application.

Example 24-4 Method Call Activity in the Summit ADF Sample Application

```
<method-call id="SetCurrentRowWithKeyValue">
      <method>#{bindings.setCurrentRowWithKeyValue.execute}</method>
      <outcome>
        <fixed-outcome>setCurrentRowWithKey</fixed-outcome>
      </outcome>
    </method-call>
```

Using Task Flow Call Activities

The ADF task flow allows you to call a bounded task flow, to perform a set of activities, from a bounded or unbounded task flow. This is helpful when you want a set of activity to be performed repeatedly in your task flow or you want to perform an activity based on the outcome of another activity.

You can use a task flow call activity to call a bounded task flow from either the unbounded task flow or a bounded task flow. A task flow call activity allows you to call a bounded task flow located within the same or a different application.

The called bounded task flow executes its default activity first. There is no limit to the number of bounded task flows that can be called. For example, a called bounded task flow can call another bounded task flow, which can call another, and so on resulting in the creation of *chained task flows* where each task flow is a link in a chain of tasks.

To pass parameters into a bounded task flow, you must specify input parameter values on the task flow call activity. These values must correspond to the input parameter definitions on the called bounded task flow. For more information, see How to Specify Input Parameters on a Task Flow Call Activity .

Also note the following:

- The value on the task flow call activity **Input Parameter** specifies where the value will be taken from within the calling task flow.
- The value on the **Input Parameter Definition** for the called task flow specifies where the value will be stored within the called bounded task flow once it is passed.

> **Tip:**
>
> When a bounded task flow is associated with a task flow call activity, input parameters are automatically inserted on the task flow call activity based on the input parameter definitions defined on the bounded task flow. Therefore, the application developer needs only to assign values to the task flow call activity input parameters.

By default, all objects are passed by reference. Primitive types (for example, `int`, `long`, or `boolean`) are always passed by value.

The technique for passing return values out of the bounded task flow to the caller is similar to the way that input parameters are passed. For more information, see Configuring a Return Value from a Bounded Task Flow.

To use a task flow call activity:

1. Call a bounded task flow using a task flow call activity.
2. Specify input parameters on a task flow call activity if you want to pass parameters into the bounded task flow.
3. Call a bounded task flow in another web application using a URL.
4. Specify before and after listeners on a task flow call activity.

How to Call a Bounded Task Flow Using a Task Flow Call Activity

Add a task flow call activity to the calling bounded or unbounded task flow to call a bounded task flow.

Before you begin:

It may be helpful to have an understanding of how a task flow call activity interacts with a task flow. For more information, see Using Task Flow Call Activities.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

To call a bounded task flow using a task flow call activity:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow (calling task flow) to which you are going to add a task flow call activity to call a bounded task flow.
2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a **Task Flow Call** activity onto the diagram.
3. Choose one of these options to identify the called task flow:
   - In the task flow diagram, double-click the task flow call activity.

     The Create Bounded Task Flow dialog appears, where you specify options for creating a new bounded task flow.
   - Drag an existing bounded task flow from the Applications window and drop it on the task flow call activity.

> **Tips:**
>
> You can drop a bounded task flow on a page or page fragment. If the bounded task flow consists of pages (not page fragments), you can choose the **Task Flow Call as Button** or **Task Flow Call as Link** menu options that appear to add a button or link component on the page where you drop the task flow. An end user can click the button or link to call the task flow. This may in turn automatically generate the task flow call activity if the page is already associated with an existing view activity in a task flow.
>
> You cannot drop a bounded task flow from one application to a task flow diagram contained in another application using the Applications window, even though both applications appear in the Applications window. In addition, you cannot drop a bounded task flow contained in one project onto a task flow diagram contained in another project.
>
> Instead, you can package the bounded task flow in an ADF library, then reuse it in your current application or project. You can then drag the bounded task flow from the Resources window or from the Components window page that is created when you import the library. For more information, see Using the Resources Window.

- If you know the name of the bounded task flow that you want to invoke, perform the following steps:

  a. In the task flow diagram, select the task flow call activity.

  b. In the Properties window, expand the **General** section, and select **Static** from the **Task Flow Reference** dropdown list.

  c. In the **Document** field, enter the name of the source file for the bounded task flow to call. For example, `called-task-flow-definition.xml`.

  d. In the **ID** field, enter the bounded task flow ID contained in the XML source file for the called bounded task flow, for example, `targetTaskFlow`.

- If you do not know the name of the bounded task flow to invoke and it is dependent on an end user selection at runtime, perform the following steps:

  a. In the task flow diagram, select the task flow call activity.

  b. In the Properties window, expand the **General** section, and select **Dynamic** from the **Task Flow Reference** dropdown list.

  c. Select **Expression Builder** from the context menu that appears when you click the icon that appears when you hover over the **Dynamic Task Flow Reference** property field.

  d. Write an EL expression that identifies the ID of the bounded task flow to invoke at runtime.

Figure 24-10 shows the `customers-task-flow` task flow in the Summit ADF task flow sample application. This task flow contains a task flow call activity (**create-edit-orders-task-flow-definition**) that invokes the task flow of the same name.

What Happens When You Call a Bounded Task Flow Using a Task Flow Call Activity

JDeveloper generates metadata entries in the source file for the task flow that calls the bounded task flow. Example 24-5 shows the metadata that corresponds to Figure 24-10 from the Summit ADF task flow sample application. At runtime, the task flow call activity invokes the `orders-select-many-items` task flow.

Example 24-5 Task Flow Call Activity in the Summit ADF Sample Application

```
<task-flow-call id="orders-select-many-items">
      <task-flow-reference>
        <document>/WEB-INF/flows/orders/orders-select-many-items.xml</document>
        <id>orders-select-many-items</id>
      </task-flow-reference>
      <run-as-dialog>
        <display-type>
          <inline-popup/>
        </display-type>
      </run-as-dialog>
    </task-flow-call>
```

How to Specify Input Parameters on a Task Flow Call Activity

The suggested method for mapping parameters between a task flow call activity and its called bounded task flow is to first specify input parameter definitions for the called bounded task flow. Then you can drag the bounded task flow from the Applications window and drop it on the task flow call activity. The task flow call activity input parameters will be created automatically based on the bounded task flow's input parameter definition. For more information, see Passing Parameters to a Bounded Task Flow.

You can, of course, first specify input parameters on the task flow call activity. Even if you have defined them first, they will automatically be replaced based on the input parameter definitions of the called bounded task flow, once it is associated with the task flow call activity.

If you have not yet created the called bounded task flow, you may still find it useful to specify input parameters on the task flow call activity. Doing so at this point allows you to identify any input parameters you expect the task flow call activity to eventually map when calling a bounded task flow.

Before you begin:

It may be helpful to have an understanding of how a task flow call activity interacts with a task flow. For more information, see Using Task Flow Call Activities.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

To specify input parameters on a task flow call activity:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow that contains the task flow call activity.
2. In the diagram, select the task flow call activity.
3. In the Properties window, expand the **Parameters** section, and click the **Add** icon to specify a new input parameter in the **Input Parameters** list as follows:
   - **Name**: Enter a name to identify the input parameter.
   - **Value**: Enter an EL expression that identifies the parameter value. The EL expression identifies where the parameter value will be retrieved from within the calling task flow. For example, enter an EL expression similar to the following:

     ```
     #{pageFlowScope.callingTaskflowParm}
     ```

     By default, all objects are passed by reference. Primitive types (for example, `int`, `long`, or `boolean`) are always passed by value.

     Click in the Value field and use the dropdown list to use the Expression Builder if needed.
4. After you have specified an input parameter, you can specify a corresponding input parameter definition for the called bounded task flow. For more information, see Passing Parameters to a Bounded Task Flow.

> **Note:**
>
> If you call a task flow without the required input parameter, the task flow is not executed and an error is logged in the `oracle.adfinternal.controller.activity` logger. Therefore, it is difficult to know the error when a task flow fails to execute.
> For a normal task flow call, an `ActivityLogicException` is thrown if the required input parameters are missing. When the task flow is invoked in a region or directly from the URL, without the required input parameters, the task flow is not processed and displays a blank region or page. In case of region, the rest of the page is rendered properly.

How to Call a Bounded Task Flow Using a URL

You can call a bounded task flow that does not use page fragments (`.jsff`) in another web application using a URL. Use a task flow call activity to call the bounded task flow that you want to invoke. You write an EL expression for the task flow call activity's `remote-app-url` property that, when evaluated, returns a URL.

In addition to writing a value for the `remote-app-url` property, you specify values for task flow reference properties that identify the bounded task flow to call. The task flow reference and the `remote-app-url` property are combined at runtime to generate a URL to the called bounded task flow in the remote web application.

You also need to set visibility properties for the bounded task flow in the remote web application that you want to call so that it invokes when it receives the URL generated from the task flow call activity in the calling task flow.

Be aware that JSF portlets provide all content from the same web application. As a result, do not configure your web application to invoke a task flow using a URL if you plan to use your web application in a JSF portlet.

> **Note:**
>
> If, in JDeveloper's Applications window, you right-click the bounded task flow that you want to call using a URL and select **Run**, the bounded task flow executes as if it were called using a URL at runtime. For this reason, make sure to set the visibility properties for the bounded task flow even if you want to execute it as part of testing in JDeveloper.

Before you begin:

It may be helpful to have an understanding of how a task flow call activity interacts with a task flow. For more information, see Using Task Flow Call Activities.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

To call a bounded task flow using a URL:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow that you want to configure to invoke a bounded task flow in a remote web application.
2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag a **Task Flow Call** activity and drop it on the diagram for the task flow.
3. In the Properties window, expand the **General** section and specify values to invoke a bounded task flow.

   For more information, see How to Call a Bounded Task Flow Using a Task Flow Call Activity.
4. For the **Remote Application URL** property, use the Expression Builder to write an EL expression that, when evaluated, returns a string with the parts required to construct a URL of the remote web application. Invoke the Expression Builder by selecting **Expression Builder** from the context menu that appears when you click the icon that appears when you hover over the property field.

   For example, the following EL expression invokes a managed bean method that returns a string with the parts required to construct a URL:

   ```
   #{myOrdersBean.createOrder}
   ```

5. Open the bounded task flow in the remote web application that you want to invoke.

> **Note:**
>
> The bounded task flow you specify cannot use page fragments (`.jsff`).

6. In the Structure window, right-click the node for the bounded task flow (**task-flow-definition- *Task Flow ID***) and choose **Go to Properties**.
7. In the Properties window, expand the **General** section and select values for the following:
   - **URL Invoke**: select **url-invoke-allowed** from the dropdown list if you want to allow a URL to invoke the bounded task flow. Select **url-invoke-disallowed** if you do not want to allow a URL to invoke the bounded task flow. Selecting this value returns a HTTP 403 status code if a URL attempts to invoke the bounded task flow. The default value (**calculated**) allows a URL to invoke the bounded task flow if the bounded task flow does not specify an initializer and it has a view activity as its default activity. If the bounded task flow does not meet these conditions, a HTTP 403 status code is returned. Selecting **url-invoke-allowed** or **url-invoke-disallowed** overrides the default behavior.
   - **Library Internal:** select **true** if you want the bounded task flow to be internal when you package it in an ADF Library JAR. The default value is **false**.

     For more information about packaging a bounded task flow in an ADF Library JAR, see Packaging a Reusable ADF Component into an ADF Library.
8. Save and close the bounded task flow.

What Happens When You Configure a Bounded Task Flow to be Invoked by a URL

JDeveloper generates metadata entries in the source file of the task flow that invokes the task flow call activity to the bounded task flow in a remote web application. The following example shows an entry for a task flow call activity.

```
<task-flow-call id="createOrder">
    <task-flow-reference>
      <document id="__6">myorders-task-flow.xml</document>
      <id id="__5">myorders-task-flow</id>
    </task-flow-reference>
    <remote-app-url id="__7">#{myOrdersBean.createOrder}</remote-app-url>
  </task-flow-call>
```

The `createOrder` method in the previous example returns a string with the URL syntax required to invoke a bounded task flow. For more information about the URL syntax, including descriptions of the required parts in the returned string and an example URL, see What You May Need to Know About Calling a Bounded Task Flow Using a URL.

JDeveloper also generates entries in the source file for the bounded task flow to invoke when you configure it so it can be called by a URL. The following example shows sample metadata entries that allow a bounded task flow to be invoked by a URL.

```
<task-flow-definition id="task-flow-definition3">
    <visibility id="__2">
      <url-invoke-allowed/>
      <library-internal/>
    </visibility>
  </task-flow-definition>
```

What You May Need to Know About Calling a Bounded Task Flow Using a URL

Adding a context parameter in your local application's deployment descriptor may ease the administration of interaction with a remote web application.

Context Parameter for Remote Web Application

Consider adding a context parameter to the deployment descriptor (`web.xml`) for your Fusion web application (local application) if you use a URL to invoke a bounded task flow in another Fusion web application (remote application). Set the value of the context parameter to the URL of the remote application. Use the context parameter name when writing EL expressions in the local application, as shown in the following example where `remoteAppUrl` is the name of the context parameter:

```
#{initParam.remoteAppUrl}
```

If the URL of the remote application changes, you can update the context parameter to reference the changed URL.

Object Type for Parameter Converters

Parameter converters, if specified, can be used to convert task flow parameter values to and from the string representations used in a URL. A parameter converter is an EL expression that evaluates to an object of the following type:

```
oracle.adf.controller.UrlParameterConverter
```

If you do not specify a parameter converter, a default converter checks the parameters for cross-site-scripting (XSS) attacks. If you know that the parameter values used in your application contain special characters, you should create your own implementation of `UrlParameterConverter` and use it to perform conversion of the task flow parameter values.

URL Syntax to Invoke a Bounded Task Flow

Typically, you write an EL expression that references a managed bean method which, in turn, retrieves the required parts of the URL or you could write an EL expression that returns the URL directly, as shown in the following example.

```
http://somecompany.com/internalApp/MyApp/faces/adf.task-flow?
adf.tfId=displayHelp&
adf.tfDoc=%2FWEB-INF%2Fdisplayhelp.xml&topic=createPurchaseOrder
```

Example 24-6 describes the parts of the URL syntax to invoke a bounded task flow.

The following list describes each part of the URL syntax in Example 24-6:

- `<server root>`: Provided by customization at site or administrator level. For example:

  ```
  http://mycompany.com/internalApp
  ```

The <server root> value depends on the application server where you deploy the bounded task flow. The bounded task flow URL is a resource within the JSF servlet's URL path.

- <app context>: The web application context root, for example, MyApp. The context root is the base path of a web application.
- faces: Faces servlet mapping.
- adf.task-flow: A reserved keyword that identifies ADF Controller for the remote web application.
- adf.tfId: A URL parameter that supplies the task flow ID to call.
- <task flow ID>: The identifier of the bounded task flow to call, for example, displayHelp. This is the same task flow ID that is used when calling locally. Note that this identifier is not the same as the task flow call activity instance ID. The parameter value must be represented as a string.
- adf.tfDoc: A URL parameter that supplies the document name containing the bounded task flow ID to be called.
- <document name>: A document name containing the bounded task flow ID to be called, for example, %2FWEB-INF%2FtoUppercase%2FdisplayHelp.xml. If you are handcrafting the bounded task flow URL, you are responsible for the appropriate encoding.
- <named parameter>: (optional) The name of an input parameter definition for the called bounded task flow, for example, topic. You must supply all required input parameter definitions.
- <named parameter value>: (optional) The value of the input parameter.

> **Note:**
>
> URL parameter names that begin with an underscore ('_') are intended for internal use only and should not be used. Although you may see these names on URLs generated by ADF Controller, you should not attempt to use or depend on them.

Example 24-6 URL Syntax for a Call to a Bounded Task Flow Using Named Parameters

```
<server root>/<app_context>/faces/adf.task-flow?adf.tfid=<task flow definition
ID>&adf.tfDoc=<document name>&<named parameter>=<named parameter value>
```

How to Specify Before and After Listeners on a Task Flow Call Activity

Use task flow call activity before and after listeners to identify the start and end of a bounded task flow. Specifying a listener in the task flow call activity means that the listener executes on that specific usage of the called bounded task flow.

You specify the listener as an EL expression for a method that will be called upon entry or exit of a bounded task flow, for example:

```
<before-listener>#{global.showState}</before-listener}>
```

The method cannot have parameters.

- Before listener: An EL expression for a Java method called before a bounded task flow is entered. It is used when the caller needs to know when a bounded task flow is being initiated.
- After listener: An EL expression for a Java method called after a bounded task flow returns. It is used when the caller needs to know when a bounded task flow exits and control flow returns to the caller.

If multiple before listeners or multiple after listeners are specified, they are called in the order in which they appear in the source document for the unbounded or bounded task flow. A task flow call activity can have only have before listener and one after listener.

In order for the task flow call after listeners to be called, control flow must return from the bounded task flow using a control flow rule. If an end user leaves a bounded task flow using the browser back button or other URL, task flow call after listeners will not be called. You must use a bounded task flow finalizer to release all acquired resources and perform cleanup of a bounded task flow that the end user left by clicking a browser back button.

Before you begin:

It may be helpful to have an understanding of how a task flow call activity interacts with a task flow. For more information, see Using Task Flow Call Activities.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

To specify a before or after listener on a task flow call activity:

1. In the Applications window, expand the **WEB-INF** node and double-click the calling task flow.
2. In the diagram for the calling bounded task flow, select the task flow call activity.
3. In the Properties window, expand the Listeners section and open the Expression Builder for either the **Before Listener** property or the **After Listener** property. To open the Expression Builder, choose **Method Expression Builder** from the context menu that invokes when you click the icon that appears when you hover over the property field.

   Use the Expression Builder to navigate to the Java class that contains the method for the listener. For example, you might create an EL expression similar to the following:

   ```
   #{pageFlowscope.managedBean.methodListener}
   ```
4. Click **OK**.

What Happens When You Add a Task Flow Call Activity

After you add a task flow call activity to a task flow diagram, you must specify a reference to the called bounded task flow using one of the methods described in How to Call a Bounded Task Flow Using a Task Flow Call Activity. For example, if you drop an existing bounded task flow on the task flow call activity, JDeveloper generates the task flow reference automatically. The task flow reference is used to invoke the called bounded task flow.

If the task flow reference is static, each task flow reference consists of:

- **Document**: The name of the XML source file containing the ID of the called bounded task flow. If **Document** is not specified, `adfc-config.xml` is assumed.

The document is a physical XML file and must be accessible via MDS.

- **ID**: The bounded task flow ID contained in the XML source file for the called bounded task flow. For example, a called task flow might have an ID called `targetFlow`. The same XML source file can contain multiple bounded task flows, each bounded task flow identified by a unique ID.

> **Note:**
>
> If you use JDeveloper to create the bounded task flow, there is only one bounded task flow per document.

The following example contains an example static task flow reference within a task flow call activity. In order to invoke a bounded task flow, you need to know its ID and the name of the file (`<document>`) containing the ID.

```
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2"
id="__1">
...
  <task-flow-definition id="task-flow-definition">
    <default-activity>view1</default-activity>
    <task-flow-call id="taskFlowCall">
      <task-flow-reference>
        <document>/WEB-INF/called-task-flow-definition.xml</document>
        <id>called-task-flow-definition</id>
      </task-flow-reference>
    </task-flow-call>
  </task-flow-definition>
...
</adfc-config>
```

The following example shows the metadata that JDeveloper generates for a dynamic task flow reference within a task flow call activity.

```
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2"
             id="__1">
  <task-flow-definition id="bounded_tf">
    <default-activity id="__2">taskFlowCall1</default-activity>
    <task-flow-call id="taskFlowCall1">
      <dynamic-task-flow-reference id="__3">#{EL_Expression_Retrieve_
                                  TaskflowID}</dynamic-task-flow-reference>
    </task-flow-call>
  </task-flow-definition>
</adfc-config>
```

What Happens at Runtime: How a Task Flow Call Activity Invokes a Task Flow

The ADF Controller performs the following steps when a bounded task flow is called using a task flow call activity:

1. Verifies that the user is authorized to call the bounded task flow.
2. Invokes task flow call activity before listener or listeners, if specified (see How to Specify Before and After Listeners on a Task Flow Call Activity).

3. Evaluates the input parameter values on the bounded task flow.
4. Pushes the called bounded task flow onto the stack and initializes its page flow scope.
5. Sets input parameter values in the called bounded task flow's context.
6. Invokes a bounded task flow initializer method, if one is specified.
7. Executes the bounded task flow's default activity.

Using Task Flow Return Activities

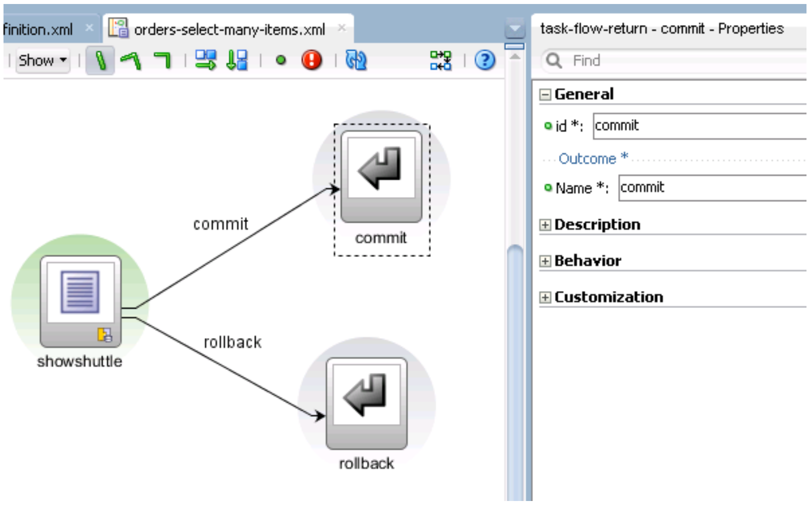
When the ADF task flow call activity is invoked and after it completes its default activity, it should return the control back to the invoked application. The task flow return activity is helpful in identifying and sending the control flow back to the caller application. This activity can be used only within a bounded task flow.

A task flow return activity identifies the point in an application's control flow where a bounded task flow completes and sends control flow back to the caller. You can use a task flow return activity only within a bounded task flow.

A gray circle around a task flow return activity icon indicates that the activity is an exit point for a bounded task flow. A bounded task flow can have zero to many task flow return activities. Figure 24-11 shows the `orders-select-many-items.xml` bounded task flow in the Summit ADF task flow sample application that contains task flow return activities named **commit** and **rollback**.

Each task flow return activity specifies an `outcome` that it returns to the calling task flow. For example, Figure 24-11 shows a task flow return activity in the Summit ADF task flow sample application. The value for the this task flow return activity's Outcome Name property is `commit`.

Figure 24-11 Multiple Task Flow Return Activities



task-flow-return - commit - Properties

General
id *: commit
Outcome *
Name *: commit

The `outcome` returned to an invoking task flow depends on the end user action. You can configure control flow cases in the invoking task flow to determine the next action by the invoking task flow. Set the **From Outcome** property of a control flow case to the value returned by the task flow return activity's `outcome` to invoke an action based on that outcome. This determines control flow upon return from the called task flow.

Set a value for the **Restore Save Point** property to specify if model changes made in a bounded task flow are saved or discarded when the bounded task flow exits by using a task flow return activity. Set to `true` to roll back transactions to the ADF Model save point that was created when the Fusion web application first entered the bounded task flow. The default value is `false`. You can specify a value for this property only if the bounded task flow on which the task flow return activity is located was entered without starting a new transaction. See How to Enable Transactions in a Bounded Task Flow .

How to Add a Task Flow Return Activity to a Bounded Task Flow

You drag a task flow return activity from the Components window and drop it on the diagram for the bounded task flow.

Before you begin:

It may be helpful to have an understanding of how a task flow return activity interacts with a task flow. For more information, see Using Task Flow Return Activities .

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

To add a task flow return activity to a bounded task flow:

1. In the Applications window, expand the **WEB-INF** node and double-click the bounded task flow to which you want to add a task flow return activity.
2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a **Task Flow Return** onto the diagram.
3. In the Properties window, expand the **General** section, and enter an outcome in the **Name** field.

   The task flow return activity returns this outcome to the calling task flow when the current bounded task flow exits. You can specify only one outcome per task flow return activity. The calling task flow should define control flow rules to handle control flow upon return. For more information, see How to Add a Control Flow Rule to a Task Flow.
4. Expand the **Behavior** section and in the **Reentry** dropdown list, choose one of the following options:
   - **<default> (not outcome dependent)**: Reentry is not dependent on an outcome.
   - **reentry-allowed**: Reentry is allowed on any view activity within the bounded task flow.
   - **reentry-not-allowed**: Reentry of the bounded task flow is not allowed.

     If you specify **reentry-not-allowed** on a bounded task flow, an end user can still click the browser back button and return to a page within the bounded task flow. However, if the user does anything on the page such as clicking a button, an exception (for example, `InvalidTaskFlowReentry`) is thrown indicating the bounded task flow was reentered improperly. The actual reentry condition is identified upon the submit of the reentered page.

For more information about reentering a bounded task flow, see Reentering Bounded Task Flows.

Your selection defines the default behavior when the bounded task flow is reentered by an end user clicking a browser's Back button. This selection applies only if **reentry-outcome-dependent** has been set on the bounded task flow where the task flow return activity is located. For more information, see Reentering Bounded Task Flows.

5. In the **End Transaction** dropdown list, choose one of the following options:
   - **commit**: Select to commit the existing transaction to the database.
   - **rollback**: Select to roll back the transaction to what it was on entry of the called task flow. This has the same effect as canceling the transaction, since it rolls back a new transaction to its initial state when it was started on entry of the bounded task flow.

     If you do not specify commit or rollback, the transaction is left open to be closed by the calling bounded task flow.
6. In the **Restore Save Point** dropdown list, select `true` when either of the following conditions apply:
   - If **Always Begin New Transaction** (`new-transaction`) is not selected on the bounded task flow on which the task flow return activity is located
   - ADF model changes made within a bounded task flow should be discarded when exiting using the task flow call activity. The transaction is rolled back to the save point created on entry of the bounded task flow.

   For more information, see How to Enable Transactions in a Bounded Task Flow .

What Happens When You Add a Task Flow Return Activity to a Bounded Task Flow

JDeveloper generates metadata entries in the source file of the bounded task flow for the changes that you configure for the task flow return activity in the Properties window. The following example shows entries that appear in the `orders-select-many-items.xml` task flow of the Summit ADF task flow sample application.

```
<task-flow-return id="commit">
     <outcome>
       <name>commit</name>
       <commit/>
     </outcome>
   </task-flow-return>
   <task-flow-return id="rollback">
     <outcome>
       <name>rollback</name>
       <rollback/>
     </outcome>
   </task-flow-return>
```

Using Task Flow Activities with Page Definition Files

A page definition file defines the binding objects that populate data in the ADF application at runtime. You can use the page definition files to bind the ADF task flow activities to data controls.

Page definition files define the binding objects that populate data at runtime. They are typically used in a Fusion web application to bind page UI components to data controls. A number of task flow activities can also use page definition files to bind to data controls. These are:

- Method call

  You can drag and drop a data control operation from the Data Controls panel onto a task flow to create a method call activity or onto an existing method call activity. In both cases, the method call activity binds to the data control operation.

- Router

  Associating a page definition file with a router activity creates a binding container. At runtime, this binding container makes sure that the router activity references the correct binding values when it evaluates the router activity cases' EL expressions. Each router activity case specifies an `outcome` to return if its EL expression evaluates to `true`. For this reason, only add data control operations to the page definition file that evaluate to `true` or `false`.

- Task flow call

  Associating a page definition file with a task flow call activity creates a binding container. At runtime, the binding container is in context when the task flow call activity passes input parameters. The binding container makes sure that the task flow call activity references the correct values if it references binding values when passing input parameters from a calling task flow to a called task flow.

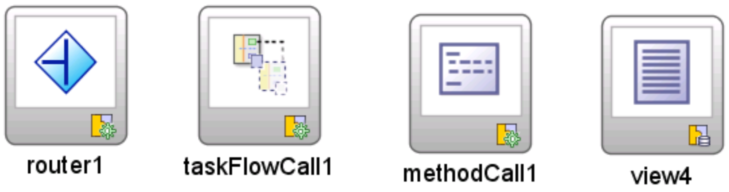
- View

  You cannot directly associate a view activity with a page definition file. Instead, you associate the page that the view activity references.

If you right-click any of the above task flow activities (except view activity) in the diagrammer for a task flow, JDeveloper displays an option on the context menu that enables you to create a page definition file (**Create Page Definition**) if one does not yet exist. If a page definition file does exist, JDeveloper displays a context menu option for all task flow activities to go to the page definition file (**Go to Page Definition**). JDeveloper also displays a context menu option (**Edit Binding**) when you right-click a method call activity that is associated with a page definition file.

A task flow activity that is associated with a page definition file displays an icon in the lower-right section of the task flow activity icon. Figure 24-12 shows an example for each of the task flow activities.

Figure 24-12 Task Flow Activities Associated with Page Definition Files



How to Associate a Page Definition File with a Task Flow Activity

JDeveloper provides a context menu option that you can access from the task flow activity. You use this context menu option to associate the task flow activity with a page definition file.

Before you begin:

It may be helpful to have an understanding of how task flow activities use page definition files. For more information, see Using Task Flow Activities with Page Definition Files.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Task Flow Activities.

To associate a page definition file with a task flow activity:

1. In the Applications window, expand the **WEB-INF** node and double-click the task flow that contains the task flow activity with which you want to associate a page definition file.
2. In the diagram, right-click the task flow activity for which you want to create a page definition file and choose **Create Page Definition**.
3. In the resulting page definition file, add the bindings that you want your task flow activity to reference at runtime.

   For more information about page definition files, see Working with Page Definition Files.

What Happens When You Associate a Page Definition File with a Task Flow Activity

At design time, JDeveloper generates a page definition file for the task flow activity. The filename of the page definition file comprises the originating task flow and either the name of the task flow activity or the data control operation to invoke. For example, `taskflowName_taskflowName_methodCall1PageDef.xml` or `taskflowName_taskflowName_CreateInsertPageDef.xml`.

JDeveloper also generates an EL expression from the task flow activity to the binding in the created page definition file. The following example shows a method call activity that references a `CreateInsert` action binding.

```
<method-call id="CreateInsert">
      <method>#{bindings.CreateInsert.execute}</method>
      <outcome>
        <fixed-outcome>CreateInsert</fixed-outcome>
      </outcome>
    </method-call>
```

At runtime, a binding container makes sure that a task flow activities' EL expressions reference the correct value.

25
Using Parameters in Task Flows

This chapter describes how to configure parameters in view activities and in ADF bounded task flows that you create in the Fusion web application. Using these capabilities allows you to manipulate data in task flows, share data between task flows across one or more transactions, and configure return values to return from one task flow to another task flow.
This chapter includes the following sections:

About Using Parameters in Task Flows

When used with an ADF task flow, parameters allow you to expand the horizon of the task flow from its default activity to multiple activities. For example, you can manipulate the data in task flows and share data between multiple task flows.

A task flow´s ability to accept input parameters and return parameter values allow you to manipulate data in task flows and share data between task flows. Using these abilities, you can optimize the reuse of task flows in your Fusion web application.

You can use view activity input page parameters as aliases. The alias allows you to map bounded task flow input parameters to page parameters. The view activity input page parameters map managed beans and any information available to the calling task flow to a managed bean on the page itself. To pass values out of view activities, store values in pageFlow scope or managed beans. For information about using view activities in a task flow, see Using View Activities.

For example, a page might specify `#{pageFlowScope.empNo}` as a page parameter and a bounded task flow might specify `#{pageFlowScope.employeeID}` as the value of an input parameter definition.

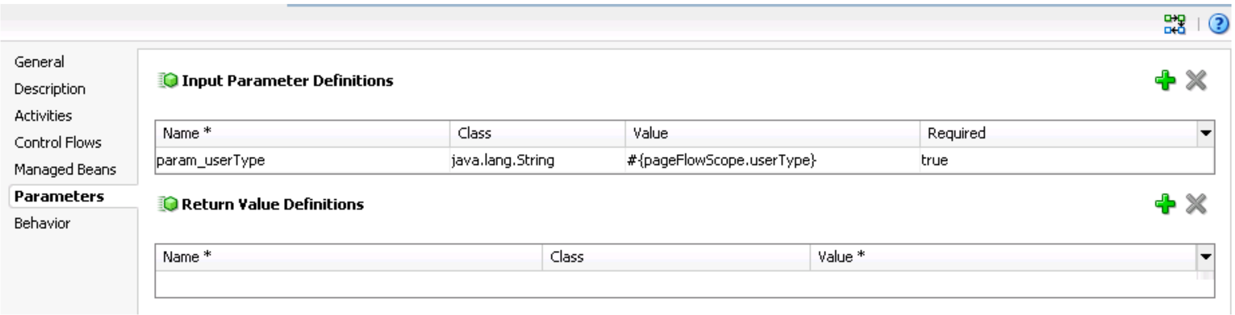
The `from-value` on the view activity input page parameter would be `#{pageFlowScope.employeeID}` and the `to-value` would be `#{pageFlowScope.empNo}`. This enables reuse of both the page definition and bounded task flow because you do not have to redefine parameters for every context in which each is used.

Other values contained within the task flow can be mapped to input page parameters, not just bounded task flow input parameter definition values.

Task Flow Parameters Use Cases and Examples

Figure 25-1 shows a task flow that defines an input parameter definition to hold information about a user in a pageFlow scope.

Figure 25-1 Task Flow Defining an Input Parameter



Input Parameter Definitions

Name *	Class	Value	Required
param_userType	java.lang.String	#{pageFlowScope.userType}	true

Return Value Definitions

Name *	Class	Value *

Additional Functionality for Task Flows Using Parameters

You may find it helpful to understand other **Oracle ADF** features before you configure or use a task flow with parameters. Additionally, you may want to read about what you can do with your configured task flows. Following are links to other functionality that may be of interest.

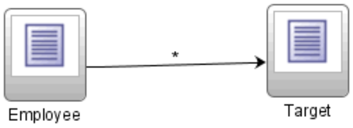
- Data controls can be shared between task flows. For more information about sharing data controls, see Sharing Data Controls Between Task Flows .
- A task flow can access a managed bean that is registered with it. For more information about managed beans and task flows, see Using a Managed Bean in a Fusion Web Application.
- Bounded task flows can be secured by defining the privileges that are required for someone to use them. For more information, see Enabling ADF Security in a Fusion Web Application.

Passing Parameters to a View Activity

In the cases where you want to pass the value from one activity to another without modifying the value, the ADF task flow view activity is useful. You can either pass a parameter to a value or a value to a managed bean using an EL expression or a literal expression.

Figure 25-2 illustrates how to configure an input page parameter mapping. You can pass a parameter to the Employee activity as a `pageFlowScope` value or a value on a managed bean. You can pass a parameter to the Employee activity using an EL expression or a literal expression. The Employee activity, in turn, can pass a value to the Target activity by specifying the value it wants to pass to the Target activity in the `to-value` element.

Figure 25-2 Task Flow with Two Activities



How to Pass Parameters to a View Activity

You add one or more input page parameters to the view activity that you want to pass parameters to.

Before you begin:

It may be helpful to have an understanding of the configuration options available to you before you define an input page parameter for a view activity. For more information, see Passing Parameters to a View Activity.

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for Task Flows Using Parameters.

To define an input page parameter for a view activity:

1. In the Applications window, double-click the task flow that contains the view activity to which you want to pass a parameter.
2. Select the view activity in the diagram for the task flow and, in the Properties window, expand the **Page Parameters** category.
3. In the **Input Page Parameters** list, click the **Add** icon and enter values as follows:
   - **From Value**: write an EL expression that, when evaluated, specifies where the view activity retrieves the value for the input page parameter. For example, write an EL expression similar to the following:

     ```
     #{pageFlowScope.EmployeeID}
     ```

     You can configure the view activity to retrieve a value that is input to the task flow if you write an EL expression for **From Value** that corresponds to the value for the input parameter that you defined for the task flow, as described in How to Pass an Input Parameter to a Bounded Task Flow.
   - **To Value**: write an EL expression, that when evaluated, specifies where the page associated with the view activity can retrieve the value of the input page parameter. For example, write an EL expression similar to the following:

     ```
     #{pageFlowScope.EmployeeNo}
     ```

What Happens When You Pass Parameters to a View Activity

JDeveloper writes entries to the source file of the task flow at design time, as illustrated in the following example.

```
<view id="reducedAccess">
 <page>/secured/Information.jsf</page>
      <input-page-parameter>
        <from-value>#{res['infoUsage.reducedAccess.messageHeader']}</from-value>
        <to-value>#{pageFlowScope.infoPageHeaderText}</to-value>
      </input-page-parameter>
      <input-page-parameter>
        <from-value>#{res['infoUsage.reducedAccess.messageHeader']}</from-value>
        <to-value>#{pageFlowScope.infoPageMsg}</to-value>
      </input-page-parameter>
      <input-page-parameter>
        <from-value>info</from-value>
        <to-value>#{pageFlowScope.infoPageType}</to-value>
```

```
        </input-page-parameter>
    </view>
```

At runtime, the view activity retrieves the value of the input parameter from the location you specified in the `<from-value>` element. The view activity makes the value of the parameter available to its associated page in the location you specified in the `<to-value>` element.

What You May Need to Know About Specifying Parameter Values

You can specify parameter values using standard EL expressions if you call a bounded task flow using a task flow call activity or you render the bounded task flow in an ADF region or an ADF dynamic region. For example, you can specify parameters using the following syntax for EL expressions:

- `#{bindings.bindingId.inputValue}`
- `#{CustomerBean.zipCode}`

The following example shows the metadata for a task flow binding that renders in an ADF region.

```
<taskFlow id="Department1" taskFlowId="/WEB-INF/Department.xml#Department"
              xmlns="http://xmlns.oracle.com/adf/Controller/binding">
    <parameters>
        <parameter id="DepartmentId" value="#{bindings.DepartmentId.inputValue}"
                   xmlns="http://xmlns.oracle.com/adfm/uimodel"/>
     </parameters>
</taskFlow>
```

Appending `inputValue` to the EL expression makes sure that you assign the parameter the value of the binding rather than the actual binding object.

Passing Parameters to a Bounded Task Flow

From an ADF task flow, you can call a bounded task flow and pass values to it. The bounded task flow can accept the values through input parameters or from a task flow binding. You must specify one or more input parameters and parameter definitions in the task flow invoking the bounded task flow.

A called bounded task flow can accept input parameters from the task flow that calls it or from a task flow binding. To pass an input parameter to a bounded task flow, you specify one or more:

- Input parameters on the task flow call activity in the calling task flow

  Input parameters specify where the calling task flow stores parameter values.
- Input parameter definitions on the called bounded task flow

  Input parameter definitions specify where the called bounded task flow can retrieve parameter values at runtime.

Specify the same name for the input parameter that you define on the task flow call activity in the calling task flow and the input parameter definition on the called bounded task flow. Do this so you can map input parameter values to the called bounded task flow.

If you do not specify an EL expression to reference the value of the input parameter, the EL expression for `value` defaults to the following at runtime:

```
#{pageFlowScope.parmName}
```

where *`parmName`* is the value you entered for the input parameter name.

In an input parameter definition for a called bounded task flow, you can specify an input parameter as required. If the input parameter does not receive a value at runtime or design time, the task flow raises a warning in a log file of the Fusion web application that contains the task flow. An input parameter that you do not specify as required can be ignored during task flow call activity creation.

Task flow call activity input parameters can be passed by reference or passed by value when calling a task flow using a task flow call activity unless you are calling a task flow in an ADF region. If the task flow renders in an ADF region, the task flow call activity passes the input parameters by reference. By default, primitive types (for example, `int`, `long`, or `boolean`) are passed by value (`pass-by-value`).

The Pass By Value checkbox applies only to objects, not primitives and is used to override the default setting of passing by reference. Mixing the two, however, can lead to unexpected behavior in cases where parameters reference each other. If input parameter A on the task flow call activity is passed by value and if input parameter B on the task flow call activity is passed by reference, and B has a reference to A, the result can be two different instances of A and B.

How to Pass an Input Parameter to a Bounded Task Flow, describes how to pass an input parameter from a calling task flow to a called bounded task flow using a task flow call activity. Although you can pass parameter values from any activity on the calling task flow, the passed parameter in How to Pass an Input Parameter to a Bounded Task Flow contains the value of an input text field on a page in the calling task flow.

If you call a bounded task flow using a URL rather than a task flow call activity, you pass parameters and values on the URL itself. See How to Call a Bounded Task Flow Using a URL.

Instead of explicitly passing data controls as parameters between task flows, you can simply share them by specifying the `data-control-scope` option on the called bounded task flow. For more information, see Sharing Data Controls Between Task Flows .

A called task flow can also return values to the task flow that called it when it exits. For more information about returning values from a bounded task flow, see Configuring a Return Value from a Bounded Task Flow.

How to Pass an Input Parameter to a Bounded Task Flow

You define values on the calling task flow and the called task flow.

Before you begin:

- It may be helpful to have an understanding of the configuration options available to you before you configure a bounded task flow to receive an input parameter. For more information, see Passing Parameters to a Bounded Task Flow.
- You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for Task Flows Using Parameters.

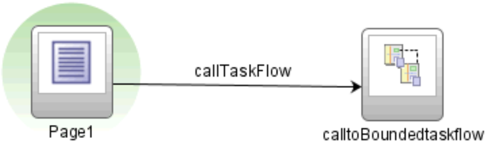
You will need to complete these tasks:

- Create a calling and called task flow

  The calling task flow can be bounded or unbounded. The called task flow must be bounded. For more information about creating task flows, see Creating a Task Flow.
- Add a task flow call activity to the calling task flow

  Figure 25-3 shows an example where the view activity passes control to the task flow call activity.

Figure 25-3 Calling Task Flow



To pass an input parameter to a bounded task flow:

1. In the Applications window, double-click the JSF page that contains an input component where an end user enters a value that gets passed to a bounded task flow as a parameter at runtime.

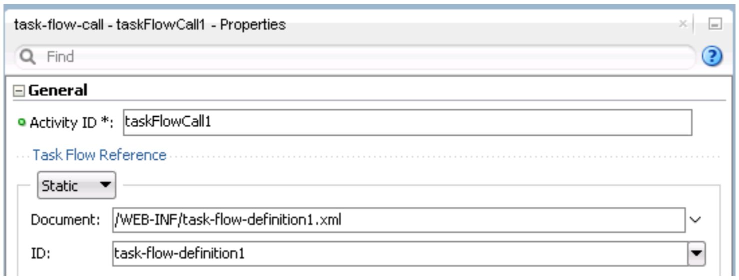
   The JSF page that you open should be referenced by a view activity in the calling task flow.
2. Select an input text component on the JSF page where an end user enters a value at runtime.
3. In the Properties window, expand the **Common** section and enter a value for the input text component in the **Value** field.

   You can specify the value as an EL expression, for example `#{pageFlowScope.inputValue}`.
4. In the Applications window, double-click the task flow that is going to be called.
5. In the editor window, click the **Overview** tab.
6. In the overview editor, click the **Parameters** navigation tab and then click the **Add** icon to define a new entry in the **Input Parameter Definition** section.
7. In the **Name** field, enter a name for the parameter, for example, `inputParm1`.
8. In the **Value** field, enter an EL expression where the parameter value is stored and referenced, for example, `#{pageFlowScope.inputValue}`.
9. In the Applications window, double-click the calling task flow that contains the task flow call activity to invoke the called bounded task flow.
10. In the Applications window, drag the called bounded task flow and drop it on top of the task flow call activity that is located in the diagram of the calling task flow.

    Dropping a bounded task flow on top of a task flow call activity in a diagram automatically creates a task flow reference to the bounded task flow. As shown in Figure 25-4, the Properties window for the task flow call activity, the task flow reference contains the bounded task flow ID and a document name. The bounded task flow ID (`id`) is an attribute of the bounded task flow's `<task-flow-`

definition> element. The document name points to the source file for the task flow that contains the ID.

Figure 25-4 Task Flow Reference



task-flow-call - taskFlowCall1 - Properties

General

Activity ID *: taskFlowCall1

Task Flow Reference

Static

Document: /WEB-INF/task-flow-definition1.xml

ID: task-flow-definition1

11. In the Properties window for the task flow call activity, expand the **Parameters** section to view the **Input Parameters** section.
12. Enter a name that identifies the input parameter.

    Because you dropped the bounded task flow on a task flow call activity having defined input parameters, the name should already be specified. You must keep the same input parameter name.
13. Enter a parameter value, for example, `#{pageFlowScope.parm1}`.

    The value on the task flow call activity input parameter specifies where the calling task flow stores parameter values.

    The value on the input parameter definition for the called task flow specifies where the value will be retrieved from for use within the called bounded task flow once it is passed.
14. At runtime, the called task flow is able to use the input parameter. Since you specified `pageFlowScope` as the `value` in the input parameter definition for the called task flow, you can use the parameter value anywhere in the called bounded task flow. For example, you can pass it to a view activity on the called bounded task flow. For more information, see What Happens When You Pass Control Between View Activities.

What Happens When You Pass an Input Parameter to a Bounded Task Flow

JDeveloper writes entries to the source files for the calling task flow and called task flow based on the values that you select. Example 25-1 shows an input parameter definition specified on a a bounded task flow.

Example 25-2 shows the input parameter metadata for the task flow call activity that calls the bounded task flow shown in Example 25-1. At runtime, the task flow call activity calls the bounded task flow and passes it the value specified by its `value` element.

Example 25-1 Input Parameter Definition

```
<task-flow-definition id="sourceTaskflow">
...
   <input-parameter-definition>
      <name>inputParameter1</name>
      <value>#{pageFlowScope.parmValue1}</value>
      <class>java.lang.String</class>
   </input-parameter-definition>
...
</task-flow-definition>
```

Example 25-2   Input Parameter on Task Flow Call Activity

```
<task-flow-call id="taskFlowCall1">
...
    <input-parameter>
      <name>inputParameter1</name>
      <value>#{pageFlowScope.newCustomer}</value>
      <pass-by-value/>
    </input-parameter>
...
</task-flow-call>
```

Configuring a Return Value from a Bounded Task Flow

A bounded task flow can be invoked from an ADF task flow and values can be passed to it. The bounded task flow, upon processing the values submitted, returns a parameter value to the task flow that has called it. The return value is in addition to the outcome activity that the bounded task flow returns to the calling task flow. You must add return value definitions in the bounded task flow and return values on the calling task flow.

You can configure a bounded task flow to return a parameter value to the task flow that calls it. The value that the bounded task flow returns is in addition to the outcome that it returns to the caller when the bounded task flow invokes a task flow return activity, as described in Using Task Flow Return Activities . To return a value, you must configure:

- Return value definitions on the called bounded task flow

  The return value definition specifies where you store the value that you want to return from the called bounded task flow.

- Return values on the task flow call activity in the calling task flow to identify where the calling task flow can find the returned value

You can configure the calling task flow to ignore return value definition from the called task flow by not identifying any return values on the task flow call activity in the calling task flow.

The task flow call activity returns values by reference. For this reason, you do not need to make a copy of the values that you want to return to the calling task flow.

How to Configure a Return Value from a Bounded Task Flow

You configure a return value definition on the called task flow and add a parameter to the task flow call activity in the calling task flow that retrieves the return value at runtime.

Before you begin:

It may be helpful to have an understanding of the interaction between the calling task flow and the called task flow. For more information, see Configuring a Return Value from a Bounded Task Flow.

You may also find it helpful to understand functionality that can be added using other task flow features and parameters. For more information, see Additional Functionality for Task Flows Using Parameters.

You will need to complete this task:

Create a bounded or unbounded task flow (calling task flow) and a bounded task flow (called task flow). For more information, see Creating a Task Flow.

To configure a return value from a called bounded task flow:

1. In the Applications window, double-click the called task flow.
2. In the editor window, click the **Overview** tab.
3. In the overview editor, click the **Parameters** navigation tab.
4. In the Parameters page, click the **Add** icon for the **Return Value Definitions** section and add values as follows to define a return value:
   - **Name**: Enter a name to identify the return value. For example, `returnValue1`.
   - **Class**: Enter a Java class that defines the data type of the return value. The default value is `java.lang.String`.
   - **Value**: Enter an EL expression that specifies where to read the return value from. For example, enter an EL expression similar to the following:

     ```
     #{pageFlowScope.ReturnValueDefinition}
     ```
5. In the Applications window, double-click the calling task flow.
6. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a task call activity onto the diagram.
7. In the Properties window for the task flow activity, expand the **Parameters** section, click the **Add** icon next to the **Return Values** entry and add values as follows to define a return value:
   - **Name**: Enter a name to identify the return value. For example, `returnValue1`.

     The value you enter must match the value you entered for the **Name** field when you defined the return value definition in Step 4.
   - **Value**: Enter an EL expression that specifies where to store the return value. For example, enter an EL expression similar to the following:

     ```
     #{pageFlowScope.ReturnValueDefinition}
     ```

     The value you enter must match the value you entered for the **Value** field when you defined the return value definition in Step 4.

What Happens When You Configure a Return Value from a Bounded Task Flow

At design time, JDeveloper writes entries to the source files for the task flows that you configured. The following example shows an entry that JDeveloper writes to the source file for the calling task flow.

```
<task-flow-call id="taskFlowCall1">
      <return-value id="__3">
        <name id="__4">returnValue1</name>
        <value id="__2">#{pageFlowScope.ReturnValueDefinition}</value>
```

```
      </return-value>
    </task-flow-call>
```

The following example shows entries that JDeveloper writes to the source file for the called task flow.

```
<return-value-definition id="__2">
      <name id="__3">returnValue1</name>
      <value>#{pageFlowScope.ReturnValueDefinition}/</value>
      <class>java.lang.String</class>
 </return-value-definition>
```

At runtime, the called task flow returns a value. If configured to do so, the task flow call activity in the calling task flow retrieves this value.

26

Using Task Flows as Regions

This chapter describes how to render ADF task flows in pages or page fragments using ADF regions in your Fusion web application. Key features such as the ability to specify parameters, how to refresh or activate an ADF region, navigate to a parent page, and create dynamic ADF regions are also described.
This chapter includes the following sections:

About Using Task Flows in ADF Regions

An ADF page fragment or a JSF page with af:region tag is the ADF region where you can execute a bounded task flow. You can use these ADF regions to add pieces of application functionality in the bounded task flow and reuse this packaged functionality throughout the application. The ADF regions are not dependent on a parent page.

You can execute a bounded task flow in a JSF page or page fragment (`.jsff`) by using an ADF region. A primary reason for executing a bounded task flow as an ADF region is reuse. You can isolate specific pieces of application functionality in a bounded task flow and an ADF region in order to reuse it throughout the application. You can extract, configure, and package application functionality within a bounded task flow so that it can be added to other pages using an ADF region. ADF regions can be reused wherever needed, which means they are not dependent on a parent page. This also means that you can isolate the presentation of the parent pages from the ADF region; menus, buttons, and navigation areas are not affected by what is displayed in the ADF region. If you modify a bounded task flow, the changes apply to any ADF region that uses the task flow.

An ADF region comprises the following:

- An `af:region` tag that appears in the page or page fragment where you render the region
- An instance object that implements `RegionModel` from the following package:

  `oracle.adf.view.rich.model`

  For more information about `RegionModel`, see the *Java API Reference for Oracle ADF Faces*
- One or other of the following:
  - A task flow binding (`taskFlow`) in the page definition that identifies the bounded task flow to use in the ADF region
  - A multi task flow binding (`multiTaskFlow`) in the page definition that identifies a list of bounded task flows to use in the ADF region

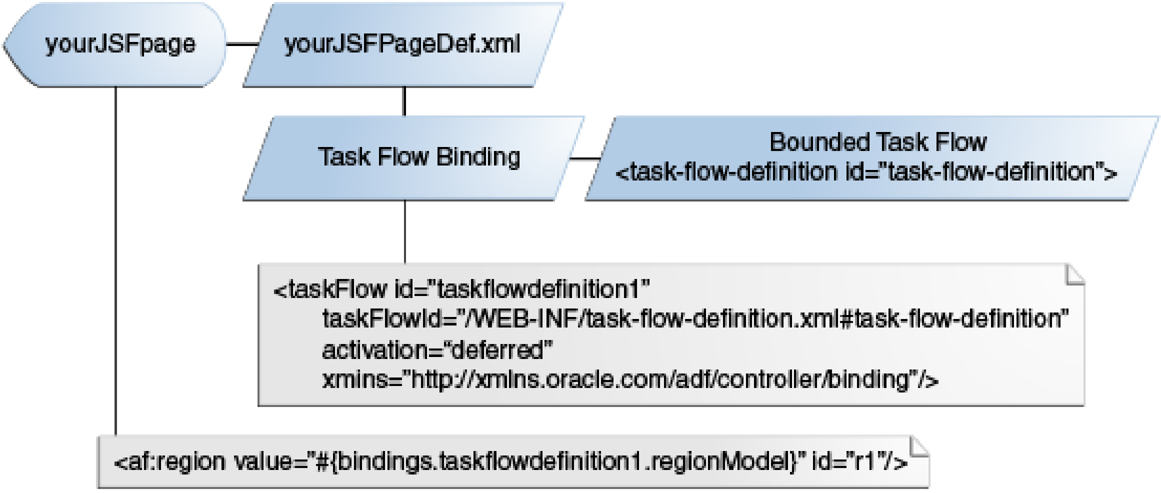
When first rendered, the ADF region's content is that of the first view activity in the bounded task flow. The view activities used in the bounded task flow must be associated with page fragments, not pages.

You can pass values to the ADF region using task flow binding input parameters or contextual events. In addition, you can configure the task flow binding's `parametersMap` property to determine what input parameters the task flow binding passes from the bounded task flow to the ADF region.

ADF regions can be configured so that you determine when the region activates or refreshes. You can also configure an ADF region and a bounded task flow so that navigation control stops in the bounded task flow and passes to the page that contains the ADF region. Finally, you can create dynamic regions (ADF dynamic regions) where the task flow binding determines at runtime what bounded task flow renders in the region and configure a dynamic region link so that end users can change the bounded task flow that renders in the ADF dynamic region at runtime.

Figure 26-1 shows how an ADF region references a bounded task flow using a task flow binding in the page definition file of the page that hosts the ADF region.

Figure 26-1   ADF Region Referencing a Bounded Task Flow



```
<taskFlow id="taskflowdefinition1"
      taskFlowId="/WEB-INF/task-flow-definition.xml#task-flow-definition"
      activation="deferred"
      xmins="http://xmins.oracle.com/adf/controller/binding"/>
```

```
<af:region value="#{bindings.taskflowdefinition1.regionModel}" id="r1"/>
```

About Page Fragments and ADF Regions

A page fragment is a JSF document (file extension is `.jsff`) that renders as content in another JSF page. A page fragment should not have more than one root component. Wrapping multiple root components in a single root component helps you to optimize the display performance of the page fragment. In addition, if a page fragment has only one visual root component and a `popup` component (which is invisible to end users until invoked), consider wrapping these components in a single root component. For example, place the `popup` component in a `panelStretchLayout` component's bottom facet with the `bottomHeight` attribute set to `0` pixels.

If a page fragment has more than one root component, the Fusion web application logs a message at runtime, as shown in the following example, where `r1` identifies the ADF region that renders the page fragment.

```
<RegionRenderer> <encodeAll> The region component with id: r1 has detected a page
 fragment with multiple root components. Fragments with more than one root
 component may not display correctly in a region and may have a negative impact
 on performance. It is recommended that you restructure the page fragment to have
 a single root component.
```

Apart from having only one root component element, a page fragment must not contain any of the following tags:

- `<af:document>`
- `<f:view>`
- `<f:form>`
- `<html>`
- `<head>`
- `<body>`

These tags can only appear once in a document and do not support nesting in a JSF page. For example, a page fragment embedded in a page cannot have an `<html>` tag because the JSF page already has one.

The following example shows a simple page fragment. Unlike a JSF page, it contains no `<f:view>` or `<f:form>` tags.

```
<?xml version='1.0' encoding='UTF-8'?>
<ui:composition xmlns:ui="http://java.sun.com/jsf/facelets"
                     xmlns:af="http://xmlns.oracle.com/adf/faces/rich">
  <af:button text="button 1" id="b1"/>
</ui:composition>
```

You must nest a page fragment that you include in another JSF page within a region (`af:region` tag). A bounded task flow that you add to a JSF page as a region cannot call pages; it must call page fragments.

About View Ports and ADF Regions

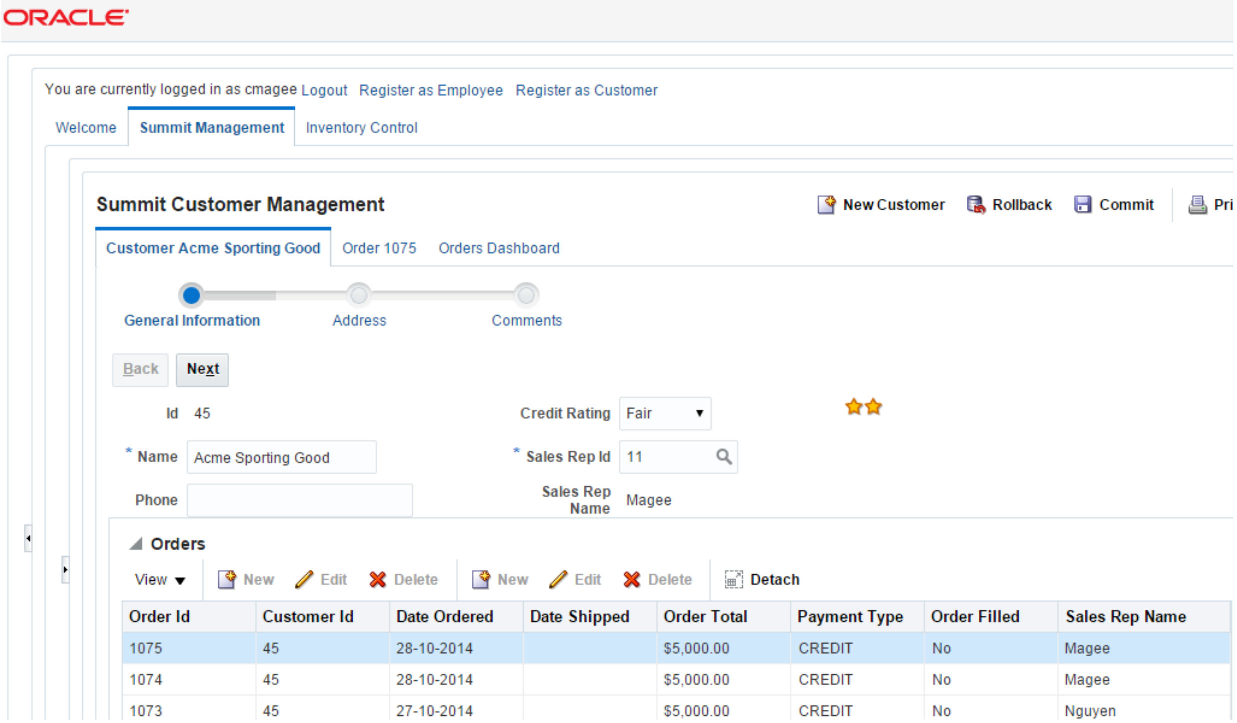
A view port is a display area capable of navigating independently of other view ports. A browser window and an ADF region are both examples of view ports. The root view port displays the main page in a browser window. The root view port may have child view ports, for example, regions on the page, but does not have a parent view port.

Java classes that implement the `ViewPortContext` interface in the `oracle.adf.controller` package get you more information about view ports. For more information, see the *Java API Reference for Oracle ADF Controller*.

Task Flows and ADF Region Use Cases and Examples

Figure 26-2 shows the General Information page fragment (`GeneralInfo.jsff`) from the `edit-customer-task-flow-definition.xml` task flow in the Summit sample application for ADF task flows. This task flow renders in an ADF region and displays information about customers in a series of page fragments that authenticated users can navigate through and edit using the provided controls. For more information about creating this type of region, see Creating an ADF Region.

Figure 26-2 ADF Region in the Summit ADF Task Flow Sample Application



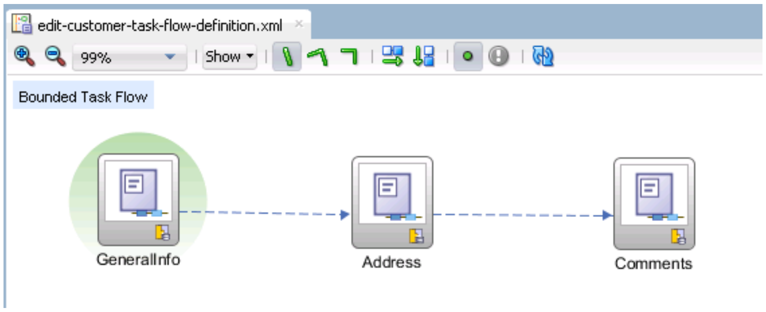
Id 45
Credit Rating Fair
* Name Acme Sporting Good
* Sales Rep Id 11
Phone
Sales Rep Name Magee

Order Id	Customer Id	Date Ordered	Date Shipped	Order Total	Payment Type	Order Filled	Sales Rep Name
1075	45	28-10-2014		$5,000.00	CREDIT	No	Magee
1074	45	28-10-2014		$5,000.00	CREDIT	No	Magee
1073	45	27-10-2014		$5,000.00	CREDIT	No	Nguyen

Figure 26-2 also shows links (labeled **Register as Employee** and **Register as Customer**) that invoke different task flows in the ADF dynamic region that the **showDetailItem** component labeled **Welcome** renders. For more information about creating this type of region, see Creating ADF Dynamic Regions.

Figure 26-3 shows the `edit-customer-task-flow-definition.xml` task flow in JDeveloper. It contains three view activities to display information about customers to end users.

Figure 26-3 Edit Customer Task Flow in ADF Summit Application for ADF Task Flows



Additional Functionality for Task Flows that Render in ADF Regions

You may find it helpful to understand how a task flow that renders in an ADF region interacts with other task flow and ADF functionality. Following are links to other functionality that may be of interest.

- You can set security on a bounded task flow that displays in an ADF region and associated page definitions. If an end user displays a page that contains an ADF region that the user is not authorized to view, the contents of the ADF region do not display. No authentication mechanism is triggered. For more information, see Enabling ADF Security in a Fusion Web Application.
- Task flows can invoke managed beans. For more information about managed beans, see Using a Managed Bean in a Fusion Web Application.
- You can use contextual events to exchange information with a bounded task flow. For more information, see Using Contextual Events.

Creating an ADF Region

You can create an ADF region in a JSF Page or an ADF page fragment by adding af:region tag. The ADF region must contain at least one view activity or one task flow call activity to the page where you want to render the ADF region.

You create an ADF region by dragging and dropping a bounded task flow that contains at least one view activity or one task flow call activity to the page where you want to render the ADF region. This makes sure that the ADF region you create has content to display at runtime.

The bounded task flow's view activities must be associated with page fragments (`.jsff`). If you attempt to drag and drop a bounded task flow that is associated with pages rather than page fragments, JDeveloper does not display the context menu that allows you to create an ADF region. You can convert a bound task flow that uses pages to use page fragments. See How to Convert Bounded Task Flows .

The context menu that appears to create an ADF region presents options to create a nondynamic and a dynamic region. A dynamic region (ADF dynamic region) determines the bounded task flow that it renders at runtime. For information about creating an ADF dynamic region, see Creating ADF Dynamic Regions. You determine at design time the bounded task flow that a nondynamic region (ADF region) displays.

How to Create an ADF Region

Drag a bounded task flow from the Applications window to the page where you want to render an ADF region.

Before you begin:

It may be helpful to have an understanding of the requirements for a bounded task flow that you use in an ADF region. For more information, see Creating an ADF Region.

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see Additional Functionality for Task Flows that Render in ADF Regions.

You will need to complete these tasks:

- Create a bounded task flow with one or more view activities associated with page fragments or one task flow call activity to a task flow with view activities.

  For more information, see Creating a Task Flow.

- Create a JSF page to host the ADF region.

  For more information, see the "How to Create JSF Pages" section of *Developing Web User Interfaces with Oracle ADF Faces*.

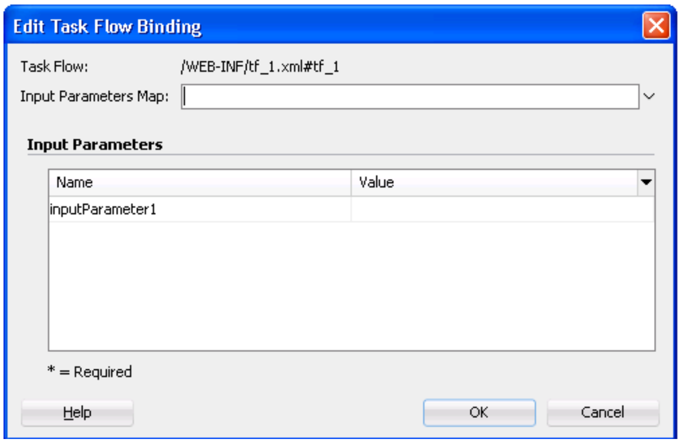
To create an ADF region:

1. In the Applications window, double-click the JSF page where you want to locate the ADF region.
2. From the Applications window, drag and drop the bounded task flow onto the JSF page, and from the context menu, choose **Create** > **Region**.
3. If the Edit Task Flow Binding dialog appears, click **OK**.

   The Edit Task Flow Binding dialog appears if the bounded task flow that you drop on the JSF page has an input parameter defined, as described in How to Pass an Input Parameter to a Bounded Task Flow.

   For more information about specifying parameters for an ADF region, see Specifying Parameters for an ADF Region.

Figure 26-4 Edit Task Flow Binding Dialog for an ADF Region



Edit Task Flow Binding

Task Flow: /WEB-INF/tf_1.xml#tf_1

Input Parameters Map:

Input Parameters

Name	Value
inputParameter1	

* = Required

4. In the Structure window, right-click the node for the ADF region that you added (**af:region**) and choose **Go to Properties**.
5. Review or modify (as appropriate) the following fields which JDeveloper automatically populates with default values in the Properties window for the ADF region:
   - **Id**: An ID that the JSF page uses to reference the ADF region, for example, `r1`.
   - **Value**: An EL reference to the ADF region model, for example, `#{bindings.region1.regionModel}`. This is the region model that describes the behavior of the region.
   - **Rendered**: If `true` (the default value), the ADF region renders when the JSF page renders.
6. For information about how to map parameters between the view activity associated with the JSF page and the ADF region, see Specifying Parameters for an ADF Region.

What Happens When You Create an ADF Region

When you drop a bounded task flow onto a JSF page to create an ADF region, JDeveloper adds an `af:region` tag to the page. The `af:region` tag references an object that implements `RegionModel`. The following example shows the `af:region` tag that appears in the `Customers.jsff` page fragment of the Summit ADF task flow sample application.

```
<af:region value="#{bindings.editcustomertaskflowdefinition1.regionModel}"
                    id="r2"/>
```

JDeveloper also adds a task flow binding to the page definition file of the page that hosts the ADF region. The following example shows a sample of the metadata that JDeveloper adds. The task flow binding provides a bridge between the ADF region and the bounded task flow. It binds a specific instance of an ADF region to its associated bounded task flow and maintains all information specific to the bounded task flow. The `taskFlowId` attribute specifies the directory path and the name of the source file for the bounded task flow.

```
<taskFlow id="editcustomertaskflowdefinition1"
    taskFlowId="/WEB-INF/flows/edit-customer-task-flow-definition.xml#edit
    -customer-task-flow-definition"
    activation="deferred"
    xmlns="http://xmlns.oracle.com/adf/controller/binding"/>
```

The bounded task flow preserves all of the data bindings when you drop it on the JSF page. At runtime, a request for a JSF page containing an ADF region initially handles like any other request for a JSF page. As the JSF page definition executes, data loads in to the JSF page. When the component tree for the parent JSF page encounters the `<af:region>` tag, it executes it in order to determine the first page fragment of content to display. Once it determine the first page fragment of content, it adds the appropriate UI components from the page fragment to the component tree for the parent JSF page.

The task flow binding creates an object for its task flow that implements the following interface in order to get the current view activity:

```
oracle.adf.controller.ViewPortContext
```

The task flow binding's `taskFlowId` attribute can also reference an EL expression that evaluates to one of the following:

- `java.lang.String`
- `oracle.adf.controller.TaskFlowId`

You use this capability if you create an ADF dynamic region. For more information, see Creating ADF Dynamic Regions.

Specifying Parameters for an ADF Region

You may need to transfer values to the ADF region for the input parameters defined for a bounded task flow in that region. For this, you can the input parameters (defined in the ADF region) to the task flow binding the ADF region. You can also access the input parameters in the memory scopes, managed beans, or the ADF binding layer by using EL expressions in the ADF region.

You can make input parameters that you defined for a bounded task flow available to an ADF region by adding them to the task flow binding that the ADF region references. Use EL expressions to reference input parameters available in memory scopes, managed beans, or the ADF binding layer.

Specifying input parameters is one method of providing information to an ADF region. An alternative method is to use contextual events. The nature of the information that you want to provide to the ADF region determines the method you choose to provide the information. For example, choose:

- Input parameters if the required information is at the beginning of the task flow and a change in the value of this information requires a restart of the task flow.

  For example, you have a page that contains a table of employees. An ADF region on that page contains a task flow to enroll a selected employee in a benefits program. A change in the selected employee requires that you restart the benefits enrollment task flow from the beginning for the newly selected employee. Using input parameters to the task flow is the right decision for this use case.

  You can pass input parameters by reference or by value. If you pass by reference, an update on the main page for the selected employee's information, such as last name, is automatically reflected in the task flow running in the ADF region without restarting the task flow.

- Contextual events if you can only determine the information to exchange after the start of a task flow and a change in the information does not require a restart of the task flow. For example, the Inventory Control tab in the Summit ADF task flow sample application uses contextual events to display the appropriate chart for product inventory in one region in response to the product that a user selects in another region. For more information, see Using Contextual Events.

For information about creating an ADF region and adding task flow bindings, see Creating an ADF Region. For information about how to define an input parameter for a bounded task flow, see Passing Parameters to a Bounded Task Flow.

How to Specify Parameters for an ADF Region

Use EL expressions to specify parameters available in memory scopes, managed beans, or the ADF binding layer as input for the ADF region.

Before you begin:

It may be helpful to have an understanding of the requirements for specifying parameters for an ADF region. For more information, see Specifying Parameters for an ADF Region.

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see Additional Functionality for Task Flows that Render in ADF Regions.

To specify input parameters for an ADF region:

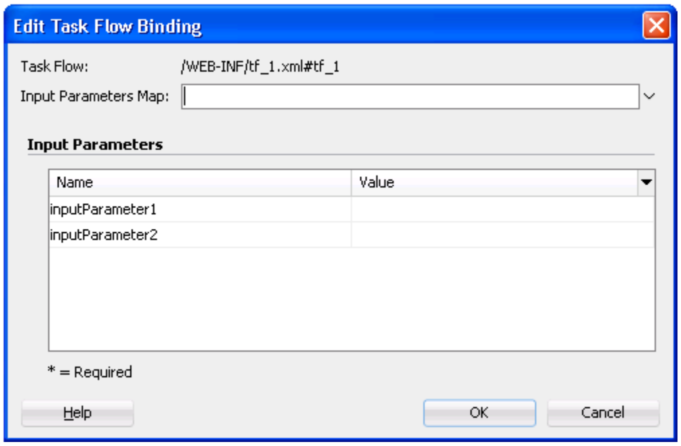
1. In the Applications window, right-click the JSF page that holds the ADF region and choose **Go to Page Definition**.
2. In the overview editor, click the **Bindings and Executables** navigation tab, select the task flow binding for which you want to specify parameters and click the **Edit** icon.
3. In the Edit Task Flow Binding dialog, write EL expressions that retrieve the values of each input parameter you want to specify for the ADF region. Note that you must write an EL expression for parameters that you defined as required. For example, write an EL expression similar to the following:

   ```
   #{pageFlowScope.inputParameter1}
   ```

   Figure 26-5 shows the Edit Task Flow Binding dialog where the Input Parameters section lists a number of input parameters that were defined for the bounded task, as described in Passing Parameters to a Bounded Task Flow.

   > **Note:**
   >
   > You can write an EL expression that references a list of input parameters specified in a managed bean using the Input Parameters Map field of the Edit Task Flow Binding dialog. For more information about implementing this functionality, see Specifying Parameters for ADF Regions Using Parameter Maps.

Figure 26-5 Edit Task Flow Binding Dialog



Edit Task Flow Binding

Task Flow: /WEB-INF/tf_1.xml#tf_1

Input Parameters Map:

Input Parameters

Name	Value
inputParameter1	
inputParameter2	

* = Required

4. Click **OK**.

What Happens When You Specify Parameters for an ADF Region

JDeveloper writes entries that are child elements of the `taskFlow` element in the page definition of the JSF page, as illustrated in the following example.

```
<taskFlow id="tflow_tf11"
   taskFlowId="/WEB-INF/tflow_tf1.xml#tflow_tf1"
   activation="deferred"
   xmlns="http://xmlns.oracle.com/adf/controller/binding">
  <parameters>
    <parameter id="inputParameter1"
      value="#{pageFlowScope.inputParameter1}"/>
    <parameter id="inputParameter2"
      value="#{pageFlowScope.inputParameter2}"/>
  </parameters>
</taskFlow>
```

At runtime, the values specified by the EL expression in the value `attribute` are passed to the ADF region.

Specifying Parameters for ADF Regions Using Parameter Maps

A parameter map object on a managed bean specifies the keys mapping to the values that you want to input to the ADF region. As you define the parameters in the parameter maps, the space required to specify them in the task flow binding element or to specify them in multiple task flow bindings in the page definition for the pages is reduced.

In addition (or as an alternative) to listing all the input parameters on the task flow binding, as described in Specifying Parameters for an ADF Region, you can use the `parametersMap` property of the task flow binding to specify a parameter map object on a managed bean. The parameter map object that you reference must be of a type that implements the following interface:

```
java.util.Map
```

The parameter map object that you reference specifies keys that map to the values you want to input to the ADF region. Using this approach reduces the number of `parameter` child elements that appear under the task flow binding (`taskFlow`) element or the multi task flow binding (`multiTaskFlow`) in the page definition for the page. This approach also allows you more flexibility in determining what input parameters pass to the ADF region. In particular, it provides a way to pass parameters to ADF dynamic regions as the number of input parameters can differ between the different task flow bindings in an ADF dynamic region. See Creating ADF Dynamic Regions.

You can configure an ADF region or an ADF dynamic region's task flow binding to reference a parameter map. You can also configure a multi task flow binding to reference a parameter map. Make sure that the name of an input parameter you define for a bounded task flow matches the name of a key that you define in the parameter map object.

If you specify a parameter with the same `id` attribute in a `<parameter>` element and in a `<parametersMap>` element, the `<parametersMap>` element always takes precedence.

This is because the `<parametersMap>` element may need to override the static value of the parameter if you create an ADF dynamic region, as described in Creating ADF Dynamic Regions.

How to Create a Parameter Map to Specify Input Parameters for an ADF Region

You configure the task flow binding's `parametersMap` property to reference the parameter map object that defines the key-value pairs you want to pass to the ADF region.

Before you begin:

It may be helpful to have an understanding of the configuration options available to you when passing input parameters to an ADF region. For more information, see Specifying Parameters for ADF Regions Using Parameter Maps.

You may also find it helpful to understand functionality that can be added using other task flow and ADF region features. For more information, see Additional Functionality for Task Flows that Render in ADF Regions.

You will need to complete this task:

> Create a managed bean or edit an existing managed bean so that it returns an object that implements the `java.util.Map` interface. Configure the managed bean so the object returns key-value pairs with the values that you want to pass to the ADF region. For more information about managed beans, see Using a Managed Bean in a Fusion Web Application.

To create a parameter map to specify input parameters for an ADF region:

1. In the Applications window, right-click the JSF page that holds the ADF region and choose **Go to Page Definition**.
2. In the overview editor, click the **Bindings and Executables** navigation tab, select the task flow binding or multi task flow binding for which you want to specify a parameter map, and then click the **Edit** icon.

   The type of task flow binding that you select determines the dialog that appears.
3. In the Edit Task Flow Binding dialog or the Edit Multi Task Flow Binding dialog, select **Expression Builder** from the **Input Parameters Map** dropdown menu.
4. Write or build an EL expression that references a parameter map. For example, write an EL expression similar to the following:

   ```
   #{pageFlowScope.userInfoBean.parameterMap}
   ```
5. Click **OK**.

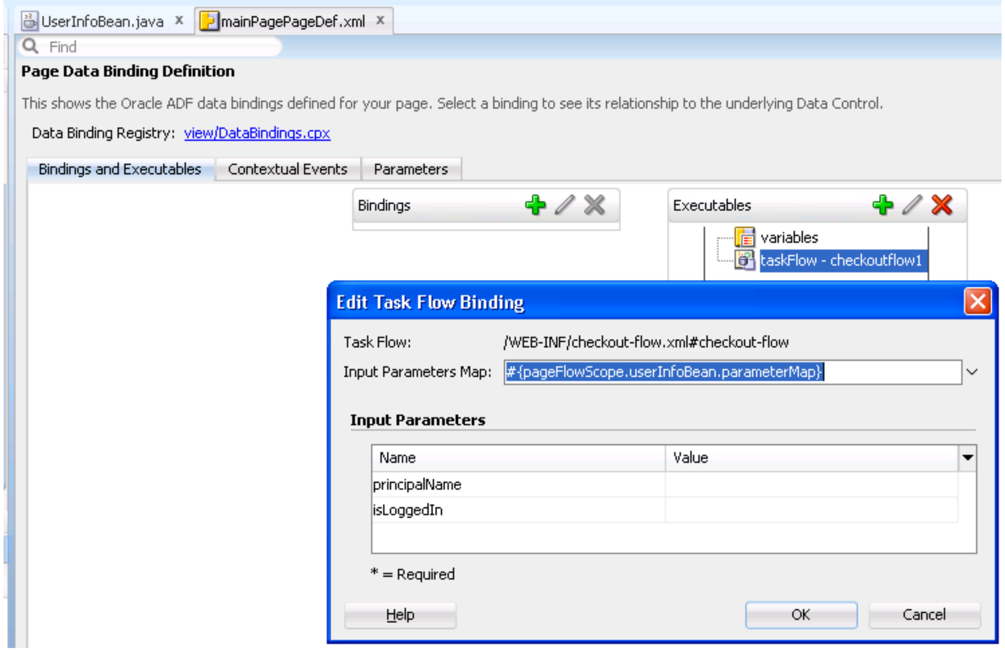
What Happens When You Create a Parameter Map to Specify Input Parameters

At runtime, the task flow binding or multi task flow binding evaluates the EL expression specified for its `parametersMap` property. It returns values to the ADF region from the managed bean for keys that match the name of the input parameters defined for the bounded task flow that render in the ADF region.

Example 26-1 shows code snippets from a managed bean that puts two values (`isLoggedIn` and `principalName`) into a parameter map named `parameterMap`.

Figure 26-6 shows the Edit Task Flow Binding dialog after you close the Expression Builder dialog, having specified the parameter map object (`parameterMap`) shown in Example 26-1. The **Input Parameters** field in the Edit Task Flow Binding dialog lists the input parameters defined for the bounded task flow associated with this ADF region (`checkout-flow`). The task flow binding retrieves the values for these parameters from the managed bean shown in Example 26-1.

Figure 26-6 EL Expression Referencing Parameter Map on Task Flow Binding



Page Data Binding Definition

This shows the Oracle ADF data bindings defined for your page. Select a binding to see its relationship to the underlying Data Control.

Data Binding Registry: view/DataBindings.cpx

Edit Task Flow Binding

Task Flow: /WEB-INF/checkout-flow.xml#checkout-flow

Input Parameters Map: #{pageFlowScope.userInfoBean.parameterMap}

Input Parameters

Name	Value
principalName	
isLoggedIn	

* = Required

The following example shows the metadata that appears for the task flow binding in the page definition file of the page that renders the ADF region. The metadata for the task flow binding references both the bounded task flow (`taskFlowId` attribute) and the managed bean (`parametersMap`).

```
<taskFlow id="checkoutflow1"
              taskFlowId="/WEB-INF/checkout-flow.xml#checkout-flow"
              activation="deferred"
              xmlns="http://xmlns.oracle.com/adf/controller/binding"
              parametersMap="#{pageFlowScope.userInfoBean.parameterMap}"/>
```

You specify the `<parameterMap>` element in the page definition.

Note:

If you specify `Refresh="ifNeeded"`, parameters are not supported in the `<parameterMap>` element. The only condition that determines whether the region need to be refreshed is the boolean value returned by the evaluation of `RefreshCondition`. For more information, see What You May Need to Know About Configuring an ADF Region to Refresh.

Example 26-1 Managed Bean Defining a Parameter Map

```
import java.util.HashMap;
import java.util.Map;

public class UserInfoBean {
    private Map<String, Object> parameterMap = new HashMap<String, Object>();

    public Map getParameterMap() {

        parameterMap.put("isLoggedIn", getSecurity().isAuthenticated());
        parameterMap.put("principalName", getSecurity().getPrincipalName());
        return parameterMap;
    }
}
```

Configuring an ADF Region to Refresh

The ADF region refreshes when the parent page binding is first displayed. For future refreshes you must configure one of these task flow binding attributes: taskFlowID, Refresh or RefreshCondition, RefreshCondition="#{EL.expression}", or Refresh="ifNeeded".

You can configure when an ADF region refreshes and whether it invokes a task flow. An ADF region can only invoke a task flow when the ADF region is in an active state. An ADF region in an inactive state cannot invoke a task flow and returns a null value for the ID of the referenced task flow to the parent page.

How to Configure the Refresh of an ADF Region

You set values for the task flow binding of the task flow associated with the ADF region to determine when an ADF region switches from an inactive to an active state and to determine when an ADF region refreshes.

Before you begin:

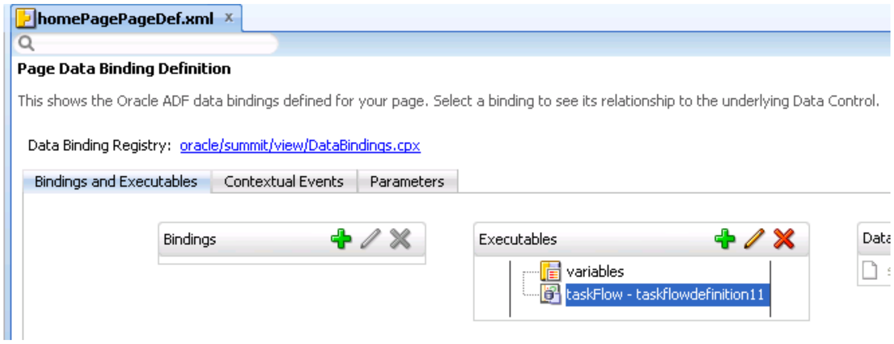
It may be helpful to have an understanding of the requirements for a bounded task flow that you use in an ADF region. For more information, see Configuring an ADF Region to Refresh.

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see Additional Functionality for Task Flows that Render in ADF Regions.

To configure the refreshing of an ADF Region:

1. In the Applications window, select the page that contains the ADF region, right-click and choose **Go to Page Definition**.
2. In the page definition file, select the task flow binding or multi task flowing binding in the **Executables** section, as illustrated in Figure 26-7.

Figure 26-7   Task Flow Binding



homePagePageDef.xml

Page Data Binding Definition

This shows the Oracle ADF data bindings defined for your page. Select a binding to see its relationship to the underlying Data Control.

Data Binding Registry: oracle/summit/view/DataBindings.cpx

3. Choose the appropriate option to refresh the ADF region.
   - Refresh if the value of a task flow binding parameter changes.

     In the Properties window, select **ifNeeded** from the **Refresh** dropdown list.

     Do not select **ifNeeded** if you want to set a value for the `RefreshCondition` property and can guarantee that the property evaluates to `true` only once. The `RefreshCondition` property will not be evaluated if you select **ifNeeded** for the `Refresh` property.
   - Refresh if a condition that you specify returns `true`. In the Properties window, write an EL expression that guarantees that `true` is returned only once and that returns a boolean in the **RefreshCondition** field. If the EL expression returns `true`, the ADF region refreshes. If the EL expression returns `true` more than once for each task flow refresh, page content may fail to load.

> **Note:**
>
> Use **ifNeeded** when possible. The usage of **RefreshCondition** is not recommended unless there is a good reason. For example, use **RefreshCondition** only when the application passes parameters to the task flow binding using a dynamic parameter map and when the application can guarantee **RefreshCondition** evaluates `true` exactly once when it refreshes the ADF task flow. For more information, see What You May Need to Know About Configuring an ADF Region to Refresh.

4. In the Properties window, select a value from the **activation** dropdown list, as described in the following list:
   - **conditional**: activates the ADF region if the EL expression set as a value for the task flow binding `active` property returns `true`.
   - **deferred**: select this option if your application uses Facelets XHTML pages in the view layer and you want to activate the ADF region when a Facelets XHTML page first requests a `viewID`. If your application uses JSP technology

in the view layer, selecting this option has the same effect as selecting **immediate** (the ADF region activates immediately) provided that the parent component for the ADF region is not a `popup` or `panelTabbed` component that has its `childCreation` attribute set to `deferred`. If this latter scenario occurs, the parent component (`popup` or `panelTabbed`) determines behavior.

Use this option if your application uses Facelets XHTML pages. For more information about Facelets with ADF Faces, see the "Getting Started with ADF Faces and JDeveloper" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

- **immediate**: activates the ADF region immediately. This is the default value.

The value that you select in the dropdown list determines when an ADF region switches from an inactive to an active state. An ADF region must have an active state before it can invoke a task flow.

5. If you selected **conditional** as the value for the activation property, write an EL expression that returns a boolean value at runtime for the active property. If the EL expression returns `true`, the ADF region invokes the task flow.
6. (Optional) For the `processRegionForRefresh` property, write an EL expression to determine if the region should participate in a refresh operation. If the EL expression evaluates to false, the region binding and its children will not be refreshed. This check is performed before the region activation, the `RefreshCondition` property, or input parameters are evaluated. If the EL expression evaluates to true or if you do not write an EL expression for the `processRegionForRefresh` property, the region will be included in refresh operations and the behavior that you specify for the activation dropdown list will be invoked. Writing an EL expression for the `processRegionForRefresh` property does not prevent the region from being rendered.

What You May Need to Know About Configuring an ADF Region to Refresh

An ADF region initially refreshes when the parent JSF page on which the region is located first displays. During the initial refresh, any ADF region task flow binding parameter values are passed in from the parent page. The parameter values are used to display the initial page fragment within the ADF region. If the bounded task flow relies on input parameter values that are not available when the page is first created, make sure that your task flow behaves correctly if the input parameter values are null by, for example, using a `NullPointerException` object. Alternatively (or additionally), make sure that the task flow does not activate until the input parameters become available by configuring the task flow binding's `active` property.

An ADF region task flow binding can be refreshed again based on one of the following task flow binding attributes:

- `taskFlowId`

  This attribute specifies the directory path and the name of the source file for the bounded task flow. The ADF region refreshes if this attribute value changes.

- Neither `Refresh` or `RefreshCondition` attributes are specified (default)

  If neither the `Refresh` or `RefreshCondition` task flow binding attribute is specified, the ADF region is refreshed only once at the time the parent page is first displayed unless you configure a value for the task flow binding's `active` property.

- `RefreshCondition="#{EL.expression}"`

  The `RefreshCondition` must evaluate to a boolean value, and the EL expression must return `true` just **one time** for each task flow refresh. This means the expression cannot be a reference to a state variable; instead, it must be a call to a method that possesses the internal check of the return value. If no check is implemented in the method call and the expression is allowed to return `true` more than once, then during the refresh of a dynamic region, the application will display the error "The content of this page failed to load as expected because data transmission was interrupted".

  > **Note:**
  >
  > A dynamic region may fail to load unless the application can guarantee that the `RefreshCondition` expression evaluates to `true` only once for each task flow refresh. For example, assume you have assigned an expression to the refresh condition for the task flow definition. If the EL expression evaluates to `true`, the region model defined by the controller is refreshed and, as a result, the client ID index for the region is incremented. This will cause any operation that expects the original client ID for the region to fail as it does not find the expected ID. One such operations is streaming of table row data.

  At the time the `RefreshCondition` is evaluated, if the variable `bindings` is used within the EL Expression, the context refers to the binding container of the parent page, not the page fragment displayed within the ADF region. `RefreshCondition` is independent of the change of value of binding parameters. If the task flow binding parameters do not change, nothing within the ADF region will change. The expression is evaluated during the `PrepareRender` phase of the ADF page lifecycle. For more information, see Understanding the Fusion Page Lifecycle .

- `Refresh="ifNeeded"`

  Any change to a task flow binding parameter value causes the ADF region to refresh. If the ADF region task flow binding does not have parameters, `Refresh="ifNeeded"` is equivalent to not specifying the `Refresh` attribute.

  `Refresh="ifNeeded"` is not supported if you pass parameters to the task flow binding using a dynamic parameter map. You must instead use the `RefreshCondition="#{EL.Expression}"`.

  For more information about specifying parameter values using a parameter map, see Specifying Parameters for ADF Regions Using Parameter Maps.

The `Refresh="ifNeeded"` property takes precedence over `RefreshCondition` and `RefreshCondition` will not be evaluated if you set `Refresh="ifNeeded"`. When possible, use the `Refresh="ifNeeded"` property to control region refresh behavior and to avoid the page content loading failure that can result when `RefreshCondition="#{EL.expression}"` evaluates to true more than once for each task flow refresh.

The following example contains a sample task flow binding located within the page definition of a page on which an ADF region has been added.

```
<taskFlow id="Department1" taskFlowId="/WEB-INF/Department#Department"
    xmlns="http://xmlns.oracle.com/adf/controller/binding">
```

```
  <parameters>
    <parameter id="DepartmentId" value="#{bindings.DepartmentId.inputValue}"
        xmlns="http://xmlns.oracle.com/adfm/uimodel"/>
  </parameters>
</taskFlow>
```

You do not need to refresh an ADF region to refresh the data controls inside the ADF region. During the ADF lifecycle, the refresh events telling the iterators to update will be propagated to the binding container of the current page of the ADF region.

What You May Need to Know About Refreshing an ADF Region

When a binding container hierarchy is refreshed, the region binding code evaluates the input parameter values and compare the new values with the previous values for the region binding only if the region binding has a refresh condition set to **ifNeeded**. See Configuring an ADF Region to Refresh. If a parameter value is changed, the region is refreshed. For example, if a region displays the employee details of an employee and if any of the details of the employee is changed, then region refreshes and displays the details for the selected employee.

Additionally, if you have added support for `childCreation` attribute set to **lazyUncached** on various UI components, the ADF view prunes the portions of the view tree and those portions are not included in the active view tree and are not visible. During the refresh of binding container hierarchy, the ADF controller evaluates the input parameters for all the regions that were pruned and are not visible in the active view tree of the page layout. The operations on the corresponding binding containers that are not in active tree view might result in poor performance.

To avoid refreshing the regions that are not visible in the active tree view, set the `oracle.adfinternal.controller.regionPruning` parameter value to `true`. This parameter checks if the region is part of the active view tree before evaluating if the input parameter values are modified. The region will then be refreshed only if the region is part of the active view tree and one or more parameter values are modified.

This property uses the Trinidad property service, therefore, you can set this property using the Fusion Apps property mechanism. Alternatively, you can enable this property using the `adf-settings.xml` file.

```
<adf-properties-settings
xmlns="http://xmlns.oracle.com/adf/properties/settings">
      <properties>
         <property>
           <name>oracle.adfinternal.controller.regionPruning</name>
           <default-value>true</default-value>
         </property>
      </properties>
   </adf-properties-settings>
```

Configuring Activation of an ADF Region

The ADF regions can be configured to be activated at the appropriate time. This is helpful to optimize the performance of the task flow binding these regions. You can set the activation of the region either as conditional, deferred, or immediate based on your requirement.

You can configure when an ADF region activates. This has the effect of determining when the task flows contained in ADF regions activate. Configuring the activation of

ADF regions can optimize the performance of a Fusion web application's page. For example, a page that contains 5 ADF regions may reference 5 task flows. You may not want these 5 task flows to execute simultaneously when the Fusion web application page loads so you configure an `activation` property to determine when a task flow executes.

How to Configure Activation of an ADF Region

You configure the `activation` property for the task flow binding associated with the ADF region to determine when to activate the ADF region.

Before you begin:

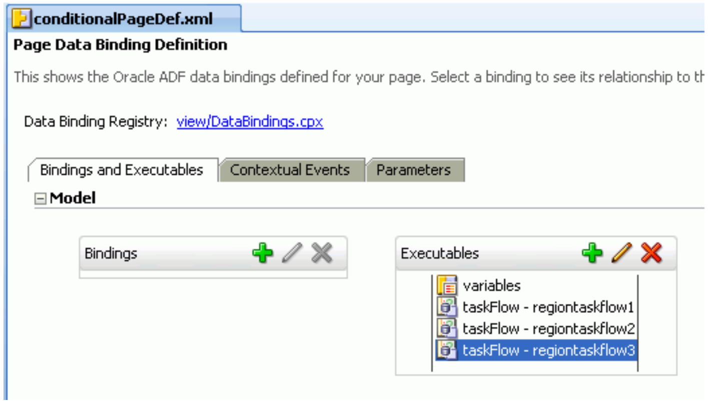
It may be helpful to have an understanding of the configuration options for activating an ADF region. For more information, see Configuring Activation of an ADF Region.

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see Additional Functionality for Task Flows that Render in ADF Regions.

To configure the activation of an ADF region:

1. In the Applications window, select the page that contains the ADF region(s), right-click and choose **Go to Page Definition**.
2. In the page definition file, select the task flow binding or multi task flow binding in the **Executables** section, as illustrated in Figure 26-8.

Figure 26-8 Task Flow Bindings for ADF Region Configured for Activation



conditionalPageDef.xml

Page Data Binding Definition

This shows the Oracle ADF data bindings defined for your page. Select a binding to see its relationship to th

Data Binding Registry: view/DataBindings.cpx

variables
taskFlow - regiontaskflow1
taskFlow - regiontaskflow2
taskFlow - regiontaskflow3

3. In the Properties window, select a value from the **activation** dropdown list, as described in the following list:
   - **conditional**: activates the ADF region if the EL expression set as a value for the task flow binding `active` property returns `true`.
   - **deferred**: select this option if your application uses Facelets XHTML pages in the view layer and you want to activate the ADF region when a Facelets XHTML page first requests a `viewID`. If your application uses JSP technology in the view layer, selecting this option has the same effect as selecting **immediate** (the ADF region activates immediately).

     Use this option if your application uses Facelets XHTML pages. For more information about Facelets with ADF Faces, see the "Getting Started with

ADF Faces and JDeveloper" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

- **immediate**: activates the ADF region immediately. This is the default value.

The value that you select in the dropdown list determines when an ADF region switches from an inactive to an active state. An ADF region must have an active state before it can invoke a task flow.

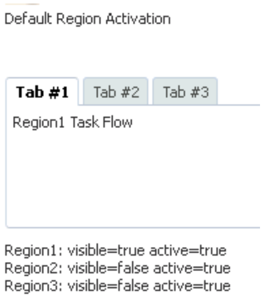
4. If you selected **conditional** as the value in the **activation** dropdown list, write an EL expression that returns a boolean value at runtime for the active property. If the EL expression returns `true`, the ADF region invokes the task flow. If the EL expression returns `false`, the ADF region deactivates a task flow that was active in the ADF region.

What Happens When You Configure Activation of an ADF Region

The behavior of the ADF region at runtime depends on the options that you set for the `activation` property.

Figure 26-9 shows the default behavior where all task flows in ADF regions execute when the page loads the ADF regions (Tab # 1, Tab # 2, Tab # 3).

Figure 26-9 Default Activation of ADF Regions

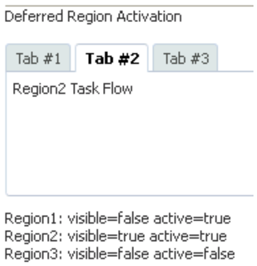


Region1 Task Flow

Region1: visible=true active=true
Region2: visible=false active=true
Region3: visible=false active=true

Figure 26-10 shows an example where the activation property was set to `deferred` and the application uses Facelets. The regions in Tab # 1 and Tab # 2 have an active state because the end user navigated to these regions. The region in Tab # 3 is inactive.

Figure 26-10 Deferred Activation of ADF Regions



Region2 Task Flow

Region1: visible=false active=true
Region2: visible=true active=true
Region3: visible=false active=false

Figure 26-11 shows an example where the `activation` property was set to `conditional` and the `active` property to an EL expression that returns a `boolean` value at runtime. The region in Tab # 1 is in an active state because the EL expression specified for the `active` property returns `true`. The regions in Tab # 2 and Tab # 3 are inactive because the EL expression specified for the `active` property returns `false`.

Note that the following events occur if a region deactivates a task flow (the value returned by the `active` property changes from `true` to `false`):

- A task flow with an active transaction rolls back the transaction.

  For more information about transaction options in task flows, see Managing Transactions in Task Flows.

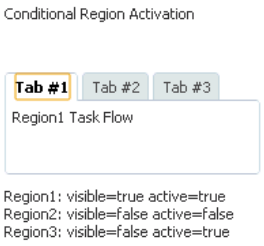
- If a task flow has a data control frame with a `data-control-scope` value of `isolated`, the task flow releases the data control frame and any data controls in the data control frame.

  For more information about data controls, see Sharing Data Controls Between Task Flows and What You May Need to Know About Sharing Data Controls and Managing Transactions.

- ADF Controller releases the view port data structures for the region (including pageFlow and view scopes).

  For more information about view ports, see About View Ports and ADF Regions. For more information about memory scopes, see What You May Need to Know About Memory Scope for Task Flows.

Figure 26-11   Conditional Activation of ADF Regions



```
Region1: visible=true active=true
Region2: visible=false active=false
Region3: visible=false active=true
```

Navigating Outside an ADF Region's Task Flow

You can navigate out of the ADF region and then display the parent view activity of the task flow that binds the region, or you can display the root page of its application. To do so, you must expose the properties (parent-outcome and root-outcome) of the parent action activity that you configure.

A bounded task flow running in an ADF region may need to trigger navigation of its parent view activity or to navigate to the root page of its application. The parent action activity exposes properties (`parent-outcome` and `root-outcome`) that you configure if you want to implement either of these use cases.

For example, you might specify a value for `parent-outcome` if you have a page that displays employee information and an ADF region that contains an enroll button for an employee. After the enroll page completes and the ADF region returns, the employee information page refreshes with the next employee.

> **Note:**
>
> An ADF region does not maintain state when you navigate away from the region.

How to Trigger Navigation Outside of an ADF Region's Task Flow

You add a parent action activity to the bounded task that runs in the ADF region and configure it so that it navigates to the parent's view activity.

Before you begin:

It may be helpful to have an understanding of the configuration options for activating an ADF region. For more information, see Configuring Activation of an ADF Region.

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see Additional Functionality for Task Flows that Render in ADF Regions.

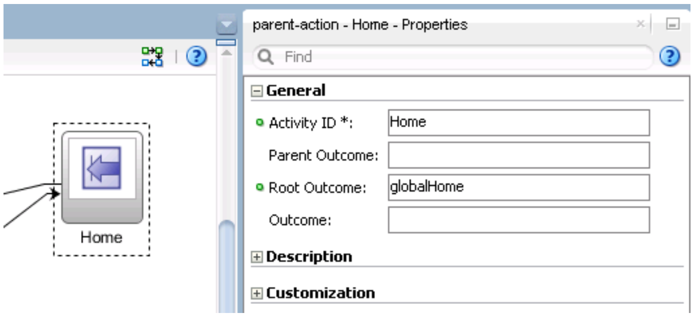
To trigger navigation outside of an ADF region's task flow:

1. In the Applications window, double-click the bounded task flow that runs in the ADF region.
2. In the ADF Task Flow page of the Components window, from the Component panel, in the Activities group, drag and drop a **Parent Action** onto the diagram for the bounded task flow.
3. Select the parent action activity in the diagram for the bounded task flow.
4. In the Properties window, choose the appropriate option:
   - **Parent Outcome**: enter a literal value or write an EL expression that returns an outcome so that the parent action activity navigates to the parent view activity. The outcome is then used to navigate the parent view activity's task flow rather than navigating the ADF region's bounded task flow.

     The parent view activity's task flow should contain a control flow case or wildcard control flow rule that accepts the value you specify for `parent-outcome`.
   - **Root Outcome**: enter a literal value or write an EL expression that returns an outcome so that the parent action activity navigates to the root page of the application.

     For example, to navigate from an ADF region to the home page in your application, you specify a value for **Root Outcome**, as illustrated in Figure 26-12.

Figure 26-12 Navigating to Home Page



Activity ID *: Home
Parent Outcome:
Root Outcome: globalHome
Outcome:

> **Note:**
>
> **Parent Outcome** and **Root Outcome** are mutually exclusive.

5. (Optional) In the **Outcome** field, enter a literal value that specifies an outcome for control flow within the ADF region after the parent action activity adds `parent-outcome` or `root-outcome` to the appropriate queue.

   Specifying an `outcome` element is useful in cases where the parent view activity or root page does not navigate as a result of the `parent-outcome` or `root-outcome` sent by the parent action activity. In addition, the ADF region should not continue to display the same view. If you do not specify a value for `outcome`, the ADF region's `viewId` remains unchanged.

What Happens When You Configure Navigation Outside a Task Flow

At design time, JDeveloper writes entries to the source file for the bounded task flow based on the property values you set for the parent action activity. The following example shows sample entries that JDeveloper generates when you write a literal value for the Parent Outcome and Outcome properties of the parent action activity.

```
<parent-action id="parentAction1">
    <parent-outcome>parent_outcome</parent-outcome>
    <outcome id="__2">outcome</outcome>
</parent-action>
```

The following example shows sample entries that JDeveloper generates when you write a literal value for the Root Outcome and Outcome properties of the parent action activity.

```
<parent-action id="parentAction1">
      <root-outcome>root_outcome</root-outcome>
      <outcome id="__2">outcome</outcome>
</parent-action>
```

At runtime, when navigation in an ADF region’s bounded task flow encounters a parent view activity, the parent view activity’s outcome is queued and the current navigation operation in the ADF region’s bounded task flow continues. Once the current navigation operation completes, the queued outcome triggers a new navigation operation on the parent. If, for example, the next activity in the bounded task flow of the ADF region is a method call activity and the parent action activity navigates to a task flow that also includes a method call activity, the method call activity in the bounded task flow of the ADF region executes first.

What You May Need to Know About How a Page Determines the Capabilities of an ADF Region

In some cases, a page may need to determine the capabilities currently available within one of the ADF regions that it contains. For example, the page may need to initiate control flow within the ADF region based on its current state using the `queueActionEventInRegion()` method. **Region capabilities** are used by a parent page to identify the current outcomes of one of its regions based on the region's current state. They identify to the parent page whether or not an outcome is possible within the region.

The following scenario describes how region capabilities might typically be used in an application:

1. An ADF region within a page displays its associated page fragment.
2. A user selects a button or performs some other action in the ADF region.
3. The parent page identifies the outcomes (region capabilities) for the ADF region.
4. The parent page updates its buttons based on the ADF region capabilities.

The syntax of an EL expression to determine an ADF region's capabilities is as follows:

```
#{bindings.[regionId].regionModel.capabilities['outcome']}
```

where `regionId` is the ID of the ADF region component on the page and `outcome` is the possible outcome being verified within the ADF region.

Region capabilities require the availability of the specified ADF region's `regionModel` through an EL expression. The EL expression should never access bindings in any other binding container other than the current binding container. Region capabilities cannot be used in some cases. For example, a nested ADF region where a `regionModel` cannot be reached within the current binding container. This is because a nested region's nested binding container might not yet exist or might have already been released.

Configuring Transaction Management in an ADF Region

The ADF task flow allows you to optionally choose if you want to allow a task flow to share or isolate its data controls with a calling talk flow. For this, you must set a value for the data-control-scope property of the bounded task flow. You can also rollback or commit the changes made by the calling task flow by exposing the methods by the DataControlFrame interface of the ADF Model layer.

In the ADF Controller layer, bounded task flows optionally provide their own abstract implementation of transactions over the underlying ADF Model layer, as described in Managing Transactions in Task Flows. You can choose whether a task flow shares or isolates its data controls with a calling task flow by setting a value for its `data-control-scope` property, as described in Sharing Data Controls Between Task Flows . Whether a task flow creates a new transaction depends on the values you choose for the `transaction` and `data-control-scope` properties, as described in What You May Need to Know About Sharing Data Controls and Managing Transactions.

If, for example, you share a task flow's data control with a calling task flow, a new transaction is created at the ADF Controller layer level if you configure the task flow's `transaction` option to **Always Begin New Transaction** (`new-transaction`) or to **Use Existing Transaction If Possible** (`requires-transaction`). The `requires-transaction` option creates a new transaction only if a transaction does not already exist. The created transaction has the same lifespan as the ADF region that renders the task flow. This may cause behavior that you do not intend when the task flow renders in an ADF region. For example, if an ADF region refreshes, it restarts the task flow that it renders and causes the following events to occur:

- Discards the current view port that the ADF region uses

  > **Note:**
  >
  > Save points require a root view port to work. For more information about view ports, see About View Ports and ADF Regions. For more information about save points, see Using Save Points in Task Flows.

- Releases the data control that the task flow uses

  This may cause the loss of changes made in the parent page of the calling task flow because it shares the data control of the task flow that renders in the ADF region.

- Executes a commit or rollback if the End Transaction property of the task flow's task flow return activity specifies one of these actions. For more information, see Using Task Flow Return Activities .

There are a number of ways to prevent the inadvertent termination of a task flow's transaction by the refresh of an ADF region. All these options disassociate the lifespan of the transaction in the task flow that renders in an ADF region from the lifespan of the ADF region. These options make sure that the region's parent page owns the transaction and/or that the transaction starts before the region renders. Choose the most appropriate option for your application:

- Set the transaction option on the task flow that renders in the ADF region to **Always Use Existing Transaction** (`requires-existing-transaction`). This throws an exception if a transaction does not exist and prevents the ADF region from owning the transaction.
- Set the calling task flow's transaction option to **Always Begin New Transaction** (`new-transaction`) so that the lifespan of the transaction is associated with the lifespan of the parent page.
- Invoke the `DataControlFrame` interface's `beginTransaction()` method in the action that navigates to the parent page that contains the region.
- Configure a method call activity that invokes the `DataControlFrame` interface's `beginTransaction()` method from a managed bean with a request scope before navigating to the parent page of the ADF region.

  The following code begins a transaction:

  ```
  public void beginTransaction()
  {
    BindingContext context = BindingContext.getCurrent();

    String dcFrameName = context.getCurrentDataControlFrame();
  ```

```
        DataControlFrame dcFrame = context.findDataControlFrame(dcFrameName);
        dcFrame.beginTransaction(new TransactionProperties());
      }
```

If you share the data controls of a task flow with a calling task flow, use the `rollback` or `commit` options exposed by the task flow's task flow return activity to commit or rollback changes rather than programmatically use the methods exposed by the ADF Model layer's `DataControlFrame` interface. Using the methods exposed by the `DataControlFrame` interface closes the transaction and may cause the task flow that renders in the ADF region to create a new transaction.

Creating ADF Dynamic Regions

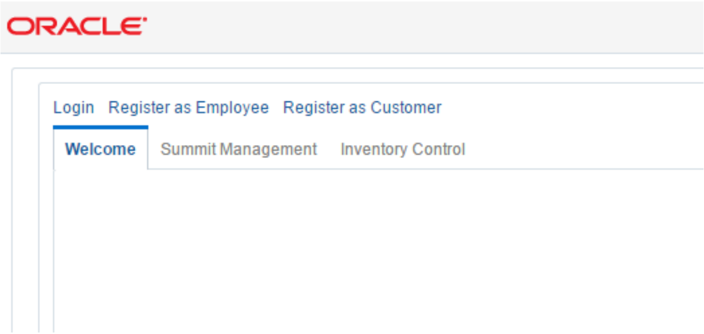
An ADF dynamic region is determined by the taskFlowId attribute of the binding task flow at runtime. This is helpful when you want to run the task flows based on the user choice at runtime. You can add additional bounded task flows to the dynamic region by creating ADF dynamic region links.

An ADF dynamic region is an ADF region where the task flow binding dynamically determines the value of its `taskFlowId` attribute at runtime. This allows the Fusion web application to determine which bounded task flow to execute within the ADF dynamic region based on the result of evaluation of the task flow binding's `taskFlowId` attribute.

Figure 26-13 shows a runtime example from the Summit ADF task flow sample application where the `index.jsf` page renders a different registration task flow in the `showDetailItem` component labeled **Welcome** in response to the link component that the end user clicks. For example, if the end user clicks **Register as Employee**, the application renders the `emp-reg-task-flow-definition.xml` task flow in the ADF dynamic region. If the end user clicks **Register as Customer**, the application renders the `edit-customer-task-flow-definition.xml` task flow in the ADF dynamic region.

At runtime, the ADF dynamic region swaps the task flows that it renders during the Prepare Render lifecycle phase. To give components from a previous task flow the opportunity to participate smoothly in the lifecycle phases, do not navigate off the `regionModel` until the JSF Invoke Application lifecycle phase. It is good practice, therefore, not to navigate a task flow in a dynamic region in response to contextual events. For information about lifecycle phases, see Understanding the Fusion Page Lifecycle , and for information about contextual events, see Using Contextual Events.

Figure 26-13 ADF Dynamic Region in the Summit ADF Task Flow Sample Application



You create an ADF dynamic region by dragging and dropping a bounded task flow to the page where you want to render the ADF dynamic region. The view activities in the bounded task flow must be associated with page fragments (`.jsff`).

If you attempt to drag and drop a bounded task flow that is associated with pages rather than page fragments, JDeveloper does not display the context menu that allows you to create an ADF dynamic region. You can convert a bound task flow that uses pages to use page fragments. See How to Convert Bounded Task Flows .

After you create an ADF dynamic region, you can add additional bounded task flows to the dynamic region by creating ADF dynamic region links, as described in Adding Additional Task Flows to an ADF Dynamic Region.

How to Create an ADF Dynamic Region

Drag and drop bounded task flows to the page where you want to render the ADF dynamic region.

Before you begin:

It may be helpful to have an understanding of the configuration options available to you when creating an ADF dynamic region. For more information, see Creating ADF Dynamic Regions.

You may also find it helpful to understand other functionality that can be added using other task flow and ADF region features. For more information, see Additional Functionality for Task Flows that Render in ADF Regions.

To create an ADF dynamic region:

1. In the Applications window, double-click the JSF page where you want to create the ADF dynamic region.
2. From the Applications window, drag and drop the first bounded task flow onto the JSF page, and from the context menu, choose **Create** > **Dynamic Region**.
3. Choose the appropriate option in the Choose Managed Bean for Dynamic Region dialog:
   - If you want an existing managed bean to store the bounded task flow's ID, select an existing managed bean from the **Managed Bean** dropdown list.

     The managed bean passes the value of the bounded task flow's ID into the task flow binding of the ADF dynamic region. Make sure that the managed bean you select is not used by another ADF dynamic region.
   - If no managed bean exists for the page, click the **Add** icon next to the **Managed Bean** dropdown list to create a new one. Enter values in the dialog that appears as follows:
   - a. **Bean Name**: Enter a name for the new managed bean. For example, enter `DynamicRegionBean`.

     b. **Class Name**: Enter the name of the new managed bean class.

     c. **Package**: Enter the name of the package that is to contain the managed bean or browse to locate it.

     d. **Extends**: Enter the name of the Java class that the managed bean extends. The default value is `java.lang.Object`.

e. **Scope**: This field is read-only and its value is set to `backingBean`. For more information about the memory scope for managed beans, see What You May Need to Know About Memory Scope for Task Flows.

f. Click **OK** to close the dialogs where you configure the managed bean.

4. Choose the appropriate option in the Edit Task Flow Binding dialog:

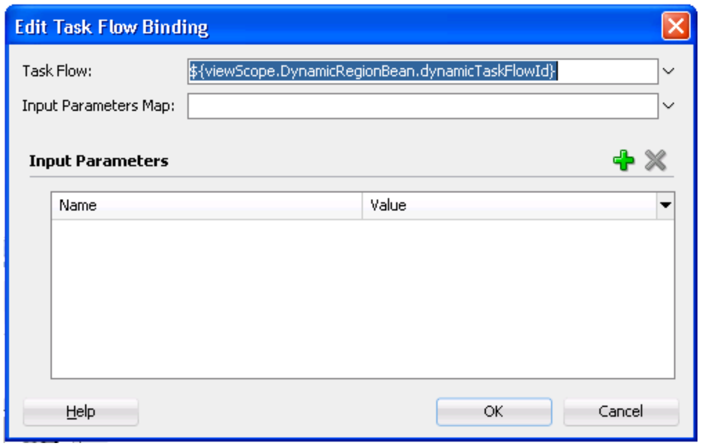
   - Click **OK** if you do not want specify input parameters or an input parameter map for the ADF dynamic region.
   - Specify input parameters for the ADF dynamic region.

     For more information, see Specifying Parameters for an ADF Region.

   Figure 26-14 shows the Edit Task Flow Binding dialog that appears after you configure a managed bean.

   > **Note:**
   >
   > You can write an EL expression that references a list of input parameters specified in a managed bean using the Input Parameters Map field of the Edit Task Flow Binding dialog. For more information about implementing this functionality, see Specifying Parameters for ADF Regions Using Parameter Maps.

Figure 26-14 Edit Task Flow Binding Dialog for an ADF Dynamic Region



Task Flow: ${viewScope.DynamicRegionBean.dynamicTaskFlowId}

Input Parameters Map:

5. Click **OK**.

What Happens When You Create an ADF Dynamic Region

When you drop a bounded task flow onto a JSF page to create an ADF dynamic region, JDeveloper adds an `af:region` tag to the page. The `af:region` tag contains a reference to a task flow binding. The following example shows the `af:region` tag that renders the ADF dynamic region in the `index.jsf` page of the Summit ADF task flow sample application.

```
<af:region value="#{bindings.dynamicRegion1.regionModel}" id="r4"
                                rendered="#{WelcomePageBean.isRegistration}"/>
```

JDeveloper also adds a task flow binding to the page definition file of the page that hosts the ADF dynamic region. The following example shows a sample of the metadata that JDeveloper adds. The task flow binding provides a bridge between the ADF dynamic region and the bounded task flow. It binds the ADF dynamic region to the bounded task flow and maintains all information specific to the bounded task flow.

```
<taskFlow id="dynamicRegion1"
       taskFlowId="${WelcomePageBean.dynamicTaskFlowId}"
       activation="deferred"
       xmlns="http://xmlns.oracle.com/adf/controller/binding"/>
```

The `taskFlowId` attribute in the task flow binding metadata specifies the managed bean that determines at runtime what bounded task flow to associate with the ADF dynamic region. JDeveloper creates this managed bean or modifies an existing managed bean to store this data. The following example shows extracts of the code that JDeveloper writes to the managed bean.

```
import oracle.adf.controller.TaskFlowId;
 ...
    private String taskFlowId = "/directoryPath/toTaskFlow";
 ...
    public TaskFlowId getDynamicTaskFlowId() {
        return TaskFlowId.parse(taskFlowId);
    }
...
```

At runtime, the managed bean stores the value of the bounded task flow's ID (`taskFlowId`) that displays inside the ADF dynamic region. The managed bean swaps the different bounded task flows into the task flow binding of the ADF dynamic region.

When an ADF dynamic region reinitializes, the Fusion web application must reinitialize the task flow binding associated with the ADF dynamic region. This includes evaluating if there are new input parameters and input parameter values to pass to the ADF dynamic region.

Adding Additional Task Flows to an ADF Dynamic Region

The ADF dynamic region helps you to display data from different task flows without navigating away from the current display area. This action is triggered by the end user by clicking a command component. This is possible as the ADF dynamic region has the ability to swap a bounded task flow with another bounded task flow.

An ADF dynamic region link swaps a bounded task flow for another bounded task flow within an ADF dynamic region. An end user clicks a command component (a button or a link) to update the ADF dynamic region with the new bounded task flow.

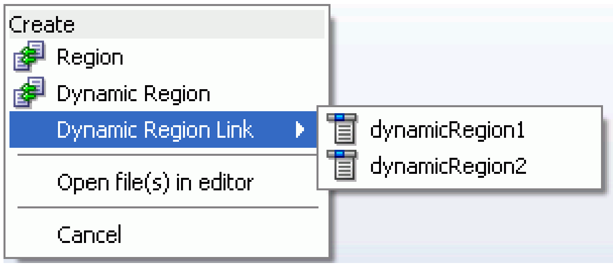
For example, a bounded task flow in the ADF dynamic region displays general information about an employee such as an ID and photo. When the end user clicks a link command component labeled **Details**, the ADF dynamic region updates with a table containing more information about the employee from another bounded task flow. The end user's action (clicking the link) invokes a method on the ADF dynamic region's managed bean. The value of the new bounded task flow is passed to the method, and the ADF dynamic region refreshes with the new bounded task flow. The new bounded task flow now displays within the ADF dynamic region.

By default, a ADF dynamic region link swaps another bounded task flow in for the original, but cannot swap back to the original. To toggle back to the original bounded task flow, you could add a second ADF dynamic region link on the page that, when clicked, swaps the current task flow back to the original one.

You can add an ADF dynamic region link if you already have at least one ADF dynamic region on a page and are adding a new bounded task flow as an ADF dynamic region to the same page. After you drop the bounded task flow on the page and choose to create an ADF dynamic region link, a menu displays all of the dynamic regions currently on the page, as shown in Figure 26-15.

A list of the current dynamic regions in a document appears when you choose **Dynamic Region Link** from the menu that appears after you drag and drop a bounded task that you want to add as an option to an existing dynamic region in the document, as shown in Figure 26-15.

Figure 26-15 ADF Dynamic Region Link Menu



Use this menu to select the ADF dynamic region within which you want to display the contents of the bounded task flow.

Tip:

You can use the values in the dynamic region link in other UI components. For example, you could create a selection list in which each of the items in the list links to a different bounded task flow. All of the linked bounded task flows would display in the same dynamic region. The links perform a method in the class behind the managed bean created to swap the bounded task flow it displays.

How to Create an ADF Dynamic Region Link

You drag and drop a bounded task flow to a page that already contains an ADF dynamic region and you select **Dynamic Region Link** on the context menu that appears to view a list of ADF dynamic regions to which you can create a link.

Before you begin:

It may be helpful to have an understanding of the configuration required before you attempt to create an ADF dynamic region link. For more information, see Adding Additional Task Flows to an ADF Dynamic Region.

You may also find it helpful to understand functionality that can be added using other task flow and ADF region features. For more information, see Additional Functionality for Task Flows that Render in ADF Regions.

You will need to complete this task:

> Add at least one ADF dynamic region to the JSF page where you are going to create an ADF dynamic region link. For information about adding an ADF dynamic region to a JSF page, see Creating ADF Dynamic Regions.

To create an ADF dynamic region link:

1. In the Applications window, double-click the JSF page where you want to create the ADF dynamic region link.
2. From the Applications window, drag and drop a bounded task flow onto the JSF page and, from the context menu, choose **Dynamic Region Link**.

   > **Note:**
   >
   > The view activities of the bounded task flow must be associated with page fragments. You can convert a bounded task flow that uses pages to use page fragments. For more information, see How to Convert Bounded Task Flows .

3. In the context menu that displays a list of the ADF dynamic regions that have already been added to the page, select the name of the ADF dynamic region in which you want to display the contents of the bounded task flow.
4. Click **OK**.

What Happens When You Create an ADF Dynamic Region

JDeveloper adds a link to the page, as shown in the following example. JDeveloper also updates the managed bean for the ADF dynamic region and updates the corresponding task flow binding with any new parameters.

```
<af:link text="region2" action="#{RegionBean.region2}"
  id="dynamicRegionLink1"/>
```

Configuring a Page To Render an Unknown Number of Regions

At times you may not know how many ADF regions might need to be rendered at runtime. This can be handled at design time by configuring the mutiTaskFlow element of the JSF page definition file.

You can configure a page at design time when you do not know the number of regions that render in the page at runtime. For example, you want to add or remove regions to tabs using the `panelTabbed` component. Each tab that you add or remove renders a region that references a bounded task flow.

To implement this functionality, you configure the JSF page definition file's `multiTaskFlow` element to reference a list of task flow bindings contained in a managed bean of the following type:

```
oracle.adf.controller.binding.TaskFlowBindingAttributes
```

The following example shows the code for the class of a managed bean named `MultiBean` that returns a list containing two task flows.

```
package view;

import java.util.ArrayList;
import java.util.List;

import oracle.adf.controller.TaskFlowId;
import oracle.adf.controller.binding.TaskFlowBindingAttributes;

public class MultiBean {
    private List<TaskFlowBindingAttributes> mTaskFlowBindingAttrs = new
                   ArrayList<TaskFlowBindingAttributes>(5);

    public MultiBean() {
        TaskFlowBindingAttributes tfAttr = new TaskFlowBindingAttributes();
        tfAttr.setId("region1");
        tfAttr.setTaskFlowId(new TaskFlowId("/WEB-INF/r1.xml", "r1"));
        mTaskFlowBindingAttrs.add(tfAttr);

        tfAttr = new TaskFlowBindingAttributes();
        tfAttr.setId("region2");
        tfAttr.setTaskFlowId(new TaskFlowId("/WEB-INF/r2.xml", "r2"));
        mTaskFlowBindingAttrs.add(tfAttr);

    }

    public List<TaskFlowBindingAttributes> getTaskFlowList() {
        return mTaskFlowBindingAttrs;
    }
}
```

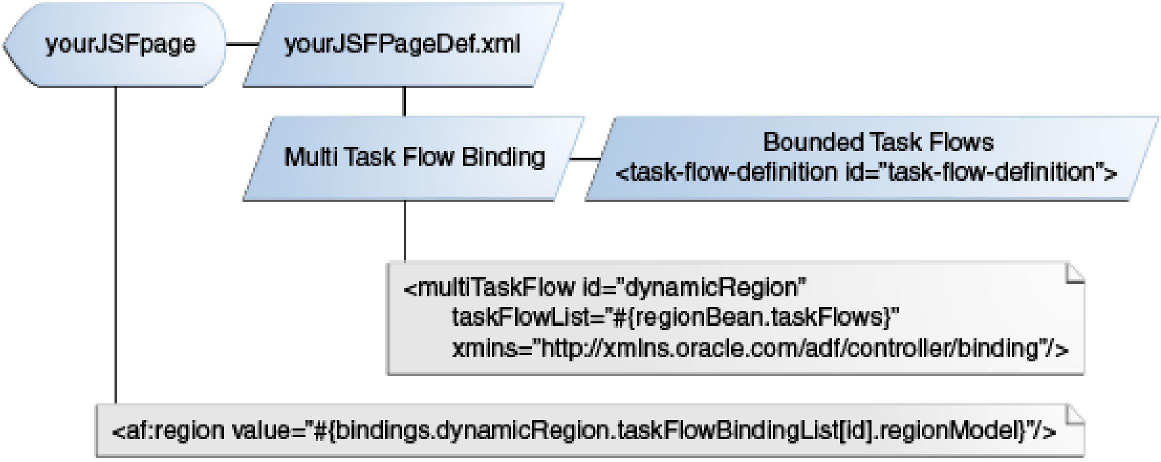
For more information about the `TaskFlowBindingAttributes` class, see the *Java API Reference for Oracle ADF Controller*.

At runtime, the `multiTaskFlow` binding references a list of one or more task flows that an end user can add or remove to the page using command components that you also expose. Figure 26-16 shows the relationships between the different parts that make up this use case.

Note:

The page fragments that the bounded task flows render must use the Facelets document type.

Figure 26-16 ADF Regions Derived from a Multi Task Flow Binding



yourJSFpage
yourJSFPageDef.xml
Multi Task Flow Binding
Bounded Task Flows
<task-flow-definition id="task-flow-definition">
<multiTaskFlow id="dynamicRegion"
taskFlowList="#{regionBean.taskFlows}"
xmlns="http://xmlns.oracle.com/adf/controller/binding"/>
<af:region value="#{bindings.dynamicRegion.taskFlowBindingList[id].regionModel}"/>

How to Configure a Page to Render an Unknown Number of Regions

Configure the JSF page definition file's `multiTaskFlow` element to reference a list of bounded task flows. This list can be modified at runtime by adding or removing elements of type `TaskFlowBindingAttributes`.

Before you begin:

It may be helpful to have an understanding of the configuration options available to you when configuring a page to render an unknown number of ADF regions. For more information, see Configuring a Page To Render an Unknown Number of Regions.

You may also find it helpful to understand other functionality that can be added using other task flow and ADF region features. For more information, see Task Flows and ADF Region Use Cases and Examples.

You will need to complete this task:

> Create a managed bean with a pageFlow scope that returns a list of type `TaskFlowBindingAttributes`. For more information about how to create a managed bean, see How to Use a Managed Bean to Store Information.

To configure a page to render an unknown number of regions:

1. In the Applications window, right-click the JSF page where you want to add or remove ADF regions at runtime and choose **Go to Page Definition**.
2. If a confirmation dialog appears, click **Yes**.
3. In the overview editor, click the **Binding and Executables** tab, and then click the **Add** icon in the Executables section.
4. In the Insert Item dialog, select **ADF Task Flow Bindings** from the dropdown menu, then select **multiTaskFlow** as the item to create and click **OK**.
5. In the Insert multiTaskFlow dialog, enter the following values:
   - **id***: Enter a unique ID for the multi task flow binding.

- **taskFlowList ***: Enter an EL expression that returns the list of `TaskFlowBindingAttributes` to return at runtime. For example, enter an EL expression similar to the following:

  `#{pageFlowScope.multiBean.taskFlowList}`

6. In the Applications window, double-click the JSF page where you want end users to add or remove ADF regions at runtime.
7. In the ADF Faces page of the Components window, from the Operations panel, drag and drop a **For Each** onto the component in the Structure window that you want to enclose the For Each component.
8. In the Properties window for the For Each component, enter values in the following fields:
   - **Items**: Enter an EL expression that references the method that return the list of task flow bindings from the multi task flow binding runtime object.

     For example, enter an EL expression similar to the following:

     `#{bindings.multiRegion1.taskFlowBindingList}`
   - **Var**: Enter a value to identify the list of task flow bindings.
9. In the JSF page that contains the For Each component, insert a Region component inside the For Each component that references the Region component's region model using an EL expression, as shown in the following example.

```
<af:forEach var="tf" items="#{bindings.multiRegion1.taskFlowBindingList}">
  <af:panelBox text="#{tf.name}" id="pb1">
    <f:facet name="toolbar"/>
    <af:region value="#{tf.regionModel}" id="r1"/>
  </af:panelBox>
</af:forEach>
```

What Happens When You Configure a Page to Render an Unknown Number of Regions

Metadata similar to that shown in the following example appears in the JSF page definition file for the multi task flow binding.

```
<multiTaskFlow id="multiRegion1"
    taskFlowList="${pageFlowScope.multiBean.taskFlowList}" activation="deferred"
    xmlns="http://xmlns.oracle.com/adf/controller/binding"/>
```

The `taskFlowList` attribute in the multi task flow binding metadata specifies the managed bean. The managed bean stores the list of objects describing the task flows that can be added to the page at runtime.

What You May Need to Know About Configuring a Page to Render an Unknown Number of Regions

- While there is no limit to the number of remote regions that you can render in a JSF page, use this capability with caution. For simple pages, where tabs are not used, regions may be combined in the page such that the maximum number of regions is determined by the design of the region and the view object queries it executes. Alternatively, for complex pages that use tabs, limit the use of regions to achieve best performance. For complex tabbed pages, ADF will not deactivate task flow transactions once a region is loaded. When switching tabs, the ongoing transaction must be stopped to achieve best performance. For details about the interaction between task flows and regions, see Configuring Transaction Management in an ADF Region.

- Each task flow binding inherits attributes defined for the multi task flow binding unless you override this behavior using the methods exposed by `TaskFlowBindingAttributes`.
- Each task flow binding inherits parameters defined in the multi task flow binding in addition to those defined using the `parametersMap` property, as described in Specifying Parameters for ADF Regions Using Parameter Maps.

Handling Access to Secured Task Flows by Unauthorized Users

When an ADF region is accessed by a user without access permission, a blank area is displayed. You can handle this by invoking a task flow that can display appropriate information or message to the user.

A bounded task flow does not render in an ADF region if it is invoked by a user who does not have the security permissions to access it. The region renders a blank area in place of the requested task flow when this occurs. This may confuse your users as it does not provide feedback as to why the task flow that they attempted to invoke does not appear. To improve the user experience, you can specify an alternative bounded task flow to render when a user attempts to access a bounded task for which they do not have the required security permissions. You can, for example, configure the alternative bounded task flow to display a page to inform users that they do not have the necessary security permissions. A more complex approach may be to render a bounded task flow that takes the users step-by-step through the process to request the necessary permissions from their system administrator.

Configure the level of security for the alternative bounded task flow to make sure that users can view it should they fail to access a bounded task flow for which they do not have security permissions. This may involve making the alternative bounded task flow public, as described in How to Make an ADF Resource Public. For more information about securing your Fusion web application, including bounded task flows, see Enabling ADF Security in a Fusion Web Application.

How to Handle Access to Secured Task Flows by Unauthorized Users

You configure an alternative bounded task flow with the content that you want to display to users when they cannot access a bounded task flow because of a lack of security permissions. You specify the alternative bounded task flow as the value for the Unauthorized Region Taskflow property in your Fusion web application's `adf-config.xml` file.

Before you begin:

It may be helpful to have an understanding of why you may need to display a message to users without security permissions for a task flow. For more information, see Handling Access to Secured Task Flows by Unauthorized Users.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Task Flows that Render in ADF Regions.

You will need to complete these tasks:

1. Create an alternative bounded task flow to display to users when they cannot access a bounded task flow for which they do not have security permissions.

   For more information about creating a bounded task flow, see Creating a Task Flow.

2. Configure this task flow so that users can access it.

   For more information, see How to Make an ADF Resource Public.

To display messages to users without security permissions for task flows:

1. In the Application Resources panel, expand the **Descriptors** and **ADF META-INF** nodes, and then double-click the **adf-config.xml** file.
2. In the overview editor, click the **Controller** navigation tab.
3. In the Controller page, in the Unauthorized Region Taskflow field, enter the name of the bounded task flow to invoke or click **Browse** to select it.

What Happens When You Handle Access to Secured Task Flows by Unauthorized Users

JDeveloper writes the name of the bounded task flow that you selected as a value for the `<unauthorized-region-taskflow>` element in the `adf-config.xml` file, as illustrated in the following example.

```
<?xml version="1.0" encoding="windows-1252" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
    xmlns:config="http://xmlns.oracle.com/bc4j/configuration"
     xmlns:adf="http://xmlns.oracle.com/adf/config/properties">
...
<adf-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
    <unauthorized-region-taskflow>/WEB-INF/task-flow-definition.xml
       </unauthorized-region-taskflow>
  </adf-controller-config>
...
</adf-config>
```

At runtime, the Fusion web application renders this alternative bounded task flow when users attempt to invoke a bounded task flow for which they do not have security permissions.

Creating Remote Regions in a Fusion Web Application

You can create an ADF remote region by invoking a task flow of a Fusion web application outside of your own application. The bounded task flow (producer) producing the remote region must have data-control-scope property set to isolated value. The task flow consuming the remote region is the consumer. A remote region can be consumed by more than one consumer task flows allowing you to reuse the remote region.

You create a remote region by invoking a task flow from another Fusion web application (the producer) in a page of your Fusion web application (the consumer). Creating a remote region allows you to reuse coarse-grained functionality in task flows that have their own data control frame rather than develop multiple task flows that implement the same functionality. It also offers performance, interactivity and ease-of-implementation advantages compared to implementing a JSF portlet in JSF pages that render ADF Faces components. At runtime, your consumer application invokes and renders a remote invocable task flow from the producer application. A remote invocable task flow may be consumed by multiple applications.

A task flow from a producer application that you configure to be invoked remotely must be a bounded task flow that renders page fragments. It must also have a value of `isolated` for the `data-control-scope` property and include the `remote-invocable` property. All of the transaction options that can be used when the `data-control-scope` property has a value of `isolated` can be configured for a task flow from a producer application that you configure to be invoked remotely. The producer and consumer applications do not share the transaction as the option chosen for the remote invocable task flow in the producer application determines the transaction behavior. For more information about the transaction options for task flows, see Managing Transactions in Task Flows.

> **Note:**
>
> The functionality described here, describing how to create a remote region to render a bounded task flow displaying JSF page fragments (`.jsff`) from another Fusion web application, differs to the functionality described in How to Call a Bounded Task Flow Using a URL. The latter section describes how you invoke a bounded task flow that renders JSF pages from another Fusion web application in a JSF page of your Fusion web application.

The producer and consumers application must run on the same version of Oracle ADF. That is, you cannot invoke a remote invocable task flow from a producer application that runs on one version of Oracle ADF and render it in a remote region of a consumer application that runs on a different version of Oracle ADF. If you attempt this type of implementation, the consumer application displays the following message to the user who attempts to launch the producer application:

```
Remote region error: Version of the richclient on the producer at "[producer
URL]" is incompatible with this consumer.
Consumer version: [Consumer Version] Producer version: [Producer Version]
```

The task flow from the producer application that you configure to be invoked remotely must not:

- Render ADF Faces components that use the Active Data Service

  For more information about the Active Data Service, see Using the Active Data Service .

- Invoke a remote invocable task flow from another application that produces remote invocable task flows. That is, you cannot configure a consumer application to invoke a remote invocable task flow from a producer application that invokes a remote invocable task flow from another producer application. A remote region cannot be nested inside another remote region.

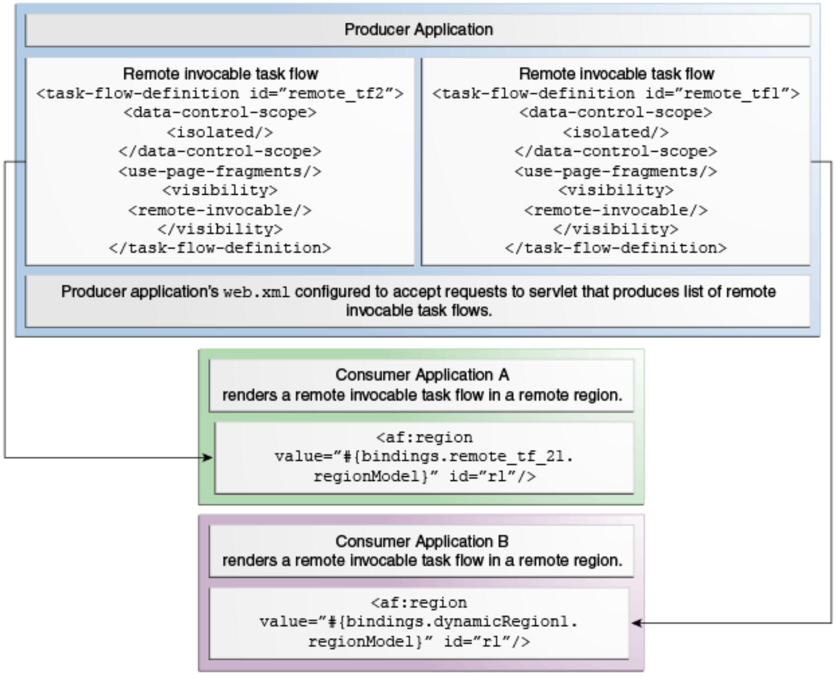
- Invoke external dialogs, as described in:
  - Running a Bounded Task Flow in a Modal Dialog. The bounded task flows that run inside these external modal dialogs must reference pages, not page fragments.
  - Using the ADF Faces Dialog Framework Instead of Bounded Task Flows.
- Use save points, as described in Using Save Points in Task Flows.
- Implement drag and drop functionality, as described in the "Adding Drag and Drop Functionality" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Be invoked through an iFrame. Only use Oracle ADF functionality to create a remote region.
- Assume its input parameters are pass-by-reference and visible to its caller. In a remote region implementation, a copy of all parameter values is sent to the producer of the remote invocable task flow (pass-by-value) because this producer typically resides in a different web application to the consumer application.

In addition, all of the following objects associated with the remote invocable task flow must be serializable:

- Input parameters and return parameter values defined for the task flow
- Exceptions that the task flow throws
- Any payload data that a contextual event passes

Figure 26-17 illustrates an example scenario where consumer applications render remote regions that invoke remote invocable task flows from a producer application.

Figure 26-17   Applications Rendering Remote Regions



Producer Application
Remote invocable task flow
Remote invocable task flow
Producer application's web.xml configured to accept requests to servlet that produces list of remote invocable task flows.
Consumer Application A
renders a remote invocable task flow in a remote region.
Consumer Application B
renders a remote invocable task flow in a remote region.

```
<task-flow-definition id="remote_tf2">
<data-control-scope>
<isolated/>
</data-control-scope>
<use-page-fragments/>
<visibility>
<remote-invocable/>
</visibility>
</task-flow-definition>
```

```
<task-flow-definition id="remote_tf1">
<data-control-scope>
<isolated/>
</data-control-scope>
<use-page-fragments/>
<visibility>
<remote-invocable/>
</visibility>
</task-flow-definition>
```

```
<af:region
value="#{bindings.remote_tf_21.
regionModel}" id="r1"/>
```

```
<af:region
value="#{bindings.dynamicRegion1.
regionModel}" id="r1"/>
```

Implementing the functionality described so far requires the completion of the following tasks:

- In the application that produces the task flows:
  - Configure the application's **Enable Remote Region producer support** property
  - Set the **Remote Invocable** property on the task flows that you want to render in a remote region
  - Configure the following properties for contextual events the application publishes that broadcast events to consumers in the consumer application:
    - Set **dispatchMode** to `remote`
    - Write an EL expression for **customPayload** that references a serializable object
    - Specify the type of the custom payload for the object

    Configuring these properties results in the following entries for the contextual event in the page definition where you publish the contextual event. For more information about contextual events, see Using Contextual Events.

    ```
    <event name="valueChangeEvent" dispatchMode="remote"
           customPayload="<EL to a serializable object>"
    customPayloadType=<type of the custom payload> />
    ```

    For more information about publishing the events to a remote consumer, see How to Publish Contextual Events.
  - Consider setting session timeout to a value greater than the session timeout of the consumer application so that you prevent the display of a session timeout warning from the producer application to the consumer application's end users. For more information about configuring session timeout, see Managing the HttpSession in Fusion Web Applications.
- In the application that consumes the task flows from the producer application:
  - Configure the application's **Enable Remote Region consumer support** property
  - Add the remote invocable task flows to the JSF pages where you want to render remote regions

> **Tip:**
>
> While there is no limit to the number of remote regions that you can render in a JSF page, use this capability with caution. For simple pages, where tabs are not used, regions may be combined in the page such that the maximum number of regions is determined by the design of the region and the view object queries it executes. Alternatively, for complex pages that use tabs, limit the use of regions to achieve best performance. For complex tabbed pages, ADF will not deactivate task flow transactions once a region is loaded. When switching tabs, the ongoing transaction must be stopped to achieve best performance. For details about the interaction between task flows and regions, see Configuring Transaction Management in an ADF Region.

The TaskFlowProducer project in the Summit standalone sample applications for Oracle ADF contains a remote invocable task flow that can be consumed by a consumer application. Run the `RemoteViewer.jsf` page in the TaskFlowProducer project to deploy the sample application that contains the remote invocable task flow. Once you deploy this sample application, you can consume the remote invocable task flow, as described in How to Configure an Application to Render Remote Regions.

For more information about the Summit standalone sample applications for Oracle ADF, see Running the Standalone Samples from the SummitADF_Examples Workspace.

How to Configure an Application to Produce Task Flows for Use in Remote Regions

You configure the project in the application that produces the task flows. You also configure each task flow in the project that you want to render in a remote region so that it can be invoked remotely and does not share data control frames with calling task flows.

Before you begin:

It may be helpful to have an understanding of the configuration required before you attempt to configure an application to produce task flows for use in remote regions. For more information, see Creating Remote Regions in a Fusion Web Application.

You may also find it helpful to understand functionality that can be added using other task flow and ADF region features. For more information, see Additional Functionality for Task Flows that Render in ADF Regions.

To configure an application to produce task flows for remote regions:

1. In the Applications window, right-click the project that you want to configure to produce remote invocable task flows and choose **Project Properties**.
2. Click the **ADF Task Flow** node and select the **Enable Remote Region producer support** checkbox.
3. Select **Allow Unauthenticated Remote Region Query servlet requests** if, at runtime, you want to permit users of the consumer application to query the servlet (`rtfquery`) in the producer application for the list of remote invocable task flows without providing user credentials. Also select this checkbox if you want to view the list of available remote invocable task flows from the producer application while developing the consumer application in JDeveloper (design time).

   Leave this checkbox clear to add a security constraint to the producer application's `web.xml` file that requires users who submit requests to `rtfquery` be authenticated. This is the default option. For more information, see What You May Need to Know About Securing Remote Regions.
4. In the Applications window, double-click the task flow that you want to be invoked remotely.
5. In the overview editor, click the **General** navigation tab and expand the **Visibility** section.
6. Select the **Remote Invocable** checkbox.
7. Click the **Behavior** navigation tab, expand the **Transaction** section, and select **Isolated** from the **Share data controls with calling task flow** dropdown list.

For more information about sharing data controls, see Sharing Data Controls Between Task Flows .

8. Repeat Steps 4 to 7 for each task flow that you want to be remote invocable so that it can render in a remote region.

What Happens When You Produce Task Flows for Use in Remote Regions

When you configure an application to produce remote invocable task flows, JDeveloper creates and/or modifies the following files:

- The application's `web.xml` file
- The application's policy store (the `jazn-data.xml` file)
- The source file of the task flow that you configure to be remote invocable

JDeveloper defines an ADF security policy in your producer application's `jazn-data.xml` file, as shown in the following example. JDeveloper creates this file if it does not exist in the producer application. This ADF security policy specifies a permission grant to grant access to a bootstrap page that acts as a container for the remote invocable task flow. You must define access policies for the individual remote invocable task flows that you want to appear in the bootstrap page by specifying permission grants. For more information, see How to Define Policies for ADF Bounded Task Flows. For more information about ADF Security, see Enabling ADF Security in a Fusion Web Application.

```
...
<jazn-policy>
  <grant>
    <grantee>
      <principals>
        <principal>
          <class>oracle.security.jps.internal.core.principals.JpsAnonymousRoleImpl</class>
          <name>anonymous-role</name>
        </principal>
      </principals>
    </grantee>
    <permissions>
      <permission>
        <class>oracle.adf.share.security.authorization.RegionPermission</class>
        <name>oracle.adfinternal.view.rich.bootstrap.remoteRegionBootstrapPageDef</name>
        <actions>view</actions>
      </permission>
    </permissions>
  </grant>
</jazn-policy>
...
```

JDeveloper also inserts the following properties in the source file of a task flow that you configure to be remote invocable when you set its `remote-invocable` property to `true` and the `data-control-scope` property to `isolated`, as shown in the following example. Setting the `data-control-scope` property to `isolated` means that the task flow will have its own data control frame at runtime. For more information about data controls and task flows, see Sharing Data Controls Between Task Flows .

```
...
<data-control-scope>
```

```
   <isolated/>
</data-control-scope>
...
<visibility>
   <remote-invocable/>
</visibility>
...
```

The entries that JDeveloper adds or configures in the application's `web.xml` file include:

- Filters (and associated filter mappings) named `remoteApplication`, `ServletADFFilter`, `ADFLibraryFilter` and `adfBindings`
- Servlets (and associated servlet mappings) named `Faces Servlet`, `adflibResources` and `rtfqueryServlet`

Example 26-2 shows these entries in a producer application configured to produce task flows for remote regions. In addition to the entries shown in Example 26-2, JDeveloper also generates a `<security-constraint>` and `<login-config>` element when you configure an application to produce remote invocable task flows. These elements are not shown in Example 26-2. For information about the values specified for these elements, see What You May Need to Know About Securing Remote Regions.

Note:

In the `web.xml` file, make sure that the `remoteApplication` filter appears:

- Immediately after the `JpsFilter` filter if this latter filter is configured.

  For more information about the `JpsFilter` filter, see What You May Need to Know About ADF Authentication.
- Before the `ADFLibraryFilter` filter, as shown in Example 26-2.

Example 26-2 Entries in the web.xml File of an Application Producing Remote Invocable Task Flows

```
<filter>
   <filter-name>remoteApplication</filter-name>
   <filter-class>oracle.adfinternal.view.rich.remote.RemoteApplicationFilter</filter-class>
</filter>
...
<filter>
   <filter-name>ADFLibraryFilter</filter-name>
   <filter-class>oracle.adf.library.webapp.LibraryFilter</filter-class>
</filter>
...
<filter-mapping>
   <filter-name>remoteApplication</filter-name>
   <url-pattern>/rr/*</url-pattern>
   <dispatcher>REQUEST</dispatcher>
</filter-mapping>
...
<filter-mapping>
   <filter-name>ADFLibraryFilter</filter-name>
   <url-pattern>/*</url-pattern>
   <dispatcher>FORWARD</dispatcher>
   <dispatcher>REQUEST</dispatcher>
</filter-mapping>
...
<servlet>
    <servlet-name>Faces Servlet</servlet-name>
    <servlet-class>javax.faces.webapp.FacesServlet</servlet-class>
    <load-on-startup>1</load-on-startup>
</servlet>
...
<!-- The remote region query servlet. -->

   <servlet-name>rtfqueryServlet</servlet-name>
   <servlet-class>oracle.adfinternal.controller.rtfquery.RemoteTaskFlowQueryServlet</servlet-
class>
   <load-on-startup>1</load-on-startup>
</servlet>
...
<!-- The servlet name here should be the same as the Faces Servlet. -->
<servlet-mapping>
   <servlet-name>Faces Servlet</servlet-name>
   <url-pattern>/rr/*</url-pattern>
</servlet-mapping>
...
<servlet-mapping>
  <servlet-name>rtfqueryServlet</servlet-name>
  <url-pattern>/rtfquery</url-pattern>
</servlet-mapping>
```

What You May Need to Know About Securing Remote Regions

By default, JDeveloper adds the `<security-constraint>` element shown in the following example when you configure an application to produce remote invocable task flows for remote regions. This security constraint restricts access to the remote region query servlet (`rtfquery`) to those users who have the role specified by the `<role-name>` element.

```
<security-constraint>
  <web-resource-collection>
     <web-resource-name>rtfquery</web-resource-name>
     <url-pattern>/rtfquery</url-pattern>
  </web-resource-collection>
  <auth-constraint>
     <role-name>valid-users</role-name>
  </auth-constraint>
</security-constraint>
```

You can remove this constraint from the `web.xml` file by selecting the **Allow Unauthenticated Remote Region Query servlet requests** checkbox when you configure an application to produce remote invocable task flows. For more information about how to access this checkbox, see How to Configure an Application to Produce Task Flows for Use in Remote Regions.

JDeveloper also generates the authentication mechanism shown in the following example when you configure an application to produce remote invocable task flows. This authentication mechanism determines if access to an ADF resource (for example, a task flow) that has been secured is permitted. The value `CLIENT-CERT` must appear here so that the producer application can authenticate clients that request access to a secured resource. The producer application ignores this setting if a client requests access to a non-secured resource.

```
<login-config>
  <auth-method>CLIENT-CERT,FORM</auth-method>
  <realm-name>Identity Assertion</realm-name>
</login-config>
```

In producer applications that define the security constraint (the default behavior), the value for the `<auth-method>` element in the associated authentication mechanism must at a minimum include `CLIENT-CERT`. If you make other changes that modify your `web.xml` file (for example, configuring ADF Security) after you configure an application to produce remote invocable task flows, you might overwrite the values required to make remote invocable task flows accessible to authenticated users. Verify the values specified for the security constraint and the authentication mechanism to make sure they are valid.

For more information about security, see Enabling ADF Security in a Fusion Web Application.

How to Configure an Application to Render Remote Regions

In the Fusion web application that you want to render remote regions, you configure a project so that it can consume remote invocable task flows from the producer application. You also create a connection to the producer application.

Once you have created this connection, you can drag a remote invocable task flow from wherever you defined the connection (Resources window or Application Resources panel) and drop it on the JSF page or page fragment where you want the remote region to render at runtime in your consumer application's page. The producer application of the remote invocable task flow that you want to invoke must be running in order for the remote invocable task flow to appear in the connection.

Before you begin:

It may be helpful to have an understanding of the configuration required before you attempt to configure an application to render remote regions. For more information, see Creating Remote Regions in a Fusion Web Application.

You may also find it helpful to understand functionality that can be added using other task flow and ADF region features. For more information, see Additional Functionality for Task Flows that Render in ADF Regions.

To configure an application to render a remote region:

1. In the Applications window, right-click the project that you want to configure to render a remote region and choose **Project Properties**.
2. Click the **ADF Task Flow** node and select the **Enable Remote Region consumer support** checkbox.
3. In the Resources window, click **New**, select **New Connection** and then **Remote Region Producer**.
4. In the Create Remote Region Connection dialog, select **Application Resources** if you want the connection to be available only within the application. Select **Resources window** if you want the connection to be available to other applications using the Resources window.

5. In the **Name** field, enter a name that the application will use to identify the connection to the producer application of the remote invocable task flows.
6. In the **URL Endpoint** field of the **Query URL** section, enter the URL endpoint for the Fusion web application that produces the remote invocable task flows. Typically, this URL has a format similar to the following:

   ```
   http://<host>:port/<context root>/rtfquery
   ```

   where `rtfquery` is the servlet that provides the list of remote invocable task flows in the producer application.
7. Click **Test Connection** to verify that the URL endpoint is valid.
8. In the **URL Endpoint** field of the **Invoke URL** section, enter the URL endpoint of the Fusion web application that produces the remote invocable task flows. Typically, this URL has a format similar to the following:

   ```
   http://<host>:port/<context root>/rr
   ```

   where `rr` is the `url-pattern` specified for the `remoteApplication` filter in the `web.xml` file of the Fusion web application that produces the remote invocable task flows.
9. If you know that the producer application requires user credentials before it will allow the consumer application access a remote invocable task flow, select the **Always Send User Identity** checkbox. This generates an identity token that the consumer application transmits to the producer application during the initial connection.

   Leave the **Always Send User Identity** checkbox clear if you do not know if the producer application requires user credentials. For more information, see What Happens at Runtime: How an Application Renders Remote Regions.
10. Click **Test Connection** to verify that the URL endpoint is valid and click **OK**.
11. Expand the **Remote Region Producer** node and drag the remote invocable task flow that you want your Fusion web application to invoke and drop it on the JSF page or page fragment where you want it to render in a remote region at runtime.
12. In the context menu that appears, select the type of region that you want to create in the page (**Region** or **Dynamic Region**).

    If you select **Dynamic Region**, you need to choose or create a managed bean that determines at runtime what bounded task flow to render in the ADF dynamic region. For more information, see Creating ADF Dynamic Regions.
13. In the Edit Task Flow Binding dialog, from the **Remote Connection** dropdown list, select the connection to the Fusion web application that produces the remote invocable task flow that you defined in Step 5.

    Typically, this is selected by default.
14. Click **OK**.

What Happens When You Configure an Application to Render Remote Regions

JDeveloper adds a context parameter to the application's `web.xml` file when you enable remote region consumer support in the project that consumes remote invocable task flows, as shown in the following example.

```
<context-param>
  <param-name>oracle.adf.view.rich.remote.AUTH_PROVIDER</param-name>
  <param-value>oracle.adf.view.rich.remote.security.ADFAuthorizationProvider</param-value>
</context-param>
```

This context parameter specifies the default authorization provider that is configured to work with ADF Security. You can add an alternative authorization provider by creating an object that implements the following interface:

`oracle.adf.view.rich.remote.AuthorizationProvider`

When you drag and drop a remote invocable task flow to the JSF page or page fragment in your application, JDeveloper adds an `af:region` tag to the JSF page and a task flow binding to the page definition file of the JSF page. These additions are similar to those generated when you drag and drop a task flow from the Applications window to a JSF page in the same application. One difference is that when you drag and drop a remote invocable task flow to a JSF page, the task flow binding that is added to the page definition file of the JSF page includes a `remoteConnectionName` attribute that references the connection name of the producer application, as shown in Example 26-3.

The task flow binding's `remoteConnectionName` attribute can also reference an EL expression that returns the name of the connection to the producer application at runtime. This is useful, for example, if the name of the producer application changes and you want to refresh the ADF region in response to this event. For more information, see Configuring an ADF Region to Refresh.

For more information about the entries that JDeveloper generates when you create an ADF region or an ADF dynamic region, see What Happens When You Create an ADF Region , and What Happens When You Create an ADF Dynamic Region.

Example 26-3   Metadata Added to Page Definition to Create a Task Flow Binding

```
<taskFlow id="dynamicRegion2"
      taskFlowId="${viewScope.ParentActionRegion.dynamicTaskFlowId}"
      activation="deferred" remoteConnectionName="RemoteAppProducingTFs"
      xmlns="http://xmlns.oracle.com/adf/controller/binding"/>
```

What Happens at Runtime: How an Application Renders Remote Regions

The initial runtime behavior of the applications that you have configured to produce remote invocable task flows and render remote regions depends on the security-related options configured for the producer application:

- It requires user credentials from the consumer application before it permits access to the `rtfquery` servlet to retrieve the list of task flows that can be invoked remotely.

  In this scenario, the producer application responds to the initial request with an error code. In response, the consumer application generates an encrypted identity token that it transmits to the producer application. The producer application uses this identity token to authenticate the consumer application and, if successful, serves the consumer application's request.

  If you know in advance that the producer application requires user credentials, you can make the consumer application submit the encrypted identity token with the initial connection by selecting the **Always Send User Identity** checkbox, as described in How to Configure an Application to Render Remote Regions. This optimizes the connection process.

- It allows unauthenticated requests to the `rtfquery` servlet.

  The consumer application retrieves the list of remote invocable task flows from the `rtfquery` servlet that the producer application configures to be invoked remotely.

After accessing the remote invocable task flow from the producer application, the consumer application renders the content from the task flow in an ADF region (the remote region) that is configured for this purpose. The appearance of this content is defined by the style properties in the ADF skin of the consumer application. The style properties in this ADF skin must match the style properties defined in the producer application's ADF skin. For more information, see What You May Need to Know About ADF Skins and Remote Regions.

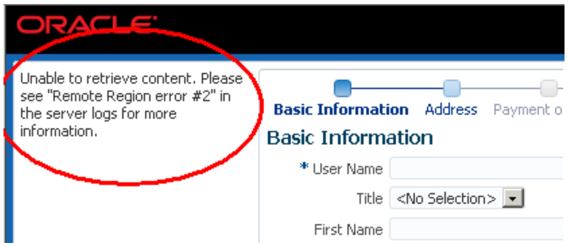
If the consumer application invalidates the session that it established with the producer application, the producer application rolls back any transaction that is in progress at the time that the consumer application invalidates the session. Examples of events that can cause the consumer application to invalidate a session include:

- Reaching the time specified for session timeout in the consumer application
- An end user logging out of the consumer application
- An end user clicking the browser's back button
- Navigation to a different page that does not render the remote region

How to Add Custom Error Messages for Remote Regions

A variety of error messages appear in the consumer application if an error occurs in a remote region implementation. For example, you may see a message similar to that shown in Figure 26-18.

Figure 26-18 Error Message for Remote Region



Unable to retrieve content. Please see "Remote Region error #2" in the server logs for more information.

The following examples show log messages that correspond to the message that appears in Figure 26-18.

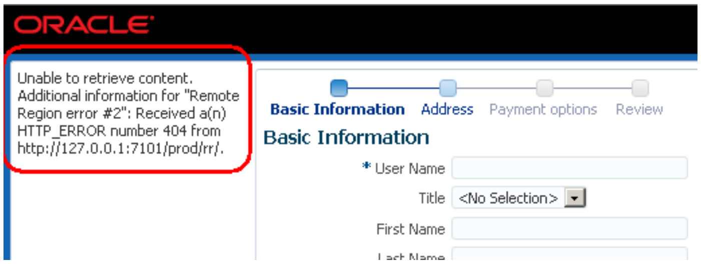
```
...
<oracle.adf.view> <RegionRenderer> <_logError> <RR_HTTP_ERROR>
...
...
<oracle.adf.view> <RegionRenderer> <_logError> <Jan 29, 2014 12:50:51 PM
oracle.adfinternal.view.faces.renderkit.rich.RegionRenderer _logError
ALL: Remote Region error #2: An uncaught exception was thrown on the producer at "http://
127.0.0.1:7101/prod/rr/" while trying to run an ADF Taskflow.
>
```

```
oracle.adf.controller.ControllerException: ADFC-14032: A required remote task flow input
parameter value was not specified. Requested remote taskFlowId
 '/WEB-INF/task-flow-definition.xml#task-flow-definition'; requested from
'localhost.localdomain'.
    at
oracle.adf.controller.internal.binding.TaskFlowRegionModelRemoteProducer.createRegionViewPortCont
ext(TaskFlowRegionModelRemoteProducer.java:173)
    at
oracle.adf.controller.internal.binding.TaskFlowRegionModelViewPort.getViewPort(TaskFlowRegionMode
lViewPort.java:649)
...
```

In many scenarios, the message in Figure 26-18 and log file entries may be sufficient to diagnose and resolve an issue with a remote region implementation. In other scenarios, you may want to present additional information to communicate to end users. Figure 26-19 shows a revised version of the consumer application page in Figure 26-18 that now displays additional information, such as the error type and the location of the producer application. Configuring your consumer application to show additional information, as in Figure 26-19, requires you to add a context parameter to the `web.xml` file of your consumer application and to write a Java class in the same application that extends `RemoteRegionErrorListener` from the following package:

```
oracle.adf.view.rich.model
```

Figure 26-19 Custom Error Message for Remote Region



Unable to retrieve content.
Additional information for "Remote Region error #2": Received a(n) HTTP_ERROR number 404 from http://127.0.0.1:7101/prod/rr/.

To add a custom error message for a remote region:

1. In the user interface project of the consumer application, create a Java class that extends the `oracle.adf.view.rich.model.RemoteRegionErrorListener` class.

   The following example shows a Java class that listens for errors on a remote region and returns a string with details of the error message.

```
package example;

import oracle.adf.view.rich.model.RemoteRegionErrorEvent;
import oracle.adf.view.rich.model.RemoteRegionErrorListener;
import oracle.adf.view.rich.model.RemoteRegionHttpErrorEvent;

public class MyRemoteRegionErrorListener extends RemoteRegionErrorListener {

    @Override
    public String getAdditionalUserInformation(RemoteRegionErrorEvent event)
{

        RemoteRegionErrorEvent.Type type = event.getErrorType();
        StringBuilder sb =
            new StringBuilder().append("Received a(n) ").append(type);
        if (RemoteRegionErrorEvent.Type.HTTP_ERROR.equals(type)) {
            sb.append(" number
").append(((RemoteRegionHttpErrorEvent)event).getHttpErrorCode());
        }

        sb.append(" from ").append(event.getProducerURL());

        String viewId = event.getViewID();
        if (null != viewId) {
            sb.append(" for viewId ").append(viewId);
        }

        return sb.toString();
    }
}
```

2. In the Applications window, in the user interface project, expand the **Web Content** and **WEB-INF** nodes, and then double-click **web.xml**.
3. In the overview editor for the `web.xml` file, click the **Application** navigation tab and in the Context Initialization Parameters section, click the **Create** icon to add a parameter that references the Java class you created in Step 1 as follows:

   Name: Enter the context parameter `oracle.adf.view.rich.REMOTE_REGION_ERROR_LISTENER`.

   Value: Enter the path to the Java class that you created in Step 1. For example, to reference the class in Step 1, enter `example.MyRemoteRegionErrorListener`.

What You May Need to Know About ADF Skins and Remote Regions

The style properties in the ADF skins of the consumer and producer applications must match in order for the remote region to render. If the ADF skins do not match, the remote region does not render its content. If the ADF skins match, the remote region renders and uses the consumer application's ADF skin to determine the look and feel.

If mismatches occur between the ADF skins for the consumer and producer applications, you need to modify one or both ADF skins so no mismatches occurs. Where mismatches occur the consumer application's client displays a message similar to the following:

```
Unable to retrieve content. Please see "Remote Region Error #1" in the
server logs for more information.
```

The server logs refers to messages that appear in the log files of the application server for the consumer application. These log messages may provide information that you can use to identify mismatches between ADF skins or to diagnose issues with the ADF skin. The following list describes issues that result in the consumer application generating log messages:

- `ADF_FACES-30209` identifies a mismatch between the ADF skins. It means that while the producer application can find the skin that the consumer application uses, the ADF skins are not the same. A message similar to the following appears:

  ```
  Remote Region Error #1: Producer at "http://myproducer.com/rr" does
  not have a skin that matches this consumer. Consumer skin information:
  {...} Producer skin information: {...}.
  ```

The ADF skin information provided contains a checksum of the ADF skins and lists all of the skinning extensions (including checksum) and features employed by each ADF skin. The consumer and producer applications should have the same ADF skins and extensions. Using this data may help identify if there are differences between the two applications.

- `ADF_FACES-30210` indicates that the producer application does not contain the ADF skin that the consumer application uses. A message similar to the following appears:

  ```
  Remote Region Error #1: Producer at "http://myproducer.com/rr" does
  not have the following skin: "simple"
  ```

- Producer application does not have a skin factory. This means that the producer application is not configured properly and cannot find an instance object that extends `SkinFactory` from the following package:

  ```
  org.apache.myfaces.trinidad.skin
  ```

  A message similar to the following appears:

  ```
  Remote Region Error #1: No skin factory available on the producer at
  "http://yourproducer.com/rr"
  ```

The consumer application logs the skin debug information using a `VERBOSE` setting.

> **Note:**
>
> The context parameter `oracle.adf.view.rich.remote.PRODUCER_STYLESHEET_DEBUG_LEVEL` that determines the level of log output is deprecated in release 12.2.1.4.0.

For a general overview of ADF skins, see the "Customizing the Appearance Using Styles and Skins" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

27

Creating Complex Task Flows

This chapter describes how to use advanced features of ADF task flows that you create in Fusion web applications. These include the ability to define transaction options for a task flow, configure reentry options to a task flow for a user that previously exited, handle exceptions, configure save points for your task flow, use ADF Faces components such as `train`, and create task flows from task flow templates.

This chapter includes the following sections:

About Creating Complex Task Flows

ADF task flows allow you to add features such as handling exceptions, reentry to the bounded task flow, using save points, and so on. Such task flows can be used to perform advance and complex activities.

After creating a task flow, adding activities to it, and configuring control flow between the activities, you can extend the task flow´s functionality by adding some of the features described in the following list:

- Bounded task flows can be configured to include additional transactional management facilities beyond those provided by the underlying data controls so that a Fusion web application can commit or roll back the data controls associated with the task flow's activities as a group.
- Reentry options can be configured for bounded task flows to determine the response if a user clicks the browser's back button.
- Task flows contain a number of features that allow you to proactively handle exceptions. In addition, you can write custom code to handle exceptions thrown by a task flow.
- Task flows can also be configured to capture the state of a Fusion web application at a particular instance using save points. These allow you to save

the application's state if, for example, a user leaves a page without finalizing a task.

- Train components are ADF Faces components that render navigation items to guide a user through a multistep process. You can configure a bounded task flow to render these navigation items by default for the view activities in a task flow.
- Task flow templates can serve as a starting point for the creation of task flows that share common elements.
- Create a page hierarchy from the view activities that the default unbounded task flow in your application (and additional task flows in the application) reference.
- Invoke initializers and finalizers when a bounded task flow is entered and exited. An **initializer** is custom code that is invoked when a bounded task flow is entered. A **finalizer** is custom code that is invoked when a bounded task flow is exited via a task flow return activity or because an exception occurred. The finalizer is a method on a managed bean. Common finalizer tasks include releasing all resources acquired by the bounded task flow and performing cleanup before exiting the task flow.

  You specify both the initializer and the finalizer as an EL expression for a method on a managed bean, for example:

  ```
  #{pageFlowScope.modelBean.releaseResources}
  ```

  There are two techniques for running initializer code at the beginning of the bounded task flow, depending on whether or not the task flow may be reentered via a browser back button:

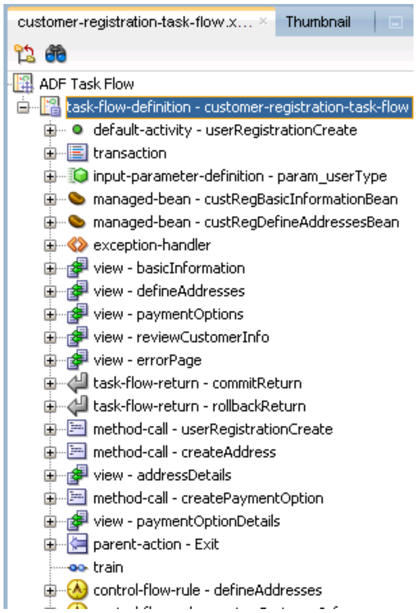
  – No reentry via back button expected: Designate a method call activity as the default activity (first to execute) in the bounded task flow. The method call activity calls a custom method containing the initializer code. See Using Method Call Activities and What You May Need to Know About the Browser Back Button and Navigating Through Records.

  – Back button reentry possible: Specify an initializer method using an option on the bounded task flow metadata. See Creating a Task Flow. Use this technique if you expect that a user may reenter the task flow using a browser back button. In such a case, the designated default activity for the bounded task flow may never be called, but a method designated using the Initializer method will.

Complex Task Flows Use Cases and Examples

Figure 27-1 shows the Structure window for a task flow that implements many of the use cases discussed in About Creating Complex Task Flows. For example, it specifies an error page to handle errors, makes use of the ADF Faces `train` component to render navigation items, and specifies two task flow return activities that either commit or roll back changes that the task flow makes as part of transaction management.

Figure 27-1 Task Flow in the Structure Window



```

    exception-handler
    view - basicInformation
    view - defineAddresses
    view - paymentOptions
    view - reviewCustomerInfo
    view - errorPage
    task-flow-return - commitReturn
    task-flow-return - rollbackReturn
    method-call - userRegistrationCreate
    method-call - createAddress
    view - addressDetails
    method-call - createPaymentOption
    view - paymentOptionDetails
    parent-action - Exit
    train
    control-flow-rule - defineAddresses
```

Additional Functionality for Complex Task Flows

You may find it helpful to understand other **Oracle ADF** features before you configure or use task flows. Additionally, you may want to read about what you can do with your task flows. Following are links to other functionality that may be of interest.

- You can specify exception handlers to manage errors that occur during execution of task flows. For more information about error handling, see Customizing Error Handling.
- Task flow save points can save application state. For more information about **application state management**, see Using State Management in a Fusion Web Application.
- Bounded task flows can be secured by defining the privileges that are required for someone to use them. For more information, see Enabling ADF Security in a Fusion Web Application.
- You can use Business Process Execution Language (BPEL) with task flows to:
  - Invoke a BPEL process from an unbounded or bounded task flow to perform a function or use services
  - Call a bounded task flow from a BPEL process in order to model user interactions with a web interface

  You can use a task flow method call activity to invoke a managed bean method or a web service that interacts with a BPEL process. For more information about the task flow method call activity, see Using Method Call Activities.
- You can write custom code that extends your task flows. For example, you can write custom code to invoke when a task flow throws an exception, as described in How to Designate Custom Code as an Exception Handler. For information about the APIs that you can use to write custom code, see the following reference documents:

- – *Java API Reference for Oracle ADF Controller*
- – *Java API Reference for Oracle ADF Faces*

Sharing Data Controls Between Task Flows

ADF task flows allow you to share data controls between one or more task flows. Either an instance of the data control or two separate, isolated, data controls can be shared. This can be used for making transaction management options when committing or rolling back. To share the data controls you must set a data-control-scope value to shared or isolated on the called bounded task flow.

When one task flow calls another, the task flows can either share an instance of a data control, or create two separate isolated instances of the same data control so the task flows can maintain independent state. The internal object that task flows use to share their data controls or to store their own isolated data control is known as a **data control frame**.

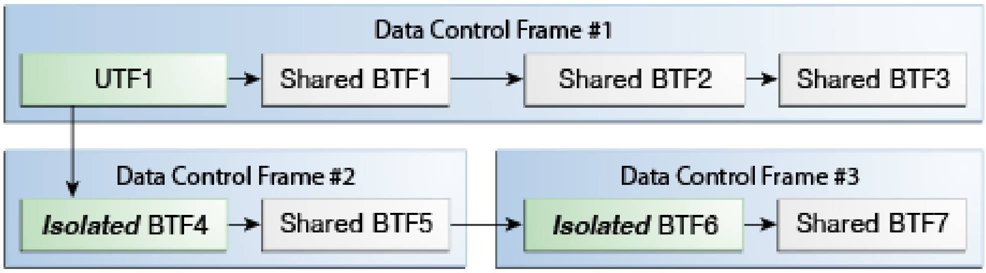
Task flows making use of the task flow transaction management options when committing or rolling back use the data control frame to know which data controls to perform the transaction operations on. A data control frame is created at runtime for your application's unbounded task flow and any bounded task flow with a `data-control-scope` value of `isolated`. When a task flow specifies a `data-control-scope` value of `shared`, the called task flow uses the data control frame of the calling task flow rather than creating its own. This allows the called task flow to share data control instances attached to the data control frame. Alternatively, if a called task flow specifies a `data-control-scope` value of `isolated`, a new data control frame is created and a new instance of any data controls used by the bounded task flow will be attached to the newly-created data control frame.

To specify whether data controls are shared between the calling and called task flows, you must set a `data-control-scope` value of either `shared` or `isolated` on the called bounded task flow. The default value is `shared`.

If `data-control-scope` is set to `shared` on both the calling and called bounded task flow, the data control frame used will be the one for the calling task flow.

In Figure 27-2, the bounded task flows BTF1, BTF2, and BTF3 use the data control frame created for the application's unbounded task flow (UTF1) because these bounded task flows all have a `data-control-scope` value of `shared`. In contrast, the bounded task flow BTF4 uses a different data control frame because it has a `data-control-scope` value of `isolated`. It shares this data control frame with the bounded task flow that it calls (BTF5) because this latter bounded task flow has a `data-control-scope` value of `shared`.

Figure 27-2 Sharing and Isolating Data Control Frames



The value that you set for the `data-control-scope` element of a called task flow determines if a calling task flow and a called task flow share flow data controls. Other factors, such as whether a task flow renders in a page or page fragment, do not change this behavior.

How to Share a Data Control Between Task Flows

You share data controls between task flows by specifying a value for the `data-control-scope` element of the called task flow.

Before you begin:

It may be helpful to have an understanding of the properties that determine how you share data controls between task flows. For more information, see Sharing Data Controls Between Task Flows .

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To share a data control between task flows:

1. In the Applications window, double-click the called task flow.
2. In the Properties window expand the **Behavior** section and select **Shared** from the **Share data controls with calling task flow** list.

> **Note:**
>
> After you select **Shared** from the **Share data controls with calling task flow** list, you may need to configure transaction options for the task flow. For more information, see What You May Need to Know About Sharing Data Controls and Managing Transactions.

What Happens When You Share a Data Control Between Task Flows

JDeveloper writes an entry in the source file for the called task flow when you select **Shared** from the **Share data controls with calling task flow** list, as illustrated in the following example.

```
<task-flow-definition id="task-flow-definition">
    ...
    <data-control-scope id="__1">
      <shared/>
    </data-control-scope>
    ...
  </task-flow-definition>
```

What Happens at Runtime: How Task Flows Share Data Controls

An end user can open the same application more than once in different browser windows or browser tabs. If an end user does this, each window or tab has its own view port, and each window or tab is isolated from all other windows or tabs within the same HTTP session. As a result, the windows or tabs do not share data controls and, therefore, state. The windows or tabs start with a new data control frame as if they were running with an isolated data control scope. The exception to this rule is if an end user opens a modal dialog in a secondary browser window, then the primary and secondary browser windows have the same server-side state and share data controls. For more information about using modal dialogs, see Running a Bounded Task Flow in a Modal Dialog. For more information about view ports, see About View Ports and ADF Regions.

Data controls are not instantiated until needed. One of two things can occur when a parent task flow calls a child task flow that specifies `data-control-scope` as `shared` (the default) and references a data control named D:

1. If a data control named D already exists in the parent task flow's data control frame, then the child task flow's reference to D resolves to the existing data control named D that is in scope.
2. If a data control named D does not exist in the parent task flow's data control frame, then Oracle ADF instantiates the first data control named D that it finds when performing a top-down search through the `DataBindings.cpx` files.

The above rules are unlikely to be applied because most applications define data controls with unique names. However, if a task flow from an application calls a task flow in an ADF Library JAR, the application and the ADF Library JAR task flows may reference data controls that use the same names.

If, when the parent task flow calls the child task flow, the data control D from the parent task flow's ADF Library JAR is already instantiated, then the child task flow uses it. If it is not already instantiated, then the data control D from the parent task flow will be instantiated using the first reference for this data control name found during a top-down search through the `DataBindings.cpx` files. In particular, in this task flow calling scenario, the child task flow's data control D will not be instantiated.

Another scenario to consider is where a task flow in a JSF page calls a task flow that renders in a region in the JSF page. If the calling task flow in the JSF page instantiates a data control D before the region renders in the page, the calling task flow's data control D is used. However, if the region is the first databound component in the JSF page, the called task flow's data control D will be instantiated and used.

For more information about data controls, see Exposing Application Modules with ADF Data Controls. For more information about the `DataBindings.cpx` file, see Working with the DataBindings.cpx File .

Managing Transactions in Task Flows

The transactions on the ADF bounded task flows can be managed by configuring the transaction type. If No Controller Transaction is chosen, then no transaction such as begin, commit, or roll back is performed. If one of these options: Always Begin New Transaction, Always Use Existing Transaction, or Use Existing Transaction if Possible is chosen then the transaction will either create a new transaction, participate in the exiting transaction, or if a transaction is in progress, then the task flow participates in this existing transaction or the task flow will create a new transaction when the bounded task flow is initiated.

In the context of systems relating to databases, a **transaction** is a persisted collection of work items that can be committed or rolled back together as a group. ADF, through technologies such as **ADF Business Components**, offers all the advantages that transactions provide. However, support for transactions does not stop at the ADF

Model layer. In the ADF Controller layer, bounded task flows optionally provide their own abstract implementation of transactions over the underlying ADF Model layer. This implementation allows you to control transactions from the task flow and also declaratively manage the transaction boundaries.

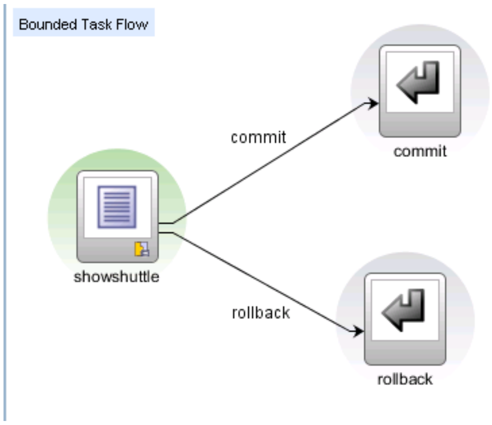
The transaction options that you can configure on a called bounded task flow can be grouped into two categories:

- You choose the **No Controller Transaction** option so the called bounded task flow does not perform a transaction operation (begin, commit, or roll back a transaction).
- You use one of the following ADF task flow transaction management options:
  - **Always Begin New Transaction**: A new transaction starts when the bounded task flow is entered, regardless of whether or not a transaction is in progress. The new transaction completes when the bounded task flow exits.
  - **Always Use Existing Transaction**: When called, the bounded task flow participates in an existing transaction already in progress.
  - **Use Existing Transaction If Possible**: When called, the bounded task flow either participates in an existing transaction if one exists, or starts a new transaction upon entry of the bounded task flow if one does not exist.

If a called bounded task flow starts a new ADF task flow transaction (based on the `transaction` option that you selected), you can specify whether the transaction commits or rolls back when the task flow returns to its caller. The commit and rollback options are set on the task flow return activity that returns control back to the calling task flow. The same task flow that starts a transaction must also resolve the transaction.

In a called bounded task flow, you can specify two different return task flow activities that result in either committing or rolling back a transaction in the called bounded task flow. Each of the task flow return activities pass control back to the same calling task flow. The difference is that one task flow return activity specifies the commit option, while the other specifies the rollback option. Figure 27-3 shows the `orders-select-many-items.xml` task flow from the Summit ADF task flow sample application. If transaction processing successfully completes, control flow passes to the commit task flow return activity, which specifies options to commit the transaction. If the transaction is cancelled before completion, the rollback task flow activity specifies options to roll back the transaction.

Figure 27-3 Task Flow Return Activities in Called Bounded Task Flow



Use the `restore-save-point` option on the task flow return activity if you want to discard the changes an end user makes within a called bounded task flow when the called bounded task flow exits. ADF Controller rolls back to the previous ADF Model save point that was created when the bounded task flow was entered. The `restore-save-point` option applies only to cases when a bounded task flow is entered by joining an existing transaction (either the `requires-existing-transaction` or `requires-transaction` option is also specified) and a save point is created upon entry.

If you use the ADF task flow transaction management features that commit and rollback the data controls associated with the data control frame of the current task flow, you must use task flow return activities with their End Transaction property set to `commit` or `rollback`, or programmatically commit the associated data control frame. Alternatively if you use the No Controller Transaction setting or you only want to commit or rollback one data control, use the associated commit or rollback operations from the Data Controls panel or programmatically execute the associated commit and rollback bindings.

In the Summit sample application for ADF task flows, a number of task flows create transactions. For example, the `orders-select-many-items.xml` task flow uses the ADF task flow transaction management's **Use Existing Transaction if Possible** option. This task flow allows an end user to add multiple items to an order and commit or rollback this change when the end user interacts with the `showshuttle.jsf` page shown in Figure 27-4.

How to Enable Transactions in a Bounded Task Flow

You define the transaction options on a bounded task flow that is called by another task flow. Add a task flow return activity on the called bounded task flow that returns control to the task flow that calls the bounded task flow.

Before you begin:

It may be helpful to have an understanding of what a transaction is and how you can configure it. For more information, see Managing Transactions in Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To enable a bounded task flow to run as a transaction:

1. In the Applications window, double-click the called bounded task flow.
2. In the editor window, click the **Overview** tab
3. In the overview editor, click the **Behavior** navigation tab.
4. In the Behavior page, expand the **Transaction** section and choose one of the following from the dropdown list:
   - **No Controller Transaction**: The called bounded task flow does not perform a transaction operation (begin, commit, or roll back a transaction).
   - **Always Use Existing Transaction**: When called, the bounded task flow participates in an existing transaction already in progress.
   - **Use Existing Transaction If Possible**: When called, the bounded task flow either participates in an existing transaction if one exists, or starts a new transaction upon entry of the bounded task flow if one does not exist.
   - **Always Begin New Transaction**: A new transaction starts when the bounded task flow is entered, regardless of whether or not a transaction is in progress. The new transaction completes when the bounded task flow exits.

   > **Note:**
   >
   > After choosing a transaction option, you may also need to configure the **Share data controls with calling task flow** option (`data-control-scope`) for the bounded task flow to determine whether there are any interactions between the options. For more information, see What You May Need to Know About Sharing Data Controls and Managing Transactions.

5. Optionally, select **Isolated** from the **Share data controls with calling task flow** checkbox (`data-control-scope`) so that data controls are not shared with the calling task flow if you chose **Always Begin New Transaction** in Step 4.

   The default behavior is to share data controls. For more information, see What You May Need to Know About Sharing Data Controls and Managing Transactions.

6. Optionally, select the **No save point on task flow entry** checkbox to prevent the creation of an ADF Model save point on task flow entry if you chose one of the following options in Step 4:

   - **Always Use Existing Transaction**
   - **Use Existing Transaction If Possible**

   An ADF Model save point is a saved snapshot of ADF Model state. Selecting the **No save point on task flow entry** checkbox means that overhead associated with a save point is not created for the transaction.

7. Select the task flow return activity in the called bounded task flow.

8. In the Properties window, expand the **Behavior** section.

9. If the called bounded task flow supports creation of a new transaction (bounded task flow specifies **Use Existing Transaction If Possible** or **Always Begin New Transaction** options), select one of the following in the **End Transaction** dropdown list:

   - **commit**: Select to commit the existing transaction to the database.
   - **rollback**: Select to roll back a new transaction to its initial state on task flow entry. This has the same effect as cancelling the transaction.

10. In the **Restore Save Point** dropdown list, select **true** if you want changes the user makes within the called bounded task flow to be discarded when the task flow exits. The save point that was created upon task flow entry will be restored.

What Happens When You Specify Transaction Options

Example 27-1 shows the metadata for transaction options on a called bounded task flow. The <new-transaction> element indicates that a new transaction always starts when the called bounded task flow is invoked. The <new-transaction> element is generated when you select **Always Begin New Transaction** value in the Transaction section's dropdown list.

Example 27-1 also shows the metadata for transaction options on the task flow return activity on the called task flow. The <commit/> element commits the existing transaction to the database. The <outcome> element specifies a literal outcome, for example, success, that is returned to the caller when the bounded task flow exits. The calling ADF task flow can define control flow rules based on this outcome. For more information about defining control flow upon return, see Using Task Flow Return Activities .

Example 27-1 Called Bounded Task Flow Metadata

```
<task-flow-definition id="trans-taskflow-definition">
   <default-activity>taskFlowReturn1</default-activity>
   <transaction>
     <new-transaction/>
   </transaction>
   <task-flow-return id="taskFlowReturn1">
     <outcome>
       <name>success</name>
       <commit/>
     </outcome>
   </task-flow-return>
 </task-flow-definition>
```

What You May Need to Know About Sharing Data Controls and Managing Transactions

Data controls cannot be shared across more than one transaction at the same time. If your task flow is involved in managing transactions, the value you select for the `data-control-scope` option may affect the `transaction` option settings for a bounded task flow. Table 27-1 describes how these options interact.

The ADF Model layer exposes the `DataControlFrame` interface to manage a transaction in which the data controls within the frame participate. The `DataControlFrame` interface exposes methods such as:

- `beginTransaction()`
- `commit()`
- `rollback()`

Similarly, ADF Controller allows a task flow to demarcate a transaction boundary, to begin a transaction at task flow entry, and to either commit or roll back the transaction on task flow exit. It does this by invoking methods exposed by ADF Model layer's `DataControlFrame` interface.

ADF Controller supports the transaction options listed in Table 27-1. The behavior of these transaction options depends on whether you select **Shared** or **Isolated** from the **Share data controls with calling task flow** list (XML element: `<data-control-scope>`) in the overview editor for a task flow.

Table 27-1 Transaction Settings Behavior

Transaction Setting	Share Data Control Scope	Isolate Data Control Scope
No Controller Transaction	The `DataControlFrame` is shared without the bounded task flow performing a transaction operation on it (begin, commit, or roll back a transaction). The existing transaction state of the data control frame remains and may be altered by other bounded task flows that share the same data control frame.	A new `DataControlFrame` is created without an open transaction.
Always Begin New Transaction XML element: `<new-transaction/>`	Begins a new transaction if one is not already open and throws an exception if one is already open.	Always begins a new transaction.
Always Use Existing Transaction XML element: `<requires-existing-transaction/>`	Throws an exception if the transaction is not already open.	Invalid. The checkbox cannot be selected.
Use Existing Transaction if Possible XML element: `<requires-transaction/>`	Begins a new transaction if one is not already open.	Always begins a new transaction.

A number of examples illustrate how bounded task flows interact when you configure different combinations of values for the data control scope and transaction properties described in Table 27-1:

- Isolate two bounded task flow transactions completely so that they can be committed or rolled back separately. For more information, see Creating Completely Separate Transactions.
- Guarantee that two bounded task flows share a transaction to save connection resources and stop the transaction if the called bounded task flow cannot join the transaction of the calling bounded task flow. For more information, see Guaranteeing a Called Bounded Task Joins an Existing Transaction.
- Call a bounded task flow that joins the transaction of the calling bounded task flow if one exists and, if not, creates its own transaction. For more information, see Using an Existing Transaction if Possible.

The above list describes common use cases rather than all possible configuration options.

Creating Completely Separate Transactions

Figure 27-5 shows a number of task flows that are configured to create separate transactions. Two bounded task flows are chained together in Figure 27-5 yet maintain completely separate transactions. This implementation may be appropriate where you have a call center agent taking an order from a customer and entering the order details in your application. At some point near the end of the order process, the customer realizes that the delivery address that they have provided is incorrect. To assist the call center agent, you designed your application so that it updates and commits the delivery address in a separate transaction to the transaction for the order details (order number, quantity, and so on). In the scenario where the customer wishes to modify the delivery address, the call center agent does not need to roll back changes to the order details in order to modify the delivery address because a separate transaction manages the order details.

In Figure 27-5, the unbounded task flow calls Bounded Task Flow #1. This results in the creation of Data Control Frame #1 because Bounded Task Flow #1 is configured as follows:

- A `data-control-scope` value of `isolated`
- **Always Begin New Transaction**

Bounded Task Flow #1 exposes attributes from two different **view objects** as data control fields (viewObject1.X and viewObject2.Y). X and Y are initially set to 10 and 20 respectively. The end user, while accessing Bounded Task Flow #1, updates X from 10 to 30 and leaves Y unchanged. This marks the transaction as changed or "dirty". That is, there are changes in the transaction that must be committed or rolled back.

Bounded Task Flow #1 calls Bounded Task Flow #2. The application creates Data Control Frame #2 because Bounded Task Flow #2 is configured as follows:

- A `data-control-scope` value of `isolated`
- **Always Begin New Transaction**

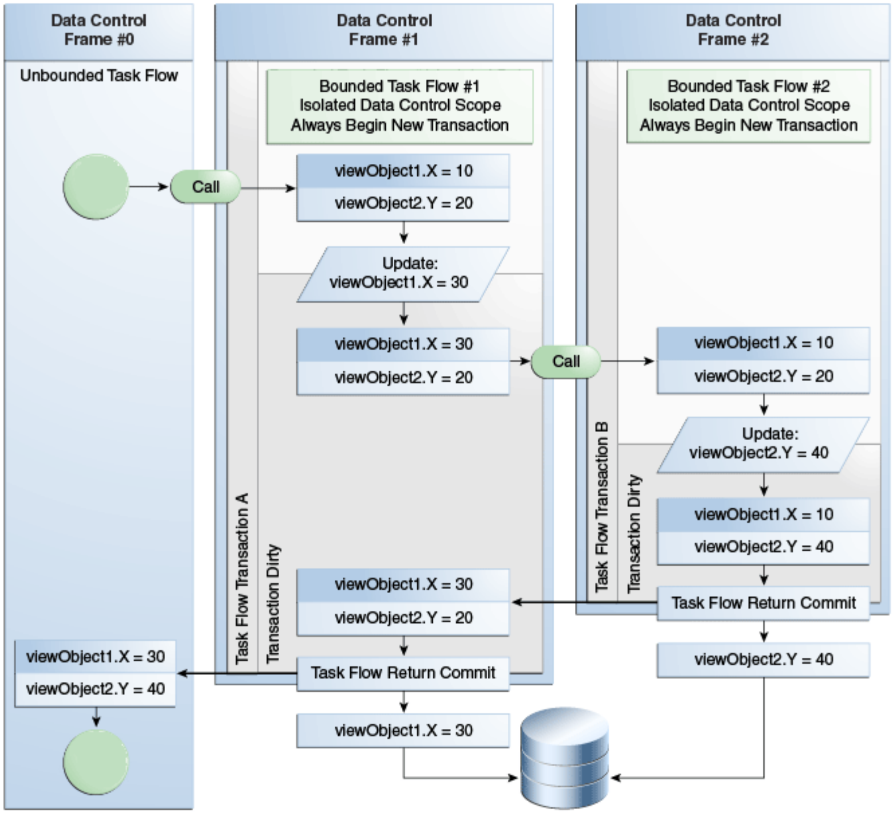
Note that the transaction of Data Control Frame #1 has yet to be committed and that Data Control Frame #2 has a separate database connection and a separate task flow transaction. As a result, the initial values of the data control fields X and Y in Bounded Task Flow #2 are 10 and 20. The end user, while accessing Bounded Task Flow #2, updates Y to 40 and leaves X unchanged. This marks the transaction for Bounded Task Flow #2 as dirty. Bounded Task Flow #2 next calls a task flow return activity that commits the change to Y to the database and returns control to Bounded Task Flow

#1. As Bounded Task Flow #2 did not modify the value of X, no change for this data control field occurs.

Because Bounded Task Flow #1 has a separate data control frame (Data Control Frame #1) and transaction, the values of the data control fields X and Y in Bounded Task Flow #1 remain at 30 and 20, their values when Bounded Task Flow #1 called Bounded Task Flow #2. Bounded Task Flow #1 now calls a task flow return activity (set to commit), saving the value of X to the database. The value of Y remains unchanged because Bounded Task #1's transaction did not modify the value of Y.

On returning to the unbounded task flow and refreshing the values of X and Y from the database, the updated values of 30 and 40 are returned.

Figure 27-5   Completely Separate Transactions



Guaranteeing a Called Bounded Task Joins an Existing Transaction

Figure 27-6 shows two bounded task flows in a configuration that guarantees that the second bounded task flow joins the transaction of the first bounded task flow that calls it. An example scenario where such an implementation may be appropriate is if your application creates invoices and, separately, the individual lines of the invoice. When creating an invoice line, it does not make sense that an invoice line is created without the parent invoice that is to contain the invoice line. If you were to build two separate task flows to create the invoice and invoice lines, the invoice line task flow needs to enforce that it wants to join a transaction of the calling task flow, in this case the invoice task flow, rather than creating a separate transaction.

Figure 27-6 illustrates how the above use case can be addressed by configuring an unbounded task flow that calls a bounded task flow (Bounded Task Flow #1). The unbounded task flow has its own data control frame (Data Control Frame #1). Bounded Task Flow #1 starts a transaction and also has a data control frame (Data Control Frame #0) because it is configured as follows:

- A `data-control-scope` value of `isolated`
- **Always Begin New Transaction**

Bounded Task Flow #1 exposes attributes from two different view objects as data control fields (viewObject1.X and viewObject2.Y). X and Y are initially set to 10 and 20 respectively. The end user, while accessing Bounded Task Flow #1, updates X from 10 to 30 and leaves Y unchanged. This marks Task Flow Transaction A associated with Data Control Frame #1 as changed or "dirty". That is, there are changes in the transaction that must be committed or rolled back.

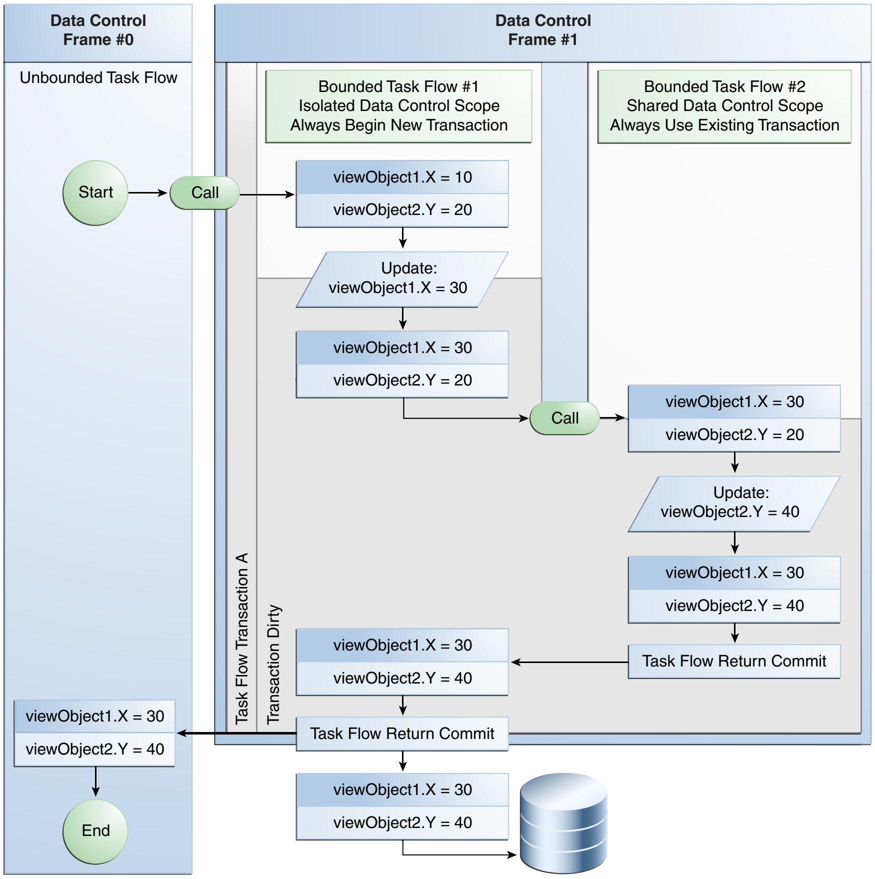
Bounded Task Flow #1 calls Bounded Task Flow #2. Bounded Task Flow #2 is configured as follows:

- A `data-control-scope` value of `shared`
- **Always Use Existing Transaction**

Because of this configuration, no new data control frames are created. Bounded Task Flow #2 uses the same data control frame (Data Control Frame #1) as Bounded Task Flow #1. The changes applied to X in Bounded Task Flow #1 are visible to Bounded Task Flow #2. Updates made to Y in Bounded Task Flow #2 are visible to Bounded Task Flow #1 when it receives control back from Bounded Task Flow #2 after it executes a task flow return activity that specifies a commit. This update to Y is visible in Bounded Task Flow #1 because of the shared data control scope, not because of the commit option that the task flow return activity of Bounded Task Flow #2 specifies.

Remember that the commit and rollback options of a task flow return activity are only valid for the bounded task flow that starts a transaction. That is why the commit of Bounded Task Flow #1´s task flow return activity finalizes changes in the database and not Bounded Task Flow #2.

Figure 27-6 Guaranteed Joined Transactions



Using an Existing Transaction if Possible

Guaranteeing a Called Bounded Task Joins an Existing Transaction, described how to configure a bounded task flow to call a second bounded task flow and guarantee that the called bounded task flow joins the transaction of the calling bounded task flow. The effect of changing the configuration of the calling bounded task flow to have:

- A `data-control-scope` value of `isolated`
- **No Controller Transaction**

while leaving the called bounded task flow unchanged is to stop execution of the bounded task flows and throw the following error message at runtime:

```
ADFC-00006: Existing transaction is required when calling task flow ''{0}''
```

The above scenario illustrates the benefit of configuring the called bounded task flow as follows:

- A `data-control-scope` value of `shared`
- **Use Existing Transaction if Possible**

This latter configuration means that the called bounded task flow creates a transaction if the calling bounded task flow has not created a transaction.

Another configuration option for a called bounded task that guarantees it creates its own transaction is to configure it as follows:

- A `data-control-scope` value of `isolated`
- **Use Existing Transaction if Possible**

This causes the called bounded task flow to create its own transaction regardless of the transaction options that you configure for the calling bounded task flow. The effect is the same as if you set the called bounded task flow to use Always Begin New Transaction.

What You May Need to Know About ADF Business Component Database Connections and Task Flow Transaction Options

ADF Controller shares the ADF Business Component application modules' database connections in an application that has more than one **root application module** (and each application module has a database connection) where task flow transaction options combine to share connections. That is, you configured a set of chained task flows in your application that have a have a `data-control-scope` value of `shared` in combination with the following transaction options:

- **Always Begin New Transaction**
- **Always Use Existing Transaction**
- **Use Existing Transaction if Possible**

When a user configures an ADF Controller to share a single transaction between task flows, by default Oracle ADF manages the application module instances of the various data controls as separate root application modules. These application modules share a single database connection and each application module is considered as an individual root application module that has its own unique configuration as defined during design time.

This implementation helps to reduce the number of database connections that each user creates and, as a result, makes the application more scalable. This is particularly useful when you add task flows and root application modules to your application through ADF Library JARs.

Users can override this default behavior and enforce nesting of the application modules under a single root application module by setting the `oracle.adfm.useSharedTransactionForFrame` property of the root application module to `false` in the `adf-config.xml` file. In such case, the nested application modules configuration settings will be based on the root application module configuration. Since it is difficult to determine the root application module, the configuration settings may be arbitrary. Hence, users must have a valid use case to set the `oracle.adfm.useSharedTransactionForFrame` property to `false`.

A set of chained task flows is where task flows call other task flows so that your application contains a chain with two or more task flows. For example, in Figure 27-2 the unbounded task flow UTF1 calls the bounded task flow BTF1 that in turn calls the bounded task flow BTF2, and so on.

> **Note:**
>
> Remember to configure your application's chained task flows to use a `data-control-scope` value of `isolated` if you do not want root application modules to share database connections.

However, you may want to configure different behavior where you want to have separate root application modules connect to different data sources within the same data model project. For example, you may want to show data from two different database systems or you need to connect to two different schemas in the same database.

To implement this last scenario (have the root application modules maintain their own database connections), you set the `transaction` property's value to No Controller Transaction (the default value) for the task flows in your application. This makes sure that each root application module manages its own database connection in isolation and that the ADF Controller does not manage the transaction behavior of the ADF Business Components.

Reentering Bounded Task Flows

ADF task flows allow you to control the reentry to the bounded task flow. By setting the value of the task-flow-reentry to reentry-allowed, reentry-not-allowed, or reentry-outcome-dependent you can either allow users, not allow users, or allow users based on the previous outcome of the bounded task flow to reenter the bounded task flow when users click on the back button of the navigation window.

To deal with cases in which the end user clicks the back button to navigate back into a bounded task flow that was already exited, you can specify `task-flow-reentry` options for the bounded task flow. These options specify whether a page in the bounded task flow can be reentered.

Upon reentry, bounded task flow input parameters are evaluated using the current state of the application, not the application state existing at the time of the original bounded task flow entry.

How to Set Reentry Behavior

You can set reentry behavior on a bounded task flow by specifying `task-flow-reentry` options.

Before you begin:

It may be helpful to have an understanding of what reentry options you can configure for a bounded task flow. For more information, see Reentering Bounded Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To set reentry behavior:

1. In the Applications window, double-click the bounded task flow.

2. In the editor window, click the **Overview** tab.
3. In the overview editor, click the **Behavior** navigation tab.
4. In the Behavior page, choose one of the following from the **Task Flow Reentry** dropdown list:
   - **reentry-allowed**: Reentry is allowed on any view activity within the bounded task flow.
   - **reentry-not-allowed**: Reentry of the bounded task flow is not allowed. If you specify `reentry-not-allowed` on a bounded task flow, an end user can still click the browser back button and return to a page within the bounded task flow. However, if the user does anything on the page such as clicking a button, an exception (for example, `InvalidTaskFlowReentry`) is thrown indicating the bounded task flow was reentered improperly. The actual reentry condition is identified upon the submit of the reentered page.

     You can set up an exception handler to display the exception and route control flow in order to navigate to the default activity of the called bounded task flow. If the bounded task flow was not called from another bounded task flow, a normal web error is posted and handled as specified in the `web.xml` file.
   - **reentry-outcome-dependent**: Reentry of a bounded task flow using the browser back button is dependent on the outcome that was received when the same bounded task flow was previously exited via task flow return activities. If specified, any task flow return activities on the called bounded task flow must also specify either `reentry-allowed` or `reentry-not-allowed` to define outcome-dependent reentry behavior.

     If you choose this option, the user can navigate to a task flow using a back button based solely on how the user originally exited the task flow. For example, a task flow representing a shopping cart can be reentered if the user exited by canceling an order, but not if the user exited by completing the order.

How to Set Outcome-Dependent Options

You can set outcome-dependent options on bounded task flows that have specified the `reentry-outcome-dependent` option, as described in How to Set Reentry Behavior .

Before you begin:

It may be helpful to have an understanding of what reentry options you can configure for a bounded task flow. For more information, see Reentering Bounded Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To set outcome-dependent options:

1. In the Applications window, double-click the bounded task flow.
2. In the task flow diagram for the bounded task flow, select the task flow return activity.

   For information about adding a task flow return activity, see Using Task Flow Return Activities .
3. In the Properties window, expand the **General** section and enter the name of a literal outcome, for example, `success` or `failure` in the **Name** field.

4. Expand the **Behavior** section and choose one of the following options in the **Reentry** dropdown list:
   - **reentry-allowed**: Reentry is allowed on any view activity within the bounded task flow.
   - **reentry-not-allowed**: Reentry of the bounded task flow is not allowed. If you specify `reentry-not-allowed` on a bounded task flow, an end user can still click the browser back button and return to a page within the bounded task flow. However, if the user does anything on the page such as clicking a button, an exception (for example, `InvalidTaskFlowReentry`) is thrown indicating the bounded task flow was reentered improperly. The actual reentry condition is identified upon the submit of the reentered page.

     You can set up an exception handler to display the exception and route control flow in order to navigate to the default activity of the called bounded task flow. If the bounded task flow was not called from another bounded task flow, a normal web error is posted and handled as specified in the `web.xml` file.

What Happens When You Configure a Bounded Task Flow for Reentry

JDeveloper updates the task flow's metadata with the configuration options that you specify for reentry. The following example shows a task flow that has been configured to allow reentry based on a specific outcome.

```
<task-flow-definition id="task-flow-definition1">
    <default-activity>view1</default-activity>
    <task-flow-reentry>
      <reentry-outcome-dependent/>
    </task-flow-reentry>
    <view id="view1">
      <page>/page1.jsf</page>
    </view>
    <task-flow-return id="taskFlowReturn1">
      <outcome>
        <name>taskFlowReturn1</name>
        <reentry-allowed/>
      </outcome>
    </task-flow-return>
</task-flow-definition>
```

At runtime, the following events occur to a task flow that is configured to allow reentry:

- The task flow is reentered if the user invokes a component that, in turn, invokes a HTTP `POST` or `GET` method.
- The task flow's managed bean values in pageFlow scope are not restored to the values they had when the task flow exited.
- If the reentered task flow defines input parameters, as described in Using Parameters in Task Flows, their values are recreated using the current state of the parent task flow at the time that the task flow is reentered.

Handling Exceptions in Task Flows

Exceptions to the normal flow of application activities can occur during ADF application runtime. ADF task flows allow you to handle such exceptions. You can designate one activity to handle exceptions in a bounded or unbounded task flow as an exception handler.

During execution of a task flow, exceptions can occur that may require some kind of exception handling, for example:

- A method call activity throws an exception.
- A custom method you have written as a task flow initializer or finalizer throws an exception.
- A user is not authorized to execute the activity.

To handle exceptions thrown from an activity or caused by some other type of ADF Controller error, you can designate one activity in a bounded or unbounded task flow as an exception handler.

When a task flow throws an exception, control flow passes to the designated exception handling activity. For example, the exception handling activity might be a view activity that displays an error message. Alternatively, the activity might be a router activity that passes control flow to a method based on an EL expression that evaluates the type of exception. For example:

```
#{controllerContext.currentViewPort.exceptionData.class.name ==
'oracle.adf.controller.ControllerException'}
```

After control flow passes to the exception handling activity, flow from the exception handling activity uses standard control flow rules. For example, you designate a router activity as the exception handling activity. At runtime, the task flow passes control to the exception handling activity (in this example, a router activity) in response to an exception. In addition to designating the router activity as an exception handler, you can define task flow control cases that the router invokes based on the type of exception that it has to handle. This allows you to manage your end user's application session gracefully when an exception occurs. See About Control Flows.

You can optionally specify an exception handler for both bounded and unbounded task flows. Each task flow can have only a single exception handler. However, a task flow called from another task flow can have a different exception handler from that of the caller. In addition, a region on a page can have a different exception handler from that of the task flow containing the page. The exception handler activity can be any supported activity type, for example, a view or router activity.

If a bounded task flow does not have a designated exception handler activity, control passes to an exception handler activity in a calling bounded task flow, if there is a calling task flow and if it contains an exception handler activity. The exception is propagated up the task flow stack until either an exception handler activity or the top-level unbounded task flow is reached. If no exception handler is found, the exception is propagated to the web container.

If a bounded task flow does have a designated exception handler activity, make sure the exception handler activity leaves the application in a valid state after it handles an exception. One way to do this is to redirect to a view activity in the same task flow after the exception handler activity.

Other modules, such as ADF Model, also provide exception handling capabilities. In certain scenarios this can determine the way that your application handles exceptions. For example, a databound method activity is a method activity that has a page definition and an EL expression with the following format:

```
#{bindings.somebindingname.execute}
```

where *somebindingname* is a method binding defined in the page definition.

An exception thrown by any type of binding is caught by ADF Model which calls the `reportException()` method and stores the exception in the binding container. Later, when the page renders, the error displays in the page.

When a method activity invokes a method binding, there is no page to display an error that the exception raises because the exception occurs during navigation between two pages. To make the application aware of an error, Oracle ADF rethrows the exception so that it is caught by ADF Controller's exception handler mechanism that navigates to an exception handler activity if one exists.

Keep this in mind, particularly if you decide to override methods, such as the `reportException()` method, described in Customizing Error Handling, because in that scenario both ADF Controller and ADF Model exception handlers will be called.

How to Designate an Activity as an Exception Handler

You can designate an exception handler activity for a bounded task flow running as an ADF region. If an exception occurs in the bounded task flow and it is not handled by the task flow's exception handler, the exception is not propagated up the task flow stack of the parent page. Instead, it becomes an unhandled exception.

Before you begin:

It may be helpful to have an understanding of what exception handling options you can configure for a task flow. For more information, see Handling Exceptions in Task Flows.

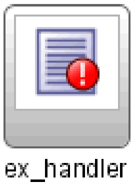
You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To designate an activity as an exception handler for a task flow:

1. In the Applications window, double-click the task flow where you want to designate an activity as an exception handler.
2. In the task flow diagram, right-click the activity and choose **Mark Activity** > **Exception Handler**.

   A red exclamation point is superimposed on the activity in the task flow to indicate that it is an exception handler. Figure 27-7 shows an example.

   Figure 27-7 Example of an Activity Designated as an Exception Handler

3. To unmark the activity, right-click the activity in the task flow diagram, and choose **Unmark Activity** > **Exception Handler**.

   If you mark an activity as an exception handler in a task flow that already has a designated exception handler, the old handler is unmarked.

What Happens When You Designate an Activity as an Exception Handler

After you designate an activity to be the exception handling activity for a task flow, JDeveloper updates the task flow metadata with an `<exception-handler>` element that specifies the ID of the activity, as shown in Example 27-2.

Example 27-2 <exception-handler> element

```
<exception-handler>activityID</exception-handler>
```

How to Designate Custom Code as an Exception Handler

Rather than designate a task flow activity as the activity to invoke, you can write custom code to invoke when a task flow throws an exception. This requires you to:

- Write a Java class that extends the class `ExceptionHandler` from the following package:

  `oracle.adf.view.rich.context.ExceptionHandler`
- Register the Java class that you write as a service in the `.adf\META-INF` directory of your Fusion web application

The following example shows custom code that checks if an exception thrown by a task flow corresponds to a particular type of error message (`ADF_FACES-30108`). If it does, the custom code redirects the task flow to the `faces/SessionExpired.jsf` page.

```
package oracle.summit.frmwkext;

import javax.faces.context.ExternalContext;
import javax.faces.context.FacesContext;
import javax.faces.event.PhaseId;
import oracle.adf.view.rich.context.ExceptionHandler;

public class CustomExceptionHandler extends ExceptionHandler {

    public CustomExceptionHandler() {
        super();
    }

    public void handleException(FacesContext facesContext, Throwable throwable,
                                PhaseId phaseId) throws Throwable {

        String error_message;
        error_message = throwable.getMessage();

        if (error_message != null &&
            error_message.indexOf("ADF_FACES-30108") > -1) {
            ExternalContext ectx = facesContext.getExternalContext();
            ectx.redirect("faces/SessionExpired.jsf");
        }

        else {
            //Code to execute if the if condition is not met
            throw Throwable
        }
    }
}
```

For information about the APIs that you can use to write custom code, see the following reference documents:

- *Java API Reference for Oracle ADF Controller*
- *Java API Reference for Oracle ADF Faces*

Before you begin:

It may be helpful to have an understanding of what exception handling options you can configure for a task flow. For more information, see Handling Exceptions in Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To designate custom code as an exception handler:

1. In the `.adf\META-INF` directory of your application, create a directory named **services** so that you have the following directory path:

   ```
   application_root\.adf\META-INF\services
   ```

   where `application_root` refers to the root directory of application.
2. Create a text file named **oracle.adf.view.rich.context.ExceptionHandler** in the **services** folder.
3. Write the package name and class name of the custom code that you wrote to handle exceptions in the text file named **oracle.adf.view.rich.context.ExceptionHandler**.

   For example, write code similar to the following:

   ```
   oracle.summit.frmwkext.CustomExceptionHandler
   ```
4. Save and close the text file.

What Happens When You Designate Custom Code as an Exception Handler

At runtime, the task flow passes control to the custom code that you specified if the task flow throws an exception.

What You May Need to Know About Handling Exceptions During Transactions

Designate an exception handling activity for a bounded task flow that is enabled to run as a transaction. A Fusion web application attempts to commit a transaction if you set `commit` as the value for a task flow return activity's End Transaction property on a bounded task flow that runs as a transaction. If an exception occurs when the Fusion web application attempts to commit a transaction, the exception handling activity receives control and provides the end user with an opportunity to correct the exception. You can use the exception handling activity (for example, a view activity) to display a warning message to an end user with information about how to correct the exception and how to recommit the transaction. For information about enabling a bounded task flow as a transaction and setting commit as a value for the End Transaction property, see How to Enable Transactions in a Bounded Task Flow .

What You May Need to Know About Handling Validation Errors

For validation errors on a JSF page, you can rely on standard JSF to attach validator error messages to specific components on a page or to the whole page. A component-level validator typically attaches an error message inline with the specific UI component. There is no need to pass control to an exception handler activity.

In addition, your application should define validation logic on data controls that are executed during the Validate Model Updates phase of the JSF lifecycle. In this way, data errors are found as they are submitted to the server without waiting until attempting the final commit.

Validations done during the Validate Model Updates phase typically do not have direct access to the UI components because the intention is to validate the model after the model has been updated. These validations are often things like checking to see whether dependent fields are synchronized. In these cases, the error message is usually attached to the whole page, which this logic can access.

You should attach errors detected during the Validate Model Updates phase to the JSF page, and call `FacesContext.renderResponse()`. This signals that following this phase, the current (submitting) page should be rendered showing the attached error messages. There is no need to pass control to an exception handler activity.

For more information, see Implementing Validation and Business Rules Programmatically.

Configuring Your Application to Use Save Points

To use save points with ADF task flows, you need to define a value for the <savepoint-datasource> element in the adf-config.xml file. This element is used to specify the JNDI name of the data source containing the database table of the save points. To create this database table, you need to run the SQL script adfc_create_save_point_table.sql. To delete the expired save points, you need to run the SQL script adfc_cleanup_save_point_table.sql.

Before you can add save points to a task flow, as described in Using Save Points in Task Flows, and configure related functionality, you need to make sure that the Fusion web application allows save points. To do this, you define a value for the `<savepoint-datasource>` element in the `adf-config.xml` file to specify the JNDI name for the data source that contains the save points' database table. You may also need to run a SQL script (`adfc_create_save_point_table.sql`), as described in What You May Need to Know About the Database Table for Save Points, to create the database table that stores save points. Once your Fusion web application starts using save points, you can use another SQL script (`adfc_cleanup_save_point_table.sql`) to delete expired save points.

How to Configure Your Fusion Web Application to Use Save Points

You define a value for the `<savepoint-datasource>` element in your application's `adf-config.xml` file to specify the JNDI name for the data source that contains the save points' database table. Optionally, you can also specify an expiration time for save points.

Before you begin:

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see Configuring Your Application to Use Save Points.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To configure your Fusion web application to allow save points:

1. In the Application Resources panel, expand the **Descriptors** and **ADF META-INF** nodes, and then double-click **adf-config.xml**.
2. In the overview editor, click the **Controller** navigation tab and then expand the **Savepoints** section to write a value for the Data Source property that specifies the JNDI name for the data source that contains the database table for save points.

   For example, write the following:

   `java:comp/env/jdbc/`*`Connection1`*`DS`

   where `Connection1` is the JDeveloper connection name.
3. Optionally, write a value in seconds for the Expiration property to specify the time between when a task flow creates a save point and when the save point manager removes it. The default value is 86400 seconds.

   For more information, see What You May Need to Know About the Time-to-Live Period for a Save Point .
4. Save the `adf-config.xml` file.

What Happens When You Configure a Fusion Web Application to Use Save Points

JDeveloper generates an entry, similar to the following example, in the `adf-config.xml` file to specify the JNDI name for the data source that contains the save points' database table.

```
<adf-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
    ...
    <savepoint-datasource>
      java:comp/env/jdbc/Connection1DS
    </savepoint-datasource>
    <savepoint-expiration>
      86399
    </savepoint-expiration>
  </adf-controller-config>
```

For more information about the `adf-config.xml` file, see adf-config.xml.

What You May Need to Know About the Database Table for Save Points

A database table named `ORADFCSAVPT` stores save points. If this database table does not exist, it is created the first time that a save point is created if your Fusion web application has the necessary permissions to create a database table. If your Fusion web application does not have the necessary permissions, you or an administrator with the necessary permissions can use SQL scripts to create and maintain the `ORADFCSAVPT` database table. These SQL scripts are:

- `adfc_cleanup_save_point_table.sql`

  Each save point in the `ORADFCSAVPT` database table has an expiration date. Use this script to delete save points that have passed their expiration date.
- `adfc_create_save_point_table.sql`

  Use this script to create the `ORADFCSAVPT` database table that stores save points.

You can find these SQL scripts in the following directory of your JDeveloper installation:

```
jdev_install\oracle_common\common\sql
```

Using Save Points in Task Flows

The ADF task flow allows you to save the current state of the application and restore the state for a later use by using save point. To invoke these save points you need to add a method call activity in the bounded task flow.

You can configure a task flow to capture the state of a Fusion web application at a particular instance creating what is called a **save point**. This allows you to save application state if, for example, a user leaves a page without finalizing it. The application state can be restored at a later point.

Table 27-2 describes what information a save point captures.

Table 27-2 Saved Application State Information

Saved State Information	Description
User Interface State	UI state of the current page, including selected tabs, selected checkboxes, selected table rows, and table column sort order. This state assumes the end user cannot select the browser back button on save point restore.

Table 27-2 (Cont.) Saved Application State Information

Saved State Information	Description
Managed Beans	State information saved in several possible memory scopes, including session and page flow scope. The managed beans must be serializable in order to be saved. If you have page flow scope beans that are not serializable and you attempt to create a save point, a runtime exception occurs. Request scope is not supported since its lifespan is a single HTTP request and its lifespan cannot be used to store cross request application state. Save points will not save and restore application-scoped managed beans since they are not passivated in failover scenarios. Therefore, the application is always responsible for making sure that all required application-scoped state is available. Potential naming conflicts for managed beans already existing within the session scope at restore time will not occur because multiple managed beans using the same name should not be implemented within an application.
Navigation State	Task flow call stack, which ADF Controller maintains as one task flow calls another at runtime. The task flow call stack tracks where the end user is in the application and the navigation path for getting there. The task flow stack also identifies the starting point of any persisted data transactions originated for the end user.
ADF Model State	Fusion web applications use ADF Model to represent the persisted data model and business logic service providers. The ADF Model holds any data model updates made from when the current bounded task flow begins. The model layer determines any limits on the saved state lifetime. For more information, see SeeUsing State Management in a Fusion Web Application.

You add a method call activity to a bounded task flow that invokes a `createSavePoint` method to create save points. Later, you use a save point restore activity to restore application state and data associated with the created save points.

The same save point can be used if a user repeatedly performs a save for later on a task flow instance that executes in one session within the same browser window. The new save point overwrites the existing save point when a user performs a save for later following navigation from page to page in a task flow. For information about restoring a save point, see How to Restore a Save Point.

You can specify the `createSavePoint` method exposed by the `currentViewPort` node of ADF Controller Objects in the Expression Builder. Alternatively, you can write a custom method that updates the save point with the values of attributes you specify in your custom method, as illustrated in the following example.

```
package viewController;

import java.io.Serializable;

import oracle.adf.controller.ControllerContext;
import oracle.adf.controller.savepoint.SavePointManager;

public class SaveForLater implements Serializable {
    public SaveForLater() {
        super();
    }

    public String saveTaskFlow() {
        ControllerContext cc = ControllerContext.getInstance();
        if (cc != null) {
            SavePointManager mgr = cc.getSavePointManager();
        if (mgr != null) {
            String id = mgr.createSavePoint();
            System.out.println("Save point is being set " + id);
        ...
```

The SavePointListener interface exposes methods that notify clients when save point events occur. The following package contains the SavePointListener interface:

oracle.adf.controller.savepoint

> **Note:**
>
> All save points created inside a bounded task flow are deleted when the bounded task flow exits.

How to Add a Save Point to a Task Flow

You drag and drop a method call activity to the task flow diagram and configure it to invoke the createSavePoint method or to invoke a custom method if you created one.

Before you begin:

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see Using Save Points in Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

You will need to complete this task:

Confirm that your Fusion web application leaves the value of the jbo.locking.mode property set to the default value optimistic. This is required if you use a save point in a Fusion web application. The value pessimistic causes an old session to lock until the session has timed out. In pessimistic mode, if you run an application and change data without committing changes to the database, you may get an error when you create a save point and try to restore it at a later point. For information about the jbo.locking.mode property, see How to Confirm That Fusion Web Applications Use Optimistic Locking.

To add a save point to a task flow:

1. In the Applications window, double-click the bounded task flow where you want to add a save point.
2. In the ADF Task Flow page of the Components window, from the Component panel, in the Activities group, drag and drop a **Method Call** onto the diagram.
3. In the Properties window, expand the **General** node and write an EL expression in the **Method** field to specify the save point method that the method call activity invokes. If needed, select **Method Expression Builder** in the dropdown menu that you invoke from the icon that appears when you hover over the property field.

   If you use the Expression Builder to specify the createSavePoint method exposed by the currentViewPort node of ADF Controller Objects, the resulting EL expression is similar to the following:

```
#{controllerContext.currentViewPort.createSavePoint}
```

4. Use a control flow to connect the method call activity with other activities in the bounded task flow.

   For more information, see How to Add a Control Flow Rule to a Task Flow.

5. Optionally, configure save point options in the Fusion web application's `adf-config.xml` file to determine, for example, if implicit save points can be created for the application.

   For more information, see How to Enable Implicit Save Points.

What Happens When You Add Save Points to a Task Flow

JDeveloper generates entries similar to those shown in the following example in the task flow's source file when you configure a method call activity to invoke the `createSavePoint` method.

```
<method-call id="methodCall1">
      <method id="__3">#{controllerContext.currentViewPort.createSavePoint}</
method>
</method-call>
```

How to Restore a Save Point

Use the save point restore activity to restore a previously persisted save point for an application. The save point restore activity uses the save point that was originally created by invoking the `createSavePoint` method to identify the save point to restore.

You can obtain a list of the current persisted save points with `createSavePoint`. However, ADF Controller does not determine which save points to restore. A user must select the save point from a list or the application developer must select it programmatically. The savepoint ID is then passed to a save point restore activity to perform the restore.

Before you begin:

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see Using Save Points in Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To add a save point restore activity to a bounded or unbounded task flow:

1. In the Applications window, double-click the task flow where you want to add the save point restore activity.
2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a **Save Point Restore** onto the diagram.
3. In the Properties window, expand the **General** section and write an EL expression in the **Save Point ID** field that, when evaluated, retrieves the save point that was originally created when the `createSavePoint` method was invoked.

   If you use the Expression Builder to specify the `getSavePoint` method of ADF Controller Objects, the resulting EL expression is similar to the following:

```
#{SessionScope.myBean.savepointID}
```

What Happens When You Restore a Save Point

JDeveloper generates entries similar to those in the following example in the task flow's source file when you add a save point restore activity that gets a save point ID.

```
<save-point-restore id="savePointRestore1">
      <save-point-id id="__4">#{sessionScope.myBean.savepointID}</save-point-id>
</save-point-restore>
```

How to Use the Save Point Restore Finalizer

When using the save point restore activity, you may need to invoke application-specific logic as part of restoring the application state. You can write an EL expression for the Save Point Restore Finalizer property of a bounded task flow that specifies a finalizer method. The bounded task flow invokes the specified method after the task flow's state has been restored. It performs any necessary logic to make sure that the application's state is correct before proceeding with the restore.

Before you begin:

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see Using Save Points in Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To use the save point restore finalizer:

1. In the Applications window, double-click the bounded task flow that you want to use a save point restore finalizer.
2. In the Structure window, right-click the node for the bounded task flow (`task-flow-definition`) and choose **Go to Properties**.
3. In the Properties window, expand the **General** section, and select **Expression Builder** in the dropdown list that you invoke from the icon that appears when you hover over the **Save Point Restore Finalizer** property field.
4. Write an EL expression that specifies the finalizer method to invoke.

What Happens When a Task Flow Invokes a Save Point Restore Finalizer

JDeveloper generates entries similar to those in the following example in the task flow's source file when you write an EL expression for the Save Point Restore Finalizer property.

```
<task-flow-definition id="task-flow-definition1">
    <save-point-restore-finalizer id="__2">#{sessionScope.MyBean.invokeFinalizer}
      </save-point-restore-finalizer>
  </task-flow-definition>
```

How to Enable Implicit Save Points

A save point in a task flow can be categorized as *implicit* or *explicit*. An explicit save point requires an end user action before a bounded or unbounded task flow creates a save point. For example, an end user clicks a button that invokes a method call activity that, in turn, creates a save point.

An implicit save point can only originate from a bounded task flow. It includes everything from when the originating task flow creates a save point. It occurs when data is saved automatically because:

- A session times out due to end user inactivity.
- An end user logs out without saving the data.
- An end user closes the only browser window, thus logging out of the application.
- An end user navigates away from the current application using control flow rules (for example, uses a `link` component to go to an external URL) and having unsaved data.

Enabling implicit save points requires you to add an element to your Fusion web application's `adf-config.xml` file and to make the bounded task flow critical.

You configure the `adf-config.xml` file in your application and the bounded task flow(s) for which you want to create implicit save points. Enabling implicit save points involves a performance cost because your Fusion web application has to do extra work that it would otherwise not do. This is why you have to explicitly enable implicit save points in your application and specify the task flows to which it applies.

Before you begin:

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see Using Save Points in Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To enable implicit save points:

1. In the Application Resources panel, expand the **Descriptors** and **ADF META-INF** nodes, and then double-click **adf-config.xml**.
2. In the overview editor, click the **Controller** navigation tab and then expand the **Savepoints** section and select the **Enable Implicit Savepoints** checkbox.

   JDeveloper generates the following entry in the `adf-config.xml` file:

   ```
   <adf-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
       ...
       <enable-implicit-savepoints>true</enable-implicit-savepoints>
   </adf-controller-config>
   ```

   For more information about the `adf-config.xml` file, see adfc-config.xml.
3. In the Applications window, double-click the bounded task flow.
4. In the editor window, click the **Overview** tab.

5. In the overview editor, click the **Behavior** navigation tab and select the **Critical** checkbox.

What You May Need to Know About Enabling Implicit Save Points

If multiple windows are open when the implicit save point is created, a different save point is created for each browser window. This includes everything from the root view port of the browser window on down. You can write an EL expression for the Method property of a method call activity to retrieve the list of implicit save points using the `savePointManager` node under ADF Controller Objects. The resulting EL expression is similar to the following:

```
ControllerContext.savePointManager.listSavePointIds
```

Implicit save points are generated only if a critical task flow is present in any of the page flow stacks for any view port under the current root view port. An implicit save point is not generated if the request is for an ADF Controller resource, such as:

- Task flow call activity
- Task flow return activity
- Save point restore activity
- A dialog

Implicit save points are deleted when the task flow at the bottom of the stack completes or a new implicit save point is generated, whichever comes earlier.

What You May Need to Know About the Time-to-Live Period for a Save Point

An application-level property (`savepoint-expiration`) that is defined in the `adf-config.xml` file determines the period between when a task flow creates a save point and when the save point manager removes it (time-to-live period). The default value is 86400 seconds (24 hours).

You can change the time-to-live period for individual save points by calling the `setSavePointTimeToLive` method on an instance of `SavePointManger` from the following package:

```
oracle.adf.controller.savepoint
```

An instance of `SavePointManager` can be obtained as follows:

```
SavePointManager mgr = ControllerContext.getInstance().getSavePointManager();
```

The following example shows the syntax for the `setSavePointTimeToLive` method.

```
    public void setSavePointTimeToLive(long timeInSeconds) {
       }
```

If you supply a value for the `setSavePointTimeToLive` method argument (`timeInSeconds`) equal to or less than zero, the default value is used (`86400`).

The `SavePointManger` defines methods that help you manage save points. For example, it defines `getSavePoint` and `removeSavePoint` methods that can retrieve and remove save points. Note that the `removeSavePoint` method does not get called automatically when a save point expires. You must explicitly call the `removeSavePoint` method to remove save points (including expired save points) from the `ORADFCSAVPT` database table. Alternatively, Oracle ADF provides a SQL script (`adfc_cleanup_save_point_table.sql`) that removes expired save points. For more information, see What You May Need to Know About the Database Table for Save Points.

Consider calling the `setSavePointTimeToLive` method at the same time that you call the method to create save points. For more information about the `SavePointManger`, see the *Java API Reference for Oracle ADF Controller*.

Minimizing the Number of Active Root View Ports in an Application

The ADF task flow allows you to limit the number of active root view ports in an application by setting a value for the Maximum Root View Ports property (<max-root-view-ports>) in the adf-config.xml of the application. Setting the limit may prevent the denial-of-service attacks. Setting the value to -1 allows unlimited view ports; however, the default value is 20.

You can minimize the number of active root view ports in an application by specifying a value for the Maximum Root View Ports property (`<max-root-view-ports>`) in the application's `adf-config.xml` file. This limits the memory footprint of the application and can help to prevent denial-of-service attacks.

The default value is `20`. The lowest permissible value is `5`. To prevent accidental misuse, the application ignores any value below `5` and enforces a value of `5`.

Specify a value of `-1` if you want to disable this feature and allow an unlimited number of active root view ports in the application.

How to Minimize the Number of Active Root View Ports

You specify a value for the `<max-root-view-ports>` property in the application's `adf-config.xml` file.

Before you begin:

It may be helpful to have an understanding of what `<max-root-view-ports>` options you can configure. For more information, see Using Save Points in Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To minimize the number of active root view ports:

1. With the Fusion web application open in JDeveloper, open the Application Resources pane in the Applications window.
2. Expand **Descriptors**, then expand **ADF META-INF**.
3. Right-click `adf-config.xml` and choose **Open** from the context menu.
4. On the Controller page of the overview editor, write a value for the Maximum Root View Ports property to specify the maximum number of active root view ports for the application.

5. Save the `adf-config.xml` file.

What Happens When You Minimize the Number of Active Root View Ports

JDeveloper generates an entry, similar to that illustrated in the following example, in the `adf-config.xml` file to specify the maximum number of active root view ports for the application.

```
<?xml version="1.0" encoding="UTF-8" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
            xmlns:config="http://xmlns.oracle.com/bc4j/configuration"
            xmlns:adf="http://xmlns.oracle.com/adf/config/properties">
    ...
  <adf-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
    <max-root-view-ports>
      19
    </max-root-view-ports>
  </adf-controller-config>
</adf-config>
```

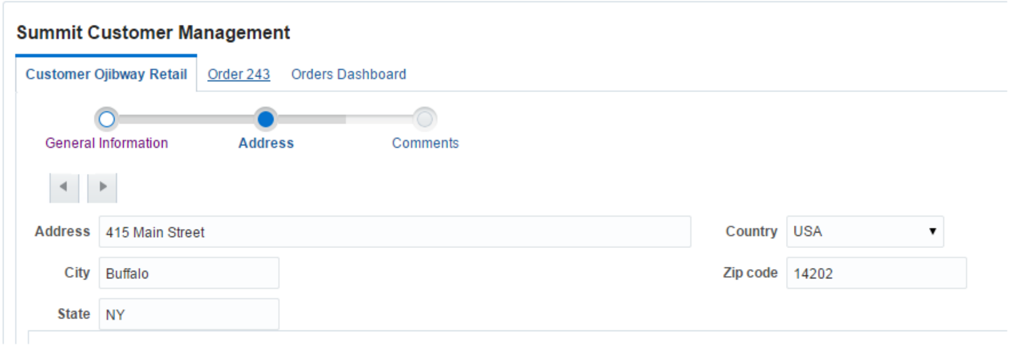
At runtime, once the specified root view port limit is reached, any request to create a new root view port automatically expires the least-recently-used root view port first. Attempts to subsequently use the expired root view port result in a `ViewExpiredException`.

Using Train Components in Bounded Task Flows

By integrating a train with an ADF task flow, you can allow users to go through a multistep process. The train and trainButtonBar components allow you to create a user interface that can render the train functionality in the task flow view activities. This feature allows you to branch out using router activities and control flow cases in the task flow.

You can create a task flow as a train. This allows you to create a user interface where you navigate end users through a multistep process. ADF Faces provides the user interface components that render the train functionality in the task flow view activities that appears to the end user. These components are the `train` and `trainButtonBar` components. Figure 27-8shows a runtime view of the `edit-customer-task-flow-definition.xml` task flow from the Summit ADF task flow sample application. This task flow uses the `train` and `trainButtonBar` components to navigate an end user through the task of editing a customer's data.

Figure 27-8 Train and Train Button Bar Components in a Task Flow



Address 415 Main Street
Country USA
City Buffalo
Zip code 14202
State NY

The `train` component in Figure 27-8 renders three train stops. Each stop corresponds to a page fragment in the `edit-customer-task-flow-definition.xml` task flow where the end user can enter and review information to complete the task of editing a customer's data. Figure 27-8 shows the Address train stop where the end user enters an address for postage. The other stops are:

- General Information
- Comments

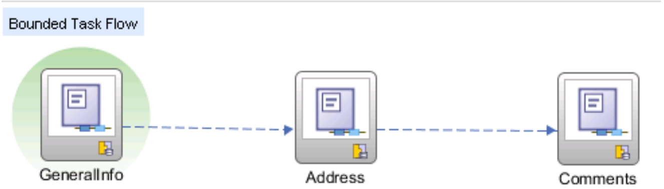
The Train Button Bar component, also shown in Figure 27-8, is optional and provides additional controls to navigate between the train stops. This component can be used in conjunction with the train component to provide multiple ways to navigate through train stops.

Bounded task flows and task flow templates can make use of these train components if you select the **Create Train** checkbox on the dialogs provided by JDeveloper to create a bounded task flow or a task flow template. A bounded task flow or a task flow template can render one train only. If you want to use multiple trains, create a separate bounded task flow or task flow template for each train.

Figure 27-9 displays an extract from the design-time view of the task flow where you can see the view activities that render at runtime as train stops in Figure 27-8.

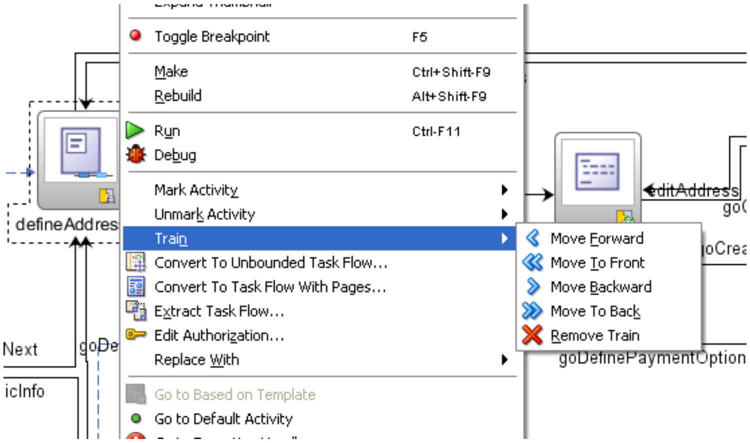
The dotted lines connecting the view activities indicates the sequence in which the end user navigates between the view activities when the view activities render as train stops.

Figure 27-9 Task Flow Configured to Render as a Train



JDeveloper displays a context menu with options to change the position of the activity when your right-click a view activity or task flow call activity that is configured as a train stop, as illustrated in Figure 27-10.

Figure 27-10   Context Menu to Edit a Train Stop



Configure a task flow call activity as a train stop when you want to group a number of activities as a train stop or call a child train stop. For example, there are cases when other task flow activities, such as router and method call activities, should be considered part of a train stop along with the corresponding view activity. A method call activity might need to precede a view activity for initialization purposes. When grouped this way, the activities can be performed as a set each time the train stop is visited. See Grouping Task Flow Activities to Execute Between Train Stops .

Branching using router activities and control flow cases is supported on the task flow diagram containing the train, as well as in child bounded task flows called from the train.

Creating a Task Flow as a Train

You need to configure a bounded task flow to use train components before you can implement the type of functionality discussed in Using Train Components in Bounded Task Flows. Use one of the methods outlined in the following list to configure a bounded task flow to use train components:

- Select the **Create Train** checkbox in the dialog that appears when you create a new bounded task flow or task flow template.

  For more information, see Creating a Task Flow or Creating Task Flow Templates .
- Right-click an existing bounded task flow in the diagram and choose **Train** > **Create Train**.
- Open an existing bounded task flow in the overview editor, click the **Behavior** navigation tab and select the **Train** checkbox.

Once you have configured the bounded task flow to use train components, you drag and drop the task flow activities that you want to render in the train to the diagram in the bounded task flow.

How to Create a Train in a Bounded Task Flow

You drag and drop the task flow activities that you want to render in the train to the diagram for the bounded task flow.

Before you begin:

It may be helpful to have an understanding of the configuration options that you can configure for a train. For more information, see Creating a Task Flow as a Train .

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

You will need to complete this task:

> Configure the bounded task flow to use train components, as described in Using Train Components in Bounded Task Flows.

To create a train in a bounded task flow:

1. In the Applications window, double-click the bounded task flow or task flow template where you want to render train stops.
2. Drag each view activity or JSF page you want to include in the train to the diagram for the bounded task flow.
   - If you drag a JSF page, JDeveloper automatically adds a view activity to the diagram. You drag a JSF page that you want to include from the Applications window to the diagram for the bounded task flow.
   - If you drag a view activity to the diagram, you can double-click it to invoke the dialog to create a new JSF page. To drag a view activity, in the ADF Task Flow page of the Components window, from the Component panel, in the Activities group, drag and drop a **View** onto the diagram.

   You can reorder the train stop sequence at a later point. For more information, see Disabling the Sequential Behavior of Train Stops in a Train.
3. In the diagram for the bounded task flow, double-click each view activity that you want to define as a train stop.

   A dialog appears to create a new JSF page if the view activity is not yet associated with a JSF page. Use the dialog to create a new JSF page.

   If the view activity is already associated with a JSF page, the JSF page opens.
4. In the ADF Faces page of the Components window, from the General Controls panel, in the Location group, drag a **Train**, and, optionally, a **Train Button Bar** component and drop it on the JSF page.

   You must manually add each Train and Train Button Bar component that you want to appear in a task flow view activity. Consider using a page template. For more information, see Using Page Templates.

What Happens When You Create a Task Flow as a Train

JDeveloper writes the `<train/>` element to the source file for the bounded task flow or task flow template that you enable as a train, using one of the methods outlined in Creating a Task Flow as a Train .

JDeveloper writes entries to the JSF page where you add `train` and `trainButtonBar` components. The following example shows code snippets from the `GeneralInfo.jsff` page fragment in the Summit ADF task flow sample application. Both types of train component bind to instances of the train model object (`trainModel`).

```
 <af:train
value="#{controllerContext.currentViewPort.taskFlowContext.trainModel}"
         id="t1"/>
  ...
  <af:trainButtonBar
value="#{controllerContext.currentViewPort.taskFlowContext.trainModel}"
        id="tbb1"/>
```

Dotted lines appear between each view activity that you add to the bounded task flow and define as a train stop, as illustrated in Figure 27-9. The dotted lines indicate the order in which the bounded task flow navigates through the train stops. JDeveloper defines the sequence in the order that you add the view activities to the bounded task flow. You can change the sequence. For more information, see Disabling the Sequential Behavior of Train Stops in a Train. You can also skip a train stop. For more information, see Configuring a Train to Skip a Train Stop.

Invoking a Child Bounded Task Flow from a Train Stop

An alternative approach to grouping task flow activities in one train stop, as described in Grouping Task Flow Activities to Execute Between Train Stops , is to create another bounded task flow as a train that you invoke from your current bounded task flow. This bounded task flow is referred to as a **child bounded task flow**. You configure the parent bounded task flow to invoke it using a task flow call activity. To implement this functionality, you:

- Create a child bounded task flow as a train
- Add the task flow activities that you want end users to access from the train stop on the parent bounded task flow to the child bounded task flow
- Designate a task flow call activity as a train stop in the parent bounded task flow to invoke the child bounded task flow
- Add a task flow return activity to the child bounded task flow that returns control to the parent bounded task flow once the child bounded task flow finishes execution

Task flow activities in the child bounded task flow execute together regardless of whether the end user visits the train stop for the first time or returns at a later point. Nonview task flow activities in the child bounded task flow typically precede the view activity in the child bounded task flow's flow control. You can invoke a child bounded task flow from a bounded task flow that itself is a child to another bounded task flow.

How to Invoke a Child Bounded Task Flow From a Train Stop

You create a bounded task flow as a train, add task flow activities to it, and configure a task flow call activity on the parent bounded task flow to invoke it.

Before you begin:

It may be helpful to have an understanding of the configuration options that you can configure for a child bounded task flow that you invoke from a train. For more information, see Invoking a Child Bounded Task Flow from a Train Stop.

You may also find it helpful to read about the additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

You will need to complete this task:

Create a bounded task flow as a train. This is a child bounded task flow that is to be invoked from a task flow call activity in the parent task flow. Add the task flow activities that you require to it. For more information, see Creating a Task Flow as a Train .

To invoke a child bounded task flow from a train stop:

1. In the Applications window, double-click the bounded task flow that is the child bounded task flow configured as a train.
2. In the ADF Task Flow page of the Components window, from the ADF Task Flow panel, in the Activities group, drag and drop a **Task Flow Return** onto the diagram.
3. Configure the task flow return activity to return control to the parent task flow when the child bounded task flow finishes execution.

   For more information, see Using Task Flow Return Activities .
4. In the Applications window, double-click the parent bounded task flow that is going to invoke the child bounded task flow.

   For more information, see Creating a Task Flow as a Train .
5. In the ADF Task Flow page of the Components window, from the ADF Task Flow panel, in the Activities group, drag and drop a **Task Flow Call** onto the diagram.
6. Configure the task flow call activity to invoke the child bounded task flow that you configured in Steps 1 to 3.

   For more information, see Using Task Flow Call Activities.

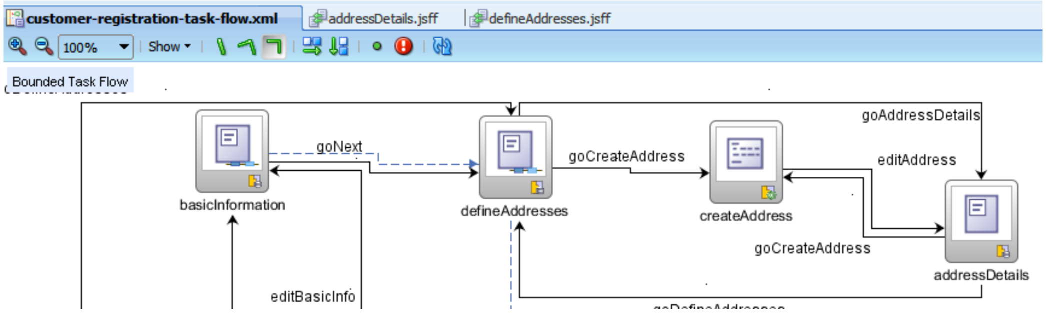
Grouping Task Flow Activities to Execute Between Train Stops

You can group task flow activities together to form a single train stop. For example, a train stop that renders as **Address** at runtime might group together the following task flow activities:

- `defineAddress` view activity
- `createAddress` method call activity
- `addressDetails` view activity

Each time a user visits the runtime **Address** train stop, the task flow would provide access to the task flow activities listed previously. The `defineAddresses` view activity renders the train stop and the associated `defineAddresses.jsff` page fragment. The `defineAddresses.jsff` page fragment, in turn, exposes a button to invoke the `createAddress` method call activity. This method call activity validates user input in the Address page and defines an outcome that (optionally) passes control to the `addressDetails` view activity. The `addressDetails` view activity renders the Address Information page at runtime where an end user may choose to enter additional addresses.

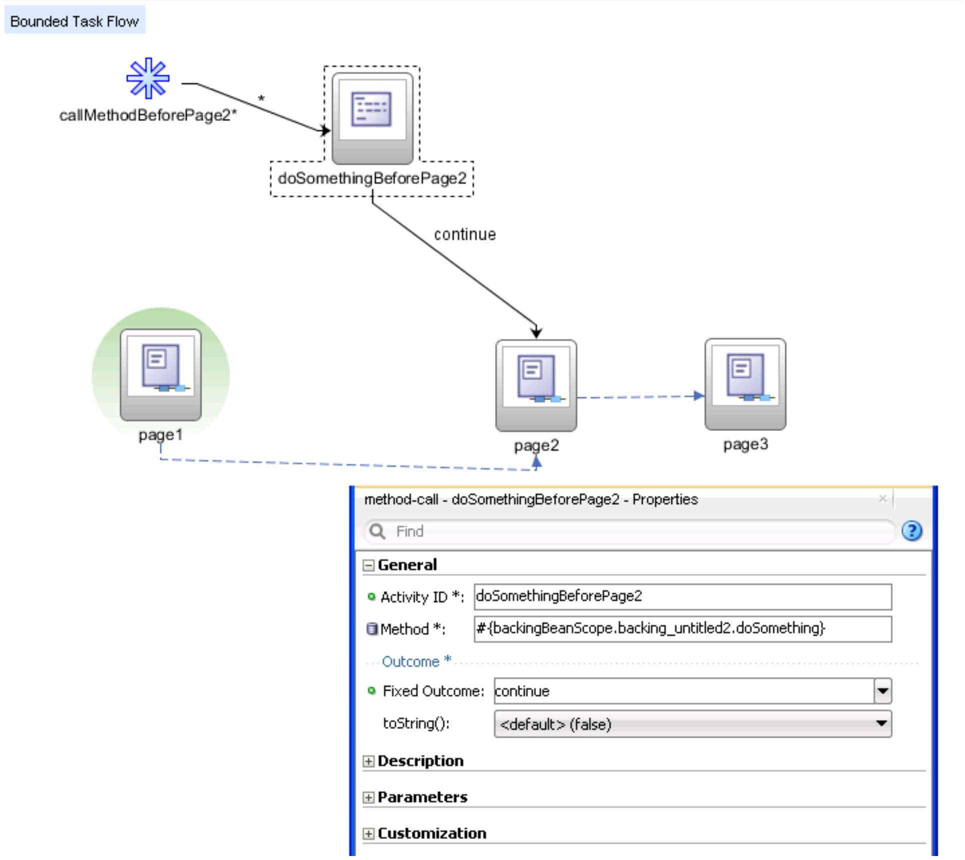
Figure 27-11   Task Flow Activities Grouped into One Train Stop



The train considers all task flow activities that lead from the first nonview activity through the next view activity to be part of the train. Make sure that all task flow activities, except for view and task flow call activities, for the train stop follow the view or task flow call activity that you define as a train stop.

You can also group task flow activities to execute between train stops. Figure 27-12 shows a possible configuration where a method call activity (`doSomethingBeforePage2`) invokes before control flow passes to `page2`. The `callMethodBeforePage2` wildcard control flow rule passes control to the `doSomethingBeforePage2` method call activity. This method call activity defines a fixed outcome (`continue`) that passes control to the next train stop (`page2`) in the train.

Figure 27-12   Method Call Activity Between Train Stops



Activity ID *: doSomethingBeforePage2

Method *: #{backingBeanScope.backing_untitled2.doSomething}

Outcome *

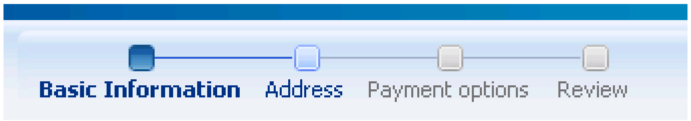
Fixed Outcome: continue

toString(): <default> (false)

Disabling the Sequential Behavior of Train Stops in a Train

By default, train stops are sequential. This means end users can select a train stop only after visiting the previous train stop in the train. Figure 27-13 shows a train component that a registration task flow renders. End users cannot visit the **Payment** options and **Review** train stops until they first visit the **Address** train stop. All train stops in this train are sequential.

Figure 27-13 Sequential Train Stops in a Task Flow



You can change this default behavior (make a train stop nonsequential) by configuring the view activity that renders the train stop to make it nonsequential.

How to Disable the Sequential Behavior of a Train

You write a value for the task flow view activity's `sequential` property that evaluates to `false` at runtime.

Before you begin:

It may be helpful to have an understanding of the configuration options that you can configure for a train. For more information, see Using Train Components in Bounded Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To disable the sequential behavior of a train stop:

1. In the Applications window, double-click the bounded task flow containing the view activity that renders the train stop.
2. In the diagram for the bounded task flow, select the view activity.
3. In the Properties window, expand the **Train Stop** section and write a value in the **Sequential** field to determine if the train stop is sequential or nonsequential.

   Write `false` or write an EL expression that resolves to `false` at runtime to make the train stop nonsequential. For example, write an EL expression similar to the following:

   ```
   #{myTrainModel.isSequential}
   ```

What Happens When You Disable the Sequential Behavior of a Train Stop

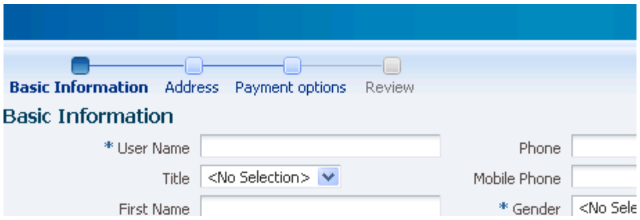
JDeveloper writes an entry to the source file for the bounded task flow, as illustrated in the following example.

```
<view id="paymentOptionDetails">
      <page>/account/paymentOptionDetails.jsff</page>
```

```
      <train-stop id="__1">
        <sequential>#{myTrainModel.isSequential}</sequential>
      </train-stop>
</view>
```

Figure 27-14 shows the corresponding runtime view when the value specified for `sequential` evaluates to `false`. End users can now navigate directly to payment options by clicking the **Payment options** train stop.

Figure 27-14   Train with a Nonsequential Train Stop



Changing the Label of a Train Stop

You can configure a train stop to display a label that you define. The label that you define can be a static value or a value in a resource bundle that you reference using an EL expression, for example. For more information about using localized strings, see the "Internationalizing and Localizing Pages" chapter of *Developing Web User Interfaces with Oracle ADF Faces*.

How to Change the Label of a Train Stop

You change the label of a train stop by configuring a value for the view activity's Display Name property.

Before you begin:

It may be helpful to have an understanding of the configuration options that you can configure for a train. For more information, see Using Train Components in Bounded Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To change the label of a train stop:

1. In the Applications window, double-click the bounded task flow containing the view activity that renders the train stop.
2. In the diagram for the bounded task flow, select the view activity.
3. In the Properties window, expand the **Description** section and write a value in the **Display Name** to specify the label that the train stop renders at runtime.

   Write a literal value or write an EL expression that references a value in a resource bundle to render at runtime.

What Happens When You Change the Label of a Train Stop

JDeveloper writes an entry to the source file for the bounded task flow, as illustrated in the following example from the `edit-customer-task-flow-definition.xml` bounded task flow in the Summit ADF task flow sample application.

```
<view id="GeneralInfo"> <page>/customers/GeneralInfo.jsff</page>
  <train-stop>
    <display-name>General Information</display-name>
    <sequential>false</sequential>
  </train-stop></view>
```

At runtime, the Fusion web application displays the value you specified for the `display-name` property as the label for the train stop.

Configuring a Train to Skip a Train Stop

You can configure a train so that it skips an individual train stop. At runtime, the Fusion web application disables the train stop that you configure to skip. The end user can only navigate to the next train stop in the train.

Implement this functionality if you want the train to execute at a train stop other than the first train stop. For example, configure train stops 1 and 2 to skip if you want to execute train stop 3 first. Use this approach rather than defining the view activity associated with the train stop as the default activity, as discussed in What You May Need to Know About the Default Activity in a Bounded Task Flow.

How to Configure a Train to Skip a Train Stop

You write a value for the view activity's `skip` property that evaluates to `true` at runtime.

Before you begin:

It may be helpful to have an understanding of the configuration options that you can configure for a train. For more information, see Using Train Components in Bounded Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To configure a train to skip a train stop:

1. In the Applications window, double-click the bounded task flow containing the view activity that renders the train stop.
2. In the diagram for the bounded task flow, select the view activity.
3. In the Properties window, expand the **Train Stop** and write a value in the **Skip** field to determine if the train navigates to the train stop or skips it.

   Write `true` or write an EL expression that resolves to `true` at runtime to make the train skip the train stop. For example, write an EL expression similar to the following:

   ```
   #{myTrainModel.shouldSkip}
   ```

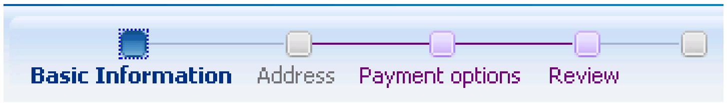
What Happens When You Configure a Train to Skip a Train Stop

JDeveloper writes an entry to the source file for the bounded task flow, as illustrated in the following example.

```
 <view id="defineAddresses">
      <display-name>Address</display-name>
      <page>/account/defineAddresses.jsff</page>
      <train-stop>
        <display-name>Address</display-name>
        <skip>#{myTrainModel.shouldSkip}</skip>
      </train-stop>
</view>
```

Figure 27-15 shows the corresponding runtime view when the value specified for `skip` evaluates to `true`. End users must now navigate to the next train stop in the train (**Payment** options) if the train is sequential.

Figure 27-15 Train Configured to Skip a Train Stop

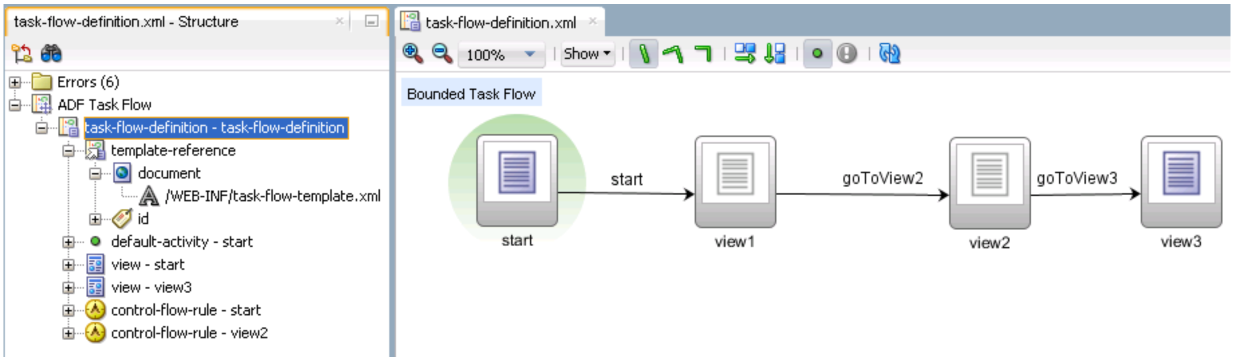


Creating Task Flow Templates

When you have a repeated set of ADF task flow activities, control flows, input parameters, and managed beans, you can create ADF task flow templates for reuse. A template serves as a starting point when creating a new bounded task flow. However, you can create templates for unbounded task flows.

You can create task flow templates for yourself or other application developers to use as a starting point when creating new bounded task flows. Unbounded task flows cannot be created using task flow templates. A bounded task flow created from a task flow template will have definitions for the same set of task flow activities, control flows, input parameters, and managed beans as the task flow template. For example, Figure 27-16 shows a bounded task flow that has been created from a task flow template. The `view1` and `view2` view activities plus the `goToView2` control flow in this bounded task flow have been defined in the task flow template while the `start` and `view3` view activities have been defined in the bounded task flow itself.

Figure 27-16 Bounded Task Flow Displaying Activities Defined in Task Flow Template



An example use case for a task flow template is where you define a task flow activity as an exception handler on a bounded task flow. The task flow activity could be a view activity associated with a page that you display to end users when an exception occurs. Rather than define this view activity in each bounded task flow, you define it in a task flow template and select the task flow template when you create new bounded task flows. For information about exception handling, see Handling Exceptions in Task Flows.

You can base a new task flow template on an existing task flow template. You can also refactor an existing bounded task flow to create a new task flow template. See How to Convert Bounded Task Flows .

When you create a bounded task flow or another task flow template based on a task flow template, you can specify that subsequent changes you make to a task flow template be automatically propagated to bounded task flows and templates. To do this, you select the **Update the Task Flow When the Template Changes** checkbox in the dialog that you use to create a bounded task flow or a template. Subsequent changes that you make to the task flow template (add new view activities, for example) get propagated to the bounded task flows. You can change, update, or disassociate the parent task flow template of a child bounded task flow or task flow template at any point during development of the child.

At runtime, the contents of a child bounded task flow or a child task flow template combine with the contents of the parent task flow template if you selected the **Update the Task Flow When the Template Changes** checkbox when creating the child. The child task flow and task flow template override the parent task flow template when conflict occurs, even if you selected the **Update the Task Flow When the Template Changes** checkbox when creating the child task flow or task flow template. For example, you create a parent task flow template to use as a train, as described in Using Train Components in Bounded Task Flows, and then create a bounded task flow based on this task flow template. Later, you disable the train component on the parent task flow template. The child task flow overrides the parent task flow template and continues to execute as a train.

Table 27-3 describes in more detail how ADF Controller resolves conflicts between parent task flow templates and child task flows and child task flow templates.

Table 27-3 Conflict Resolution between Parent Templates and Child Task Flows

Bounded Task Flow Metadata	Combination Algorithm
Default activity	Child bounded task flow or child task flow template overrides parent task flow template.
Transaction	Child bounded task flow or child task flow template overrides parent task flow template as an entire block of metadata, including all subordinate elements.
Task flow reentry	Child bounded task flow or child task flow template overrides parent task flow template as an entire block of metadata, including all subordinate elements.
Control flow rules	Combination algorithm occurs at the control flow case level, not the control flow rule level. Control flow cases fall into the following categories: • Both from action and from outcome specified • Only from action specified • Only from outcome specified • Neither from action nor from outcome specified Each of these categories is merged additively. The child bounded task flow or template overrides parent task flow template for identical matches within each of the four categories.
Input parameter definitions	Child bounded task flow or child task flow template overrides parent task flow template for identical input parameter definition names.
Return value definitions	Child bounded task flow or child task flow template overrides parent task flow template for identical return value definition names.
Activities	Child bounded task flow or child task flow template overrides parent task flow template for identical activity IDs.
Managed beans	Child bounded task flow or child task flow template overrides parent task flow template for identical managed bean names.
Initializer	Child bounded task flow or child task flow template overrides parent task flow template.
Finalizer	Child bounded task flow or child task flow template overrides parent task flow template.
Critical	Child bounded task flow or child task flow template overrides parent task flow template.
Use page fragments	Child bounded task flow or child task flow template overrides parent task flow template.
Exception handler	Child bounded task flow or child task flow template overrides parent task flow template.
Security - permission	Child bounded task flow or child task flow template overrides parent task flow template. Privilege maps are additive. Child bounded task flow or child task flow template overrides parent task flow template for identical privilege map operations.
Security - transport guarantee	Child bounded task flow or child task flow template overrides parent task flow template.

Table 27-3 (Cont.) Conflict Resolution between Parent Templates and Child Task Flows

Bounded Task Flow Metadata	Combination Algorithm
Train	Child bounded task flow or child task flow template overrides parent task flow template.

Validations at both design time and runtime verify that the resulting parent-child extension hierarchy does not involve cycles of the same task flow template.

How to Create a Task Flow Template

You create a task flow template by selecting ADF Task Flow Template from the New Gallery.

Before you begin:

It may be helpful to have an understanding of what task flow template options you can configure. For more information, see Creating Task Flow Templates .

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To create a task flow template:

1. In the Applications window, right-click the project where you want to create the task flow template and choose **New** > **From Gallery**.
2. In the New Gallery, expand **Web Tier**, select **JSF/Facelets** and then **ADF Task Flow Template**, and click **OK**.
3. In the Create ADF Task Flow Template dialog, choose the appropriate options:
   - **File Name**: Accept the default value proposed by JDeveloper or enter a new file name. The value is used to name the XML source file for the task flow template you create. The source file includes the activities and control flow rules that are in the task flow template. The default name for the XML source file is `task-flow-template.xml`.
   - **Create with Page Fragments**: Leave this checkbox selected (the default) if you expect that a bounded task flow based on the template will be used as an ADF region. Clear the checkbox if you want to add JSF pages instead of JSF page fragments to a task flow based on the task flow template.
4. Click **OK**.

What Happens When You Create a Task Flow Template

As shown in the following example, an XML file is created each time you create a new task flow template using JDeveloper. You can find the XML file in the Applications window in the location that you specified in the **Directory** field of the Create ADF Task Flow Template dialog, for example,`.../WEB-INF`.

The contents of the XML source file for the task flow template can be similar to those of a bounded task flow. One difference is the inclusion of the `<task-flow-template>` tag.

```
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2"
id="__1">
  <task-flow-template id="task-flow-template">
     <default-activity>view1</default-activity>
     <view id="view1">view1.jsff</view>
  </task-flow-template>
</adfc-config>
```

What You May Need to Know About Task Flow Templates

If you use a task flow template that contains bindings, you must change the component IDs of task flows based on the task flow template. Doing this makes sure that the IDs are unique. Task flows generated from the template inherit the same ID as the template. This may cause an exception at runtime. For more information, see How to Use ADF Data Binding in ADF Page Templates.

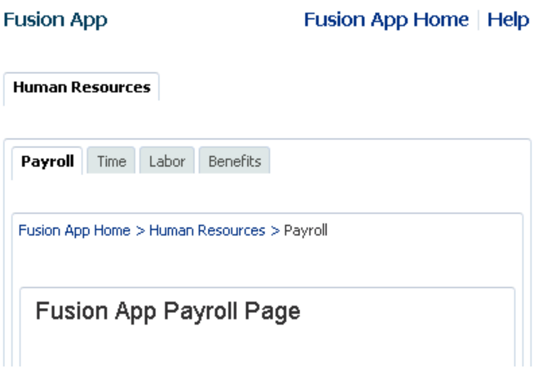
If your Fusion web application has configured ADF security, you have to make grants on both the task flow template and task flows that use the template. Usually, the grant on the task flow template is to the `anonymous-role` application role so that the grant that really matters is on the task flow, but not always. For more information about ADF security, see Enabling ADF Security in a Fusion Web Application.

Creating a Page Hierarchy Using Task Flows

The page hierarchy is a useful way of organizing the JSF pages in your Fusion web application. You can create a page hierarchy for ADF task flows using ADF Controller or using an XMLMenuModel implementation. You can allow users to access information on the pages by navigating a path of links.

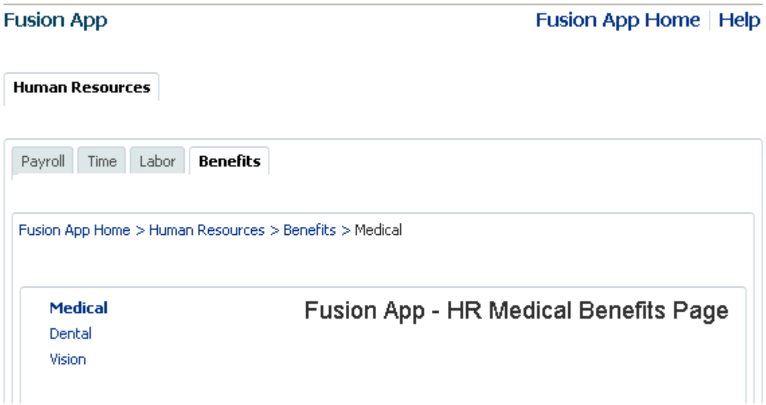
Creating a page hierarchy is a useful way of organizing the JSF pages in your Fusion web application so that end users can more easily navigate the application. End users access information on the pages by navigating a path of links. Figure 27-17 shows a sample page hierarchy that allows the user to navigate between the home page of a Fusion application, a Human Resource page, and a Payroll page.

Figure 27-17   Page Hierarchy



To navigate this hierarchy, an end user clicks links on each page to drill down or up to another level of the hierarchy. For example, clicking **Human Resources** on the Fusion App home page displays the Human Resources page hierarchy shown in Figure 27-17. Clicking the link on the **Benefits** tab displays the page hierarchy shown in Figure 27-18.

Figure 27-18 Benefits Page

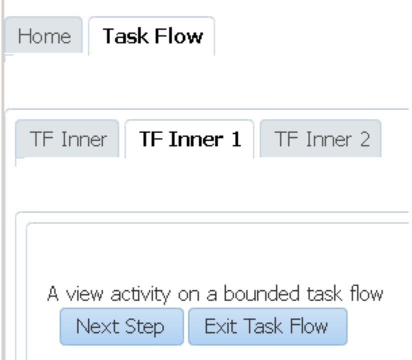


Fusion App
Fusion App Home | Help
Human Resources
Payroll
Time
Labor
Benefits
Fusion App Home > Human Resources > Benefits > Medical
Medical
Dental
Vision
Fusion App - HR Medical Benefits Page

The user can click links on the Benefits page to display other pages, for example, the Medical, Dental or Vision pages. The breadcrumbs on each page indicate where the current page fits in the hierarchy. The user can click each node in a breadcrumb to navigate to other pages in the hierarchy. The bold tab labels match the path to the current page shown by the breadcrumbs.

Pages referenced by view activities in a bounded task flow can also be included in any page hierarchy that you generate. Figure 27-19 shows the runtime view of a page hierarchy that renders view activities referenced by a bounded task flow.

Figure 27-19 Runtime Menu Hierarchy Including a Bounded Task Flow



You can use ADF Controller with an `XMLMenuModel` implementation to create the previously discussed page hierarchies. If you do, JDeveloper generates the following for you:

- Control flow metadata that determines the view or page to display when an end user selects a menu item

- An `XMLMenuModel` metadata file
- Default navigation widgets such as **Previous** and **Next** buttons
- Breadcrumbs
- Managed bean configuration

If you decide not to use ADF Controller, you can create the page hierarchy using an `XMLMenuModel` implementation. For information about this method of building a page hierarchy, see Using a Menu Model to Create a Page Hierarchy.

How to Create a Page Hierarchy

Create an unbounded task flow or open an existing one. Add view activities or bounded task flows to the unbounded task flow. Each view activity or bounded task flow that you add to the unbounded task flow contains references to pages to appear in the proposed page hierarchy. Use JDeveloper's Create ADF Menu Model dialog to generate an `XMLMenuModel` metadata file. Organize the item nodes in the generated `XMLMenuModel` metadata file to create the page hierarchy you want. Connect submenus to parent menus to finalize the hierarchy.

Figure 27-20 shows an example page hierarchy that consists of view activities:

- The top-level menu (**Home Page**) is the root parent page. It contains a single tab that links to the **Human Resources** submenu.

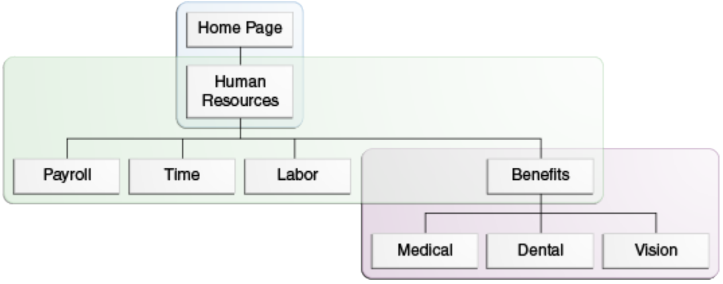
  In JDeveloper, **Home Page** page is represented as an item node and **Human Resources** page as a shared node.

- **Human Resources** has four tab links to **Payroll**, **Time**, **Labor**, and **Benefits** pages.

  In this menu, **Human Resources** is a group node that references child item nodes (**Payroll**, **Time**, and **Labor**) and a shared node (**Benefits**) that references the Benefits submenu.

- **Benefits** is a group node that references child item nodes (**Medical**, **Dental**, and **Vision**) pages.

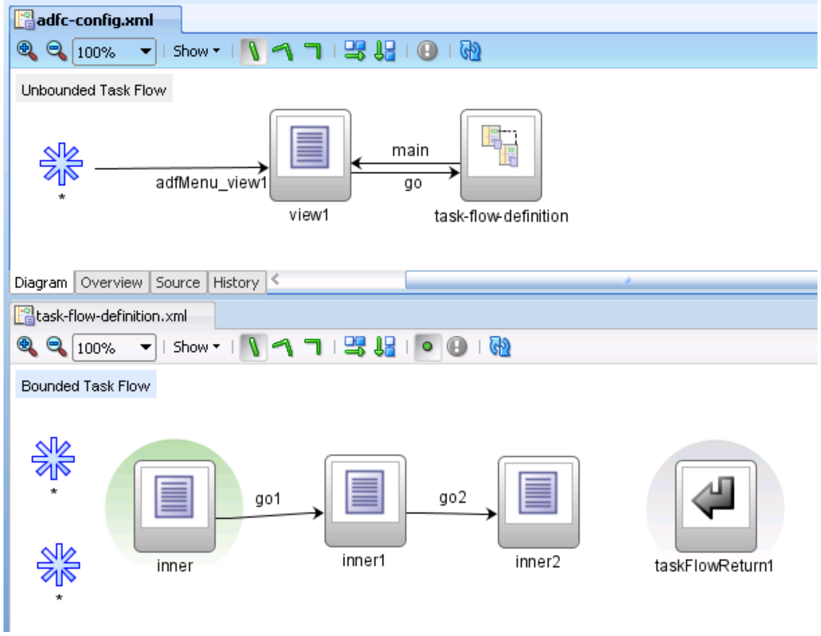
Figure 27-20 Menu Hierarchy



> **Note:**
>
> It is possible to create the entire menu hierarchy in one menu model. However, breaking a menu hierarchy into submenus makes maintenance easier. In addition, breaking the menu hierarchy into smaller submenu models enables each separate development organization to develop its own menu. These separate menus can later be combined using shared nodes to create the complete menu hierarchy.

Figure 27-21 shows the corresponding design-time view in JDeveloper of the unbounded and bounded task flows that render the page hierarchy shown in Figure 27-19. The unbounded task flow (`adfc-config.xml`) contains a view activity (**view1**) and a task flow call activity (**task-flow-definition**) that invokes the bounded task flow (`task-flow-definition.xml`) shown in the lower part of Figure 27-21.

Figure 27-21 Design Time Menu Hierarchy Including a Bounded Task Flow



How to Create an XMLMenuModel Metadata File

You use JDeveloper's Create ADF Menu Model dialog to generate an `XMLMenuModel` metadata file once you have defined what menus (unbounded task flows) and nodes (pages) you want to appear in the final page hierarchy.

Before you begin:

It may be helpful to have an understanding of what page hierarchy options you can configure. For more information, see Creating a Page Hierarchy Using Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

You will need to complete these tasks:

1. Create an unbounded task flow for each menu in the final page hierarchy.

   For example, to achieve the page hierarchy illustrated in Figure 27-20, you create two unbounded task flows (Human Resources menu and Benefits menu).

   For more information about creating an unbounded task flow, see How to Create a Task Flow.

   > **Tip:**
   >
   > Prefix the name of the file for unbounded task flows that you create with `adfc-` to help you to identify the file as the source of an unbounded task flow, as opposed to a bounded task flow.

2. Add view activities that reference pages to each unbounded task flow. The pages referenced by the view activities correspond to the menu nodes in the menu.

   For example, the Benefits menu contains one group node (benefits) and three item nodes (medical, dental and vision) so you add four view activities to the unbounded task flow for the Benefits menu, as illustrated in Figure 27-22.

   Figure 27-22 View Activities on a Task Flow

   Do not add view activities for menus that include other menus using shared nodes. For example, the Human Resources menu in Figure 27-20 has a tab called **Benefits** that references the Benefits menu using a shared node. The bounded task flow for the Benefits menu already includes a view activity for Benefits so there is no need to add a view activity to the bounded task flow for the Human Resources menu.

   For more information about view activities, see Using View Activities.

   > **Note:**
   >
   > If the page hierarchy includes pages referenced by a bounded task flow, add a task flow call activity to the unbounded task flow that calls the bounded task flow.

To create the XMLMenuModel metadata file:

1. In the Applications window, right-click the file(s) for each of the unbounded task flows you created and choose **Create ADF Menu Model**.

2. In the Create ADF Menu Model dialog, enter a file name for the `XMLMenuModel` metadata file and a directory to store it.
3. Click **OK**.

How to Create a Submenu with a Hierarchy of Group and Child Nodes

You open the `XMLMenuModel` metadata file you created and convert the item nodes that you want to make group nodes to group nodes. You then create a hierarchy where a group node is a parent to one or more item nodes.

Before you begin:

It may be helpful to have an understanding of what page hierarchy options you can configure. For more information, see Creating a Page Hierarchy Using Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To create a submenu with a hierarchy of group and item nodes:

1. In the Applications window, double-click the `XMLMenuModel` metadata file.

   An item node appears in the Structure window for each view activity in the unbounded task flow. By default, no hierarchy is defined.

2. In the Structure window, drag and drop the item nodes to become child nodes of the item node that you are going to convert to a group node.

   Each item node that you convert to a group node must have at least one child item node. For example, to create the menu hierarchy in Figure 27-20, you convert the item node for Benefits to a group node, you drag and drop the item nodes for Medical, Dental, and Vision so that they become child nodes of the Benefit item node.

3. In the Structure window, right-click the parent item node and choose **Convert To groupNode**.
4. In the groupNode Properties dialog, in the **id** field, enter a new identifier or accept the default value.

   The identifier must be unique among all of the nodes in all of the `XMLMenuModel` metadata files. It is good practice to specify a value that identifies the node. For example, if you change the Benefits node to a group node, you can update its default ID, `itemNode_benefits`, to `groupNode_benefits`.

5. In the **idref** field, enter the ID of one of the other nodes in the menu, for example, `itemNode_Medical`.

   The value you enter can be an ID of a child item node that is a group node or an item node.

6. Enter or change the existing default value in the **label** field to match what you want to appear at runtime.

   For example, you might change `label_benefits` to `Benefits`.

7. Accept the rest of the default values in the fields and click **Finish**

   A Confirm Convert dialog asks if you want to delete the `action` and `focusViewID` attributes on the `groupNode` element. Group nodes do not use these attributes, always click **OK**

8. Click **OK**

How to Attach a Menu Hierarchy to Another Menu Hierarchy

You use a shared node element to link two menus together. For example, the Human Resources menu shown in the menu hierarchy in Figure 27-20 contains four submenus (Payroll, Time, Labor, and Benefits). The Benefits submenu is itself a menu with submenu entries. In the `XMLMenuModel` metadata file for the Human Resources menu, you convert the item node for the Benefits submenu to a shared node. You write an EL expression for an attribute (`ref`) of the newly created shared node that references the `XMLMenuModel` metadata file for the Benefits menu.

Before you begin:

It may be helpful to have an understanding of what page hierarchy options you can configure. For more information, see Creating a Page Hierarchy Using Task Flows.

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Additional Functionality for Complex Task Flows.

To attach a menu hierarchy to another hierarchy using a shared node:

1. In the Applications window, double-click the `XMLMenuModel` metadata file for the menu that is going to reference the other menu.
2. In the Structure window, select a node, right-click and select the appropriate menu options to insert a `sharedNode` element.
3. In the Insert sharedNode dialog, in the **ref** field, enter an EL expression to reference the `XMLMenuModel` metadata file for the other menu.
4. Click **OK**.

> **Note:**
>
> If your page hierarchy has more than one unbounded task flow, make sure that the file name for each additional unbounded task flow appears as a value for the `<metadata-resources>` element in the `adfc_config.xml` file. For more information, see What Happens When You Create a Page Hierarchy.

What Happens When You Create a Page Hierarchy

Changes occur in a number of different files when you create a page hierarchy.

Changes to the adfc-config.xml File

When you create a new unbounded task flow, JDeveloper automatically adds a reference in the `adfc-config.xml` file to the source file for the newly created unbounded task flow. In the following example, `adfc-unbounded_tflow.xml` is the name of the source file for a newly created unbounded task flow.

```
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2"
             id="__1">
```

```
  <metadata-resource id="__2">
      /WEB-INF/adfc-unbounded_tflow.xml
  </metadata-resource>
</adfc-config>
```

For more information about `adfc-config.xml`, see adfc-config.xml.

At runtime, the Fusion web application loads the `adfc-config.xml` file when it first starts. The `adfc-config.xml` file can contain:

- ADF navigation metadata for an unbounded task flow
- ADF activity metadata for an unbounded task flow
- Managed bean definitions used by ADF activities

XMLMenuModel Metadata File

JDeveloper generates an `XMLMenuModel` metadata file with nodes for each of the view activities that you added to the unbounded task flow, as illustrated in the following example.

```
<?xml version="1.0" encoding="windows-1252" ?>
<menu xmlns="http://myfaces.apache.org/trinidad/menu">
  <groupNode id="groupNode_benenfits" label="Benefits" idref="itemNode_medical">
    <itemNode id="itemNode_medical" label="label_medical"
              action="adfMenu_medical" focusViewId="/medical"/>
    <itemNode id="itemNode_dental" label="label_dental" action="adfMenu_dental"
              focusViewId="/dental"/>
    <itemNode id="itemNode_vision" label="label_vision" action="adfMenu_vision"
              focusViewId="/vision"/>
  </groupNode>
</menu>
```

Diagram for an Unbounded Task Flow

JDeveloper updates the file for the unbounded task flow with the control flow rules and managed beans used to navigate the page hierarchy. Figure 27-23 shows the updated unbounded task flow in the diagrammer that corresponds to the unbounded task flow in Figure 27-22.

Figure 27-23 Updated Unbounded Task Flow

Reporting Incidents to the Oracle Fusion Middleware Diagnostic Framework

An Oracle Fusion Middleware Diagnostic Framework enables you to collect and retrieve information about incidents that occur in Fusion web applications. You can use the collected information to troubleshoot problems or to send it to Oracle Support for resolution. ADF Controller can report incidents, such as version information, hierarchy of the ADF binding container, metadata and so on, to this framework.

The Diagnostic Framework collects and manages information about incidents that occur in Fusion web applications. ADF Controller can report incidents to this framework. You can use this information to resolve problems or send it to Oracle Support for resolution. Examples of the information that the ADF Controller reports to the Diagnostic Framework when an incident occurs include the following:

- Version information
- Information about the view port hierarchy, including page flow stack entries
- Hierarchy of the ADF binding container
- Metadata information, for example the list of files that contribute to the unbounded task flow

Furthermore, information about recent events within the runtime of the ADF Controller can also be sent to the Diagnostic Framework. Examples of these events includes permission checks, region refreshes, navigation between activities, and the retrieval of metadata from the Oracle Metadata Services (MDS) framework. Sending this latter category of information (events within the runtime of ADF Controller) requires you to enable QuickTrace, a mechanism that Oracle Fusion Middleware provides to enable fine-grained logging to memory. For information about QuickTrace, including how to specify the history (number) of recent events that ADF Controller sends to the Diagnostic Framework, see Configuring and Using QuickTrace. For information about using the Diagnostic Framework, see Diagnosing Problems.

28

Using Dialogs in Your Application

This chapter describes how to create dialogs in your Fusion web application. It describes how you can use ADF Controller and task flows to create dialogs or, alternatively, use the ADF Faces dialog framework.
This chapter includes the following sections:

About Using Dialogs in Your Application

ADF dialogs are the secondary windows that can display additional information external to the browser window displaying the current page. You can also use modal dialogs that allows users to work on both primary and secondary windows at the same time.

Use dialogs if you want to show information to end users in a secondary browser window external to the browser window that displays the end user's current page. For example, you want to display help information to end users to assist them with a task in the primary browser window or you want end users to choose a value from a list of values. The help information example is a use case where a modeless dialog is appropriate. A **modeless dialog** allows end users work in both the primary window and the dialog at the same time. For the use case where you want an end user to choose a value, a modal dialog is more appropriate. A **modal dialog** prevents an end user accessing the page that invoked the dialog until they execute an action requested by the dialog (for example, choose a value).

Use the ADF Faces dialog framework if you want to configure modeless dialogs for your end users. If you plan to configure modal dialogs for your end users, configure an ADF Controller bounded task flow to invoke one or more dialogs. You can define view activities that reference either a JSF page or a page fragment file (`.jsff`) to invoke a dialog.

Using Dialogs in Your Application Use Cases and Examples

Running a Bounded Task Flow in a Modal Dialog describes how you can run a bounded task flow in a modal dialog to retrieve input from an end user, and return to a view activity that called the bounded task with the retrieved input. If your application does not use ADF Controller task flows or you want to use modeless dialogs, Using the ADF Faces Dialog Framework Instead of Bounded Task Flows, describes how you can use the ADF Faces dialog framework to render one or more pages in a dialog.

Additional Functionality for Using Dialogs in Your Application

You may find it helpful to understand other **Oracle ADF** features before you configure or use dialogs in your application. Additionally, you may want to read about what you can do with the dialogs you configure. Following are links to other functionality that may be of interest.

- If your application uses ADF Controller task flows, you may find it helpful to understand more about the features that task flows offer. For more information, see Getting Started with ADF Task Flows .
- For more information about ADF Faces components, see *Developing Web User Interfaces with Oracle ADF Faces*.
- You can also write custom code for your dialogs using the APIs provided by Oracle ADF. Make sure when you write custom code that you do not import packages that are marked internal, as in this example:

  ```
  import oracle.adfinternal.controller.*;
  ```

  For information about the APIs that you can use to write custom code, see the following reference documents:

  - *Java API Reference for Oracle ADF Controller*
  - *Java API Reference for Oracle ADF Faces*

Running a Bounded Task Flow in a Modal Dialog

In the cases where you want to accept the values from a user and return the application to an activity, running an ADF bounded task flow in a modal dialog is appropriate to be used. The modal dialogs can be used in the ADF Controller and task flows by specifying the dialog:syntax in the control flow rules.

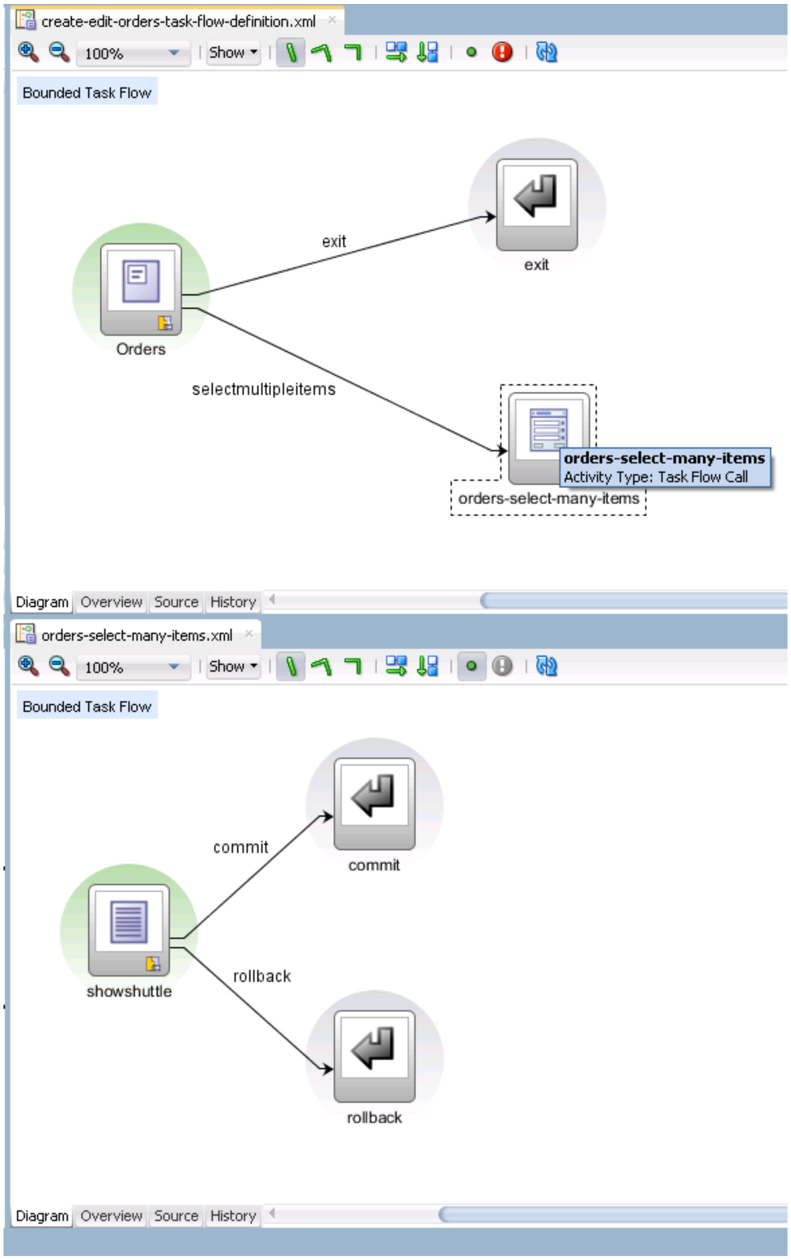
You can configure a bounded task flow to run in a modal dialog, retrieve input from an end user, and return to the view activity that called the bounded task flow with the retrieved input. The bounded task flow that you configure must reference pages, not page fragments.

Figure 28-1 shows an example of the configuration required from the Summit sample application for ADF task flows. The task flow in `create-edit-orders-task-flow-definition` contains a view activity (**Orders**) from where the end user invokes the `orders-select-many-items.xml` task flow that renders a modal dialog. For more information, see How to Run a Bounded Task Flow in a Modal Dialog.

When the end user closes the dialog, control and any modified values return to the launch page in the calling task flow in `create-edit-orders-task-flow-definition`. For more information, see How to Return a Value From a Modal Dialog.

In addition, you can configure the application to refresh part of the launch page after the modal dialog returns control. For more information, see How to Refresh a Page After a Modal Dialog Returns.

Figure 28-1 Task Flow Activities to Invoke a Modal Dialog in Summit ADF Sample Application



How to Run a Bounded Task Flow in a Modal Dialog

You add a view activity and a task flow call activity to an existing task flow. The view activity invokes a page where an end user can invoke an action that, in turn, invokes the bounded task flow to appear in a modal dialog.

Before you begin:

It may be helpful to have an understanding of how the attributes you configure affect the functionality of a bounded task flow in a modal dialog. For more information, see Running a Bounded Task Flow in a Modal Dialog.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Using Dialogs in Your Application.

To run a bounded task flow in a modal dialog box:

1. In the Applications window, double-click the existing task flow.
2. In the diagram for the task flow, double-click the view activity to open the associated page.
3. Select the command component that the end user clicks at runtime to invoke the bounded task flow as a modal dialog box (for example, a `button` component).
4. In the Properties window, expand the **Common** section and enter the control flow case to invoke the bounded task flow in the **Action** field.

   For example, `selectmultipleitems` in Figure 28-1.
5. From the **UseWindow** dropdown list, select **true** to invoke the bounded task flow in a popup dialog.
6. In the diagram for the existing task flow, select the task flow call activity.
7. In the Properties window, expand the **Behavior** section and select **true** from the **Run As Dialog** dropdown list to run the bounded task flow as a dialog.

   The bounded task flow that the task flow activity calls can now behave as a dialog; it can be invoked by the command component you configured in Steps 3 to 5 and can return a value to the view activity that renders the command component, as described in How to Return a Value From a Modal Dialog. Note that you need to make these other changes to run a bounded task flow in a modal dialog. Setting the `run-as-dialog` attribute to `true` is not sufficient.
8. Select **external-window** (the default value) from the **Display Type** dropdown list if you want to render the dialog in an external browser window or **inline-popup** if you want to render the dialog in the same browser window.

How to Return a Value From a Modal Dialog

You can configure a bounded task flow that renders in a modal dialog to return a value to the view activity that invoked the bounded task flow when the end user dismisses the modal dialog. The returned value can, for example, be displayed in an input component on the page associated with the view activity.

You must configure the bounded task flow that is called by the task flow call activity to declare input parameters and return values. For more information, see Passing Parameters to a Bounded Task Flow.

You specify a method binding for a method with one argument (a return event) as the value for the `returnListener` attribute of the command component (for example, a `button` component). The `returnListener` attribute sets this value in the input component on the page associated with the view activity. Specify a backing bean for the input component and set the input component's `partialTrigger` attribute to the ID of the command component.

You also need to specify:

- A return value definition on the called bounded task flow to indicate where to take the return value from upon exit of the called bounded task flow.

- Return values on the task flow call activity in the existing task flow to indicate where the existing task flow can find return values.

  For more information, see Configuring a Return Value from a Bounded Task Flow.

For more information about creating backing beans, input components, and command components, see the "Using Input Components and Defining Forms" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

Before you begin:

It may be helpful to have an understanding of how the attributes you configure affect the functionality of bounded task flows in modal dialogs. For more information, see Running a Bounded Task Flow in a Modal Dialog.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Using Dialogs in Your Application.

You will need to complete this task:

> Configure a bounded task flow to run in a modal dialog. For more information, see How to Run a Bounded Task Flow in a Modal Dialog.

To specify a return value:

1. In the Applications window, double-click the task flow that contains the task flow call activity to invoke the bounded task flow to render in a modal dialog.
2. In the diagram editor, select the task flow call activity.
3. In the Properties window, expand the **Behavior** section and select **true** from the **Run As Dialog** dropdown list.
4. In the **Dialog Return Value** field, enter the name of the return value definition you specified for the target bounded task flow.

   For information about how to specify the return value definition on a bounded task flow, see Configuring a Return Value from a Bounded Task Flow.
5. In the Applications window, double-click the page that launches the modal dialog.
6. In the design editor, select the input component and, in the Properties window, expand the **Behavior** section to specify an EL expression in the **PartialTriggers** field.

   The EL expression you specify identifies the command component, accepts the return value of the command component, and specifies a backing bean. For example, enter an EL expression with syntax similar to the following:

   ```
   #{pageFlowScope.backingBean.gotoModalDialog}
   ```

   where `gotoModalDialog` identifies the command component.
7. In the design editor, select the command component and, in the Properties window, expand the **Behavior** section and enter an EL expression that references a return listener method in the page's backing bean as a value in the **ReturnListener** field.

   The return listener method you specify processes the return event that is generated when an end user dismisses the modal dialog. In the Summit ADF task flow sample application, the command component in the `Orders.jsff` page fragment specifies the following EL expression:

```
#{viewScope.OrdersBackingBean.onShuttleTaskFlowReturn}
```

How to Refresh a Page After a Modal Dialog Returns

You can configure the page from where end users invoke a modal dialog to refresh after end users close the modal dialog. You may want to configure this behavior if the modal dialog returns a value or end users edit existing data in the page through controls in the modal dialog.

You implement this functionality by configuring the command component that invokes the modal dialog to listen for a return event. When it receives the return event, it invokes a backing bean method that executes a partial page render event on your page. The following example shows a `button` component that invokes a modal dialog and listens for a return event.

```
<af:button text="Edit"
    id="b1" binding="#{backingBeanScope.backing_launch_page.b1}"
    action="edit" useWindow="true"
    returnListener="#{backingBeanScope.backing_launch_page.backFromPopup}"/>
```

The `button` component's `returnListener` attributes listens for the return event from invoking the modal dialog. When it receives the return event, it invokes a backing bean method similar to the following example.

```
public void backFromPopup(ReturnEvent returnEvent) {
        AdfFacesContext adfFacesContext;
        adfFacesContext = AdfFacesContext.getCurrentInstance();
        adfFacesContext.addPartialTarget(this.getF1());
}
```

The backing bean method (`backFromPopup`) takes the return event as an argument and, in our example, invokes a partial page render event on a form in the page.

Before you begin:

It may be helpful to have an understanding of how you configure other options for modal dialogs that you invoke from a page associated with a view activity in a task flow. For more information, see Running a Bounded Task Flow in a Modal Dialog.

You may also find it helpful to understand other functionality that can be added using other task flow and dialog framework features. For more information, see Using Dialogs in Your Application Use Cases and Examples.

To refresh a page after a modal dialog returns:

1. In the Applications window, double-click the task flow that invokes the bounded task flow that renders in a modal dialog.
2. In the diagram, double-click the view activity that references the page where your end user invokes a command component to launch the modal dialog.
3. In the design editor, select the command component.
4. In the Properties window, expand the **Behavior** section and, from the **ReturnListener** field under the **Secondary Window** label, select **Edit** from the icon that appears when you hover over the property field to specify the name of the backing bean method that you want JDeveloper to generate.
5. In the Edit Property: ReturnListener dialog, click **New** beside the **Managed Bean** field.

6. In the Create Managed Bean dialog, name the bean and the class, set the bean's scope, and click **OK**.
7. In the Edit Property: ReturnListener dialog, click **New** beside the **Method** field.
8. In the Create Method dialog, name the method and click **OK**.
9. In the Edit Property: ReturnListener dialog, click **OK**.
10. In the Applications window, expand **Application Sources** and then expand the package that contains the backing bean class and method that you created in Steps 3 to 9.
11. Write a method body to invoke a partial page render event on your page.

What You May Need to Know About Dialogs in an Application that Uses Task Flows

If your Fusion web application renders modeless dialogs (non modal dialogs without task flows) and also uses ADF Controller features, such as task flows, you specify the `dialog:syntax` in the control flow rules of the application's `adfc-config.xml` file rather than the `faces-config.xml` file. Specify `dialog:syntax` in navigation rules within the `faces-config.xml` file if your Fusion web application does not use ADF Controller features, as described in Using the ADF Faces Dialog Framework Instead of Bounded Task Flows.

The following example shows what you can specify in the `adfc-config.xml` file. Note that although this example references a JSP page, you can define a view activity that invokes either a JSF page or a page fragment file.

```
<?xml version="1.0" encoding="windows-1252" ?>
  <adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2"
id="__1">
    <view id="view1"
        <page>/view1.jsf</page>
    </view>
    <view id="dialog">
       <page>/dialog/untitled1.jsf</page>
   </view>
   <control-flow-rule>
        <from-activity-id>test</from-activity-id>
        <control-flow-case>
          <from-outcome>dialog:test</from-outcome
          <to-activity-id>dialog</to-activity-id>
         </control-flow-case>
</adfc-config>
```

Using the ADF Faces Dialog Framework Instead of Bounded Task Flows

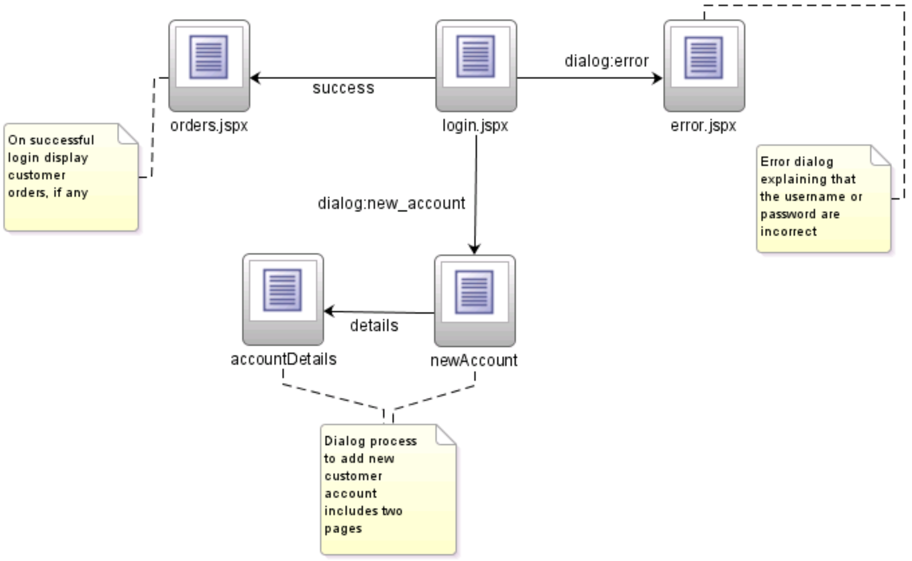
The ADF Faces dialog framework displays a page or a series of pages in a new browser window. To create modal and modeless dialogs in an application using ADF Faces dialog framework, you must define a JSF navigation rule to open a dialog, create the JSF page from which the dialog is opened, and create dialog page and return dialog values.

You can use the ADF Faces dialog framework to create modal and modeless dialogs in an application that does not use ADF Controller and task flows. The dialog framework enables you to display a page or series of pages in a new browser window instead of displaying it in the same window (using the same view ID) as the current page. There may also be cases where you want to use a series of inline dialogs, that is, dialogs that are part of the parent page, but that have a flow of their own, but that do not use a separate view ID. This is important for applications that do not support popups such as, for example, applications that run on client devices or that use the Active Data Service described in Using the Active Data Service . Ordinarily, you would need to use JavaScript to open the dialog and manage the process. With the dialog framework, ADF Faces makes it easy to open a new browser window as well as manage dialogs and processes without using JavaScript.

> **Note:**
>
> If your application uses the Fusion technology stack with ADF Controller, then you should use task flows to create dialogs launched in a separate window, or multiple dialog processes. See Running a Bounded Task Flow in a Modal Dialog.

Consider a simple application that requires users to log in to see their orders. Figure 28-2 shows the page flow for the application, which consists of five pages: `login.jspx`, `orders.jspx`, `new_account.jspx`, `account_details.jspx`, and `error.jspx`.

Figure 28-2 Page Flow of an External Dialog Sample Application



success
dialog:error
orders.jspx
login.jspx
error.jspx
On successful login display customer orders, if any
Error dialog explaining that the username or password are incorrect
dialog:new_account
details
accountDetails
newAccount
Dialog process to add new customer account includes two pages

When an existing user logs in successfully, the application displays the Orders page, which shows the user's orders, if any. When a user does not log in successfully, the Error page displays in a separate popup dialog window, as shown in Figure 28-3.

Note:

The dialog framework should not be used to have more than one dialog open at a time, or to launch dialogs that have a life span outside of the life span of the base page.

To make it easy to support dialog page flows in your applications, ADF Faces has built in the dialog functionality to action components (such as `commandMenuItem` and `button`). For ADF Faces to know whether or not to open a page in a new flow from an action component, the following conditions must exist:

- There must be a JSF navigation rule with an outcome that begins with `dialog:`.
- The command component's action outcome must begin with `dialog:`.
- The `useWindow` attribute on the command component must be `true`.

Note:

If the `useWindow` attribute is `false`, or if you configure the popup to be a separate window (and not inline) and the client device does not support popups, ADF Faces automatically shows the page in the current window instead of using a popup window; code changes are not required to facilitate this action.

The page that displays in a dialog is an ordinary JSF page, but for purposes of explaining how to implement external dialogs in this chapter, a page that displays in a popup dialog is called the *dialog* page, and a page from which the dialog is opened is called the *originating* page. A **dialog process** starts when the originating page opens a dialog (which can contain one dialog page or a series of dialog pages), and ends when the user dismisses the dialog and returns to the originating page.

To create a dialog page flow in an application:

1. Define a JSF navigation rule for opening a dialog.
2. Create the JSF page from which a dialog is opened.
3. Create the dialog page and return a dialog value.

4. Optional: Pass a value into a dialog.
5. Handle the return value.

The tasks can be performed in any order.

How to Define a JSF Navigation Rule for Opening a Dialog

You manage the navigation into a dialog flow by defining a standard JSF navigation rule with a special `dialog:` outcome.

To define a navigation rule to open a dialog:

1. In the Applications window, expand the WEB-INF node and double-click **adfc-config.xml**.
2. In the diagram editor, create a page flow for your originating page and dialog pages.

   For more information, see How to Add a Control Flow Rule to a Task Flow.
3. When creating navigation rules to the dialog pages, the outcome must begin with `dialog:`. For example, in the login sample application shown in Figure 28-2, the outcome from the Login page to the New Account dialog page is `dialog:newAccount`.

At runtime, the dialog navigation rules on their own simply show the specified pages in the originating page. But when used with command components with `dialog:` action outcomes and with `useWindow` attributes set to `true`, ADF Faces opens the pages in dialogs.

How to Create the JSF Page That Opens a Dialog

In the originating page, you need to use a command component to launch the dialog. The command component's action value needs to be the outcome to the dialog that is to be launched.

Before you begin:

It may be helpful to have an understanding of how the attributes you configure affect the functionality of the ADF Faces dialog framework. For more information, see About Using Dialogs in Your Application.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Using Dialogs in Your Application.

You will need to complete this task:

> You also need to create the JSF page that opens a dialog. For more information, see the "Creating a View Page" section in *Developing Web User Interfaces with Oracle ADF Faces*.

To create the JSF Page that opens a dialog:

1. In the Applications window, double-click the JSF page.
2. In the ADF Faces page of the Components window, from the General Controls panel, drag and drop a command component (for example, a **Button**) onto the JSF page.

For more information about adding a command component to a page, see the "Using Buttons and Links for Navigation" section in *Developing Web User Interfaces with Oracle ADF Faces.*

Note the following when setting the attributes on the command component:

- **Action**: Set the action attribute to the outcome that navigates to the dialog, as created in How to Define a JSF Navigation Rule for Opening a Dialog.

  > **Tip:**
  >
  > The action value can be either a static string or the return of a method on a managed bean.

  For example, the action attribute on the command component of the Login page is bound to a method that determines whether to navigate to the Orders page or to the Error dialog page, based on the returned outcome. If the method returns `dialog:error`, the error dialog opens. If the method returns success, the user navigates to the Orders page.

- **ActionListener**: As an alternative to setting the action attribute, configure the `actionListener` attribute to invoke the `launchDialog` method from an instance of the following class:

  ```
  oracle.adf.view.rich.context.AdfFacesContext
  ```

  For more information about the `launchDialog` method and the `AdfFacesContext` class, see the *Java API Reference for Oracle ADF Faces*.

- **UseWindow**: Set to `true` to have the dialog open.

  > **Tip:**
  >
  > When set to `false`, ADF Faces shows the dialog page in the current window after preserving all of the state of the current page. You do not have to write any code to facilitate this.

- **WindowHeight** and **WindowWidth**: Set the desired size of the dialog window. These values will set the `contentWidth` and `contentHeight` attributes on the popup component for the dialog.

  > **Tip:**
  >
  > While the user can change the values of these attributes at runtime, the values will not be retained once the user leaves the page unless you configure your application to use change persistence. For information about enabling and using change persistence, see the "Allowing User Customization on JSF Pages" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

- **PartialSubmit**: Set to true. This prevents the originating page from reloading (and hence being visible only momentarily) when the popup dialog is displayed.

- **WindowEmbedStyle**: Set to `inlineDocument` if you want the dialog to open in a popup that belongs to the originating page. Set to `window` if you want the dialog to open in a separate browser.
- **WindowModalityType**: Set to `applicationModal` if you want the dialog to be modal. Modal dialogs do not allow the user to return to the originating page until the dialog has been dismissed. Set to `modeless` if you want the user to be able to go back and forth between the originating page and the dialog.

When a command component is about to open a dialog, it delivers a `LaunchEvent` event. The `LaunchEvent` event stores information about the component that is responsible for opening a popup dialog, and the root of the component tree to display when the dialog process starts. A `LaunchEvent` can also pass a map of parameters into the dialog. For more information, see How to Pass a Value into a Dialog.

How to Create the Dialog Page and Return a Dialog Value

A dialog page is just like any other JSF page, with one exception. In a dialog page, you must provide a way to tell ADF Faces when the dialog process finishes, that is, when the user dismisses the dialog or series of dialogs.

For example, the New Account page and Account Details page belong in the same dialog process. A dialog process can have as many pages as you desire, you only need to notify the framework that the dialog process has ended once.

You do this declaratively using the `returnActionListener` tag as a child to the command component used to close the dialog. However, if you need to provide a return value or other action event processing, you can bind the `actionListener` attribute on the command component to a method that calls the `AdfFacesContext.returnFromDialog()` method. This method lets you send back a return value in the form of a `java.lang.Object` or a `java.util.Map` of parameters. You do not have to know where you are returning the value to - ADF Faces automatically takes care of it.

At runtime, the `AdfFacesContext.returnFromDialog()` method tells ADF Faces when the user dismisses the dialog. This method can be called whether the dialog page is shown in a popup dialog or in the main window. If a popup dialog is used, ADF Faces automatically closes it.

Before you begin:

It may be helpful to have an understanding of how the attributes you configure affect the functionality of the ADF Faces dialog framework. For more information, see About Using Dialogs in Your Application.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Using Dialogs in Your Application.

To close a dialog window and optionally return a value:

1. In the Applications window, double-click the dialog page.
2. In the ADF Faces page of the Components window, from the General Controls panel, drag and drop a command component (for example, a **Button**) onto the dialog page.

For more information about adding a command component to a page, see the "Using Buttons and Links for Navigation" section in *Developing Web User Interfaces with Oracle ADF Faces.*

3. If the command component will be used to close the window, in the Properties window, expand the **Behavior** section and select **true** from the **Immediate** dropdown list.
4. If the command component will be used to navigate to another page in the dialog process, configure the command component as though it were standard navigation. To do this, in the Properties window, expand the **Common** section and select **false** from the **UseWindow** dropdown list. This causes the next page to display in the same dialog window, preserving the state of the previous page.
5. If you need to end the dialog process and close the dialog, but do not need to return a value, in the Components window, from the Operations panel, in the Listeners group, drag a **Return Action Listener** and drop it as a child to the command component.

   The `returnActionListener` tag calls the `returnFromDialog` method on the `AdfFacesContext` object - no backing bean code is needed.

   No attributes are used with the `af:returnActionListener` tag. The `immediate` attribute on the `af:button` component is set to `true` if the user clicks **Cancel** without entering values in the required **Password** and **Confirm Password** fields, the default JSF `ActionListener` can execute during the Apply Request Values phase instead of the Invoke Application phase, thus bypassing input validation. For more information, see the "Using the JSF Lifecycle with ADF Faces" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
6. If you need to end the dialog process and do need to return a value, create a method on a managed bean that handles the `action` event and returns the needed values using the `returnFromDialog` method on the current instance of `AdfFacesContext`.

   > **Note:**
   >
   > The `AdfFacesContext.returnFromDialog()` method returns `null`. This is all that is needed in the backing bean to handle the Cancel action event.

   For example, when the user clicks **Done** on the Account Details page, the process ends and returns the user input values. The following example shows the code for the event handler method to which the **Done** button binds. The method gets the customer information, then either creates a Faces message for an incorrect password, or sets the values on the new customer object and return that object.

```
public void done(ActionEvent e)
{
  AdfFacesContext afContext = AdfFacesContext.getCurrentInstance();
  String firstname = afContext.getPageFlowScope().get("firstname").toString();
  String lastname = afContext.getPageFlowScope().get("lastname").toString();
  String street = afContext.getPageFlowScope().get("street").toString();
  String zipCode = afContext.getPageFlowScope().get("zipCode").toString();
  String country = afContext.getPageFlowScope().get("country").toString();
  String password = afContext.getPageFlowScope().get("password").toString();
  String confirmPassword =
   afContext.getPageFlowScope().get("confirmPassword").toString();
  if (!password.equals(confirmPassword))
  {
    FacesMessage fm = new FacesMessage();
    fm.setSummary("Confirm Password");
    fm.setDetail("You've entered an incorrect password. Please verify that you've
     entered a correct password!");
    FacesContext.getCurrentInstance().addMessage(null, fm);
  }
  else
  {
    //Get the return value
    Customer cst = new Customer();
    cst.setFirstName(firstname);
    cst.setLastName(lastname);
    cst.setStreet(street);
    cst.setPostalCode(zipCode);
    cst.setCountry(country);
    cst.setPassword(password);
    // And return it
    afContext.getCurrentInstance().returnFromDialog(cst, null);
  }
}
```

What Happens at Runtime: How to Raise the Return Event from the Dialog

When the dialog is dismissed, ADF Faces generates a return event (ReturnEvent). The AdfFacesContext.returnFromDialog() method sends a return value as a property of the return event. The return event is delivered to the return listener (ReturnListener) that is registered on the command component that opened the dialog (for example, the **New User** link on the Login page). How you handle the return value is described in How to Handle the Return Value.

How to Pass a Value into a Dialog

To pass a value into a dialog, you use a LaunchListener listener bound to a handler method for the LaunchEvent. You can use the getDialogParameters() method to add a parameter to a Map using a key-value pair.

Before you begin:

It may be helpful to have an understanding of how the attributes you configure affect the functionality of the ADF Faces dialog framework. For more information, see About Using Dialogs in Your Application.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Using Dialogs in Your Application.

To pass a value into a dialog:

1. In the Applications window, double-click the JSF page that contains the command component used to navigate to the dialog page.
2. In the design editor, select the command component used to navigate to the dialog page.
3. In the Properties window, expand the **Behavior** section.

4. From the icon that appears when you hover over the **LaunchListener** property field, select **Edit**.
5. In the Edit Property: LaunchListener dialog, click **New** beside the **Managed Bean** field.
6. In the Create Managed Bean dialog, name the bean and the class, set the bean's scope, and click **OK**.
7. In the Edit Property: LaunchListener dialog, click **New** beside the **Method** field.
8. In the Create Method dialog, name the method and click **OK** and click **OK** to close the Edit Property: LaunchListener dialog.
9. In the Applications window, expand **Application Sources** and then expand the package that contains the bean class and method that you created in Steps 3 to 8.
10. In the source editor, write a handler method for the `LaunchEvent` that uses the `getDialogParameters` method to get the parameters from a dialog.

    For example, in the sample application, a new user can enter a name in the **Username** field on the Login page, and then click the **New User?** link. When the New Account dialog page displays in a popup dialog, the **First Name** input field is automatically populated with the name that was entered in the Login page. To accomplish this, you create a handler that uses the `getDialogParameters` method to put the value of the username field into the dialog, as shown in the following example.

    ```
    public void handleLaunch(LaunchEvent event)
    {
      //Pass the current value of the field into the dialog
      Object usr = username;
      event.getDialogParameters().put("firstname", getUsername());
    }
    // Use by inputText value binding
    private String username;
    public String getUsername()
    {
      return username;
    }
    public void setUsername(String username)
    {
      this.username = username;
    }
    ```

11. In the Applications window, double-click the dialog page.
12. On the dialog page, use the `pageFlowScope` object to retrieve the key and value via a special EL expression in the format `#{pageFlowScope.someKey}`, as shown in the following example.

    ```
    <af:inputText label="First name" value="#{pageFlowScope.firstname}"/>
    ```

What Happens at Runtime: How the LaunchEvent is Handled

In ADF Faces, a process always gets a copy of all the values that are in the `pageFlowScope` of the page from which a dialog is launched. When the `getDialogParameters()` method has added parameters to a `Map`, those parameters also become available in `pageFlowScope`, and any page in the dialog process can get the values out of `pageFlowScope` by referring to the `pageFlowScope` objects via EL expressions.

> **Note:**
>
> Unlike `sessionScope`, `pageFlowScope` values are visible only in the current page flow or process. If the user opens a new window and starts navigating, that series of windows has its own process; values stored in each window remain independent. Clicking on the browser's Back button automatically resets `pageFlowScope` to its original state. When you return from a process the `pageFlowScope` is back to the way it was before the process started. To pass values out of a process you use `AdfFacesContext.returnFromDialog()`, `sessionScope` or `applicationScope`.

How to Handle the Return Value

To handle a return value once the dialog is dismissed, you define a return listener on the command component that launched the dialog. For example, in the sample application, once a new user enters information, that information needs to be handled once the dialog process is complete.

Before you begin:

It may be helpful to have an understanding of how the attributes you configure affect the functionality of the ADF Faces dialog framework. For more information, see About Using Dialogs in Your Application.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Using Dialogs in Your Application.

To handle the return value:

1. In the Applications window, double-click the JSF page that contains the command component used to navigate to the dialog page.
2. In the design editor, select the command component used to navigate to the dialog page.
3. In the Properties window, expand the **Behavior** section.
4. From the icon that appears when you hover over the **ReturnListener** property field, select **Edit**.
5. In the Edit Property: ReturnListener dialog, click **New** beside the **Managed Bean** field.
6. In the Create Managed Bean dialog, name the bean and the class, set the bean's scope, and click **OK**.
7. In the Edit Property: ReturnListener dialog, click **New** beside the **Method** field.
8. In the Create Method dialog, name the method and click **OK** and click **OK** to close the Edit Property: LaunchListener dialog.
9. In the Applications window, expand **Application Sources** and then expand the package that contains the bean class and method that you created in Steps 3 to 8.

10. In the source editor, write a handler method for the `returnEvent`. You use the `getReturnValue()` method to retrieve the return value, because the return value is automatically added as a property of the `ReturnEvent`.

    The following example shows the code for the return listener method that handles the return value.

    ```
    public void handleReturn(ReturnEvent event)
    {
      if (event.getReturnValue() != null)
      {
        Customer cst;
        String name;
        String psw;
        cst = (Customer)event.getReturnValue();
        name = cst.getFirstName();
        psw = cst.getPassword();
        CustomerList.getCustomers().add(cst);
        inputText1.setSubmittedValue(null);
        inputText1.setValue(name);
        inputText2.setSubmittedValue(null);
        inputText2.setValue(psw);
      }
    }
    ```

What Happens at Runtime: How the Launching Component Handles the ReturnEvent

At runtime in the sample application, when ADF Faces delivers a `ReturnEvent` to the `ReturnListener` registered on the `link` component, the `handleReturn()` method is called and the return value is processed accordingly. The new user is added to a customer list, and as a convenience to the user any previously submitted values in the Login page are cleared and the input fields are populated with the new information.

Part V

Creating a Databound Web User Interface

This part describes how to design the user interface of the Fusion web application using ADF Faces components.

Part V contains the following chapters:

29

Getting Started with Your Web Interface

This chapter describes how to get started with ADF data controls to create databound UI components, using ADF Faces components in the Fusion web application. It describes how to use page templates and page fragments to build a page. It also describes how to use managed beans to store logic for the page.
This chapter includes the following sections:

About Developing a Web Application with ADF Faces

ADF Faces is a set of Ajax-enabled JavaServer Faces (JSF) components that can be used to develop web applications with a minimal amount of hand-coded Javascript. You can use ADF Model data binding during the development of the web application that provides additional functionality.

Most of what you need to know to get started with your web interface is covered in Introduction to ADF Faces in *Developing Web User Interfaces with Oracle ADF Faces*. However, using the ADF Model layer for data binding instead of JSF managed beans provides additional functionality, such as the ability to declaratively bind components to your business services. For information on what ADF Model can provide, see Using ADF Model in a Fusion Web Application.

This chapter provides a high-level overview of the web interface development process as detailed in the Faces guide, and also provides information about the additional functionality available when you use ADF Model data binding.

Following the development process outlined in Introduction to Building Fusion Web Applications with Oracle ADF, developing a web application with ADF Faces and using ADF Model for data binding involves the following steps:

- Creating ADF Faces templates for your pages (optional)
- Creating the individual pages and page fragments for regions to be used within a page
- Creating any needed managed beans

Additionally, the lifecycle of a Fusion web application is different from that of a standard JSF or ADF Faces application. For information about how the lifecycle works, see Understanding the Fusion Page Lifecycle .

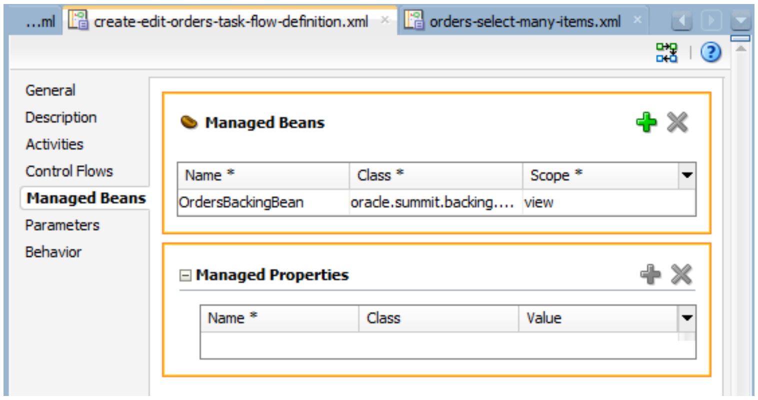
Managed beans are Java classes that give you the flexibility to add UI level code to your pages and task flows. You can use them for functions such as front end data manipulation and event handling.

ADF Faces page templates provides structure, consistency, and reusability for building web pages. You can create a page template and apply it to several pages for a consistent look and feel. It saves you time and effort because you do not need to layout the same elements each time you create a page.

Page Template and Managed Beans Use Cases and Examples

In the `create-edit-orders-task-flow-definition`, the `ShuttleBean` is used for code to support a shuttle component to shuttle the available products from the leading list to the selected products in the trailing list. The managed bean contains the code necessary to populate the available products list and the selected products list. Figure 29-1 shows the managed beans used in the `create-edit-orders-task-flow-definition`.

Figure 29-1   Managed Beans in the create-edit-orders-task-flow-definition



Managed Beans

Name *	Class *	Scope *
OrdersBackingBean	oracle.summit.backing....	view

Managed Properties

Name *	Class	Value

Additional Functionality for Page Templates and Managed Beans

You may find it helpful to understand other **Oracle ADF** features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- For more information about using page templates, see Using ADF Model in a Fusion Web Application, and the How to Create a Page Template section of *Developing Web User Interfaces with Oracle ADF Faces*.
- For more information about managed beans in a standard JSF application, see the Java EE tutorial on the Oracle Technology Network website (`http://www.oracle.com/technetwork/java/javaee/overview/index.html`). For more information about managed beans and scope values, see About Object Scope Lifecycles.

Using Page Templates

ADF Page templates let you define entire page layouts, including values for certain attributes of the page. You can use any of the quick layout designs or you can create your own layout for a template.

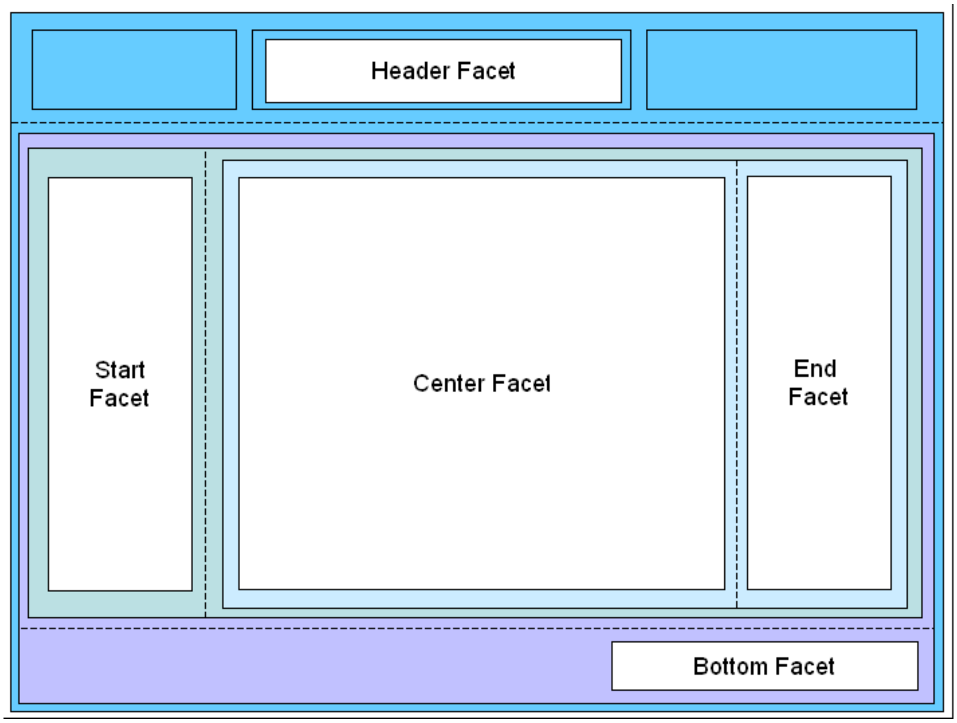
As you design the flow of your application, you can begin to think about the design of your pages. To ensure consistency throughout your application, you use ADF page templates. These page templates provide structure and consistency for other developers building web pages. Page templates typically contain static areas which cannot be changed when they are used, and dynamic areas, where developers can place content specific to the page they are building.

For example, a page template can provide a top area for branding and navigation, a bottom area for copyright information, and a center area for the main content of the page. Page developers do not need to do anything to the branding and copyright information when they use the template. They need only to develop the main content area.

In addition to using ADF Faces components to build a page template, you can add attributes to the template definition. These attributes provide placeholders for specific information that the page developer needs to provide when using the page template. For instance, if you have added an attribute for a welcome message and when page developers use this page template, they can add a different welcome message for each page.

You can also add facet references to the page template. These references act as placeholders for content on the page. Figure 29-2 shows a rendition of how facets can be used in a page template.

Figure 29-2 Facets in the Page Template



In this page template, facet references are used inside four different `panelSplitter` components. When the home page was created using this page template, the navigational links were placed in the Header facet and the accordion panels that hold the navigation trees and search panels were placed in the Start facet. The cart summary was placed in the End facet, and the main portion of the page was placed in the Center facet. The copyright information was placed in the Bottom facet.

When you choose to add databound components to a page template, an associated page definition file and the other metadata files that support ADF Model layer data binding are created. Each component is bound in the same fashion as for standard JSF pages, as described in Using ADF Model in a Fusion Web Application. You can also create model parameters for the page template. The values for these parameters can then be set at runtime by the calling page.

For example, if you wanted a list of products to appear on each page that uses the page template, you could drag and drop the `Name` attribute of the `ProductVO` collection as a list. Or, if you wanted the pages to display the currently selected product Id, you could create a model parameter for the page template that would evaluate to that product's Id.

> **Note:**
>
> Page templates are primarily a project artifact. While they can be reused between projects and applications, they are not fully self-contained and will always have some dependencies to external resources, for example, any ADF data binding, `Strings` from a message bundle, images, and managed beans.

If a page template does not contain databound components, it can be referenced dynamically by the calling page using an EL expression. That is, the page template to be used can be determined at runtime. For instance, a page may use templateA or templateB based on user selection. When you add a page template to a page, an `af:pageTemplate` tag is added to the page. The `af:pageTemplate` tag includes a `viewId` attribute that specifies the page template the page will use. You can set `viewId` with an EL expression to a managed bean method that returns the page template `Id`, as shown in the following example.

```
<af:pageTemplate
    id="pt1"
    viewId="#{myBean.templateViewId}"
```

If the page template has databound components, setting the `viewId` with an EL expression is not enough. Because databound components require access to the binding container, you must specify the page template as well as its associated binding container.

For databound page templates, you use the `pageTemplateModel` to manage both the page template `Id` and the associated binding container. In the JSF page, instead of using the `viewId` attribute, you set the `value` attribute to the `pageTemplateModel`. You must also modify the page executable section of the calling page's page definition file and create a managed bean with methods to process the page template `Ids`. For detailed instructions, see How to Add a Databound Page Template to a Page Dynamically.

How to Use ADF Data Binding in ADF Page Templates

Creating a page template for use in an application that uses **ADF Business Components** and ADF Model layer data binding is the same as creating a standard ADF Faces page template, as documented in the Using Page Templates section of *Developing Web User Interfaces with Oracle ADF Faces*. Once you create the template, you can drag and drop items from the Data Controls panel. JDeveloper automatically adds the page definition file when you drag and drop items from this panel.

The Create a Page Template wizard also allows you to create model parameters for use by the template.

Before you begin:

It may help to understand the options that are available to you when you create a basic page template. For more information, see Using Page Templates.

You may also find it useful to understand additional functionality that can be used with page templates. For more information, see Additional Functionality for Page Templates and Managed Beans.

You will need to complete this task:

> Create a page template that uses ADF Business Components and ADF Model layer data binding by following the instructions in the How to Create a Page Template section of *Developing Web User Interfaces with Oracle ADF Faces*. However, do not complete the dialog

To add model parameters to a template:

1. In the Data Binding page of the Create a Page Template wizard, select **Create Page Definition File**.

   > **Note:**
   >
   > You only need to select this checkbox if you wish to add parameters. JDeveloper automatically adds the page definition file when you drag and drop items from the Data Controls panel.

2. Click the **Add** icon.
3. Enter the following for the parameter:
   - **Id**: Enter a name for the parameter.
   - **Value**: Enter a value or an EL expression that can resolve to a value. If needed, click the Invoke Expression Builder (...) button to open the Expression Builder. You can use this to build the expression. For more information about EL expressions and the EL expression builder, see Creating ADF Data Binding EL Expressions.
   - **Option**: Select the option that determines how the parameter value will be specified.
     - **optional**: The binding definition's value is used only if the parameter is not specifically set by the caller. This is the default.

   - **final**: The binding definition has the expression to access the value that should be used for this parameter.
   - **mandatory**: The parameter value has to be set by the caller.
- **Read Only**: Select if the parameter's value is to be read-only and should not be overwritten

4. Create more parameters as needed. Use the order buttons to arrange the parameters into the order in which you want them to be evaluated.

You can now use the Data Controls panel to add databound UI components to the page, as you would for a standard JSF page, as described in the remaining chapters in this part of the book.

> **Note:**
>
> If your template contains any method actions bound to a method iterator, you cannot change the value of the `refresh` attribute on the iterator to anything other than `Default`. If set to anything other than `Default`, the method will not execute.

What Happens When You Use ADF Model Layer Bindings on a Page Template

When you add ADF databound components to a template or create model parameters for a template, a page definition file is created for the template, and any model parameters are added to that file.

> **Note:**
>
> This section describes what happens for a statically assigned page template. For information about dynamic templates, see How to Add a Databound Page Template to a Page Dynamically.

The following example shows what the page definition file for a template for which you created a `productId` model parameter might look like.

```
<parameters>
  <parameter id="productID" readonly="true"
             value="#{bindings.productId.inputValue}"/>
</parameters>
<executables/>
<bindings/>
```

Parameter binding objects declare the parameters that the page evaluates at the beginning of a request. For more information about binding objects and the ADF lifecycle, see Using ADF Model in a Fusion Web Application. However, since a template itself is never executed, the page that uses the template (the *calling* page) must access the binding objects created for the template (including parameters or any other type of binding objects created by dragging and dropping objects from the Data Controls panel onto the template).

In order to access the template's binding objects, the page definition file for the calling page must instantiate the binding container represented by the template's page definition file. As a result, a reference to the template's page definition is inserted as an executable into the calling page's page definition file, as shown in the following example.

```
<executables>
  <page path="oracle.summt.view.pageDefs.MyTemplatePageDef"
        id="pageTemplateBinding"/>
</executables>
```

In this example, the calling page was built using the `MyTemplate` template. Because the page definition file for the `MyTemplate` template appears as an executable for the calling page, when the calling page's binding container is instantiated, it will in turn instantiate the `MyTemplatePageDef`'s binding container, thus allowing access to the parameter values or any other databound values.

Because there is an ID for this reference (in this case, `pageTemplateBinding`), the calling page can have components that are able to access values from the template. When you create a JSF page from a template, instead of you having to repeat the code contained within the template, you can use the `af:pageTemplate` tag on the calling page. This tag contains the path to the template JSF page.

Additionally, when the template contains any ADF data binding, the value of that tag is the ID set for the calling page's reference to the template's page definition, as shown in the following example.

```
<af:pageTemplate viewId="/MyTemplate.jspx"
                 value="#{bindings.pageTemplateBinding}".../>
```

How to Add a Databound Page Template to a Page Dynamically

You can dynamically add a page template without databound components by using an EL expression to select the page template. For more information on how to do this, see Using Page Templates.

You can also statically add a page template with databound components. For more information on how to do this, see How to Use ADF Data Binding in ADF Page Templates.

This section describes how to dynamically add a page template with databound components to a page. For more information, see Using Page Templates.

You use the `pageTemplateModel` to dynamically manage a page template and its binding container. You use an EL expression in the page definition file to set the page template `Id`. You create managed bean methods to return the page template `Id`.

Before you begin:

It may help to understand the options that are available to you when you create a basic page template. For more information, see Using Page Templates.

You may also find it useful to understand additional functionality that can be used with page templates. For more information, see Additional Functionality for Page Templates and Managed Beans.

You will need to complete this task:

> Create a page template that uses ADF Business Components and ADF Model layer data binding as described in How to Use ADF Data Binding in ADF Page Templates.

To add a databound page template to a page dynamically:

1. In the JSF page source editor, remove the `viewId` attribute and change the `value` attribute to the `pageTemplateModel`. You do not need to create a `pageTemplateModel` explicitly. You can use the `pageTemplateModel` from the corresponding page definition file's page executable binding. For example, for a page executable binding called `pageTemplate1`, you would add the following line under the `af:pageTemplate` tag:

   ```
   value="#{bindings.pageTemplate1.templateModel}"/>
   ```

2. In the page definition file `<executable>` section, make the following changes to the `<page>` section:

   - Remove the `path` attribute. It is no longer needed. The `pageTemplateModel` manages databound components' access to the binding container.
   - Change the `id` attribute to the page executable binding. In this example, it is `pageTemplate1`.
   - Add a `Refresh` attribute and set it to `ifNeeded`.
   - Add a `viewId` attribute and set it to an EL expression with a managed bean method that returns the current page template `Id`.

   For example, for a page executable binding of `pageTemplate1`, the `id` attribute would also be `pageTemplate1`:

   ```
   <executables>
     <page id="pageTemplate1"
           viewId="#{myBean.templateViewId}"
           Refresh="ifNeeded"/>
     ...
   </executables>
   ```

3. Create a `pageFlowScope` managed bean with a method that returns the current page template `Id`.

   The managed bean code should be similar to that in the following example. In this example, `gettemplateViewId()` obtains the user's page template selection and returns the page template `Id`. `setMDTemplateViewId()` sets the page template to be `MDPageTemplate` and `setPopupTemplateViewId()` sets the page template to be `PopupPageTemplate`.

   ```
   public class myClass {
       final private String MDPageTemplate = "/MDPageTemplate.jspx";
       final private String PopupPageTemplate = "/PopupPageTemplate.jspx";
       private String templateViewId;

       public myClass() {
           super();
           templateViewId = MDPageTemplate;
       }
       public String gettemplateViewId() {
           return templateViewId;
       }
       public void setMDTemplateViewId(ActionEvent ae) {
   ```

```
            templateViewId = MDPageTemplate;
        }
        public void setPopupTemplateViewId(ActionEvent ae) {
            templateViewId = PopupPageTemplate;
        }
    }
```

What Happens at Runtime: How Pages Use Templates

When a page is created using a template that contains ADF data binding, like a page without a template, the page definition file is used to create the page. During the lifecycle, the binding container for page template is also created and the UI components and biding for both the page and template are processed.

Specifically, the following happens:

1. The calling page follows the standard JSF/ADF lifecycle, as documented in Understanding the Fusion Page Lifecycle. As the page enters the Restore View phase, the URL for the calling page is sent to the binding context, which finds the corresponding page definition file.
2. During the Initialize Context phase, the binding container for the calling page is created based on the page definition file.
3. During the Prepare Model phase, the page template executable is refreshed. At this point, the binding container for the template is created based on the template's page definition file, and added to the binding context.
4. The lifecycle continues, with UI components and bindings from both the page and the template being processed.

Creating a Web Page

During the development of a Fusion web application, web pages are built using page templates and page fragments. You can create a web page using the Create JSF Page dialog and you can also secure web pages within the ADF Security framework.

You can create pages either by double-clicking a view activity in a task flow or by using the New Gallery. When creating the page (or dropping a view activity onto a task flow), you can choose to create the page as a JSF JSP or as a JSF JSP fragment. JSF fragments provide a simple way to create reusable page content in a project, and are what you use when you wish to use task flows as regions on a page. When you modify a JSF page fragment, the JSF pages that consume the page fragment are automatically updated.

> **Note:**
>
> Although JDeveloper supports XHTML files to be used in applications that use Facelets, the `faces-config.xml` and `adfc-config.xml` diagrammers do not support XHTML. In order to add navigation to these files, you have to manually edit the code by clicking the **Source** tab.

When you begin adding content to your page, you typically use the Components window and Data Controls panel of JDeveloper. The Components window contains all the ADF Faces components needed to declaratively design your page. Once you have the basic layout components placed on the page, you can then drag and drop items from the Data Controls panel to create ADF Model databound UI components. The remaining chapters in this part of the book explain in detail the different types of databound components and pages you can create using ADF Model data binding.

How to Create a Web Page

You create web pages using the Create JSF Page dialog.

Before you begin:

It may be helpful to have an understanding of the different options when creating a page. For more information, see Creating a Web Page.

To create a web page:

1. In the Applications window, right-click the node (directory) where you would like the page to be saved, and choose **New > Page**.
2. Complete the Create JSF Page dialog. For help, click **Help** in the dialog.

For more information on the templates available and what happens when you create the page, see Creating a View Page section in *Developing Web User Interfaces with Oracle ADF Faces*.

What You May Need to Know About Creating Blank Web Pages

When you create a new blank web page, the generated code might differ depending on the type of project you are working in and the tag libraries that have been imported in the project. For example, if you are working in a project created from the Custom Project template and you select the **Create Blank Page** option in the Create JSF page dialog, the generated code might not include ADF Faces tags as it would under similar circumstances in the UI project of an ADF Fusion Web Application workspace.

If you want to create a page without a pre-defined layout that includes ADF Faces tags, it might be easiest to select the **Copy Quick Start Layout** option in the Create JSF page dialog and select a simple layout. Selecting this option will trigger the importing of the ADF Faces tag library into the project. In addition, any subsequent pages that you create in the project, even those created with the **Create Blank Page** option selected, will use ADF Faces tags.

What You May Need to Know About Securing a Web Page

When creating web pages, you should have a plan for how you will apply security to them.

To secure a web page within the ADF Security framework, you actually secure the page's page definition file. If the page is within a bounded task flow, you secure the bounded task flow (and the security policies applied to that bounded task flow apply to all of the pages within the task flow). If a page is within a bounded task flow, you should *not* apply security policies to the page definition file, as that could enable a user to access the page directly.

For more information on securing web pages, see Defining ADF Security Policies.

Using a Managed Bean in a Fusion Web Application

A standard JSF application includes one or more managed beans, each of which can be associated with the components used in a particular page. Managed Beans must be registered in the configuration files of JSF application or Fusion web application.

Managed beans are Java classes that you register with the application using various configuration files. When the JSF application starts up, it parses these configuration files, and the beans listed within them are made available. The managed beans can be referenced in an EL expression, allowing access to the beans' properties and methods. Whenever a managed bean is referenced for the first time and it does not already exist, the Managed Bean Creation Facility instantiates the bean by calling the default constructor method on it. If any properties are also declared, they are populated with the declared default values.

Often, managed beans handle events or some manipulation of data that is best handled at the front end. For a more complete description of how managed beans are used in a standard JSF application, see the Java EE tutorial on the Oracle Technology Network website (`http://www.oracle.com/technetwork/java/javaee/overview/index.html`).

> **Best Practice:**
>
> Use managed beans to store logic that is related to the UI rendering only. All application data and processing should be handled by logic in the business layer of the application. Similar to how you store data-related logic in the database using PL/SQL rather than a Java class, the rule of thumb in a Fusion web application is to store business-related logic in the middle tier. This way, you can expose this logic as business service methods, which can then become accessible to the ADF Model layer and be available for data binding.

In an application that uses ADF data binding and ADF task flows, managed beans are registered in different configuration files from those used for a standard JSF application. In a standard JSF application, managed beans are registered in the `faces-config.xml` configuration file. In a Fusion web application, managed beans can be registered in the `faces-config.xml` file, the `adfc-config.xml` file, or a task flow definition file. Which configuration file you use to register a managed bean depends on what will need to access that bean, whether or not it needs to be customized at runtime, what the bean's scope is, and in what order all the beans in the application need to be instantiated. Table 29-1 describes how registering a bean in each type of configuration file affects the bean.

> **Note:**
>
> Fusion web applications take advantage of the functionality provided by ADF task flows. Managed beans accessed within the task flow definition must be registered in that task flow's definition file and not in the `faces-config.xml` file.

Table 29-1 Effects of Managed Bean Configuration Placement

Managed Bean Placement	Effect
`adfc-config.xml`	• Managed beans can be of any scope. However, any backing beans for page fragments or declarative components should use `BackingBean` scope. For information regarding scope, see About Object Scope Lifecycles. • When executing within an unbounded task flow, `faces-config.xml` will be checked for managed bean definitions before the `adfc-config.xml` file. • Lookup precedence is enforced per scope. Request-scoped managed beans take precedence over session-scoped managed beans. Therefore, a request-scoped managed bean named `foo` in the `adfc-config.xml` file will take precedence over a session-scoped managed bean named `foo` in the current task flow definition file. • Already instantiated beans take precedence over new instances being instantiated. Therefore, an existing session-scoped managed bean named `foo` will always take precedence over a request-scoped bean named `foo` defined in the current task flow definition file.
Task flow definition file	• Managed bean can be of any scope. However, managed beans of `pageFlow` scope or `view` scope that are to be accessed within the task flow definition must be defined within the task flow definition file. Any backing beans for page fragments in a task flow should use `BackingBean` scope. • Managed bean definitions within task flow definition files will be visible only to activities executing within the same task flow. • When executing within a bounded task flow, `faces-config.xml` will be checked for managed bean definitions before the currently executing task flow definition. If no match is found in either location, `adfc-config.xml` and other bootstrap configuration files will be consulted. However, this lookup in other `adfc-config.xml` and bootstrap configuration files will only occur for session- or application-scoped managed beans. • Lookup precedence is enforced per scope. Request-scoped managed beans take precedence over session-scoped managed beans. Therefore, a request-scoped managed bean named `foo` in the `adfc-config.xml` file will take precedence over a session-scoped managed bean named `foo` in the current task flow definition file. • Already instantiated beans take precedence over new instances being instantiated. Therefore, an existing session-scoped managed bean named `foo` will always take precedence over a request-scoped bean named `foo` registered in the current task flow definition file. • Customizations are allowed.

Table 29-1 (Cont.) Effects of Managed Bean Configuration Placement

Managed Bean Placement	Effect
faces-config.xml	• Managed beans can be of any scope other than pageFlow scope or view scope. • When searching for any managed bean, the faces-config.xml file is always consulted first. Other configuration files will be searched only if a match is not found. Therefore, beans registered in the faces-config.xml file will always win any naming conflict resolution. • No customizations can be made.

As a general rule for Fusion web applications, a bean that may be used in more than one page or task flow, or one that is used by pages within the main unbounded task flow (adfc-config), should be registered in the adfc-config.xml configuration file. A managed bean that will be used only by a specific task flow should be registered in that task flow's definition file. There should be no beans registered in the faces-config.xml file.

Note:

If you create managed beans from dialogs within JDeveloper, the bean is registered in the adfc-config.xml file, if it exists.

For example, in the Summit sample application for Oracle ADF, the ShuttleBean is a managed bean used by the showshuttle page to handle the selections in the shuttle component on that page. Because it is used solely within the create-edit-orders-task-flow-definition task flow, it is registered in the create-edit-orders-task-flow-definition definition file.

You can create a managed bean for use within a task flow (either the default adfc-config flow or any bounded task flow). For more information regarding managed beans and how they are used as backing beans for JSF pages, see Creating and Using Managed Beans in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Use a Managed Bean to Store Information

Within the editors for a task flow definition, you can create a managed bean and register it with the JSF application at the same time.

Before you begin:

It may help to understand the options that are available to you when you create a managed bean. For more information, see Using a Managed Bean in a Fusion Web Application.

You may also find it useful to understand additional functionality that can be used with managed beans. For more information, see Additional Functionality for Page Templates and Managed Beans.

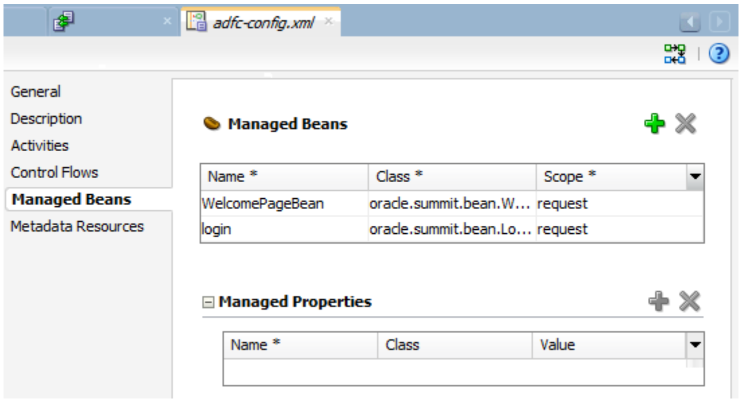
You will need to complete this task:

Create the configuration file (if it doesn't already exist) that you want the managed bean to be associated with. This can be `faces-config.xml`, `adfc-config.xml`, or a bounded task flow definition file.

To create a managed bean for adfc-config.xml or a task flow:

1. In the Applications window, double-click either the **adfc-config.xml** file or any other task flow definition file.
2. In the overview editor, click the **Managed Beans** navigation tab. Figure 29-3 shows the editor for the `adfc-config.xml` file.

Figure 29-3 Managed Beans in the adfc-config.xml File



Name *	Class *	Scope *
WelcomePageBean	oracle.summit.bean.W...	request
login	oracle.summit.bean.Lo...	request

Name *	Class	Value

3. In the Managed Bean page, click the **Add** icon to add a row to the **Managed Beans** table.
4. In the fields, enter the following:
   - **Name**: A name for the bean.
   - **Class**: If the corresponding class has already been created for the bean, use the browse (...) button for the **managed-bean-class** field to search for and select the class. If a class does not exist, enter the name you'd like to use. Be sure to include any package names as well. You can then use the drop-down menu to choose **Generate Class**, and the Java file will be created for you.
   - **Scope**: The bean's scope. For more information about the different object scopes, see About Object Scope Lifecycles.

> **Note:**
>
> When determining what scope to register a managed bean with or to store a value in, keep the following in mind:
>
> – Always try to use the narrowest scope possible.
>
> – If your managed bean takes part in component binding by accepting and returning component instances (that is, if UI components on the page use the binding attribute to bind to component properties on the bean), then the managed bean must be stored in `BackingBean` scope. If it can't be stored in one of those scopes (for example, if it needs to be stored in `sessionScope` for high availability reasons), then instead of using component binding, you need to use the ComponentReference API. For more information, see the What You May Need to Know About Component Bindings and Managed Beans section of *Developing Web User Interfaces with Oracle ADF Faces*
>
> – Use the `sessionScope` scope only for information that is relevant to the whole session, such as user or context information. Avoid using the `sessionScope` scope to pass values from one page to another.
>
> – You can also set the scope to `none`. While not technically a scope, `none` means that the bean will not live within any particular scope, but will instead be instantiated each time it is referenced. You should set a bean's scope to `none` when it is referenced by another bean.

5. You can optionally add needed properties for the bean. With the bean selected in the **Managed Beans** table, click the **Add** icon for the **Managed Properties** table. Enter a property name (other fields are optional).

> **Note:**
>
> While you can declare managed properties using this editor, the corresponding code is not generated on the Java class. You will need to add that code by creating private member fields of the appropriate type and then using the **Generate Accessors** menu item on the context menu of the source editor to generate the corresponding getter and setter methods for these bean properties.

What Happens When You Create a Managed Bean

When you use the configuration editor to create a managed bean and elect to generate the Java file, JDeveloper creates a stub class with the given name and a default constructor. The following example shows the code added to the `MyBean` class stored in the view package.

```
package view;
```

```
public class MyBean {
    public MyBean() {
    }
}
```

You now need to add the logic required by your task flow or page. You can then refer to that logic using an EL expression that refers to the `managed-bean-name` value given to the managed bean. For example, to access the `myInfo` property on the bean, the EL expression would be:

```
#{my_bean.myInfo}
```

JDeveloper also adds a `managed-bean` element to the appropriate task definition file. The following shows the `managed-bean` element created for the `MyBean` class.

```
<managed-bean>
  <managed-bean-name>my_bean</managed-bean-name>
  <managed-bean-class>view.MyBean</managed-bean-class>
  <managed-bean-scope>session</managed-bean-scope>
</managed-bean>
```

How to Set Managed Bean Memory Scopes in a Server-Cluster Environment

Typically, in an application that runs in a clustered environment, a portion of the application's state is serialized and copied to another server or a data store at the end of each request so that the state is available to other servers in the cluster.

> **Note:**
>
> If the managed bean will be calling `set` and `get` methods on ADF Faces components, you cannot serialize the managed beans because ADF Faces components are not serializable. You will need to access the ADF Faces components in another way.

When you are designing an application to run in a clustered environment, you must:

- Ensure that all managed beans with a lifespan longer than one request are serializable (that is, they implement the `java.io.Serializable` interface). Specifically, beans stored in session scope, page flow scope, and view scope need to be serializable.

  > **Tip:**
  >
  > To identify failures with objects stored in page flow scope and view scope, use `writeObject()`. This method provides additional information in an exception about the object and scope that failed to serialize. Additional information might be a region's page flow scope and the key of the object.

- Make sure that the framework is aware of changes to managed beans stored in ADF scopes (view scope and page flow scope).

When a value within a managed bean in either view scope or page flow scope is modified, the application needs to notify the framework so that it can ensure that the bean's new value is replicated.

In this example, an attribute of an object in view scope is modified.

```
Map<String, Object> viewScope =
    AdfFacesContext.getCurrentInstance().getViewScope();
MyObject obj = (MyObject)viewScope.get("myObjectName");
Obj.setFoo("newValue");
```

Without additional code, the framework will be unaware of this change and it will not know that a new value needs to be replicated within the cluster. To inform the framework that an object in an ADF scope has been modified and that replication is needed, use the `markScopeDirty()` method, as shown in the following example. The `markScopeDirty()` method accepts only `viewScope` and `pageFlowScope` as parameters.

```
    ControllerContext ctx = ControllerContext.getInstance();
    ctx.markScopeDirty(viewScope);
```

This code is needed for any request that modifies an existing object in one of the ADF scopes. If the scope itself is modified by the scope's `put()`, `remove()`, or `clear()` methods, it is not necessary to notify the framework.

If an application is not deployed to a clustered environment, the tracking of changes to ADF memory scopes is not needed, and by default, this functionality is disabled. To enable ADF Controller to track changes to ADF memory scopes and replicate the page flow scope and view scope within the server cluster, set the `<adf-scope-ha-support>` parameter in the `adf-config.xml` file to `true`. Because scope replication has a small performance overhead, it should be enabled only for applications running in a server-cluster environment.

The folllowing shows `adf-scope-ha-support` set to `true` in the `adf-config.xml` file.

```
<?xml version="1.0" encoding="US-ASCII" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
      xmlns:adfc="http://xmlns.oracle.com/adf/controller/config">
   <adfc:adf-controller-config>
   ...
    <adfc:adf-scope-ha-support>true</adfc:adf-scope-ha-support>
   ...
  </adfc:adf-controller-config>
   ...
</adf-config>
```

30
Understanding the Fusion Page Lifecycle

This chapter describes the ADF page lifecycle, its phases, and how to best use the lifecycle within a Fusion web application.
This chapter includes the following sections:

About the Fusion Page Lifecycle

The Fusion page lifecycle provides support for a web page to interact with ADF Model data bindings. You can learn about the sequence of events that occur while processing a web page request using JSF and Oracle ADF.

When a JSF page is submitted and a new page is requested, the JSF page request lifecycle is invoked. This lifecycle handles the submission of values on the page, validation for components on the current page, navigation to and display of the components on the resulting page, as well as saving and restoring state. The JSF lifecycle phases use a UI component tree to manage the display of the components. This tree is a runtime representation of a JSF page: each UI component tag in a page corresponds to a UI component instance in the tree.

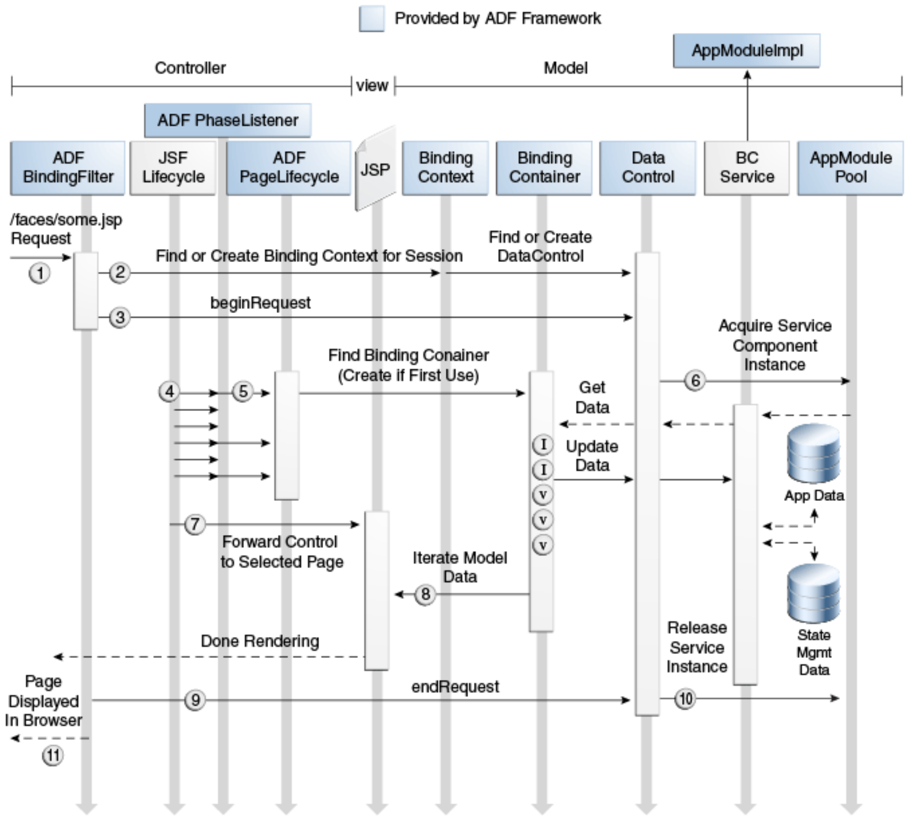
The `FacesServlet` object manages the page request lifecycle in JSF applications. The `FacesServlet` object creates an object called `FacesContext`, which contains the information necessary for request processing, and invokes an object that executes the lifecycle.

In addition to the JSF lifecycle, the ADF Faces and ADF page lifecycle are also run. The ADF Faces lifecycle extends the JSF lifecycle, providing additional functionality, such as a client-side value lifecycle, a subform component that allows you to create independent submittable sections on a page without the drawbacks (for example, lost user edits) of using multiple forms on a single page, and additional scopes. For information about both the JSF lifecycle and the ADF Faces lifecycle, including what you can do with the lifecycle for your application, see Using the JSF Lifecycle with ADF Faces.

The ADF page lifecycle handles preparing and updating the data model, validating the data at the model layer, and executing methods on the business layer. The ADF page lifecycle uses the binding container to make data available for easy referencing by the page during the current page request.

The combined JSF and ADF page lifecycle is only one sequence within a larger sequence of events that begins when an HTTP request arrives at the application server and continues until the page is returned to the client. This overall sequence of events can be called the **web page lifecycle**. It follows processing through the model, view, and controller layers as defined by the MVC architecture. The page lifecycle is not a rigidly defined set of events, but is rather a set of events for a typical use case. Figure 30-1 shows a sequence diagram of the lifecycle of a web page request using JSF and **Oracle ADF** in tandem.

Figure 30-1 Lifecycle of a Web Page Request Using JSF and Oracle ADF



The basic flow of processing a web page request using JSF and Oracle ADF happens as follows:

1. A web request for `http://yourserver/yourapp/faces/some.jsp` arrives from the client to the application server.
2. The `ADFBindingFilter` object looks for the ADF binding context in the HTTP session, and if it is not yet present, initializes it for the first time. Some of the functions of the `ADFBindingFilter` include finding the name of the binding context metadata file, and finding and constructing an instance of each data control.
3. The `ADFBindingFilter` object invokes the `beginRequest()` method on each data control participating in the request. This method gives the data control a notification at the start of every request so that it can perform any necessary setup.
4. The JSF `Lifecycle` object, which is responsible for orchestrating the standard processing phases of each request, notifies the `ADFPhaseListener` class during each phase of the lifecycle, so that it can perform custom processing to coordinate the JSF lifecycle with the ADF Model data binding layer. For information about the details of the JSF and ADF page lifecycle phases, see About the JSF and ADF Page Lifecycles.

> **Note:**
>
> The FacesServlet class (in javax.faces.webapp), configured in the web.xml file of a JSF application, is responsible for initially creating the JSF Lifecycle class (in javax.faces.lifecycle) to handle each request. However, since it is the Lifecycle class that does all the interesting work, the FacesServlet class is not shown in the diagram.

5. The ADFPhaseListener object creates an ADF PageLifecycle object to handle each request and delegates the appropriate before and after phase methods to corresponding methods in the ADF PageLifecycle class. If the binding container for the page has never been used before during the user's session, it is created.
6. The first time an **application module data control** is referenced during the request, it acquires an instance of the application module from the **application module pool**.
7. The JSF Lifecycle object forwards control to the page to be rendered.
8. The UI components on the page access value bindings and iterator bindings in the page's binding container and render the formatted output to appear in the browser.
9. The ADFBindingFilter object invokes the endRequest() method on each data control participating in the request. This method gives a data control notification at the end of every request, so that they can perform any necessary resource cleanup.
10. An application module data control uses the endRequest notification to release the instance of the application module back to the application module pool.
11. The user sees the resulting page in the browser.

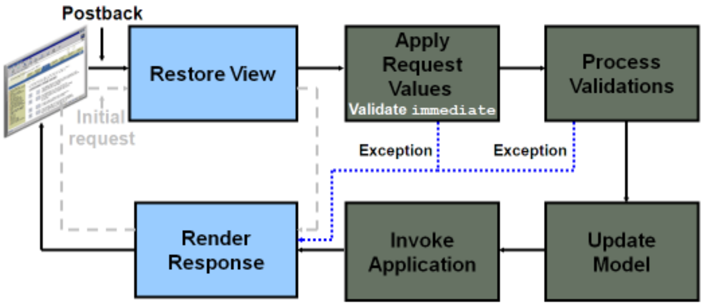
The ADF page lifecycle also contains phases that are defined simply to notify ADF page lifecycle listeners before and after the corresponding JSF phase is executed (that is, there is no implementation for these phases). These phases allow you to create custom listeners and register them with any phase of both the JSF and ADF page lifecycles, so that you can customize the ADF page lifecycle if needed, both globally or at the page level.

About the JSF and ADF Page Lifecycles

The JSF and ADF page lifecycles perform a sequence of events that begins when an HTTP request arrives at the application server and continues until the page is returned to the client. You can learn about the different phases of a page lifecycle in a JSF application that uses an ADF Model.

Figure 30-2 shows a high-level view of the combined JSF and ADF page lifecycles.

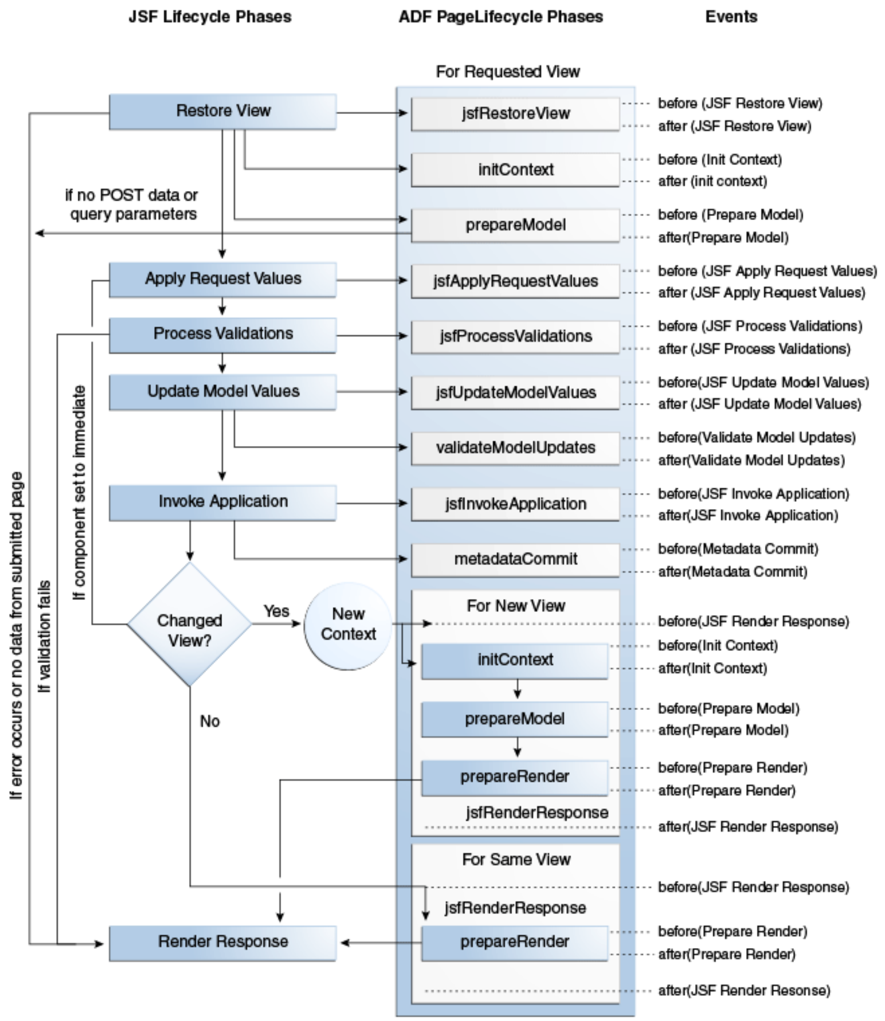
Figure 30-2 JSF and ADF Page Lifecycles



Say for example, you have a page with some text displayed in an input text component and a button. When that page is first rendered, the component tree is built during the Restore View phase and then the lifecycle goes straight to the Render Response phase, as the components are rendered. When the user clicks the button, the full lifecycle is invoked. The component tree is rebuilt, the input text component extracts any new value during the Apply Request Values phase and Process Validations phase, and if there is an error, for example due to validation, then the lifecycle jumps to the Render Response phase. Otherwise, the model is then updated with the new value during the Update Model phase, and then any application processing associated with the button (such as navigation), is executed during the Invoke Application phase.

Figure 30-3 shows the details of how the JSF and ADF Faces and ADF Model phases integrate in the lifecycle of a page request.

Figure 30-3 Lifecycle of a Page Request in a Fusion Web Application



In a JSF application that uses ADF Model, the phases in the page lifecycle are as follows:

- Restore View: The URL for the requested page is passed to the `bindingContext` object, which finds the page definition file that matches the URL. The component tree of the requested page is either newly built or restored. All the component tags, event handlers, converters, and validators on the submitted page have access to the `FacesContext` instance. If the component tree is empty, (that is, there is no data from the submitted page), the page lifecycle proceeds directly to the Render Response phase.

  If any discrepancies between the request state and the server-side state are detected, an error will is thrown and the page lifecycle jumps to the Render Response phase.

- JSF Restore View: Provides before and after phase events for the Restore View phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Restore View phase. The Initialize Context phase of the ADF Model page lifecycle listens for the `after(JSF Restore View)` event and then executes. ADF Controller uses listeners for the before and after events of this phase to synchronize the server-side state with the request. For example, it is in this phase that browser back button detection and bookmark reference are handled. After the before and after listeners are executed, the page flow scope is available.

- Initialize Context: The page definition file is used to create the `bindingContainer` object, which is the runtime representation of the page definition file for the requested page. The `LifecycleContext` class used to persist information throughout the ADF page lifecycle phases is instantiated and initialized with values for the associated request, binding container, and lifecycle.
- Prepare Model: The ADF page lifecycle enters the Prepare Model phase by calling the `BindingContainer.refresh(PREPARE_MODEL)` method. During the Prepare Model phase, `BindingContainer` page parameters are prepared and then evaluated. If parameters for a task flow exist, they are passed into the flow.

  Next, any executables that have their refresh property set to `prepareModel` are refreshed based on the order of entry in the page definition file's `<executables>` section and on the evaluation of their `RefreshCondition` properties (if present). When an executable leads to an iterator binding refresh, the corresponding data control will be executed, and that leads to execution of one or more collections in the service objects. If an iterator binding fails to refresh, a JBO exception will be thrown and the data will not be available to display. For more information about the `RefreshCondition` property, see pageNamePageDef.xml.

  If the incoming request contains no `POST` data or query parameters, then the lifecycle forwards to the Render Response phase.

  If the page was created using a template, and that template contains bindings using ADF Model, the template's page definition file is used to create the binding container for the template. The container is then added to the binding context.

  If any `taskFlow` executable bindings exist (for example, if the page contains a region), the `taskFlow` binding creates an ADF Controller `ViewPortContext` object for the task flow, and any nested binding containers for pages in the flow are then executed.
- Apply Request Values: Each component in the tree extracts new values from the request parameters (using its decode method) and stores those values locally. Most associated events are queued for later processing. If you have set a component's `immediate` attribute to `true`, then the validation, conversion, and events associated with the component are processed during this phase and the lifecycle skips the Process Validations, Update Model Values, and Invoke Application phases. Additionally, any associated iterators are invoked. For more information about ADF Faces validation and conversion, see the Validating and Converting Input chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- JSF Apply Request Values: Provides before and after phase events for the Apply Request Values phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Apply Request Values phase.
- Process Validations: Local values of components are converted and validated on the client. If there are errors, the lifecycle jumps to the Render Response phase. At the end of this phase, new component values are set, any validation or conversion error messages and events are queued on `FacesContext`, and any value change events are delivered. Exceptions are also caught by the binding container and cached.

- JSF Process Validations: Provides before and after phase events for the Process Validations phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Process Validations phase.
- Update Model Values: The component's validated local values are moved to the model and the local copies are discarded. For any updateable components (such as an `inputText` component), corresponding iterators are refreshed, if the refresh condition is set to the default (`deferred`) and the refresh condition (if any) evaluates to `true`.

  If you are using a backing bean for a JSF page to manage your UI components, any UI attributes bound to a backing bean property will also be refreshed in this phase.
- JSF Update Model Values: Provides before and after phase events for the Update Model Values phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Update Model Values phase.
- Validate Model Updates: The updated model is now validated against any validation routines set on the model. Exceptions are caught by the binding container and cached.
- Invoke Application: Any action bindings for command components or events are invoked.
- JSF Invoke Application: Provides before and after phase events for the Invoke Application phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Invoke Application phase.
- Metadata Commit: Changes to runtime metadata are committed. This phase stores any runtime changes made to the application using the Metadata Service (MDS). For more information about using MDS to persist runtime changes, see Customizing Applications with MDS.
- Initialize Context (only if navigation occurred in the Invoke Application lifecycle): The Initialize Context phase listens for the `beforeJSFRenderResponse` event to execute. The page definition file for the next page is initialized.
- Prepare Model (only if navigation occurred in the Invoke Application lifecycle): Any page parameters contained in the next page's definition are set.
- Prepare Render: The binding container is refreshed to allow for any changes that may have occurred in the Apply Request Values or Validation phases. Any iterators that correspond to read-only components (such as an `outputText` component) are refreshed. Any dynamic regions are switched, if needed. The `prepareRender` event is sent to all registered listeners, as is the `afterJSFRenderResponse` event.

> **Note:**
>
> Instead of displaying `prepareRender` as a valid phase for a selection, JDeveloper displays `renderModel`, which represents the `refresh(RENDER_MODEL)` method called on the binding container.

- Render Response: The components in the tree are rendered as the Java EE web container traverses the tags in the page. State information is saved for subsequent requests and the Restore View phase.

  In order to lessen the wait time required to display both a page and any associated data, certain ADF Faces components such as the `table` component, use data streaming for their initial request. When a page contains one or more of these components, the page goes through the normal lifecycle. However, instead of fetching the data during that request, a special separate request is run. Because the page has just rendered, only the Render Response phase executes for the components that use data streaming, and the corresponding data is fetched and displayed. If the user's action (for example scrolling in a table), causes a subsequent data fetch another request is executed. Collection-based components, such as tables, trees, tree tables, and data visualization components all use data streaming.
- JSF Render Response: Provides before and after phase events for the Render Response phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Render Response phase.

What You May Need to Know About Partial Page Rendering and Iterator Bindings

ADF Faces provides an optimized lifecycle that you can use when you want the page request lifecycle (including conversion and validation) to be run only for certain components on a page, usually for components whose values have changed.

One way to use the optimized lifecycle is to manually set up dependencies so that the events from one component act as triggers for another component, known as the *target*. When any event occurs on the trigger component, the lifecycle is run on any target components, as well as on any child components of both the trigger and the target, causing only those components to be rerendered. This is considered a partial page rendering (PPR)

The following example shows radio buttons as triggers and a `panelGroupLayout` component that contains the output text to be the target (the `panelGroupLayout` component must be the target because the `outputText` component may not always be rendered).

```
<af:form>
  <af:inputText label="Required Field" required="true"/>
  <af:selectBooleanRadio id="show" autoSubmit="true"
text="Show"
                        value="#{validate.show}"/>
  <af:selectBooleanRadio id="hide" autoSubmit="true" text="Hide"
                         value="#{validate.hide}"/>
  <af:panelGroupLayout partialTriggers="show hide" id="panel">
    <af:outputText value="You can see me!" rendered="#{validate.show}"/>
  </af:panelGroupLayout>
</af:form>
```

Because the `autoSubmit` attribute is set to `true` on the radio buttons, when they are selected, a `SelectionEvent` is fired. Because the `panelGroupLayout` component is set to be a target for both radio components, when that event is fired, only the `selectOneRadio` (the trigger), the `panelGroupLayout` component (the trigger's target), and its child component (the `outputText` component) are processed through the lifecycle. Because the `outputText` component is configured to render only when the **Show** radio button is selected, the user is able to select that radio button and see the output text, without having to enter text into the required input field above the radio buttons.

Instead of having to set partial triggers and targets within code manually, the ADF Faces framework provides automatic PPR. Automatic PPR happens when an event has a corresponding event root component, or when the component itself is an event root. An event root component determines the boundaries of PPR. For example, the `attributeChangeEvent` considers the `inputText` component that invokes the event, its event root. Therefore, in the previous example, when the value changes for the `inputText` component, because it is the initial boundary for the PPR, the lifecycle would be run only on that `inputText` component and any child components.

Along with event roots, by default for Fusion web applications, automatic PPR also occurs for all UI components associated with the same iterator binding. All associated components refresh whenever any one of them has a value change event. This functionality is controlled by setting the `changeEventPolicy` attribute for iterators to `ppr`. By default, this is set globally.

For example, say you create a number of `inputText` components using the Data Controls panel (for example, when you create a form). When the `attributeChangeEvent` occurs on one of those `inputText` components, because the other `inputText` components are associated with the same iterator, all those `inputText` components will also be refreshed.

Another example might be a page that contains a `panelSplitter` component, where the left part of the splitter contains a form to create a new customer (created by dropping a form using the `Customer` collection), and the right part of the splitter contains instructions for using the form. Because the bindings for the `inputText` components that make up the form are all associated with the `Customer` iterator, anytime the form is submitted and a value for one of the `inputText` components has changed, only the `inputText` components associated with the `Customer` will be processed through the lifecycle. The rest of the page, including the instructions in the right side of the splitter, will not be refreshed.

Note:

In order for automatic PPR to happen, the event and event root component must be listed in Table 5-1 of the Events and Partial Page Rendering section of *Developing Web User Interfaces with Oracle ADF Faces*. If it is not listed, you will need to set up PPR manually, as described in the Using Partial Triggers section of the same guide.

For example, say you create a form and a table from the same data control collection. The form shows the details for a row of data, while the table shows all rows in a collection, with the row currently displayed in the form shown as selected. When you click the **Next** button on the form, you want the table to refresh to show the new row as selected. Because the selection event is not supported by automatic PPR, the table will not refresh, even though the table and form both use the same iterator. You will need to set the **Next** and **Previous** buttons to be triggers of PPR for the target table.

> **Note:**
>
> Only UI components that have a control binding defined in the page definition file associated with the configured iterator will be refreshed.
>
> If you directly access the iterator from a managed bean and expose iterator values to UI components through that bean, then automatic PPR will not happen for those UI components. In these cases, you need to configure PPR manually. For more information, see the Using Partial Triggers section of *Developing Web User Interfaces with Oracle ADF Faces*.

By default, all new applications use global PPR. You do not have to set it. You can however, override the setting in the page definition file for a page.

Before you begin:

It may be helpful to have an understanding of partial page rendering. For more information, see What You May Need to Know About Partial Page Rendering and Iterator Bindings.

To set iterator bindings to use PPR:

1. To set a specific iterator binding to use or not use PPR, open the associated page definition file, select the iterator, and in the Properties window, set **ChangeEventPolicy**.
2. To set all iterator bindings to use PPR:
   a. In the Applications Resource panel, expand the **Descriptors** and **ADF META-INF** nodes, and then double click **adf-config.xml**.
   b. In the overview editor, click the **Model** navigation tab, and then select **Default Change Event Policy is Partial Page Rendering (PPR)**.

For more information about how the ADF Faces framework uses PPR, see the Rerendering Partial Page Content chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

What You May Need to Know About Task Flows and the Lifecycle

Task flows are initially refreshed when the parent binding container (the one associated with the page) is refreshed. This happens in the Prepare Model phase. On a subsequent request, the task flow will be refreshed during the Prepare Render phase, depending on its `refresh` and `refreshCondition` attributes and its parameter value.

> **Note:**
>
> Any child page fragment's page definition still handles the refresh of the bindings of the child page fragments.

Tip:

If you have a region on a page that is not initially disclosed (for example, a popup dialog), the parameters still need to be available when the parent page is rendered, even though the region might not be displayed. If a region requires parameters, but those parameter values will not be available when the parent page is rendered, then you should use dynamic regions. If the parameters are null, an empty task flow can be used until the parameters for the region are ready and that region can display. To swap in an empty task flow, you set the dynamic region's `taskFlowId` attribute to an empty string.

If you set an EL expression as the value of the `refreshCondition` attribute, it will be evaluated during the Prepare Render phase of the lifecycle. When the expression evaluates to `true`, the task flow will be refreshed again. When `refreshCondition` evaluates to `false`, the behavior is the same as if the `refreshCondition` had not been specified.

Note:

If the variable `bindings` is used within the EL expression, the context refers to the binding container of the parent page, not the page fragment displayed within the region.

The valid values for the `refresh` property of a task flow executable are as follows:

- `default`: The region will be refreshed only once, when the parent page is first displayed.
- `ifNeeded`: Refreshes the region only if there has been a change to `taskFlow` binding parameter values. If the `taskFlow` binding does not have parameters, then `ifNeeded` is equivalent to the default. When `ifNeeded` is used, the `refreshCondition` attribute is not considered.

> **Note:**
>
> Setting the `refresh` attribute to `ifNeeded` takes precedence over any value for the `refreshCondition` attribute. Also note that `ifNeeded` is not supported when you pass parameters to the `taskFlow` binding using a dynamic parameter `Map`. Instead, use `refreshCondition="#{EL.Expression}"`.

Because the only job of the `taskFlow` binding is to refresh its parameters, setting `Refresh` to `always` does not make sense. If the `taskFlow` binding's parameters don't change, there is no reason to refresh the ADF region.

Note that the child page fragment's page definition still handles the refresh of the bindings of the child page fragments.

About Object Scope Lifecycles

When an object is created in a JSF application, it defines or defaults to a given scope; this object scope describes how widely it is available and who has access to it. You can use the standard JSF scopes or the ADF Faces scopes that are available for an object in a JSF application.

At runtime, ADF objects such as the binding container and managed beans are instantiated. Each of these objects has a defined lifespan set by its scope attribute. You can access a scope as a `java.util.Map` from the `RequestContext` API. For example, to access an object named `foo` in the request scope, you would use the expression `#{requestScope.foo}`.

Object scopes are analogous to global and local variable scopes in programming languages. The wider the scope, the higher and longer the availability of an object. During their life, these objects may expose certain interfaces, hold information, or pass variables and parameters to other objects. For example, a managed bean defined in session scope will be available for use during multiple page requests. However, a managed bean defined in request scope will only be available for the duration of one page request.

There are six types of scopes in a Fusion web application:

- Application scope: The object is available for the duration of the application.
- Session scope: The object is available for the duration of the session.

> **Note:**
>
> There is no window uniqueness for session scope, all windows in the session share the same session scope instance. If you are concerned about multiple windows being able to access the same object (for example to ensure that managed beans do not conflict across windows), you should use a scope that is window-specific, such as page flow or view scope.

- Page flow scope: The object is available for the duration of a task flow. As its name suggests, page flow scope is specific to an instance of a task flow (bounded or unbounded). So if you have a page with two or more regions (created by a task flow), separate instances of the page flow scope will exist for each region. Additionally, if the user opens the page with the regions in separate browser tabs, a separate instance of the page flow scope bean will be instantiated for each browser tab.

> **Note:**
>
> Because this is not a standard JSF scope, EL expressions must explicitly include the scope to reference bean. For example, to reference the `MyBean` managed bean from the `pageFlowScope` scope, your expression would be `#{pageFlowScope.MyBean}`.

- Request scope: The object is available from the time an HTTP request is made until a response is sent back to the client.
- Backing bean scope: Used for managed beans for page fragments and declarative components only, the object is available from the time an HTTP request is made until a response is sent back to the client. This scope is needed for fragments and declarative components because there may be more than one page fragment or declarative component on a page, and to prevent collisions, any values must be kept in separate scope instances. Therefore, any managed bean for a page fragment or declarative component must use backing bean scope.

> **Note:**
>
> Because this is not a standard JSF scope, EL expressions must explicitly include the scope to reference bean. For example, to reference the `MyBean` managed bean from the backing bean scope, your expression would be `#{backingBeanScope.MyBean}`.

- View scope: The object is available until the view ID for the current view activity changes. This scope can be used to hold values for a given page. However, unlike request scope, which can be used to store a value needed from one page to the next, anything stored in view scope will be lost once the view ID changes.

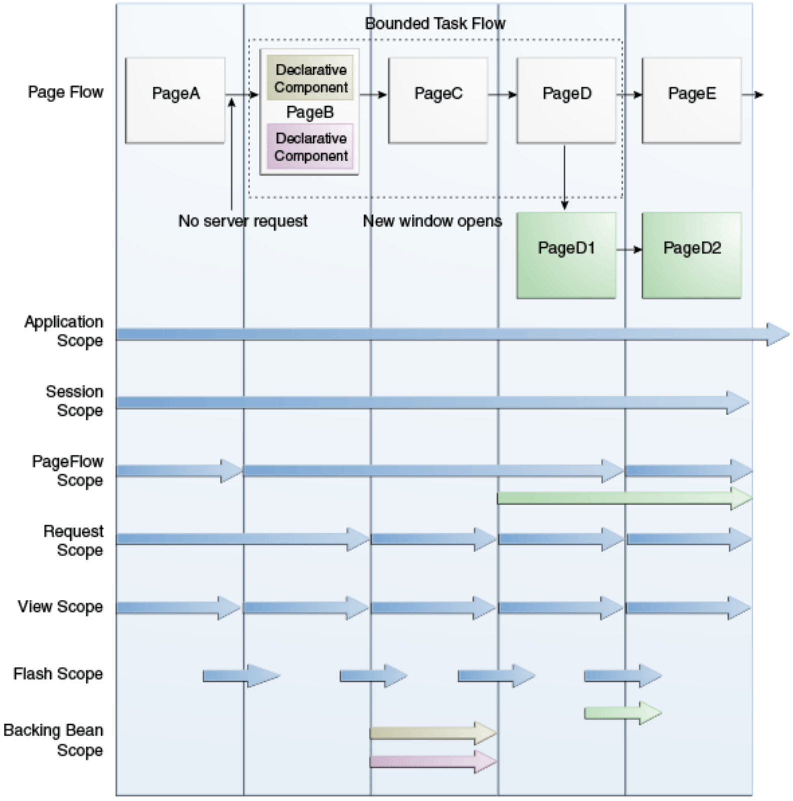
> **Note:**
>
> Both JSF and ADF Faces have an implementation of view scope. Only the ADF Faces view scope survives page redirects and refreshes. In a Fusion web application, when you use `viewScope` in an expression, it resolves to the ADF Faces view scope.
>
> Because this view scope is not a standard JSF scope, EL expressions must explicitly include the scope to reference bean. For example, to reference the `MyBean` managed bean from the view scope, your expression would be `#{viewScope.MyBean}`.

> **Note:**
>
> When you create objects (such as a managed bean) that require you to define a scope, you can set the scope to `none`, meaning that it will not live within any particular scope, but will instead be instantiated each time it is referenced.

By default, the binding container and the binding objects it contains are defined in session scope. However, the *values* referenced by value bindings and iterator bindings are undefined between requests and for scalability reasons do not remain in session scope. Therefore, the values that binding objects refer to are valid only during a request in which that binding container has been prepared by the ADF lifecycle. What stays in session scope are only the binding container and binding objects themselves.

Figure 30-4 shows the time period during which each type of scope is valid.

Figure 30-4 Relationship Between Scopes and Page Flow



When determining what scope to register a managed bean with, always try to use the narrowest scope possible. Only use the session scope for information that is relevant to the whole session, such as user or context information. Avoid using session scope to pass values from one task flow to another. When creating a managed bean for a page fragment or a declarative component, you must use backing bean scope.

Managed beans can be registered in either the `adfc-config.xml` or the configuration file for a specific task flow. For more information about using managed beans in a Fusion application, see Using a Managed Bean in a Fusion Web Application.

Note:

Do not register managed beans in the `faces-config.xml` in a Fusion web application.

What You May Need to Know About Object Scopes and Task Flows

When determining what scope to use for variables within a task flow, you should use any of the scope options other than application or session scope. These two scopes will persist objects in memory beyond the life of the task flow and therefore compromise the encapsulation and reusable aspects of a task flow. In addition, application and session scopes may keep objects in memory longer than needed, causing unneeded overhead.

When you need to pass data values between activities within a task flow, you should use page flow scope. View scope should be used for variables that are needed only within the current view activity, not across view activities. Request scope should be used when the scope does not need to persist longer than the current request. It is the only scope that should be used to store UI component information. Lastly, backing bean scope must be used for backing beans in your task flow if there is a possibility that your task flow will appear in two region components or declarative components on the same page and you would like to achieve region instance isolations.

Customizing the ADF Page Lifecycle

The ADF page lifecycle performs a sequence of events that occur while processing a web page request using JSF and Oracle ADF. You can create and register a custom phase listeners to customize the ADF page lifecycle.

The ADF lifecycle contains clearly defined phases that notify ADF lifecycle listeners before and after the corresponding JSF phase is executed. You can customize this lifecycle by creating a custom phase listener that invokes your needed code, and then registering it with the lifecycle to execute during one of these phases.

> **Note:**
>
> An application cannot have multiple phase listener instances. An initial `ADFPhaseListener` instance is, by default, registered in the `META-INF/faces-config.xml` configuration file. Registering, for example, a customized subclass of the `ADFPhaseListener` creates a second instance. In this scenario, only the instance that was most recently registered is used.
>
> The following warning message indicates when an instance has been replaced by a newer one: "ADFc: Replacing the ADF Page Lifecycle implementation with *class name of the new listener*."

How to Create a Custom Phase Listener

To create a custom phase listener, you must create a listener class that implements the `PagePhaseListener` interface. You then add methods that execute code either before or after the phase that the code needs to execute.

The following example contains a template that you can modify to create a custom phase listener. See How to Generate Custom Classes, for more information about creating a class in JDeveloper.

```
public class MyPagePhaseListener implements PagePhaseListener
{
   public void afterPhase(PagePhaseEvent event)
   {
      System.out.println("In afterPhase " + event.getPhaseId());
   }

   public void beforePhase(PagePhaseEvent event)
```

```
    {
       System.out.println("In beforePhase " + event.getPhaseId());
    }
}
```

Once you create the custom listener class, you need to register it with the phase in which the class needs to be invoked. You can either register it globally (so that the whole application can use it), or you can register it only for a single page.

How to Register a Listener Globally

To customize the ADF lifecycle globally, register your custom phase listener by editing the `adf-settings.xml` configuration file. The `adf-settings.xml` file is shared by several ADF components, including ADF Controller, to store configuration information.

To register the listener in adf-settings.xml:

1. In the Applications window, beneath the **META-INF** node, double-click the **adf-settings.xml** file.
2. In the editor window, click the **Source** tab
3. In the source editor, scroll down to `<adfc-controller-config xmlns= "http://xmlns.oracle.com/adf/controller/config">`

   If this entry does not exist, add it to the file.
4. Enter the remaining elements shown in italics:

```
 <?xml version="1.0" encoding="US-ASCII" ?> <adf-config xmlns="http://
xmlns.oracle.com/adf/config">
  .
  .
  .
    <adfc-controller-config xmlns="http://xmlns.oracle.com/adf/controller/
config">
       <lifecycle>
         <phase-listener>
            <listener-id>MyPagePhaseListener</listener-id>
            <class>mypackage.MyPagePhaseListener</class>
         </phase-listener>
      </lifecycle>
   </adfc-controller-config>
  .
  .
  .
</adf-config>
```

5. Add values for the following elements:
   - `<listener-id>` A unique identifier for the listener (you can use the fully qualified class name)
   - `<class>` The class name of the listener

What You May Need to Know About Listener Order

You can specify multiple phase listeners in the `adf-settings.xml` and, optionally, the relative order in which they are called. When registering a new listener in the file, you determine the position in the list of listeners using two parameters:

- `beforeIdSet`: The listener is called before any of the listeners specified in `beforeIdSet`
- `afterIdSet`: The listener is called after any of the listeners specified in `afterIdSet`

The following example contains an example configuration file in which multiple listeners have been registered for an application.

```
<lifecycle>
   <phase-listener>
      <listener-id>MyPhaseListener</listener-id>
      <class>view.myPhaseListener</class>
      <after-id-set>
         <listener-id>ListenerA</listener-id>
         <listener-id>ListenerC</listener-id>
      </after-id-set>
      <before-id-set>
         <listener-id>ListenerB</listener-id>
         <listener-id>ListenerM</listener-id>
         <listener-id>ListenerY</listener-id>
      </before-id-set>
   </phase-listener>
</lifecycle>
```

In the example, `MyPhaseListener` is a registered listener that executes after listeners A and C but before listeners B, M, and Y. To execute `MyPhaseListener` after listener B, move the `<listener-id>` element for listener B under the `<after-id-set>` element.

How to Register a Lifecycle Listener for a Single Page

To customize the lifecycle of a single page, you set the `ControllerClass` attribute on the page definition file. This listener will be valid only for the lifecycle of the particular page described by the page definition. For more information about the page definition file and its role in a Fusion web application, see Working with Page Definition Files.

You specify a different controller class depending on whether it is for a standard JSF page or a page fragment.

To customize the ADF Lifecycle for a single page or page fragment:

1. In the Applications window, right-click the page or page fragment and choose **Go To Page Definition**.
2. In the Structure window, select the page definition node.
3. In the Properties window, click the icon that appears when you hover over the **ControllerClass** field, and choose **Edit**.
4. Click the **Hierarchy** tab and navigate to the appropriate controller class for the page or page fragment. Following are the controller classes to use for different types of pages:
   - Standard JSF page - specify `oracle.adf.controller.v2.lifecycle.PageController`

     If you need to receive afterPhase/beforePhase events, specify `oracle.adf.controller.v2.lifecycle.PagePhaseListener`
   - Page fragment - specify `oracle.adf.model.RegionController`

Tip:

You can specify the value of the page definition's `ControllerClass` attribute as a fully qualified class name or you can enter an EL expression that resolves to a class directly in the **ControllerClass** field.

When using an EL expression for the value of the `ControllerClass` attribute, the Structure window may show a warning indicating that e "`#{YourExpression}`" is not a valid class. You can safely ignore this warning.

Creating a Basic Databound Page

This chapter describes how to create databound forms in the Fusion web application with data modeled from ADF Business Components, using ADF data controls and ADF Faces components. It describes how to create text fields from individual attributes, generate entire forms from collections for editing and creating new records, and create dynamic forms.
This chapter includes the following sections:

About Creating a Basic Databound Page

A simple data bound web UI helps you to get a feel of the visual and declarative development experience offered by the JDeveloper IDE along with Oracle ADF framework. You can drag and drop UI components as per your requirement.

You can create UI pages that allow you to display and collect information using data controls created for your business services. For example, using the Data Controls panel, you can drag an attribute for an item, and then choose to display the value either as output text or as an input text field with a label. JDeveloper creates all the necessary JSF tags and binding code needed to display and update the associated data. For more information about the Data Controls panel and the declarative binding experience, see Using ADF Model in a Fusion Web Application.

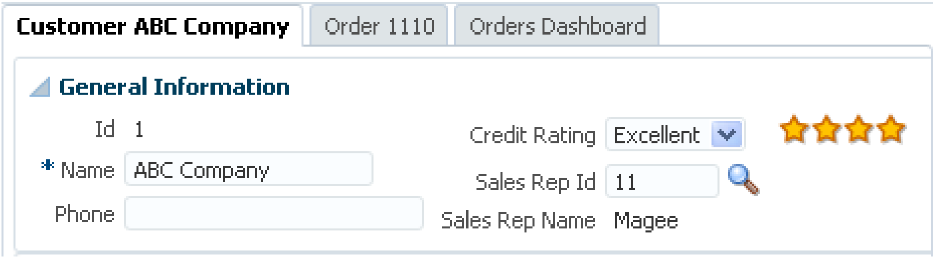
In addition to being able to drop individual attributes, you can drop all attributes for an object at once as a form, table, or single-column list view. This chapter includes information on creating forms that display values, forms that allow users to edit values, and forms that collect values (input forms). For information on creating tables and list views, see Creating ADF Databound Tables .

Once you drop the UI components, you can then drop built-in operations as command UI components that allow you to navigate through the records in a collection or that allow users to operate on the data, such as committing, deleting, or creating a record. For example, you can create a button that allows users to delete data objects displayed in the form. You can also modify the default components to suit your needs.

ADF Databound Form Use Cases and Examples

You use forms when you need to collect or display a row of data. For example, the Summit sample application for **Oracle ADF** contains a panel that allows users to update information about their customers as shown in Figure 31-1. This form was created by dragging and dropping the `Customers` collection from the Data Controls panel and then selecting the fields to display.

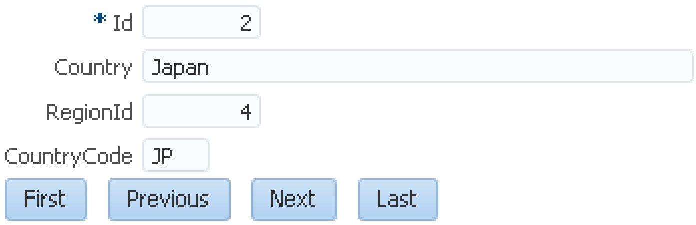
Figure 31-1 Customer General Information Form in the Summit ADF Sample Application



Id 1
* Name ABC Company
Phone
Credit Rating Excellent ★★★★
Sales Rep Id 11
Sales Rep Name Magee

When you create a form, you can also choose to add navigation, so that the user can navigate quickly between records, as shown in Figure 31-2.

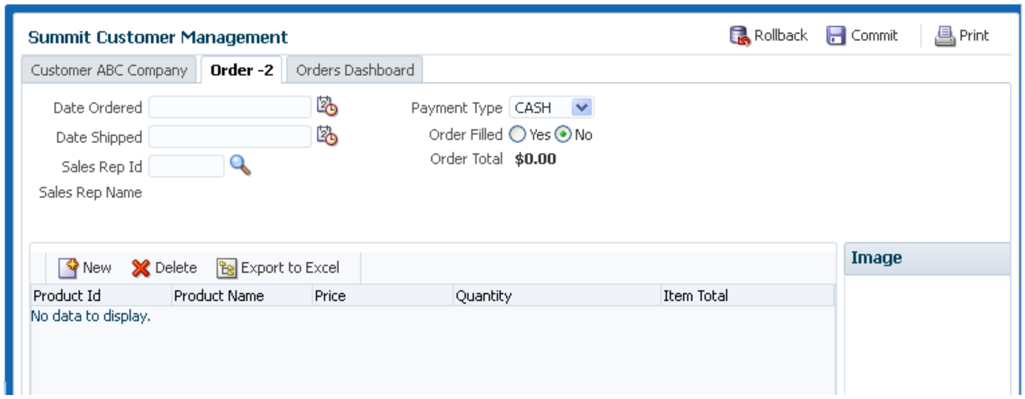
Figure 31-2 Navigate Between Records in a Form



* Id 2
Country Japan
RegionId 4
CountryCode JP

You can also add command buttons that invoke processing on the row displayed in the form. For example, you can change values for a record and save those changes in an edit form, or you can create an input form that allows users to create a new record. Figure 31-3 shows an input form where a user can create a new order.

Figure 31-3 Input Form



Date Ordered

Date Shipped

Sales Rep Id

Sales Rep Name

Order Total $0.00

Product Id	Product Name	Price	Quantity	Item Total

No data to display.

> **Note:**
>
> When the attributes to display in a form are only available at runtime, you can create a dynamic form. For more information, see Creating a Form with Dynamic Components.

Additional Functionality for Databound Pages

You may find it helpful to understand other Oracle ADF features before you implement your databound pages. Following are links to other functionality that you may find useful.

- **ADF view objects**: Much of how the components display and function in the form is controlled by the corresponding **view objects**. See Defining SQL Queries Using View Objects.
- **ADF application modules**: The Data Controls panel, from which you drag databound components to your pages, is populated with representations of view objects that you have added to application modules. See Implementing Business Services with Application Modules.
- **Adapter-based data controls**: If you are using other types of business services, such as EJB components or web services, you can create data controls for those business services as described in Creating and Configuring EJB Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- **ADF Model and data binding**: When you create forms in an ADF web application, you use ADF Model and data binding. See Using ADF Model in a Fusion Web Application.
- **ADF Faces**: You also use ADF Faces UI components. For detailed information about developing with ADF Faces, see Introduction to ADF Faces in *Developing Web User Interfaces with Oracle ADF Faces*.
- **Advanced UI controls**: Basic forms use input and output components. You can also use more advanced components, such as lists, tables, trees, search forms, LOV components, graphs, gauges, treemaps, and more. See the remaining chapters in Creating a Databound Web User Interface .

- **Task flows**: If your form takes part in a transaction, for example an input form, then you may need to use an ADF task flow to invoke certain operations before or after the form is rendered. See Creating ADF Task Flows .
- **Page lifecycle:** For information about how forms work with the page lifecycle, see Understanding the Fusion Page Lifecycle .
- **Validation**: You may want certain fields to be validated before they are submitted to the data store. See Defining Validation and Business Rules Declaratively and Using Validation in the ADF Model Layer .
- **Active data**: If your application uses active data, then you can have the data in your UI components update automatically, whenever the data in the data source changes. See Using the Active Data Service .

Creating Text Fields Using Data Control Attributes

The Data Controls panel helps you to create text fields that can display or update an attribute. A page definition file is created for the page (if one does not already exist) after you drag an attribute onto a JSF page and drop it as a UI component.

JDeveloper allows you to create text fields declaratively in a WYSIWYG development environment for your JSF pages, meaning you can design most aspects of your pages without needing to look at the code. When you drag and drop items from the Data Controls panel, JDeveloper declaratively binds ADF Faces text UI components to attributes on a data control using an attribute binding.

How to Create a Text Field

To create an individual text field that can display or update an attribute, you drag and drop an attribute of a collection from the Data Controls panel. For **ADF Business Components**, the Data Controls panel is populated with elements of your data model that you have defined in at least one **application module**.

Before you begin:

It may be helpful to have a general understanding of using data control attributes to create text fields. For more information, see Creating Text Fields Using Data Control Attributes.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

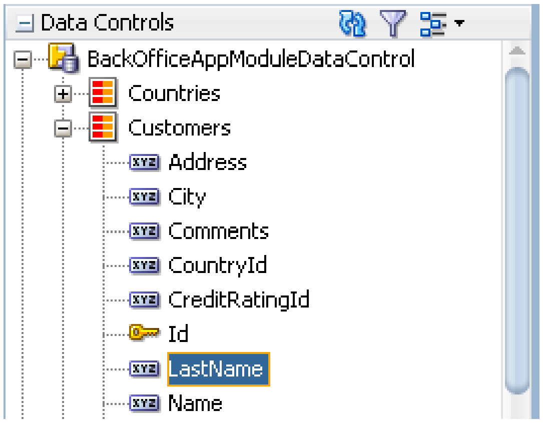
To create a databound text field:

1. From the Data Controls panel, select an attribute from a collection. For a description of the icons that represent attributes and other objects in the Data Controls panel, see Using the Data Controls Panel.

   For example, Figure 31-4 shows the `LastName` attribute under the `Customers` collection of the `BackOfficeAppModuleDataControl` data control in the Summit

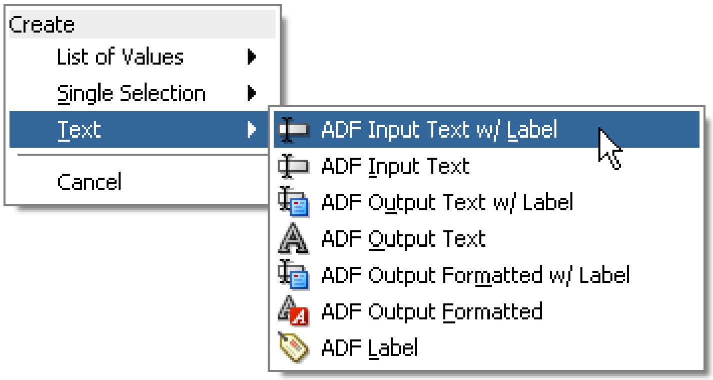
ADF sample application. This is the attribute to drop to display, update, or insert the customer's last name.

Figure 31-4 Attributes Associated with a Collection in the Data Controls Panel



2. Drag the attribute onto the page, and from the context menu choose the type of UI component to display or collect the attribute value, as shown in Figure 31-5.

Figure 31-5 Context Menu When Dropping Attributes on a Page



For an attribute, you are given the following choices:

- **Text**:
  - **ADF Input Text w/ Label**: Creates an ADF Faces `inputText` component in which the `label` attribute is populated. In addition, a nested `validator` component is created, which you can use to add client-side validation.

    > **Tip:**
    >
    > For more information about the various attributes of the `inputText` component, see the Using Input Components and Defining Forms chapter of *Developing Web User Interfaces with Oracle ADF Faces*.

  - **ADF Input Text**: Creates an ADF Faces `inputText` component without a label. In addition, a nested `validator` component is generated, which you can use for client-side validation.
  - **ADF Output Text w/ Label**: Creates a `panelLabelAndMessage` component that holds an ADF Faces `outputText` component. The `label` attribute on the `panelLabelAndMessage` component is populated.
  - **ADF Output Text:** Creates an ADF Faces `outputText` component.
  - **ADF Output Formatted w/Label**: Same as ADF Output Text w/Label, but uses an `outputFormatted` component instead of an `outputText` component. The `outputFormatted` component allows you to add a limited amount of HTML formatting. For more information, see the Displaying Output Text and Formatted Output Text section of *Developing Web User Interfaces with Oracle ADF Faces*.
  - **ADF Output Formatted**: Same as ADF Output Formatted w/Label, but without the label.
  - **ADF Label**: An ADF Faces `outputLabel` component.
- **List of Values:** Creates ADF LOV lists. For more information about how these lists work for Business Components, see Working with List of Values (LOV) in View Object Attributes. For more information on how these lists work for adapter-based data controls, see Creating List of Values Objects in *Developing Applications with Oracle ADF Data Controls*. For more information about using the lists on a JSF page, see Creating a Selection List.
- **Single selections**: Creates single selection lists. For more information about creating lists on a JSF page, see Creating a Selection List.

> **Note:**
>
> These selections are your choices by default. However, the list of components available to use for an attribute can be configured as a control hint on the associated entity or view object. For more information, see Defining Attribute Control Hints for Entity Objects and Defining UI Hints for View Objects. For information on adding control hints for adapter-based data controls, see How to Set UI Hints on Attributes in *Developing Applications with Oracle ADF Data Controls*.

For the purposes of this chapter, only the text components (and not the lists) will be discussed.

What Happens When You Create a Text Field

Among other things, when you drag an attribute onto a JSF page and drop it as a UI component, a page definition file is created for the page (if one does not already exist). For a complete account of what happens when you drag an attribute onto a page, see What Happens When You Use the Data Controls Panel. Bindings for the iterator and attributes are created and added to the page definition file. Additionally, the necessary JSPX or JSF page code for the UI component is added to the JSF page.

Iterator Bindings Created in the Page Definition File

Whenever you create UI components on a page by dropping an item that is part of a collection from the Data Controls panel (or you drop the whole collection as a form or table), JDeveloper creates an iterator binding if it does not already exist. An iterator binding references an iterator for the data collection, which facilitates iterating over its data objects. It also manages currency and state for the data objects in the collection. An iterator binding does not actually access the data. Instead, it simply exposes the object that can access the data and it specifies the current data object in the collection. Other bindings then refer to the iterator binding in order to return data for the current object or to perform an action on the object's data. Note that the iterator binding is not an iterator. It is a binding to an iterator. In the case of ADF Business Components, the actual iterator is the default **row set iterator** for the default row set of the view object instance in the application module's data model.

For example, if you drop the `LastName` attribute of the `Customers` collection, JDeveloper creates an iterator binding for the `Customers` collection.

> **Tip:**
>
> There is one iterator binding created for each collection. This means that when you drop two attributes from the same collection (or drop the collection twice), they use the same binding. One advantage of this behavior is that the currency of components stays in sync. For example, if the page has a table and a form dropped from the same collection, the form will show the record of the selected row in the table. If you need the binding to behave differently for the different components, you need to manually create separate iterator bindings.

The iterator binding's `rangeSize` attribute determines how many rows of data are fetched from a data control each time the iterator binding is accessed. This attribute gives you a relative set of 1-*n* rows positioned at some absolute starting location in the overall row set. When you create the iterator binding by dragging an attribute or collection on to a page, the attribute is initially set to `25`. For more information about using this attribute, see Iterator RangeSize Attribute Defined. The following example shows the iterator binding created when you drop an attribute from the `Customers` collection.

```
<executables>
  <iterator Binds="Customers" RangeSize="25"
            DataControl="BackOfficeAppModuleDataControl"
            id="Customers"/>
</executables>
```

For information regarding the iterator binding element attributes, see Oracle ADF Binding Properties.

This metadata allows the ADF binding container to access the attribute values. Because the iterator binding is an executable, by default, it is invoked when the page is loaded, thereby allowing the iterator to access and iterate over the `Customers` collection. This means that the iterator will manage all the `Customers` objects in the collection, including determining the current `Customers` object or range of `Customers` objects.

Value Bindings Created in the Page Definition File

When you drop an attribute from the Data Controls panel, JDeveloper creates an attribute binding that is used to bind the UI component to the attribute's value. This type of binding presents the value of an attribute for a single object in the current row in the collection. Value bindings can be used both to display and to collect attribute values.

For example, if you drop the LastName attribute under the Customers collection as an ADF Output Text w/Label widget onto a page, JDeveloper creates an attribute binding for the LastName attribute. This allows the binding to access the attribute value of the current record. The following example shows the attribute binding for LastName created when you drop the attribute from the Customers collection. Note that the attribute value references the iterator named CustomersIterator.

```
<bindings>
    ...
  <attributeValues IterBinding="CustomersIterator"
                   id=""LastName
    <AttrNames>
      <Item Value="LastName">
    </AttrNames>
  </attributeValues>
</bindings>
```

For information regarding the attribute binding element properties, see Oracle ADF Binding Properties.

Component Tags Created in JSF Page

When you create a text field by dropping an attribute from the Data Controls panel, JDeveloper creates the UI component associated with the widget dropped by writing the corresponding tag to the JSF page.

For example, when you drop the LastName attribute as an Output Text w/Label widget, JDeveloper inserts the tags for a panelLabelAndMessage component and an outputText component. It creates an EL expression that binds the label attribute of the panelLabelAndMessage component to the label property of hints created for the LastName's binding. This expression evaluates to the label hint set on the view object (for more information about hints, see Defining UI Hints for View Objects). It creates another expression that binds the outputText component's value attribute to the inputValue property of the LastName binding, which evaluates to the value of the LastName attribute for the current row. An ID is also automatically generated for both components.

> **Tip:**
>
> JDeveloper automatically generates IDs for all ADF Faces components. You can override these values as needed.

The following example shows the code generated on the JSF page when you drop the LastName attribute as an Output Text w/Label widget.

```
<af:panelLabelAndMessage label="#{bindings.LastName.hints.label}" id="plam1">
  <af:outputText value="#{bindings.LastName.inputValue}" id="ot1"/>
</af:panelLabelAndMessage>
```

If instead you drop the `LastName` attribute as an Input Text w/Label widget, JDeveloper creates an `inputText` component. As the following example shows, the value is bound to the `inputValue` property of the `LastName` binding. Additionally, the following properties are also set:

- `label`: Bound to the object's `label` UI hint.
- `required`: Bound to the object's `mandatory` property.
- `columns`: Bound to the object's `displayWidth` UI hint, which determines how wide the text box will be.
- `maximumLength`: Bound to the object's `precision` property, which determines the maximum number of characters per line that can be entered into the field.
- `shortDesc`: Bound to the `tooltip` UI hint.

In addition, JDeveloper nests a `validator` tag within the `inputText` component. You can use this tag to create client-side validation rules to supplement any validation rules that exist in the model or business service layers.

```
<af:inputText value="#{bindings.LastName.inputValue}"
              label="#{bindings.LastName.hints.label}"
              required="#{bindings.LastName.hints.mandatory}"
              columns="#{bindings.LastName.hints.displayWidth}"
              maximumLength="#{bindings.LastName.hints.precision}">
              shortDesc="#{bindings.LastName.hints.tooltip}" id="it1">
  <f:validator binding="#{bindings.LastName.validator}"/>
</af:inputText>
```

For further information regarding the `validator` and `converter` tags, see the Validating and Converting Input chapter of *Developing Web User Interfaces with Oracle ADF Faces*.

You can change any of these values to suit your needs. For example, the `mandatory` control hint on the view object is set to `false` by default, which means that the `required` attribute on the component will evaluate to `false` as well. You can override this value by setting the `required` attribute on the component to `true`. If you decide that all instances of the attribute should be mandatory, then you can change the control hint on the view object, and all instances will then be required. For more information about these properties, see Oracle ADF Binding Properties. For more information on changing these properties at the entity object level, see Setting Attribute Properties. For more information on changing these properties at the view object level, see How to Edit a View Object.

Creating Basic Forms Using Data Control Collections

A basic form helps you to created a page and display data from a collection. The Data Controls panel helps you to drag and drop a collection to create a form. You can also modify the data present in the form.

Instead of dropping each of the individual attributes of a collection to create a form, you can drop the collection node to create a form from multiple attributes in the collection.

For example, you could create a page that displays basic information about customers in the Summit ADF sample application by dragging and dropping the `Customers` collection.

You can also create forms that provide more functionality than simply displaying data from a collection. For information about creating a form that allows a user to update data, see Creating a Form to Edit an Existing Record. For information about creating forms that allow users to create a new object for the collection, see Creating an Input Form. You can also create search forms. For more information, see Creating ADF Databound Search Forms .

How to Create a Form Using a Data Control Collection

When you create a form using a data control, you bind the UI components to the attributes on the corresponding object in the data control. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

Before you begin:

It may be helpful to have an understanding of basic databound forms. For more information, see Creating Basic Forms Using Data Control Collections.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Pages.

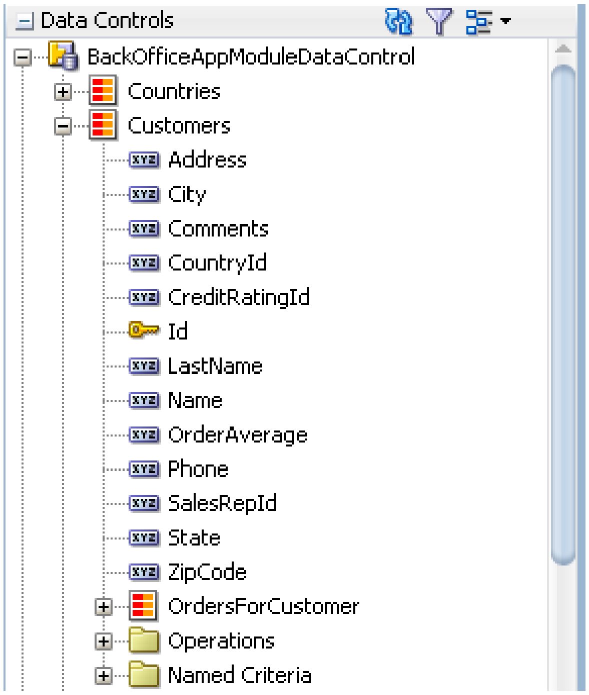
You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To create a basic form:

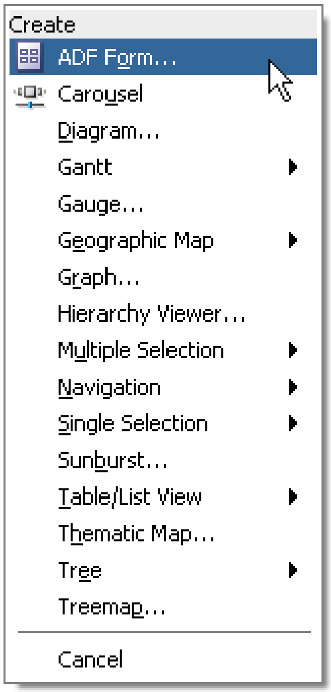
1. From the Data Controls panel, select the collection that represents the data you wish to display. Figure 31-6 shows the `Customers` collection for the `BackOfficeAppModuleDataControl` data control.

Figure 31-6 CustomerVO Object in the Data Controls Panel



2. Drag the collection onto the page, and from the context menu choose **ADF Form**.

Figure 31-7 Context Menu When Dropping a Collection to a Page



3. In the Create Form dialog, configure your form.

   - You can exclude attributes from appearing in the form.

- If you do not select the **Read-Only Form** checkbox, ADF `inputText` components are used for most attributes. Each `inputText` component has the `label` attribute populated. By default, the label obtains its value from a binding to the `label` property on the associated binding object.

  Attributes that are dates use the `InputDate` component.

  If a control type control hint has been created for an attribute, or if the attribute has been configured to be a list, then the component set by the hint is used instead.

  `InputText` components contain a `validator` tag that allows you to set up client-side validation for the attribute. If the attribute is a number or a date, a `converter` is also included.

  > **Tip:**
  >
  > For more information about the various attributes of the `inputText` component, see the Using Input Components and Defining Forms chapter of *Developing Web User Interfaces with Oracle ADF Faces.*

- If you select the **Read-Only Form** checkbox, read-only `outputText` components are used. Since the form is meant to display data, no `validator` tags are added (though converters are included). Attributes of type `Date` use the `outputText` component when in a read-only form. All components are placed inside `panelLabelAndMessage` components, which have the `label` attribute populated, and are placed inside a `panelFormLayout` component. This ensures that the labels are aligned appropriately with the `outputText` components at runtime.
- You can elect to include navigational controls that allow users to navigate through all the data objects in the collection. For more information, see Incorporating Range Navigation into Forms.
- You can also include a **Submit** button to submit the HTML form and apply the data in the form to the bindings as part of the JSF/ADF page lifecycle. For additional help in using the dialog, click **Help**.

4. If you are building a form that allows users to update data, you now need to drag and drop an operation that will commit the changes to update the record. For more information, see Creating a Form to Edit an Existing Record.

> **Note:**
>
> If you select the **Fields Generated at Runtime** in the Create Form dialog, the attributes to display are determined at runtime based on configuration of the business service. For more information, see Creating a Form with Dynamic Components.

What Happens When You Create a Form Using a Data Control Collection

Dropping an object as a form from the Data Controls panel has a similar effect as dropping a single attribute, except that multiple attribute bindings and associated UI components are created and all UI components are placed inside a `panelFormLayout` component. The attributes on the UI components (such as `value`) are bound to properties on that attribute's binding object (such as `inputValue`) or to the values of control hints set on the corresponding business object. The following example shows some of the code generated on the JSF page when you drop the `Customers` collection as a default ADF Form.

> **Note:**
>
> If an attribute is marked as hidden on the associated view or entity object, then no corresponding UI is created for it.

```
<af:panelFormLayout id="pfl1">
    <af:inputText value="#{bindings.Id.inputValue}"
                  label="#{bindings.Id.hints.label}"
                  required="#{bindings.Id.hints.mandatory}"
                  columns="#{bindings.Id.hints.displayWidth}"
                  maximumLength="#{bindings.Id.hints.precision}"
                  shortDesc="#{bindings.Id.hints.tooltip}" id="it1">
        <f:validator binding="#{bindings.Id.validator}"/>
        <af:convertNumber groupingUsed="false" pattern="#{bindings.Id.format}"/>
    </af:inputText>
    <af:inputText value="#{bindings.Name.inputValue}"
                  label="#{bindings.Name.hints.label}"
                  required="#{bindings.Name.hints.mandatory}"
                  columns="#{bindings.Name.hints.displayWidth}"
                  maximumLength="#{bindings.Name.hints.precision}"
                  shortDesc="#{bindings.Name.hints.tooltip}" id="it2">
        <f:validator binding="#{bindings.Name.validator}"/>
    </af:inputText>
    <af:inputText value="#{bindings.Phone.inputValue}"
                  label="#{bindings.Phone.hints.label}"
                  required="#{bindings.Phone.hints.mandatory}"
                  columns="#{bindings.Phone.hints.displayWidth}"
                  maximumLength="#{bindings.Phone.hints.precision}"
                  shortDesc="#{bindings.Phone.hints.tooltip}" id="it3">
        <f:validator binding="#{bindings.Phone.validator}"/>
    </af:inputText>
. . .
</af:panelFormLayout>
```

For more information about the code that is generated when you drop an item from the Data Controls panel, see What Happens When You Create a Text Field .

When you choose to create an input form using an object that contains a defined **list of values (LOV)**, then a `selectOneChoice` component is created instead of an `inputText` component. For example, the `CustomerVO` view object contains defined LOVs for the `CountryId` and `CreditRatingId` attributes. When you drop the `Customers` data control object as an ADF Form, a dropdown list showing all values is created for each LOV (instead of an empty input text field). For more information about how these lists work, see Working with List of Values (LOV) in View Object Attributes. For more information on how these lists work for adapter-based data controls, see Creating List of Values Objects in *Developing Applications with Oracle ADF Data Controls*. For more information about using the lists on a JSF page, see Creating a Selection List.

> **Note:**
>
> If the object contains a structured attribute (an attribute that is neither a Java primitive type nor a collection), that attribute will not appear in the dialog, and it will not have a corresponding component in the form. You will need to create those fields manually.

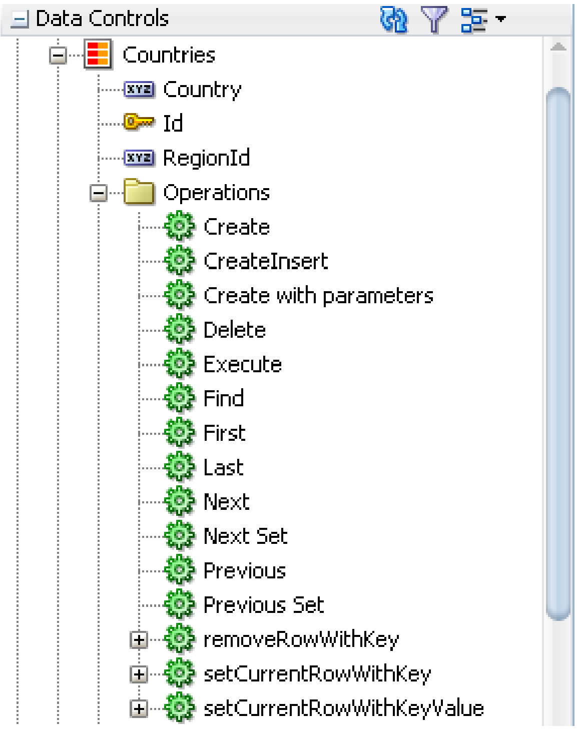
Creating Command Components Using Data Control Operations

Command components are represented by the UICommand component, which performs an action when it is activated. The Data Controls panel helps you to drag and drop a command component based on a data control operation to a page.

In addition to providing a representation of your data objects, the Data Controls panel also has nodes that represent standard operations for use in a form. These built-in operations enable you to declaratively handle common form functions such as navigating between records and committing changes to a database. Most operations are available for individual data collections in a data control. The Commit and Rollback operations are available on the whole data control. When you drag an operation from the Data Controls panel to a page, you are prompted to choose what kind of command component to create, such as a button or a link.

Figure 31-8 shows the operations available for the `Countries` collection in the Summit ADF sample application.

Figure 31-8 Data Control Collection Operations



Data Controls
- Countries
  - Country
  - Id
  - RegionId
  - Operations
    - Create
    - CreateInsert
    - Create with parameters
    - Delete
    - Execute
    - Find
    - First
    - Last
    - Next
    - Next Set
    - Previous
    - Previous Set
    - removeRowWithKey
    - setCurrentRowWithKey
    - setCurrentRowWithKeyValue

This section shows how to create command components from built-in data control operations. For information on other ways you can use command components in a databound page, see Using Command Components to Invoke Functionality in the View Layer.

How to Create Command Components From Operations

To create a command component based on a data control operation, you drag and drop the operation from the Data Controls panel to a page.

Before You Begin:

It may be helpful to have a general understanding of using data control operations to create command components. For more information, see Creating Command Components Using Data Control Operations.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To create a command component from an operation:

1. From the Data Controls panel, drag the operation onto the page.
2. From the ensuing context menu, choose either **ADF Button** or **ADF Link**.

What Happens When You Create Command Components Using Operations

When you drop an operation to create a command component, JDeveloper:

- Defines an action binding in the page definition file for the associated operation
- Configures the iterator binding to use partial page rendering for the collection
- Inserts code in the JSF page for the command component

Action Bindings Created for Operations

Action bindings execute business logic. For example, they can invoke operations on the action binding object. These operations operate on the iterator or on the data control itself.

Like value bindings, action bindings for operations contain a reference to the iterator binding when the action binding is bound to one of the iterator-level actions, such as `Next` or `Previous`. These types of actions are performed by the iterator, which determines the current object and can therefore determine the correct object to display when a navigation button is clicked. Action bindings to actions that are not at the iterator level, such as custom methods on an application module or the commit or rollback operations, will not contain this reference.

Action bindings use the `RequiresUpdateModel` property, which determines whether or not the model needs to be updated before the action is executed. In the case of navigation operations, by default this property is set to `true`, which means that any changes made at the view layer must be moved to the model before navigation can occur.

The following example shows the action bindings for the navigation operations.

```
<action IterBinding="CustomersIterator" id="First"
         RequiresUpdateModel="true" Action="first"/>
<action IterBinding="CustomersIterator" id="Previous"
        RequiresUpdateModel="true" Action="previous"/>
<action IterBinding="CustomersIterator" id="Next"
        RequiresUpdateModel="true" Action="next"/>
<action IterBinding="CustomersIterator" id="Last"
        RequiresUpdateModel="true" Action="last"/>
```

Iterator RangeSize Attribute Defined

Iterator bindings have a `rangeSize` attribute that the binding uses to determine the number of data objects to make available for the page for each iteration. This attribute helps in situations when the number of objects in the data source is quite large. Instead of returning all objects, the iterator binding returns only a set number, which then become accessible to the other bindings. Once the iterator reaches the end of the range, it accesses the next set. The following example shows the default range size for the `Customers` iterator.

```
<iterator Binds="Customers" RangeSize="25"
          DataControl="BackOfficeAppModuleDataControl"
          id="CustomersIterator"
          ChangeEventPolicy="ppr"/>
```

> **Note:**
>
> This `rangeSize` attribute is not the same as the `rows` attribute on a table component. For more information, see Table 32-1.

When the iterator binding is initially generated, the `RangeSize` attribute is set to `25`. This means that a user can view 25 objects, navigating back and forth between them, without needing to access the data source. The iterator keeps track of the current object. Once a user clicks a button that requires a new range (for example, clicking the **Next** button on object number 25), the binding object executes its associated method against the iterator, and the iterator retrieves another set of 25 records. The bindings then work with that set. You can change this setting as needed. You can set it to `-1` to have the full record set returned. If the `RangeSize` attribute is not specified, the full record set is returned.

EL Expressions Created to Bind to Operations

When you create command components using data control operations, JDeveloper creates an EL expression that binds a command button's `actionListener` attribute to the `execute` property of the action binding for the given operation.

At runtime an action binding will be an instance of the `FacesCtrlActionBinding` class, which extends the core `JUCtrlActionBinding` implementation class. The `FacesCtrlActionBinding` class adds the following methods:

- `public void execute(ActionEvent event)`: This is the method that is referenced in the `actionListener` property, for example `#{bindings.First.execute}`.

  This expression causes the binding's operation to be invoked on the iterator when a user clicks the button. For example, the **First** command button's `actionListener` attribute is bound to the `execute` method on the `First` action binding.

- `public String outcome()`: This can be referenced in an `Action` property, for example `#{bindings.Next.outcome}`.

  This can be used for the result of a method action binding (once converted to a `String`) as a JSF navigation outcome to determine the next page to navigate to.

  > **Note:**
  >
  > Using the outcome method on the action binding breaks the separation between the view-controller layer and the model layer, so it should be rarely used.

Every action binding for an operation has an `enabled` boolean property that Oracle ADF sets to `false` when the operation should not be invoked. By default, JDeveloper binds the UI component's `disabled` attribute to this value to determine whether or not the component should be enabled. For example, the UI component for the **First** button has the following as the value for its `disabled` attribute:

```
#{!bindings.First.enabled}
```

This expression evaluates to `true` whenever the binding is not enabled, that is, when the operation should not be invoked, thereby disabling the button. In this example, because the framework will set the `enabled` property on the binding to `false` whenever the first record is being shown, the **First** button will automatically be disabled because its `disabled` attribute is set to be `true` whenever `enabled` is `False`. For more information about the `enabled` property, see Oracle ADF Binding Properties.

The following example shows the code generated after dropping the `Create` and `Delete` operations as buttons on a page.

```
<af:button actionListener="#{bindings.Create.execute}" text="Create"
           disabled="#{!bindings.Create.enabled}" id="b5"/>
<af:button actionListener="#{bindings.Delete.execute}" text="Delete"
           disabled="#{!bindings.Delete.enabled}" id="b6"/>
```

What Happens at Runtime: How Action Events and Action Listeners Work

When the user clicks a command component, the form is submitted and then an action event is fired. Action events might affect only the user interface (for example, a link to change the locale, causing different field prompts to display), or they might involve some logic processing in the back end (for example, a button to navigate to the next record). That event object then takes information about the current data object from the iterator and then passes it to the action binding's method, which is bound to the command component through its `actionListener` attribute.

> **Note:**
>
> An action listener is a class that registers to be notified when a command component fires an action event. An action listener contains an action listener method that processes the action event object passed to it by the command component.

For example, when the user clicks a **Delete** button that was created from the ADF `Delete` operation, an action event is fired. This event object stores currency information about the current data object, taken from the iterator. Because the component's `actionListener` attribute is bound to the `execute` method of the `Delete` action binding, the `Delete` operation is invoked when the event fires. This method takes the currency information passed in the event object to determine which data object to delete.

Typically, the `actionListener` property's value is in the form of an EL expression. For example, if the value of the `actionListener` attribute is `{bindings.Delete.execute}`, the `execute()` method of the `Delete` action binding is called.

What You May Need to Know About Overriding Declarative Methods

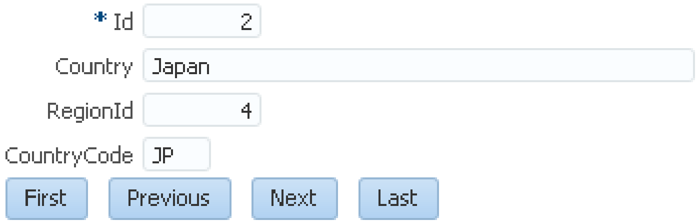
When you drop an operation or method as a command button, JDeveloper binds the button to the execute method for the operation or method. However, there may be occasions when you need to add logic before or after the existing logic. JDeveloper allows you to add logic to a declarative operation by creating a new method and property on a managed bean that provides access to the binding container. By default, this generated code executes the operation or method. You can then add logic before or after this code. JDeveloper automatically binds the command component to this new method, instead of to the execute property on the original operation or method. Now when the user clicks the button, the new method is executed. For more information, see Overriding Declarative Methods.

Incorporating Range Navigation into Forms

You may choose to include navigational controls when you create an ADF Form. By default, JDeveloper creates First, Last, Previous, and Next buttons to navigate within the collection. You can also include navigational buttons manually, as required.

When you create an ADF Form, if you choose to include navigational controls, JDeveloper includes ADF Faces command components bound to existing navigational logic on the data control. This built-in logic allows the user to navigate through all the data objects in the collection. For example,Figure 31-9 shows a form that would be created if you drag the `Countries` collection and drop it as an ADF Form that uses navigation.

Figure 31-9 Navigation in a Form



* Id	2
Country	Japan
RegionId	4
CountryCode	JP

Table 31-1 shows the built-in navigation operations provided on data controls and the result of invoking the operation or executing an event bound to the operation. For more information about action events, see What Happens at Runtime: How Action Events and Action Listeners Work .

Table 31-1 Built-in Navigation Operations

Operation	When invoked, the associated iterator binding will...
First	Move its current pointer to the beginning of the result set.
Last	Move its current pointer to the end of the result set.
Previous	Move its current pointer to the preceding object in the result set. If this object is outside the current range, the range is scrolled backward a number of objects equal to the range size.
Next	Move its current pointer to the next object in the result set. If this object is outside the current range, the range is scrolled forward a number of objects equal to the range size.
Previous Set	Move the range backward a number of objects equal to the range size attribute.
Next Set	Move the range forward a number of objects equal to the range size attribute.

How to Manually Insert Navigation Controls into a Form

By default, when you choose to include navigation when creating a form using the Data Controls panel, JDeveloper creates **First**, **Last**, **Previous**, and **Next** buttons that allow the user to navigate within the collection.

You can also add navigation buttons to an existing form manually.

Before you begin:

It may be helpful to have an understanding of navigation controls. For more information, see Incorporating Range Navigation into Forms.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Pages.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To manually add navigation buttons:

1. From the Data Controls panel, select the operation associated with the collection of objects on which you wish the operation to execute, and drag it onto the JSF page.

   For example, if you want to navigate forward through a collection of countries, you would drag the **Next** operation associated with the `Countries` collection. Figure 31-8 shows the operations associated with the `Countries` collection.
2. From the ensuing context menu, choose either **ADF Button** or **ADF Link**.

> **Tip:**
>
> You can also drop the **First**, **Previous**, **Next**, and **Last** buttons at once. To do so, drag the corresponding collection, and from the context menu, choose **Navigation > ADF Navigation Buttons**.

What Happens When You Manually Add Navigation Buttons

When you drop a navigation operation from the Data Controls panel, JDeveloper:

- Defines an action binding in the page definition file for the associated operations
- Configures the iterator binding to use partial page rendering for the collection
- Inserts code in the JSF page for the command components
- Inserts the `partialSubmit` attribute for the component in the JSF page and sets it to `true` in order to fire a partial page request when the button is clicked. For

more information, see the Using Partial Triggers section of *Developing Web User Interfaces with Oracle ADF Faces*.

For more information on code generated for command components, see What Happens When You Create Command Components Using Operations.

The following example shows the code generated on the JSF page for navigation operation buttons.

```
<f:facet name="footer">
   <af:panelGroupLayout>
     <af:button actionListener="#{bindings.First.execute}"
                       text="First"
                       disabled="#{!bindings.First.enabled}"
                       partialSubmit="true" id="cb1"/>
     <af:button actionListener="#{bindings.Previous.execute}"
                       text="Previous"
                       disabled="#{!bindings.Previous.enabled}"
                       partialSubmit="true" id="cb2"/>
     <af:button actionListener="#{bindings.Next.execute}"
                       text="Next"
                       disabled="#{!bindings.Next.enabled}"
                       partialSubmit="true" id="cb3"/>
     <af:button actionListener="#{bindings.Last.execute}"
                       text="Last"
                       disabled="#{!bindings.Last.enabled}"
                       partialSubmit="true" id="cb4"/>
   </af:panelGroupLayoutr>
 </f:facet>
```

What Happens at Runtime: Navigation Controls

When the user clicks a navigation control button, an action event is fired. That event object then takes information about the current data object from the iterator and then passes it to the operation's method, which is bound to the button through its `actionListener` attribute.

For more information, see What Happens at Runtime: How Action Events and Action Listeners Work .

In addition, when a user clicks a navigation button, only those components associated with the same iterator as the button's action binding are processed through the lifecycle. For more information, see What You May Need to Know About Partial Page Rendering and Iterator Bindings.

What You May Need to Know About the Browser Back Button and Navigating Through Records

You must use the navigation buttons to navigate through the records displayed in a form; you cannot use the browser's back or forward buttons. Because navigation forms automatically use PPR, only part of the page goes through the lifecycle, meaning that when you click a navigation button, the components displaying the data are refreshed and display new data, and you actually remain on the same page. Therefore, when you click the browser's back button, you will be returned to the page that was rendered before the page with the form, instead of to the previous record displayed in the form.

For example, say you are on a page that contains a link to view all current orders. When you click the link, you navigate to a page with a form and the first order, Order #101, is displayed. You then click **Next** and Order #102 is displayed. You click **Next** again, and Order #103 is displayed. If you click the browser's back button, you will not be shown Order #102. Instead, you will be returned to the page that contained the link to view all current orders.

What You May Need to Know About the CacheResults Property

When you create a navigable form using the Data Controls panel, the `CacheResults` property on the associated iterator is set to `true`. This ensures that the iterator's state, including currency information, is cached between requests, allowing it to determine the current object. If this property is set to `false`, navigation will not work.

Creating a Form to Edit an Existing Record

Edit forms allow you to make amendments to the existing data in the form. In order to create an edit form, you need to drop a collection on your page as a form and then drop the appropriate operations as command components.

You can create a form that allows a user to edit the current data, and then commit those changes to the data source. To do this, you use operations that can modify data records associated with the collection or the data control itself to create command buttons. For example, you can use the `Delete` operation to create a button that allows a user to delete a record from the current range.

For data controls based on ADF Business Components or on EJB session beans that have an explicit commit model, it is important to note that these operations are executed only against objects in the ADF cache. You need to use the `Commit` operation on the root data control to actually commit any changes to the data source. You use the data control's `Rollback` operation to roll back any changes made to the cached object. If the page is part of a transaction within a bounded task flow, you would most likely use these operations to resolve the transaction in a task flow return activity. See Managing Transactions in Task Flows.

How to Create an Edit Form

To create an edit form, you drop a collection on your page as a form and then drop the appropriate operations as command components.

Before you begin:

It may be helpful to have an understanding of creating edit forms. For more information, see Creating a Form to Edit an Existing Record.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Pages.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.

- Create a JSF page as described in Creating a Web Page.

To create an edit form:

1. From the Data Controls panel, drag the collection for which you wish to create the form, and choose **ADF Form** from the context menu.

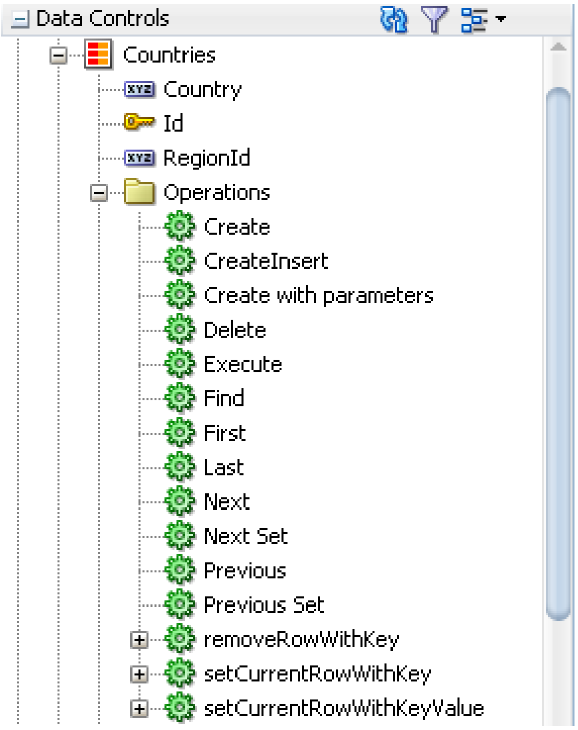
   This creates a form using `inputText` components, which will allow the user to edit the data in the fields.

2. In the Create Form dialog, set the fields and buttons that you would like added to the form and click **OK**.

3. Optionally, from the Data Controls panel, select any additional operation associated with the collection that you would like to add to the form, drag it to the page, and choose **ADF Button** or **ADF Link** from the context menu.

   For example, if you want to be able to delete a country, you would select the `Delete` operation associated with the `Countries` collection. Figure 31-10 shows the operations associated with the `Countries` collection.

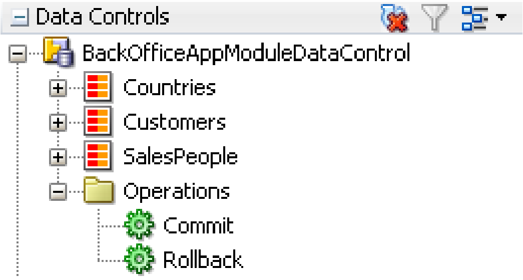
   Figure 31-10   Operations Associated with a Collection



4. Add operations to the page to save or cancel changes.

   If the page is not part of a transaction within a bounded task flow, then you need to create buttons that allow the user either to commit or roll back the changes. From the Data Controls panel, drag the **Commit** and **Rollback** operations associated with the root-level data control, and drop them as either a command button or a command link. Figure 31-11 shows the commit and rollback operations for the `BackOfficeAppModuleDataControl` data control.

Figure 31-11 Commit and Rollback Operations for a Data Control



If the page is part of a transaction within a bounded task flow, then you can simply enter `Commit` and `Rollback` as the values for the transaction resolution when creating the task flow return activity. For more information, see Managing Transactions in Task Flows.

If you are basing the form on a data control that is based on business services other than ADF Business Components, the `Commit` and `Rollback` operations might not be available. For more information, see What You May Need to Know About Working With Data Controls for Stateless Business Services.

5. Optionally, change the `autoSubmit` property of each editable field to `true`.

   Doing so enables any user changes to be submitted to the page when tabbing out of the field and thus enabling the `Commit` and `Rollback` operations, if they have not already been enabled by another sequence of events, such as a change to a field plus a button click.

   You can access the `autoSubmit` property for a field by selecting the field and then scrolling to the **Behavior** section in the Properties window.

> **Tip:**
>
> If the same page on which you create your edit form also has a table created from the same collection as the form, the table and the form use the same iterator binding, which enables the user to select the record to edit in the form by selecting a row in the table. For more information on creating databound tables, see Creating a Basic Table.

What Happens When You Create Edit Forms

For information on what happens when you drop a collection on to a page, see What Happens When You Create a Form Using a Data Control Collection.

Dropping any data control operation as a command button causes code generation similar to when you drop navigation operations. For more information, see What Happens When You Create Command Components Using Operations.

The only difference is that the action bindings for the `Commit` and `Rollback` operations do not require a reference to the iterator, because they execute a method on the application module (the data control itself), as opposed to the iterator. Note that the `Rollback` action has the `RequiresUpdateModel` property set to `false`. This is because the model should not be updated before the operation is executed, since all changes need to be discarded. The following example shows the action bindings generated in the page definition file for these operations.

```
<action id="Commit" RequiresUpdateModel="true" Action="commitTransaction"
        DataControl="BackOfficeAppModuleDataControl"/>
<action id="Rollback" RequiresUpdateModel="false"
        Action="rollbackTransaction"
        DataControl="BackOfficeAppModuleDataControl"/>
```

Table 31-2 shows the built-in non-navigation operations provided on data controls and data control objects, along with the result of invoking the operation or executing an event bound to the operation. For more information about action events, see What Happens at Runtime: How Action Events and Action Listeners Work .

Table 31-2 More Built-in Operations

Operation	When invoked, the associated iterator binding will...
`CreateInsert`	Creates a row directly before the current row, inserts the new record into the row set, then moves the current row pointer to the new row. Note that the range does not move, meaning that the last row in the range may now be excluded from the range. For more information about using the `CreateInsert` operation to create objects, see Creating an Input Form. **Note:** `CreateInsert` is only available for data controls based on ADF Business Components application modules.
`Create`	Creates a row directly before the current row, then moves the current row pointer to the new row. Note that the range does not move, meaning that the last row in the range may now be excluded from the range. For data controls based on application modules and most other business services, the record will not be inserted into the row set, preventing a blank row should the user navigate away without actually creating data. The new row will be created when the user submits the data. For more information, see What You May Need to Know About Create and CreateInsert. However, for JPA-based data controls, the `Create` operation does insert data into the row set and can be configured to persist the data. For more information, see Data Control Built-in Operations in *Developing Applications with Oracle ADF Data Controls*.
`CreateWith Parameters`	Same as the `CreateInsert` operation (the new record is inserted into the row set). However, it uses named parameters to create the object. **Note:** `Create With Parameters` is only available for data controls based on ADF Business Components application modules.
`Delete`	Deletes the current row from the cache and moves the current row pointer to the next row in the result set. Note that the range does not move, meaning that a row may be added to the end of the range. If the last row is deleted, the current row pointer moves to the preceding row. If there are no more rows in the collection, the enabled attribute is set to `disabled`.
`RemoveRowWithKey`	Uses the row key as a `String` converted from the value specified by the input field to remove the data object in the bound data collection.

Table 31-2 (Cont.) More Built-in Operations

Operation	When invoked, the associated iterator binding will...
SetCurrentRowWithKey	Sets the row key as a String converted from the value specified by the input field. The row key is used to set the currency of the data object in the bound data collection. For an example of when this is used, see What You May Need to Know About Setting the Current Row in a Table.
SetCurrentRowWithKeyValue	Sets the current object on the iterator, given a key's value. For more information, see What You May Need to Know About Setting the Current Row in a Table.
ExecuteWithParams	Refreshes the data collection by first assigning new values to the named bind variables passed as parameters, then (re)executing the view object's query. You would use this operation in the same manner as you would use the CreateInsert operation to create an input form. For more information, see Creating an Input Form. This operation appears only for view objects that have defined one or more named bind variables at design time. For more information, see Working with Bind Variables. For EJB and bean data controls, this operation is only available on data control collection objects that are based on parameterized queries.
Commit	Causes all items currently in the cache to be committed to the database.
Rollback	Clears the cache and returns the transaction and iterator to the initial state. Resets the ActionListener method.
Execute and Find	These operations are used only in search forms. See Creating ADF Databound Search Forms for more information.

What You May Need to Know About Working With Data Controls for Stateless Business Services

When you create user interfaces based on ADF Business Components services, any data changes that a user makes are not propagated to the underlying database until the user triggers the Commit operation through a command component.

For user interfaces that are based on data controls for stateless business services, such as stateless EJB session beans or RESTful web services, the Commit and Rollback operations are not available. In such cases, you can use custom methods to handle interactions with the underlying database. In the case of EJB data controls, any persistEntity and mergeEntity methods in the session bean are exposed through the Data Controls panel, and you can create command components from them. For more information, see About Commit Models for EJB Session Beans in *Developing Applications with Oracle ADF Data Controls*.

Using Parameters to Create a Form

You can create ADF parameter forms using different mechanisms. You need to gather information about the creation of the ADF Parameter Form using ExecuteWithParams operation.

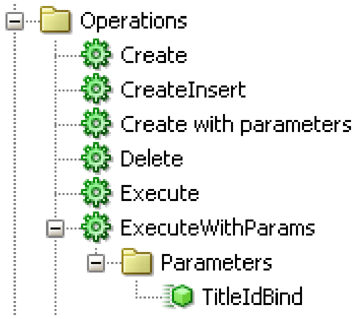
In Oracle ADF, there are several ways that you can create a form where the record that is displayed is determined by an input parameter. The following are some of those mechanisms:

- Create an ADF Parameter Form based on a data control collection's `ExecuteWithParams` operation or on a custom method that takes parameters.
- Pass a parameter to the form through a task flow.
- Nest a `setPropertyListener` tag within a command component and provide application logic within a managed bean to access the parameters and invoke any needed logic.

This section covers the creation of ADF parameter forms based on the `ExecuteWithParams` operation. For information on passing parameters to a form through a task flow, see Using Parameters in Task Flows and Specifying Parameters for an ADF Region. For information on using the `setPropertyListener` tag, see Setting Parameter Values Using a Command Component.

The `ExecuteWithParams` operation is available only for data control objects that contain parameters, such as those based on view objects containing bind variables and those based on JPA-based beans that contain named queries with parameters. For example, the Summit ADF sample application contains a view object instance called `SalesPeople`, which is based on the `EmpVO` view object, which contains the bind variable `TitleIdBind`. So, as shown in Figure 31-12, the `SalesPeople` object contains an `ExecuteWithParams` operation with a subnode for the `TitleIdBind` parameter.

Figure 31-12 ExecuteWithParams Operation in the Data Controls Panel



View object bind variables and JPA parameterized queries allow you to supply attribute values at runtime to the view object or **view criteria**. The `ExecuteWithParams` operation refreshes the data collection by first assigning new values to the named bind variables passed as parameters, then (re)executing the view object's query. For more information about bind variables in view objects, see Working with Bind Variables. For more information on named parameters in JPA queries, see EJB Data Control Prerequisites and Considerations in *Developing Applications with Oracle ADF Data Controls*.

How to Create a Form Using Parameters

To create a form using parameters, you drop the `ExecuteWithParams` operation of a collection on to a page as an ADF Parameter Form and then drop the collection itself as an ADF Form.

Before you begin:

It may be helpful to have an understanding of creating parameter forms. For more information, see Using Parameters to Create a Form.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Pages.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.

  Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Add bind variables to the view criteria definition as described in How to Add WHERE Clause Bind Variables to a View Object Definition.

  For JPA-based data controls you can create named queries in the session bean or service facade that specify named parameters. For more information, see EJB Data Control Prerequisites and Considerations in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To create a parameter form based on the ExecuteWithParams operation:

1. From the Data Controls panel, drag the `ExecuteWithParams` operation for the collection for which you wish to create the form, and choose **ADF Parameter Form** from the context menu.
2. In the Create Form dialog, select the parameters on which you want users to be able to query and click **OK**.
3. From the Data Controls panel, drag the corresponding collection, and drop it as the type of table or form that you want to display the results of the query based on the user input.

> **Note:**
>
> You can also declaratively incorporate selection lists into parameter forms. To create a selection list, drag a parameter node that is a child of the `ExecuteWithParams` operation on to the form. Then drag the `ExecuteWithParams` operation and drop it as a button.

What Happens When You Create a Parameter Form

When you drop the `ExecuteWithParams` operation as a parameter form, JDeveloper:

- Inserts code in the JSF page for the form using `inputText` components bound to the attribute bindings, and a `button` component bound to the `ExecuteWithParams` operation.
- Defines the following in the page definition file:

- A variable iterator for the attributes to use to access the variables (as opposed to a collection's iterator which is used for other forms).
- A variableUsage variable for each parameter to hold the data values. These variables inherit the default value and UI control hints from the view object named bind variables to which they are bound. The variables are local, meaning they live only during a single request. Though they are carried across subsequent post-backs to the same form, they are forgotten (and re-initialized) when a user navigates to some other page.
- An action binding for the operation that contains NamedData elements for each parameter. Each NamedData element is bound to a corresponding variable. These bindings allow the operation to access the value for the parameter upon execution.
- Attribute bindings for the associated attributes.

The following example shows the executables and bindings in the page definition file that are created by dropping the SalesPeople collection's ExecuteWithParams operation on a page.

```
<executables>
  <variableIterator id="variables">
    <variableUsage DataControl="BackOfficeAppModuleDataControl"
                   Binds="SalesPeople.variablesMap.TitleIdBind"
                   Name="ExecuteWithParams_TitleIdBind" IsQueriable="false"/>
  </variableIterator>
  <iterator Binds="SalesPeople" RangeSize="25"
            DataControl="BackOfficeAppModuleDataControl"
            id="SalesPeopleIterator"/>
</executables>
<bindings>
  <action IterBinding="SalesPeopleIterator" id="ExecuteWithParams"
          RequiresUpdateModel="true"
          Action="executeWithParams">
    <NamedData NDName="TitleIdBind" NDType="java.lang.Integer"
               NDValue="${bindings.ExecuteWithParams_TitleIdBind}"/>
  </action>
  <attributeValues IterBinding="variables" id="TitleIdBind">
    <AttrNames>
      <Item Value="ExecuteWithParams_TitleIdBind"/>
    </AttrNames>
  </attributeValues>
</bindings>
```

When you drop the collection that will be used to display the results of the parameter form, code is generated for a basic form, as described in What Happens When You Create a Form Using a Data Control Collection. In addition, if you use a table to display the results, the partialTriggers property on table is set to the command button in the parameter form.

What Happens at Runtime: How Parameters are Populated

When the page is rendered, the framework checks if the page is being rendered for the first time and if the exception list has any items. If both are false, then the framework executes the ExecuteWithParams action binding. This action binding executes the query, taking the values of the named data elements as values for the needed parameters.

Creating an Input Form

An input form is similar to an edit form that helps you to enter information for a new record. In order to create a basic input form, you need to first create an edit form and add a command component for creating new records.

You can create a form that allows a user to enter information for a new record and then commit that record to the data source. Creating a basic input form is similar to creating an edit form, except that the input form also contains the `CreateInsert` operation, which causes a blank row to be inserted into the row set which the user can then populate using a form.

You can create a simple input form by dragging and dropping a collection and the appropriate operations from the Data Controls panel on to a page. However, you might need to employ a selection of other techniques to control the user workflow and insert other form processing logic. Such techniques may include:

- Using parameters in ADF task flows to pass values with which to pre-populate given attributes of a new record. For more information, see Passing Parameters to a View Activity.
- Using task flow return activities to set the transaction boundary in the UI, as shown in Using Task Flow Return Activities .
- Embedding operations in task flow method calls, as shown in Passing Parameters to a Bounded Task Flow.
- Using managed beans to carry out some operations as shown in Overriding Declarative Methods.
- Incorporating the form into a region in a task flow as shown in Using Task Flows as Regions .
- Incorporating the form into a multi-step flow, as shown in Using Train Components in Bounded Task Flows.
- Placing the form inside a dialog as shown in Running a Bounded Task Flow in a Modal Dialog.
- Using save points as described inManaging Transactions in Task Flows.

The following section shows how to create a basic input form and provides information on a couple of variants.

How to Create an Input Form

Creating a basic input form involves creating an edit form and adding a command component for creating new records.

Before you begin:

It may be helpful to have an understanding of input forms. For more information, see Creating an Input Form.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Pages.

You will need to complete this task:

Create an edit form as described in How to Create an Edit Form.

To create an input form:

1. In the Data Controls panel, expand the node for the collection object on which the form is based.
2. Expand the collection's **Operations** node and drag the `CreateInsert` operation to the edit form.

> **Note:**
>
> The `CreateInsert` operation is available only for data controls based on ADF Business Components application modules. If your data control is based on another business service, use the `Create` operation instead. For more information on the differences between the two, see Table 31-2.

Creating an Input Form Using a Bounded Task Flow

You can use a task flow to provide the workflow for input forms. Instead of using command components to create new objects, you use a method call activity in the task flow or a method in a managed bean. Instead of using a command component to commit changes, you use a task flow return activity.

For example, you can use a method call activity in a task flow to call a data control object's `CreateInsert` operation and then pass control to a view activity that displays a form where the user can enter the data.

To create an input form within a bounded task flow:

1. Create a bounded task flow as described in Creating a Task Flow.
2. In the Properties window, set the **Transaction** property to **Always Begin New Transaction**.

   For more information, see Managing Transactions in Task Flows.
3. In the bounded task flow, add a method call activity.

   For more information, see Using Method Call Activities.
4. From the Data Controls panel, drag the `CreateInsert` operation associated with the collection for which you are creating the form and drop it on the method activity.
5. With the method call activity still selected, in the Properties window, enter a string for the `fixed-outcome` property. After dropping the `CreateInsert` operation on to the method call activity, this value is set to `CreateInsert`, but you may want to change it to something more specific.
6. In the overview editor for the task flow, add a view activity that represents the page for the input form. For information on adding view activities, see Adding Activities to a Task Flow.
7. Add a control flow case from the method activity to the view activity.
8. With the control flow case still selected in the design editor, in the Properties window, make sure that the `from-outcome` property of the control flow case is the

same as the value of the fixed-outcome property of the method activity set in Step 5.

9. Open the page for the view activity in the design editor, and from the Data Controls panel, drag the collection for which the form will be used to create a new record, and choose **ADF Form** from the context menu.
10. In the task flow, add a return activity. This return activity must execute the commit operation on the data control. For these procedures, see Using Task Flow Return Activities .

Using a Commit Button Instead of a Return Activity Within a Task Flow

Generally you should use a return activity to call the Commit operation. However, there might be cases where you need to use a command component for the Commit operation, such as when the task flow contains data managed by more than one data control or you need to commit the data before the end of the flow.

To create an input form that has a Commit button within the form:

1. Create an input form as described in Creating an Input Form Using a Bounded Task Flow, but without setting the task flow return activity.
2. In the Data Controls panel, drag the Commit operation for the data control that contains the collection associated with the input form, and drop it as a command button.
3. In the Structure window, select the command button for the commit operation.
4. In the Properties window, set the action to the outcome string that will navigate back to the method activity. You then need to add a control flow case from the page back to the activity, using the same outcome value.
5. Set the command button's disabled property to false.

   By default, JDeveloper binds the disabled attribute of the button to the enabled property of the binding, causing the button to be disabled when the enabled property is set to false. For this binding, the enabled property is false until an update has been posted. For the purposes of an input form, the button should always be enabled, since there will be no changes posted before the user needs to create the new object.

Creating an Input Form That Allows Multiple Entries in a Single Transaction

If you want the user to be able to create multiple entries before committing to the database, do the following:

To enable an input form to allow multiple entries in a single transaction:

1. Create an input form as described in Creating an Input Form Using a Bounded Task Flow
2. In the task flow, add another control flow case from the view activity back to the method activity, and enter a value for the from-outcome method. For example, you might enter createAnother.
3. Drag and drop a command component from the Components window onto the page, and set the action attribute to the from-outcome just created. This will cause the task flow to return to the method activity and reinvoke the CreateInsert operation.

What Happens When You Create an Input Form

When you use an ADF Form to create an input form, JDeveloper:

- Creates an iterator binding for the collection and an action binding for the `CreateInsert` operation in the page definition for the method activity. The `CreateInsert` operation is responsible for creating a row in the row set and populating the data source with the entered data. In the page definition for the page, JDeveloper creates an iterator binding for the collection and attribute bindings for each of the attributes of the object in the collection, as for any other form. If you created command buttons or links using the `Commit` and `Rollback` operations, JDeveloper also creates action bindings for those operations.
- Inserts code in the JSF page for the form using ADF Faces `inputText` components, and in the case of the operations, `button` components.

What Happens at Runtime: CreateInsert Action from the Method Activity

When the `CreateInsert` button is clicked (or a method corresponding to that operation is called), the `CreateInsert` action binding is invoked, which executes the `CreateInsertRow` action, and a new blank instance for the collection is created.

> **Note:**
>
> When you use a task flow method activity to the call the `CreateInsert` operation, the method activity's binding container skips validation for required attributes during routing from the method activity to the view activity, allowing the blank instance to be displayed in the form on the page.

What You May Need to Know About Displaying Sequence Numbers

Because the `Create` action is executed before the page is displayed, if you are populating the primary key using sequences, the next number in the sequence will appear in the input text field, unlike the rest of the fields, which are blank. The sequence number is displayed because the associated entity class contains a method that uses an eager fetch to generate a sequence of numbers for the primary key attribute. The eager fetch populates the value as the row is created. Therefore, using sequences works as expected with input forms.

However, if instead you've configured the attribute's type to `DBSequence` (which uses a database trigger to generate the sequence), the number would not be populated until the object is committed to the database. In this case, the user would see a negative number as a placeholder. To avoid this, you can use the following EL expression for the `Rendered` attribute of the input text field:

```
#{bindings.EmployeeId.inputValue.value > 0}
```

This expression will display the component only when the value is greater than zero, which will not be the case before it is committed. Similarly, you can simply set the

`Rendered` attribute to `false`. However, then the page will never display the input text field component for the primary key.

What You May Need to Know About Input Forms Backed By Stateless Services

If the data control on which your input form is based is a data control for a stateless business service, there is no built-in `Commit` operation for you to use to save changes back to the data source.

Instead, you need to use a custom method to save to the database. For more information, see What You May Need to Know About Working With Data Controls for Stateless Business Services .

Creating a Form with Dynamic Components

A form can be created dynamically. ADF Faces dynamic components are used to create a form that can display different data each time you run it.

Instead of creating static databound forms where you provide tags for each component directly in the page, you can use a dynamic component to create forms where the binding metadata and the components used to display the bound content are determined at runtime.

This section provides information on creating databound dynamic forms. You can also use the dynamic component to create databound tables. See Creating a Table with Dynamic Components.

For information on the dynamic form component, including how to create a custom data model, see Determining Components at Runtime in *Developing Web User Interfaces with Oracle ADF Faces*.

About Dynamic Components

ADF Faces provides the `af:dynamicComponent` tag that you can use to create model-driven forms and tables where the binding metadata and the tags used to display the bound content are determined at runtime.

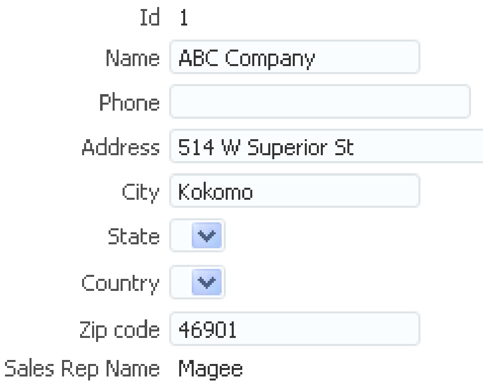
The dynamic building of the bindings provides the following possibilities:

- Enables you to create pages where the fields displayed and the ADF Faces components used to display them are determined by the data model. Any changes to the data model, such as additional columns or changed UI hints are reflected in the page without having to redesign the page. For more information about UI hints on view objects, see Defining UI Hints for View Objects.
- Enables you to create pages based on polymorphic view objects, in which the fields available for a given record can differ depending on the record's base entity object. Since the fields to display are determined at runtime, you do not have to include fields in the page that may not apply to certain records or do coding in the view layer to adjust the fields that are displayed for a given record. For more information about building business components that work with multiple row types, see Defining Polymorphic View Objects.

You set display information using UI hints on a view object instead of configuring the information in the Create Form or Create Table dialog when you drop the control onto the page. Then if you want to change how the data displays, you need only change it on the view object, and all dynamic components bound to that view object will change their display accordingly.

Figure 31-13 shows a dynamic form at runtime that was designed by setting UI hints for attributes on the `CustomerVO` view object and then dropping the `Customers` data control collection as a dynamic form. Among the UI hints set were `LABEL` and `DISPLAYHINT` (the latter of which can be set to `Hide` in order to not include the given attribute in the dynamic form).

Figure 31-13 Dynamic Form Displays Based on Hints Set on the View Object



Id	1
Name	ABC Company
Phone	
Address	514 W Superior St
City	Kokomo
State	
Country	
Zip code	46901
Sales Rep Name	Magee

The following ADF Faces components can be rendered at runtime when you use `af:dynamicComponent` at design time:

- `af:inputText`
- `af:inputDate`
- `af:inputListOfValues`
- `af:selectOneChoice`
- `af:selectManyChoice`
- `af:selectOneListbox`
- `af:selectManyListbox`
- `af:selectOneRadio`
- `af:selectBooleanRadio`
- `af:selectBooleanCheckbox`
- `af:selectManyCheckbox`

How to Create a Dynamic Form

To create a dynamic form, you drop a collection from the data controls panel as an ADF Form and specify that the fields be generated dynamically.

Before you begin:

It may be helpful to have an understanding of dynamic forms. See Creating a Form with Dynamic Components.

If you want to take advantage of dynamic forms to display records that contain varying attributes, you first need to have data objects that contain that capability. For information on creating view objects with this capability, see Defining Polymorphic View Objects.

You may also find it helpful to understand other ADF functionality and features. See Additional Functionality for Databound Pages.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

UI hints determine things such as the type of UI component to use to display the attribute, the label, the tooltip, whether the field should be automatically submitted, etc. You can also determine whether a given attribute is displayed or hidden. For the procedure to create UI hints, see Defining UI Hints for View Objects.

To create a dynamic form:

1. Set UI hints on the view object or data control structure definition file that corresponds to the collection for which you are creating the dynamic form.
2. Optionally, for the `Category` hint on each view object attribute, specify a category or click the **New Category** icon to create a new category.

   Any attributes that have the same category can be grouped together in dynamic forms that you create based on that view object.
3. Optionally, for any categories that you have created set the UI hints for the category's label and tooltip. These can be set in the **UI Categories** tab of the view object's overview editor.
4. From the Data Controls panel, select the collection that represents the view object.
5. Drag the collection onto the page, and from the context menu, choose **ADF Form**.
6. In the Create Form dialog, select the **Fields Generated at Runtime** checkbox.
7. If you have specified any categories for attributes, select the **Include Field Groups** checkbox in order for the form to group the attributes according to those categories.

What Happens When You Create Dynamic Forms

When you drop a collection as a dynamic form on a page, the following things happen:

- The page definition is populated with a `variableIterator` binding, an `iterator` binding to the iterator, and a `tree` value binding.
- The JSF page is populated with one or more `af:iterator` and `af:dynamicComponent` tags. In addition, if the **Include Field Groups** option is selected, `af:switcher` and `af:group` tags are added.

Bindings Created for the Dynamic Form

The page definition file for a dynamic form contains the following executables and bindings:

- **variableIterator**: an internal iterator that contains variables declared for the binding container.
- **iterator**: the iterator binding for the collection. For more information on iterator bindings, see Iterator Bindings Created in the Page Definition File.
- **tree**: the value binding for the attributes of the collection. Unlike a standard form, which has individual value bindings for each attribute set at design time, a dynamic form uses a single tree value binding to encompass the attributes that are exposed at runtime.

  Tree value bindings are also used for databound tables (both standard and dynamic). For more information, see Iterator and Value Bindings for Tables.

The following example shows the bindings for a page that contains a dynamic form component based on the `Customers` collection.

```
<executables>
  <variableIterator id="variables"/>
  <iterator
Binds="SummitAppModuleDataControl.dataProvider.BackOfficeAM.Customers"
            DataControl="SummitAppModuleDataControl" RangeSize="25"
id="CustomersIterator"/>
</executables>
<bindings>
  <tree IterBinding="CustomersIterator" id="Customers">
    <nodeDefinition DefName="oracle.summit.model.views.CustomerVO"
Name="Customers0"/>
  </tree>
</bindings>
```

Tags Created for a Dynamic Form without Grouping

In the JSF page, JDeveloper inserts an `af:iterator` tag, within which it nests an `af:dynamicComponent` tag. The `af:iterator` tag loops through all of the attributes that are exposed by the collection at runtime and uses the `af:dynamicComponent` tag to render the appropriate component for each attribute on the page.

The following example shows the code that is generated when you drop the `Customers` data control object as a dynamic form (but do not select the **Include Field Groups** option).

```
<af:panelFormLayout id="pfl1">
    <af:iterator id="i1" value="#{bindings.Customers.attributesModel.attributes}"
                 var="attr">
        <af:dynamicComponent id="d2" attributeModel="#{attr}">
                   value="#{bindings[attr.containerName]
[attr.name].inputValue}"/>
    </af:iterator>
</af:panelFormLayout>
```

The `value` attribute of the `af:iterator` tag uses an EL expression that evaluates to the `attributesModel.attributes` property of the collection's tree binding. The `attributesModel` property is used to retrieve the data object's attributes and their metadata, such as component type, label, tooltip, and other properties of the real component to be rendered. The `attributes` property of `attributesModel` signifies that a flat (unhierarchical) list of displayable attributes and their metadata is provided.

The `attributeModel` attribute of the `dynamicComponent` tag is bound to the EL expression `#{attr}`, which references the variable that is defined in the iterator's `var` attribute and that serves as a pointer to the current attribute of the data control collection and its corresponding metadata. The EL expression for the `dynamicComponent`'s `value` attribute also references the variable `attr`.

Tags Created for a Dynamic Form with Grouping

If you have selected the **Include Field Groups** checkbox in the Create Form dialog, the generated JSF page includes the `af:switcher` and `af:group` tags, in addition to the tags described in Tags Created for a Dynamic Form without Grouping.

The `af:switcher` tag is nested directly within a an `af:iterator` tag. Within the `af:switcher` tag are nested `f:facet` tags named `GROUP` and `ATTRIBUTE`. The `GROUP` facet contains an `af:group` tag, within which is an `afoutputText` tag to display the group name and an `iterator` tag, which contains an `af:dynamicComponent` tag. The `ATTRIBUTE` facet only contains an `af:dynamicComponent` tag.

For each attribute that the high-level `iterator` iterates over, the switcher dynamically determines whether to render a group or a component for the individual attribute. If it renders a group, the iterator within the group then is used to render the components for the attributes within that group.

The following example shows the code that is generated if you create a dynamic form based on the `Customers` collection and choose to include field groups.

```
<af:panelFormLayout id="pfl1">
    <af:iterator id="i1"

value="#{bindings.Customers.attributesModel.hierarchicalAttributes}"
              var="attr">
        <af:switcher id="sw1" facetName="#{attr.descriptorType}"
                     defaultFacet="ATTRIBUTE">
            <f:facet name="GROUP">
                <af:group title="#{attr.label}" id="g1">
                    <af:outputText value="#{attr.name}" id="ot1"/>
                    <af:iterator id="gi1" value="#{attr.descriptors}"
                                 var="nestedAttr">
                        <af:dynamicComponent id="gd1"
                                             attributeModel="#{nestedAttr}"/>
                    </af:iterator>
                </af:group>
            </f:facet>
            <f:facet name="ATTRIBUTE">
                <af:dynamicComponent id="ad1" attributeModel="#{attr}"/>
            </f:facet>
        </af:switcher>
    </af:iterator>
</af:panelFormLayout>
```

The `value` attribute of the `af:iterator` tag uses an EL expression that evaluates to the `attributesModel.hierarchicalAttributes` property of the collection's tree binding. The `attributesModel` property is used to retrieve the data object's attributes and their metadata, such as component type, label, tooltip, and other properties of the real component to be rendered. The `hierarchicalAttributes` property signifies that a hierarchical list of displayable attributes and their metadata is provided, including any categories that have been set for any attributes in the UI hints.

The `attributeModel` attribute of the `af:dynamicComponent` tag is set to the EL expression `#{attr}`, which references the variable that is defined in the iterator's `var` attribute and that serves as a pointer to the current attribute (or category) of the data control collection and its corresponding metadata.

What Happens at Runtime: How Attribute Values Are Dynamically Determined

When a page with dynamic components is rendered, the bindings are created just as they are when items are dropped from the Data Controls panel at design time, except that they are created at runtime.

At runtime, the `iterator` iterates over the set of attributes and instantiates a `dynamicComponent` for each attribute. The dynamic component uses its `attributeModel` property to obtain information from the iterator about the current attribute, such as label and control type. Each `dynamicComponent` then renders a component based on the metadata that is returned for the attribute.

If the `DISPLAYHINT` UI hint for an attribute is set to `Hide`, no component for the attribute is rendered.

If the dynamic form is created from a data control object that is based on a polymorphic view object, the rendered components depend on the row type for the currently selected record.

How to Apply Validators and Converters to a Dynamic Component

By default, standard ADF Faces converters and validators are applied to the components generated at runtime when using dynamic components. For example, `converterDateTime` converters are applied to components based on attributes of type `TimeStamp`.

If you need to add more specific validation or conversion to a component, you can do so by adding ADF Faces validator and converter tags to the source for the dynamic component and use the tags' `disabled` attribute to determine on which attributes the validators and converters are applied.

Before you begin:

It may be helpful to have an understanding of dynamic forms. For more information, see Creating a Form with Dynamic Components.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Pages.

You will need to complete this task:

> Create a dynamic form as shown in How to Create a Dynamic Form or a dynamic table as shown in How to Create a Dynamic Table.

To manually insert an ADF Faces validator or converter into a dynamic form:

1. Open the page containing the dynamic component in the source editor.

2. Within the `af:dynamicComponent` tag, insert any validator and converter components that you want to use.
3. Within the each validator and converter tag, insert the `disabled` attribute and bind it to an EL expression that disables the tag for all attributes except for those to which you want to apply it.

   For example, the following expression would enable a validator only for the `Hiredate` attribute:

   ```
   #{attr.name == 'Hiredate' ? false : true}
   ```

The following example shows a dynamic component with two validators and two converters applied.

```
<af:panelFormLayout id="pfl1">
  <af:iterator id="i1" value="#{bindings.EmpVO1.attributesModel.attributes}"
                     var="attr">
    <af:dynamicComponent
                  value="#{bindings[attr.containerName][attr.name].inputValue}"
                  attributeModel="#{attr}" id="dc1"/>
      <af:convertDateTime disabled="#{attr.name == 'Hiredate' ? false : true}"
                          pattern="yyyy/MM/dd"/>
      <af:convertNumber disabled="#{attr.name == 'Sal' ? false : true}"
                        pattern="#,###,###" />
      <af:validateLength disabled="#{attr.name == 'Job' ? false : true}"
                         maximum="10" hintMaximum="maxmum length is 10"/>
      <af:validateLongRange disabled="#{attr.name == 'Sal' ? false : true}"
                            minimum="1000"/>
    </af:dynamicComponent>
  </af:iterator>
</af:panelFormLayout>
```

What You May Need to Know About Mixing Dynamic Components with Static Components

When you create a dynamic form, you essentially create a block of components that are rendered dynamically. It is possible place static components before and after that block of components, but you can not intersperse static components within that block.

The following example illustrates the granularity of mixing static and dynamic components that is possible. It consists of three `af:group` tags, the first and third of which contain static content and the second of which contains an `af:iterator` tag with a nested `af:dynamicComponent` tag.

```
<af:group title="static before dynamic" id="g1">
    <af:separator id="sp2"/>
    <af:inputText value="#{bindings.Empno.inputValue}" label="Static Empno"
                  required="#{bindings.Empno.hints.mandatory}"
                  columns="#{bindings.Empno.hints.displayWidth}"
                  maximumLength="#{bindings.Empno.hints.precision}"
                  shortDesc="#{bindings.Empno.hints.tooltip}" id="it1">
        <f:validator binding="#{bindings.Empno.validator}"/>
        <af:convertNumber groupingUsed="false"
                          pattern="#{bindings.Empno.format}"/>
    </af:inputText>
</af:group>
<af:group title="dynamic part" id="g2">
    <af:separator id="sp3"/>
    <af:panelFormLayout id="pfl1">
```

```
        <af:iterator id="i1"
value="#{bindings.EmpVO1.attributesModel.attributes}"
                     var="attr">
            <af:dynamicComponent
                     value="#{bindings[attr.containerName]
[attr.name].inputValue}"
                     id="dc1" attributeModel="#{attr}"/>
        </af:iterator>
    </af:panelFormLayout>
</af:group>
<af:group title="static after dynamic" id="g3">
    <af:separator id="sp4"/>
    <af:inputText value="#{bindings.Ename.inputValue}" label="Static Ename"
                  required="#{bindings.Ename.hints.mandatory}"
                  columns="#{bindings.Ename.hints.displayWidth}"
                  maximumLength="#{bindings.Ename.hints.precision}"
                  shortDesc="#{bindings.Ename.hints.tooltip}" id="it2">
        <f:validator binding="#{bindings.Ename.validator}"/>
    </af:inputText>
</af:group>
<af:button text="Back" id="cbb1" action="back"/>
```

How to Programmatically Set Dynamic Component Behavior

If you have any custom processing that you need to do to determine how the dynamic component is rendered, you can do so in a managed bean and then bind the dynamic component's `attributeModel` property to the appropriate bean method.

Before you begin:

It may be helpful to have an understanding of dynamic forms. For more information, see Creating a Form with Dynamic Components.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Pages.

You will need to complete this task:

> Create a dynamic form as shown in How to Create a Dynamic Form or a dynamic table as shown in How to Create a Dynamic Table.

For information about creating managed beans see Using a Managed Bean in a Fusion Web Application

To programmatically set a dynamic component's behavior:

1. In the UI project that contains the dynamic component, create a Java class that extends the `oracle.adf.view.rich.model.BaseAttributeDescriptor` class.

   As the following example shows a sample class that adds a method to apply a custom style to the label for the `Sal` attribute.

   ```
   public class CustomizedDescriptor extends BaseAttributeDescriptor
   {
     public CustomizedDescriptor(BaseAttributeDescriptor base)
     {
       _base = base;
     }

     public Object getLabelStyle()
     {
   ```

```
    if (getName().equals("Sal"))
      return "color:red; font-weight:bold";
    else
      return null;
  }
```

2. Create a managed bean for the page.
3. In the managed bean, create a method that returns an instance of the custom descriptor. As the following example shows such a method.

   ```
   public CustomizedDescriptor getCustomizedAttributes(String attrName)
     {
     // create value expression for "#{attrName}" and evaluate it to get object
     // of "attr"
       BaseAttributeDescriptor attrMetadata = null;
       Class klass = null;

       try
       {
         klass =
   ClassLoaderUtils.loadClass("oracle.adf.view.rich.model.BaseAttributeDescripto
   r");
       }
       catch (ClassNotFoundException e)
       {
         throw new RuntimeException("Can not find class
   oracle.adf.view.rich.model.BaseAttributeDescriptor");
       }

       FacesContext facesContext = FacesContext.getCurrentInstance();
       ELContext elContext = facesContext.getELContext();
       ValueExpression valueExpression = createValueExpression(attrName, klass);

       if (valueExpression != null)
         attrMetadata =
   (BaseAttributeDescriptor)valueExpression.getValue(elContext);

       return new CustomizedDescriptor(attrMetadata);
     }
   ```

4. In the source editor for the page containing the dynamic component, bind the dynamic component's `attributeModel` property to the managed bean method that returns the customized attribute descriptor.

   As the following example shows an `af:dynamicComponent` tag where its `attributeModel` attribute has been set to an EL expression that references the `getCustomizedAttributes` method of the `attributeCustomBean` managed bean.

   ```
   <af:panelFormLayout id="pfl1">
     <af:iterator id="i1" value="#{bindings.EmpVO1.attributesModel.attributes}"
                  var="attr">
       <af:dynamicComponent value="#{bindings[attr.containerName]
   [attr.name].inputValue}"
   attributeModel="#{attributeCustomBean.getCustomizedAttributes('attr')}" /
   >
     </af:iterator>
   </af:panelFormLayout>
   ```

How to Access a Dynamic Component Programmatically

If you need to access a dynamic component instance programmatically to make changes based on a user action, you can do so by using a managed bean.

Before you begin:

It may be helpful to have an understanding of dynamic forms. For more information, see Creating a Form with Dynamic Components.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Pages.

You will need to complete this task:

> Create a dynamic form as shown in How to Create a Dynamic Form or a dynamic table as shown in How to Create a Dynamic Table.

To programmatically access a dynamic component's binding instance:

1. Create a managed bean method that identifies dynamic component, casts the component to `RichDynamicComponent`, and then applies any changes.

   For more information, see Using a Managed Bean in a Fusion Web Application.

2. In the page containing the dynamic component, add a command component to the page and bind its `actionListener` property to the managed bean method.

The following example shows a managed bean method that changes the label style for a dynamic component.

```
public void changeLabelColor (ActionEvent event)
  {
    UIComponent component = event.getComponent().getParent();
    component = component.findComponent("pfl1");

    while(component != null)
    {
      if(component.getId().equals("it1"))
      {
        RichDynamicComponent rdc = (RichDynamicComponent)component;
        rdc.setLabelStyle("color:red");
        break;
      }
      else
        component = component.getChildren().get(0);
    }
  }
```

How to Access a Dynamic Component's Binding Instance Programmatically

If you need to access a runtime binding instance of a dynamic component programmatically, you can do so using a managed bean.

Before you begin:

It may be helpful to have an understanding of dynamic forms. For more information, see Creating a Form with Dynamic Components.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Pages.

You will need to complete this task:

Create a dynamic form as shown in How to Create a Dynamic Form or a dynamic table as shown in How to Create a Dynamic Table.

To access a dynamic component's binding instance programmatically:

1. Create a managed bean method that accesses the binding container through the `FacesContext`, gets the `AttributesModel`, and then applies the desired business logic.

   For more information, see Using a Managed Bean in a Fusion Web Application.

2. In the page containing the dynamic component, add a command component to the page and bind its `actionListener` property to the managed bean method.

The following example illustrates a managed bean method that will set the `DeptNo` value of the current row to 9999.

```
public void setValueThroughBinding(ActionEvent event)
  {
    // get binding container
    FacesContext facesContext = FacesContext.getCurrentInstance();
    ELContext elContext = facesContext.getELContext();
    ValueExpression valueExpression = createValueExpression("bindings",
                                  DCBindingContainer.class);
    DCBindingContainer binding = (DCBindingContainer)
                             valueExpression.getValue(elContext);

    // get AttributesModel and attribute metadata list
    valueExpression = createValueExpression("bindings.EmpVO1.attributesModel",
                      AttributesModel.class);
    AttributesModel attributesModel = (AttributesModel)
                                  valueExpression.getValue(elContext);
    List<BaseAttributeDescriptor> attrList = attributesModel.getAttributes();

    // get AttributeMetadata for "Empno"
    BaseAttributeDescriptor deptNoAttributeBase = null;
    FacesAttributeDescriptor deptNoAttribute = null;
    for (BaseAttributeDescriptor attrDescriptor: attrList)
    {
      if ("Comm".equals(attrDescriptor.getName()))
      {
        deptNoAttributeBase = attrDescriptor;
        break;
      }
    }

    deptNoAttribute = (FacesAttributeDescriptor)deptNoAttributeBase;
    if (deptNoAttribute == null || deptNoAttribute.getContainerName() == null)
    {
      System.out.println("AttributesModel of Empno or its model name");
      System.out.println("can not be found.");
      return;
    }

    // get Deptno attribute value binding, set input value
    JUFormBinding fb = (JUFormBinding) binding.findExecutableBinding((String)
                                    deptNoAttribute.getContainerName());
    JUCtrlValueBinding valueBinding = (JUCtrlValueBinding)

fb.getControlBinding(deptNoAttribute.getName());
    valueBinding.setInputValue(Integer.valueOf(9999));

    System.out.println("Found JUCtrlValueBinding " + deptNoAttribute.getName()");
    System.out.println("set its value to 9999.");
  }
```

Modifying the UI Components and Bindings on a Form

The Data Controls panel is used to modify any type of form (except a dynamic form) and ADF bindings on a form. You can customize the display of the UI as per requirement.

Once you use the Data Controls panel to create any type of form (except a dynamic form), you can then delete attributes, change the order in which they are displayed, change the component used to display data, and change the attribute to which the components are bound.

> **Note:**
>
> You cannot change how a dynamic form displays using the following procedures. You must change display information on the view object or entity object instead.

How to Modify the UI Components and Bindings

You can modify certain aspects of the default components dropped from the Data Controls panel. You can use the Structure window to change the order in which components are displayed, to add new components or change existing components, or to delete components. You can use the Properties window to change or delete bindings, or to change the label displayed for a component.

Before you begin:

It may be helpful to have a general understanding of working with UI components after they have been generated. For more information, see Modifying the UI Components and Bindings on a Form.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Pages.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To modify default components and bindings:

1. Use the Structure window to do the following:
   - Change the order of the UI components by dragging them up or down the tree. A black line with an arrowhead denotes where the UI component will be placed.
   - Add a UI component. Right-click an existing UI component in the Structure window and choose to place the new component before, after, or inside the selected component. You then choose from a list of UI components.
   - Bind a UI component. Right-click an existing UI component in the Structure window and choose **Bind to ADF Control**. You can then select the object to which you want your component bound.
   - Rebind a UI component. Right-click an existing UI component in the Structure window and choose **Rebind to another ADF Control**. You can then select the new control object to which you want your component bound.
   - Delete a UI component. Right-click the component and choose **Delete**. If you wish to keep the component, but delete the binding, you need to use the Properties window. See the second bullet point in Step 2.
2. With the UI component selected in the Structure window, you can then do the following in the Properties window:
   - Add a non-ADF binding for the UI component. Enter an EL expression in the **Value** field, or use the dropdown menu and choose **Edit**.
   - Delete a binding for the UI component by deleting the EL expression.
   - Change the label for the UI component. By default, the label is bound to the binding's `label` property of its hint. This property allows your page to use the UI control hints for labels that you have defined for your entity object attributes or view object attributes. The UI hints allow you to change the value once and have it appear the same on all pages that display the label.

     You can change the label just for the current page. To do so, select the `label` attribute. You can enter text or an EL expression to bind the label value to something else, for example, a key in a properties or resource file.

     For example, the `inputText` component used to display the name of a product might have the following for its `Label` attribute:

     ```
     #{bindings.ProductName.hints.label}
     ```

     However, you could change the expression to instead bind to a key in a properties file, for example:

     ```
     #{properties['productName']}
     ```

     In this example, `properties` is a variable defined in the JSF page used to load a properties file.

What Happens When You Modify Attributes and Bindings

When you modify how an attribute is displayed by moving or changing the UI component, JDeveloper changes the corresponding code on the JSF page. When you use the binding editors to add or change a binding, JDeveloper adds the code to the JSF page, and also adds the appropriate elements to the page definition file.

32
Creating ADF Databound Tables

This chapter describes how to create tables with data modeled from ADF Business Components, using ADF data controls and ADF Faces components, including editable tables, input tables, and dynamic tables.
This chapter includes the following sections:

About Creating ADF Databound Tables

A table is used to display tabular data. You can bind the ADF Faces table component to the complete collection of data objects at a time from the collection. You can create and modify data in the table.

Unlike forms, tables allow you to display more than one data object from a collection at a time.

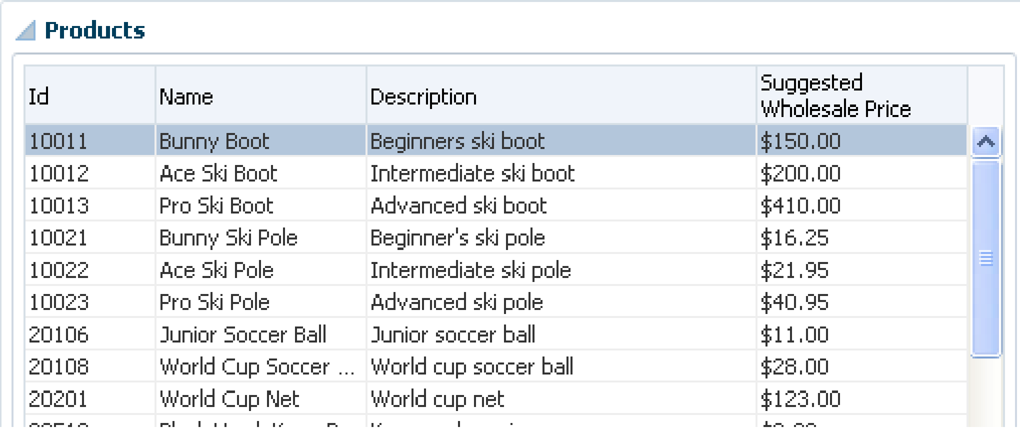
You can create tables that simply display data, or you can create tables that allow you to edit or create data. Once you drop a collection as a table, you can add command buttons bound to actions that execute some logic on a selected row. You can also modify the default components to suit your needs.

You can also display a collection of objects in a list that uses a grid to display each object's attributes, similar to a simple table.

ADF Databound Tables Use Cases and Examples

Figure 32-1 shows the Products table on the Inventory Control tab of the Summit sample application for **Oracle ADF**. This table is used to display all of the products in the inventory and enables the user to select a product to see its inventory status in an adjoining graph.

Figure 32-1 Read-only Table

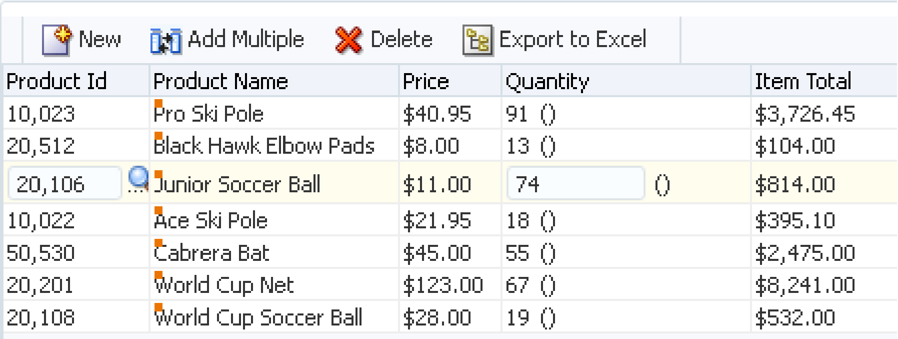


Products

Id	Name	Description	Suggested Wholesale Price
10011	Bunny Boot	Beginners ski boot	$150.00
10012	Ace Ski Boot	Intermediate ski boot	$200.00
10013	Pro Ski Boot	Advanced ski boot	$410.00
10021	Bunny Ski Pole	Beginner's ski pole	$16.25
10022	Ace Ski Pole	Intermediate ski pole	$21.95
10023	Pro Ski Pole	Advanced ski pole	$40.95
20106	Junior Soccer Ball	Junior soccer ball	$11.00
20108	World Cup Soccer ...	World cup soccer ball	$28.00
20201	World Cup Net	World cup net	$123.00

You can create a table that simply displays information, as shown in Figure 32-1, or you can allow the user to edit the information and create new records, as shown in Figure 32-2.

Figure 32-2 Edit Table



Product Id	Product Name	Price	Quantity	Item Total
10,023	Pro Ski Pole	$40.95	91 ()	$3,726.45
20,512	Black Hawk Elbow Pads	$8.00	13 ()	$104.00
20,106	Junior Soccer Ball	$11.00	74 ()	$814.00
10,022	Ace Ski Pole	$21.95	18 ()	$395.10
50,530	Cabrera Bat	$45.00	55 ()	$2,475.00
20,201	World Cup Net	$123.00	67 ()	$8,241.00
20,108	World Cup Soccer Ball	$28.00	19 ()	$532.00

Additional Functionality for Databound Tables

You may find it helpful to understand other ADF Faces features before you implement your table and tree components. Additionally, once you have added a tree or table component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that table and tree components can use.

- **ADF view objects**: Much of how the components display and function in the table is controlled by the corresponding **view objects**. See Defining SQL Queries Using View Objects.
- **ADF application modules**: The Data Controls panel, from which you drag databound components to your pages, is populated with representations of view objects that you have added to **application modules**. See Implementing Business Services with Application Modules.
- **Adapter-based data controls**: If you are using other types of business services, such as EJB components or web services, you can create data control for those

business services as described in Creating and Configuring EJB Data Controls of the *Developing Applications with Oracle ADF Data Controls*.

- **ADF Model and data binding**: When you create databound tables in an ADF web application, you use ADF Model and data binding. See Using ADF Model in a Fusion Web Application.
- **ADF Faces**: For detailed information about developing with ADF Faces, see Introduction to ADF Faces in *Developing Web User Interfaces with Oracle ADF Faces*.
- **Command buttons**: You may want to add command button or links that invoke some functionality against the data set. For more advanced functionality than what is covered in this chapter, see Using Command Components to Invoke Functionality in the View Layer.
- **Filtered tables**: You can create tables that provide filtering, in effect executing a query-by-example search against the data in the table. See Creating Standalone Filtered Search Tables from Named View Criteria.
- **Task flows**: If your table takes part in a transaction, for example an input table, then you may need to use an ADF task flow to invoke certain operations before or after the table is rendered. See Creating ADF Task Flows .
- **Validation**: You may want certain fields to be validated before they are submitted to the data store. See Defining Validation and Business Rules Declaratively and Using Validation in the ADF Model Layer .
- **Active data**: If your application uses active data, then you can have the data in your tables and trees update automatically, whenever the data in the data source changes. See Using the Active Data Service .

> **Note:**
>
> If you wish to use active data, and your application uses ADF Business Components, then your tables must conform to the following:
>
> – The binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
>
> – The binding rule contains a single attribute.
>
> – The table does not use filtering.
>
> – The tree component's `nodeStamp` facet contains a single `outputText` tag and contains no other tags.

Creating a Basic Table

In order to create a table using data control, you need to bind the ADF Faces table component to a collection of data objects. With the help of JDeveloper, you can perform this declaratively by dragging and dropping a collection from the Data Controls panel.

Unlike with forms where you bind the individual UI components that make up a form to the individual attributes on the collection, with a table you bind the ADF Faces `table` component to the complete collection or to a range of *n* data objects at a time from the collection. The individual components used to display the data in the columns are then bound to the attributes. The iterator binding handles displaying the correct data for each object, while the `table` component handles displaying each object in a row. JDeveloper allows you to do this declaratively, so that you don't need to write any code.

How to Create a Basic Table

To create a table using a data control, you bind the `table` component to a collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

Before you begin:

It may be helpful to have an understanding of ADF Faces databound tables. For more information, see Creating a Basic Table.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Tables.

You will need to complete these tasks:

- Create an **application module** that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To create a databound table:

1. From the Data Controls panel, select a collection.

   For example, to create a simple table in the Summit ADF sample application that displays all of the customers, you would select the `Customers` collection.

2. Drag the collection onto a JSF page, and from the context menu, choose **Table/ List View > ADF Table**.

3. The Create Table dialog shows each attribute in the collection, and allows you to determine how these attributes will behave and appear as columns in your table.

   Using this dialog, you can do the following:

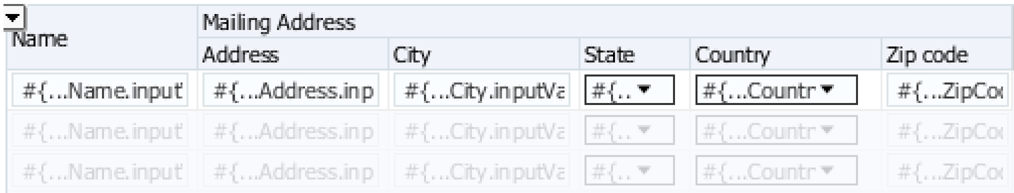
   - Make the table read-only.
   - Allow the ADF Model layer to handle selection by selecting the **Single Row** or **Multiple Rows** radio button. Selecting either of these options means that the iterator binding will access the iterator to determine the selected row or rows. Select one of these options unless you do not want the table to allow selection.
   - Allow the ADF Model layer to handle column sorting by selecting the **Enabling Sorting** checkbox. Selecting this option means that the iterator binding will access the iterator, which will perform an order-by query to determine the order. Select this option unless you do not want to allow column sorting.
   - Allow the columns in the table to be filtered using entered criteria by selecting the **Enabling Filtering** checkbox. Selecting this option allows the user to enter criteria in text fields above each column. That criteria is then used to build a Query-by-Example (QBE) search on the collection, so that the table

will display only the results returned by the query. For more information, see Creating Standalone Filtered Search Tables from Named View Criteria.

> **Note:**
>
> For JPA-based data controls, filtering does not work on tables that are created from nested collections in the data control. If you drop such a collection on a page, you should leave this checkbox unselected to avoid runtime errors. For more information on JPA-based data controls, see About EJB Data Controls in *Developing Applications with Oracle ADF Data Controls*.

- Group columns for selected attributes together under a parent column, by selecting the desired attributes (shown as rows in the dialog), and clicking the **Group** button. Figure 32-3 shows how five grouped columns appear in the visual editor after the table is created.

Figure 32-3 Grouped Columns in an ADF Faces Table



Name	Mailing Address				
	Address	City	State	Country	Zip code
#{...Name.input	#{...Address.inp	#{...City.inputVa	#{.. ▼	#{...Countr ▼	#{...ZipCo
#{...Name.input	#{...Address.inp	#{...City.inputVa	#{.. ▼	#{...Countr ▼	#{...ZipCo
#{...Name.input	#{...Address.inp	#{...City.inputVa	#{.. ▼	#{...Countr ▼	#{...ZipCo

- Change the display label for a column. By default, the label is bound to the `labels` property for any control hint defined for the attribute on the table binding. This binding allows you to change the value of a label text once on the view object, and have the change appear the same on all pages that display the label.

  Instead of using this default, you can enter text or an EL expression to bind the label value to something else, for example, a key in a resource file.

- Change the value binding for a column. You can change the column to be bound to a different attribute. If you simply want to rearrange the columns, you should use the order buttons. If you do change the attribute binding for a column, the label for the column also changes.
- Change the UI component used to display an attribute. The UI components are set based on the table you selected when you dropped the collection onto the page, on the type of the corresponding attribute (for example, `inputDate` components are used for attributes that are dates), and on whether or not default components were set as control hints on the corresponding view object. You can change to another component using the dropdown list.

> **Tip:**
>
> If one of the attributes for your table is also a primary key, you may want to choose a UI component that will not allow a user to change the value.

> **Tip:**
>
> If you want to use a component that is not listed in the dropdown menu, use this dialog to select the `outputText` component, and then manually add the other tag to the page.

- Change the order of the columns using the order buttons.
- Add a column using the **Add** icon. There's no limit to the number of columns you can add. When you first click the icon, JDeveloper adds a new column line at the bottom of the dialog and populates it with the values from the first attribute in the bound collection; subsequent new columns are populated with values from the next attribute in the sequence, and so on.
- Delete a column using the **Delete** icon.
- Make the table dynamic by selecting the **Generate columns dynamically at runtime** checkbox. For more information on dynamic tables, see Creating a Table with Dynamic Components.

4. Once the table is dropped on the page, you can use the Properties window to set other display properties of the table. For example, you may want to set the width of the table to a certain percentage or size. For more information about display properties, see the Using Tables, Trees, and Other Collection-Based Components chapter of *Developing Web User Interfaces with Oracle ADF Faces*.

   > **Tip:**
   >
   > When you set the table width to 100%, the table will not include borders, so the actual width of the table will be larger. To have the table set to 100% of the container width, expand the **Style** section of the Properties window, select the **Box** tab, and set the `Border Width` attribute to 0 pixels.

5. By default, the table will enforce delayed scrolling behavior which waits until the user stops scrolling and the position of the scroller is established to scroll the table rows. You can use the Property window that you display for the table iterator binding to configure smooth scrolling behavior. For more information, see What You May Need to Know About Table Scrolling Behavior and Row Count.
6. If you want the user to be able to edit information in the table and save any changes, you need to provide a way to submit and persist those changes. For more information, see Creating an Editable Table. For procedures on creating tables that allow users to input data, see Creating an Input Table.

What Happens When You Create a Table

Dropping a table from the Data Controls panel has the same effect as dropping a text field or form. Briefly, JDeveloper does the following:

- Creates the bindings for the table and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

For more information, see What Happens When You Create a Text Field .

Iterator and Value Bindings for Tables

When you drop a table from the Data Controls panel, a tree value binding is created. A tree consists of a hierarchy of nodes, where each subnode is a branch off a higher level node. In the case of a table, it is a flattened hierarchy, where each attribute (column) is a subnode off the table. Like an attribute binding used in forms, the tree value binding references the iterator binding, while the iterator binding references an iterator for the data collection, which facilitates iterating over the data objects in the collection. Instead of creating a separate binding for each attribute, only the tree binding to the table node is created. In the tree binding, the AttrNames element within the nodeDefinition element contains a child element for each attribute that you want to be available for display or reference in each row of the table.

The tree value binding is an instance of the FacesCtrlHierBinding class that extends the core JUCtrlHierBinding class to add two JSF specific properties:

- collectionModel: Returns the data wrapped by an object that extends the javax.faces.model.DataModel object that JSF and ADF Faces use for collection-valued components like tables.
- treeModel: Extends collectionModel to return data that is hierarchical in nature. For more information, see Displaying Master-Detail Data.

The following example shows the value binding for the table created when you drop the Summit sample application for ADF task flows's ProductVO1 collection.

```
<bindings>
  <tree IterBinding="ProductVO1Iterator" id="ProductVO1">
    <nodeDefinition
            DefName="oracle.summit.model.views.ProductVO"
            Name="ProductVO10">
      <AttrNames>
        <Item Value="Id"/>
        <Item Value="Name"/>
        <Item Value="ShortDesc"/>
        <Item Value="LongtextId"/>
        <Item Value="ImageId"/>
        <Item Value="SuggestedWhlslPrice"/>
        <Item Value="WhlslUnits"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

Only the table component needs to be bound to the model (as opposed to the columns or the text components within the individual cells), because only the table needs access to the data. The tree binding for the table drills down to the individual structure attributes in the table, and the table columns can then derive their information from the table component.

Code on the JSF Page for an ADF Faces Table

When you use the Data Controls panel to drop a table onto a JSF page, JDeveloper inserts an ADF Faces table component, which contains an ADF Faces column component for each attribute named in the table binding. Each column then contains another component (such as an inputText or outputText component) bound to the attribute's value. Each column's heading is bound to the `labels` property for the control hint of the attribute.

> **Tip:**
>
> If an attribute is marked as hidden on the associated view or entity object, no corresponding UI is created for it.

The following example shows a code excerpt from a table created by dropping the `ProductsVO1` collection as a read- only table.

```
<af:table value="#{bindings.ProductVO1.collectionModel}" var="row"
          rows="#{bindings.ProductVO1.rangeSize}"
          emptyText="#{bindings.ProductVO1.viewable ? 'No data to display.' :
'Access Denied.'}"
          fetchSize="#{bindings.ProductVO1.rangeSize}" rowBandingInterval="0"
          selectedRowKeys="#{bindings.ProductVO1.collectionModel.selectedRow}"
          selectionListener="#{bindings.ProductVO1.collectionModel.makeCurrent}"
          rowSelection="single" id="t1">
    <af:column headerText="#{bindings.ProductVO1.hints.Id.label}" id="c1">
        <af:outputText value="#{row.Id}"
                  shortDesc="#{bindings.ProductVO1.hints.Id.tooltip}"
                  id="ot1">
            <af:convertNumber groupingUsed="false"
                         pattern="#{bindings.ProductVO1.hints.Id.format}"/>
        </af:outputText>
    </af:column>
    <af:column headerText="#{bindings.ProductVO1.hints.Name.label}" id="c2">
        <af:outputText value="#{row.Name}"
                       shortDesc="#{bindings.ProductVO1.hints.Name.tooltip}"
                       id="ot2"/>
    </af:column>
    <af:column headerText="#{bindings.ProductVO1.hints.ShortDesc.label}" id="c3">
        <af:outputText value="#{row.ShortDesc}"
                  shortDesc="#{bindings.ProductVO1.hints.ShortDesc.tooltip}"
                  id="ot3"/>
    </af:column>
.
.
.
</af:table>
```

The tree binding iterates over the data exposed by the iterator binding. Note that the table's value is bound to the `collectionModel` property, which accesses the `collectionModel` object. The table wraps the result set from the iterator binding in a `collectionModel` object. The `collectionModel` allows each item in the collection to be available within the table component using the `var` attribute.

In the example, the table iterates over the rows in the current range of the `ProductVO1` iterator binding. The iterator binding binds to a **row set iterator** that keeps track of the current row. When you set the `var` attribute on the table to `row`, each column then accesses the current data object for the current row presented to the table tag using the `row` variable, as shown for the value of the `af:outputText` tag:

```
<af:outputText value="#{row.Id}"/>
```

When you drop an ADF Table and do not specify it as a read-only table, input components are generated instead of output components, as shown in the following example. The value of the input component is implicitly bound to a specific row in the binding container through the bindings property, instead of being bound to the row variable. Additionally, JDeveloper adds validator components for each input component. By using the bindings property, any raised exception can be linked to the corresponding binding object or objects. The controller iterates through all exceptions in the binding container and retrieves the binding object to get the client ID when creating FacesMessage objects. This retrieval allows the table to display errors for specific cells. This strategy is used for all input components, including selection components such as lists.

```
<af:table value="#{bindings.ProductVO1.collectionModel}" var="row"
          rows="#{bindings.ProductVO1.rangeSize}"
          emptyText="#{bindings.ProductVO1.viewable ? 'No data to display.' :
          'Access Denied.'}"
          fetchSize="#{bindings.ProductVO1.rangeSize}" rowBandingInterval="0"
          id="t1">
    <af:column headerText="#{bindings.ProductVO1.hints.Id.label}" id="c1">
        <af:inputText value="#{row.bindings.Id.inputValue}"
                      label="#{bindings.ProductVO1.hints.Id.label}"
                      required="#{bindings.ProductVO1.hints.Id.mandatory}"
                      columns="#{bindings.ProductVO1.hints.Id.displayWidth}"
                      maximumLength="#{bindings.ProductVO1.hints.Id.precision}"
                      shortDesc="#{bindings.ProductVO1.hints.Id.tooltip}"
                      id="it1">
            <f:validator binding="#{row.bindings.Id.validator}"/>
            <af:convertNumber groupingUsed="false"
                              pattern="#{bindings.ProductVO1.hints.Id.format}"/>
        </af:inputText>
    </af:column>
```

For more information about using ADF Faces validators and converters, see the Validating and Converting Input chapter of *Developing Web User Interfaces with Oracle ADF Faces*.

Table 32-1 shows the other attributes defined by default for ADF Faces tables created using the Data Controls panel.

Table 32-1 ADF Faces Table Attributes and Populated Values

Attribute	Description	Default Value
rows	Determines how many rows to display at one time.	An EL expression that, by default, evaluates to the rangeSize property of the associated iterator binding, which determines how many rows of data are fetched from a data control at one time. Note that the value of the rows attribute must be equal to or less than the corresponding iterator's rangeSize value, as the table cannot display more rows than are returned.
first	Index of the first row in a range (based on 0).	An EL expression that evaluates to the rangeStart property of the associated iterator binding.

Table 32-1 (Cont.) ADF Faces Table Attributes and Populated Values

Attribute	Description	Default Value
`emptyText`	Text to display when there are no rows to return.	An EL expression that evaluates to the viewable property on the iterator. If the table is viewable, the attribute displays **No data to display** when no objects are returned. If the table is not viewable (for example, if there are authorization restrictions set against the table), it displays **Access Denied**.
`fetchSize`	Number of rows of data fetched from the data source.	An EL expression that, by default, evaluates to the `rangeSize` property of the associated iterator binding. For more information about the `rangeSize` property, see Iterator RangeSize Attribute Defined. This attribute can be set to a larger number than the `rows` attribute. Note that to improve scrolling behavior in a table, when the table's iterator binding is expected to manage a data set consisting of over 200 items, and the view object is configured to use range paging, the iterator actually returns a set of ranges instead of just one range. For more information about using range paging for view objects, see Using Range Paging to Efficiently Scroll Through Large Result Sets. For more information on range paging for JPA-based data controls, see Paginated Fetching of Data in EJB Data Controls in *Developing Applications with Oracle ADF Data Controls*.
`selectedRowKeys`	The selection state for the table.	An EL expression that by default, evaluates to the selected row on the collection model.
`selectionListener`	Reference to a method that listens for a selection event.	An EL expression that by default, evaluates to the `makeCurrent` method on the collection model.
`rowSelection`	Determines whether rows are selectable.	Set to `single` to allow one row to be selected at a time. Set to `multiple` to allow more than one row to be selected.
Column Attributes		
`sortProperty`	Determines the property on which to sort the column.	Set to the columns corresponding attribute binding value.
`sortable`	Determines whether a column can be sorted.	Set to `false`. When set to `true`, the iterator binding will access the iterator to determine the order.
`headerText`	Determines the text displayed at the top of the column.	An EL expression that, by default, evaluates to the label control hint set on the corresponding attribute.

What You May Need to Know About Setting the Current Row in a Table

When you use tables in an application and you allow the ADF Model layer to manage row selection, the current row is determined by the iterator. When a user selects a row in an ADF Faces table, the row in the table is shaded, and the component notifies the iterator of the selected row. To do this, the `selectedRowKeys` attribute of the table is bound to the collection model's selected row, as shown in the following example.

```
<af:table value="#{bindings.ProductVO1.collectionModel}" var="row"
.
.
.
          selectedRowKeys="#{bindings.ProductVO1.collectionModel.selectedRow}"
          selectionListener="#{bindings.ProductVO1.collectionModel.makeCurrent}"
          rowSelection="single">
```

This binding binds the selected keys in the table to the selected row of the collection model. The `selectionListener` attribute is then bound to the collection model's `makeCurrent` property. This binding makes the selected row of the collection the current row of the iterator.

> **Note:**
>
> If you create a custom selection listener, you must create a method binding to the `makeCurrent` property on the collection model (for example `#{binding.Products.collectionModel.makeCurrent}`) and invoke this method binding in the custom selection listener before any custom logic.

Although a table can handle selection automatically, there may be cases where you need to programmatically set the current row for an object on an iterator.

You can call the `getKey()` method on any view row to get a `Key` object that encapsulates the one or more key attributes that identify the row. You can also use a `Key` object to find a view row in a row set using the `findByKey()` method. At runtime, when either the `setCurrentRowWithKey` or the `setCurrentRowWithKeyValue` built-in operation is invoked by name by the data binding layer, the `findByKey()` method is used to find the row based on the value passed in as a parameter before the found row is set as the current row.

The `setCurrentRowWithKey` and `setCurrentRowWithKeyValue` operations both expect a parameter named `rowKey`, but they differ precisely by what each expects that `rowKey` parameter value to be at runtime:

setCurrentRowWithKey Operation
`setCurrentRowWithKey` expects the `rowKey` parameter value to be the **serialized string representation** of a view row key. This is a hexadecimal-encoded string that looks similar to this:

```
000200000002C20200000002C102000000010000010A5AB7DAD9
```

The serialized string representation of a key encodes all of the key attributes that might comprise a view row's key in a way that can be conveniently passed as a single value in a browser URL string or form parameter. At runtime, if you inadvertently pass a parameter value that is not a legal serialized string key, you may receive exceptions like `oracle.jbo.InvalidParamException` or `java.io.EOFException` as a result. In your web page, you can access the value of the serialized string key of a row by referencing the `rowKeyStr` property of an ADF control binding (for example. `#{bindings.SomeAttrName.rowKeyStr}`) or the row variable of an ADF Faces table (e.g. `#{row.rowKeyStr}`).

setCurrentRowWithKeyValue Operation
The `setCurrentRowWithKeyValue` operation expects the `rowKey` parameter value to be the literal value representing the key of the view row. For example, its value would be simply "`201`" to find product number `201`.

> **Note:**
>
> If you write custom code in an application module class and need to find a row based on a serialized string key passed from the client, you can use the `getRowFromKey()` method in the `JboUtil` class in the `oracle.jbo.client` package:
>
> ```
> static public Row getRowFromKey(RowSetIterator rsi, String sKey)
> ```
>
> The first parameter is the view object instance in which you'd like to find the row. The second parameter is the serialized string format of the key.

What You May Need to Know About Getting Row Data Programmatically

`CollectionModel` supports a version of the `getRowData` method that takes a row key parameter and thus allows you to get row data without changing currency.

For example, you can replace this code:

```
CollectionModelInstance.setRowKey(RowKeyInstance);
JUCtrlHierNodeBinding rowData = (JUCtrlHierNodeBinding)
   CollectionModelInstance.getRowData();
```

with this code:

```
JUCtrlHierNodeBinding rowData = (JUCtrlHierNodeBinding)
   CollectionModelInstance.getRowData(RowKeyInstance);
```

This is particularly useful when your view object uses range paging, since it enables you to avoid having to use the `setRowKey` method. (If you use `setRowKey`, you might also need to provide custom code to ensure that the row that you specify with that method is within the current range of rows.)

What You May Need to Know About Table Scrolling Behavior and Row Count

When you add the table component to a page, you size the table to display fewer rows than the fetch size set on the backing view object and therefore only a portion of the total row count. At runtime, when the user scrolls through the result set and the total number of rows is much larger than table rows, it is usually desirable to wait until the user stops scrolling and the final position of the scroller is established to render the corresponding rows. This default behavior is called delayed scrolling because the table rows don’t change until the position of the scroller is established. In contrast, when few fetches are needed to scroll through the result set (because the row count is a small multiple of the backing view object’s fetch size), smooth scrolling may be desired to allow the user to view table rows corresponding to the changing position of the scroller.

You can configure the desired table scrolling behavior using the **RowCountThreshold** attribute on the table’s iterator binding. The default attribute value (0) gets the estimated row count when the table is first rendered and supports delayed scrolling through a large result set. In this case, the size of the scroller will be determined from the start and will not change as the user scrolls through the result set.

To support smooth scrolling, set the **RowCountThreshold** attribute on the iterator binding of the table component to a value less than 0 (for example, -1). This will enforce smooth scrolling through a small result set and defer getting an estimated row count until the last set of rows is fetched. In this case, the scroller size and position will be determined by the number of rows fetched by the table, and the scroller will get smaller as the user scrolls through the result set.

Alternatively, you can set the **RowCountThreshold** attribute to a value greater than 0 when you want to configure a threshold for smooth scrolling to begin. When the table renders, it executes the estimated row count and if the row count is less than the value you specify, the framework will enforce the default behavior (delay row scrolling until the scroller position is established). If the estimated row count exceeds the threshold value, the table enforces the smooth scrolling behavior.

Creating an Editable Table

The process of creating an editable table is similar to that of a basic table apart from the addition of command buttons bound to operations. You can add an ADF Faces component if you need your table to contain a toolbar and place the command buttons on it.

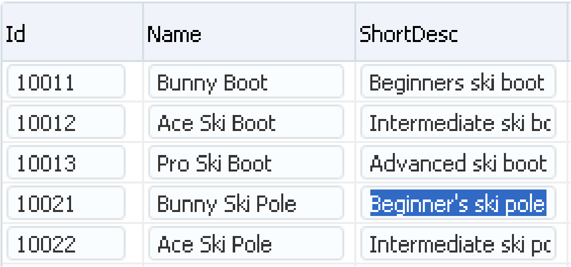
You can create a table that allows the user to edit information within the table, and then commit those changes to the data source. You can use built-in data control operations to create command buttons for changing the data, and place those buttons in a toolbar in the table. For example, you might use the `Delete` operation to create a button that allows a user to delete a record from the current range.

It is important to note that the collection-specific operations are executed only against objects in the ADF cache. You need to use the `Commit` operation on the root data control to actually commit any changes to the data source. You use the data control's `Rollback` operation to roll back any changes made to the cached object. If the page is part of a transaction within a bounded task flow, you would most likely use these operations to resolve the transaction in a task flow return activity. See Managing Transactions in Task Flows.

> **Note:**
>
> For data controls which do not have the `Commit` and `Rollback` operations available, such as data controls based on web services or stateless EJB session beans, you need to provide custom methods to save the data to the data source. For JPA-based data controls, you can use the `mergeEntity` or `persistEntity` methods to save changes, but these methods only work on a single row. For more information on working with JPA-based data controls, see About Commit Models for EJB Session Beans in *Developing Applications with Oracle ADF Data Controls*.

When you decide to use editable components to display your data, you have the option of the table displaying all rows as editable immediately, or displaying all rows as read-only until the user double-clicks within the row. Figure 32-4 shows a table whose rows all have editable fields. The page renders using the components that were added to the page (for example, `inputText` and `inputDate`, components).

Figure 32-4 Table with Editable Fields



Id	Name	ShortDesc
10011	Bunny Boot	Beginners ski boot
10012	Ace Ski Boot	Intermediate ski bc
10013	Pro Ski Boot	Advanced ski boot
10021	Bunny Ski Pole	Beginner's ski pole
10022	Ace Ski Pole	Intermediate ski pc

Figure 32-5 shows the same table, but configured so that the user must double-click (or single-click if the row is already selected) a row in order to edit or enter data. Note that `outputText` components are used to display the data in the nonselected rows, even though the same input components as in Figure 32-4 were used to build the page. The only row that actually renders those components is the row selected for editing.

For more information about how ADF Faces table components handle editing, see Editing Data in Tables, Trees, and Tree Tables in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create an Editable Table

To create an editable table, you follow similar procedures to creating a basic table, then you add command buttons bound to operations. However, in order for the table to contain a toolbar, you need to add an ADF Faces component that associates the toolbar with the items in the collection used to build the table.

Before you begin:

It may be helpful to have an understanding of editable databound tables. For more information, see Creating an Editable Table.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Tables.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To create an editable table:

1. From the Data Controls panel, select a collection.

   For example, to create a simple table in the Summit ADF task flow sample application that will allow you to edit products in the system, you would select the `ProductVO1` collection.

2. Drag the collection onto a JSF page, and from the context menu, choose **Table / List View > ADF Table**.

   This creates an editable table using input components.

3. Use the ensuing Create Table dialog to determine how the attributes should behave and appear as columns in your table. Be sure to select the **Single Row** or **Multiple Rows** radio button in order to allow the user to select a row to edit.

   For more information about using this dialog to configure the table, see How to Create a Basic Table.

4. With the table selected in the Structure window, expand the **Behavior** section of the Properties window and set the **EditingMode** attribute. If you want all the rows to be editable select **editAll**. If you want the user to click into a row to make it editable, select **clickToEdit**.

5. From the Structure window, right-click the table component and choose **Surround With**.

6. In the Surround With dialog, ensure that **ADF Faces** is selected in the dropdown list, select the **Panel Collection** component, and click **OK**.

   The `panelCollection` component's toolbar facet will hold the toolbar which, in turn, will hold the command components used to update the data.

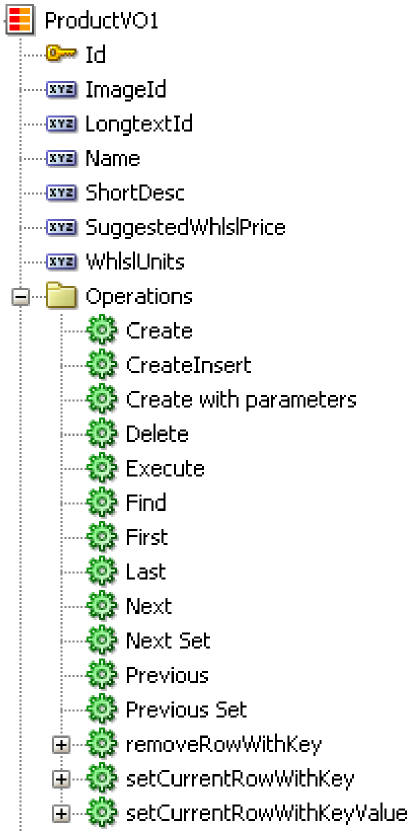
7. In the Structure window, right-click the `panelCollection`'s **f:facet - toolbar** facet node and choose **Insert inside f:facet - toolbar** > **Toolbar**.

This creates a toolbar that already contains a default menu that allows users to change how the table is displayed and a **Detach** link that detaches the entire table and displays it such that it occupies the majority of the space in the browser window. For more information about the `panelCollection` component, see the Displaying Table Menus, Toolbars, and Status Bars section of *Developing Web User Interfaces with Oracle ADF Faces*.

8. From the Data Controls panel, select the operation associated with the collection of objects on which you wish the operation to execute, drag it onto the `toolbar` component in the Structure window, and choose **Create > ADF Button** from the context menu. This will place the databound command component inside the toolbar.

   For example, if you want to be able to delete a product record, you would drag the `Delete` operation associated with the `ProductVO1` collection. Figure 32-6 shows the operations associated with he `ProductVO1` collection.

Figure 32-6 Operations Associated with a Collection



- ProductVO1
  - Id
  - ImageId
  - LongtextId
  - Name
  - ShortDesc
  - SuggestedWhlsPrice
  - WhlsUnits
  - Operations
    - Create
    - CreateInsert
    - Create with parameters
    - Delete
    - Execute
    - Find
    - First
    - Last
    - Next
    - Next Set
    - Previous
    - Previous Set
    - removeRowWithKey
    - setCurrentRowWithKey
    - setCurrentRowWithKeyValue

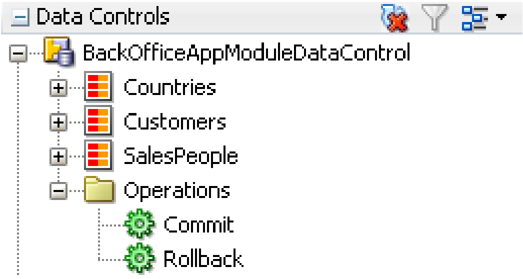
9. If you need a button for submitting changes to the cache, right-click the **af:toolbar** component in the Structure window and choose **Insert Inside Toolbar** > **Button**.

> **Note:**
>
> You can use other means to submit changes to the cache, such as setting the `autoSubmit` property to `true` for the input components in the table. For more information, see Using Partial Triggers in *Developing Web User Interfaces with Oracle ADF Faces*.

10. If the page is not part of a transaction within a bounded task flow, then you need to create buttons that allow the user to either commit or rollback the changes. From the Data Controls panel, drag the `Commit` and `Rollback` operations associated with the root-level data control, and drop them as either a button or link into the toolbar.

    Figure 32-7 shows the commit and roll back operations for the `BackOfficeAppModuleDataControl` data control.

    Figure 32-7 Commit and Rollback Operations for a Data Control



Data Controls
BackOfficeAppModuleDataControl
Countries
Customers
SalesPeople
Operations
Commit
Rollback

    If the page is part of a transaction within a bounded task flow, then you can simply enter `Commit` and `Rollback` as the values for the transaction resolution when creating the task flow return activity. For more information, see Managing Transactions in Task Flows.

> **Tip:**
>
> To create a table that allows you to insert a new record into the data store, see Creating an Input Table.

What Happens When You Create an Editable Table

Creating an editable table is similar to creating a form used to edit records. Action bindings are created for the operations dropped from the Data Controls panel. For details, see What Happens When You Create Command Components Using Operations.

Creating an Input Table

In order to create an input table, you need to first create an editable table and add a command component for creating new blank rows used to create new records.

You can create a table that allows users to insert a new blank row into a table and then add values for each column (any default values set on the corresponding entity or view object will be automatically populated).

How to Create an Input Table

When you create an input table, you want the user to see the new blank row in the context of the other rows within the current row set. To allow this insertion, you use the `CreateInsert` operation. As opposed to the `Create` operation, the `CreateInsert` operation actually creates the new row within the row set instead of only in the cache. In addition, you need to configure the table to respond to that user action. ADF Faces components can be set so that one component refreshes based on an interaction with another component, without the whole page needing to be refreshed. This is known as **partial page rendering**.

> **Note:**
>
> The `CreateInsert` operation is not available for adapter-based data controls, such as those based web services or Java classes. However, for JPA-based data controls, the `Create` operation adds the new row to the row set like `CreateInsert` does for data controls based on application modules. For more information, see Data Control Built-in Operations in *Developing Applications with Oracle ADF Data Controls*.

Before you begin:

It may be helpful to have an understanding of ADF Faces input tables. For more information, see Creating an Input Table.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Tables.

You will need to complete these tasks:

- Create an editable table, as described in Creating an Editable Table.
- If your table is not part of a bounded task flow, include buttons bound to the `Commit` and `Rollback` operations.

To create an input table:

1. From the Data Controls panel, drag the **CreateInsert** operation associated with the dropped collection and drop it as a toolbar button into the toolbar. You may want to change the ID to something more recognizable, such as `CreateNewRow`. This will make it easier to identify when you need to select it as the partial trigger.

> **Note:**
>
> If the collection is a child to another collection (for example, in the Summit ADF sample application the `OrdersForCustomer` collection is a child to the `Customers` collection), then instead of using the `CreateInsert` operation, you need to use the `Create with Parameters` operation so that the record to create for the child collection is associated with the parent collection.

2. In the Structure window, select the table component. In the Properties window, expand the **Behavior** section.
3. In the Properties window, mouse over the **PartialTriggers** attribute, click the dropdown menu, and choose **Edit**.
4. In the Edit Property dialog, expand the toolbar facet for the `panelCollection` component and then expand the toolbar that contains the **CreateInsert** command component. Select that component and shuttle it to the **Selected** panel. Click **OK**. This sets that component to be the trigger that will cause the table to refresh.

What Happens When You Create an Input Table

When you use the `CreateInsert` operation to create an input table, JDeveloper:

- Creates an iterator binding for the collection, an action binding for the `CreateInsert` operation, and attribute bindings for the table. The `CreateInsert` operation is responsible for creating the new row in the row set. If you created command buttons or links using the `Commit` and `Rollback` operations, JDeveloper also creates an action bindings for those operations.
- Inserts code in the JSF page for the table using ADF Faces `table`, `column`, and `inputText` components, and in the case of the operations, `button` components.

The following example shows the page definition file for an input table created from the `ProductVO1` collection (some attributes were deleted in the Create Table dialog when the collection was dropped).

```
<executables>
  <iterator Binds="ProductVO1" RangeSize="25"
            DataControl="BackOfficeAppModuleDataControl"
id="ProductVO1Iterator"/>
</executables>
  <tree IterBinding="ProductVO1Iterator" id="ProductVO1">
    <nodeDefinition
            DefName="oracle.summit.model.views.ProductVO"
            Name="ProductVO10">
      <AttrNames>
        <Item Value="Id"/>
        <Item Value="Name"/>
        <Item Value="ShortDesc"/>
        <Item Value="LongtextId"/>
        <Item Value="ImageId"/>
        <Item Value="SuggestedWhlslPrice"/>
        <Item Value="WhlslUnits"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
  <action IterBinding="ProductVOIterator" id="CreateInsert"
          RequiresUpdateModel="true" Action="createInsertRow"/>
  <action id="Commit" RequiresUpdateModel="true" Action="commitTransaction"
          DataControl="BackOfficeAppModuleDataControl"/>
  <action id="Rollback" RequiresUpdateModel="false"
          Action="rollbackTransaction"
          DataControl="BackOfficeAppModuleDataControl"/>
</bindings>
```

The following example shows the code added to the JSF page that provides partial page rendering, using the `CreateInsert` command toolbar button as the trigger to refresh the table.

```
<af:form>
  <af:panelCollection id="pc1">
    <f:facet name="menus"/>
    <f:facet name="toolbar">
      <af:toolbar id="tb1">
        <af:button actionListener="#{bindings.CreateInsert.execute}"
                                 text="CreateInsert"
                                 disabled="#{!bindings.CreateInsert.enabled}"
                                 id="CreateInsert"/>
        <af:button actionListener="#{bindings.Commit.execute}"
                                 text="Commit"
                                 disabled="false" id="b2"/>
        <af:button actionListener="#{bindings.Rollback.execute}"
                                 text="Rollback"
                                 disabled="#{!bindings.Rollback.enabled}"
                                 immediate="true" id="b3">
          <af:resetActionListener/>
        </af:button>
      </af:toolbar>
    </f:facet>
    <f:facet name="statusbar"/>
    <af:table value="#{bindings.ProductVO1.collectionModel}" var="row"
              rows="#{bindings.ProductVO1.rangeSize}"
              emptyText="#{bindings.ProductVO1.viewable ? \'No data to
display.\' :
                                                      \'Access Denied.\'}"
              fetchSize="#{bindings.ProductVO1.rangeSize}"
              rowSelection="single" partialTriggers="CreateInsert" id="t1">
      <af:column sortProperty="Id" sortable="false"
                 headerText="#{bindings.ProductVO1.hints.Id.label}"
                 id="c1">
        <af:inputText value="#{row.ProductId}" simple="true"
                      required="#{bindings.ProductVO1.hints.Id.mandatory}"
                      columns="#{bindings.ProductVO1.hints.Id.displayWidth}"
                      maximuumLength="#{bindings.ProductVO1.hints.Id.precision}"
                     id="it1"/>
      </af:column>
.
.
.
    </af:table>
  </af:panelCollection>
</af:form>
```

What Happens at Runtime: How CreateInsert and Partial Page Refresh Work

When the button bound to the `CreateInsert` operation is invoked, the action executes, and a new instance for the collection is created and inserted as the page is rerendered. Because the button was configured to be a trigger that causes the table to refresh, the table redraws with the new empty row shown at the top. When the user clicks the button bound to the `Commit` action, the newly created rows in the row set are inserted into the database. For more information about partial page refresh, see the Rerendering Partial Page Content chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

What You May Need to Know About Creating a Row and Sorting Columns

If your table columns allow sorting, and the user has sorted on a column before inserting a new row, then that new row will not be sorted. To have the column sort with the new row, the user must first sort the column opposite to the desired sort, and then resort. This is because the table assumes the column is already sorted, so clicking on the desired sort order first will have no effect on the column.

For example, say a user had sorted a column in ascending order, and then added a new row. Initially, that row appears at the top. If the user first clicks to sort the column again in ascending order, the table will not resort, as it assumes the column is already in ascending order. The user must first sort on descending order and then ascending order.

If you want the data to automatically sort on a specific column in a specific order after inserting a row, then programmatically queue a `SortEvent` after the commit, and implement a handler to execute the sort.

If you want to allow sorting on a column for which the view object attribute is defined by a custom domain data type, you must implement the `compareTo()` method for the table's sort button click event:

```
public int compareTo(Object theObject)
```

The method will return `0` for values that are equal, less then `0` if the current object is less than `theObject`, and greater than `0` if the current object is greater. The object comparison for attributes behaves just like String comparisons.

What You May Need to Know About Create and CreateInsert

When you use the `Create` or `CreateInsert` operation to declaratively create a new row, it performs the following lines of code:

```
// create a new row for the view object
Row newRow = yourViewObject.createRow();
// mark the row as being "initialized", but not yet new
newRow.setNewRowState(Row.STATUS_INITIALIZED);
```

However, if you are using the `CreateInsert` operation, it performs the additional line of code to insert the row into the row set:

```
// insert the new row into the view object's default rowset
yourViewObject.insertRow(newRow);
```

When you create a row in an entity-based view object, the `Transaction` object associated with the current application module immediately takes note of the fact. The new entity row that gets created behind the view row is already part of the `Transaction`'s list of pending changes. When a newly created row is marked as having the *initialized* state, it is removed from the `Transaction`'s pending changes list and is considered a blank row in which the end user has not yet entered any data values. The term *initialized* is appropriate since the end user will see the new row initialized with any default values that the underlying entity object has defined. If the user never enters any data into any attribute of that initialized row, then it is as if the row never existed. At transaction commit time, since that row is not part of the `Transaction`'s pending changes list, no `INSERT` statement will be attempted for it.

As soon as at least one attribute in an initialized row is set, it automatically transitions from the initialized status to the new status (`Row.STATUS_NEW`). At that time, the underlying entity row is enrolled in the `Transaction`'s list of pending changes, and the new row will be permanently saved the next time you commit the transaction.

Note:

If the end user performs steps that result in creating many initialized rows but never populating them, it might seem likely to cause a slow memory leak. However, the memory used by an initialized row that never transitions to the new state will eventually be reclaimed by the Java virtual machine's garbage collector.

What You May Need to Know About Saving Multiple Rows in a JPA-Based Data Control

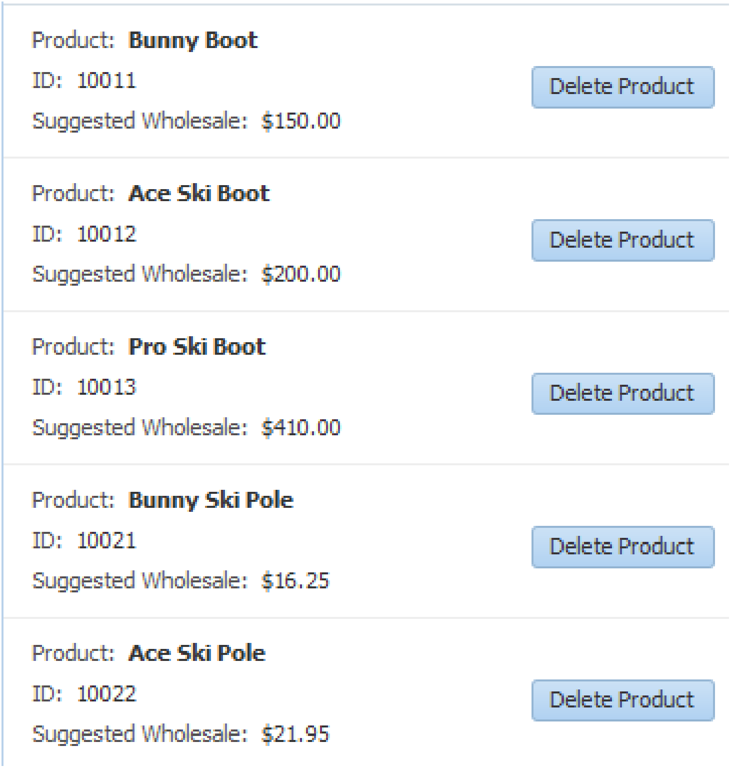
EJB data controls and JPA-based bean data controls do not have the built-in `CreateInsert` operation available. However, it is possible to replicate the behavior of `CreateInsert` with the `Create` operation in these data controls by setting the data control's `EagerPersist` property to `true`. This property is set to `true` by default for data controls based on stateful session beans that use container-managed transactions and an explicit commit model. For more information, see About Commit Models for EJB Session Beans in *Developing Applications with Oracle ADF Data Controls*

Creating a List View of a Collection

The listview component uses a model to display data in a list. You can choose between a panelGroupLayout or a panelGridLayout component to arrange the components for your list item.

You can use the `listView` component when you need to display a collection of objects in a list. The attributes of each object are displayed in a group or grid within a single row and single column. Figure 32-8 shows a collection of products displayed using a `listView` component.

Figure 32-8 A Collection Displayed in a List in a Single Column



Product: **Bunny Boot**
ID: 10011
Suggested Wholesale: $150.00

Product: **Ace Ski Boot**
ID: 10012
Suggested Wholesale: $200.00

Product: **Pro Ski Boot**
ID: 10013
Suggested Wholesale: $410.00

Product: **Bunny Ski Pole**
ID: 10021
Suggested Wholesale: $16.25

Product: **Ace Ski Pole**
ID: 10022
Suggested Wholesale: $21.95

In this `listView`, a child `listItem` component contains a `panelGridLayout` component that, in turn, contains `outputFormatted` components that display the data and a button component that allows users to delete the item. The `listView` component is bound to the collection, in the same way that a table is bound to a collection, using the `value` attribute. The `listItem` component is a direct child to the `listView` component, and is the container for the components that display the data, in the same way that the column component holds the data components for a table.

If your collection has a **master-detail relationship** with another collection, you can group the child collection under the parent collection using grouping functionality in the `listView` component. For more information, see Using List Views to Display Master-Detail Objects.

For complete information about the `listView` and `listItem` components, see the Displaying a Collection in a List section of the *Developing Web User Interfaces with Oracle ADF Faces*. For complete information about using the `panelGridLayout` component to group items in grid within the list (as shown in Figure 32-8), see the Arranging Content in a Grid section of the *Developing Web User Interfaces with Oracle ADF Faces*. You can also use a `panelGroupLayout` component to group components when you don't need a grid layout. For more information, see the Grouping Related Items section of the *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create a Databound List View

You use the Create List View wizard to create your list. This wizard allows you to choose between a `panelGroupLayout` or a `panelGridLayout` component to arrange the components for your list item. If you are creating the list for a child of a master-detail relationship, you can also use the wizard to configure the headers for the list.

Before you begin:

It may be helpful to have an understanding of ADF Faces list views. For more information, see Creating a List View of a Collection.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Tables.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To create a list view:

1. From the Data Controls panel, drag a collection onto the page and choose **Table/List View > ADF List View**. If you want to create a list with headers from a parent collection, drag a collection that is a child to another collection.
2. Use the Create List View wizard to select your layout component to organize your display of the data, and to select the attributes and components to display. If you are creating a group, on the first page of the wizard, select **Include header using parent collection**.

   For more information about using the wizard, press the F1 key or click **Help**.
3. Use the Properties window to further configure the layout components.

   For complete information about using the `panelGridLayout` component, see the Arranging Content in a Grid section of the *Developing Web User Interfaces with Oracle ADF Faces*. For more information about the `panelGroupLayout` component, see the Grouping Related Items section of the *Developing Web User Interfaces with Oracle ADF Faces*.

What Happens When You Create a Databound List View

When you use the wizard to create a `listView` component, JDeveloper creates and configures the `listView`, `listItem`, and layout components. The bindings are the same as for a table—the `listView` component is bound to the collection dropped from the Data Controls panel. The value of the `var` attribute on this component is used by the `outputFormatted` components to access the data, in the same way as a table. For more information about the page definition code and the JSP code for collections, see What Happens When You Create a Table.

The following example shows the page code for the simple table shown in Figure 32-8.

```
<af:listView value="#{bindings.SProductView1.collectionModel}" var="item"
             emptyText="#{bindings.SProductView1.viewable ? 'No data to display.'
                                                           : 'Access Denied.'}"
             fetchSize="#{bindings.SProductView1.rangeSize}" id="lv1">
    <af:listItem id="li1">
        <af:panelGridLayout id="pgl2" dimensionsFrom="parent">
            <af:gridRow marginTop="5px" height="15px" id="gr2">
```

```
                <af:gridCell marginStart="5px" width="50%" id="gc2">
                    <af:panelLabelAndMessage label="Product:" id="plam1"
                                                  inlineStyle="font-
weight:bold;">
                        <af:outputFormatted
                               value="#{item.bindings.Name.inputValue}"
id="of1"/>
                    </af:panelLabelAndMessage>
                </af:gridCell>
                <af:gridCell marginStart="5px" width="50%" marginEnd="5px"
                             id="gc3"/>
            </af:gridRow>
            <af:gridRow marginTop="5px" height="15px" id="gr3">
                <af:gridCell marginStart="5px" width="50%" id="gc4">
                    <af:panelLabelAndMessage label="ID:" id="plam2">
                        <af:outputFormatted
value="#{item.bindings.Id.inputValue}"
                                            id="of2">
                            <af:convertNumber groupingUsed="false"

pattern="#{bindings.SProductView1.hints.Id.format}"/>
                        </af:outputFormatted>
                    </af:panelLabelAndMessage>
                </af:gridCell>
                <af:gridCell marginStart="5px" width="50%" marginEnd="5px"
                             id="gc5">
                    <af:button actionListener="#{bindings.Delete.execute}"
                               text="Delete Product"
                               disabled="#{!bindings.Delete.enabled}" id="b1"/>
                </af:gridCell>
            </af:gridRow>
            <af:gridRow marginTop="5px" height="15px" marginBottom="5px"
id="gr4">
                <af:gridCell marginStart="5px" width="50%" id="gc6">
                    <af:panelLabelAndMessage label="Suggested Wholesale:"
                                             id="plam3">
                        <af:outputFormatted

value="#{item.bindings.SuggestedWhlslPrice.inputValue}"
                           id="of3">
                            <af:convertNumber groupingUsed="false"
           pattern="#{bindings.SProductView1.hints.SuggestedWhlslPrice.format}"/>
                        </af:outputFormatted>
                    </af:panelLabelAndMessage>
                </af:gridCell>
                <af:gridCell marginStart="5px" width="50%" marginEnd="5px"
                             id="gc7"/>
            </af:gridRow>
        </af:panelGridLayout>
    </af:listItem>
</af:listView>
```

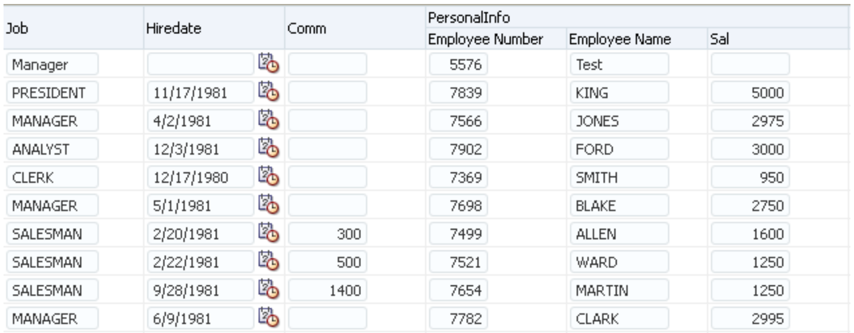
Creating a Table with Dynamic Components

A table can be created using ADF Faces dynamic components. The dynamic component in the table helps you to determine the binding metadata and the tags used to display the bound content each time you run it.

Instead of creating static databound tables where you provide tags for each component directly in the page, you can use a dynamic component to create tables where the binding metadata, columns, and the components used to display the bound content are determined at runtime.

Figure 32-9 shows a dynamic table at runtime that was created by setting UI hints for attributes on the `CustomerVO` view object and then dropping the `Customers` data control collection as a dynamic table. Among the UI hints set were `LABEL` and `DISPLAYHINT` (the latter of which can be set to `Hide` in order to not include the given attribute in the dynamic form).

Figure 32-9 Dynamic Table Including a Column Group Based on Category Hint



Job	Hiredate	Comm	PersonalInfo		
			Employee Number	Employee Name	Sal
Manager			5576	Test	
PRESIDENT	11/17/1981		7839	KING	5000

MANAGER	6/9/1981		7782	CLARK	2995

For more general information on dynamic components, see About Dynamic Components.

How to Create a Dynamic Table

To create a dynamic table, you drop a collection from the data controls panel as an ADF Table and specify that the fields be generated dynamically.

Before you begin:

It may be helpful to have an understanding of the dynamic component feature and dynamic databound tables. For more information, see About Dynamic Components and Creating a Table with Dynamic Components.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Tables.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

UI hints determine things such as the type of UI component to use to display the attribute, the label, the tooltip, whether the field should be automatically submitted, and so forth. You can also determine whether a given attribute is displayed or hidden. For the procedure to create UI hints, see Defining UI Hints for View Objects.

To create a dynamic table:

1. Set UI Hints either on the view object or on the data control structure definition file that corresponds to the collection for which you are creating the dynamic form.
2. Optionally, for the `Category` hint on each view object attribute, specify a category or click the **New Category** icon to create a new category.

   Any attributes that have the same category can be grouped together in dynamic tables that you create based on that view object.
3. Optionally, for any categories that you have created set the UI hints for the category's label and tooltip. These can be set in the **UI Categories** tab of the view object's overview editor.
4. From the Data Controls panel, select the collection that represents the view object.
5. Drag the collection onto the page, and from the context menu, choose **Table/List View > ADF Table**.
6. In the Create Table dialog, select the **Generate columns dynamically at runtime** checkbox.
7. If you have specified any categories for attributes select the **Include Column Groups** checkbox in order for the form to organize the display of columns into any checkbox in order for the table to group the columns according to those categories.

What Happens When You Use Dynamic Components

When you drop a collection as a dynamic table on a page, the following things happen:

- The page definition is populated with a `variableIterator` binding, an `iterator` binding to the iterator, and a `tree` value binding. See Bindings Created for the Dynamic Form.
- The JSF page is populated with an `af:table` tag and one or more `af:iterator`, `af:column` and `af:dynamicComponent` tags. In addition, if the **Include Column Groups** option is selected, `af:switcher` and `af:group` tags are added.

Tags Created for a Dynamic Table without Grouping

In the JSF page, JDeveloper inserts an `af:table` tag, within which it nests an `af:iterator` tag that iterates over the attributes of the collection. Within that `af:iterator` tag is nested an `af:column` tag, which contains an `af:dynamicComponent` tag. The `af:dynamicComponent` in turn displays the appropriate component for each column as determined at runtime.

The following example shows the code that is generated when you drop the `Countries` data control object as a dynamic table (but do not select the **Include Column Groups** option).

```
<af:table value="#{bindings.Countries.collectionModel}" var="row"
          rows="#{bindings.Countries.rangeSize}"
          emptyText="#{bindings.Countries.viewable ? 'No data to display.' :
                                                    'Access Denied.'}"
          rowBandingInterval="0" fetchSize="#{bindings.Countries.rangeSize}"
          id="t1">
    <af:iterator id="i1"
                 value="#{bindings.Countries.attributesModel.attributes}"
                 var="column">
        <af:column headerText="#{column.label}" id="c1">
```

```
            <af:dynamicComponent id="d2" attributeModel="#{column}"

value="#{row.bindings[column.name].inputValue}"/>
        </af:column>
    </af:iterator>
</af:table>
```

The value attribute of the af:iterator tag uses an EL expression that evaluates to the attributesModel.attributes property of the collection's tree binding. The attributesModel property is used to retrieve the data object's attributes and their metadata, such as component type, label, tooltip, and other properties of the real component to be rendered. The attributes property of attributesModel signifies that a flat (unhierarchical) list of displayable attributes and their metadata is provided.

The attributeModel attribute of the af:dynamicComponent tag is bound to the EL expression #{column}, which references the variable that is defined in the iterator's var attribute and that serves as a pointer to the current attribute of the data control collection and its corresponding metadata. The EL expression for the dynamicComponent's value attribute also references the variable column.

Tags Created for a Dynamic Table with Grouping

If you have selected the **Include Column Groups** checkbox in the Create Table dialog, the generated JSF page includes the af:switcher and af:group tags, in addition to the tags described in Tags Created for a Dynamic Table without Grouping.

The af:switcher tag is nested directly within an af:column tag. Within the af:switcher tag are nested facet tags named GROUP and ATTRIBUTE. The GROUP facet contains an af:group tag, within which is an af:outputText tag to display the group name and an af:iterator tag, which contains an af:column tag that in turn contains an af:dynamicComponent tag. The ATTRIBUTE facet only contains an af:dynamicComponent tag.

For each attribute that the high-level iterator iterates over, the switcher dynamically determines whether to render a group or a column. If it renders a group, the iterator within the group then is used to render the columns within that group.

The following example shows the code that is generated if you create a dynamic form based on the Countries collection and choose to include column groups.

```
<af:table value="#{bindings.Countries.collectionModel}" var="row"
          rows="#{bindings.Countries.rangeSize}"
          emptyText="#{bindings.Countries.viewable ? 'No data to display.' :
'Access Denied.'}"
          rowBandingInterval="0" fetchSize="#{bindings.Countries.rangeSize}"
          id="t1">
    <af:iterator id="i1"

value="#{bindings.Countries.attributesModel.hierarchicalAttributes}"
                 var="column">
        <af:column headerText="#{column.label}" id="c1">
            <af:switcher id="sw1" facetName="#{column.descriptorType}"
                         defaultFacet="ATTRIBUTE">
                <f:facet name="GROUP">
                    <af:iterator id="gi1" value="#{column.descriptors}"
                                 var="nestedCol">
                        <af:column headerText="#{nestedCol.label}" id="c2">
                            <af:dynamicComponent id="gd1"
```

```
                                                   attributeModel="#{nestedCol}"

value="#{row.bindings[nestedCol.name].inputValue}"/>
                        </af:column>
                    </af:iterator>
                </f:facet>
                <f:facet name="ATTRIBUTE">
                    <af:dynamicComponent id="ad1" attributeModel="#{column}"
                                value="#{row.bindings[column.name].inputValue}"/>
                </f:facet>
            </af:switcher>
        </af:column>
    </af:iterator>
</af:table>
```

The `value` attribute of the `af:iterator` tag uses an EL expression that evaluates to the `attributesModel.hierarchicalAttributes` property of the collection's tree binding. The `attributesModel` property is used to retrieve the data object's attributes and their metadata, such as component type, label, tooltip, and other properties of the real component to be rendered. The `hierarchicalAttributes` property signifies that a hierarchical list of displayable attributes and their metadata is provided, including any categories that have been set for any attributes in the UI hints.

The `attributeModel` attribute of the `af:dynamicComponent` tag is set to the EL expression `#{column}`, which references the variable that is defined in the iterator's `var` attribute and that serves as a pointer to the current column (or category) of the data control collection and its corresponding metadata.

What Happens at Runtime: How Attribute Values Are Dynamically Determined

When a page with dynamic components is rendered, the bindings are created just as they are when items are dropped from the Data Controls panel at design time, except that they are created at runtime. For more information, see What Happens at Runtime: How Attribute Values Are Dynamically Determined.

How to Create a Dynamic Table with a detailStamp Facet

You can create a dynamic table that displays master content and includes `detailStamp` facet that enables a user to display detail for a given record. The detail content is obtained through the dynamic component's bindings to a **view link accessor** on the master view object. Figure 32-10 shows a part of a dynamic table that contains such a detail facet. For more information on using `detailStamp` facets in tables, see Adding Hidden Capabilities to a Table in *Developing Web User Interfaces with Oracle ADF Faces*.

Figure 32-10 Dynamic Table with detailStamp Facet

	Employee Number	Employee Name	Job	Mgr
▷	5576	Test	Manager	7902 🔍
▷	7839	KING	PRESIDENT	🔍
◢	7566	JONES	MANAGER	7839 🔍
	Deptno 20 Dname RESEARCH Loc DALLAS			
▷	7902	FORD	ANALYST	7566 🔍
▷	7369	SMITH	CLERK	7902 🔍
▷	7698	BLAKE	MANAGER	7839 🔍

Before you begin:

It may be helpful to have an understanding of dynamic tables. See Creating a Table with Dynamic Components.

You may also find it helpful to understand other ADF functionality and features. See Additional Functionality for Databound Tables.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects and view links that establish the desired master-detail hierarchy, as described in How to Create a Master-Detail Hierarchy Based on View Objects Alone.
- Create a dynamic table as shown in How to Create a Dynamic Table.

To create a dynamic table with a detailStamp facet:

1. In the source editor for the JSF page, insert a `f:facet` tag within the dynamic table's `af:table` tag.
2. Within the `f:facet` tag, insert an `af:panelFormLayout` tag.
3. Within the `af:panelFormLayout` tag, insert an `af:iterator` tag.
4. Bind the iterator's `value` attribute to the `attributesModel.getLinkedViewAttributes(`*`LinkedViewName`*`)` property of your data object, where *`LinkedViewName`* is the name of a view link accessor that accesses the detail content.
5. Within the `af:iterator` tag, insert an `af:dynamicComponent` tag.
6. Bind the `af:dynamicComponent` tag's `attributeModel` attribute to the value of the `af:iterator` tag's `var` attribute.
7. Bind the `af:dynamicComponent` tag's `value` attribute to an expression that returns the detail data for the selected row.

The following example shows the JSF page code for a dynamic table that uses a `detailStamp` facet to display data retrieved through a view link accessor.

```
<af:table value="#{bindings.EmpVO3.collectionModel}" var="row" id="t1" ...>
  <f:facet name="detailStamp">
```

```
    <af:panelForm id="pgl1" layout="vertical">
      <af:iterator id="iter3" var="detail"

value="#{bindings.EmpVO3.attributesModel.getLinkedViewAttributes('DeptView')}">
        <af:dynamicComponent
value="#{row['DeptView'].bindings[detail.name].inputValue}"/>
attributeModel="#{detail}" id="dc1"/>
      </af:iterator>
    </af:panelForm>
  </f:facet>
  <af:iterator id="itr1" var="column"
      value="#{bindings.EmpVO3.attributesModel.attributes}">
    <af:column headerText="#{column.label}" id="dcc1">
      <af:dynamicComponent value="#{row.bindings[column.name].inputValue}"
attributeModel="#{column}" id="dc1"/>
    </af:column>
  </af:iterator>
</af:table>
```

Modifying the Attributes Displayed in the Table

You can modify and delete attributes displayed in a table that you don’t want to see in the UI.

Once you use the Data Controls panel to create a table, you can then delete attributes, change the order in which they are displayed, change the component used to display them, and change the attribute binding for the component. You can also add new attributes, or rebind the table to a new data control.

How to Modify the Displayed Attributes

You can modify the following aspects of a table that was created using the Data Controls panel:

- Change the binding for the label of a column
- Change the UI component bound to an attribute
- Add or delete columns that represent the attributes
- Reorder the columns in the table
- Enable selection and sorting

Before you begin:

It may be helpful to have an understanding of modifying databound tables. For more information, see Modifying the Attributes Displayed in the Table.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Tables.

You will need to complete this task:

Create a databound table as described in Creating a Basic Table.

To change the attributes for a table:

1. In the Structure window, select the table component.

2. In the Properties window, expand the Columns section to change, add, or delete the attributes that are displayed as columns. You can also change the UI component used within the column to display the data.
3. Expand other sections of the Properties window to change the display and behavior of the table, such as filtering and sorting.

How to Change the Binding for a Table

Instead of modifying a binding, you can completely change the object to which the table is bound.

Before you begin:

It may be helpful to have an understanding of modifying databound tables. For more information, see Modifying the Attributes Displayed in the Table.

You may also find it helpful to understand other ADF functionality and features. For more information, see Additional Functionality for Databound Tables.

You will need to complete this task:

- Create a databound table as described in Creating a Basic Table.

To rebind a table:

1. Right-click the table in the Structure window and choose **Rebind to Another ADF Control**.
2. In the Bind to ADF Control dialog, select the new collection to which you want to bind the table.

   Note that changing the binding for the table will also change the binding for all the columns. You can then use the procedures in How to Modify the Displayed Attributes to modify those bindings.

> **Tip:**
>
> You can also rebind a table by dragging a different view object on top of the existing table.

What Happens When You Modify Bindings or Displayed Attributes

When you simply modify how an attribute is displayed by moving the UI component or changing the UI component, JDeveloper changes the corresponding code on the JSF page. When you use the binding editors to add or change a binding, JDeveloper adds the code to the JSF page, and also adds the appropriate elements to the page definition file.

33 Using Command Components to Invoke Functionality in the View Layer

This chapter describes how to invoke custom methods on ADF Business Components using ADF Faces command components and ADF Model data bindings in the Fusion web application. Specifically, it describes how you can use ADF Faces components to invoke ADF Business Components client interface methods, including how to pass parameters to a method and how to override the declarative method created when you drag and drop a method from the Data Controls panel.
This chapter includes the following sections:

About Command Components

Command components are represented by the UICommand component, which performs an action when it is activated. ADF Faces command components deliver action events when the components are activated.

Once you create a basic page and add navigation capabilities, you may want to add more complex features, such as passing parameters between pages or providing the ability to override declarative actions. **Oracle ADF** provides many features that allow you to add this complex functionality using very little actual code.

Some of the implementation methods in this chapter are intended for page-level designs. You may be able to perform many of the same functions by using task flows. See Getting Started with ADF Task Flows.

Command Component Use Cases and Examples

You can use command components to perform an action, such as passing parameters, overriding declarative actions, or performing some logic. You can bind a command component to a custom method in the Data Controls panel. For example, if you have a custom method called `deleteOrderItem()`, you can create a button bound to this method so that when the user presses this button, the order item will be deleted.

You can also use the `setPropertyListener` tag within a command component to assign values when an event fires. For example, assume you have a button that initiates a search and displays the results on another page depending on a parameter value stored in a managed bean. You can use the `setPropertyListener` property to pass this parameter value to the method that checks this value.

You can add code to a declarative method that is bound to a command component. For example, after you have created a declarative Commit button, you can add code to a managed bean and then override the Commit operation for additional processing

Additional Functionality for Command Components

You may find it helpful to understand other Oracle ADF features before you work with command components. Following are links to other functionality that may be of interest.

- For information about creating custom methods that can be added to the page as a command component, see Customizing an Application Module with Service Methods and Publishing Custom Service Methods to UI Clients.
- For information about creating command components from operations, see What Happens When You Create Command Components Using Operations.
- If you want to use EL expressions in your methods, see EL Expressions Created to Bind to Operations.
- For more information about the command button's actionListener attribute, see What Happens at Runtime: How Action Events and Action Listeners Work.
- For more information about ADF bindings, see Using ADF Model in a Fusion Web Application.
- If you are using task flows, you can use the task flow parameter passing mechanism. For more information, see Using Parameters in Task Flows.
- If you considering using task flow call methods, see Using Method Call Activities.
- If you are using managed beans, see Using a Managed Bean in a Fusion Web Application.

Creating Command Components to Execute Methods

The Data Controls panel contains custom methods that invoke application logic from anywhere within an ADF application's control flow. You can drag a method and drop it as a command button to execute the method.

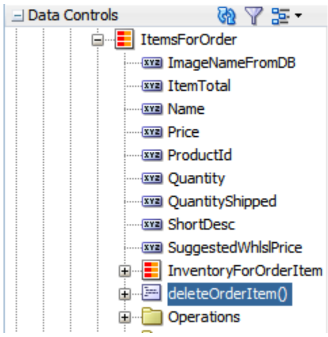
When your application contains custom methods, these methods appear in the Data Controls panel. You can then drag these methods and drop them as command buttons. When a user clicks the button, the method is executed.

For more information about creating custom methods, see Customizing an Application Module with Service Methods, and Publishing Custom Service Methods to UI Clients.

> **Note:**
>
> If you are using task flows, you can call methods directly from the task flow definition. For more information, see Using Method Call Activities.

For example, the ItemsForOrder view object in the Summit sample application for Oracle ADF contains the deleteOrderItem() method. This method updates the items in the shopping cart. To allow the user to execute this method, you drag the `deleteOrderItem()` method from the Data Controls panel, as shown in Figure 33-1.

Figure 33-1   Methods in the Data Controls Panel



In order to perform the required business logic, many methods require a value for their parameter or parameters. This means that when you create a button bound to the method, you need to create an EL expression to specify where the value for the parameter(s) is to be retrieved from. For example, if you use the `populateInventoryForProduct(String productId)` method, you need to configure the method action binding to retrieve a product ID so that the method can display the inventory for the product with that ID.

How to Create a Command Component Bound to a Custom Method

You create a command component bound to custom method by dragging the custom method from the Data Controls panel to a form.

Before you begin:

It may be helpful to have an understanding of custom methods. For more information, see Creating Command Components to Execute Methods.

You may also find it helpful to understand functionality that can be added using other command components. For more information, see Additional Functionality for Command Components.

You will need to complete these tasks:

- Create an **application module** that contains instances of the **view objects** and any custom methods that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To create a command component bound to a custom method:

1. From the Data Controls panel, drag the method onto the page.

> **Tip:**
>
> If you are dropping a button for a method that needs to work with data in a table or form, that button must be dropped inside the table or form.

2. From the context menu, choose **Create > Methods** > **ADF Button**.

   If the method takes parameters, the Edit Action Binding dialog opens. In the Edit Action Binding dialog, enter values for each parameter or click the **Show EL Expression Builder** menu selection in the **Value** column of **Parameters** to launch the EL Expression Builder.

What Happens When You Create Command Components Using a Method

When you drop a method as a command button, JDeveloper:

- Defines a method action binding for the method.
- If the method takes any parameters, JDeveloper creates `NamedData` elements that hold the parameter values.
- Inserts code in the JSF page for the ADF Faces command component.
- Binds the button to the method using `actionListener`.
- Uses the return value from the method call.

Action Bindings

JDeveloper adds an action binding for the method. Action bindings use the `RequiresUpdateModel` property, which determines whether or not the model needs to be updated before the action is executed. For command operations, this property is set to `true` by default, which means that any changes made at the view layer must be moved to the model before the operation is executed.

Method Parameters

When you drop a method that takes parameters onto a JSF page, JDeveloper creates a method action binding. This binding is what causes the method to be executed when a user clicks the command component. When the method requires parameters to run, JDeveloper also creates `NamedData` elements for each parameter. These elements represent the parameters of the method.

For example, in the Summit sample application for ADF task flows, the `populateInventoryForProduct(String)` method action binding contains a `NamedData` element for the `String` parameter. This element is bound to the value specified when you created the action binding. The following example shows the method action binding created when you drop the `populateInventoryForProduct(String)` method, and bind the `String` parameter (named `productId`) to the appropriate variable.

```
<methodAction id="populateInventoryForProduct" RequiresUpdateModel="true"
              Action="invokeMethod"
              MethodName="populateInventoryForProduct" IsViewObjectMethod="true"
              DataControl="BackOfficeAppModuleDataControl"
```

```
            InstanceName="data.BackOfficeAppModuleDataControl.InventoryVO1">
    <NamedData NDName="productId" NDType="java.lang.String"/>
</methodAction>
```

ADF Faces Component Code

JDeveloper adds code for the ADF Faces component to the JSF page. This code is similar to the code for any other command button, as described in EL Expressions Created to Bind to Operations. However, instead of being bound to the `execute` method of the action binding for a built-in operation, the button is bound to the `execute` method of the method action binding for the method that was dropped.

EL Expressions Used to Bind to Methods

Like creating command buttons using operations, when you create a command button using a method, JDeveloper binds the button to the method using the `actionListener` attribute. The button is bound to the `execute` property of the action binding for the given method using an EL expression. This EL expression causes the binding's method to be invoked on the application module. For more information about the command button's `actionListener` attribute, see What Happens at Runtime: How Action Events and Action Listeners Work.

> **Tip:**
>
> Instead of binding a button to the `execute` method on the action binding, you can bind the button to the method in a backing bean that overrides the `execute` method. Doing so allows you to add logic before or after the original method runs. For more information, see Overriding Declarative Methods.

Like navigation operations, the `disabled` property on the button uses an EL expression to determine whether or not to display the button. The following example shows the EL expression used to bind the command button to the `populateInventoryForProduct(String)` method.

```
<af:button actionListener="#{bindings.populateInventoryForProduct.execute}"
                       text="populateInventoryForProduct"
                       disabled="#{!
bindings.populateInventoryForProduct.enabled}"
                       id="b1"/>
```

> **Tip:**
>
> When you drop a command button component onto the page, JDeveloper automatically gives it an ID based on the number of the same type of component that was previously dropped. For example, `b1` and `b2` for the first two buttons dropped. If you change the ID to something more descriptive, you must manually update any references to it in any EL expressions in the page.

Using the Return Value from a Method Call

You can also use the return value from a method call. The following example shows a custom method that returns a string value.

```
/**
 * Custom method.
*/
    public String getHelloString() {
        return ("Hello World");
    }
```

The following example shows the code in the JSF page for the command button and an `outputText` component.

```
<af:button actionListener="#{bindings.getHelloString.execute}"
        text="getHelloString"
        disabled="#{!bindings.getHelloString.enabled}"
        id="helloButtonId"/>
<af:outputText value="#{bindings.return.inputValue}"
        id="helloOutputId"/>
```

When the user clicks the command button, it calls the custom method. The method returns the string "Hello World" to be shown as the value of the `outputText` component.

What Happens at Runtime: Command Button Method Bindings

When the user clicks the button, the method binding causes the associated method to be invoked, passing in the value bound to the `NamedData` element as the parameter. For example, if a user clicks a button bound to the `populateInventoryForProduct(String productId)` method, the method takes the value of the `productId` parameter and displays the inventory for that product.

Setting Parameter Values Using a Command Component

In order to determine complex ADF application functionality, you may need to set parameters to an action on a page. A managed bean can be used to successfully pass the parameter and a method on the bean checks the parameter.

There may be cases where an action on one page needs to set parameters that will be used to determine application functionality. For example, you can create a search button on one page that will navigate to a results table on another page. But the results table will display only if a parameter value is `false`.

You can use a managed bean to pass this parameter between the pages, and to contain the method that is used to check the value of this parameter. The managed bean is instantiated as the search page is rendered, and a method on the bean checks that parameter. If it is `null` (which it will be the first time the page is rendered), the bean sets the value to `true`.

For more information about creating custom methods, see Customizing an Application Module with Service Methods, and Publishing Custom Service Methods to UI Clients.

> **Note:**
>
> If you are using task flows, you can use the task flow parameter passing mechanism. See Using Parameters in Task Flows.

A `setPropertyListener` component with `type` property set to `action`, which is nested in the command button that executed this search, is then used to set this flag to `false`, thus causing the results table to display once the search is executed. For information about using managed beans, see Using a Managed Bean in a Fusion Web Application.

How to Set Parameters Using setPropertyListener Within a Command Component

You can use the `setPropertyListener` component to set values on other objects. This component must be a child of a command component.

Before you begin:

It may be helpful to have an understanding of how `setPropertyListener` and managed bean can be used to set a value. For more information, see Setting Parameter Values Using a Command Component.

You may also find it helpful to understand functionality that can be added using other command components. For more information, see Additional Functionality for Command Components.

You will need to complete this task:

- Create an application module that contains instances of the view objects and any custom methods that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To use the setPropertyListener component:

1. In the Applications window, double-click the web page that contains the command component to which you want to add the listener.
2. In the design editor for the page, right-click the command component and choose **Insert Inside Button > ADF Faces**.
3. In the Insert ADF Faces Item dialog, select **Set Property Listener** and click **OK**.
4. In the Insert Set Property Listener dialog, enter the parameter value in the **From** field.

   You can bring up an expression builder for this field by hovering to the right of the field, clicking the icon that appears, and choosing **Expression Builder**.
5. Enter the parameter target in the **To** field.

You can bring up an expression builder for this field by hovering to the right of the field, clicking the icon that appears, and choosing **Expression Builder**.

> **Tip:**
>
> Consider storing the parameter value on a managed bean or in scope instead of setting it directly on the resulting page's page definition file. By setting it directly on the next page, you lose the ability to easily change navigation in the future. For more information, see Using a Managed Bean in a Fusion Web Application. Additionally, the data in a binding container is valid only during the request in which the container was prepared. The data may change between the time you set it and the time the next page is rendered.

6. From the **Type** dropdown menu, select **Action**.
7. Click **OK**.

What Happens When You Set Parameters Using a setPropertyListener

The `setPropertyListener` component lets the command component set a value before it navigates to the next page. When you set the `from` attribute either to the source of the value you need to pass or to the actual value, the component will be able to access that value. When you set the `to` attribute to a target, the command component is able to set the value on the target. The following example shows the code on the JSF page for a command component that takes the value `false` and sets it as the value of the `initialSearch` flag on the `searchResults` managed bean.

```
<af:button actionListener="#{bindings.Execute.execute}"
                 text=Search>
      <af:setPropertyListener from="#{false}"
                          to="#{searchResults.initialSearch}"/>
                          type="action"/>
</af:button>
```

What Happens at Runtime: setPropertyListener for a Command Component

When a user clicks the command component, before navigation occurs, the `setPropertyListener` component sets the parameter value. As the example in What Happens When You Set Parameters Using a setPropertyListener illustrates, the `setPropertyListener` takes the value `false` and sets it as the value for the `initialSearch` attribute on the `searchResults` managed bean. Now, any component that needs to know this value in determining whether or not to render can access it using the EL expression `#{searchResults.initialSearch}`.

Overriding Declarative Methods

You can override the functionality of an existing declarative method to define a behavior that is specific to the method requirement. In order to add logic after or before the declarative method , you will need a new method and property on a managed bean that provides access to the associated action binding.

When you drop an operation or method as a command button, JDeveloper binds the button to the `execute` method for the operation or method. However, there may be occasions when you need to add logic before or after the existing logic.

> **Note:**
>
> If you are using task flows, you can call custom methods from the task flow. For more information, see Getting Started with ADF Task Flows.

JDeveloper allows you to add logic to a declarative operation by creating a new method and property on a managed bean that provides access to the binding container. By default, this generated code executes the operation or method. You can then add logic before or after this code. JDeveloper automatically binds the command component to this new method, instead of to the `execute` property on the original operation or method. Now when the user clicks the button, the new method is executed.

For example, in the `Customers.jsff` fragment of the Summit ADF task flow sample application, you can click the New icon to create a new order. However, the declarative `CreateInsert` operation requires additional processing. When the button is clicked, a new tab needs to be displayed showing the order details. To provide this processing, logic is added to the `createNewOrder` method in the `CustomersBackingBean` managed bean.

In order to override a declarative method, you must have a managed bean to hold the new method to which the command component will be bound. If your page has a backing bean associated with it, JDeveloper adds the code needed to access the binding object to this backing bean. If your page does not have a backing bean, JDeveloper asks you to create one.

How to Override a Declarative Method

You can add a command component and override its declarative methods using a managed bean.

Before you begin:

It may be helpful to have an understanding of how to override declarative methods. For more information, see Overriding Declarative Methods.

You may also find it helpful to understand functionality that can be added using other command components. For more information, see Additional Functionality for Command Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects and any custom methods that you want in your data model, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in

Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.

- Create a JSF page as described in Creating a Web Page.

> **Note:**
>
> You cannot override the declarative method if the command component currently has an EL expression as its value for the `Action` attribute, because JDeveloper will not overwrite an EL expression. You must remove this value before continuing.

To override a declarative method:

1. Drag the operation or method to be overridden onto the JSF page and drop it as a UI command component.

   The component is created and bound to the associated binding object in the ADF Model layer with the `ActionListener` attribute.

   For more information about creating command components using methods on the Data Controls panel, see Creating Command Components to Execute Methods.

   For more information about creating command components from operations, see What Happens When You Create Command Components Using Operations.

2. On the JSF page, double-click the component.

3. In the Bind Action Property dialog, identify the backing bean and the method to which you want to bind the component, using one of the following techniques:

   - If auto-binding has been enabled on the page (by selecting the **Automatically Expose UI Components in a New Managed Bean** option that is available on the Managed Bean tab of the Create JSF Page wizard), the backing bean is already selected for you.

     – To create a new method, enter a name for the method in the **Method** field, which initially displays a default name.

       or

     – To use an existing method, select a method from the dropdown list in the **Method** field.

     – Select **Use ADF Binding for Generation**.

   - If the page is not using auto-binding, you can select from an existing backing bean or create a new one.

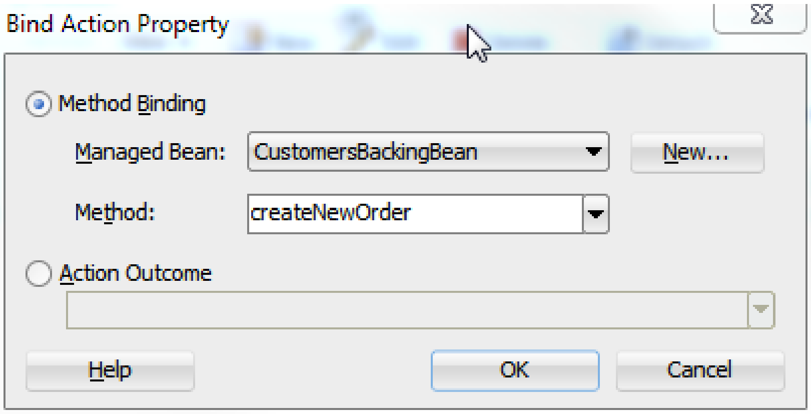
     – Click **New** to create a new backing bean. In the Create Managed Bean dialog, name the bean and the class, and set the bean's scope.

       or

     – Select an existing backing bean and method from the dropdown lists.

     Figure 33-2 shows the Bind Action Property dialog with a method from a managed bean specified for the method binding.

Figure 33-2 Bind Action Property Dialog



● Method Binding

Managed Bean: CustomersBackingBean

Method: createNewOrder

○ Action Outcome

> **Note:**
>
> Whenever there is a value for the `ActionListener` attribute on the command component, JDeveloper understands that the button is bound to the `execute` property of a binding. If you have removed that binding, you will not be given the choice to generate the ADF binding code. You will need to insert the code manually, or to set a dummy value for the `ActionListener` before double-clicking the command component.

4. After identifying the backing bean and method, click **OK** in the Bind Action Property dialog

   The managed bean opens in the source editor. The following example shows the code inserted into the bean in the Summit ADF task flow sample application. In this example, a command button is bound to the `CreateInsert` operation.

```
public void createNewOrder() {
        BindingContainer bindings = getBindings();
        OperationBinding operationBinding =
              bindings.getOperationBinding("CreateInsert");
        Object result = operationBinding.execute();
        if (!operationBinding.getErrors().isEmpty()) {
            return null;
        }
}
```

5. You can now add logic either before or after the binding object is accessed, as shown by the code in bold in the following example.

```
public void createNewOrder() {
//This method is called when creating a new order
//to create the record and switch the tab
  getSdi3().setDisclosed(false);
  getSdi4().setDisclosed(true);
  BindingContainer bindings = getBindings();
  OperationBinding operationBinding =
       bindings.getOperationBinding("CreateInsert");
  operationBinding.execute();
  AdfFacesContext adfFacesContext =
AdfFacesContext.getCurrentInstance();
```

```
  adfFacesContext.addPartialTarget(getSdi4());
}
```

In addition to any processing logic, you may also want to write conditional logic to return one of multiple outcomes. For example, you might want to return `null` if there is an error in the processing, or another outcome value if the processing was successful. A return value of `null` causes the navigation handler to forgo evaluating navigation cases and to immediately redisplay the current page.

> **Tip:**
>
> To trigger a specific navigation case, the outcome value returned by the method must exactly match the outcome value in the navigation rule, including case.

The command button is now bound to this new method using the `Action` attribute instead of the `ActionListener` attribute. If a value had previously existed for the `Action` attribute (such as an outcome string), that value is added as the return for the new method. If there was no value, the return is kept as `null`.

What Happens When You Override a Declarative Method

When you override a declarative method, JDeveloper adds a managed property to your backing bean with the managed property value of `#{bindings}` (the reference to the binding container), and it adds a strongly typed bean property to your class of the `BindingContainer` type, which the JSF runtime will then set with the value of the managed property expression `#{bindings}`. JDeveloper also adds logic to the UI command action method. This logic includes the strongly typed `getBindings()` method used to access the current binding container.

The code does the following:

- Accesses the binding container.
- Finds the binding for the associated method, and executes it.
- Adds a return for the method that can be used for navigation. By default, the return is `null`. If an outcome string had previously existed for the button's `Action` attribute, that attribute is used as the return value. You can change this code as needed.

JDeveloper automatically rebinds the UI command component to the new method using the `Action` attribute, instead of the `ActionListener` attribute. The following example shows the code when a `CreateInsert` operation is declaratively added to a page.

```
<af:button actionListener="#{bindings.CreateInsert.execute}"
                 text="CreateInsert"
                 disabled="#{!bindings.CreateInsert.enabled}"/>
```

The following example shows the code for the button tag after the method on the page's backing bean is overridden. Note that the `action` attribute is now bound to the backing bean's method.

```
<af:button text="New"
           action="#{backingBeanScope.CustomersBackingBean.createNewOrder}"/>
```

> **Tip:**
>
> If when you click the button that uses the overridden method you receive this error:
>
> `SEVERE: Managed bean main_bean could not be created The scope of the referenced object: '#{bindings}' is shorter than the referring object`
>
> it is because the managed bean that contains the overriding method has a scope that is greater than `request` (that is, either `session` or `application`). Because the data in the binding container referenced in the method has a scope of `request`, the scope of this managed bean must be set to the same or a lesser scope.

34
Displaying Master-Detail Data

This chapter describes how to create master-detail objects with data modeled from ADF Business Components, using ADF data controls and ADF Faces components. It describes how to display master-detail data by using prebuilt master-detail widgets, tables, trees and tree tables and how to work with selection events.
This chapter includes the following sections:

For information about using a selection list to populate a collection with a key value from a related master or detail collection, see Creating Databound Selection Lists and Shuttles .

About Displaying Master-Detail Data

A master-detail relationship is a one-to-many type relationship. Master-detail relationships using Oracle ADF allows you to view data from related tables at the same time.

There are many instances where data needs to be presented in a hierarchical manner. In a **master-detail relationship**, when the user changes the selected item in the master data object, the data set displayed in the detail data object changes with it. For example, selecting the television categories in the master object would display all the models of televisions in the detail object.

When using ADF Model in combination with ADF Faces UI components, you can declaratively create master-detail pages that display the data from multiple objects simultaneously when those objects have a master-detail relationship defined. ADF iterator bindings automatically manage the synchronization of the detail data objects displayed for a selected master data object.

In ADF Business Components, a master-detail relationship is established when a view link is created to associate two **view object instances**. As described in About View Objects, a **view link** represents the relationship between two view objects, which is usually, but not necessarily, based on a foreign-key relationship between the underlying data tables. The view link associates a row of one view object instance (the master object) with one or more rows of another view object instance (the detail object).

Master-Detail Tables, Forms, and Trees Use Cases and Examples

When objects have a master-detail relationship, you can declaratively create pages that display the data from both objects simultaneously. For example, the page shown in Figure 34-1 displays an entry for a customer in a form at the top of the page and a table of the customer's orders at the bottom of the page. This is possible because the objects have a master-detail relationship. In this example, the `Customers` view object is the master object and `OrdersForCustomer` is the detail object. ADF iterators automatically manage the synchronization of the detail data objects displayed for a selected master data object. Iterator bindings simplify building user interfaces that allow scrolling and paging through collections of data and drilling-down from summary to detail information.

Figure 34-1   Master Form and Detail Table

285	203	27-05-2011	30-05-2011	$4,441.65	CASH
99	203	21-05-2011	27-05-2011	$7,707.00	CREDIT
291	203	11-05-2011	15-05-2011	$6,944.05	CASH
284	203	11-05-2011	15-05-2011	$2,440.80	CASH

You display master and detail objects in forms, tables, trees, and tree tables. You can display these objects on the same page or on separate pages. For example, you can display the master object in a table on one page and detail objects in a read-only form on another page.

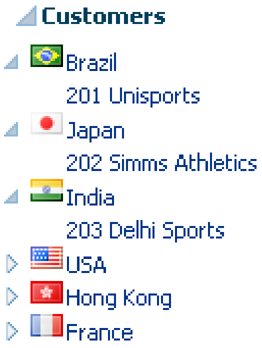
A master object can have many detail objects, and each detail object can in turn have its own detail objects, down to many levels of depth. If one of the detail objects in this hierarchy is dropped from the Applications window as a master-detail form on a page, only its immediate parent master object displays on the page. The hierarchy will not display all the way up to the topmost parent object.

If you display the detail object as a tree or tree table object, it is possible to display the entire hierarchy with multiple levels of depth, starting with the topmost master object, and traversing detail children objects at each node.

Figure 34-1 shows an example of a master form with detail table. When the user navigates through the customers using the command buttons, the table lists the orders that the customer has made.

Figure 34-2 shows a tree that has two levels of nodes. You can use trees to display hierarchical information. In this example, a tree is used to display customers grouped by countries. The user can expand nodes to traverse down a branch of the tree to access the leaf items.

Figure 34-2 Multi-level Tree



Customers
- Brazil
  - 201 Unisports
- Japan
  - 202 Simms Athletics
- India
  - 203 Delhi Sports
- USA
- Hong Kong
- France

Figure 34-3 shows the same grouping of customers by country, but using a tree table instead of a tree. In addition to the hierarchical node levels of a tree, a tree table can also display column information for each node. You can also focus on subtrees as well as collapsing and expanding the elements.

Additional Functionality for Master-Detail Tables, Forms, and Trees

You may find it helpful to understand other **Oracle ADF** features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- **ADF view objects and view links**: Much of how the components display and function in the form is controlled by the corresponding view objects. For more information about creating view objects and establishing a master-detail hierarchy in your data model with view links, see Working with Multiple Tables in a Master-Detail Hierarchy.

- **ADF application modules**: The Data Controls panel, from which you drag databound components to your pages, is populated with representations of view objects that you have added to application modules. See Implementing Business Services with Application Modules.
- **Adapter-based data controls**: If you are using other types of business services, such as EJB components or web services, you can create data control for those business services as described in Creating and Configuring EJB Data Controls of the *Developing Applications with Oracle ADF Data Controls*.
- **ADF Model and data binding**: When you create forms in an ADF web application, you use ADF Model and data binding. See Using ADF Model in a Fusion Web Application.
- **ADF Faces**: You also use ADF Faces UI components. For detailed information about developing with ADF Faces, see Introduction to ADF Faces in *Developing Web User Interfaces with Oracle ADF Faces*.
- **ADF forms and tables**: If you want to modify the default forms or tables, see Creating Basic Forms Using Data Control Collections or Creating a Basic Table.
- **Task flows**: If your form takes part in a transaction, then you may need to use an ADF task flow to invoke certain operations before or after the form is rendered. See Creating ADF Task Flows.
- **Event handling**: You may need to write listener methods to process client-side events. See Handling Events in *Developing Web User Interfaces with Oracle ADF Faces*.
- **Managed beans**: You may need to create managed beans for event handling and other front-end processing. For information about creating and using managed beans, see Using a Managed Bean in a Fusion Web Application.

Prerequisites for Master-Detail Tables, Forms, and Trees

A master-detail relationship relates two view object instances by a view link. A view link represents the relationship between two view objects, which is usually, but not necessarily, based on a foreign-key relationship between the underlying data tables, forms, and trees.

Master-detail tables, forms, trees, and tree tables require a master-detail relationship to be established in the data model. That master-detail relationship is then reflected in the Data Controls panel, from where you can drag and drop objects to declaratively create pages that display master-detail data.

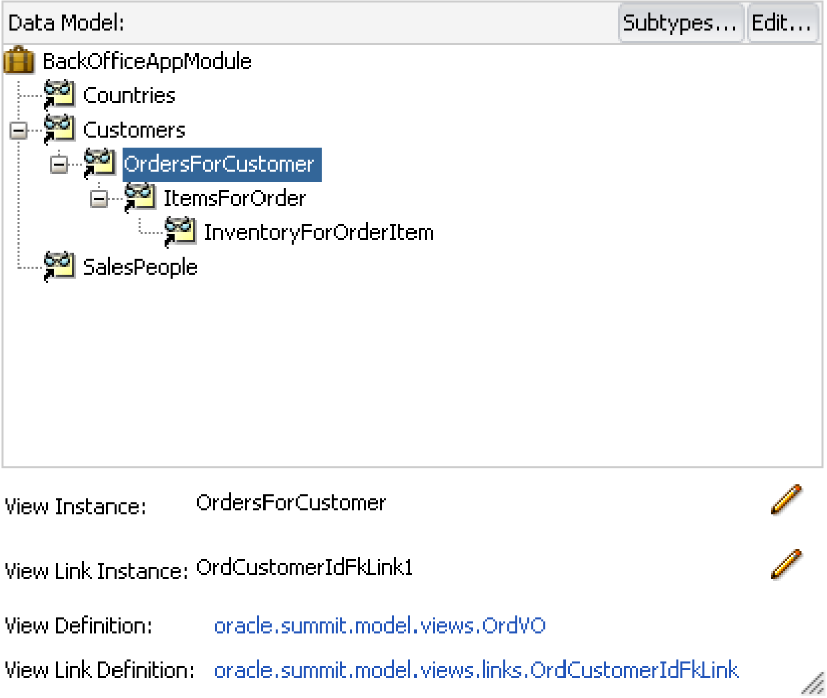
In an ADF Business Components application, you indicate a master-detail relationship by creating a view link between two view objects. Then you add the master view object and the detail view object instances to the application module data model. For more information, see How to Enable Active Master-Detail Coordination in the Data Model.

Note:

For data controls based on other business services, such as web services or EJB session beans, the master-detail relationship is typically inferred from standard mechanisms within those services, such as definition files for web services or `JoinColumn` annotations in JPA-based beans.

For example, in the Summit sample application for Oracle ADF, there is a view link from the `CustomerVO` view object to the `OrdVO` view object based on the `CustomerId` attribute, both contained in the application module data model, as shown in Figure 34-4. A change in the current row of the master view object instance causes the row set of the detail view object instance to refresh to include the details for the current master.

Figure 34-4 View Link between CustomerVO and OrdVO View Objects



View Instance: OrdersForCustomer

View Link Instance: OrdCustomerIdFkLink1

View Definition: oracle.summit.model.views.OrdVO

View Link Definition: oracle.summit.model.views.links.OrdCustomerIdFkLink

Note:

In the Summit ADF sample application, the view link between the `CustomerVO` view object and `OrdVO` view object is a one-way relationship. If the view link were bidirectional and both sets of master and detail view objects were added to the application module data model, then the Data Controls panel would also display the `OrdersForCustomer` collection at the same node level as the `Customers` collection, and the detail instance of the `OrdersForCustomer` collection as a child of the `Customers` collection.

How to Identify Master-Detail Objects on the Data Controls Panel

You can identify master-detail objects by looking at the hierarchy in the Data Controls panel.

Before you begin:

It may help to understand the basics of master-detail relationships. For more information, see Prerequisites for Master-Detail Tables, Forms, and Trees.

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Additional Functionality for Master-Detail Tables, Forms, and Trees.

You will need to complete this task:

- Create an **application module** that contains instances of the view objects and view links that establish the desired master-detail hierarchy, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.

To identify master-detail objects:

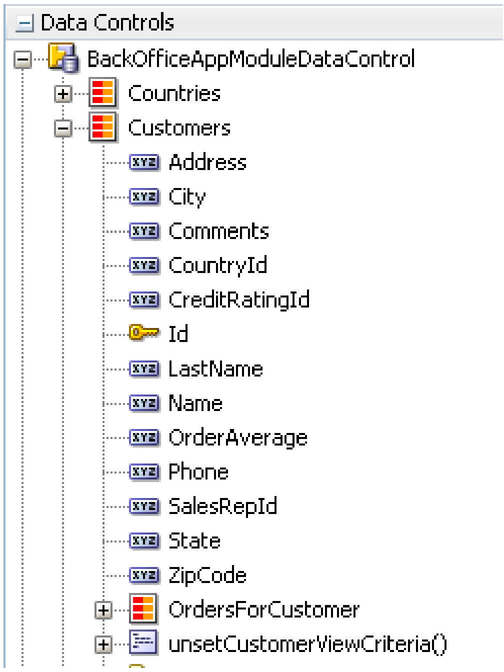
- In the Applications window, open the Data Controls panel, expand any collection nodes, and look for collection child nodes of those collections.

Any child collection node of a collection node represents the detail part of a master-detail relationship with the parent node. A parent collection can be part of a master-detail relationship with multiple child collections. And collections can be nested in multiple layers, meaning that a collection can be the detail part of one master-detail relationship and the master part of another master-detail relationship.

Figure 34-5 shows two master-detail related collections in the Data Controls panel of the Summit ADF sample application. The `Customers` collection is an instance of the `CustomerVO` view object, and the `OrdersForCustomer` collection, which appears as a child of the `Customers` collection, is an instance of the `OrdVO` view object.

> **Note:**
>
> The master-detail hierarchy displayed in the Data Controls panel does not reflect the cardinality of the relationship (that is, one-to-many, one-to-one, many-to-many). The hierarchy simply shows which collection (the master) is being use to retrieve one or more objects from another collection (the detail).

Figure 34-5 Master-Detail Objects in the Data Controls Panel



```

The master-detail hierarchy on the Data Controls panel reflects the hierarchy defined in the application module data model, as shown in Figure 34-4. For more information about the icons displayed on the Data Controls panel, see How to Use the Data Controls Panel.

Using Tables and Forms to Display Master-Detail Objects

The Data Controls panel enables you to create both the master and detail widgets on one page with a single declarative action using prebuilt master-detail forms and tables. If you do not want to use the prebuilt master-detail widgets, you can drag and drop the master and detail objects individually from the Data Controls panel as tables and forms.

You can create master-detail functionality on a page with form and table components. You can do so either by creating individual form and table components or by using pre-built widgets that encompass both the master and detail components.

The pre-built widgets enable you to create a read-only master-detail browse page in a single declarative action using the Data Controls panel. All you have to do is drop the detail collection on the page and choose the type of widget you want to use. The generated components include range navigation that enables the end user to scroll through the data objects in collections. You can delete unwanted attributes by removing the text field or column from the page.

Figure 34-6 shows an example of prebuilt master-detail widget, which displays general order information in a form at the top of the page and order details in a table at the bottom of the page. When the user clicks the **Next** button to scroll through the records in the master data at the top of the page, the page automatically updates to display the detail data for the currently displayed master record.

There are some cases when the pre-built master-detail UI components that JDeveloper provides cannot provide the functionality you require. For example, you may need to make a component editable or bind components programatically instead of using the master-detail UI components. In these cases, you can create master-detail pages by creating forms and tables separately. When components are created from a collection and nested collection, the nested collection's iterator binding manages coordination between the master and detail component automatically. See How to Create Master-Detail Forms from Separate Components and How to Display Master-Detail Components on Separate Pages.

> **Note:**
>
> You can also use the `detailStamp` facet of a master table to display the detail for selected rows. See How to Create a Dynamic Table with a detailStamp Facet for information on doing so with a dynamic component.

How to Display Master-Detail Objects in Tables and Forms Using Master-Detail Widgets

The Data Controls panel enables you to create both the master and detail widgets on one page with a single declarative action using prebuilt master-detail forms and tables. These prebuilt master-detail widgets are read-only. For information about displaying master and detail data on separate pages, see How to Create Master-Detail Forms from Separate Components. For information about displaying master and detail data on separate pages, see How to Display Master-Detail Components on Separate Pages.

Before you begin:

It may help to understand the options that are available to you when you create a master-detail table and form. For more information, see Using Tables and Forms to Display Master-Detail Objects.

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Additional Functionality for Master-Detail Tables, Forms, and Trees.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects and view links that establish the desired master-detail hierarchy, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To create a master-detail page using the prebuilt ADF master-detail forms and tables:

1. From the Data Controls panel, locate the detail object, as described in How to Identify Master-Detail Objects on the Data Controls Panel.
2. Drag and drop the detail object onto the JSF page.
3. From the **Master-Detail** submenu of the context menu, choose one of the following components:
   - **ADF Master Table, Detail Form**: Displays the master objects in a read-only table and the detail objects in a read-only form under the table.

     When a specific data object is selected in the master table, the first related detail data object is displayed in the form below it. The user must use the form navigation to scroll through each subsequent detail data object.
   - **ADF Master Form, Detail Table**: Displays the master objects in a read-only form and the detail objects in a read-only table under the form.

     When a specific master data object is displayed in the form, the related detail data objects are displayed in a table below it.
   - **ADF Master Form, Detail Form**: Displays the master and detail objects in separate read-only forms.

     When a specific master data object is displayed in the top form, the first related detail data object is displayed in the form below it. The user must use the form navigation to scroll through each subsequent detail data object.
   - **ADF Master Table, Detail Table**: Displays the master and detail objects in separate read-only tables.

     When a specific master data object is selected in the top table, the first set of related detail data objects is displayed in the table below it.

If you want to modify the default forms or tables, see Modifying the UI Components and Bindings on a Form and Modifying the Attributes Displayed in the Table.

How to Create Master-Detail Forms from Separate Components

Instead of using the pre-built master-detail widgets to create master-detail forms, you can create table and form components separately from data control objects that have a master-detail relationship and take advantage of the detail object's iterator bindings to provide the master-detail coordination. Creating master-detail forms from separate components enables you more flexibility in how the components and their bindings are generated.

Before you begin:

It may help to understand the options that are available to you when you create a master-detail table and form. For more information, see Using Tables and Forms to Display Master-Detail Objects.

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Additional Functionality for Master-Detail Tables, Forms, and Trees.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects and view links that establish the desired master-detail hierarchy, as described in How to Create a Master-Detail Hierarchy Based on View Objects Alone. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To create a master-detail form with individual components:

1. Create the detail widget by dragging a child collection from the Data Controls panel and dropping it as a table or a form on the JSF page or fragment that corresponds to the detail view activity. For more information, see How to Identify Master-Detail Objects on the Data Controls Panel.

   For more information on creation of the individual components, see Creating Basic Forms Using Data Control Collections and Creating a Basic Table.
2. Create the master widget by dragging the collection that is the parent of the collection in step 1 and dropping it as a table or a form on the JSF page or fragment that corresponds to the master view activity.

What Happens When You Create Master-Detail Tables and Forms

When you drag and drop a collection from the Data Controls panel, JDeveloper does many things for you, including adding code to the JSF page and the corresponding entries in the page definition file. For a general description of what happens and what is created when you use the Data Controls panel, see What Happens When You Use the Data Controls Panel.

Code Generated in a Master-Detail JSF Page

The JSF code generated for a prebuilt master-detail widget is similar to the JSF code generated when you use the Data Controls panel to create a read-only form or table. If you are building your own master-detail widgets, you might want to consider including similar components that are automatically included in the prebuilt master-detail tables and forms.

The tables and forms in the prebuilt master-detail widgets include a `panelHeader` tag that contains the name of the data control populating the master form or table. You can change this label as needed using a string or an EL expression that binds to a resource bundle.

If there is more than one object in a collection, a form in a prebuilt master-detail widget includes four `button` tags for range navigation: `First`, `Previous`, `Next`, and `Last`. These range navigation buttons enable the user to scroll through the objects in the collection. The `actionListener` attribute of each button is bound to a data control operation, which performs the navigation. The `execute` property used in the `actionListener` binding, invokes the operation when the button is clicked. (If the form displays a single object, JDeveloper automatically omits the range navigation components.) For more information about range navigation, see Incorporating Range Navigation into Forms.

> **Tip:**
>
> If you drop an **ADF Master Table, Detail Form** or **ADF Master Table, Detail Table** widget on the page, the parent tag of the detail component (for example, `panelHeader` tag or `table` tag) automatically has the `partialTriggers` attribute set to the `id` of the master component (see How to Create an Input Table for more information about partial triggers). At runtime, the `partialTriggers` attribute causes only the detail component to be rerendered when the user makes a selection in the master component, which is called **partial page rendering**. Partial page rendering is used because only the detail component needs to be rerendered to display the new data. The table does not need to be rerendered when the user simply makes a selection in the facet.

Binding Objects Defined in a Master-Detail Page Definition File

The following example shows the page definition file created for a master-detail page that was created by dropping the `OrdersFromCustomer` collection, which is a detail object under the `Customers` object, on the page as an **ADF Master Form, Detail Table**.

The `executables` element defines two iterators: one for the master object and one for the detail object. At runtime, the data model and the **row set iterator** for the detail view object instance keep the row set of the detail view object refreshed to the correct set of rows for the current master row as that current row changes. For more information, see What Happens at Runtime: ADF Iterator for Master-Detail Tables and Forms.

The bindings element defines the value bindings for the form and the table. The attribute bindings that populate the text fields in the form are defined in the attributeValues elements. The id attribute of the attributeValues element contains the name of each data attribute, and the IterBinding attribute references an iterator binding to display data from the master object in the text fields.

The range navigation buttons in the form are bound to the action bindings defined in the action elements. As in the attribute bindings, the IterBinding attribute of the action binding references the iterator binding for the master object.

The table, which displays the detail data, is bound to the table binding object defined in the table element. The IterBinding attribute references the iterator binding for the detail object.

For more information about the elements and attributes of the page definition file, see pageNamePageDef.xml.

```
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="Customers" RangeSize="25"
DataControl="BackOfficeAppModuleDataControl" id="CustomersIterator"
            ChangeEventPolicy="ppr"/>
  <iterator Binds="OrdersForCustomer" RangeSize="25"
DataControl="BackOfficeAppModuleDataControl"
            id="OrdersForCustomerIterator" ChangeEventPolicy="ppr"/>
</executables>
<bindings>
  <action IterBinding="CustomersIterator" id="First" RequiresUpdateModel="true"
Action="first"/>
  <action IterBinding="CustomersIterator" id="Previous"
RequiresUpdateModel="true" Action="previous"/>
  <action IterBinding="CustomersIterator" id="Next" RequiresUpdateModel="true"
Action="next"/>
  <action IterBinding="CustomersIterator" id="Last" RequiresUpdateModel="true"
Action="last"/>
  <attributeValues IterBinding="CustomersIterator" id="Id">
    <AttrNames>
      <Item Value="Id"/>
    </AttrNames>
  </attributeValues>
  <attributeValues IterBinding="CustomersIterator" id="Name">
    <AttrNames>
      <Item Value="Name"/>
    </AttrNames>
  </attributeValues>
  <attributeValues IterBinding="CustomersIterator" id="Phone">
    <AttrNames>
      <Item Value="Phone"/>
    </AttrNames>
  </attributeValues>
. . .
  <tree IterBinding="OrdersForCustomerIterator" id="OrdersForCustomer">
    <nodeDefinition DefName="oracle.summit.model.views.OrdVO"
                    Name="OrdersForCustomer0">
      <AttrNames>
        <Item Value="Id"/>
        <Item Value="CustomerId"/>
        <Item Value="DateOrdered"/>
...
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

> **Note:**
>
> For data controls that are based on other types of business services, such as EJB session beans, `accessorIterator` elements are used instead of `iterator` elements to handle the iterator binding.

What Happens at Runtime: ADF Iterator for Master-Detail Tables and Forms

At runtime, an ADF iterator determines which row from the master table object to display in the master-detail form. When the form first displays, the first master table object row appears highlighted in the master section of the form. Detail table rows that are associated with the master row display in the detail section of the form.

As described in Binding Objects Defined in a Master-Detail Page Definition File, ADF iterators are associated with underlying `rowsetIterator` objects. These iterators manage which data objects, or *rows*, currently display on a page. At runtime, the row set iterators manage the data displayed in the master and detail components.

Both the master and detail row set iterators listen to row set navigation events, such as the user clicking the range navigation buttons, and display the appropriate row in the UI. In the case of the default master-detail components, the row set navigation events are the command buttons on a form (**First**, **Previous**, **Next**, **Last**).

The row set iterator for the detail collection manages the synchronization of the detail data with the master data. Because of the underlying view link from the master view object to the detail view object, the detail row set iterator listens for row navigation events in both the master and detail collections. If a row set navigation event occurs in the master collection, the detail row set iterator automatically executes and returns the detail rows related to the current master row.

How to Display Master-Detail Components on Separate Pages

The default master-detail components display the master-detail data on a single page. However, using the master and detail objects on the Data Controls panel, you can also display the collections on separate pages (or on separate fragments on the same page), and still have the binding iterators manage the synchronization of the master and detail objects.

Before you begin:

It may help to understand the options that are available to you when you create a master-detail table and form. For more information, see Using Tables and Forms to Display Master-Detail Objects.

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Additional Functionality for Master-Detail Tables, Forms, and Trees.

You will need to complete this task:

- Create an application module that contains instances of the view objects and view links that establish the desired master-detail hierarchy, as described in How to Create a Master-Detail Hierarchy Based on View Objects Alone. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.

To create master and detail objects on separate pages:

1. Create an ADF task flow as described in How to Create a Task Flow.

   If you plan to use page fragments to hold the master and detail components, select the Create with Page Fragments checkbox in this step.

2. Add two view activities to the task flow, one for the master view and one for the detail view, as described in How to Add an Activity to a Task Flow.

3. In the task flow definition file, add a control flow case from the master view to the detail view, and a control flow case to return from the detail view to the master view. For more information, see How to Add a Control Flow Rule to a Task Flow.

4. Create two JSF pages or two JSF fragments to hold the master and detail components.

   You can create a page or fragment for a view activity by clicking on the view activity in the overview editor for task flow.

   If you already have pages or fragments that you want to map to the view activities, you can do so by selecting the view activity in the overview editor for the task flow, navigating to the Properties window, and specifying the JSF page or fragment in the `Page` property.

5. Create the detail component by dragging a child collection from the Data Controls panel and dropping it as a table or a form on the JSF page or fragment that corresponds to the detail view activity. For more information, see How to Identify Master-Detail Objects on the Data Controls Panel.

   For more information on creating forms and tables, see Creating Basic Forms Using Data Control Collections and Creating a Basic Table.

6. Create the master component by dragging the collection that is the parent of the collection in step 5 and dropping it as a table or a form on the JSF page or fragment that corresponds to the master view activity.

7. Add command buttons or links to each page.

8. In the `action` attribute of each button, specify the control flow case that is used to navigate to the other page. You can get this value from the `from-outcome` property of the corresponding control flow case.

For example, in the Summit ADF sample application, the `Customers.jsff` fragment contains a table created from the `OrdersFromCustomer` collection. That table serves as both a detail view of customer orders and a master view for the Order Items table that is created from the `ItemsFromOrder` collection and is located in `Orders.jsff` (and appears on the Order tab). Figure 34-7 shows the Orders table as a detail view for a customer, and Figure 34-8 shows the order that is selected in that table and displays that order's detail. Though the `OrdersFromCustomer` collection is used in both the `Customers.jsff` and `Orders.jsff` fragments, it does not have to be used in both places to maintain master-detail coordination. The iterator binding for the `ItemsFromOrder` maintains the master -detail coordination, even across the page fragments.

Using Trees to Display Master-Detail Objects

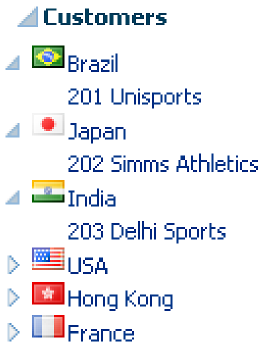
The ADF Faces tree component can be used to display model-driven master-detail data relationships in a hierarchical manner. In this case, the parent node of the tree indicates the master object, while the child nodes of the tree are detail objects.

In addition to tables and forms, you can also display master-detail data in hierarchical trees. The ADF Faces `tree` component is used to display hierarchical data. It can display multiple root nodes that are populated by a binding on a master object. Each root node in the tree may have any number of branches, which are populated by bindings on detail objects. A tree can have multiple levels of nodes, each representing a detail object of the parent node. Each node in the tree is indented to show its level in the hierarchy.

The `tree` component includes mechanisms for expanding and collapsing the tree nodes; however, it does not have focusing capability. If you need to use focusing, consider using the ADF Faces `treeTable` component (for more information, see Using Tree Tables to Display Master-Detail Objects). By default, the icon for each node in the tree is a folder; however, you can use your own icons for each level of nodes in the hierarchy.

Figure 34-9 shows an example of a tree located in the `Customers.jsff` fragment of the Summit ADF sample application. The tree displays two levels of nodes: root and branch. The root nodes display countries. The branch nodes display customers.

Figure 34-9 Databound ADF Faces Tree



How to Display Master-Detail Objects in Trees

A *tree* consists of a hierarchy of nodes, where each subnode is a branch off a higher level node. Each node level in a databound ADF Faces `tree` component is populated by a different data collection. In JDeveloper, you define a databound tree using the Edit Tree Binding dialog, which enables you to define the rules for populating each node level in the tree. There must be one rule for each node level in the hierarchy. Each rule defines the following node-level properties:

- The data collection that populates that node level
- The attributes from the data collection that are displayed at that node level

To enable creation of the Customers tree in the Summit ADF sample application as shown in Figure 34-9, a view object, `CountryVO` was first created to return a list of countries. Another view object, `CustomerVO` was then created to return customers. And a view link was created from `CountryVO` to `CustomerVO` in order to establish a master-detail relationship.

In this case, it is also possible to add a third-level and fourth-level nodes, since `CustomerVO` has a view link to the view object `OrdVO`, and `OrdVO` has a view link to `ItemVO`.

In the case where a branch of the tree is recursive, a single view object accompanied by a self-referential view link must be defined in the data model project. For example, take a collection defined by `EmployeesView`, where the root node of each branch is specified by the `ManagerId` attribute and the child nodes of the same branch are the employees (also known as "direct reports") who are related to the `ManagerId`. The source and destination view object named by the self-referential view link are both defined as `EmployeesView`, but the destination can be renamed to `DirectReports` for clarify. For more information about creating self-referential view links, see How to Create a Recursive Master-Detail Hierarchy for an Entity-Based View Object.

> ✎ **Note:**
>
> When your business services are based on ADF Business Components, you can programmatically access a master view object's **view link accessor** attribute to return a detail object to be displayed as a branch of the current node level. For information about view link accessors, see How to Access the Detail Collection Using the View Link Accessor.

Before you begin:

It may help to understand the options that are available to you when you create a master-detail table and form. For more information, see Using Trees to Display Master-Detail Objects.

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Additional Functionality for Master-Detail Tables, Forms, and Trees.

You will need to complete these tasks:

- Create the master-detail view objects and view links in the data model project, optimize the performance of row set access for tree components, and add the master view object (and optionally the detail view object) to the application module. For details about setting the optimization flag **Retain Row Set**, see Optimizing View Link Accessor Access to Display Master-Detail Data. For information on creating the master-detail hierarchy and adding it to the application module, see How to Create a Master-Detail Hierarchy Based on View Objects Alone.

  Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To display master-detail objects in a tree:

1. Drag the master object from the Data Controls panel, and drop it onto the page. This should be the master data that will represent the root level of the tree.
2. From the context menu, choose **Tree** > **ADF Tree**.

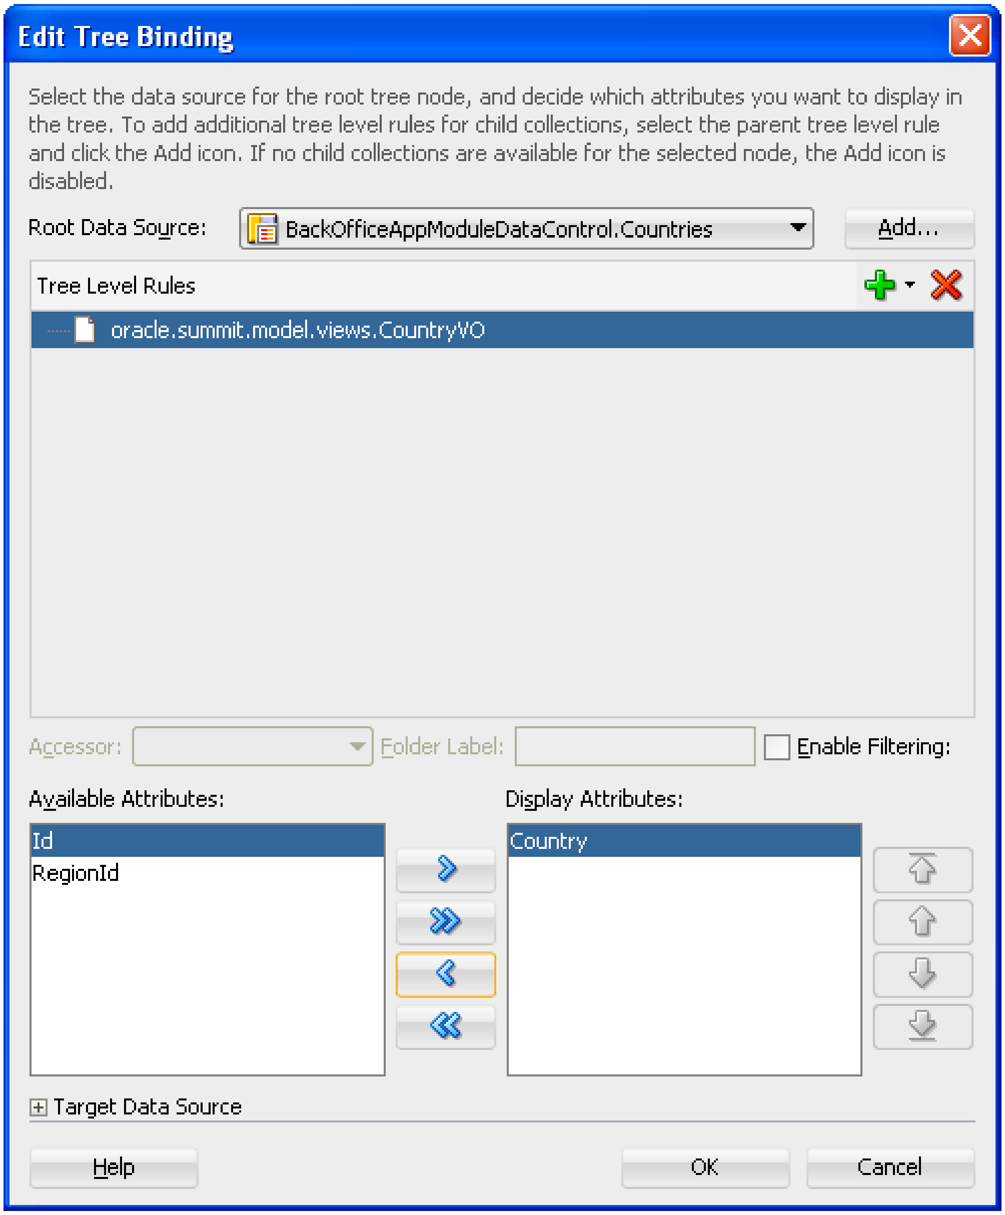
   JDeveloper displays the Edit Tree Binding dialog, as shown in Figure 34-10. You use the binding editor to define a rule for each level that you want to appear in the tree.

   When the dialog first appears, the collection that you dragged is displayed in the **Root Data Source** dropdown list and the corresponding view object is displayed in the **Tree Level Rules** list. This will represent the master data collection.

Tip:

If you don't see the data collection you want in the **Root Data Source** list, click the **Add** button. In the Add Data Source dialog, select a data control and an iterator name to create a new data source. Then click the **Add Rule** icon and select **Add Rule** to add the master rule.

Figure 34-10   Edit Tree Binding Dialog



Edit Tree Binding

Select the data source for the root tree node, and decide which attributes you want to display in the tree. To add additional tree level rules for child collections, select the parent tree level rule and click the Add icon. If no child collections are available for the selected node, the Add icon is disabled.

Root Data Source: BackOfficeAppModuleDataControl.Countries

Tree Level Rules: oracle.summit.model.views.CountryVO

Accessor:

Folder Label:

□ Enable Filtering:

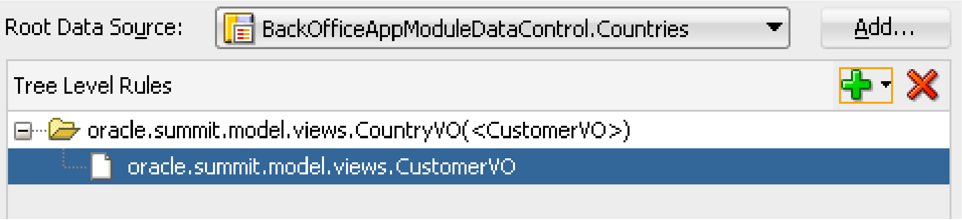
Available Attributes: Id, RegionId

Display Attributes: Country

3. Click the **Add Rule** icon and then select a detail collection to add to the **Tree Level Rules** list.

   A detail data source should appear under the master data source, as shown in Figure 34-11.

Figure 34-11 Master-Detail Tree Level Rules



Root Data Source: BackOfficeAppModuleDataControl.Countries

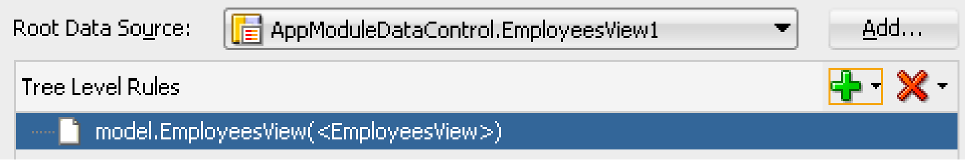
Tree Level Rules

oracle.summit.model.views.CountryVO(<CustomerVO>)
oracle.summit.model.views.CustomerVO

If you are creating a tree with a recursive master-detail hierarchy, then you only need to define a rule that specifies a data source with a self accessor. A recursive tree displays root nodes based on a single collection and displays the child nodes from the attributes of a self accessor that recursively fetches data from that collection. The recursive tree differs from a typical master-detail tree because it requires only a single rule to define the branches of the tree. A recursive data source should display the data source followed by the name of the self accessor in brackets, as shown in Figure 34-12.

Repeat this step for any additional nodes (or further levels of hierarchy) that you want to add to the tree.

Figure 34-12 Recursive Tree Level Rule



Root Data Source: AppModuleDataControl.EmployeesView1

Tree Level Rules

model.EmployeesView(<EmployeesView>)

4. In the **Tree Level Rules** list, select one of the rules.
5. In the bottom part of the dialog, set the attribute or attributes that you want to be used for the node's display by shuttling those attributes to the to the **Display Attributes** list.
6. Repeat steps 4 and 5 for each of the rest of the rules.
7. Click **OK**.

What Happens When You Create an ADF Databound Tree

When you drag and drop from the Data Controls panel, JDeveloper does many things for you. For a general description of what happens and what is created when you use the Data Controls panel, see How to Use the Data Controls Panel.

When you create a databound tree using the Data Controls panel, JDeveloper adds binding objects to the page definition file, and it also adds the `tree` tag to the JSF Page. The resulting UI component is fully functional and does not require any further modification.

Code Generated in the JSF Page

The following example shows the code generated in a JSF page when you use the Data Controls panel to create a tree. This sample tree displays two levels of nodes:

countries and customers. The Countries collection was used to populate the root node.

```
<af:tree value="#{bindings.Countries.treeModel}"
          var="node"
          selectionListener="#{bindings.Countries.treeModel.makeCurrent}"
          rowSelection="single" id="t1"
   <f:facet name="nodeStamp">
      <af:outputText value="#{node}" id="ot1"/>
   </f:facet>
</af:tree>
```

By default, the af:tree tag is created inside a form. The value attribute of the tree tag contains an EL expression that binds the tree component to the Countries tree binding object in the page definition file. The treeModel property in the binding expression refers to an ADF class that defines how the tree hierarchy is displayed, based on the underlying data model. The var attribute provides access to the current node.

In the f:facet tag, the nodeStamp facet is used to display the data for each node. Instead of having a component for each node, the tree repeatedly renders the nodeStamp facet, similar to the way rows are rendered for the ADF Faces table component.

The ADF Faces tree component uses an instance of the oracle.adf.view.faces.model.PathSet class to display expanded nodes. This instance is stored as the treeState attribute on the component. You may use this instance to programmatically control the expanded or collapsed state of an element in the hierarchy. Any element contained by the PathSet instance is deemed expanded. All other elements are collapsed. For more information, see What You May Need to Know About Programmatically Expanding and Collapsing Nodes in *Developing Web User Interfaces with Oracle ADF Faces*.

Binding Objects Defined in the Page Definition File

The following example shows the binding objects defined in the page definition file that pertain to the Countries ADF databound tree in the Summit ADF sample application.

```
<executables>
...
      <iterator Binds="Countries" RangeSize="25"
                DataControl="BackOfficeAppModuleDataControl"
                id="CountriesIterator"/>
</executables>
<bindings>
...
   <tree IterBinding="CountriesIterator" id="Countries">
      <nodeDefinition DefName="oracle.summit.model.views.CountryVO"
                      Name="Countries0">
         <AttrNames>
            <Item Value="Country"/>
         </AttrNames>
         <Accessors>
            <Item Value="CustomerVO"/>
         </Accessors>
      </nodeDefinition>
      <nodeDefinition DefName="oracle.summit.model.views.CustomerVO"
                      Name="Countries1"
                      TargetIterator="${bindings.CustomersIterator}">
         <AttrNames>
            <Item Value="Id"/>
            <Item Value="Name"/>
         </AttrNames>
      </nodeDefinition>
   </tree>
</bindings>
```

The page definition file contains the rule information defined in the Tree Binding Editor. In the `executables` element, notice that although the tree displays two levels of nodes, only one iterator binding object is needed. This iterator iterates over the master collection, which populates the root nodes of the tree. The accessor you specified in the node rules returns the detail data for each branch node.

The `tree` element is the value binding for all the attributes displayed in the tree. The `iterBinding` attribute of the `tree` element references the iterator binding that populates the data in the tree. The `AttrNames` element within the `tree` element defines binding objects for *all* the attributes in the master collection. However, the attributes that you select to appear in the tree are defined in the `AttrNames` elements within the `nodeDefinition` elements.

The `nodeDefinition` elements define the rules for populating the nodes of the tree. There is one `nodeDefinition` element for each node, and each one contains the following attributes and subelements:

- `DefName`: An attribute that contains the fully qualified name of the data collection that will be used to populate the node.
- `id`: An attribute that defines the name of the node.
- `AttrNames`: A subelement that defines the attributes that will be displayed in the node at runtime.
- `Accessors`: A subelement that defines the accessor attribute that returns the next branch of the tree.

The order of the `nodeDefintion` elements within the page definition file defines the order or level of the nodes in the tree, where the first `nodeDefinition` element defines the root node. Each subsequent `nodeDefinition` element defines a subnode of the one before it.

For more information about the elements and attributes of the page definition file, see pageNamePageDef.xml.

What Happens at Runtime: How an ADF Databound Tree Is Displayed

`Tree` components use `org.apache.myfaces.trinidad.model.TreeModel` to access data. This class extends `CollectionModel`, which is used by the ADF Faces `table` component to access data. For more information about the `TreeModel` class, refer to the ADF Faces Javadoc.

When a page with a `tree` is displayed, the iterator binding on the tree populates the root nodes. When a user collapses or expands a node to display or hide its branches, a `DisclosureEvent` event is sent. The `isExpanded` method on this event determines whether the user is expanding or collapsing the node. The `DisclosureEvent` event has an associated listener.

The DisclosureListener attribute on the tree is bound to the accessor attribute specified in the node rule defined in the page definition file. This accessor attribute is invoked in response to the DisclosureEvent event; in other words, whenever a user expands the node the accessor attribute populates the branch nodes.

How to Synchronize Other Parts of a Page With a Tree Selection

In addition to synchronizing a detail view with a master view, you can synchronize other parts of a page with a tree selection. For each node definition (rule), you can specify an optional TargetIterator property and set it to an EL expression for an iterator binding in the current binding container. The expression is evaluated at runtime when the user selects a row in the tree. The iterator binding's view row key attributes match (in order, number, and data type) the view row key of the iterator from which the nodeDefinition type's rows are retrieved for the tree. At runtime, when the tree control receives a selectionChanged event, it passes in the list of keys for each level of the tree. These keys uniquely identify the selected node.

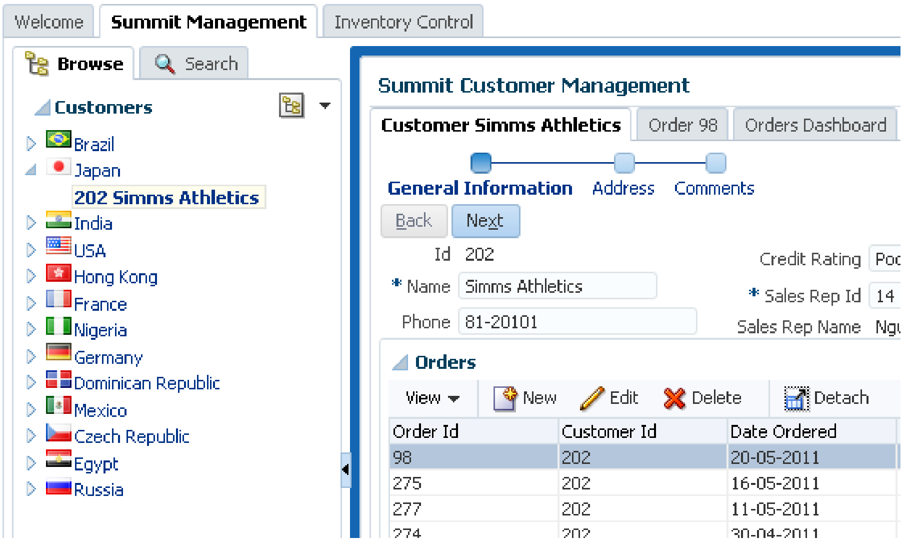
Note:

You can view a page's nodeDefinition elements by expanding a node binding in the page definition editor. These are the same tree binding rules that you can configure in the tree binding dialog.

The tree binding starts at the top of the tree. For each tree level whose key is present in the Currently Selected Tree Node Keys list, if there is a TargetIterator property configured for that nodeDefinition, the tree binding performs a setCurrentRowWithKey() operation on the selected target iterator. It uses the key from the appropriate level of the Currently Selected Tree Node Keys list.

For example, the Summit ADF sample application contains a tree that displays countries at the top node and customers at the second level. When a user selects a customer in the tree, a form displaying the customer information is displayed in the Summit Customer Management panel of the page as shown in Figure 34-13. This functionality consists of a tree that was created from the Countries data control object, a form created from the Customers object, and a detail table created from the OrdersFromCustomer object (which is nested under Customers in the Data Controls panel).

Figure 34-13 Form Synchronized with Tree Selection



Id 202
* Name Simms Athletics
Phone 81-20101
Credit Rating Poo
* Sales Rep Id 14
Sales Rep Name Ngu

Order Id	Customer Id	Date Ordered
98	202	20-05-2011
275	202	16-05-2011
277	202	11-05-2011
274	202	30-04-2011

Before you begin:

It may help to understand the options that are available to you when you create a tree. For more information, see Using Trees to Display Master-Detail Objects.

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Additional Functionality for Master-Detail Tables, Forms, and Trees.

You will need to complete these tasks:

- Create the master-detail view objects and view links in the data model project, optimize the performance of row set access for tree components, and add the master view object (and optionally the detail view object) to the application module. For details about setting the optimization flag **Retain Row Set**, see Optimizing View Link Accessor Access to Display Master-Detail Data. For information on creating the master-detail hierarchy and adding it to the application module, see How to Create a Master-Detail Hierarchy Based on View Objects Alone.

  Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To synchronize another part of the page with the tree selection:

1. From the Data Controls panel, drag the detail collection from which a record will be displayed based on the user selection in a tree, and drop it as a form or another databound component.
2. From the Data Controls panel, drag the parent collection of the detail collection that you just dropped and choose **Create** > **Tree** > **ADF Tree** (or **ADF Tree Table**).
3. In the Edit Tree Binding dialog, configure tree binding rules for all of the levels of the tree hierarchy as described in How to Display Master-Detail Objects in Trees, and leave the dialog open.

4. Select the detail tree-level rule that corresponds to the same collection that is used in step 1.
5. Expand the Target Data Source node and click the EL Picker button.
6. In the Variables dialog, expand **ADF Bindings**, expand **bindings**, and select the iterator binding for the component that you created in step 1.

   The expression will display in the **Expression** text area. The expression should look something like `${bindings.CustomersIterator}`. This expression will then be used to set the target iterator when a user clicks a detail node.
7. Click **OK** to exit the Variables dialog, and click **OK** to exit the Edit Tree Binding dialog.

Using Tree Tables to Display Master-Detail Objects

The ADF Faces treeTable component is used to display master-detail data relationships in a hierarchical format. This component displays a hierarchy in a UI similar to a table, and is more elaborate than the tree component.

Use the ADF Faces `treeTable` component to display a hierarchy of master-detail collections in a table. The advantage of using a `treeTable` component rather than a `tree` component is that the `treeTable` component provides a mechanism that enables users to focus the view on a particular node in the tree.

For example, you can create a tree table that displays levels of nodes for countries and customers where each root node represents an individual country. The branches off the root nodes display the customers for that country. As with trees, to create such a tree table, it is necessary to have master-detail relationships between the collections in the hierarchy.

A databound ADF Faces `treeTable` displays one root node at a time, but provides navigation for scrolling through the different root nodes. Each root node can display any number of branch nodes. Every node is displayed in a separate row of the table, and each row provides a focusing mechanism in the leftmost column.

You can edit the following `treeTable` component properties in the Properties window:

- Range navigation: The user can click the **Previous** and **Next** navigation buttons to scroll through the root nodes.
- List navigation: The list navigation, which is located between the **Previous** and **Next** buttons, enables the user to navigate to a specific root node in the data collection using a selection list.
- Node expanding and collapsing mechanism: The user can open or close each node individually or use the **Expand All** or **Collapse All** command links. By default, the icon for opening and closing the individual nodes is an arrowhead with a plus or minus sign. You can also use a custom icon of your choosing.
- Focusing mechanism: When the user clicks on the focusing icon (which is displayed in the leftmost column) next to a node, the page is redisplayed showing only that node and its branches. A navigation link is provided to enable the user to return to the parent node.

How to Display Master-Detail Objects in Tree Tables

The steps for creating an ADF Faces databound tree table are exactly the same as those for creating an ADF Faces databound tree, except that you drop the data collection as an **ADF Tree Table** instead of an **ADF Tree**. For more information, see How to Display Master-Detail Objects in Trees.

What Happens When You Create a Databound Tree Table

When you drag and drop from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see How to Use the Data Controls Panel.

When you create a databound tree table using the Data Controls panel, JDeveloper adds binding objects to the page definition file, and it also adds the `treeTable` tag to the JSF Page. The resulting UI component is fully functional and does not require any further modification.

Code Generated in the JSF Page

The following example shows the code generated in a JSF page when you use the Data Controls panel to create a tree table. This sample tree table displays two levels of nodes: countries and customers.

By default, the `treeTable` tag is created inside a form. The `value` attribute of the `treeTable` tag contains an EL expression that binds the `tree` component to the binding object that will populate it with data. The `treeModel` property refers to an ADF class that defines how the tree hierarchy is displayed, based on the underlying data model. The `var` attribute provides access to the current node.

```
<af:treeTable value="#{bindings.Countries.treeModel}" var="node"
              selectionListener="#{bindings.Countries.treeModel.makeCurrent}"
              rowSelection="single"
              id="tt1">
    <f:facet name="nodeStamp">
        <af:column id="c1">
            <af:outputText value="#{node}" id="ot1"/>
        </af:column>
    </f:facet>
    <f:facet name="pathStamp">
        <af:outputText value="#{node}" id="ot2"/>
    </f:facet>
</af:treeTable>
```

The `nodeStamp` facet is used to display the data for each node. Instead of having a component for each node, the tree repeatedly renders the `nodeStamp` facet, similar to the way rows are rendered for the ADF Faces `table` component. The `pathStamp` facet renders the column and the path links above the table that enable the user to return to the parent node after focusing on a detail node.

Binding Objects Defined in the Page Definition File

The binding objects created in the page definition file for a tree table are exactly the same as those created for a tree. For more information, see Binding Objects Defined in the Page Definition File.

What Happens at Runtime: Events for Tree Tables

Tree components use oracle.adf.view.faces.model.TreeModel to access data. This class extends CollectionModel, which is used by the ADF Faces table component to access data. For more information about the TreeModel class, refer to the ADF Faces Javadoc.

When a page with a tree table is displayed, the iterator binding on the treeTable component populates the root node and listens for a row navigation event (such as the user clicking the **Next** or **Previous** buttons or selecting a row from the range navigator). When the user initiates a row navigation event, the iterator displays the appropriate row.

If the user changes the view focus (by clicking on the component's focus icon), the treeTable component generates a focus event (FocusEvent). The node to which the user wants to change focus is made the current node before the event is delivered. The treeTable component then modifies the focusPath property accordingly. You can bind the FocusListener attribute on the tree to a method on a managed bean. This method will then be invoked in response to the focus event.

When a user collapses or expands a node, a disclosure event (DisclosureEvent) is sent. The isExpanded method on the disclosure event determines whether the user is expanding or collapsing the node. The disclosure event has an associated listener, DisclosureListener. The DisclosureListener attribute on the tree table is bound to the accessor attribute specified in the node rule defined in the page definition file. This accessor attribute is invoked in response to a disclosure event (for example, the user expands a node) and returns the collection that populates that node.

The treeTable component includes **Expand All** and **Collapse All** links. When a user clicks one of these links, the treeTable sends a DisclosureAllEvent event. The isExpandAll method on this event determines whether the user is expanding or collapsing all the nodes. The table then expands or collapses the nodes that are children of the root node currently in focus. In large trees, the expand all command will not expand nodes beyond the immediate children. The ADF Faces treeTable component uses an instance of the oracle.adf.view.faces.model.PathSet class to determine expanded nodes. This instance is stored as the treeState attribute on the component. You can use this instance to programmatically control the expanded or collapsed state of a node in the hierarchy. Any node contained by the PathSet instance is deemed expanded. All other nodes are collapsed. This class also supports operations like addAll() and removeAll().

For more information about the ADF Faces treeTable component, refer to the oracle.adf.view.faces.component.core.data.CoreTreeTable class in the ADF Faces Javadoc.

Using List Views to Display Master-Detail Objects

The ADF Faces listView component is used to display a list of items based on rows of a master-detail collection model. The listView component uses a model to access the data in the underlying list.

Use the ADF Faces listView component to display a hierarchy of master-detail collections in a simple tree table. The attributes of each object are displayed in a group or grid within a single row and single column.

For example, as shown in Figure 34-14, you can create a `listView` that displays orders and groups them by customer.

Figure 34-14 Master-Detail with the listView Component

For more information on using databound list views, see Creating a List View of a Collection.

How to Display Master-Detail Objects in List Views

You use the Create List View wizard to create your list. This wizard allows you to choose between a `panelGroupLayout` or a `panelGridLayout` component to arrange the components for your list item.

Before you begin:

It may help to understand the options that are available to you when you create a master-detail list view. For more information, see Using List Views to Display Master-Detail Objects.

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Additional Functionality for Master-Detail Tables, Forms, and Trees.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects and view links that establish the desired master-detail hierarchy, as described in Creating and Modifying an Application Module. Alternatively, if you are using another type of business service, create a data control for that business service as described in Exposing Business Services with Data Controls in *Developing Applications with Oracle ADF Data Controls*.
- Create a JSF page as described in Creating a Web Page.

To create a list view:

1. From the Data Controls panel, locate the detail object, as described in How to Identify Master-Detail Objects on the Data Controls Panel.
2. From the Data Controls panel, drag the detail collection onto the page and choose **Table/List View > ADF List View.**
3. On the first page of the create List View wizard, select a layout component and select **Include header using parent collection**.
4. If you have selected the **Panel Grid Layout** option on the first page the wizard, use the next two pages of the wizard to organize the size and arrangement of the grid cells.

   For more information about using these wizard pages, press the F1 key or click **Help**.
5. On the List Item Data page, determine which fields to display for the detail data by setting the bindings and setting the corresponding components to use for each.
6. In the same page, click the **Group Header Data** tab, and set the bindings and components for the master data.
7. Click **Finish**.
8. Use the Properties window to further configure the layout components.

   For complete information about using the `panelGridLayout` component, see the Arranging Content in a Grid section of the *Developing Web User Interfaces with Oracle ADF Faces*. For more information about the `panelGroupLayout` component, see the Grouping Related Items section of the *Developing Web User Interfaces with Oracle ADF Faces*.

What Happens When You Create a Master-Detail List View

When you use the wizard to create a `listView` component with group headers, JDeveloper creates and configures the `listView`, `listItem`, and layout components. The `listView` contains a `listItem` for the detail items and a `facet` for the group header stamp, which in turn contains a `listItem` for the master items.

The bindings are the same as for a table—the `listView` component is bound to the parent of the collection dropped from the Data Controls panel. The value of the `var` attribute on this component is used by the `outputFormatted` components to access the data, in the same way as a table. For more information about the page definition code and the JSP code for collections, see What Happens When You Create a Table.

The following example shows the page code for the simple table shown in Figure 34-14.

```
<af:form id="f1">
  <af:panelGridLayout id="pgl1">
```

```
    <af:gridRow height="100%" id="gr1">
      <af:gridCell width="100%" halign="stretch" valign="stretch" id="gc1">
        <!-- Content -->
        <af:listView value="#{bindings.Customers.treeModel}" var="item"
                     emptyText="#{bindings.Customers.viewable ? 'No data to
                                  display.' : 'Access Denied.'}"
                     fetchSize="#{bindings.Customers.rangeSize}" id="lv1">
          <af:listItem id="li1">
            <af:panelGroupLayout layout="horizontal" id="pgl2">
              <f:facet name="separator">
                <af:spacer width="10" id="s1"/>
              </f:facet>
              <af:outputFormatted
                    value="#{item.bindings.DateOrdered.inputValue}" id="of1">
                <af:convertDateTime
                    pattern="#{bindings.Customers.hints.DateOrdered.format}"/>
              </af:outputFormatted>
              <af:outputFormatted value="#{item.bindings.Total.inputValue}"
                                  id="of2">
                <af:convertNumber groupingUsed="false"
                           pattern="#{bindings.Customers.hints.Total.format}"/>
              </af:outputFormatted>
            </af:panelGroupLayout>
          </af:listItem>
          <f:facet name="groupHeaderStamp">
            <af:listItem id="li2" inlineStyle="font-size:medium;">
              <af:panelGroupLayout layout="horizontal" id="pgl3">
                <f:facet name="separator">
                  <af:spacer width="10" id="s2"/>
                </f:facet>
                <af:outputFormatted value="#{item.bindings.Name.inputValue}"
                                    id="of3"/>
              </af:panelGroupLayout>
            </af:listItem>
          </f:facet>
        </af:listView>
      </af:gridCell>
    </af:gridRow>
  </af:panelGridLayout>
</af:form>
```

About Selection Events in Trees and Tree Tables

Selection Listener is fired when the server receives a selectionEvent from the client which indicates that whenever you select a node in a tree or row in a table, the server will process the event and executes the Selection Listener defined in a managed bean.

There may be cases when you need to determine which node in a tree or tree table has been selected in order to handle some processing in your application. For example, an application might require processing to determine the products that match a product category node that is selected by the user.

Whenever a user selects a node in a tree (or a row in a table), the component triggers selection events. A `selectionEvent` event reports which rows were just deselected and which rows were just selected. The current selection, that is, the selected row or rows, is managed by the `RowKeySet` object, which keeps track of all currently selected nodes by adding and deleting the associated key for the row into or out of the key set. When a user selects a new node, and the tree or table is configured for single selection, then the previously selected key is discarded and the newly selected key is added. If the tree or table is configured for multiple selection, then the newly selected keys are added to the set, and the previously selected keys may or may not be discarded, based on how the nodes were selected. For example, if the user pressed the `CTRL` key, then the newly selected nodes would be added to the current set.

For more information on selection events, see What You May Need to Know About Performing an Action on Selected Rows in Tables in *Developing Web User Interfaces with Oracle ADF Faces*.

> **Note:**
>
> In cases where you merely need to synchronize the row currency between the selected node and other UI components on the page, you can do so declaratively using the `TargetIterator` property for each node definition. For more information, see How to Synchronize Other Parts of a Page With a Tree Selection.

Selection changes in a tree or table will also trigger contextual events for communicating between regions within a page. See Using Contextual Events.

35

Creating Databound Selection Lists and Shuttles

This chapter describes how to create lists and shuttle components from data modeled with ADF Business Components, using ADF data binding and ADF Faces components. It describes how to create the List of Value (LOV) components that utilize a query to populate the selection list. It includes instructions for creating standard selection components that use a model-driven, fixed-value, or dynamically generated list. It describes how to add navigation list bindings to let users navigate through a list of objects in a collection. It also describes how to use the shuttle component to allow the user to quickly move items between two lists.
This chapter includes the following sections:

About Selection Lists and Shuttles

ADF Faces provides selection list and shuttle components that can display a list of objects from which a user can select a value or select multiple values. Use the List of Values (LOV) component, navigation list bindings, or the `selectManyShuttle` component to create the list with multiple items.

Selection list components present the user with a list of choices as input values. The selection list may be model-driven, obtained from a fixed list, or dynamically created at runtime. Selection list components can be rendered as lists, radio buttons, checkboxes, and list boxes. Some selection types can also be singular (select one) or multiple (select many).

Selection lists and shuttles work the same way as do standard JSF list components. ADF Faces list components, however, provide extra functionality such as support for label and message display, automatic form submission, and partial page rendering. When you present users with a list, they can readily see the available choices and make a selection. Picking from a list also eliminates typing errors that may occur.

List of values (LOV) components are UI components that allow the user to enter values by picking from a list that is generated by a query. The LOV displays inside a modal popup dialog that typically includes search capabilities. The `af:inputListOfValues` and `af:inputComboboxListOfValues` and `af:inputSearch` components, for example, offer additional features that are not available in selection lists, such as search fields inside the LOV modal dialog and queries based on multiple table columns. See How to Create a Popup List of Values and *Developing Web User Interfaces with Oracle ADF Faces*.

List of values components offer more complex search and input capabilities by using the query component to create a popup search panel with a results table. The query component also has features such as auto-suggestion, smart list filtering, and custom facets for additional functionality.

When the user selects an item from a navigation list, a corresponding component bound to the list also changes its value in response to the selection. For example, when the user selects a product from a shopping list, the table that is bound to the products list updates to display the details of the selected product.

A shuttle allows the user to easily see the available items on an available list and the selected items in the selected list and to quickly move those items back and forth between the lists.

Shuttles provide a visual way to select items from an available list and at the same time see those selected items. ADF Faces provides the `selectManyShuttle` component and the `selectOrderShuttle` component, which allow reordering of the selected list. Both components can be implemented by adding code in a managed bean to populate the lists.

Selection Lists and Shuttles Use Cases and Examples

You can use a selection list component such as `selectOneChoice` for a single value input selection situation in which the list is relatively small. For example, you can use a `selectOneChoice` to select from a list of product colors or the type of credit card being used.

For larger lists and with more complex filtering, use an `af:inputListOfValues` or `af:inputComboboxListOfValues` component. These components use the query component to perform a transactional search to populate the list. For instance, you can use the `af:inputComboboxListOfValues` to select from a list of countries in an address input page.

Use the selectShuttle components when you want the user to be able to assemble a list of items and be able to select and unselect them. You should use the shuttle components when the number of items is large but not overwhelming to display. The user can review the selection and be able to iteratively select and unselect the items until the user is satisfied with the final selection. For instance, the available list could be the options available for a particular automobile and the user can shuttle the options the user likes to the selected list.

Additional Functionality for Selection Lists and Shuttles

You may find it helpful to understand other ADF features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- For more information about using LOV components with search forms and the `af:query` component, see List of Values (LOV) Input Fields.
- You can use the LOV in a task flow that uses an isolated data control. For more information about shared and isolated data controls, see Sharing Data Controls Between Task Flows.
- LOVs are associated with a named **view criteria**. For more information about setting view criteria options, see How to Create Named View Criteria Declaratively.

- LOV components uses the af:query component to populate the selection list. For more information about the af:query component, see Creating ADF Databound Search Forms.

Creating List of Values (LOV) Components

ADF Faces provides List of Values (LOV) components that can display a model-driven list of objects from which a user can select a value or optionally search for the needed item. Use the af:inputListOfValues, af:inputSearchor the af:inputComboboxListOfValues component to create an LOV.

LOV components are input components that allow the user to enter values by picking from a list that is generated by a query. ADF Faces provides the af:inputListOfValues, af:inputSearch and af:inputComboboxListOfValues components. If you are creating a fully featured LOV component, you must define the LOV in the **view object** as described in Working with List of Values (LOV) in View Object Attributes.

If you are using dependent LOVs as part of your search form, you must use them with the af:query component. For more information about using LOV components with search forms, see List of Values (LOV) Input Fields.

The af:inputListOfValues component has a search icon next to the search criteria field, as shown in Figure 35-1.

Figure 35-1 Search Criteria Input Field Defined as an inputListOfValues

The af:inputComboboxListOfValues component has a dropdown icon next to the field, as shown in Figure 35-2 for the State attribute.

Figure 35-2 Search Criteria Input Field Defined as an inputComboboxListOfValues

The af:inputSearch component filters and highlights matching suggestions. You use this LOV component with an ADF REST resource. Filtering of suggestions is case insensitive. The difference between af:inputSearch and af:inputComboboxListOfValues is that the latter component fetches the list from the server every time you launch the dropdown. However, af:inputComboboxListOfValues has an attribute named contentDelivery which if set to immediate will not fetch the list while launching the dropdown. The list would have to be pre-fetched while loading or rendering the component. In the case ofaf:inputSearch , this component fetches the list from an ADF REST resource based on a RESTful web service. If caching is enabled by way of HTTP headers on the ADF REST service, the resource can also be cached on the client. Caching is controlled by the ADF REST service implementor. In such a scenario, subsequent LOV dropdown launches retrieve the list from the cache. If caching is enabled by way of HTTP headers, it facilitates in-browser filtering based on user input, and also managing MRU (Most Recently Used) suggestions within the browser.

The default display of `af:inputSearch` component's suggestion list is in the list and table modes as shown in Figure 35-3 and Figure 35-4.

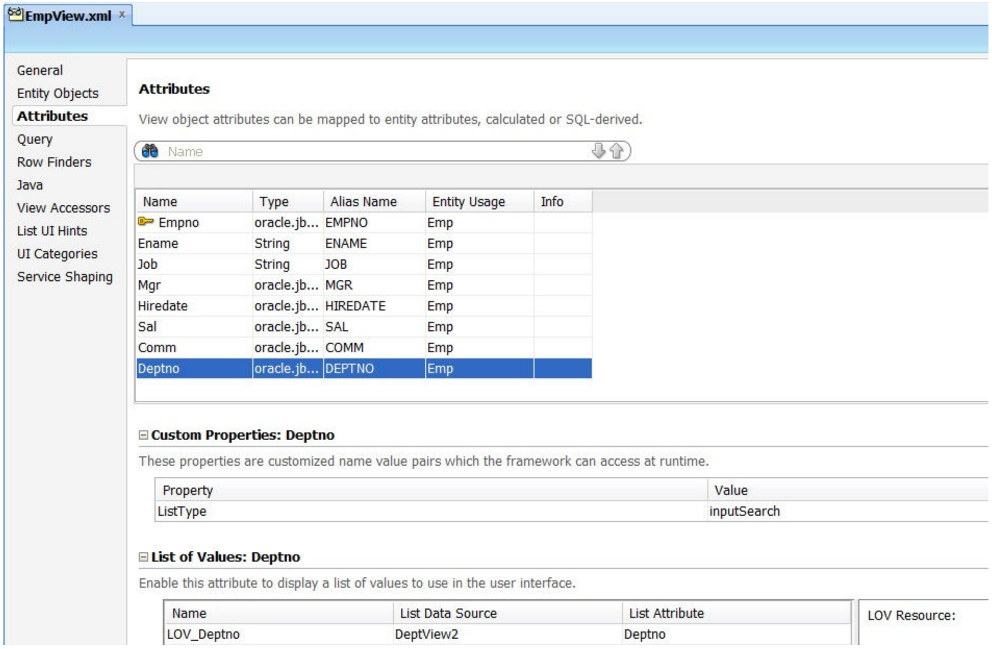
Abe	Prentice	641

You can customize the display of this component's suggestion list using the `contentStamp` and `contentHeader` facets. The code populates within the `af:inputSearch` tag. The code has the `ValueAttribute` attribute, which is the LOV attribute for which the `af:inputSearch` is configured. In this example, the LOV attribute is `Deptno` and hence the `ValueAttribute` attribute is assigned the value `deptnoid`. The `contentMode` attribute is assigned the value of table, which indicates that the suggestion list rendered by this component for this LOV attribute will display in tabular format. Further, `f:facet` tags encloses the code for the `contentStamp` facet (as indicated by `name = contentStamp`). In this example, the LOV attribute is `Deptno`, and this attribute retrieves data from the Dept (Department) table. As indicated in the `f:facet` tag, Dname (Department Name) and Deptno (Department Number) are the columns configured to appear in the suggestion list when the user enters input in the LOV component.

You can configure the columns that appear in the suggestion list. To illustrate this with an example, see Figure 35-5 of `EmpView.xml`; `Deptno` attribute selected in the Attributes tab, and LOV_Deptno entry is selected in the **List of Values: Deptno** section. **Deptno** is already configured as an LOV attribute of type `af:inputSearch`. Double-click on LOV_Deptno entry in the **List of Values: Deptno** section to open the **Edit List of Values** dialog. Figure 35-6 displays this dialog – Edit List of Values. Select **UI Hints** tab and move the columns from the **Available** section to **Selected** section. The entries in the **Selected** section appear in the suggestion list when a user enters input into the LOV component.

Figure 35-5 LOV attribute configured as `af:inputSearch`



Attributes

View object attributes can be mapped to entity attributes, calculated or SQL-derived.

Name	Type	Alias Name	Entity Usage	Info
Empno	oracle.jb...	EMPNO	Emp	
Ename	String	ENAME	Emp	
Job	String	JOB	Emp	
Mgr	oracle.jb...	MGR	Emp	
Hiredate	oracle.jb...	HIREDATE	Emp	
Sal	oracle.jb...	SAL	Emp	
Comm	oracle.jb...	COMM	Emp	
Deptno	oracle.jb...	DEPTNO	Emp	

Custom Properties: Deptno

These properties are customized name value pairs which the framework can access at runtime.

Property	Value
ListType	inputSearch

List of Values: Deptno

Enable this attribute to display a list of values to use in the user interface.

Name	List Data Source	List Attribute
LOV_Deptno	DeptView2	Deptno

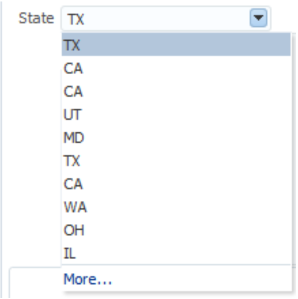
□ Include "No Selection" Item: Blank Item (First of List)

For `af:inputComboboxListOfValues`, clicking the dropdown icon displays the LOV dropdown list and either a **More** or a **Search** link, as shown in Figure 35-7. A **Search** link appears when the LOV Search and Select popup dialog contains a search panel to refine the search. A **More** link appears when the popup dialog contains only the list-of-values table or when a **smart list** is used.

Figure 35-7 LOV Dropdown List with Search Link for inputComboboxListOfValues



The user can select any of the items in the dropdown list to populate the input field. The dropdown list includes a filtered list of values and an optional list of most recently used items. The width of each attribute in the dropdown list can be configured using the **DisplayWidth** UI hint for that attribute in the view object definition. The width of the dropdown list will be the sum of the widths of all the attributes in the dropdown list.

The user can also enter the value into the field. If the user enters data that is of a different data type than what is defined for the `inputComboboxListOfValues`, a conversion error will be thrown. For example, if the `inputComboboxListOfValues` is of `NUMBER` datatype and the user enters an alphanumeric string, a conversion error will result.

You can create custom content to be rendered in the Search and Select dialog using the `searchContent` facet. You can add components such as input text, `tables`, and `trees` to display the custom content. You will need to define the `returnPopupDataValue` attribute and implement a `returnPopupListener`. When you want to add the auto-complete feature with your custom popup, you can disable the popup by adding `launchPopupEvent.setLaunchPopup(false)` to your `LaunchPopupListener()` code. However, clicking on the **Search** link will still launch the Search and Select dialog. For information about adding custom content, see Using List-of-Values Components.

The `resultsTable` facet is used to display a custom message when the results table of the Search and Select dialog is empty.

If the component's `readOnly` attribute is set to true, then the input field will not be rendered and the value cannot be changed. By default, the `readOnly` attribute is set to `false`, which also enables the `editMode` attribute to determine whether the user is permitted only to select a value from the list (`editMode` set to `select`) or whether the user can also enter a value into the input field (`editMode` set to `input`).

You can also set up the LOV component to display a list of selectable suggested items when the user types in a partial value. For example, when the user types in `CA`, then a suggested list which partially matches `CA` is displayed as a suggested items list. The user can select an item from the list to be entered into the input field. If there are no matches, a "No results found" message will be displayed. You add the `af:autoSuggestBehavior` tag from the Components window into the LOV and set the `selectedItem` attribute to the `suggestedItems` method implemented in ADF Model.

Note that auto suggest behavior occurs in the Apply Request Values phase. If the `immediate` property is set to `true`, validation will be performed in the same phase. If there is a validation error, the suggestion list will not be displayed. If you want to add auto suggest behavior, do not set `immediate` to `true`.

If the LOV attribute is not unique and has multiple entries with the same value, auto-suggest will only display one value in the list. To display all duplicate values in the auto-suggest selection list, you need to select an attribute that has a unique foreign key to be the LOV attribute. You can select a more readable attribute to be the display attribute in the LOV definition by adding the `f:converter binding` tag inside the `inputListOfValues` or `inputComboboxListOfValues` component. The display attribute values will be shown in the input field and in the auto-suggest list.

```
f:converter binding = "#{bindings.LOV_ATTR.converter}"
```

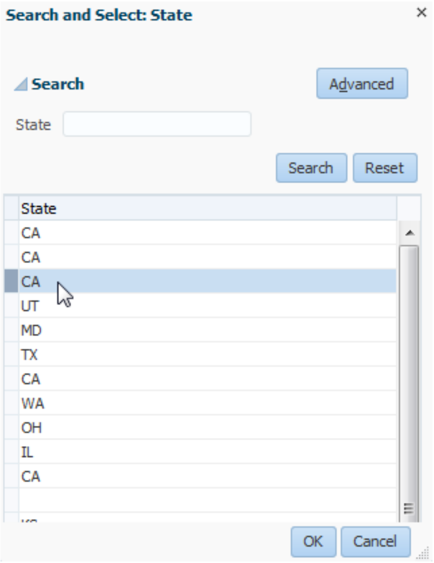
For instance, if the Research department has multiple entries with different department numbers and you defined the `DeptName` attribute as a LOV, the auto-suggest list will only display one department entry for Research. Instead, you can define `Deptno` as the LOV attribute because `Deptno` is a unique foreign key. Auto-suggest will then list all entries for the Research department. However, to make the LOV display more readable, define `DeptName` as the display attribute and use the `f:converter binding` tag to display `DeptName` instead of `Deptno` in the rendered selection field, as shown in the following example.

```
<af:inputComboboxListOfValues id="deptnoId"
                              popupTitle="Search and Select:
                              #{bindings.Deptno.hints.label}"
                              value="#{bindings.Deptno.inputValue}"
                              label="#{bindings.Deptno.hints.label}"
                              model="#{bindings.Deptno.listOfValuesModel}"
                              required="#{bindings.Deptno.hints.mandatory}"
                              columns="#{bindings.Deptno.hints.displayWidth}"
                              shortDesc="#{bindings.Deptno.hints.tooltip}">
  <f:validator binding="#{bindings.Deptno.validator}"/>
  <f:converter binding="#{bindings.Deptno.converter}"/>
  <af:autoSuggestBehavior suggestItems="#{bindings.Deptno.suggestItems}"/>
</af:inputComboboxListOfValues>
```

The LOV will display the department name to the user, but will use the unique department number when interacting with the model.

When the user clicks the **Search** or **More** link (or for `af:inputListOfValues`, the search icon), the LOV Search and Select dialog appears with the full list of values in a table format. The LOV Search and Select dialog launched from a **More** link is shown in Figure 35-8.

Figure 35-8   LOV Search and Select Dialog



State
CA
CA
CA
UT
MD
TX
CA
WA
OH
IL
CA

If a user enters a partial string in the LOV and click **Search** or tab out, a Search and Select dialog will appear with the partial string displayed in the search field and the resulting list of matching values in a table. The user can then select an entry from the list to be the LOV value.

The Search and Select popup dialog also presents a create function that allows the user to add a new row. Be aware that if you are creating a new record using the LOV Search and Select dialog, the new row will appear as an empty row in the table if the LOV has the **Query Automatically** control hint set to `false`. The content of the row will appear when you perform a query using the **Search** button. The following example shows a code sample that uses a link to invoke the create function.

```
<f:facet name="customActions">
      <af:link id="createLink" text="Create..."
         partialSubmit="true">
                 <af:showPopupBehavior popupId="createSLPopup"
                 alignId="createLink"/>
      </af:link>
</f:facet>
```

If the LOV is part of a task flow that is using an isolated data control, and you use the create function to add a new record, the newly added record will not be displayed in the parent page. This is because the search region is also using an isolated data control scope, so the underlying view object updates are not displayed. For information about shared and isolated data controls, see Sharing Data Controls Between Task Flows.

To programmatically refresh the LOV and display the view object updates, add a `returnListener` to the **Create** link with code similar to that shown in the following example.

```
public void refreshLOV() {
     BindingContainer bindings = this.getBindings();
     oracle.jbo.uicli.binding.JUCtrlListBinding lovBinding =
         (oracle.jbo.uicli.binding.JUCtrlListBinding)
```

```
          bindings.get("Description1");
     JUIteratorBinding lovIter = lovBinding.getIteratorBinding();
     RowSet rs = lovIter.getRowSetIterator().getRowSet();
     rs.executeQuery();

    //Add LOV as the partialTrigger

AdfFacesContext.getCurrentInstance().addPartialTarget(this.getPlatformDesc());
```

An LOV is associated with a data source via the view accessor. You can apply one or more view criteria to the view accessor associated with the LOV. The **view accessor** provides permanent filtering to the LOV data source. In addition to this permanent filtering, you may be able to apply other filters.

The LOV dialog may include a query panel to allow the user to enter criteria to search for the list of values, or it may contain only a table of results. When you define the LOV in the view object, you can use the UI hints to specify whether a search region should be displayed, which view criteria should be used as the search to populate the list of values, and which LOV component to use. Figure 35-9 shows the Create List of Values dialog and some of its options. In this example, the search region will be made available with the `All Queryable Attributes` named view criteria used for the query, and `af:inputComboboxListOfValues` as the component. Another useful option for the `af:inputComboboxListOfValues` is the **Show in Combo Box** option, which allows you to select the number of attributes to display in the dropdown list and in the Search and Select dialog. For information on LOV UI hints, see How to Set User Interface Hints on a View Object LOV-Enabled Attribute.

For both `af:inputListOfValues` and `af:inputComboboxListOfValues`, if the user enters a partial match in the input search field and presses the Tab or Enter key, the LOV automatically launches the LOV Search and Select dialog and executes the query after applying an auto-generated view criteria with a single item representing the partial match value entered by the user. If there are matches, the Search and Select dialog displays all the entries matching the partially entered criteria. If there are no entries that match the entered partial match, then the dialog displays all the entries.

By default, in the `af:inputComboboxListOfValues` component **auto-complete** feature, the search is case-sensitive. If you want the search to be case-insensitive, create a view criteria to be associated with that LOV attribute. In the Create View Criteria dialog, deselect the **Ignore Case** checkbox for that view criteria item before you apply that view criteria to the LOV definition. For information about setting view criteria options, see How to Create Named View Criteria Declaratively.

☐ Query List Automatically

Choice List Options

☑ Query Limit: 10

Most Recently Used Count: 0

☐ Filter Combo Box Using: CustomerViewCriteria

☐ Include "No Selection" Item: Blank Item (First of List)

You can also set up the LOV component to display a list of selectable suggested items when the user types in a partial value. For example, when the user types in `Ca`, then a suggested list which partially matches `CA` is displayed as a suggested items list. The user can select an item from the list to be entered into the input field. You add this **auto-suggest behavior** feature by including an `af:autoSuggestBehavior` tag from the Components window in the LOV and set the `selectedItem` attribute to the `suggestedItems` method implemented in ADF Model.

If the LOV is an `af:inputComboboxListOfValues`, you can apply an additional view criteria to further filter the values in the dropdown list to create a smart list. If the **Filter Combo Box Using** UI hint is not applied, the dropdown list is filtered by the view criteria applied to the view accessor. Note that this smart list filter applies only to the dropdown list. The full list is still used for validation and for searching from the LOV Search and Select popup dialog. When smart list is enabled, the LOV's Search and Select dialog will display a **More** link instead of the **Search** link.

If both the auto-suggest behavior and smart list filter are enabled for an LOV, auto-suggest will search from the smart list first. If the user waits for two seconds without clicking, then auto-suggest will also search from the full list and append the results. You can also specify the number of suggested items returned by setting the `maxSuggestedItems` attribute (-1 indicates a complete list). If `maxSuggestedItems > 0`, a **More** link is rendered for the user to click on to launch the LOV's Search and Select dialog. The following example shows the code from an LOV with both auto-suggest behavior and a smart list.

```
af:autoSuggestBehavior
    suggestItems="#{bindings.CountryName.suggestItems}"
```

```
smartList="#{bindings.CountryName.smartList}"/>
maxSuggestedItems="5"
```

You can define an attribute in the view object to be one or more LOVs. If multiple LOVs are defined on an attribute, each LOV has its own name, view accessor, data mappings, validator, and UI hints (except for the **Default List Type** hint, which is defined once for the attribute). To switch between LOVs to be used at runtime, an LOV switcher is used. The LOV switcher can be based on an existing attribute of type `String`, or created as a new `String` attribute solely for switching between LOVs. The LOV switcher returns the name of the LOV to use at runtime. For instance, you can create three LOVs for the price attribute, and designate the `CountryName` attribute as the LOV switcher. At runtime, the value of `CountryName` will switch the price attribute to use the LOV that reflects the country's price and currency.

If an attribute is defined as an LOV, you can set the **Support Multiple Value Selection** control hint in its view criteria to enable users to make multiple selections in the search criteria field. If multiple selection is enabled on an LOV attribute, and the `Equal to` or `Not equal to` operator is chosen, a `selectManyChoice` component will render in the query panel. The user can select multiple items as the search criteria.

If the value of an LOV depends on the value of another LOV, then the two LOVs are called **cascading** LOVs. For instance, the list of values for the City LOV depends on the value of the CountryName LOV that was selected. If the LOV is defined as a named bind variable, or if validation is enabled, the LOV query may behave differently depending on such conditions as whether null values for the named bind variable are acceptable. If the bind variable is null, you may want the LOV query to return an empty list. The view criteria's **Ignore Null Values** and **Validation** options can be used to define LOV query behavior.

If the view object has an LOV with a bind variable, you should set that view object bind variable's control hint to **Hide**. Otherwise, the bind variable will be displayed in the LOV Search and Select popup dialog. In the view object overview editor's **Query** tab, double-click the bind variable, click the **Control Hints** tab and select **Hide** from the **Display Hint** dropdown list.

> **Note:**
>
> List of values are designed to return valid values only. As a result, validation rules defined on data source view object attributes will be suppressed. You should ensure that the list of values returned only contains valid values. See What You May Need to Know About List of Values and Attribute Validation Rules.

> **Best Practice:**
>
> An attribute that has been enabled as an LOV should not be used as search criteria in a manually created search form using the "Find Mode" iterator. Creating a search form in this way could result in SQL exception: `java.sql.SQLException: Attempt to set a parameter name that does not occur in the SQL`. It is best practice to use the query and quick query components for creating search forms. For more information, see Creating ADF Databound Search Forms.

Displaying an LOV list for a name attribute when the view object's key attribute is a numerical value requires mapping supplemental attributes on the LOV-enabled attribute. For example, to display a list of credit cards by name instead of by their payment option ID value, you can create an LOV on the name reference attribute and define the primary key attribute as a supplemental attribute to the LOV. For details about creating an LOV-enabled reference attribute, see How to Define an LOV to Display a Reference Attribute.

> **Note:**
>
> `af:inputListOfValues` and `af:inputComboboxListOfValues` assume the list of values returned from the Search and Select dialog to be valid. Any ADF Business Components validation errors will not be displayed.

For information about different usage scenarios and other view criteria options, see How to Create Named View Criteria Declaratively, and What You May Need to Know About Bind Variables in View Criteria.

How to Create an LOV

You can create the LOV using either the `af:inputListOfValues` or the `af:inputComboboxListOfValues` component. You can add auto-suggest behavior to the component to display a list of possible matches from user input.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an LOV. For more information, see Creating List of Values (LOV) Components.

You may also find it helpful to understand functionality that can be used with LOVs. For more information, see Additional Functionality for Selection Lists and Shuttles.

You will need to complete this task:

> Define the attribute to be an LOV in the view object by following the procedure described in Working with List of Values (LOV) in View Object Attributes.

To create an LOV:

1. In the Application window, double-click the web page that will display the component.

2. From the Data Controls panel, drag and drop the attribute onto the JSF page and choose **Create > List of Values > ADF LOV Input** or **Create > List of Values > ADF LOV Choice List**.
3. In the ADF Faces page of the Components window, from the Operations panel drag and drop **Auto Suggest Behavior** as a child to the LOV component.
4. In the Property Inspector, enter values for **Auto Suggest Behavior**:
   - **SuggestItems**: EL expression that resolves to the `suggestItems` method.
   - **SmartList**: EL expression that resolves to the `smartList` method.
   - **MaxSuggestedItems**: Number of items to be displayed in the auto-suggest list. Enter -1 to display the complete list.
5. If you want to set a different display attribute for the LOV, add the `f:converter binding` tag to the component. For instance, you want the LOV to display the sales rep name instead of the sales rep id, you can add this tag to the component: `f:converter binding="#{bindings.SalesRepId.converter}"` and define `SalesRepName` as the display attribute.
6. If you added the auto-suggest behavior, you must not set the component's `immediate` property to `true`.

   The following example shows an `inputListOfValues` component with the auto-suggest behavior and smart list features.

```
<af:inputListOfValues id="salesRepIdId"
                 popupTitle="Search and Select:
#{bindings.SalesRepId.hints.label}"
                 value="#{bindings.SalesRepId.inputValue}"
                 label="#{bindings.SalesRepId.hints.label}"
                 model="#{bindings.SalesRepId.listOfValuesModel}"
                 required="#{bindings.SalesRepId.hints.mandatory}"
                 columns="#{bindings.SalesRepId.hints.displayWidth}"
                 shortDesc="#{bindings.SalesRepId.hints.tooltip}">
<f:validator binding="#{bindings.SalesRepId.validator}">
<f:converter binding="#{bindings.SalesRepId.converter}">
<af:autoSuggestBehavior suggestItems="#{bindings.SalesRepId.suggestedItems}"
         smartList="#{bindings.SalesRepId.smartList}"
         maxSuggestedItems="5"/>
</af:inputListOfValues>
```

How to Configure an LOV Attribute as inputSearch

You create an `af:inputSearch` LOV component by defining an LOV attribute initially and then configuring the LOV attribute as `inputSearch`.

Before you begin

See How to Define a Single LOV-Enabled View Object Attribute to understand how to define an attribute as LOV attribute. After configuring the LOV attribute as `inputSearch`, you proceed to create an `af:inputSearch` LOV component.

See How to Create an LOV to understand how to create an LOV component. After building the `af:inputSearch` component, you specify the URL of the ADF REST resource so that the `af:inputSearch` LOV component fetches the LOV from this ADF REST resource.

See Creating ADF REST Resources Using the Application Module to understand how to create a RESTful web service with application modules.

See How to Provide af:inputSearch LOV Component the REST URL to understand how to provide the REST URL to the af:inputSearch LOV component.

To configure an LOV attribute as `inputSearch`:

1. In the Applications Navigator, double-click the view object that contains the LOV attribute that you wish to configure as `inputSearch`.
2. In the **Attributes** page, select the LOV attribute and in **Custom Properties** section, click the plus icon and select **Non-translatable Property** to add a row with columns **Property** and **Value**.
3. Double-click the row and enter `ListType` in the **Property** column and `inputSearch` in the **Value** column of this row.
4. Click **Save** to save the project.

What Happens When You Create an inputSearch Component

When you drag and drop an attribute defined as an LOV and also defined as an `inputSearch` from the Data Controls panel onto a `.jspx` page as an `inputSearch` component, JDeveloper adds code to the page similar to that shown in the following example. JDeveloper also does many other things - see What Happens When You Create an LOV to know more.

```
<af:inputSearch id="deptnoID" contentMode="table"
        valueAttribute="#{bindings.Deptno.valueAttribute}"
        displayAttributes="#{bindings.Deptno.displayAttributes}"
        value="#{bindings.Deptno.inputValue}"
        selectionConverter="#{bindings.Deptno.selectionConverter}"
        label="#{bindings.Deptno.hints.label}"
        required="#{bindings.Deptno.hints.mandatory}"
        columns="#{bindings.Deptno.hints.displayWidth}"
        shortDesc="#{bindings.Deptno.hints.tooltip}">
<f:facet name ="contentStamp">
<af:sanitized>
<td>{{Dname}}</td><td>{{Deptno}}</td>
</af:sanitized>
</f:facet>
</af:inputSearch>
```

In the page definition file, JDeveloper adds code as shown in the following example. The code sample shows the `Deptno` attribute designated as `inputSearch` list type.

```
<listOfValues StaticList="false" IterBinding="EmpView1Iterator"
                                Uses="LOV_Deptno" id="Deptno"
ListType="inputSearch"/>
</bindings>
```

How to Provide af:inputSearch LOV Component the REST URL

After configuring an attribute as an LOV attribute, and defining it as of type `inputSearch`, the next step is to create the `af:inputSearch` LOV component and provide this component the REST URL.

You do this so that this component uses the REST URL to fetch the LOV list from the ADF REST resource. See How to Configure an LOV Attribute as inputSearch to understand how to create an LOV attribute and configure it as an LOV attribute that works with `af:inputSearch`. To provide a REST URL to an `inputSearch` LOV component:

1. Ensure that the RESTful web service is running when running the `.jspx` page that contains the `af:inputSearch` component.
2. In the `.jspx` page that contains the `af:inputSearch` LOV component, click the Source tab to view the source code.
3. Locate the `af:searchSection` tag and enter the REST URL as a value to the `dataURL` attribute of this tag. An example REST URL is `dataUrl="//Application3-RESTWebService-context-root/rest/v1/Dept"`. In this REST URL, `Application3-RESTWebService-context-root` is the context root of the RESTful web service. `rest` is the URL pattern of the `RESTServlet` in the `web.xml` file of the RESTful web service. `v1` is the version of the ADF REST resource. `Dept` is the name of the REST resource.
4. Build the `.jspx` page to view LOV component and retrieve the LOV from the ADF REST resource.

What Happens When You Create an LOV

When you drag and drop an attribute from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see What Happens When You Create a Text Field.

When you drag and drop an attribute defined as an LOV from the Data Controls panel onto a JSF page as an `inputListOfValues` or `inputComboboxListOfValues` component, JDeveloper adds code to the page similar to that shown in the following example. The `State` attribute in the `CustomerVO` view object has been defined as an LOV and its default component is set to be an `inputComboboxListOfValues`. The component gets its properties from the control hints defined declaratively in the view object. If you want to include the auto-suggest behavior, you must manually add that tag from the Components window.

```
<af:inputComboboxListOfValues id="stateId"
        popupTitle="Search and Select: #{bindings.State.hints.label}"
        value="#{bindings.State.inputValue}"
        label="#{bindings.State.hints.label}"
        model="#{bindings.State.listOfValuesModel}"
        required="#{bindings.State.hints.mandatory}"
        columns="#{bindings.State.hints.displayWidth}"
        shortDesc="#{bindings.State.hints.tooltip}">
        <f:validator binding="#{bindings.State.validator}"/>
</af:inputComboboxListOfValues>
```

In the page definition file, JDeveloper adds code as shown in the following example. The bindings section of the page definition specifies that the LOV is for the `State` attribute and the name of the LOV is `LOV_State`. JDeveloper adds the definitions for the iterator binding objects into the `executables` element, and the list of values binding object into the `bindings` element.

```
<executables>
    <variableIterator id="variables"/>
    <iterator Binds="Customers" RangeSize="25"
              DataControl="BackOfficeAppModuleDataControl"
              id="CustomersIterator"/>
```

```
</executables>
<bindings>
    <listOfValues StaticList="false" IterBinding="CustomersIterator"
                  Uses="LOV_State" id="State"/>
</bindings>
```

For more information about the page definition file and ADF data binding expressions, see Working with Page Definition Files, and Creating ADF Data Binding EL Expressions.

What You May Need to Know About List Validators and LOV

If you are defining an attribute in the view object to be a list of values attribute, you can define an equivalent list validation rule in the underlying entity object as long as the list validation rule is based on the same list. You should not define other types of validation rules in the entity object for an attribute already defined as a list of values in the view object. Doing so may result in unexpected behavior and validation errors. For more information about defining validation rules, see Figure 10-3, and Using the Built-in Declarative Validation Rules.

What You May Need to Know About InputComboboxListOfValues and Null Values

If you create an `inputComboboxListOfValues` component with a view object list data source and that list may be modified at runtime so that list items can be deleted, you must define a custom property `displayMode` on the LOV attribute to support null values. By default, the `inputComboboxListOfValues` component will display the value of the list attribute defined by the LOV attribute when no display value is available. To ensure a deleted display attribute value is not substituted by its corresponding attribute list value, define the custom property `displayMode` with the name of the LOV display attribute as a value. For example, Figure 35-10 shows the LOV attribute `DeptId` that defines the custom property with the LOV display attribute `Name` as a value. Then, at runtime, when a department name is deleted from the list of available departments, the custom property ensures that entering the deleted name returns no match.

Creating a Selection List

ADF Faces provides a number of different selection components, ranging from simple boolean radio buttons to list boxes that allow the user to select multiple items. You can create a model-driven selection list, a fixed selection list, or a dynamic selection list using different procedures.

ADF Faces Core includes components for selecting a single value and multiple values from a list. For example, `selectOneChoice` allows the user to select an item from a dropdown list, and `selectManyChoice` allow the user to select several items from a list of checkboxes. Selection lists are described in Table 35-1.

Table 35-1 ADF Faces Single and Multiple List Components

ADF Faces component	Description	Example
`SelectOneChoice`	Select a single value from a list of items.	
Table 35-1 (Cont.) ADF Faces Single and Multiple List Components

ADF Faces component	Description	Example
`SelectOneRadio`	Select a single value from a set of radio buttons.	`SelectOneListbox`	Select a single value from a scrollable list of items.	`SelectManyChoice`	Select multiple values from a scrollable list of checkboxes. Each selection displays at the top of the list.	 Drinks tea; lemonade □ All □ coffee ☑ tea □ fizz □ beer ☑ lemonade □ item14
`SelectManyCheckbox`	Select multiple values from a group of checkboxes.	`SelectManyListbox`	Select multiple values from a scrollable list of checkboxes,	 Drinks □ All ☑ coffee ☑ tea;green □ orange juice □ wine

You can create selection lists using the `SelectOneChoice` ADF Faces component. The steps are similar for creating other single-value selection lists, such as `SelectOneRadio` and `SelectOneListbox`.

A databound selection list displays values from a data control collection or a static list and updates an attribute in another collection or a method parameter based on the user's selection. When adding a binding to a list, you use an attribute from the data control that will be populated by the selected value in the list.

> **Note:**
>
> By default, ADF Model list binding passes the index to the component. If you set `valuePassThru=true`, then you should set the list binding entry in the corresponding page definition file `Mode` attribute to `Object`. When `Mode=Object`, the list binding will pass an object instead of an index to the component. See What Happens When You Create a Fixed Selection List.

To create a selection list, you choose a base data source and a list data source in the Edit List Binding dialog:

- Base data source: Select the data collection that you want to bind to your control and that contains the attributes to be updated from user selections.
- List data source: Select the data collection that contains the attributes to display.

The data collection is based on the view object. For information about creating a view object, see How to Create an Entity-Based View Object.

You can create three types of selection lists in the Edit List Binding dialog:

- Model-driven list: List selections are based on a list of values bound to a data collection. This type of selection list offers significant advantages over the other two, as described in How to Create a Model-Driven List.
- Static list: List selections are based on a fixed list that you create a manually by entering values one at a time into the editor. See How to Create a Selection List Containing Fixed Values.
- Dynamic list: List selections are generated dynamically based on one or more databound attribute values. See How to Create a Selection List Containing Dynamically Generated Values.

How to Create a Model-Driven List

A model-driven list is based on a list of values that is bound to a view data object. Lists of Values are typically used in forms to enable an end user to select an attribute value from a dropdown list instead of having to enter it manually. When the user submits the form with the selected values, ADF data bindings in the ADF Model layer update the value on the view object attributes corresponding to the databound fields.

Note:

One way to create a model-driven list is to drag a collection from the Data Controls panel onto a JSF page, choose one of the ADF Forms in the context menu, and accept the defaults. The advantage is that if there are LOVs defined on the underlying view object attributes, all the LOVs on the entire form will be configured automatically. For more information, see How to Define a Single LOV-Enabled View Object Attribute.

You can also use the list of values as the basis for creating a selection list. The advantages of creating a model-driven list based on a list of values are:

- Reuse: The list of values is bound to a view data collection. Any selection list that you create based on the data collection can use the same list of values. Because you define the LOV on the individual attributes of view objects in a data model project with ADF Business Components, you can customize the LOV usage for an attribute once and expect to see the changes anywhere that the business component is used in the user interface.
- Translation: Values in the list of values can be included in resource bundles used for translation.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an selection list component. For more information, see Creating a Selection List.

You may also find it helpful to understand functionality that can be used with selection lists. For more information, see Additional Functionality for Selection Lists and Shuttles.

You will need to complete these tasks:

1. Create a view object.
2. Create a view accessor on the object.
3. Create a list of values that is bound to an attribute on the base data source for the selection list. For example, you can create a list of values bound to the `CountryId` attribute of the `Addresses` view data object.

   For more information, see How to Define a Single LOV-Enabled View Object Attribute.

To create a model-driven selection list:

1. From the Data Controls panel, drag and drop the attribute onto the JSF page and, from the context menu, choose **Create > Single Selections > ADF Select One Choice**.
2. In the Edit List Binding dialog, click the **Model Driven List** radio button.
3. In the **Base Data Source Attribute** dropdown list, select an attribute on which you want to display a list of values.

   The **Base Data Source** should be the collection you dragged from the Data Controls panel. If the collection does not appear in the dropdown list, click the **Add** button to select the collection you want.

4. In the **Server List Binding Name** dropdown list, select the name of the list-of-values definition that was created for the base attribute.

   If a list-of-values definition was created for the attribute you have selected, the definition will appear in the dropdown list. For example, if you have defined `LOV_State` as the list-of-value definition for the **State** attribute, then **LOV_State** should appear in the **Server List Binding Name** dropdown list.

5. Click **OK**.

What Happens When You Create a Model-Driven Selection List

When you drag and drop an attribute from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see What Happens When You Create a Text Field.

The following example shows the page source code after you add a model-driven `SelectOneChoice` component to it.

```
<af:selectOneChoice value="#{bindings.State.inputValue}"
                    label="#{bindings.State.label}"
                    required="#{bindings.State.hints.mandatory}"
                    shortDesc="#{bindings.State.hints.tooltip}"
                    id="soc1">
                    <f:selectItems value="#{bindings.State.items}" id="si1"/>
</af:selectOneChoice>
```

The `f:selectItems` tag, which provides the list of items for selection, is bound to the `items` property on the `State` list binding object in the binding container. For more information about ADF data binding expressions, see Configuring the ADF Binding Filter.

In the page definition file, JDeveloper adds the list binding object definitions in the bindings element, as shown in the following example.

```
<executables>
    <variableIterator id="variables"/>
    <iterator Binds="Customers" RangeSize="25"
              DataControl="BackOfficeAppModuleDataControl"
              id="CustomersIterator"/>
</executables>
<bindings>
    <list IterBinding="CustomersIterator"
          StaticList="false" Uses="LOV_State"
          id="State" DTSupportsMRU="true"
          SelectItemValueMode="ListObject"/>
</bindings>
```

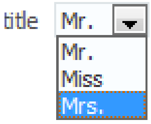
In the `list` element, the `id` attribute specifies the name of the list binding object. The `IterBinding` attribute references the variable iterator, whose current row is a row of attributes representing each variable in the binding container. The variable iterator exposes the variable values to the bindings in the same way as do other collections of data.

For more information about the page definition file and ADF data binding expressions, see Working with Page Definition Files, and Creating ADF Data Binding EL Expressions.

How to Create a Selection List Containing Fixed Values

You can create a selection list containing selections that you code yourself, rather than retrieving the values from another data source. See How to Create a Selection List Containing Dynamically Generated Values, for information about populating selection lists with values that are dynamically generated from another data source.

Figure 35-11 Selection List Bound to a Fixed List of Values



Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a selection list component. For more information, see Creating a Selection List.

You may also find it helpful to understand functionality that can be used with selection lists. For more information, see Additional Functionality for Selection Lists and Shuttles.

You will need to complete this task:

Prepare a list of values that you will enter into the component as a fixed list.

To create a list bound to a fixed list of values:

1. From the Data Controls panel, drag and drop the attribute onto the JSF page and, from the context menu, choose **Create > Single Selections > ADF Select One Choice**.
2. In the Edit List Binding dialog, click the **Fixed List** radio button.
3. In the **Base Data Source Attribute** dropdown list, select an attribute on which you want to display a list of values.

   The **Base Data Source** should be the collection you dragged from the Data Controls panel. If the collection does not appear in the dropdown list, click the **Add** button to select the collection you want.
4. In the **Set of Values** box, enter each value you want to appear in the list. Press the Enter key to set a value before typing the next value. For example, if your attribute is Country, you could add the country codes `India`, `Japan`, and `Russia`.

   The order in which you enter the values is the order in which the list items are displayed in the `SelectOneRadio` control at runtime.

   The `SelectOneRadio` component supports a `null` value. If the user has not selected an item, the label of the item is shown as blank, and the value of the component defaults to an empty string. Instead of using blank or an empty string, you can specify a string to represent the `null` value. By default, the new string appears at the top of the list.

5. Click **OK**.

What Happens When You Create a Fixed Selection List

When you add a fixed selection list, JDeveloper adds source code to the JSF page and list and iterator binding objects to the page definition file.

The following example shows the page source code after you add a fixed `SelectOneChoice` component to it.

```
<af:selectOneChoice value="#{bindings.CountryIdStatic.inputValue}"
                            label="#{bindings.CountryIdStatic.label}">
          <f:selectItems value="#{bindings.CountryIdStatic.items}"/>
        </af:selectOneChoice>
```

The `f:selectItems` tag, which provides the list of items for selection, is bound to the `items` property on the `CountryId` list binding object in the binding container. For more information about ADF data binding expressions, see Creating ADF Data Binding EL Expressions.

In the page definition file, JDeveloper adds the definitions for the iterator binding objects into the `executables` element, and the list binding object into the `bindings` element, as shown in the following example.

```
<executables>
    <iterator Binds="Addresses1" RangeSize="10"
              DataControl="BackOfficeAppModuleDataControl"
              id="Addresses1Iterator"/>
  </executables>
  <bindings>
    <list IterBinding="Addresses1Iterator" id="CountryIdStatic" ListOperMode="0"
          StaticList="true">
      <AttrNames>
        <Item Value="CountryIdStatic"/>
      </AttrNames>
      <ValueList>
        <Item Value="India"/>
        <Item Value="Japan"/>
        <Item Value="Russia"/>
      </ValueList>
    </list>
  </bindings>
```

For complete information about page definition files, see Working with Page Definition Files.

How to Create a Selection List Containing Dynamically Generated Values

You can populate a selection list component with values dynamically at runtime.

> **Tip:**
>
> Another option is to create a static view object or a database view object within a **shared application module**. Then use a model- driven LOV to create the list. This provides caching and translatability.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a selection list component. For more information, see Creating a Selection List.

You may also find it helpful to understand functionality that can be used with selection lists. For more information, see Additional Functionality for Selection Lists and Shuttles.

You will need to complete these tasks:

1. Define a data source for the list data source that provides the dynamic list of values.
2. Define a data source for the base data source that is to be updated based on the user's selection.

To create a selection list bound containing dynamically generated values:

1. From the Data Controls panel, drag and drop the attribute onto the JSF page and, from the context menu, choose **Create > Single Selections > ADF Select One Choice**.
2. In the Edit List Binding dialog, click the **Dynamic List** radio button.
3. Select the **Base Data Source** from the dropdown list or click **Add**.
4. In the Add Data Source dialog, select the data collection that contains the attribute to be updated and click **OK**.
5. Select the **List Data Source** from the dropdown list or click **Add**.
6. In the Add Data Source dialog, select the data collection that contains the attribute that will be displayed and click **OK**.

   > **Note:**
   >
   > The list and base collections do not have to form a **master-detail relationship**, but the attribute in the list collection must have the same type as the base collection attributes.

7. In the Data Mapping section, you can accept the default mapping or select different attributes items from the **Data Value** and **List Attribute** lists to update the mapping.

   The **Data Value** control contains the attribute on the data collection that is updated when the user selects an item in the selection list. The **List Attribute** control contains the attribute that populates the values in the selection list.

   To add a second mapping, click **Add**.

8. In the List Items section, select values for:
   - **Display Attribute**: Select the attribute you want to be displayed.
   - **"No Selection" Item**: Specify whether or not the list displays a NULL value selection and how it is displayed.
   - **MRU**: Select to show a list of most recently used items. Specify the number of items to display in the MRU list and the separator to be used.
9. Click **OK**.

What Happens When You Create a Dynamic Selection List

When you add a dynamic selection list to a page, JDeveloper adds source code to the JSF page and list and iterator binding objects to the page definition file.

The following example shows the page source code after you add a dynamic `SelectOneChoice` component to it.

```
<af:selectOneChoice value="#{bindings.SalesRepId.inputValue}"
                    label="#{bindings.SalesRepId.label}"
                    required="#{bindings.SalesRepId.hints.mandatory}"
                    shortDesc="#{bindings.SalesRepId.hints.tooltip}" id="soc2">
        <f:selectItems value="#{bindings.SalesRepId.items}" id="si4"/>
        <f:validator binding="#{bindings.SalesRepId.validator}"/>
</af:selectOneChoice>
```

The `f:selectItems` tag, which provides the list of items for selection, is bound to the `items` property on the `SalesRepId` list binding object in the binding container. For more information about ADF data binding expressions, see Creating ADF Data Binding EL Expressions.

In the page definition file, JDeveloper adds the definitions for the iterator binding objects into the `executables` element, and the list binding object into the `bindings` element, as shown in the following example.

```
<executables>
    <variableIterator id="variables"/>
    <iterator Binds="SummitAppModuleDataControl.dataProvider.
              BackOfficeAM.Customers"
              DataControl="SummitAppModuleDataControl" RangeSize="25"
              id="CustomersIterator"/>
    <iterator Binds="Countries" RangeSize="10"
              DataControl="BackOfficeAppModuleDataControl"
              id="CountriesIterator"/>
    <iterator Binds="Customers" RangeSize="-1"
              DataControl="BackOfficeAppModuleDataControl"
              id="CustomersIterator1"/>
</executables>
<bindings>
    <list IterBinding="CountriesIterator" StaticList="false" id="SalesRepId"
          DTSupportsMRU="true" SelectItemValueMode="ListObject"
          ListIter="CustomersIterator1">
      <AttrNames>
        <Item Value="Id"/>
      </AttrNames>
      <ListAttrNames>
        <Item Value="Id"/>
      </ListAttrNames>
      <ListDisplayAttrNames>
```

```
        <Item Value="Id"/>
      </ListDisplayAttrNames>
    </list>
</bindings>
```

By default, JDeveloper sets the RangeSize attribute on the iterator element for the Customers iterator binding to a value of -1 thus allowing the iterator to furnish the full list of valid products for selection. In the list element, the id attribute specifies the name of the list binding object. The IterBinding attribute references the iterator that iterates over the Countries collection. The ListIter attribute references the iterator that iterates over the Customers collection. The AttrNames element specifies the base data source attributes returned by the base iterator. The ListAttrNames element defines the list data source attributes that are mapped to the base data source attributes. The ListDisplayAttrNames element specifies the list data source attribute that populates the values users see in the list at runtime.

For complete information about page definition files, see Working with Page Definition Files.

What You May Need to Know About Values in a Selection List

Once you have created a list binding, you may want to access a value in the list. You can set the component's valuePassThru attribute to true either in the visual editor or in the Property Inspector. The following example shows the code for a selectOneChoice component.

```
 <af:selectOneChoice value="#{bindings.Language.inputValue}"
                     label="#{bindings.Language.label}"
                     required="#{bindings.Language.hints.mandatory}"
                     shortDesc="#{bindings.Language.hints.tooltip}"
                     valueChangeListener="#{myBean.valueChanged}"
                     id="soc1" valuePassThru="true">
      <f:selectItems value="#{bindings.Language.items}" id="si1"/>
</af:selectOneChoice>
```

Only when the valuePassThru attribute is set to true and the Mode attribute in the corresponding page definition file is set to Object can the value passed to the valueChangeListener be of type Object (which is the actual value). By default, Mode is set to Index. The following example shows the Mode attribute in the page definition file.

```
<list IterBinding="AvailableLanguagesView1Iterator" id="Language"
      DTSupportsMRU="true" StaticList="false"
      ListIter="CountryCodesView1Iterator"
      Mode="Object"/>
```

Creating a List with Navigation List Binding

In ADF Faces, navigation list binding lets users navigate through the objects in a collection. As the user changes the current object selection using the navigation list component, any other component that is also bound to the same collection through its attributes will display from the newly selected object.

In addition, if the collection whose current row you change is the master view object instance in a data model master-detail relationship, the row set in the detail view object instance is automatically updated to show the appropriate data for the new current master row.

How to Create a List with Navigation List Binding

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a navigation list. For more information, see Creating a List with Navigation List Binding.

You may also find it helpful to understand functionality that can be used with navigation lists. For more information, see Additional Functionality for Selection Lists and Shuttles.

To create a list that uses navigation list binding:

1. From the Data Controls panel, drag and drop the master collection to the page and choose **Create > Navigation > ADF Navigation List**.

   The master collection is where the user selects from.

2. In the Edit List Binding dialog, from the **Base Data Source** dropdown list, select the collection whose members will be used to create the list.

   This should be the collection you dragged from the Data Controls panel. If the collection does not appear in the dropdown list, click the **Add** button to select the collection you want.

3. From the **Display Attribute** dropdown list, select the attribute that will display in the list. You can choose the selection that includes all the attributes, and you can choose **Select Multiple** to launch a selection dialog.
4. In the Select Multiple Display Attributes dialog, shuttle the attributes you want to display from the **Available Attributes** list to the **Attributes to Display** list. Click **OK** to close the dialog.
5. Click **OK**.
6. From the Data Controls panel, drag and drop the detail collection inside the **Details** section of the page as an output component.

   The output component can be any component that is used to display the data. If you decide to use a table, you can choose **Create> Table > ADF Table**.

   The **Detail** section is an `af:panelHeader` component that was added by JDeveloper when you created the navigation list in Step 1.

What Happens When You Create a Navigational List Binding

When you add a navigation list to a page, JDeveloper adds source code to the JSF page and list and iterator binding objects to the page definition file.

On the page, JDeveloper adds a `selectOneChoice` component with a `f:selectItems` tag. The `selectOneChoice` component allows the user to select from a list of values based on the selected attribute in the source data collection. JDeveloper also adds an `af:panelHeader` component that will contain the component you chose to display the data based on the selection. In this example, a table component is added to display the data. Note that the `af:panelHeader` component has `partialtriggers` set to the `selectOneChoice` component `id` so that when the selection changes, new data will be displayed. The following example shows the page source code after you add a navigation list.

```
<af:selectOneChoice id="nl1" autoSubmit="true"
    value="#{bindings.Customers.inputValue}"
    label="#{bindings.Customers.label}">
    <f:selectItems value="#{bindings.Customers.items}" id="si1"/>
</af:selectOneChoice>
<af:panelHeader text="Details" partialTriggers="nl1" id="ph1">
    <af:table value="#{bindings.OrdersForCustomer.collectionModel}" var="row"
        rows="#{bindings.OrdersForCustomer.rangeSize}"
        emptyText="#{bindings.OrdersForCustomer.viewable ?
                   'No data to display.' : 'Access Denied.'}"
        fetchSize="#{bindings.OrdersForCustomer.rangeSize}"
rowBandingInterval="0"
        id="t1">
     <af:column headerText="#{bindings.OrdersForCustomer.hints.Id.label}"
id="c1">
        <af:inputText value="#{row.bindings.Id.inputValue}"
...
```

In the page definition file, JDeveloper adds the definitions for the iterator binding objects into the `executables` element. The following example shows the iterator bindings and navigation list bindings in the page definition file.

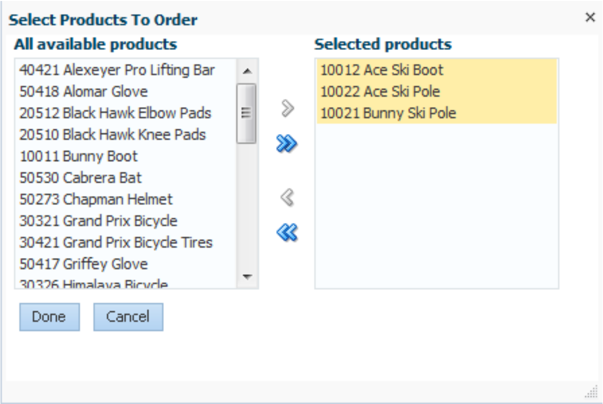
```
<executables>
    <variableIterator id="variables"/>
    <iterator Binds="Customers" RangeSize="25"
         DataControl="BackOfficeAppModuleDataControl" id="CustomersIterator"/>
    <iterator Binds="OrdersForCustomer" RangeSize="25"
         DataControl="BackOfficeAppModuleDataControl"
              id="OrdersForCustomerIterator"/>
</executables>
<bindings>
    <navigationlist IterBinding="CustomersIterator" ListOperMode="navigation"
              ListIter="CustomersIterator"
              id="Customers" DTSupportsMRU="false">
      <AttrNames>
        <Item Value="Name"/>
      </AttrNames>
    </navigationlist>
    <tree IterBinding="OrdersForCustomerIterator" id="OrdersForCustomer">
      <nodeDefinition DefName="oracle.summit.model.views.OrdVO"
             Name="OrdersForCustomer0">
        <AttrNames>
          <Item Value="Id"/>
          <Item Value="CustomerId"/>
          <Item Value="DateOrdered"/>
          <Item Value="LastName"/>
          <Item Value="Name"/>
        </AttrNames>
      </nodeDefinition>
    </tree>
</bindings>
```

Creating a Databound Shuttle

ADF Faces provides shuttle components that provides a mechanism for selecting multiple values from a list of values by allowing the user to move items between two lists. Use the selectManyShuttle and selectOrderShuttle components to create a databound shuttle.

The selectManyShuttle and selectOrderShuttle components render two list boxes and buttons that allow the user to select multiple items from the leading (or available) list box and to move or shuttle those items over to the trailing (or selected) list box, and vice versa. You can also double-click an item to move it to the other list box. Figure 35-12 shows an example of a rendered selectManyShuttle component that is implemented in the Summit ADF sample application. You can specify any text you want for the headers that display above the list boxes.

Figure 35-12 SelectManyShuttle Component



40421 Alexeyer Pro Lifting Bar
50418 Alomar Glove
20512 Black Hawk Elbow Pads
20510 Black Hawk Knee Pads
10011 Bunny Boot
50530 Cabrera Bat
50273 Chapman Helmet
30321 Grand Prix Bicycle
30421 Grand Prix Bicycle Tires
50417 Griffey Glove
30326 Himalaya Bicycle

10012 Ace Ski Boot
10022 Ace Ski Pole
10021 Bunny Ski Pole

The only difference between selectManyShuttle and selectOrderShuttle is that in the selectOrderShuttle component, the user can reorder the items in the trailing list box by using the up and down arrow buttons on the side.

The Summit ADF sample application uses a selectManyShuttle component to allow the user to select the products to order from a **All available products** list box to an **Selected Products** list box. The leading list box on the left displays all the available products. The trailing list box on the right displays the products the customer has selected.

Like other ADF Faces selection list components, the selectManyShuttle and selectOrderShuttle components can use the f:selectItems tag to provide the list of items available for display and selection in the leading list.

Before you can bind the f:selectItems tag, create a generic class that can be used by any page that requires a shuttle. In the class, declare and include getter and setter methods for the properties that describe the view object instance names that should be used for the list of all available choices (leading list or available product categories) and the list of selected choices (trailing list or assigned product categories). In the Summit ADF sample application, f:selectItems uses the binding container to retrieve the list of available products. Example 35-1 shows the ShuttleBean class that is created to manage the population and selection state of the shuttle component on the showshuttle.jsf page.

The getSelectedProducts() method returns a List that defines the items in the shuttle's trailing list. The values returned by getSelectedProducts() are a subset of the values in the leading list. Values that are in the leading list but not in getSelectedProducts() will be ignored (and will generate an error in the server log).

Note that the ShuttleBean class can call utility methods in the ADFUtils class if required. Also note that this class uses values for several properties of the base bean.

Example 35-2 shows the managed bean and managed properties configured in order-select-many-item.xml task flow for working with the shuttle component.

Example 35-1 Shuttle Bean Class

```
public class ShuttleBean {

    private List<oracle.jbo.domain.Number> _selectedProducts =
         new ArrayList<oracle.jbo.domain.Number>();

    public ShuttleBean()
    {
    }

    public void setSelectedProducts(List<oracle.jbo.domain.Number>
         _allocatedRoles) {
        this._selectedProducts = _allocatedRoles;
    }

    public List<oracle.jbo.domain.Number> getSelectedProducts() {
        return _selectedProducts;
    }

    public void onAddMultipleProducts(ActionEvent actionEvent) {
      DCBindingContainer dcBindings =

(DCBindingContainer)BindingContext.getCurrent().getCurrentBindingsEntry();
      OperationBinding createMethod =
         dcBindings.getOperationBinding("CreateInsert");
      if ( createMethod != null && _selectedProducts.size() > 0 ) {
            DCIteratorBinding iterator =
                 dcBindings.findIteratorBinding("ItemsForOrderIterator");
            for ( oracle.jbo.domain.Number productId : _selectedProducts )
            {
                createMethod.execute();
                iterator.getCurrentRow().setAttribute("ProductId", productId );
            }
        }
    }
}
```

Example 35-2 Managed Bean for the Shuttle Component in the order-select-many-items Task Flow

```
<managed-bean id="__3">
      <managed-bean-name>ShuttleBean</managed-bean-name>
      <managed-bean-class>oracle.summit.backing.ShuttleBean</managed-bean-class>
      <managed-bean-scope>backingBean</managed-bean-scope>
</managed-bean>
<view id="showshuttle">
      <page>/orders/showshuttle.jsf</page>
```

How to Create a Databound Shuttle

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a shuttle. For more information, see Creating a Databound Shuttle.

You may also find it helpful to understand functionality that can be used with selection lists. For more information, see Additional Functionality for Selection Lists and Shuttles.

You will need to complete these tasks:

1. Create the relevant iterator bindings in the page definition file. Use Example 35-3 as a guide.

   In the `Summit` ADF sample application, a list binding for `ProductId` with `ItemsForOrderIterator` is added to the `showshuttlePageDef.xml` file to provide the list of products for populating the leading list.

2. Create a class similar to the `ShuttleBean` class and provide methods to process the values as required. Use Example 35-1 as a guide.

3. Configure the required managed bean and managed properties in the task flow definition or, in the case of an unbounded task flow, the `adfc-config.xml` file. Use Example 35-2 as a guide.

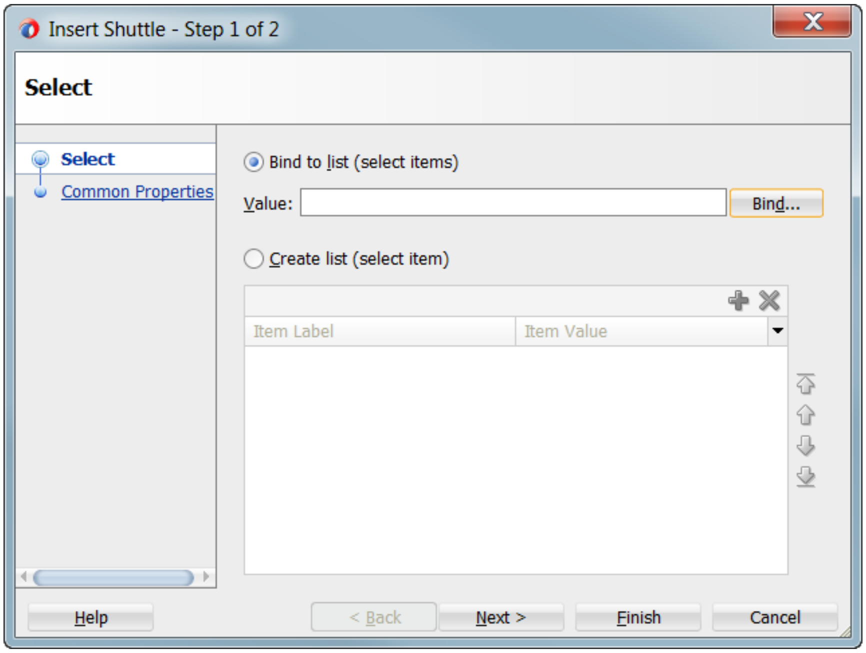
To create a shuttle component:

1. In the Applications window, double-click the web page that will display the component.

2. In the ADF Faces page of the Components window, from the Text and Selection panel, drag and drop **SelectManyShuttle** or **SelectOrderShuttle** onto the page.

   JDeveloper displays the Insert Shuttle wizard, as illustrated in Figure 35-13.

Figure 35-13   Insert SelectManyShuttle Wizard



3. Select **Bind to list (select items)** and click **Bind**.

4. In the Expression Builder, expand tree structure to create an expression that will populate the values for the leading list and click **OK.**

In the Summit ADF sample application, select **ADF Bindings > bindings > ProductId > items** to build the expression #{bindings.ProductId.items} and click **Finish**. This binds the f:selectedItem tag of the selectManyShuttle component to the data collection that populates the shuttle's leading list with a list of products.

If you decide to retrieve the values for the leading list using a method, for example, getAllProducts(), you should create this method in the managed bean. You would then bind to this method in the expression builder.

5. Click **Next**.
6. In the Common Properties page, click **Bind** next to the **Value** field.
7. In the Expression Builder, expand the tree to create an expression that will populate the values for the trailing list and click **OK**.

   In the Summit ADF sample application, select **ADF Managed Beans > BackingBeanScope > ShuttleBean > selectedProducts** to build the expression #{backingBeanScope.ShuttleBean.selectedProducts} and click **Finish**. This binds the value attribute to the selectedProducts() method that populates the shuttle's trailing list.
8. You may want to add additional controls to process the selected values.

   In the Summit ADF sample application, an af:button component labeled **Done** is added to the page to process the selected products by calling the onAddMultipleProducts method defined in the ShuttleBean.

What Happens When You Create a Databound Shuttle

All the bindings of the showshuttle.jsf page are defined in the file showshuttlePageDef.xml. Example 35-3 shows part of the page definition file for the showshuttle.jsf page.

Example 35-4 shows the code for the selectManyShuttle component after you complete the Insert SelectManyShuttle dialog.

Example 35-3 Page Definition File for the showshuttle Page

```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
 version="12.1.2.61.86" id="showshuttlePageDef" Package="orders">
  <parameters/>
  <executables>
    <variableIterator id="variables"/>
    <iterator Binds="ItemsForOrder" RangeSize="25"
              DataControl="BackOfficeAppModuleDataControl"
              id="ItemsForOrderIterator"/>
  </executables>
  <bindings>
    <list IterBinding="ItemsForOrderIterator" StaticList="false"
          Uses="LOV_ProductId" id="ProductId"
          DTSupportsMRU="true" SelectItemValueMode="ListObject"/>
    <action IterBinding="ItemsForOrderIterator" id="CreateInsert"
            RequiresUpdateModel="true" Action="createInsertRow">
    </action>
  </bindings>
</pageDefinition>
```

Example 35-4   SelectManyShuttle Component in showshuttle.jsff File

```
<af:selectManyShuttle id="sms1"
    value="#{backingBeanScope.ShuttleBean.selectedProducts}"
    leadingHeader="All available products" trailingHeader="Selected products">
    <f:selectItems value="#{bindings.ProductId.items}" id="si1"/>
</af:selectManyShuttle>
```

36
Creating ADF Databound Search Forms

This chapter describes how to create search forms from data modeled from ADF Business Components, using ADF data binding and ADF Faces components to perform complex searches on multiple attributes and search forms to search on a single attribute. For complex query search forms, it describes how to set up the query search form mode, results table, saved searches list, and personalization. For single attribute search forms, it describes how to configure the form layout. In addition, it includes information on using named bind variables and Query-by-Example (QBE) filtered table searches.
This chapter includes the following sections:

About Creating Search Forms

Oracle ADF supports a context option that helps to create a quick and effective search page. Based on different search criteria, you can either use query search forms or quick query search forms.

You can create search forms that allow users to enter search criteria into input fields for known attributes of an object. The search criteria can be entered via input text fields or selected from a list of values in a popup list picker or dropdown list box. The entered criteria is constructed into a query to be executed. **Named bind variables** can be used to supply attribute values during runtime for the query. The results of the query can be displayed as a table, a form, or another UI component.

Oracle ADF supports two types of search forms: query and quick query. The **query search form** is a full-featured search form. The **quick query search form** is a simplified form with only one search criteria. Each of these search forms can be combined with a filtered table to display the results, thereby enabling additional search capabilities. You can also create a standalone filtered table to perform searches without the query or quick query search panel.

Search forms are based either on **view criteria** defined in **view objects** or on implicit view criteria defined by JDeveloper. Search forms are region-based components that are reusable and personalizable. They encapsulate and automate many of the actions and iterator management operations required to perform a query. You can create several search forms on the same page without any need to change or create new iterators.

A **filtered table** is a table that has additional Query-by-Example (QBE) search criteria fields above each searchable column. When the filtering option of a table is enabled, you can enter QBE-style search criteria for each column to filter the query results. For more information about tables, see Creating ADF Databound Tables.

For information about individual query and table components, see the Using Query Components and the Using Tables, Trees, and Other Collection-Based Components chapters of *Developing Web User Interfaces with Oracle ADF Faces*.

Implicit and Named View Criteria

When you create data controls, all data collections will automatically include an implicit view criteria node in the **Named Criteria** node with an **All Queriable Attributes** criteria. This is the default view criteria that includes all the searchable attributes or columns of the data collection. You cannot edit or modify this implicit view criteria. Implicit view criteria can be used in the same way as declaratively created (or named) view criteria during the creation of query and quick query search forms. For more information about creating named view criteria, see Working with Named View Criteria.

When you add additional named view criteria for that view object or collection, the new view criteria will be added to the **Named Criteria** node in the Data Controls panel with the default implicit view criteria. In the Data Controls panel, a data collection's Named Criteria node will always include the implicit view criteria, regardless of whether any named view criteria were defined. The implicit view criteria is always available for every data collection.

> **Note:**
>
> Query search forms have certain restrictions for working with expressions that have nested view criteria and may not work with all types of nested expressions. For more information about the nested expressions supported by search forms, see What You May Need to Know About Nested View Criteria Expressions.

List of Values (LOV) Input Fields

List of values (LOV) components are input components that allow the user to enter values by picking from a list that is generated by a query. ADF Faces provides the `af:inputListOfValues` and `af:inputComboboxListOfValues` components. If you are using dependent LOVs as part of your search form, you must use them with the `af:query` component. For more information about LOV components, see Creating List of Values (LOV) Components.

If an attribute is defined as an LOV, you can set the **Support Multiple Value Selection** control hint in its view criteria to enable users to make multiple selections in the search criteria field. If multiple selection is enabled on an LOV attribute, and the `Equal to` or `Not equal to` operator is chosen, a `selectManyChoice` component will render in the query panel. The user can select multiple items as the search criteria.

When the LOV is in a query component, if the **Support Multiple Value Selection** hint is not set and the `Equal to` or `Not equal to` operator is chosen, the query component will render a search criteria component according to the **Default List Type** control hint for the corresponding attribute in the view object.

The quick query component does not support multiple selection. It will always render the component specified by the **Default List Type** control hint. Table 36-1 shows the control hint selection and the default list component.

Table 36-1 Query and Quick Query Search Criteria Field Input Components

Default List Type Control Hint	Component
Input Text with List of Values	`af:inputListOfValues`
Combo Box with List of Values	`af:inputComboboxListOfValues`
Choice List, Combo Box, List Box, Radio Group	`af:selectOneChoice`

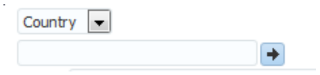
For more information about view criteria options, see How to Create Named View Criteria Declaratively, and What You May Need to Know About Bind Variables in View Criteria.

Search Form Use Cases and Examples

The search forms are based on the model-driven `af:query` and `af:quickQuery` components. Because these underlying components are model-driven, the search form will change automatically to reflect changes in the model. The view layer does not need to be changed. For example, if you define a list of values (LOV) on an attribute in the view object or entity object, the LOV will automatically show up in the search form as an LOV component. Or, if you modify a view criteria to include a new attribute for the `WHERE` clause, the search panel using this view criteria will automatically reflect that change by adding a search field for that attribute.

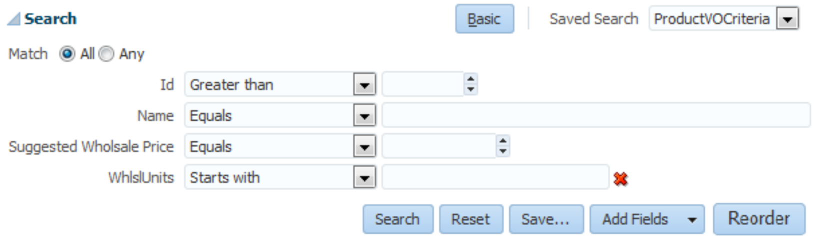
Figure 36-1 shows a quick query component.

Figure 36-1 Quick Query



For more complex searches, such as including criteria for product name, price ranges, and availability, a query component is used. You can create the query component in several different modes to give the user different capabilities, as shown in Figure 36-2. The user can even add their own search criteria using the **Add Fields** button. The user can save the searches that were created to be used later.

Figure 36-2 Query Component



Saved Search ProductVOCriteria

Match ● All ○ Any

Id Greater than

Name Equals

15	Dumas	Andre

Additional Functionality for Search Forms

You may find it helpful to understand other ADF features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- Both the query and quick query components are based on the view criteria defined in a view object. You use the view criteria to set up the initial search fields and search criteria. You use control hints to further define the query component. For information about creating named view criteria, see Working with Named View Criteria.
- Since filtered tables also provide search functions, you should consider them for simple searches. For information about tables, see Creating ADF Databound Tables.
- List of value components use the query component in their search panel for creating the list of values selection list. For information about LOV components, see Creating List of Values (LOV) Components.
- If your application is set up with a Metadata Storage (MDS), you can persist saved searches across transactions and personalize your searches. Apart from column order and column display, you can save the sort order of the results layout. The sort order is saved as part of a Saved Search. You can restore the saved search including the sort order of the results layout by re-invoking this Saved Search entry. This means that apart from display index and visible properties of the column, the sort order property is also saved as part of the saved layout. For information about using MDS, see Customizing Applications with MDS.

Creating Query Search Forms

Query search form is a full-featured search form that is based on a view criteria defined in ADF Business Components view object. You can use different methods to create query search forms with binding variables.

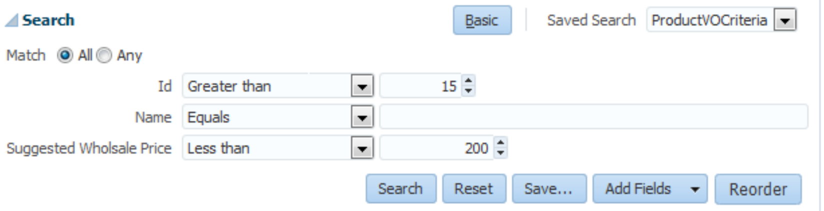
The query search form is the standard form for complex transactional searches. You can build complex search forms with multiple search criteria fields each with a dropdown list of built-in operators. You can also add custom operators and customize the list. The query search form supports lists of values, `AND` and `OR` conjunctions, and saving searches for future use.

A query is associated with the view object that it uses for its query operation. In particular, a query component is the visual representation of the view criteria defined for that view object. For information on creating view criteria, see Working with Named View Criteria. The view criteria items defined in the view criteria is the source for the search criteria in the search panel of the query component. The **Rendered Mode** option in the view criteria editor controls the search criteria will be displayed.

Search criteria can be grouped together to provide a logical grouping of attributes. For instance, you can group the address attributes together.

A query search form has a basic mode and an advanced mode. The user can toggle between the two modes using the basic/advanced button. At design time, you can declaratively specify form properties (such as setting the default state) to be either basic or advanced. Figure 36-4 shows an advanced mode query search form with three search criteria.

Figure 36-4 Advanced Mode Query Search Form



Saved Search: ProductVOCriteria

Match ● All ○ Any

Id: Greater than 15

Name: Equals

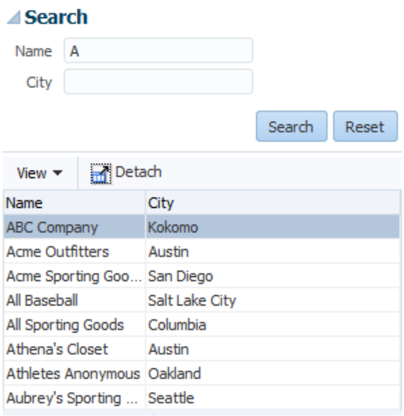
Suggested Wholsale Price: Less than 200

The advanced mode query form features are:

- Selecting search criteria operators from a dropdown list
- Adding custom operators and deleting standard operators
- Selecting `WHERE` clause conjunctions of either `AND` or `OR` (match all or match any)
- Dynamically adding and removing search criteria fields at runtime
- Saving searches for future use
- Personalizing saved searches

Typically, the query search form in either mode is used with an associated results table or tree table. In the Summit sample application for Oracle ADF, the query panel and results table is shown in Figure 36-5.

Figure 36-5   Results Table for a Query Search

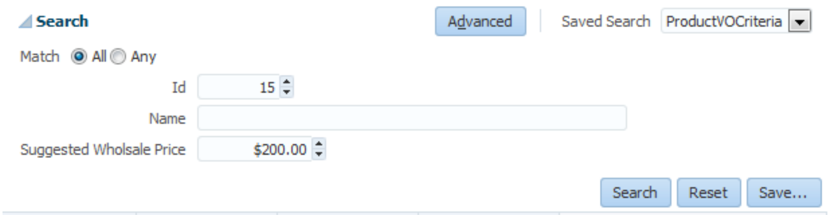


Name: A
City:

Name	City
ABC Company	Kokomo
Acme Outfitters	Austin
Acme Sporting Goo...	San Diego
All Baseball	Salt Lake City
All Sporting Goods	Columbia
Athena's Closet	Austin
Athletes Anonymous	Oakland
Aubrey's Sporting ...	Seattle

The basic mode has all the features of the advanced mode except that it does not allow the user to dynamically add search criteria fields. Figure 36-6 shows a basic mode query search form with three search criteria field. Notice the lack of a dropdown list next to the **Save** button used to add search criteria fields in the advanced mode.

Figure 36-6   Basic Mode Query Form with Three Search Criteria Field



Saved Search: ProductVOCriteria
Match ● All ○ Any
Id: 15
Name:
Suggested Wholsale Price: $200.00

In either mode, each search criteria field can be modified by selecting operators such as `Greater Than` and `Equal To` from a dropdown list, and the entire search panel can be modified by the **Match All/Any** radio buttons. Partial page rendering is also supported by the search forms in almost all situations. For example, if a `Between` operator is chosen, another input field will be displayed to allow the user to select the upper range.

A `Match All` selection implicitly uses `AND` conjunctions between the search criteria in the `WHERE` clause of the query. A `Match Any` selection implicitly uses `OR` conjunctions in the `WHERE` clause. Here is a simplified `WHERE` clause (the real `WHERE` in the view criteria is different) when `Match All` is selected for the search criteria shown in Figure 36-4:

```
WHERE (Id < 4) AND (InStock > 20) AND (Name="Shoes")
```

This is a simplified `WHERE` clause if **Match Any** is selected for the search criteria shown in Figure 36-4.

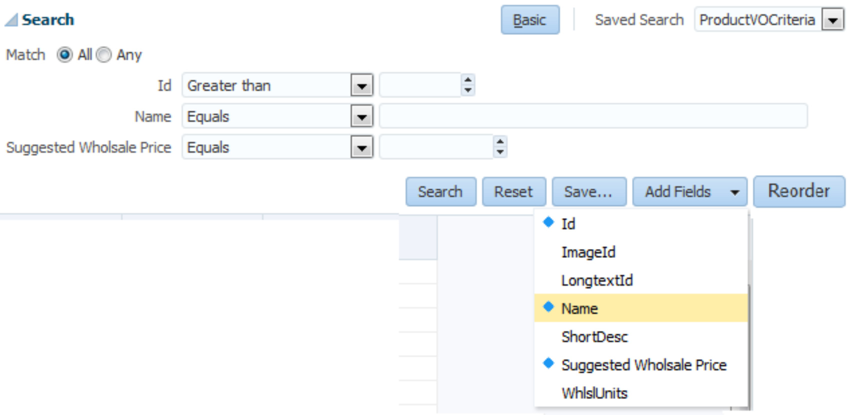
```
WHERE (Id < 4) OR (InStock > 20) OR (Name="Shoes")
```

If the view criteria for the query has mixed `AND` and `OR` conjunctions between the criteria items, then neither **Match All** nor **Match Any** will be selected when the component first renders. However, the user can select **Match All** or **Match Any** to override the conjunctions defined as the initial state in the view criteria.

Advanced mode query forms allow users to dynamically add search criteria fields to the query panel to perform more complicated queries. These user-created search criteria fields can be deleted, but the user cannot delete existing fields. You use the **Add Fields** dropdown list to add a search criteria field or all the fields within the group.

Figure 36-7 shows a query search form and how the **Add Fields** dropdown list is selected to add a criteria field to the search form.

Figure 36-7   Dynamically Adding Search Criteria Fields at Runtime



Saved Search: ProductVOCriteria

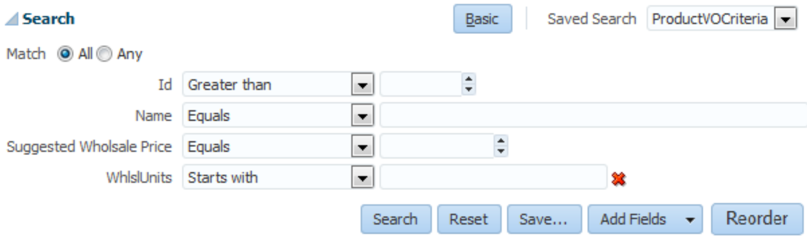
Name: Equals

Suggested Wholsale Price: Equals

Figure 36-8 shows a query search form with a new user-added search criteria with the delete icon to its right. Users can click the delete icon to remove the criteria.

Figure 36-8   User-Added Search Criteria with Delete Icon



Saved Search: ProductVOCriteria

Match ● All ○ Any

Id: Greater than

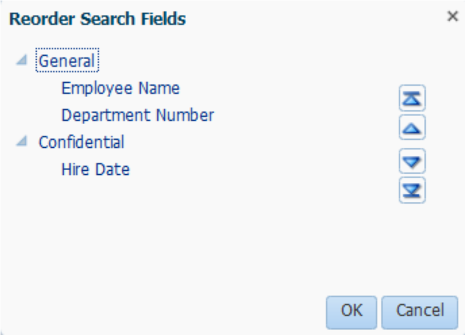
Name: Equals

Suggested Wholsale Price: Equals

WhlslUnits: Starts with ✖

You can use the **Reorder** button to open the Reorder Search Fields dialog to reorder the search fields in the search panel, as shown in Figure 36-9.

Figure 36-9 Reorder Search Fields dialog

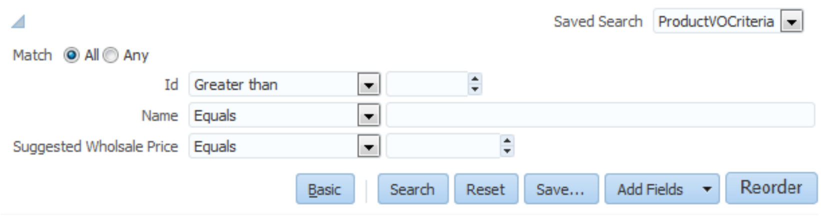


If either **Match All** or **Match Any** is selected and then the user dynamically adds the second instance of a search criterion, then both **Match All** and **Match Any** will be deselected. The user must reselect either **Match All** or **Match Any** before clicking the **Search** button.

If you intend for a query search form to have both a basic and an advanced mode, you can define each search criteria field to appear only for basic, only for advanced, or for both. When the user switches from one mode to the other, only the search criteria fields defined for that mode will appear. For example, suppose three search fields for basic mode (A, B, C) and three search fields for advanced mode (A, B, D) are defined for a query. When the query search form is in basic mode, search criteria fields A, B, and C will appear. When it is in advanced mode, then fields A, B, and D will appear. Any search data that was entered into the search fields will also be preserved when the form returns to that mode. If the user entered 35 into search field C in basic mode, switched to advanced mode, and then switched back to basic, field C would reappear with value 35.

Along with using the basic or advanced mode, you can also determine how much of the search form will display. The default setting displays the whole form. You can also configure the query component to display in compact mode or simple mode. The compact mode has no header or border, and the **Saved Search** dropdown lists moves next to the expand/collapse icon. Also, the **Basic** button has been moved to the bottom of the form and the Search label is omitted. Figure 36-10 shows a query search form set to compact mode.

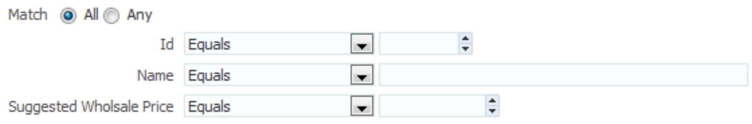
Figure 36-10 Query Component in Compact Mode



Saved Search ProductVOCriteria
Match ● All ○ Any
Id Greater than
Name Equals
Suggested Wholsale Price Equals

The simple mode displays the component without the header and footer, and without the buttons normally displayed in those areas. Figure 36-11 shows the same query search form set to simple mode.

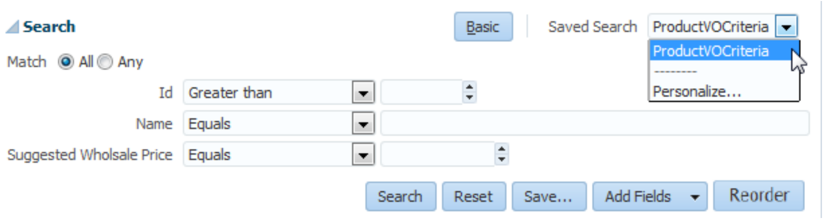
Figure 36-11 Query Component in Simple Mode



If there are multiple view criteria defined, each can be selected from the **Saved Search** dropdown list. These saved searches are created at design time and are called **system searches**. For example, if you have defined two view criteria in the view object, both view criteria are available for selection in the query search form Saved Search dropdown list, as shown in Figure 36-12.

> **Note:**
>
> Be aware that opening and closing the query panel by clicking the panel expansion/collapse icon does not reset the applied view criteria. You can click the **Reset** button to reset the applied view criteria.

Figure 36-12 Query Form Saved Search Dropdown List



If there are no explicitly defined view criteria for a view object, you can use the default implicit view criteria.

Users can also create saved searches at runtime to save the state of a search for future use. Apart from display index and visible properties of the column, the sort order property is also saved as part of the saved layout. In other words, apart from column order and column display, the sort order of each column is saved as part of a saved search. This means that the user can sort any column on the results table layout in ascending or descending order and subsequently save the sorted layout of the results table as part of the saved search. When the user invokes this saved search again, the sorted layout of the results table displays. If no sort order is specified on any columns on the layout of the results table of a query search, and the user saves the search as a Saved Search, the sort order of the layout of the results table that is saved, is the sort order specified in the view object. The entered search criteria values, the basic/advanced mode state, and the layout of the results table/ component can be saved by clicking the **Save** button to open a Save Search dialog, as shown in Figure 36-13. Saved searches appear in alphabetical order in the **Saved Search** dropdown list. User-created saved searches persist for the session. If they are intended to be available beyond the session, you must configure a persistent data store to store them. For Oracle ADF, you can use an access-controlled data source such as MDS. For more information about using MDS, see Customizing Applications with MDS .

When you perform a saved search, you can specify whether the layout of the results component is also saved. Creating saved searches and saving the results components layout require that MDS is configured. If you set the query component's `saveResultsLayout` attribute to `always`, the results component layout will be saved. If `saveResultsLayout` is set to `never`, the layout is not saved.

```
<context-param>
   <description>Saving results layout</description>
       <param-name>oracle.adf.view.rich.query.SAVE_RESULTS_LAYOUT</param-name>
   <param-value>true</param-value>
</context-param>
```

If `saveResultsLayout` is not defined, saving layout defaults to the application-level property `oracle.adf.view.rich.query.SAVE_RESULTS_LAYOUT` in the `web.xml` file. The default value of `oracle.adf.view.rich.query.SAVE_RESULTS_LAYOUT` is `true`.

If the user made changes to the layout of a saved search and proceeds without saving, a warning message appears to remind the user to save, otherwise the changes will be lost. In addition, if the user adds or deletes search fields and proceeds without saving, a warning message also appears.

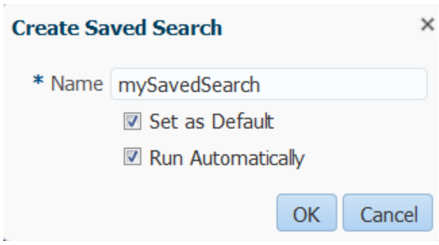
Table 36-2 shows the `saveResultsLayout` and `SAVE_RESULTS_LAYOUT` values and their resultant action. Note that MDS must be configured to save layout.

Table 36-2 Save Results Component Layout Attributes

web.xml SAVE_RESULT_LAYOUT	Query Component saveResultsLayout	Resultant action
true	always	Saves layout
true	never	Not saved
true	not defined	Saves layout
false	always	Saves layout
false	never	Not saved
false	not defined	Not saved

Figure 36-13 shows the Create Saved Search dialog with an entry field for the name of the saved search and checkbox selections for **Set as Default** and **Run Automatically**.

Figure 36-13 Runtime Saved Search Dialog Window



Create Saved Search

* Name: mySavedSearch

☑ Set as Default

☑ Run Automatically

Table 36-1 lists the possible scenarios for creators of saved searches, the method of their creation, and their availability.

Table 36-3 Design Time and Runtime Saved Searches

Creator	Created at Design time as View Criteria	Created at Runtime with the Save Button
Developer	Developer-created saved searches (system searches) are created during application development and typically are a part of the software release. They are created at design time as view criteria. They are usually available to all users of the application and appear in the lower part of the **Saved Search** dropdown list.	
Administrator		Administrator-created saved searches are created during predeployment by site administrators. They are created before the site is made available to the general end users. Administrators can create saved searches (or view criteria) using the JDeveloper design time when they are logged in with the appropriate role. These saved searches (or view criteria) appear in the lower part of the **Saved Search** dropdown list.
End User		End-user saved searches are created at runtime using the query form **Save** button. They are available only to the user who created them. End-user saved searches appear in the top part of the **Saved Search** dropdown list.

You can use the **runQueryAutomatically** property as listed in the Property Inspector to specify whether a saved search will run the query automatically. Setting the property to **allSavedSearches** means all system and user-created saved searches will run automatically when the query component is initially loaded, whenever the saved search has changed, or the reset button is pressed. If you set the **runQueryAutomatically** property to **searchDependent**, you can specify at design time whether that specific query will run automatically. **searchDependent** is the default value.

For new user-created saved searches with **runQueryAutomatically** property set to **searchDependent**, the Create Saved Search dialog, as shown in Figure 36-13, will have the **Run Automatically** option set as the default. For new user-created saved searches with **runQueryAutomatically** property set to **allSavedSearches**, the Create Saved Search dialog will not display the **Run Automatically** option, but it will be set implicitly.

End users can manage their saved searches by using the Personalize function in the **Saved Search** dropdown list to bring up the Personalize Saved Searches dialog, as shown in Figure 36-14.

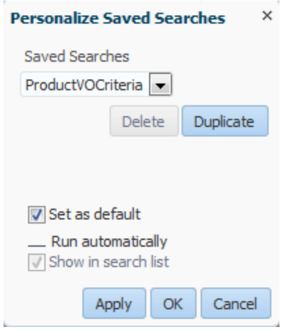
End users can use the Personalize function to:

- Update a saved search.

  Users can add and/or remove search criterion, update operators, update values, modify conjunctions and save it using the existing saved search name (to override an existing saved search).
- Delete a saved search (including the currently active Saved Search)

  Users can delete the default saved search, in which case the next USER level saved search will become the default.
- Duplicate an existing saved search
- Set a saved search as the default
- Set a saved search to run automatically
- Set the saved search to show or hide from the **Saved Search** dropdown list

Figure 36-14 Personalize Saved Searches Dialog



Personalize Saved Searches

Saved Searches: ProductVOCriteria

☑ Set as default
Run automatically
☑ Show in search list

> **Note:**
>
> If in you are changing the value of a view criteria item programmatically, you must invoke the `ViewCriteria.saveState()` method to prevent the searchRegion binding from resetting the value of the view criteria item to the value that was specified at design time.

You create a query search form by dropping a named view criteria item from the Data Controls panel onto a page. You have a choice of dropping only a search panel, dropping a search panel with a results table, or dropping a search panel with a tree table.

If you choose to drop the search panel with a table, you can select the filtering option in the dialog to turn the table into a filtered table.

Typically, you would drop a query search panel with the results table or tree table. JDeveloper will automatically create and associate a results table or tree table with the query panel.

If you drop a query panel by itself and want a results component or if you already have an existing component for displaying the results, you will need to match the query panel's `ResultsComponentId` with the results component's `Id`.

> **Note:**
>
> When you drop a named view criteria onto a page, that view criteria will be the basis for the initial search form. All other view criteria defined against that data collection will also appear in the **Saved Search** dropdown list. Users can then select any of the view criteria search forms, and also any end-user created saved searches.

How to Create a Query Search Form with a Results Table or Tree Table

You create a search form by dragging and dropping a view criteria from the Data Controls panel onto the page. You have the option of having a results table or only the query panel.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Creating Query Search Forms.

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Additional Functionality for Search Forms.

You will need to complete these tasks:

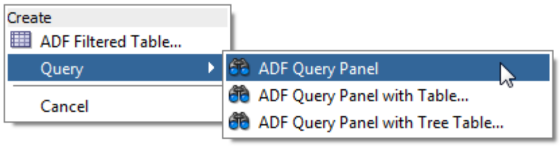
1. Create a view object. For more information about view objects, see Populating View Object Rows from a Single Database Table, and Working with Multiple Tables in Join Query Results.
2. Create view criteria if you intend to create search forms based on view criteria. You can also use the default implicit view criteria, which would include all queriable attributes in the collection. For more information about view criteria, see Working with Named View Criteria.
3. Set the search form default properties. For more information about setting the default state of the search form, see How to Set Search Form Properties on the View Criteria. For information on how to create view criteria, see Working with Named View Criteria.

To create a query search form with a results table or tree table:

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the named view criteria item and drop it onto the page or onto the Structure window.

3. From the context menu, choose **Create > Query > ADF Query Panel with Table** or **Create > Query > ADF Query Panel with Tree Table**, as shown in Figure 36-15.

Figure 36-15 Data Controls Panel with Query Context Menu



Create
ADF Filtered Table...
Query
Cancel
ADF Query Panel
ADF Query Panel with Table...
ADF Query Panel with Tree Table...

4. In the Edit Table Columns dialog, you can rearrange any column and select table options. If you choose the filtering option, the table will be a filtered table.

After you have created the form, you may want to set some of its properties or add custom functions. For more information on how to do this, see Setting Up Search Form Properties.

How to Create a Query Search Form and Add a Results Component Later

You create a search form by dragging and dropping a view criteria from the Data Controls panel onto the page. You have the option of having a results table or only the query panel.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Creating Query Search Forms.

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Additional Functionality for Search Forms.

You will need to complete these tasks:

1. Create a view object.
2. Create view criteria if you intend to create search forms based on view criteria. You can also use the default implicit view criteria, which would include all queriable attributes in the collection.
3. Set the search form default properties. For more information about setting the default state of the search form, see How to Set Search Form Properties on the View Criteria. For information on how to create view criteria, see Working with Named View Criteria.

To create a query search form and add a results component in a separate step:

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the named view criteria item and drop it onto the page or onto the Structure window.
3. From the context menu, choose **Create > Query > ADF Query Panel**, as shown in Figure 36-15.

4. If you do not already have a results component, then drop the data collection associated with the view criteria as a component.
5. In the Properties window for the table, copy the value of the **Id** field.
6. In the Properties window for the query panel, paste the value of the table's ID into the query's **ResultsComponentId** field.

After you have created the search form, you may want to set some of its properties or add custom functions. See Setting Up Search Form Properties, for more information.

How to Persist Saved Searches into MDS

If you want saved searches to be persisted to MDS, you need to define the `/persdef` namespace in the `adf-config.xml` file. In addition, you need to perform the regular MDS configuration, such as specifying `metadatapath`. The following example shows an `adf-config.xml` file with the `/persdef` namespace defined.

```
<persistence-config>
   <metadata-namespaces>
        <namespace path="/persdef" metadata-store-usage="mdsstore"/>
   </metadata-namespaces>
   <metadata-store-usages>
        <metadata-store-usage id="mdsstore" deploy-target="true"
                 default-cust-store="true">
        </metadata-store-usage>
   </metadata-store-usages>
</persistence-config>
```

In order for the added saved searches to be available the next time the user logs in, `cust-config` needs to be defined as part of the MDS configuration. For more information about setting `cust-config` and MDS, see How to Create Customization Classes.

If you are also saving the layout of the results component, the application must have the ADF PageFlow Runtime and ADF Controller Runtime libraries installed. Set the project's technology scope to include **ADF Page Flow** or automatically include these libraries by using the ADF Fusion Web Application application template.

What You May Need to Know About Named Bind Variables in Search Forms

Instead of specifying a literal operand in a view criteria to be used in a search form, you have the option of specifying a named bind variable. The named bind variable performs like a parameter whose value can change at runtime without the need to change the SQL statement. It must be defined in the view object before it can be used in a view criteria.

If you specify a literal operand in the view criteria and leave the value blank, it will not appear in the SQL preview. When the view criteria is applied as a search form at runtime, that attribute is rendered as a blank input search field. If a value is specified for the literal operand, then the SQL preview will generate a SQL clause for it. When the view criteria is applied as a search form at runtime, the SQL statement is not automatically applied even though the value specified in the view criteria appears in the input search field. The SQL statement won't get applied until the user clicks **Search** (or when auto-execute is set to true).

If a named bind variable is used in the query defined in the view criteria, the SQL preview will display the WHERE clause with the bind variable. When the view criteria is applied as a search form at runtime, the bind variable will be rendered with a prompt and an input search field based on the name of the attribute (not on the name of the bind variable). The named bind variable input field may be NULL, it may contain the default value, or it may contain a value that has loaded from previous processing, such as from another page. The user can enter values for the named bind variable as in any other search criteria. When the search is executed, the value of the named bind variable will be evaluated with the other criteria, as defined by the SQL query statement.

> **Note:**
>
> To avoid the possibility of SQL injection for search forms with literal values, you can force all input search fields to use bind variables by setting the useBindVarsForViewCriteriaLiterals property to true in the adf-config.xml file. The default value is true. When set to true, each input search field in the application will display the default value defined by the literal operand based on the query component's associated view criteria.
>
> For more information about the adf-config.xml file, see adf-config.xml.
>
> You can also use the overview editor to edit this property. In the overview editor for adf-config.xml, click the **Model** tab and check or uncheck the **Use Bind Variable for ViewCriteria literals** checkbox.

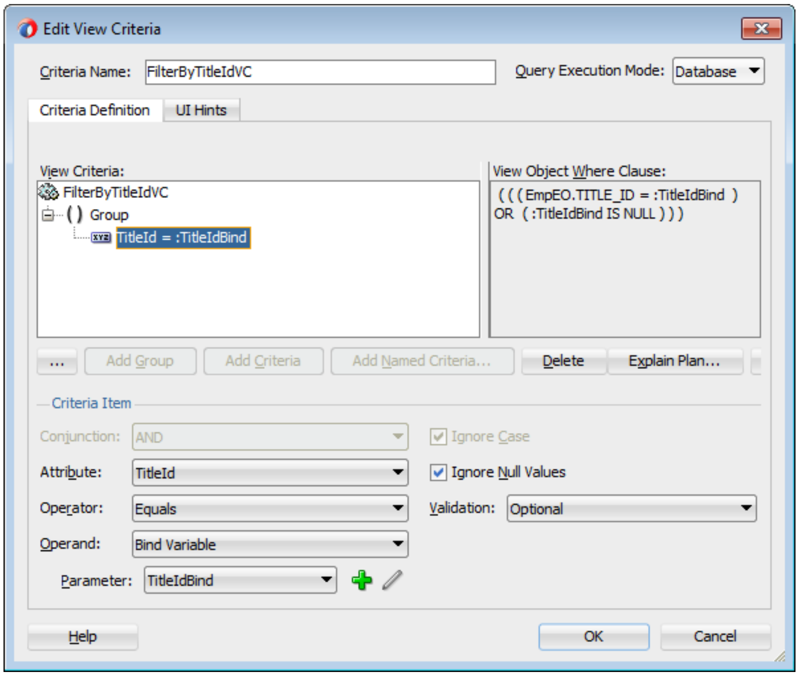
If the bind variable is used more than once in the same view criteria, each occurrence of the bind variable will be rendered as an individual input field. Because there is only one bind variable backing all the input fields, the value of all the fields will be synchronized. For instance, if you specify a view criteria that uses the same bind variable three times, then three input fields will be rendered. When the user enters a value into one input field, the other two input fields will have the same value. Using bind variables in this way eliminates the need for the user to enter the same value multiple times.

Another use of the bind variable is to pass a value from the base row into a search for an LOV search form.

Bind variables can also be used to pass parameter values from one page to another, such as when a customer ID is passed to another page for more detail processing. And, depending on the construct of the SQL statement, using the named bind variable may speed up the query because it may lessen the need to prepare a new statement, which means that the database does not need to reparse. For more information about creating and using named bind variables, see Working with Bind Variables.

For example, in the listCustomerAddresses view criteria, the WHERE clause checks to see whether the AssociatedOwnerId is the same as the value of the paramCustomerId named bind variable. This view criteria is in the AddressesLookupVO view object. The listCustomerAddresses view criteria as defined in the Edit View Criteria dialog is shown in Figure 36-16.

Figure 36-16 View Criteria with Named Bind Variable



Criteria Name: FilterByTitleIdVC

Query Execution Mode: Database

View Criteria:
FilterByTitleIdVC
( ) Group
TitleId = :TitleIdBind

View Object Where Clause:
(((EmpEO.TITLE_ID = :TitleIdBind)
OR (:TitleIdBind IS NULL)))

Conjunction: AND

☑ Ignore Case

Attribute: TitleId

☑ Ignore Null Values

Operator: Equals

Validation: Optional

Operand: Bind Variable

Parameter: TitleIdBind

A query search form for a view criteria with a named bind variable will render with a search field for the variable using the `inputText` component. Figure 36-17 shows the **AssociatedOwnerId** search field displayed as an `inputText` component.

What You May Need to Know about Default Search Binding Behavior

A **search binding** provides the model-driven behavior for a search form at runtime. The search binding is related to a particular iterator and the view criteria on that iterator, whose runtime defaults are specified by the Binds and Criteria properties of the search binding, respectively. The behavior of the search binding depends on the **Query Automatically** control hint. For more information about creating named view criteria, see Working with Named View Criteria.

The first time a search form is rendered in a task flow, the search binding's runtime behavior, also known as the initial AutoQuery-or-ClearRowSet behavior, is as follows:

- If **Query Automatically** is set to `true`: The search binding automatically executes the iterator when the search binding is initialized in a task flow. The user will be presented with the results of the search based on the view criteria.
- If **Query Automatically** is set to `false`: The search binding clears the row set related to its iterator. The user will be presented with an empty search results component, which allows the user to enter search criteria and click the **Search** button to execute the search.

The **Query Automatically** control hint is available declaratively only for named view criteria. For the All Queriable Attributes view criteria, you can use the `setProperty()` method on the view criteria API interface to configure the hint at runtime. You can also use this method to set the hint on named view criteria. In the method, set the `ViewCriteriaHints.CRITERIA_AUTO_EXECUTE` property to `true`.

If the user changes the search form by selecting a different view criteria from the dropdown **Saved Search** list, the runtime behavior is as follows:

- If **Query Automatically** is set to `true`: The search binding automatically executes the iterator after applying the new view criteria. The user will be presented with the results of the newly selected saved search.
- If **Query Automatically** is set to `false`: The search binding applies the new view criteria only, leaving any existing search results intact. The user is presented with the results of the previous search.

The search binding's `queryPerformed` property evaluates to `true` if the search binding has performed the query, either automatically or by the user clicking the **Search** button. Clicking the **Reset** button in the search form resets the view criteria and sets the `queryPerformed` property to `false`.

The search binding offers two properties that allow you to customize its default behavior: `TrackQueryPerformed` and `InitialQueryOverridden`. You can set the `TrackQueryPerformed` and the `InitialQueryOverridden` properties in the Properties window.

A search binding's `TrackQueryPerformed` property controls whether it manages its `queryPerformed` property during runtime at the page flow level or at the individual page or page fragment level. The valid values for `TrackQueryPerformed` are `pageFlow` and `page`, and the default is `pageFlow`. The search binding's behavior is as follows:

- If `TrackQueryPerformed` is set to `pageFlow`, then `queryPerformed` is initialized once per page flow and tracked at the page flow level. The user can navigate away from the search form page, return to the page within the life of the page flow, and the value of the `queryPerformed` flag will remain the same.
- If `TrackQueryPerformed` is set to `page`, then `queryPerformed` is initialized each time the user navigates to the page or page fragment. This happens when the page is navigated to for the first time and when the page is returned from another page within the page flow.

When `TrackQueryPerformed` of a search binding is set to `pageFlow`, its initial AutoQuery-or-ClearRowSet behavior is performed once during the page flow. In contrast, when `TrackQueryPerformed` is set to `page`, the initial AutoQuery-or-ClearRowSet behavior is performed each time the user visits the page or page fragment.

A search binding's `InitialQueryOverridden` property controls whether it should suppress its initial AutoQuery-or-ClearRowSet behavior the first time the search binding is used in a page flow. If `InitialQueryOverridden` is `true`, then all valid values, including `true`, `false`, or a boolean-valued EL expression, are suppressed. The default value is `false`.

When you set the `InitialQueryOverridden` property to `true`, you are responsible for writing custom application logic to execute the query. Typically, the query should execute after the code applies some view criteria, sets some bind variables, or performs some other programmatic query setup. If your custom code fails to execute the query as expected with `InitialQueryOverridden` set to `true`, unless **Query Automatically** is set to `false`, the framework will still implicitly execute your query the first time during a user session in which there is an iterator binding reference. This occurs because when **Query Automatically** is not set to `false`, the iterator binding's default `executeQueryIfNeeded` behavior takes effect and executes the query.

When `InitialQueryOverridden` evaluates to `true` or boolean `true`, then the initial AutoQuery-or-ClearRowSet behavior is suppressed the first time the search binding is used in a page flow. If `TrackQueryPerformed` is set to `pageFlow`, then only the initial AutoQuery-or-ClearRowsSet behavior (that would have occurred for this search binding) is suppressed.

In contrast, if a search binding's `TrackQueryPerformed` property is set to `page`, then only the initial AutoQuery-or-ClearRowSet behavior is suppressed. Subsequent initial AutoQuery-or-ClearRowSet behaviors that occur due to the user's navigating back to the same page (or page fragment) are not affected by the `InitialQueryOverridden` property.

If you want to avoid the search binding's performing any initial AutoQuery-or-ClearRowSet behavior, then leave the `TrackQueryPerformed` set to `pageFlow` and set `InitialQueryOverridden` to `true`.

You should not use the `RefreshCondition` property of an iterator to reference the `queryPerformed` property of a search binding. Doing so will inadvertently prevent new rows from being created in that iterator's row set until after the search binding's query has been performed.

What You May Need to Know About Dependent Criterion

There are situations when one search criteria is dependent on the value of another criteria. For example, a bug database has a search form with a `Component` and a `Subomponent` search criteria, both defined as LOVs. When the user selects a value from the Component search criteria, that value must be submitted to the model so that `Subomponent` can be filtered and populated with the appropriate search list for the user to choose from.

If you have a search criteria that has dependents, you must set the root and dependent criteria's underlying view attribute's **Auto Submit** control hint to `true`. You can create a custom listener to trigger a partial submit to update the model and refresh the search panel when the query component detects a value change for the root criteria. You need to create a custom listener because the standard `QueryOperationListener` does not handle this event type. You can create a custom `QueryOperationListener` class using the `QueryOperationListener` interface. You then register this class by implementing it in a managed bean or by directly setting it in the JSF page.

What Happens When You Create a Query Form

When you drop a query search form onto a page, JDeveloper creates an `af:query` tag on the page. If you drop a query with table or tree table, then an `af:table` tag or `af:treeTable` tag will follow the `af:query` tag.

Under the `af:query` tag are several attributes that define the query properties. They include:

- The `id` attribute, which uniquely identifies the query.
- The `resultsComponentId` attribute, which identifies the component that will display the results of the query. Typically, this will be the table or tree table that was dropped onto the page together with the query. You can change this value to be the `id` of a different results component. For more information, see How to Create a Query Search Form and Add a Results Component Later.

In the page definition file, JDeveloper creates an iterator and a `searchRegion` entry in the `executables` section. The following example shows the sample code for a page definition file that was created when the `CustomerViewCriteria` from the `Customers` collection of the `BackOfficeAppModuleDataControl` is dropped onto the page.

In the page definition file `executable` section:

- The iterator `binds` property is set to the name of the data collection. In the example, the value is set to `Customers.`
- The iterator `id` property is set to a data collection iterator. In the example, the value is set to `CustomersIterator`
- If there is more than one view criteria defined for that data collection, the `searchRegion Criteria` property is set to the name of the view criteria that was dropped. In the example, the value is set to `CustomerViewCriteria`. If there is only one view criteria defined, then there will not be a `Criteria` property.
- The `searchRegion Binds` property is set to the same value as the `iterator id` property. In the example, the value is set to `CustomersIterator`
- The `searchRegion id` property is set to the name of the view criteria concatenated with `Query`. In the example, the value is set to `CustomerViewCriteria.`

If the query was dropped onto the page with a table or tree, then in the page definition file `bindings` section, a tree element is added with the `Iterbinding` property set to the search iterator. In this example, the value is set to `CustomersIterator`. This should be the same iterator defined in the `executable` section.

```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
version="12.1.2.66.41" id="searchPageDef"
                Package="oracle.summit.view.pageDefs">
 <parameters/>
 <executables>
    <variableIterator id="variables"/>
    <iterator Binds="Customers" RangeSize="25"
          DataControl="BackOfficeAppModuleDataControl" id="CustomersIterator"/>
          <searchRegion Criteria="CustomerViewCriteria"
                Customizer="oracle.jbo.uicli.binding.JUSearchBindingCustomizer"
                Binds="CustomersIterator" id="CustomerViewCriteriaQuery"/>
 </executables>
 <bindings>
    <tree IterBinding="CustomersIterator" id="Customers">
      <nodeDefinition DefName="oracle.summit.model.views.CustomerVO"
           Name="Customers0">
        <AttrNames>
          <Item Value="Id"/>
          <Item Value="Name"/>
          <Item Value="City"/>
          <Item Value="State"/>
          <Item Value="CountryId"/>
          <Item Value="LastName"/>
        </AttrNames>
      </nodeDefinition>
    </tree>
  </bindings>
</pageDefinition>
```

What Happens at Runtime: Search Forms

At runtime, the search form displays as a search panel on the page. The search panel will display in either basic mode or advanced mode, depending on the mode control hint when its corresponding view criteria was created. The **Saved Search** dropdown list will contain all the view criteria that are enabled (**Show in List** control hint enabled). The **Match All/Any** conjunction radio button may be enabled.

A search criteria field will be rendered for each search criteria defined in the view criteria. If the **Default List Type** control hint in the view object has been declared as an LOV or a selection list component, the search criteria field component is as shown in Table 36-1.

After the user enters the search criteria and clicks **Search**, a query against the view criteria is executed and the results are displayed in the associated table, tree table, or component.

When the users changes the mode of the query component from advanced to basic, the operators displayed by the query component may change depending upon how you have configured the view criteria control hint **Show Operators** and depending on whether the view criteria is a predefined, named view criteria or the automatically defined implicit criteria. In the case of named view criteria, the query component will only preserve the user's selection between modes when you set **Show Operators** to **Always** to allow the full list of operators in both modes. However, if you set **Show Operators** to **In Advanced Mode** to only show the full list of operators in advanced mode, then after the user makes their selections and switches to basic mode, the operators will default to the ones defined by the view criteria and for this reason the user's selections may appear to change. In the case of an implicit view criteria, because the implicit criteria does not have predefined operators, the query component retains the operators selected by the user when user switches between advanced mode and basic mode.

Setting Up Search Form Properties

For a query search form in Oracle ADF, you can set search form properties on view criteria or on the query component. You can set the properties either during the creation of view criteria or after you have dropped the query search form onto a page.

A query search form is based on a view criteria defined in a view object. When you create the view criteria, you also specify some of the search form properties. Later on, when you drop the named criteria onto the page to create a query component, you can specify other search form properties.

Search form properties that can be set on the view object include grouping related and dependent fields together in the query panel. For information on setting hints in the view object, see How to Define UI Category Hints.

Search form properties that can be set when the view criteria is being created include:

- Default mode in basic or advanced mode
- Automatic query execution when the page loads
- Rendering of the search criteria field
- Enabling multiple selections for attributes defined as an LOV

Search form properties that can be set after the query component has been added to the JSF page include:

- `id` of the results table or results component
- Show or hide of the basic/advanced button
- Position of the mode button
- Default, simple, or compact mode for display

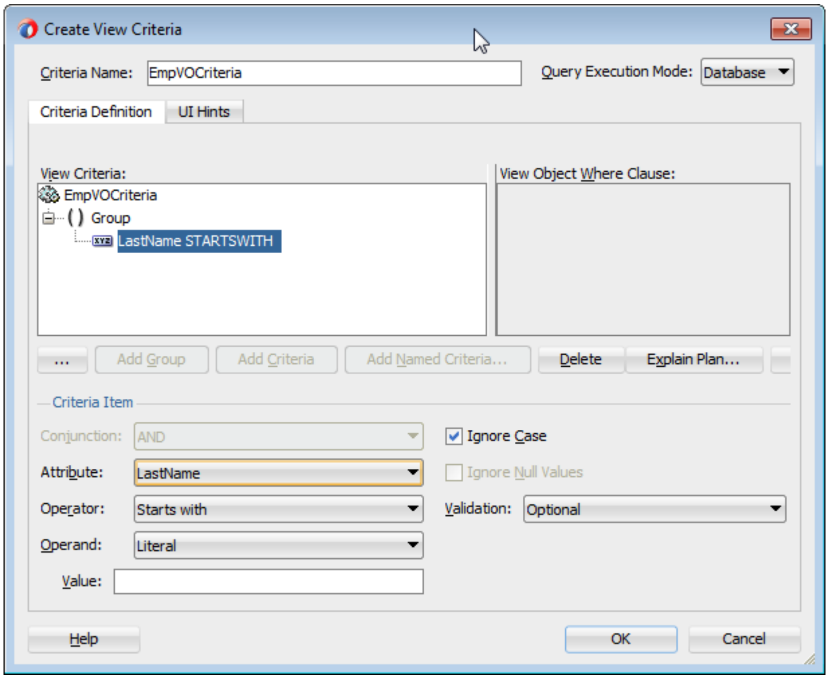
Search form attribute properties that can be set when the view object is being created include:

- `timezone` control hint for a `timestamp` attribute

How to Set Search Form Properties on the View Criteria

When you are creating a view criteria, you can declaratively set the initial state of several properties. Figure 36-18 shows the Edit View Criteria dialog for setting default options. For more information about view criteria, see Working with Named View Criteria.

Figure 36-18   Create View Criteria Dialog



Criteria Name: EmpVOCriteria

Query Execution Mode: Database

Conjunction: AND

☑ Ignore Case

Attribute: LastName

☐ Ignore Null Values

Operator: Starts with

Validation: Optional

Operand: Literal

Value:

You must select the default mode of the query search form as either basic or advanced. The default is basic.

You also must declare whether each individual search criteria field will be available only in basic mode, only in advanced mode, available in both modes, or never displayed. If a search criteria field is declared only for basic mode, it will not appear when the user switches to advanced mode, and the reverse is true. If the field is declared for all, then it will appear in all modes. The default for search criteria field rendering is all modes.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. See Setting Up Search Form Properties.

You may also find it useful to understand functionality that can be used with query search forms. See Additional Functionality for Search Forms.

You will need to complete this task:

> Create a view criteria for the query search form, as described in Working with Named View Criteria.

To set the default mode and search criteria field display option:

1. In the Applications window, double-click the view object that contains the view criteria you created for the query search form.
2. In the overview editor for the view object, click the View Criteria navigation tab.
3. In the View Criteria page, select the view criteria from the list and click **Edit**.
4. In the Edit View Criteria dialog, click the **Item UI Hints** tab on the Criteria Definition page.

5. In the **Rendered Mode** dropdown list, select **All**, **Basic**, **Advanced**, or **Never**.
6. In the Edit View Criteria dialog, click the **Criteria UI Hints** tab.
7. From the **Search Region Mode** dropdown list, select either **Basic** or **Advanced**.
8. In the **Criteria Item UI Hints** section, select the criteria item you want to set.
9. In the **Show Operators** dropdown list, select **Always**, **In Basic Mode**, **Never**, **In Advanced Mode**, or **Never** to specify whether or not the user may change the operators displayed by the query component backed by this view criteria.

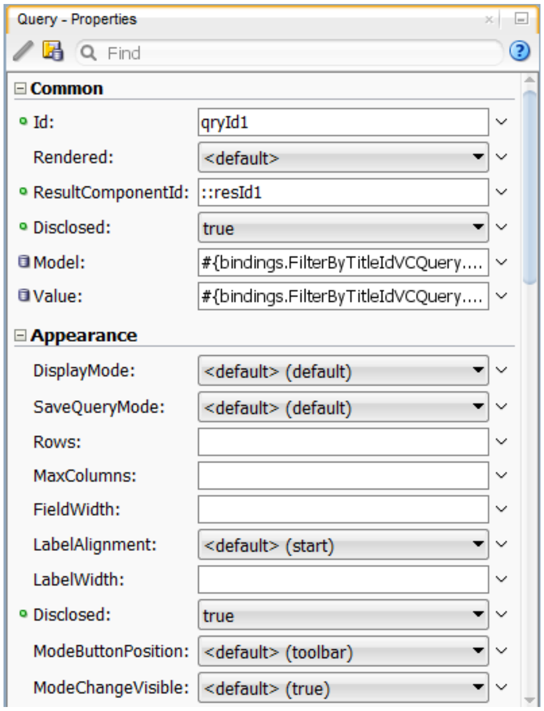
   The operators displayed by the query component when the users changes the mode of the query component from advanced to basic may change depending upon how you have configured **Show Operators**. The query component will only preserve the user's selection between modes when you set **Show Operators** to **Always** to allow the full list of operators in both modes. However, if you set **Show Operators** to **In Advanced Mode** to only show the full list of operators in advanced mode, then after the user makes their selections and switches to basic mode, the operators will default to the ones defined by the view criteria and for this reason the user's selections may appear to change. Select **Never** when you want the view criteria to be executed using ONLY the operators it defines (where the full list of operators will not be exposed in either basic or advance modes).
10. Click **OK**.

How to Set Search Form Properties on the Query Component

After you have dropped the query search form onto a page, you can edit other form properties in the Properties window, as shown in Figure 36-19. Some of the common properties you may set are:

- Enabling or disabling the basic/advanced mode button
- Setting the ID of the query search form
- Setting the ID of the results component (for example, a results table)
- Selecting the default, simple, or compact mode for display
- Setting the `criterionFeatures` to `matchCaseDisplayed` to require all string-based search criterion to be case-sensitive or to `requiredDisplayed` to require all the criterion to be displayed.

Figure 36-19 Properties window for a Query Component



Query - Properties

Common

Id:	qryId1
Rendered:	<default>
ResultComponentId:	::resId1
Disclosed:	true
Model:	#{bindings.FilterByTitleIdVCQuery....
Value:	#{bindings.FilterByTitleIdVCQuery....

Appearance

DisplayMode:	<default> (default)
SaveQueryMode:	<default> (default)
Rows:	
MaxColumns:	
FieldWidth:	
LabelAlignment:	<default> (start)
LabelWidth:	
Disclosed:	true
ModeButtonPosition:	<default> (toolbar)
ModeChangeVisible:	<default> (true)

One common option is to show or hide the basic/advanced button. For more information on some of the other properties, see the How to Add the Query Component section in *Developing Web User Interfaces with Oracle ADF Faces*.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Setting Up Search Form Properties.

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Additional Functionality for Search Forms.

To enable or hide the basic/advanced button in the query form:

1. In the Structure window, double-click **af:query**.
2. In the Properties window, click the **Appearance** tab.
3. To enable the basic/advanced mode button, select **true** from the **ModeChangeVisible** field. To hide the basic/advance mode button, select **false** from the **ModeChangeVisible** field.

How to Set Timezone Control Hint for Timestamp Attribute

If a query includes a `Date` attribute, you can set its `timezone` using control hints on the view object or entity object where the attribute is defined. For instance, you can set the `Hiredate` of an employee to have the correct `timezone` for the employee's local office.

Before you begin:

Create the desired view objects as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.

To customize view object timestamp attribute with control hints:

1. In the Applications window, double-click the view object.
2. In the overview editor, click the **Attributes** navigation tab and select the `Date` attribute that you want to customize with control hints.
3. Click the **UI Hints** tab to expose the **Timezone** property.
4. Select a time zone from the **Timezone** dropdown list.

   The time zone values are listed as Universal Time Coordinated (UTC) +/- hours.

How to Create Custom Operators

You can create custom operators for each view criteria item by adding code to the view object XML file. For example, you can create a new operator called `more than a year`, which operates on a date attribute (greater than 365 days from the current date).

You can add custom operators for a view object attribute by adding code for that attribute in the view object XML file.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Setting Up Search Form Properties.

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Additional Functionality for Search Forms.

To add a custom operator:

1. In the Applications window, select the view object for the view criteria in which you want to add a custom operator.
2. In the overview editor, click the **Source** tab.
3. In the XML editor, locate the code for the view criteria attribute, and add the `CompOper` code statements after the last item within the `ViewCriteriaItem` group. Example 36-1 shows code for the view criteria: the `CompOper` code statements appear in bold.

   The `CompOper` properties are:

   - `Name`: Specify an `id` for the operation.
   - `ToDo`: Set to `1` to add this custom operator. Set to `-1` to remove an operator.
   - `OperDescStrCode`: Specify the `id` used in the message bundle to map to the description string, as described in Step 4.
   - `Oper`: Set to a value that will be used programmatically to denote this operation in the SQL statement. In Example 36-1, `Oper` was set to `>Y` to denote greater than 1 year.
   - `MinCardinality`: If there is an input range, set this property to the minimum value for the range. For example, if the range is months in a year, this value should be set to `1`. If there is no range, set it to `0`.

- MaxCardinality: If there is an input range, set this property to the maximum value for the range. For example, if the range is months in a year, this value should be set to 12. If there is no range, set it to 0.
- TransientExpression: Set the expression to perform the custom operator function. In Example 36-1, the expression is ![CDATA[return " > SYSDATE -365"]], which returns the string " > SYSDATE -365".

4. Open the message bundle file for the view object and add an entry for the custom operator, using the OperDescStrCode identifier defined in the view object XML in Step 3.

   Example 36-2 shows the message bundle code for the LastUpdateDate custom operator described in Example 36-1.

Example 36-1   Adding the Custom Operator Code to the View Object XML

```
<ViewCriteriaRow
  Name="vcrow50"
  UpperColumns="1">
   <ViewCriteriaItem
     Name="LastUpdateDate"
     ViewAttribute="LastUpdateDate"
     Operator="="
     Conjunction="AND"
     Required="Optional">
        <CompOper
            Name="LastUpdateDate"
            ToDo="1"
            OperDescStrCode="LastUpdateDate_custOp_grt_year"
            Oper=">Y"
            MinCardinality="0"
            MaxCardinality="0" >
            <TransientExpression><![CDATA[ return " < SYSDATE - 365"
                ]]></TransientExpression>
        </CompOper>
   </ViewCriteriaItem>
```

Example 36-2   Adding the Custom Operator Entry for LastUpdateDate to the Message Bundle

```
public class AvailLangImplMsgBundle extends JboResourceBundle {
     static final Object[][] sMessageStrings =
  {
       { "LastUpdateDate_custOp_grt_year", "more than a year old"
   },
```

How to Remove Standard Operators

You can remove standard operators from a view criteria item. For example, you can remove the standard operator before from the list.

For a list of standard operators, see the Using Query Components chapter of *Developing Web User Interfaces with Oracle ADF Faces*.

You can remove standard operators for a view object attribute by adding code for that attribute in the view object XML file.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Setting Up Search Form Properties.

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Additional Functionality for Search Forms.

To remove a standard operator:

1. In the Applications window, select the view object for the view criteria in which you want to remove a standard operator.

   > **Note:**
   >
   > Before you attempt to remove the standard operator, make sure you do not remove the default operator for that view criteria item.

2. In the overview editor, click the **Source** tab.
3. In the XML editor, locate the code for the view criteria attribute, and add the `CompOper` code statements after the last item within the `ViewCriteriaItem` group.

   In the following example, the `CompOper` code statements appear in bold. The code in this example removes the `BEFORE` operator from the list of operators for the `LastUpdateDate` attribute.

   ```
   <ViewCriteriaRow
     Name="vcrow50"
     UpperColumns="1">
      <ViewCriteriaItem
        Name="LastUpdateDate"
        ViewAttribute="LastUpdateDate"
        Operator="="
        Conjunction="AND"
        Required="Optional">
           <CompOper
               Name="LastUpdateDate"
               ToDo="-1"
               Oper="BEFORE"
           </CompOper>
      </ViewCriteriaItem>
   ```

   The `CompOper` properties are:

   - `Name`: Specify an `id` for the operation.
   - `ToDo`: Set to `-1` to remove an operator. Set to `1` to add an operator.

     Do not set `ToDo` to `-2`, which would remove all the operators.
   - `Oper`: Set to the standard operator you want to remove from the list.

How to Set Uniform Operator Field Width

If you want a uniform width for all the operator dropdown fields in the search panel, you can set the following skinning property:

```
af|query {
 -tr-operator-size: constant;

}
```

Having a uniform operator field width would vertically align the operator and search boxes for all the search fields, which results in a more organized appearance.

For more information about skins, see the Customizing the Appearance Using Styles and Skins chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

Creating Quick Query Search Forms

In Oracle ADF, quick query search form is a simplified form with only one search criteria that creates a dropdown list of all searchable attributes in the associated view object. You can use different methods to create quick query search forms and can also set quick query layout format.

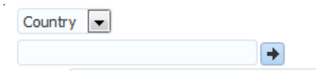
A quick query search form is intended to be used in situations where a single search will suffice or as a starting point to evolve into a full query search. Both the query and quick query search forms are ADF Faces components. A quick query search form has one search criteria field with a dropdown list of the available searchable attributes from the associated data collection. Typically, the searchable attributes are all the attributes in the associated view object. You can exclude attributes by setting the attribute's **Display Hint** property in the Control Hints page of the Edit Attribute dialog to **Hide**. The user can search against the selected attribute or search against all the displayed attributes. The search criteria field type will automatically match the type of its corresponding attribute. An **Advanced** link built into the form offers you the option to create a managed bean to control switching from quick query to advanced mode query search form. For more information, see the Using Query Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

You can configure the form to have a horizontal layout, as shown in Figure 36-20.

Figure 36-20 Quick Query Search Form in Horizontal Layout

You can also choose a vertical layout, as shown in Figure 36-21.

Figure 36-21 Quick Query Search Form in Vertical Layout



You can use quick query search forms to let users search on a single attribute of a collection. Quick query search form layout can be either horizontal or vertical. Because they occupy only a small area, quick query search forms can be placed in different areas of a page. You can create a managed bean to enable users to switch from a quick query to a full query search. For more information about switching from quick query to query using a managed bean, see the Using Query Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

If you drop a quick query panel with a results table or tree, JDeveloper will automatically create the results table, as described in How to Create a Quick Query Search Form with a Results Table or Tree Table. If you drop a quick query panel by itself and subsequently want a results table or component or if you already have one, you will need to match the quick query `Id` with the results component's `partialTrigger` value, as described in How to Create a Quick Query Search Form and Add a Results Component Later.

> **Note:**
>
> A quick query search creates a dropdown list of all searchable attributes defined in the underlying view object. If you want to show only a subset of those attributes, you can set the attribute's **Display** control hint to **Hide** for those attributes you want to exclude. For more information about setting control hints on view objects, see Defining SQL Queries Using View Objects.

How to Create a Quick Query Search Form with a Results Table or Tree Table

You can create quick query searches using the full set of searchable attributes and simultaneously add a table or tree table as the results component.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Creating Quick Query Search Forms.

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Additional Functionality for Search Forms.

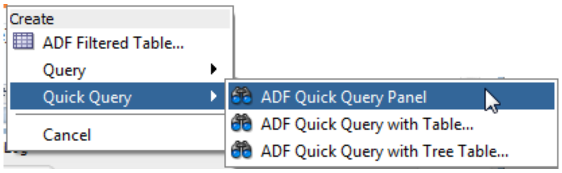
You will need to complete this task:

Create a view object to be the basis of the search form.

To create a quick query search form with a results table:

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the **All Queriable Attributes** item and drop it onto the page or onto the Structure window.
3. From the context menu, choose **Create > Quick Query > ADF Quick Query Panel with Table** or **Create > Quick Query > ADF Quick Query Panel with Tree Table**, as shown in Figure 36-22.
4. In the Edit Table Columns dialog, you can rearrange any column and select table options. If you choose the filtering option, the table will be a filtered table.
5. Click **OK**.

Figure 36-22 Data Controls Panel with Quick Query Context Menu



How to Create a Quick Query Search Form and Add a Results Component Later

You can create quick query searches using the full set of searchable attributes and add a table or tree table as the results component later.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Creating Quick Query Search Forms.

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Additional Functionality for Search Forms.

You will need to complete this task:

Create a view object to be the basis of the search form.

To create a quick query search form and add a results component in a separate step:

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the **All Queriable Attributes** item and drop it onto the page or onto the Structure window.
3. From the context menu, choose **Create > Quick Query > ADF Quick Query Panel**.
4. If you do not already have a results component, then drop the data collection associated with the view criteria as a component.
5. In the Properties window for the quick query panel, copy the value of the **Id** field.
6. In the Properties window for the results component (for example, a table), paste or enter the value into the **PartialTriggers** field.

How to Set the Quick Query Layout Format

The default layout of the form is horizontal. You can change the layout option using the Properties window.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Creating Quick Query Search Forms.

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Additional Functionality for Search Forms.

To set the layout:

1. In the Structure window, double-click **af:quickQuery**.
2. In the Properties window, on the Commons page, select the **Layout** field using the dropdown list to specify **default**, **horizontal**, or **vertical**.

What Happens When You Create a Quick Query Search Form

When you drop a quick query search form onto a page, JDeveloper creates an `af:quickQuery` tag. If you have dropped a quick query with table or tree table, then an `af:table` tag or `af:treeTable` tag is also added.

Under the `af:quickQuery` tag are several attributes and facets that define the quick query properties. Some of the tags are:

- The `id` attribute, which uniquely identifies the quick query. This value should be set to match the results table or component's `partialTriggers` value. JDeveloper will automatically assign these values when you drop a quick query with table or tree table. If you want to change to a different results component, see How to Create a Quick Query Search Form and Add a Results Component Later.
- The `layout` attribute, which specifies the quick query layout to be default, horizontal, or vertical.
- The `end` facet, which specifies the component to be used to display the **Advanced** link (that changes the mode from quick query to the query). For more information about creating this function, see the Using Query Components chapter of *Developing Web User Interfaces with Oracle ADF Faces*.

What Happens at Runtime: Quick Query

At runtime, the quick query search form displays a single search criteria field with a dropdown list of selectable search criteria items. If there is only one searchable criteria item, then the dropdown list box will not be rendered. An input component that is compatible with the selected search criteria type will be displayed, as shown in Table 36-4. For example, if the search criteria type is date, then `inputDate` will be rendered.

Table 36-4 Quick Query Search Criteria Field Components

Attribute Type	Rendered Component
`DATE`	`af:inputDate`
`VARCHAR`	`af:inputText`
`NUMBER`	`af:inputNumberSpinBox`

If the **Default List Type** control hint in the view object has been declared as an LOV or a selection list component, the search criteria field component appears as shown in Table 36-1 in List of Values (LOV) Input Fields.

In addition, a **Search** button is rendered to the right of the input field. If the end facet is specified, then any components in the end facet are displayed. By default, the end facet contains an **Advanced** link.

Creating Standalone Filtered Search Tables from Named View Criteria

In Oracle ADF, you can create a filtered table to perform searches without the search forms or as a results table of the search forms. You can use different methods to create a standalone filtered table and Query-by-Example searches.

A filtered table can be created standalone or as the results table of a query or quick query search form. Filtered table searches are based on Query-by-Example and use the QBE text or date input field formats. The input validators are turned off to allow for entering characters such as > and <= to modify the search criteria. For example, you can enter `>1500` as the search criteria for a number column. Wildcard characters may also be supported. If a column does not support QBE, the search criteria input field will not render for that column. The input field rendered will depend on the attribute's data type. For instance, a date column will have a date picker component rendered and a column for an attribute defined as a List of Values will have the corresponding List of Values component rendered.

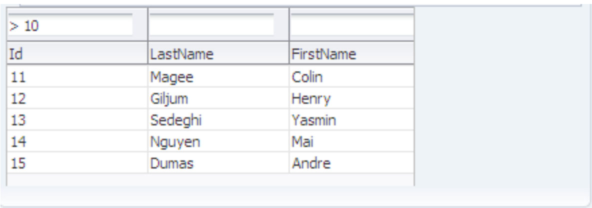
The filtered table search criteria input values are used to build the query `WHERE` clause with the `AND` operator. If the filtered table is associated with a query or quick query search panel, the composite search criteria values are also combined to create the `WHERE` clause.

Note:

If the filtered table is used with a query component in a search form and the search region is using an existing named criteria, the results of the query will be filtered by all the view criteria rows in an iterative manner. For example, a filtered table has two view criteria rows: `PersonId` and `DeptId`. The first view criteria row has `PersonId` > `1`. When the user enters > 100 in the filter field, then the second view criteria row `DeptId` is used to accept input to further filter the results. This process iterates through all the view criteria rows until the final query result is reached.

Figure 36-23 shows a filtered table. When the user enters a QBE search criteria, such as `>10` for the `Id` field, the query result is the `AND` of the query search criteria and the filtered table search criteria.

Figure 36-23 Filtered Table



> 10		
Id	LastName	FirstName
11	Magee	Colin
12	Giljum	Henry
13	Sedeghi	Yasmin
14	Nguyen	Mai
15	Dumas	Andre

Table 36-5 lists the acceptable QBE search operators that can be used to modify the search value.

Table 36-5 Query-by-Example Search Criteria Operators

Operator	Description
>	Greater than
<	Less than
>=	Greater than or equal to
<=	Less than or equal to
`AND`	And
`OR`	Or
=	Equal to
<>	Does not contain
`!=`	Does not contain

You use query search forms for complex searches, but you can also perform simple QBE searches using the filtered table. You can create a standalone ADF-filtered table without the associated search panel and perform searches using the QBE-style search criteria input fields. For information about filtered tables, see How to Create Filtered Table and Query-by-Example Searches.

You can set the QBE search criteria for each filterable column to be a case-sensitive or case-insensitive search using the `filterFeature` attribute of `af:column` in the `af:table` component. See the Enabling Filtering in Tables section of *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create Filtered Table and Query-by-Example Searches

When creating a table, you can make almost any table a filtered table by selecting the filtering option if the option is enabled. There are three ways to create a standalone filtered table:

- You can drop a table onto a page from the Components window, bind it to a data collection, and set the filtering option. For more information, see the Using Query Components chapter of *Developing Web User Interfaces with Oracle ADF Faces*.
- You can create a filtered table by dragging and dropping a data collection onto a page and setting the filtering option. For more information, see How to Create a Basic Table.
- You can also create a filtered table or a read-only filtered table by dropping named criteria onto a page. You can use either the implicitly created named criteria **All Queriable Attributes** or any declaratively created named view criteria. The resulting filtered table will have a column for each searchable attribute and an input search field above each column.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Creating Standalone Filtered Search Tables from Named View Criteria.

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Additional Functionality for Search Forms.

To create a filtered table using named view criteria:

1. From the Data Controls panel, select the data collection and expand the **Named Criteria** node to display a list of named view criteria.
2. Drag the named view criteria item and drop it onto the page or onto the Structure window.
3. From the context menu, choose **Create > ADF Filtered Table**.
4. In the Edit Table Columns dialog, you can rearrange any column and select table options.

   Because the table is created by JDeveloper during quick query creation, the filtering option is automatically enabled and not user-selectable, as shown in Figure 36-24.

Figure 36-24   Edit Table Columns Dialog for Filtered Table

Creating Databound Calendar and Carousel Components

This chapter describes how to create calendar and carousel components from data modeled with ADF Business Components, using ADF data controls and ADF Faces components.
This chapter includes the following sections:

About Databound ADF Faces Calendar and Carousel Components

The ADF Faces calendar component displays user activities by day, week, month, or by list view. The carousel component gives the user the ability to view an image from a series of images.

ADF Faces calendar and ADF Faces carousel are complex components that you can use to include calendar functions or display rotating images in your application. The ADF Faces calendar displays activities in daily, weekly, monthly, or list views for a given provider. The calendar is configurable to display only some of the views. The calendar includes a toolbar with built-in functionality that allows a user to change the view (between daily, weekly, monthly, or list), go to the previous or next day, week, or month, and return to today. The toolbar is customizable and allows you to choose which buttons and text to display, and you can also add buttons or other components.

The ADF Faces carousel displays images in a revolving loop that the user can select by using the slider or clicking on images. It can be configured to have either a horizontal or vertical orientation. You can use other components in conjunction with the carousel. You can add a toolbar or menu bar, and then add buttons or menu items that allow users to perform actions on the current object.

Databound ADF Faces Calendar and Carousel Components Use Cases and Examples

The ADF Faces calendar can be used whenever you want to add a calendar feature to your application. You will need to have the relevant data in your data store that represents the content provided by the calendar, such as the date, time, title, location, and owner. You can use the familiar patterns of **entity objects** and **view objects** to model the data and then use drag and drop from the Data Controls panel to create the calendar.

The carousel component gives the user the ability to view an image from a series of images. The user can see partial views of the images before and after the image being viewed and can scroll through each image in the sequence. The user can do so using a slider or navigation buttons. The carousel is useful for showing objects that require a highly visual presentation. For example, it can be used to display a photographic collection or merchandise in a catalog.

Additional Functionality of Databound ADF Faces Calendar and Carousel Components

You may find it helpful to understand other **Oracle ADF** features before you configure or use ADF Faces calendar and carousel components. Additionally, you may want to read about what you can do with your calendar and carousel components. Following are links to other functionality that may be of interest.

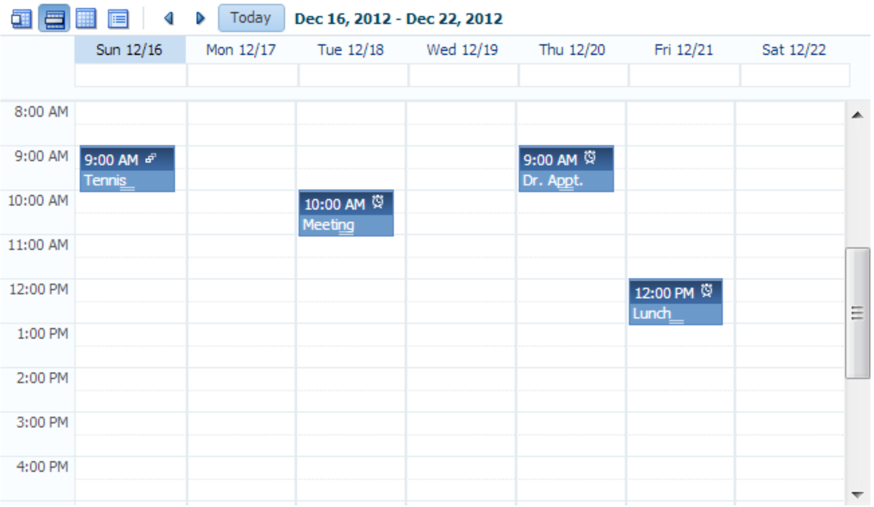
- You can customize the calendar for individual users so that the calendar appears in the selected configuration when that user accesses the calendar. For more information, see Allowing User Customizations at Runtime.
- Calendars are based on entity objects. For information on creating entity objects, see Creating a Business Domain Layer Using Entity Objects.
- For more information about partial page rendering and the partialTriggers attribute, see the Rerendering Partial Page Content chapter of *Developing Web User Interfaces with Oracle ADF Faces*.
- The carousel component uses a tree binding to iterate over the data. For more information about the tree binding, see Iterator and Value Bindings for Tables.

Using the ADF Faces Calendar Component

The ADF Faces calendar can be used whenever you want to add a calendar feature to your application. You will need to have the relevant data in your data store that represents the content provided by the calendar, such as the date, time, title, location, and owner.

ADF Faces includes a calendar component that displays activities in daily, weekly, or monthly views. Figure 37-1 shows an ADF Faces calendar in weekly view mode with some sample activities.

Figure 37-1 ADF Faces Calendar



The calendar component also includes the following functionality:

- A toolbar that allows users to switch between monthly, weekly, daily, and list views.

> **Tip:**
>
> When these toolbar buttons are used, attribute values on the calendar are changed. You can configure these values to be persisted so that they remain for a particular user whenever they accesses the calendar. For more information, see Allowing User Customizations at Runtime.

- Configurable start of the week days and start of the day hours. For example, a calendar's week might start on Sunday and the day might show 8:00 am at the top.
- Configurable styles using skinning keys.

Additionally, you can implement the following functionality using other ADF Faces components and the rich client framework:

- Popup functionality. Components placed in supported facets that respond to certain events and allow the user to act on activities or the calendar. For example, when a user clicks an activity in the calendar, the `CalendarActivityEvent` is invoked and any popup component in the `ActivityDetail` facet is displayed. You might use a dialog component that contains a form where users can view and edit the activity, as shown in Figure 37-2.

Figure 37-2 Edit Dialog for ActivityDetail Facet

Status Confirmed

Access Public

- Drag and drop capability: You can add the `calendarDropTarget` tag that allows a user to drag an activity to another place on the calendar. You then implement the functionality so that the time is actually changed on the activity and persisted to the data store.
- Toolbar customization: By default, the toolbar contains buttons that allow the user to switch between the different views, along with previous and next buttons and a button that returns to the current date. The toolbar also displays the current date range (or the date when in day view). You can customize the toolbar by adding facets that contain additional buttons of your choosing.
- Skinning: The calendar uses skinning keys to determine things like colors and icons used. You can extend the skin to change the appearance of the calendar.

Details for configuring the built-in functionality or for implementing additional functionality can be found in the Using a Calendar Component chapter of *Developing Web User Interfaces with Oracle ADF Faces*.

An ADF Faces Calendar component must be bound to a `CalendarModel` class. This class can be created for you when you use ADF Business Components to manage your calendar's data. For example, say you have data in your data store that represents the details of an activity, such as the date, time, title, location, and owner. When you create an entity object to represent that data, and then a view object to display the data, you can drag and drop the associated collection from the Data Controls panel to create the calendar. JDeveloper will declaratively create the model and bind the view to that model so that the correct data will display when the calendar is launched. However, in order for the model to be created, your entity objects in the data model project with ADF Business Components and your view objects in the same project must contain date-effective attributes. Additionally, the view objects must contain variables that will be used to modify the query to return the correct activities for the given date range.

How to Create the ADF Faces Calendar

Before you can create a calendar on a JSF page, you must first create an entity object with specific attributes that represent attributes on a calendar. You then must create a view object from that entity object, and modify the query to use named bind variables that represent the date range and current time zone to display. This will allow the query to return only the activities that should be displayed in the given view on the calendar.

For example, say you have a database table that represents an activity. It has a column for title, start time, end time, and a reference to a provider object that represents the owner. You would create an entity object and a view object based on that table (ensuring that it meets the requirements, as described in the following steps). To the view object, you would then add named bind variables for the start and end times currently displayed on the calendar, along with the time zone currently in use by the calendar, so that the query returns only those activities that fall within that time range.

Once you add the calendar component to a JSF page, you can configure it and add functionality.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a calendar. For more information, see Using the ADF Faces Calendar Component.

To create an ADF Faces calendar:

1. Create an entity object based on your data source. The entity object must include the attributes shown in Table 37-1. The attributes do not have to use the names shown in the table; they can be named anything. However, they must be of one of the types noted. You will map these attributes to attributes in the `CalendarModel` in a later step.

   Table 37-1 Required Attributes for a Calendar

Attribute	Valid Types	Description

Start time	`java.util.Date,`
	`java.sql.Date,`
	`oracle.jbo.domain.Date,`
	`oracle.jbo.domain.TimeStamp`
		Start time for the activity

End time	`java.util.Date,`
	`java.sql.Date,`
	`oracle.jbo.domain.Date,`
	`oracle.jbo.domain.TimeStamp`
		End time for the activity

ID	`String`	Unique ID
Provider ID	`String`	ID of the provider object that represents the owner of the activity
Title	`String`	Short description of the activity

   The entity object can also contain the known (but not required) attributes shown in Table 37-2:

Table 37-2 Optional Attributes for a Calendar

Attribute	Type	Description
Recurring	`String` or `CalendarActivity.Recurring`	Status of recurrence for the activity. Valid values are `SINGLE` (does not recur), `RECURRING`, or `CHANGED` (this activity was part of the recurring activity but has been modified to be different from parent activity).
Reminder	`String` or `CalendarActivity.Reminder`	Whether or not the activity has an associated reminder. Valid values are `ON` or `OFF`.
Time Type	`String` or `CalendarActivity.TimeType`	Type of time associated with the activity. Valid values are `ALLDAY` and `TIME`. Activities that have a value of `ALLDAY` do not have any time associated with them. They are considered to span the entire day. Activities with a value of `TIME` have a specific time duration.
Location	`String`	Location of an activity.
Tags	`Set` of `String` values or a semicolon-separated list of `String` values.	Keywords for the activity.

Your entity objects can also contain other attributes that the `CalendarModel` has no knowledge of. You will be able to add these to the model as custom properties in a later step.

For information on creating entity objects, see Creating a Business Domain Layer Using Entity Objects.

2. Create an associated view object. In the Query page of the overview editor, create named bind variables for the following:
   - A string that represents the time zone
   - A date that represents the start time for the current date range shown on the calendar
   - A date that represents the end time for the current date range shown on the calendar

   > **Tip:**
   >
   > Dates in an ADF Faces calendar are "half-open," meaning that the calendar returns all activities that start on or after the start time and before (but not on) the end time.

   For more information about creating named bind variables, see Working with Bind Variables.

3. Create an entity object that represents the provider (owner) of activities. The entity object must include the attributes shown in Table 37-3. The attributes do not have to use the names shown in the table; they can be named anything. However,

they must be of the type noted. You will map these attributes to attributes in the `CalendarProvider` class in a later step.

Table 37-3 Attributes for a CalendarProvider Class

Attribute	Type	Description
Id	`String`	Unique ID.
Display Name	`String`	The name of the provider that can be displayed in the calendar.

4. Create a view object for the provider.
5. Ensure that the new view objects are part of the **application module**, and if needed, refresh the Data Controls panel.
6. Create your JSF page, as documented in Creating a Web Page.
7. From the Data Controls panel, drag the collection that represents the view object for the activity created in Step 2 and drop it as a **Calendar**.

> **Tip:**
>
> The Calendar option will appear in the context menu only if the view object contains the required attributes documented in Table 37-1 and the bind variables described in Step 2.

8. Complete the Calendar Bindings dialog to map the bind variables and attributes to the `CalendarModel` and the `CalendarProvider` classes. For additional help, click **Help** or press F1.
9. By default, the calendar will be read-only and will return only those activities currently in the data store. You will need to configure the calendar and implement additional functionality as described in the Using a Calendar Component chapter of *Developing Web User Interfaces with Oracle ADF Faces*.

   For example, to allow creation of a new activity, you might create an input form in a dialog (as described in the How to Create a Dialog section of *Developing Web User Interfaces with Oracle ADF Faces*) using the same data control collection used to create the calendar. For more information about creating input forms, see Creating an Input Form.

What Happens When You Create a Calendar

When you drop a collection as a calendar, JDeveloper:

- Defines an iterator binding to the collection of activities, and another iterator binding to the collection of providers.
- Defines an action binding to the `executeWithParams` operation on the activities collection. It is this operation that will be invoked to execute the query to return the activities to display. Because the operation requires parameters to determine the date range and time zone, `NamedData` elements are also created for each of the parameters (created as named bind variables on the view object). For more information about `NamedData` elements, see Method Parameters.

Note:

A runtime error will occur if you specify `java.sql.Date` as the `NDType` in the calendar page definition file. Use one of the following supported data types instead:

- `oracle.jbo.domain.Timestamp`
- `oracle.jbo.domain.Date`
- `java.sql.Timestamp`
- `java.util.Date`

- Defines a calendar binding. This binding contains a `node` element that represents a row in the collection and maps the data control attributes to the calendar activity's attributes, as defined when using the wizard.The `value` is the data control attribute and the `type` is the calendar attribute. For any custom defined attributes, the `type` will be `custom` and `value` will be the data control attribute. Each row (node) is represented by a `rowKey`, which is the activity ID.

  There is also a `providerDefinition` element that determines the source and mapping of available providers. This mapping allows the calendar model to filter activities based on the state of the provider (either enabled or disabled).

Tip:

To access a custom attribute, use the `CalendarActivity.getCustomAttributes()` method, passing in the name of the attribute as defined by the `value` element.

The following example shows the page definition code for a calendar.

```
<executables>
    <iterator Binds="ActivityView1" RangeSize="-1"
              DataControl="AppModuleDataControl" id="ActivityView1Iterator"/>
    <iterator Binds="EmployeesView1" RangeSize="25"
              DataControl="AppModuleDataControl" id="EmployeesView1Iterator"/>
  </executables>
  <bindings>
    <action IterBinding="ActivityView1Iterator" id="ExecuteWithParams"
            RequiresUpdateModel="true" Action="executeWithParams">
      <NamedData NDName="startTime"
                 NDValue="#{bindings.ActivityView1.startDate}"
                 NDType="oracle.jbo.domain.Date"/>
      <NamedData NDName="endTime" NDValue="#{bindings.ActivityView1.endDate}"
                 NDType="oracle.jbo.domain.Date"/>
      <NamedData NDName="timeZone"
                 NDValue="#{bindings.ActivityView1.timeZoneId}"
                 NDType="java.lang.String"/>
    </action>
    <calendar IterBinding="ActivityView1Iterator" id="ActivityView1"
              xmlns="http://xmlns.oracle.com/adf/faces/binding"
              ActionBindingName="ExecuteWithParams">
      <nodeDefinition DefName="model.ActivityView">
        <AttrNames>
```

```
              <Item Type="id" Value="Id"/>
              <Item Type="providerId" Value="ProviderId"/>
              <Item Type="title" Value="Title"/>
              <Item Type="startTime" Value="StartTime"/>
              <Item Type="endTime" Value="EndTime"/>
            </AttrNames>
          </nodeDefinition>
          <providerDefinition IterBindingName="EmployeesView1Iterator">
            <AttrNames>
              <Item Type="id" Value="EmployeeId"/>
              <Item Type="displayName" Value="FirstName"/>
            </AttrNames>
          </providerDefinition>
        </calendar>
      </bindings>
```

JDeveloper inserts code onto the JSF page that binds the calendar value to the `CalendarModel` class, as shown in the following example.

```
<af:form>
  <af:calendar value="#{bindings.ActivityView1.calendarModel}"/>
</af:form>
```

The `CalendarModel` class uses `CalendarActivityDefinition` class to access the calendar binding.

What Happens at Runtime: How the Calendar Binding Works

When the calendar is accessed, the `executeWithParams` operation is invoked, with the value of the `startDate` and `endDate` parameters determined by the value of the calendar component's `view` and `activeDay` attributes. For example, if the `view` attribute is set to `month` and the `activeDay` is set to the current date (say, May 5, 2013), then the value for the `startDate` would be `May 1, 2013` and the `endDate` value would be `May 31, 2013`. By default, the time zone value is taken from the `time-zone` setting in the `trinidad-config.xml` file (for more information, see the Configuration in trinidad-config.xml section of *Developing Web User Interfaces with Oracle ADF Faces*). Therefore, the query would be restricted to return only activities that fall within that date range.

When the query returns data, because the calendar component is bound to the `CalendarModel`, the `CalendarModel` uses the `CalendarActivityDefinition` class to access the calendar binding class and map the values from the data source to the calendar, using the mappings provided by the binding.

Using the ADF Faces Carousel Component

The ADF Faces carousel component gives the user the ability to view an image from a series of images. The user can see partial views of the images before and after the image being viewed and can scroll through each image in the sequence.

You can display images in a revolving carousel, as shown in Figure 37-3. Users can change the image at the front by using either the slider at the bottom or by dragging another image to the front.

Figure 37-3   Carousel Component

Instead of containing a child `carouselItem` component for each image to be displayed, and then binding these components to the individual images, the `carousel` component is bound to a complete collection and repeatedly renders one `carouselItem` component by stamping the value for each item, similar to the way a tree stamps out each row of data. As each item is stamped, the data for the current item is copied into a property that can be addressed using an EL expression using the `carousel` component's `var` attribute. Once the carousel has completed rendering, this property is removed or reverted back to its previous value. Carousels contain a `nodeStamp` facet, which is a holder for the `carouselItem` component used to display the text and short description for each item, and is also the parent component to the image displayed for each item. For more information about the carousel component, see the Displaying Images in a Carousel section of *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create a Databound Carousel Component

When using a carousel component in a Fusion web application, you create the component using the Data Controls panel. You also use a managed bean to handle the carousel spin event and for other logic you may need to display your items.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a carousel. For more information, see Using the ADF Faces Carousel Component.

You may also find it useful to understand functionality that can be used with carousels. For more information, see Additional Functionality of Databound ADF Faces Calendar and Carousel Components.

Perform the following in JDeveloper:

1. Create a view object for the collection to be displayed in the carousel. For example, to create the carousel shown in Figure 37-3, you use the `Inventory` view object.l
2. Create a managed bean to hold a method that handles the spinning of the carousel. The following example shows the handler method that might be used to display items in the carousel.

   ```
   public void handleCarouselSpin(CarouselSpinEvent event)
   {
   // This method is invoked when there is a spin event on the carousel in
   // InventoryControl.jsff. The purpose is to get the newly selected item in
   the
   // carousel and update the iterator current row with the value

   // get the bindingContainer
     DCBindingContainer dcBindings = (DCBindingContainer)
     BindingContext.getCurrent().getCurrentBindingsEntry();
     // get the NewItemKey from the event object. The first entry in the list
   is the
     // currently selected item
     List itemKeyList = (List) event.getNewItemKey();
     // create a Key ojbect instance and set it to the first key in the list
     Key currentItemKey = (Key) itemKeyList.get(0);
     // get the iteratorBinding
     DCIteratorBinding inventoryIterator =
    dcBindings.findIteratorBinding("InventoryIterator");
    // set the iterator
    inventoryIterator.setCurrentRowWithKey(currentItemKey.toStringFormat(true));
   }
   ```

To create a databound carousel component:

1. From the Data Controls panel, drag the collection for the view object on to the page and choose **Carousel** from the context menu.
2. In the Properties window, in the Behavior section, bind the **CarouselSpinListener** to a handler method that you created in the prerequisites.
3. In the Structure window, expand the `carousel` component and the `nodeStamp` facet, and select the `carouselItem` component.
4. Bind the `CarouselItem` component's `text` attribute to the associated property on the view object using variable value set on the carousel's `var` attribute, which by default is set to `item`. So for example, to use the `Name` attribute on the view object, the value of the `carouselItem`'s `text` attribute might be `#{item.Name}`.

   You can also bind other properties to the `text` attribute if you want to display more information. For example, the inventory carousel binds both the `Name` and the `AmountInStock` properties to the `text` attribute.
5. In the ADF Faces page of the Components window, from the General Controls panel, drag an **Image** and drop it as a child to the `carouselItem`.

   In the Insert Image dialog, enter the path to the source for the images, being sure to use the variable for the item in the carousel. For example, the path to the image files for the products would normally be:

   ```
   /images/products/#{item.Filename}
   ```

   Bind the `shortDesc` attribute to the text you want to appear when the mouse hovers over the image. For example:

```
#{item.Name}
```

For information about setting other attributes of the `carousel` and `carouselItem` components, see the How to Create a Carousel section of *Developing Web User Interfaces with Oracle ADF Faces*.

6. If you want to provide additional information about the items in the carousel, you can drag and drop the same view object onto the page, for example, as a table. For the components in the table to redisplay the information for the current item displayed once the carousel is spun, you need to set the `partialTrigger` attribute of the component containing the form to the carousel component's ID.

   For example, a table displays the information for each item in Figure 37-3. The `partialTrigger` attribute for the `table` component is set to `c1`, which is the carousel component's ID. This means that whenever the `carouselItem` invokes the `CarouselSpinEvent`, the `table` will be refreshed, causing the row that displays information about the item that was just made current in the carousel is also made current in the table.

   Additionally, the `partialTrigger` attribute for the carousel and carousel item is set to `t1`, which is the table's ID. This means that whenever a selection event occurs on the table, the carousel is refreshed to make the item that was just made current in the table, the current item in the carousel.

   For more information about partial page rendering and the `partialTriggers` attribute, see the Rerendering Partial Page Content chapter of *Developing Web User Interfaces with Oracle ADF Faces*.

   The following example shows the page code for the carousel displayed in Figure 37-3.

```
<f:facet name="first">
  <af:carousel
currentItemKey="#{bindings.Inventory.treeModel.rootCurrencyRowKey}"
               value="#{bindings.Inventory.treeModel}" var="item" id="c1"
               carouselSpinListener="#{InventoryControl.handleCarouselSpin}"
               partialTriggers="::t1">
    <f:facet name="nodeStamp">
      <af:carouselItem id="ci1" text="#{item.Name} #{item.AmountInStock}"
                       partialTriggers="::t1">
        <af:image source="/images/products/#{item.Filename}"
                  shortDesc="#{item.Name}" id="i1"/>
      </af:carouselItem>
    </f:facet>
  </af:carousel>
</f:facet>
<f:facet name="second">
  <af:table value="#{bindings.Inventory.collectionModel}" var="row"
            rows="#{bindings.Inventory.rangeSize}"
            emptyText="#{bindings.Inventory.viewable ? 'No data to
display.' :
                        'Access Denied.'}"
            fetchSize="#{bindings.Inventory.rangeSize}"
rowBandingInterval="0"

selectedRowKeys="#{bindings.Inventory.collectionModel.selectedRow}"

selectionListener="#{bindings.Inventory.collectionModel.makeCurrent}"
            rowSelection="single" id="t1"
            columnStretching="last" partialTriggers="::c1">
```

What Happens When You Create a Carousel

When you drop a collection from the Data Controls panel as a carousel, a tree value binding is created. A tree consists of a hierarchy of nodes, where each subnode is a branch off a higher-level node.

The tree binding iterates over the data exposed by the iterator binding. The carousel wraps the result set from the iterator binding in a `treeModel` object, which is an extension of the `collectionModel`. The `collectionModel` allows each item in the collection to be available within the carousel component using the `var` attribute. For more information about the tree binding, see Iterator and Value Bindings for Tables.

JDeveloper adds both a `carousel` component and its child `carouselItem` component onto the page, as shown in the following example.

```
<af:carousel
        currentItemKey="#{bindings.Products.treeModel.rootCurrencyRowKey}"
        value="#{bindings.Products.treeModel}" var="item"
        id="c1"
        carouselSpinListener="#{InventoryControl.handleCarouselSpin}">
  <f:facet name="nodeStamp">
    <af:carouselItem id="ci1" text="#{item.Name}"/>
  </f:facet>
</af:carousel>
```

The carousel value is bound to the `treeModel` for the associated collection, and the `currentItemKey` attribute of the carousel is bound to the `rootCurrencyRowKey` of the binding object. In this example, the carousel iterates over the items in the `Products` iterator binding. The iterator binding binds to a `rowKeySet` that keeps track of the current product. By default, the `currentItemKey` attribute of the carousel is bound to the `rootCurrencyRowKey` of the binding object, which causes the product currently displayed at the front of the carousel to be the root and the current item. The `carouselItem` component accesses the current data object for the current item presented to the carousel tag using the `item` variable.

Creating Databound Chart, Picto Chart, and Gauge Components

This chapter describes how to create charts, picto charts, or gauges from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization Tools (DVT) `area`, `bar`, `bubble`, `funnel`, `horizontal bar`, `line`, `pie`, `polar`, `radar`, `scatter`, and `spark` charts, `pictoCharts` and `dial`, `LED`, `rating`, and `status meter` gauges that visually represent business data. It describes how to use ADF data controls to create these components with data-first development.
If you are designing your page using simple UI-first development, then you can add the chart or gauge to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the chart and gauge components, see Using Chart Components, Using Picto Chart Components and Using Gauge Components in *Developing Web User Interfaces with Oracle ADF Faces*.

This chapter includes the following sections:

About ADF Data Visualization Chart, Picto Chart, and Gauge Components

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component must be bound to data before it can be rendered since the appearance of the components is dictated by the data that is displayed.

Both chart and gauge components render graphical representations of data. However, charts allow you to evaluate multiple data points on multiple axes in a variety of ways. Many chart types assist in the comparison of results from one group with the results from another group. In contrast, gauges focus on a single data point and examine that point relative to minimum, maximum, and threshold indicators to identify problems.

Picto charts are versatile components that represent absolute numbers or parts of a population. They are arranged in a flowing layout, and hence can be used in a variety of ways to represent data points in an aesthetically pleasing manner.

The prefix `dvt:` occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.

Data Visualization Components Use Cases and Examples

For detailed descriptions of data visualization use cases and examples, see the following:

- Chart components: Chart Component Use Cases and Examples section in *Developing Web User Interfaces with Oracle ADF Faces*.
- Gauge components: Gauge Component Use Cases and Examples section in *Developing Web User Interfaces with Oracle ADF Faces*.
- Picto Chart components: Picto Chart Component Use Cases and Examples section in *Developing Web User Interfaces with Oracle ADF Faces*.

End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for each component, see the following:

- Chart components: End User and Presentation Features of Charts section in *Developing Web User Interfaces with Oracle ADF Faces*.
- Gauge components: End User and Presentation Features of Gauge Components section in *Developing Web User Interfaces with Oracle ADF Faces*.
- Picto Chart components: End User and Presentation Features of Picto Charts section in *Developing Web User Interfaces with Oracle ADF Faces*.

Additional Functionality for Data Visualization Components

You may find it helpful to understand other **Oracle ADF** features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see the Rerendering Partial Page Content chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see the Allowing User Customization on JSF Pages chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Accessibility: You can make your data visualization components accessible. For more information, see the Developing Accessible ADF Faces Pages chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (`styleClass` or `inlineStyle`). For more information, see the Customizing the Appearance Using

Styles and Skins chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

- Placeholder data controls: If you know the data visualization components on your page will eventually use ADF data binding, but you need to develop the pages before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see Designing a Page Using Placeholder Data Controls .

Creating Databound Charts

Charts are based on data collections. To create a databound chart, you drag and drop a collection from the Data Controls panel onto the JSF page and use a dialog to bind the data collection attributes in the chart.

Charts display series and groups of data. Series and groups are analogous to the rows and columns of a grid of data. Typically, the rows in the grid appear as a series in a chart, and the columns in the grid appear as groups.

For most charts, a series appears as a set of markers that are the same color. Typically, the chart legend shows the identification and associated color of each series. For example, in a bar chart, the yellow bars might represent the sales of shoes and the green bars might represent the sales of boots.

Groups appear differently in different chart types. For example, in a stacked bar chart, each stack is a group. A group might represent time periods, such as years. A group might also represent geographical locations such as regions.

Depending on the data requirements for a chart type, a single group might require multiple data values. For example, a scatter chart requires two values for each data marker. The first value determines where the marker appears along the x-axis while the second value determines where the marker appears along the y-axis. For details about chart data requirements, see Chart Component Data Requirements in *Developing Web User Interfaces with Oracle ADF Faces*.

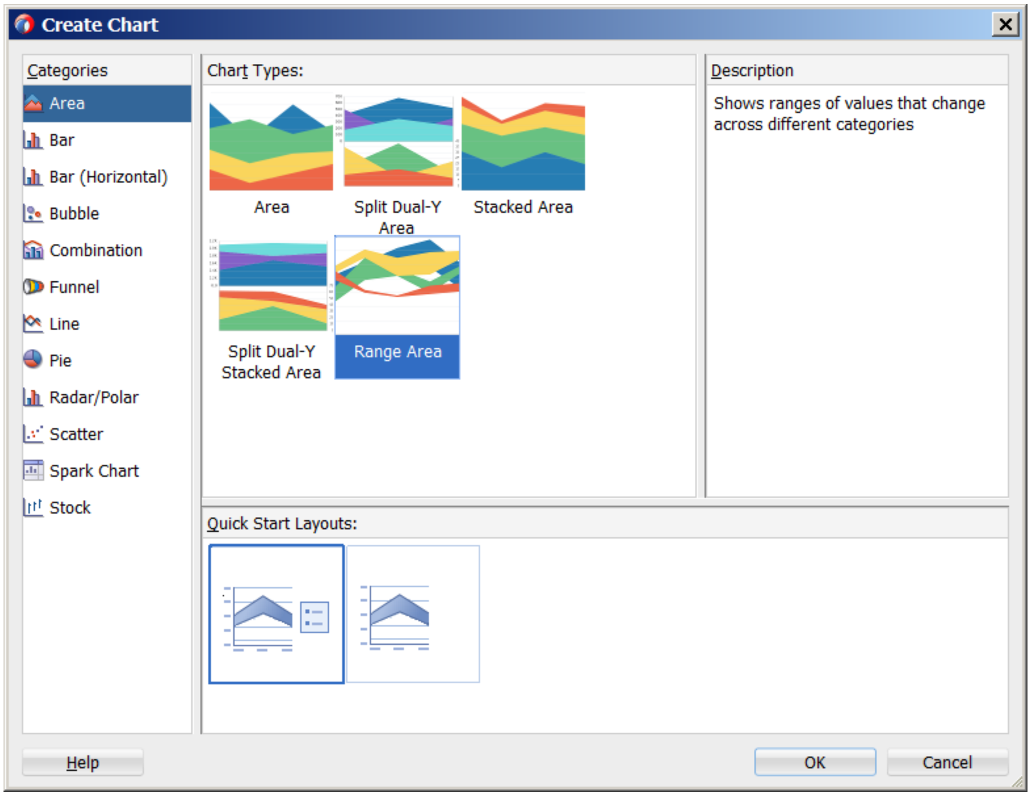
The attributes in a data collection can be data values or categories of data values. Data values are numbers represented by markers, like bar height or points in a scatter chart. Categories of data values are members represented as axis labels or appear as additional properties in a tooltip. The role that an attribute plays in the bindings (either data values or identifiers) is determined by both its data type and where it gets mapped (for example, bars vs. x-axis).

When you create a chart using a data collection inserted from the Data Controls panel, a Component Gallery allows you to choose from a wide number of chart categories, chart types, and layout options. Chart categories group together one or more types of chart. For example, the Area category includes the following types of charts:

- Area
- Split Dual-Y Area
- Stacked Area
- Split Dual-Y Stacked Area
- Range Area

Explore the Component Gallery that appears when you create a chart to view available chart categories, types, and descriptions for each one. Figure 38-1 shows the Component Gallery that appears for ADF charts when you use the Data Controls panel.

Figure 38-1 Component Gallery for Charts



Shows ranges of values that change across different categories

Table 38-1 lists the categories that appear in the Component Gallery for charts. Each category has one or more chart types associated with it.

Table 38-1 ADF Chart Categories in the Component Gallery

Image	Category	Description
	Area	Creates a chart in which data is represented as a filled-in area. Use area charts to show trends over time, such as sales for the last 12 months. Area charts require at least two groups of data along an axis. The axis is often labeled with time periods such as months.

Table 38-1 (Cont.) ADF Chart Categories in the Component Gallery

Image	Category	Description
Bar	Bar	Creates a chart in which data is represented as a series of vertical bars. Use to compare values across products or categories, or to view aggregated data broken out by a time period.
Bar (Horizontal)	Bar (Horizontal)	Creates a chart that displays bars horizontally along the y-axis. Use to provide an orientation that allows you to show trends or compare values.
Bubble	Bubble	Creates a chart in which data is represented by the location and size of round data markers (bubbles). Use to show correlations among three types of values, especially when you have a number of data items and you want to see the general relationships. For example, use a bubble chart to plot salaries (x-axis), years of experience (y-axis), and productivity (size of bubble) for your work force. Such a chart allows you to examine productivity relative to salary and experience.
Combination	Combination	Creates a chart that uses different types of data markers (bars, lines, or areas) to display different kinds of data items. Use to compare bars and lines, bars and areas, lines and areas, or all three.
Funnel	Funnel	Creates a chart that represents data related to steps in a process. Use to compare actual versus target values or to compare values in a sequence of steps. For examples, use the funnel chart to watch a process where the different sections of the funnel represent different stages in the sales cycle.
Line	Line	Creates a chart in which data is represented as a line, as a series of data points, or as data points that are connected by a line. Line charts require data for at least two points for each member in a group. For example, a line chart over months requires at least two months. Typically a line of a specific color is associated with each series of data such as the Americas, Europe, or Asia. Use to compare items over the same time.

Table 38-1 (Cont.) ADF Chart Categories in the Component Gallery

Image	Category	Description
Pie	Pie	Creates a chart that represents a set of data items as proportions of a total. The data items are displayed as sections of a circle causing the circle to look like a sliced pie. Use to show relationship of parts to a whole such as how much revenue comes from each product line.
Scatter	Scatter	Creates a chart in which data is represented by the location of data markers. Use to show correlation between two different kinds of data values such as sales and costs for top products. Scatter charts are especially useful when you want to see general relationships among a number of items.
Spark Chart	Spark	Creates a simple, condensed chart that displays trends or variations, often in the column of a table, or inline with text.
Stock	Stock	Creates a chart in which data shows the high, low, opening and closing prices of a stock and, optionally, the trading volume of the stock.

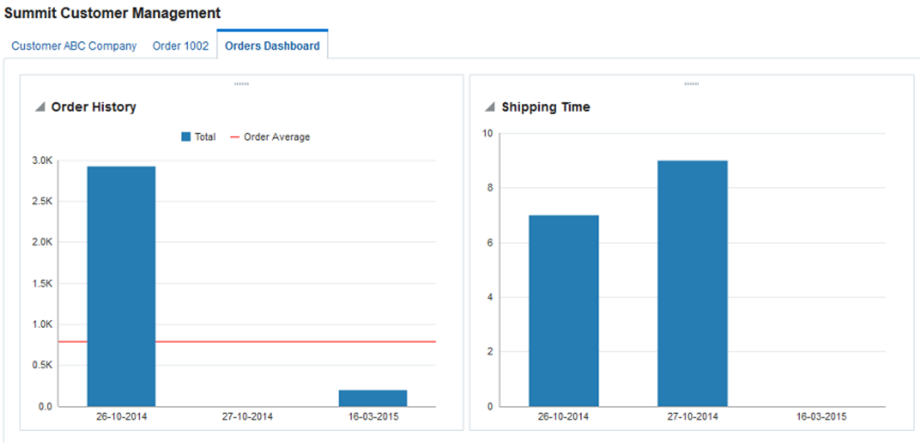
You can also create a chart by dragging a chart component from the Components window. This approach allows you the option of designing the chart's user interface before binding the component to data. A Create Chart dialog appears to view chart types, descriptions, and quick layout options. For more information about creating charts using UI-first development, see Using Chart Components in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create an Area, Bar, Combination, Horizontal Bar, or Line Chart Using Data Controls

Area, bar, horizontal bar, and line charts require at least two groups of data, with one or more series. The groups are displayed along the chart's X Axis for area, bar, and line charts and on the chart's Y Axis for horizontal bar charts. Series are displayed as the areas, bars, or lines on the chart.

Figure 38-2 shows two bar charts in the Summit ADF sample application. The bar chart on the left is configured to show the customer's order history and order average, and the bar chart on the right shows the ship time for each order. In these examples, the bar charts are configured with groups that represent order and ship dates, and the series are the order totals and ship time averages. The order average is displayed as a red reference line on the Order History chart.

Figure 38-2 Bar Charts in Summit ADF Sample Application



For information about adding reference lines to charts after the chart is created, see "Adding Reference Objects to a Chart" in *Developing Web User Interfaces with Oracle ADF Faces*.

Before you begin:

It may be helpful to have an understanding of databound data visualization charts. See Creating Databound Charts.

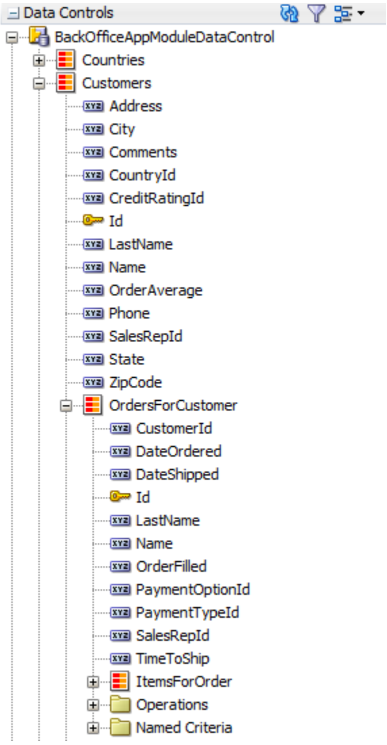
You may also find it helpful to understand functionality that can be added using other Oracle ADF features. See Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an **application module** that contains instances of the **view objects** that you want in your data model, as described in Creating and Modifying an Application Module.

  For example, the Summit ADF Shipping Time bar chart is based on the `OrdersForCustomer` data collection. Figure 38-3 shows the `OrdersForCustomer` collection in the Data Controls panel.

Figure 38-3 Data Collection for Order Ship Times

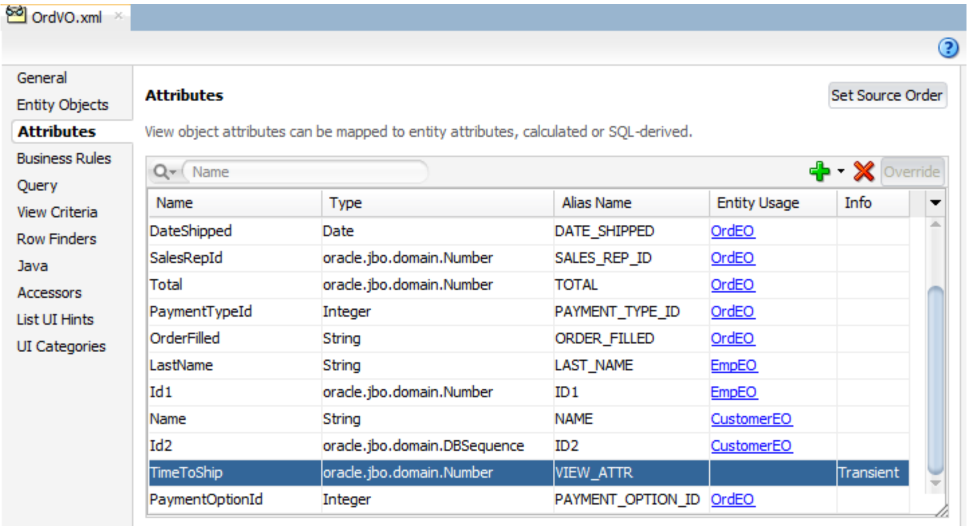


Data Controls

- BackOfficeAppModuleDataControl
  - Countries
  - Customers
    - Address
    - City
    - Comments
    - CountryId
    - CreditRatingId
    - Id
    - LastName
    - Name
    - OrderAverage
    - Phone
    - SalesRepId
    - State
    - ZipCode
    - OrdersForCustomer
      - CustomerId
      - DateOrdered
      - DateShipped
      - Id
      - LastName
      - Name
      - OrderFilled
      - PaymentOptionId
      - PaymentTypeId
      - SalesRepId
      - TimeToShip
      - ItemsForOrder
      - Operations
      - Named Criteria

The `OrdersForCustomer` data control is based on the `OrdVO` view object. Figure 38-4 shows the `OrdVO` view object which contains attributes from the `OrdEO`, `EmpEO`, and `CustomerEO` entity objects. The `OrdEO`, `EmpEO`, and `CustomerEO` entity objects are derived from the `SOrd`, `SEmp`, and `SCustomer` tables in the Summit schema.

Figure 38-4 OrdVO View Object in Summit ADF Sample Application



Attributes

View object attributes can be mapped to entity attributes, calculated or SQL-derived.

Name	Type	Alias Name	Entity Usage	Info
DateShipped	Date	DATE_SHIPPED	OrdEO	
SalesRepId	oracle.jbo.domain.Number	SALES_REP_ID	OrdEO	
Total	oracle.jbo.domain.Number	TOTAL	OrdEO	
PaymentTypeId	Integer	PAYMENT_TYPE_ID	OrdEO	
OrderFilled	String	ORDER_FILLED	OrdEO	
LastName	String	LAST_NAME	EmpEO	
Id1	oracle.jbo.domain.Number	ID1	EmpEO	
Name	String	NAME	CustomerEO	
Id2	oracle.jbo.domain.DBSequence	ID2	CustomerEO	
TimeToShip	oracle.jbo.domain.Number	VIEW_ATTR		Transient
PaymentOptionId	Integer	PAYMENT_OPTION_ID	OrdEO	

The OrdVO object also contains the TimeToShip transient attribute which is represented by the bars on the Summit ADF Shipping Time bar chart. The TimeToShip attribute's value is obtained by a call to the calculateTimeToShip() method: adf.object.calculateTimeToShip(DateOrdered, DateShipped). The calculateTimeToShip() method determines the number of days that the order took to ship and is added to OrdVORowImpl.java. OrdVORowImpl.java contains the implementation methods for the OrdVO view object.

The example below shows the calculateTimeToShip() method in the Summit ADF sample application. The method returns the number of days as an oracle.jbo.domain.Number, which is the type expected by the chart's value attribute.

```
public oracle.jbo.domain.Number calculateTimeToShip(Date ordered,
Date shipped) {
  if (null != shipped) {
    long days = (shipped.getTime() - ordered.getTime()) / (1000 *
60 * 60 * 24);
    return new Number(days);
  } else
    return new Number(0);
}
```

For additional information about adding transient attributes to a view object, see Adding Calculated and Transient Attributes to a View Object.

- Create a JSF page as described in How to Create JSF Pages in *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound area, bar, combination, horizontal bar, or line chart:

1. From the Data Controls panel, select a collection.

   For example, to create the bar chart that displays the shipping times for each order on the Orders Dashboard page of the Summit ADF sample application, select the OrdersForCustomer collection.

2. Drag the collection onto a JSF page and, from the context menu, choose **Charts.**

3. In the Component Gallery, select a chart category and a chart type and click **OK**.

   The name of the dialog and the input field labels that appear depend on the category, type of chart, and data collection that you select. For example, if you select **Bar** as the chart category and **Bar** as the chart type, then the name of the dialog that appears is Create Bar Chart and the input fields are labeled **Bars** and **X Axis**.

4. Do the following in the dialog to configure the chart to display data:

   - Drag attributes from the **Available** list to the input fields, depending on where you want the values for the attributes to appear at runtime.

     For example, to configure the bar chart in the Summit ADF sample application to display the order dates along the X Axis, drag the DateOrdered attribute from the **Available** list to the **X Axis** field in the Create Bar Chart dialog. To configure the chart to display the time to ship as bars, drag the TimeToShip attribute from the **Available** list to the **Bars** field in the Create Bar Chart dialog.

If you selected a chart type that includes a dual y-axis, the second area, bar, or line that you add will be rendered on the second y-axis. In addition, a `chartSeriesStyle` component will be added to the chart for the series represented on the second y-axis, and the `assignedToY2` attribute of the `chartSeriesStyle` component will be set to true.

If you selected a combination chart, each attribute that you add to the Data Points input field will be rendered as an area, bar, or line chart. By default, the first attribute will be rendered as a bar chart, the second attribute will be rendered as a line chart, and the third attribute will be rendered as an area chart. To change the chart type, you can add a `chartSeriesStyle` component to the combination chart's `seriesStamp` facet.

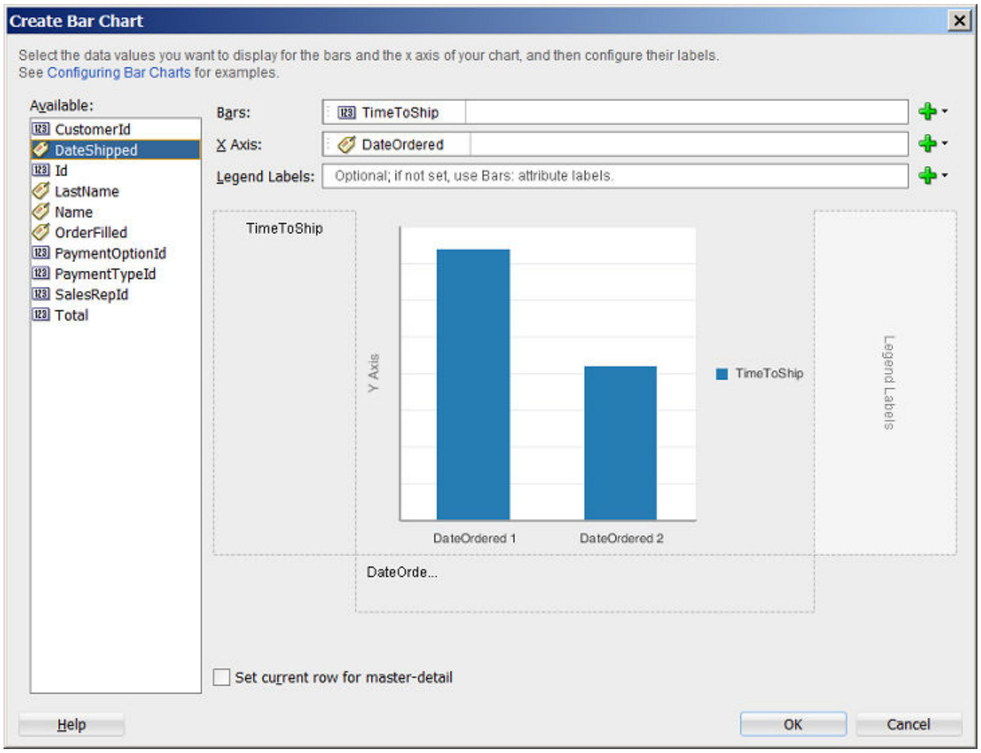
If you selected a range area or range bar chart, there will be two required fields for the y-axis. To configure the chart to display a range of data, drag attributes from the **Available** list to the **High Values** and **Low Values** fields in the Create Range Area Chart or Create Range Bar Chart dialog.

- In the **Attribute Labels** table, accept the default value or select a value from the dropdown list in the **Label** field to specify the label that appears at runtime.

  The underlying data type determines the choices available in the **Label** field. The choice you make determines how that attribute's label is rendered in the chart.

Figure 38-5 shows the Create Bar Chart dialog that generates the Summit ADF sample application Shipping Time bar chart using data from the `DateOrdered` and `TimeToShip` attributes in the `OrdersForCustomer` data collection.

Figure 38-5 Create Bar Chart Dialog for Summit ADF Shipping Time Chart



Create Bar Chart

Select the data values you want to display for the bars and the x axis of your chart, and then configure their labels.
See Configuring Bar Charts for examples.

Available:
CustomerId
DateShipped
Id
LastName
Name
OrderFilled
PaymentOptionId
PaymentTypeId
SalesRepId
Total

Bars: TimeToShip
X Axis: DateOrdered
Legend Labels: Optional; if not set, use Bars: attribute labels.

☐ Set current row for master-detail

5. Click **OK**.

After completing the data binding dialog, you can use the Properties window to specify settings for the chart attributes and you can also use the child tags associated with the chart tag to customize the chart further. For example, the legend display is turned off for the Shipping Time chart in the Summit ADF sample application. For more information about configuring chart components, see Using Chart Components in *Developing Web User Interfaces with Oracle ADF Faces*.

What Happens When You Use the Data Controls Panel to Create a Chart

Dropping a chart from the Data Controls panel has the following effect:

- Creates the bindings for the chart and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

The data binding XML that JDeveloper generates represents the physical model of the specific chart type you create. The example below shows the bindings that JDeveloper generated in the page definition file where a vertical bar chart was created using data from the `DateOrdered` and `TimeToShip` attributes in the `OrdersForCustomer` data collection.

```
<tree IterBinding="OrdersForCustomerIterator" id="OrdersForCustomer5"
      ChangeEventPolicy="ppr">
  <nodeDefinition DefName="oracle.summit.model.views.OrdVO"
                  Name="OrdersForCustomer5">
    <AttrNames>
      <Item Value="TimeToShip"/>
      <Item Value="DateOrdered"/>
    </AttrNames>
  </nodeDefinition>
</tree>
```

Charts use a standard tree binding as shown in the example. The node definition shows the name and instance of the data control (`OrdersForCustomer5`), and the view object (`OrdVO`) on which the data control is based. Each displayed attribute is listed in the `AttrNames` definition. For a chart configured for a dual y-axis, the `AttrNames` definition would include an additional item for the series displayed on the second y-axis.

The example below shows the code generated for a vertical bar chart when you drag the `OrdersForCustomer` data collection onto a JSF page and specify `DateOrdered` for the x-axis and `TimeToShip` for the bars.

```
<dvt:barChart id="barChart2" var="row"
              value="#{bindings.OrdersForCustomer5.collectionModel}">
<dvt:chartLegend id="cl2"/>
  <f:facet name="dataStamp">
    <dvt:chartDataItem id="di2" value="#{row.TimeToShip}"
                 group="#{row.DateOrdered}"

series="#{bindings.OrdersForCustomer5.hints.TimeToShip.label}"/>
  </f:facet>
</dvt:barChart>
```

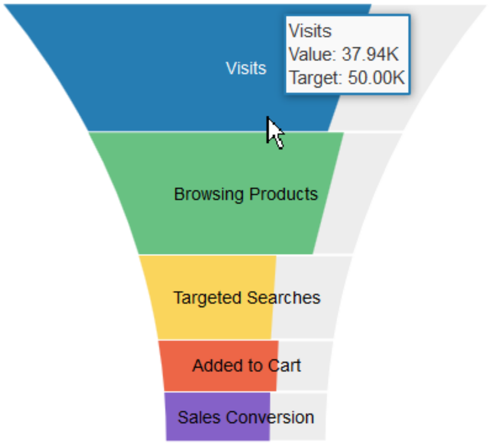
How to Create Databound Funnel Charts

A funnel chart is used to represent the steps in a process. You can create a funnel chart by using the Data Controls panel.

A funnel chart requires at least two values, with a maximum of three. The values represent the actual and target data values for each stage, and the stage value.

Figure 38-6 shows a sample funnel chart. The funnel shows the different stages in a sales conversion process for an online store. Each funnel section shows the number of customers who reached the given stage in the process versus the desired target number of customers for the stage. As the user moves over each section, a tooltip provides the numerical quantity of the actual value and target value for that stage.

Figure 38-6 Sample Funnel Chart



Before you begin:

It may be helpful to have an understanding of databound data visualization charts. For more information, see Creating Databound Charts.

You will need to complete these tasks:

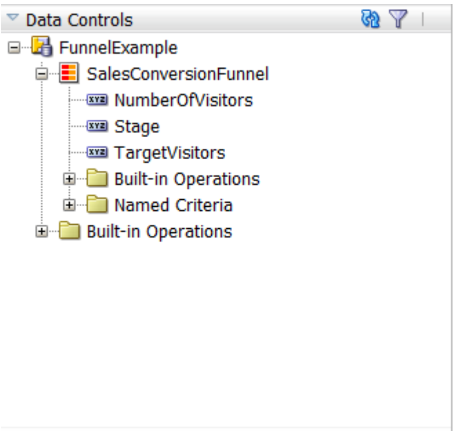
- Create an **application module** that contains instances of the **view objects** that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of the *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound funnel chart:

1. From the Data Controls panel, select a collection.

   For example, the funnel chart displayed above is made using the `SalesConversionFunnel` collection. Figure 38-7 shows the `SalesConversionFunnel` collection in the Data Controls panel.

Figure 38-7 Data Collection for SalesConversionFunnel Collection



Data Controls
- FunnelExample
  - SalesConversionFunnel
    - NumberOfVisitors
    - Stage
    - TargetVisitors
    - Built-in Operations
    - Named Criteria
  - Built-in Operations

2. Drag the collection onto a JSF page and, from the context menu, choose **Charts.**
3. In the Component Gallery, select the funnel chart category and a chart type and click **OK**.

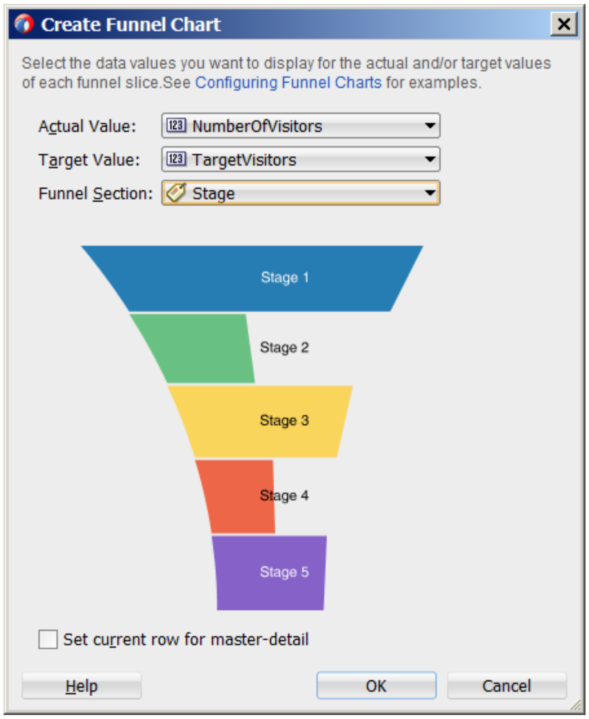
   For example, select the **Funnel** chart category and the **Funnel** chart type to create a vertical funnel chart.
4. Do the following in the dialog to configure the chart to display data:
   - From the dropdown menus of the **Actual Value** and **Target Value** fields, select an attribute to represent series of data.

     For example, to configure the funnel chart in the sample, select the `NumOfVisitors` attribute from the **Actual Value** field's dropdown menu, and the `TargetVisitors` attribute from the **Target Value** field's dropdown menu.
   - From the dropdown menu of the **Funnel Section** field, select an attribute to represent a group of data.

     For example, to configure the funnel chart in the sample, select the `Stage` attribute from the **Funnel Section** field's dropdown menu.

   Figure 38-8 shows the Create Funnel Chart dialog that generates a funnel chart using the `NumberOfVisitors`, `TargetVisitors`, `Stage` attributes in the `SalesConversionFunnel` collection.

Figure 38-8 Create Funnel Chart for SalesConversionFunnel



Create Funnel Chart
Select the data values you want to display for the actual and/or target values of each funnel slice.See Configuring Funnel Charts for examples.

Actual Value: NumberOfVisitors

Target Value: TargetVisitors

Funnel Section: Stage

□ Set current row for master-detail

5. Click **OK**.

The example below shows the code generated for the funnel chart when you drag the `SalesConversionFunnel` data collection onto a JSF page and specify `NumOfVisitors` for the **Actual Value** attribute, `TargetVisitors` for the **Target Value** attribute and `Stage` for the **Funnel Section**.

```
<dvt:funnelChart id="funnelChart1" var="row"
         value="#{bindings.SalesConversionFunnel.collectionModel}">
<dvt:funnelDataItem id="di1" value="#{row.NumberOfVisitors}"
                             targetValue="#{row.TargetVisitors}"
                             label="#{row.Stage}"/>
</dvt:funnelChart>
```

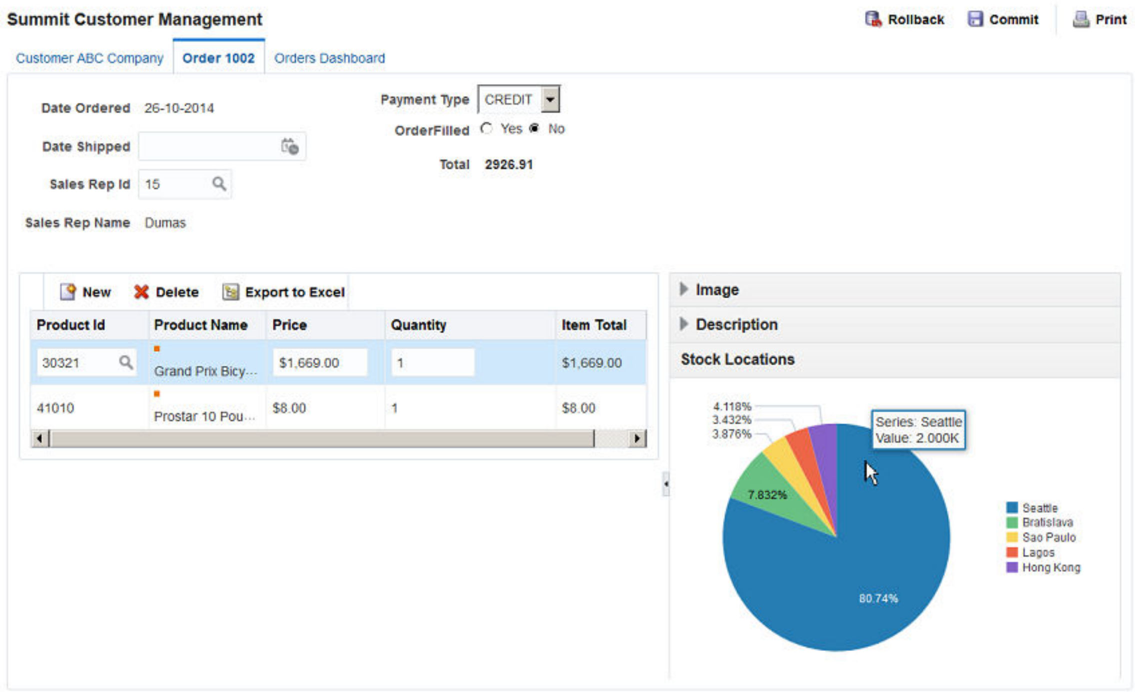
After completing the data binding dialog, you can use the Property Inspector to specify settings for the chart attributes and you can also use the child tags associated with the chart tag to customize the chart further. For more information about configuring chart components, see the Using Chart Components section in the *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create Databound Pie Charts

A pie chart displays one group of data, each slice representing a different series. This chart type requires one column, with multiple rows, one for each slice. You can create a pie chart using the Data Controls panel.

Figure 38-9 shows a pie chart in the Summit ADF sample application that displays the inventory available for the ordered item at each stock location as a percentage of the total available inventory for the item. As the user moves the mouse over each slice, a tooltip shows the actual quantity at the location. The column of data in this example represents the total inventory for the ordered item, and the slices represent the inventory levels at each stocking location.

Figure 38-9 Pie Chart Showing Inventory Levels at Stock Locations



Summit Customer Management

Customer ABC Company | Order 1002 | Orders Dashboard

Date Ordered	26-10-2014	Payment Type	CREDIT
Date Shipped		OrderFilled	○ Yes ● No
Sales Rep Id	15	Total	2926.91
Sales Rep Name	Dumas		

Product Id	Product Name	Price	Quantity	Item Total
30321	Grand Prix Bicy...	$1,669.00	1	$1,669.00
41010	Prostar 10 Pou...	$8.00	1	$8.00

Before you begin:

It may be helpful to have an understanding of databound data visualization charts. For more information, see Creating Databound Charts.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

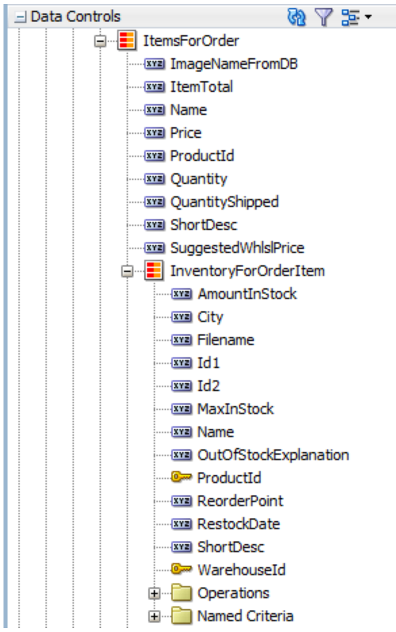
- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound pie chart:

1. From the Data Controls panel, select a collection.

   For example, to create the pie chart that displays the inventory levels at each stock location in the Summit Customer Management page of the Summit ADF sample application, select the **BackOfficeAppModuleDataControl** > **Customers** > **OrdersForCustomer** > **ItemsForOrder** > **InventoryForOrderItem** collection. Figure 38-10 shows the `InventoryForOrderItem` collection in the Data Controls panel.

Figure 38-10   Data Collection for InventoryForOrderItem Collection



- Data Controls
  - ItemsForOrder
    - ImageNameFromDB
    - ItemTotal
    - Name
    - Price
    - ProductId
    - Quantity
    - QuantityShipped
    - ShortDesc
    - SuggestedWhlslPrice
    - InventoryForOrderItem
      - AmountInStock
      - City
      - Filename
      - Id1
      - Id2
      - MaxInStock
      - Name
      - OutOfStockExplanation
      - ProductId
      - ReorderPoint
      - RestockDate
      - ShortDesc
      - WarehouseId
      - Operations
      - Named Criteria

2. Drag the collection onto a JSF page and, from the context menu, choose **Charts.**
3. In the Component Gallery, select the **Pie** chart category and a chart type and click **OK**.

   For example, select the **Pie** chart category and the **Pie** chart type to create the pie chart in Figure 38-9.
4. Do the following in the Create Pie Chart dialog to configure the pie chart to display data:
   - From the **Pie** field's dropdownx‘ menu, select an attribute to represent the column of data.

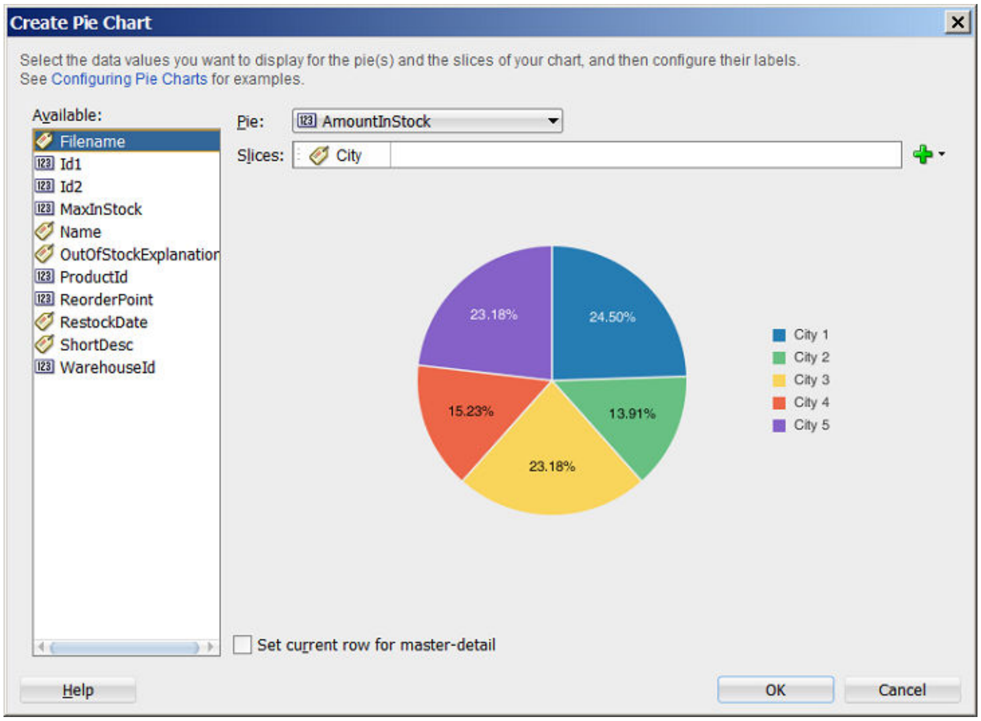
     For example, to configure the pie chart in the Summit ADF sample application to display inventory levels, select the `AmountInStock` attribute from the **Pie** field's dropdown menu.
   - Drag attributes from the **Available** list to the **Slices** field, depending on where you want the values for the attributes to appear at runtime.

     For example, to configure the pie chart in the Summit ADF sample application to display the ordered item's inventory levels at each stock location, drag the `City` attribute from the **Available** list to the **Slices** field in the Create Pie Chart dialog.
   - In the **Attribute Labels** table, accept the default value or select a value from the dropdown list in the **Label** field to specify the label that appears at runtime.

     The underlying data type determines the choices available in the **Label** field. The choice you make determines how that attribute's label is rendered in the chart. For more information, see What You May Need to Know About Using Attribute Labels.

   Figure 38-11 shows the Create Pie Chart dialog that generates a pie chart using the `AmountInStock` and `City` attributes in the `InventoryForOrderItem` collection.

Figure 38-11 Create Pie Chart for InventoryForOrderItem



Create Pie Chart

Select the data values you want to display for the pie(s) and the slices of your chart, and then configure their labels.
See Configuring Pie Charts for examples.

Pie: AmountInStock

Slices: City

☐ Set current row for master-detail

5. Click **OK**.

   The example below shows the code generated for the pie chart when you drag the `InventoryForOrderItem` data collection onto a JSF page and specify `AmountInStock` for the **Pie** value and `City` for the **Slices**.

```
<dvt:pieChart id="pieChart1" var="row"

value="#{bindings.InventoryForOrderItem1.collectionModel}">
  <dvt:chartLegend/>
  <dvt:pieDataItem id="di1" value="#{row.AmountInStock}"
label="#{row.City}"/>
</dvt:pieChart>
```

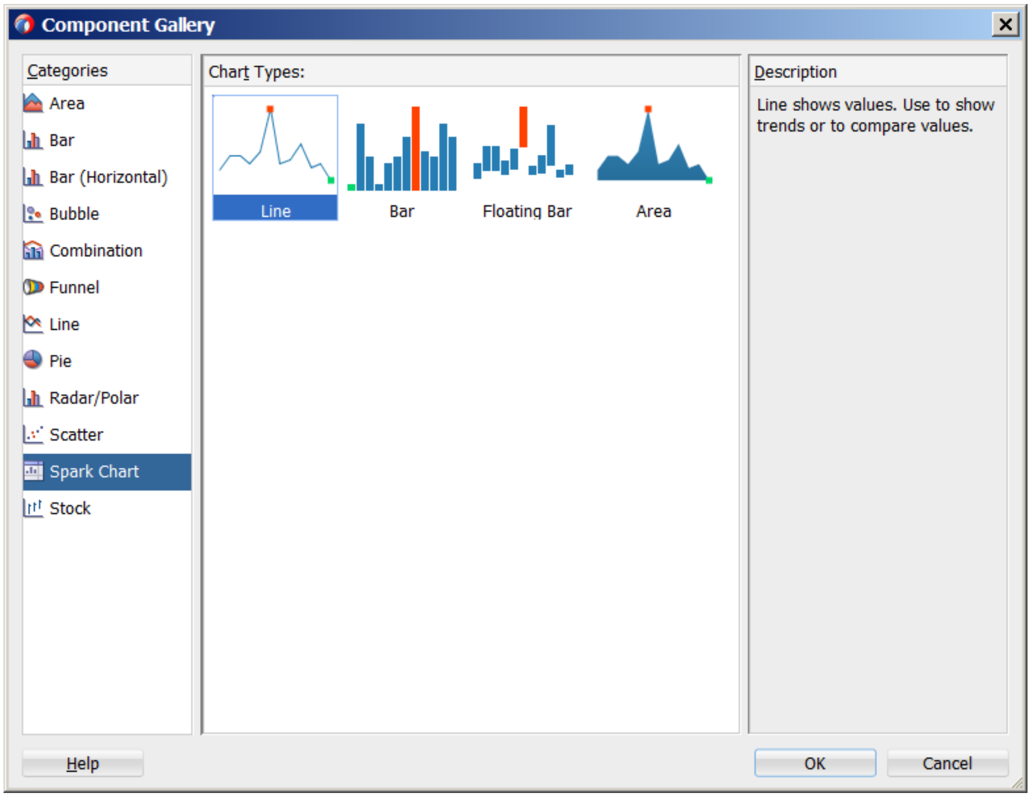
After completing the data binding dialog, you can use the Properties window to specify settings for the chart attributes and you can also use the child tags associated with the chart tag to customize the chart further. For example, you can configure an exploding pie slice which causes one slice of the pie to appear separated from the other slices. For more information, see Using Chart Components in *Developing Web User Interfaces with Oracle ADF Faces*.

Creating a Databound Spark Chart Using Data Controls

Spark charts are simple, condensed charts that display trends or variations, often in the column of a table, or inline with text. You can create a sparkchart by inserting a data control from the Data Controls Panel.

Figure 38-12 shows the Component Gallery that displays when you drag a spark chart onto your page from the Data Controls panel.

Figure 38-12 Create Spark Chart Component Gallery



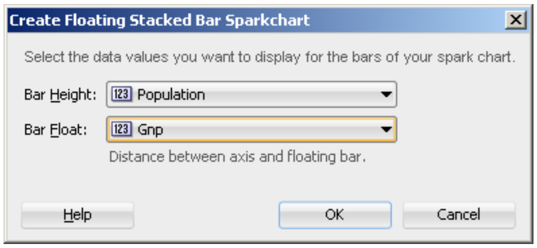
Line shows values. Use to show trends or to compare values.

A binding dialog prompts you to specify the value you wish to display for the selected spark chart type. Line, bar, and area spark charts require a single series of data values, for example the changing value of a stock. Floating bar spark charts require two series of data values, one for the float offset, and one for the bar value. For example, in the Create Floating Stacked Bar Sparkchart dialog you specify:

- **Bar Height**: Use to select the data value to use for the bar value.
- **Bar Float**: Use to select the data value to use for the float offset, the distance between the axis and the floating bar.

Figure 38-13 shows a completed Create Floating Stacked Bar Sparkchart dialog.

Figure 38-13 Sparkchart Binding Dialog



Select the data values you want to display for the bars of your spark chart.

Bar Height: Population

Bar Float: Gnp

Distance between axis and floating bar.

In a simple UI-first development scenario you can insert a sparkchart using the Components window and bind it to data afterwards. For additional information about providing data to spark charts, see How to Add Data to Spark Charts in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create Databound Bubble and Scatter Charts

Bubble and scatter charts represent data by the location of the data marker. Bubble charts also use the size of the markers to represent an additional aspect of the data.

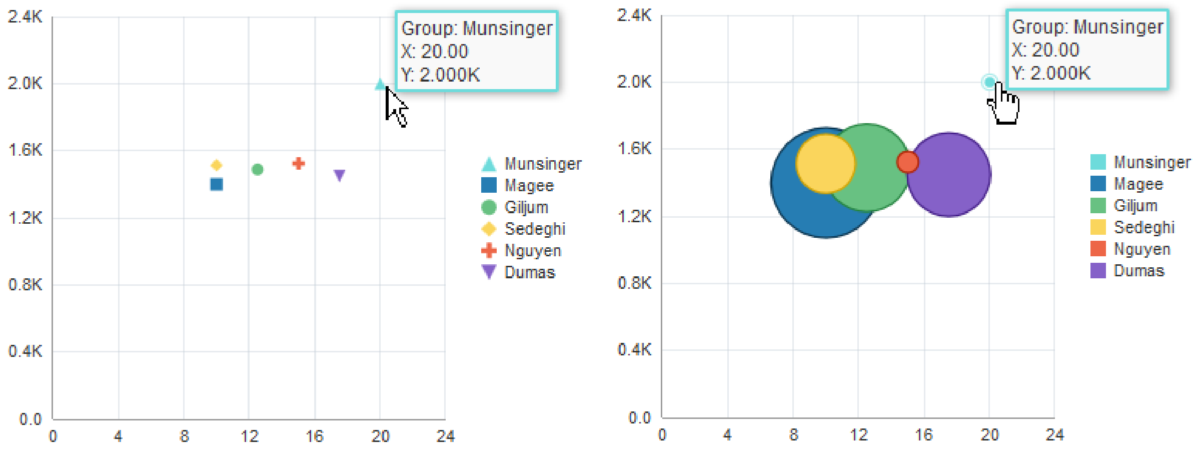
Scatter charts require at least two data values for each marker. Bubble charts require an additional data value for the marker size. Each data marker represents the following:

- The x value that determines the marker's location along the x-axis.
- The y value that determines the marker's location along the y-axis.
- The z value that determines the size of the marker on bubble charts

For more than one group of data, the data must be in multiples of two for scatter charts and three for bubble charts.

Figure 38-14 shows a scatter and a bubble chart displaying salary and commission for salesmen in the Summit organization. In this example, the x value is determined by the commission, and the y value is determined by the salary. The bubble chart is configured to use the salesmen's total sales for the z value. In this example, Magee has the lowest salary and commission but is the salesman with the highest sales total.

Figure 38-14 Databound Scatter and Bubble Chart Examples



Before you begin:

It may be helpful to have an understanding of databound data visualization charts. For more information, see Creating Databound Charts.

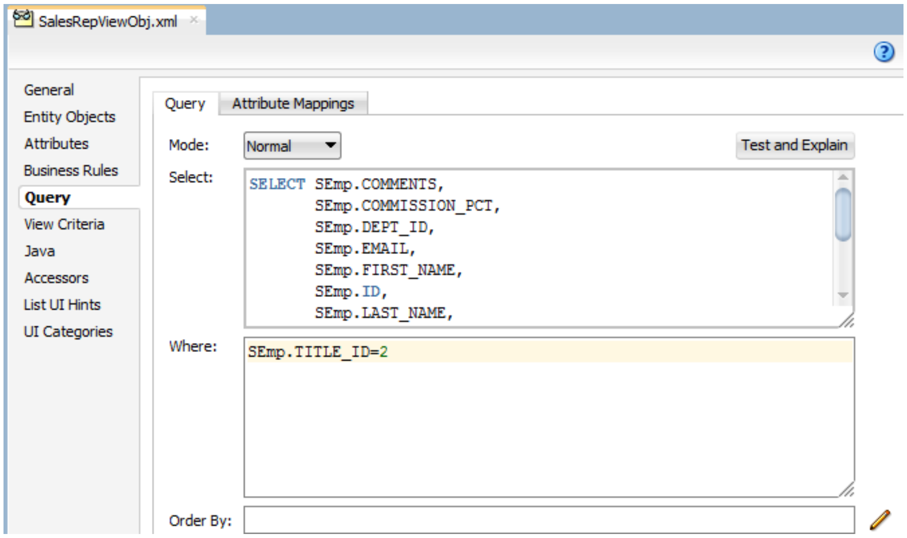
You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.

  For example, the bubble and scatter charts in Figure 38-14 in uses a top level view object based on the `SEmp` entity in the Summit ADF DVT sample application. In this example, the view object retrieves all sales representatives in the Summit ADF employee database by retrieving all employee records with a `TITLE_ID` of `2`. Figure 38-15 shows the `SalesRepViewObj` view object.

Figure 38-15 SalesRepViewObj View Object in Summit DVT Sample Application



Mode: Normal

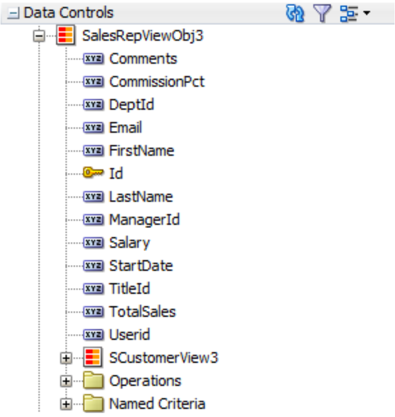
Select:
```
SELECT SEmp.COMMENTS,
       SEmp.COMMISSION_PCT,
       SEmp.DEPT_ID,
       SEmp.EMAIL,
       SEmp.FIRST_NAME,
       SEmp.ID,
       SEmp.LAST_NAME,
```

Where:
```
SEmp.TITLE_ID=2
```

Order By:

Figure 38-16 shows the `SalesRepViewObj3` data control.

Figure 38-16 SalesRepViewObj3 Data Control in Summit DVT Sample Application



```
Data Controls
  SalesRepViewObj3
    Comments
    CommissionPct
    DeptId
    Email
    FirstName
    Id
    LastName
    ManagerId
    Salary
    StartDate
    TitleId
    TotalSales
    Userid
    SCustomerView3
    Operations
    Named Criteria
```

The `TotalSales` attribute is a transient attribute that calculates the salesman's total sales from the `Total` attribute in the `SOrdView` view object: `SOrdView.sum`

('Total'). For information about adding transient attributes to view objects, see Adding Calculated and Transient Attributes to a View Object.

- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound bubble or scatter chart:

1. From the Data Controls panel, select a collection.

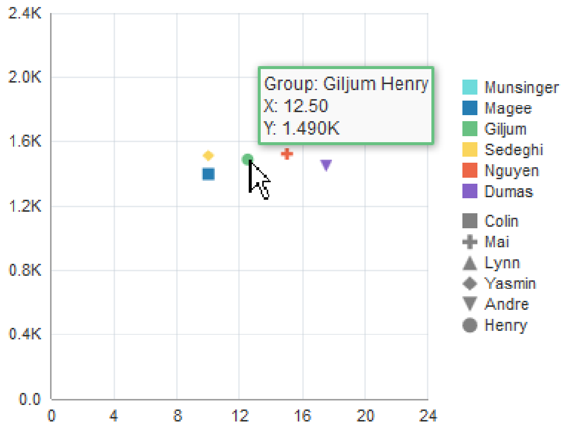
   For example, to create the bubble or scatter chart shown in Figure 38-14, select the SalesRepViewObj3 collection.
2. Drag the collection onto a JSF page and, from the context menu, choose **Charts.**
3. In the Component Gallery, select the bubble or scatter chart category and a chart type and click **OK**.
4. In the Create Bubble Chart or Create Scatter Chart dialog, do the following in the dialog to configure the bubble or scatter chart axis values:
   - In the **X Axis Data Point** field, use the dropdown list to specify the attribute in the data collection to use for the x-axis data point.

     For example, to configure the bubble or scatter chart to display the commission percent along the X Axis, select **CommissionPct** from the dropdown list.
   - In the **Y Axis Data Point** field, use the dropdown list to specify the attribute in the data collection to use for the y-axis data point.
   - For bubble charts, in the **Z Axis Data Point** field, use the dropdown list to specify the attribute in the data collection to use for the z-axis data point.
5. If you are configuring a scatter chart, in the Markers section, do the following in the dialog to configure the scatter chart's color, shape, and tooltip:
   - Select **Automatically** to use system-generated values for color/shape combinations. Select **Manually** to use distinct attributes to determine color and shape.

     If you select **Manually**, select the attributes in the dropdown list for **Marker Color** and **Marker Shape**.

     For example, you could select LastName and FirstName to be used for Marker Color and Marker Shape for the scatter chart displayed in Figure 38-14. When the scatter chart is rendered, the legend will contain entries for both the color and shape as shown in Figure 38-17. The scatter chart's tooltip displays the value associated with both the marker and shape attributes.

Figure 38-17 Scatter Chart Configured Manually for Color and Shape



- From the **Marker Type** field's dropdown list, specify one or more attributes in the data collection that determine the values that appear in the legend of the scatter chart. Each attribute will be represented by its own color/shape combination in the scatter chart's legend. You can drag and drop attributes from the **Available** list, or select from the **Add** dropdown list.

  After specifying attributes for the input field, you can right click on any attribute to display a context menu for actions such as **Move Right**, **Move Left**, **Delete**, or **Treat as Text**.

- From the **Marker Tooltip** field's dropdown list, select the attribute to use for the scatter chart's tooltip.

6. If you are configuring a bubble chart, in the Markers section, do the following in the dialog to configure the bubble colors and tooltip:

   - Select **Automatically** to use system-generated values for color. Select **Manually** to use distinct attributes to determine color and shape.

     If you select **Manually**, select the attribute in the dropdown list for **Marker Color** and **Marker Shape**.

   - If you selected **Automatically**, from the **Bubble Color** field's dropdown list, specify one or more attributes in the data collection that determine the values that appear in the legend of the bubble chart. Each attribute will be represented by its own color in the bubble chart's legend. You can drag and drop attributes from the **Available** list, or select from the **Add** dropdown list.

     After specifying attributes for the input field, you can right click on any attribute to display a context menu for actions such as **Move Right**, **Move Left**, **Delete**, or **Treat as Text**.

   - From the **Bubble Tooltip** field's dropdown list, select the attribute to use for the bubble chart's tooltip.

     By default, the bubble chart's tooltip will display the attribute or attributes associated with the bubble chart's legend. For example, the bubble chart's tooltip in Figure 38-14 shows the last name of the salesman for the Group. You can select a different attribute in the collection to be used for the Group item in the tooltip.

7. In the **Attribute Labels** table, accept the default value or select a value from the dropdown list in the **Label** field to specify the label that appears at runtime.

The underlying data type determines the choices available in the **Label** field. The choice you make determines how that attribute's label is rendered in the chart. For more information, see What You May Need to Know About Using Attribute Labels.

8. Click **OK**.

Figure 38-18 shows the Create Bubble Chart dialog that generates a bubble chart using data from the `CommissionPct`, `Salary`, and `Total Sales` attributes in the `SalesRepViewObj3` data collection.

Figure 38-18 Create Bubble Chart Dialog

</dvt:bubbleChart>
```

If you chose to configure the scatter chart manually using attributes from the data collection for marker and shape, JDeveloper adds an additional `dvt:legendSection` and `dvt:attributeGroups` tag to the JSF page. The example below shows the revised code, with the modified entries highlighted in bold.

```
<dvt:scatterChart id="scatterChart1" var="row"
                  value="#{bindings.SalesRepViewObj3.collectionModel}">
  <dvt:chartLegend rendered="true" id="cl1">
    <dvt:legendSection source="ag1" id="ls1"/>
    <dvt:legendSection source="ag2" id="ls2"/>
  </dvt:chartLegend>
  <f:facet name="dataStamp">
    <dvt:chartDataItem id="di1" group="#{row.LastName} #{row.FirstName}"
                       x="#{row.CommissionPct}"
                       y="#{row.Salary}">
      <dvt:attributeGroups id="ag1" value="#{row.LastName}"
type="color"/>
      <dvt:attributeGroups id="ag2" value="#{row.FirstName}"
type="shape"/>
    </dvt:chartDataItem>
  </f:facet>
</dvt:scatterChart>
```

After completing the data binding dialog, you can use the Properties window to specify settings for the chart attributes, and you can also use the child tags associated with the chart tag to customize the chart further. For example, you can specify where you want the chart's legend to appear. For more information, see Using Chart Components in *Developing Web User Interfaces with Oracle ADF Faces*.

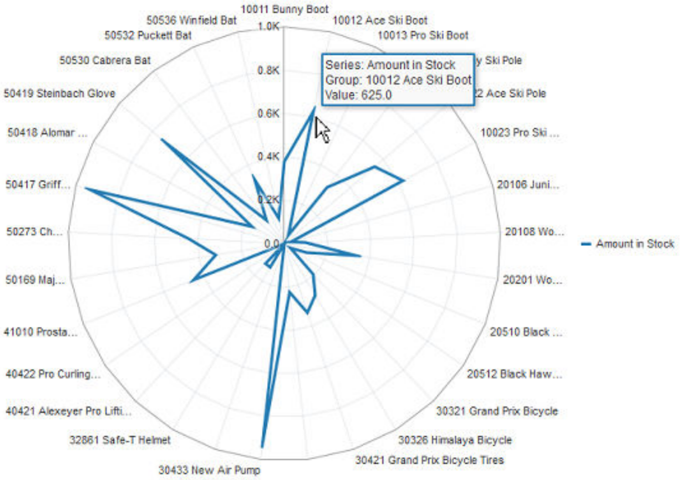
How to Create Databound Polar and Radar Charts

Polar and Radar charts are variations of the line, bar, area, bubble and scatter charts. You can create a polar or radar chart using the Data Controls panel.

The requirements of polar and radar charts vary based on the type of chart used. Radar line, radar area, and polar bar charts require at least two groups of data, with one or more series. Polar scatter charts require at least two data values to indicate position, while polar bubble charts require three values - two for position and one for bubble size.

Figure 38-20 shows a sample polar line chart, configured to show the available inventory levels of different products against the product ID and name.

Figure 38-20   Sample Polar Bar Chart



Before you begin:

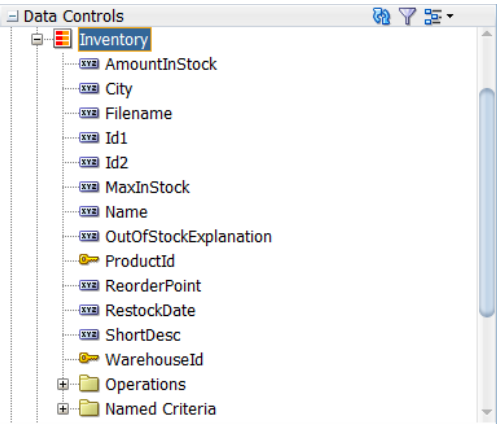
It may be helpful to have an understanding of databound data visualization charts. For more information, see Creating Databound Charts.

You will need to complete these tasks:

- Create an **application module** that contains instances of the **view objects** that you want in your data model, as described in Creating and Modifying an Application Module.

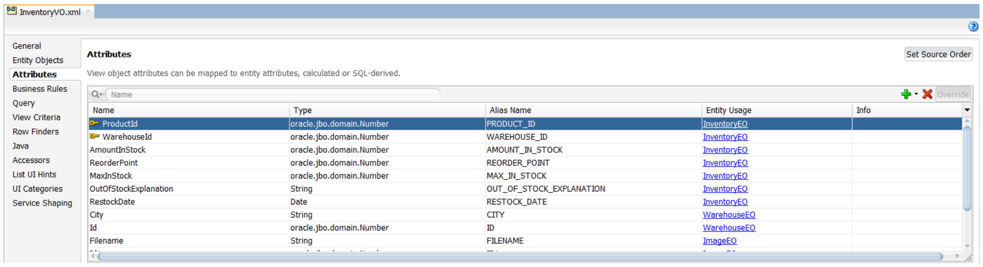
  For example, the sample polar bar chart is based on the `Inventory` data collection. Figure 38-21 shows the `Inventory` collection in the Data Controls panel.

Figure 38-21   Data Collection for Inventory



The Inventory data collection is based on the `InventoryVO` view object. Figure 38-22 shows the `InventoryVO` view object.

Figure 38-22 InventoryVO View Object in Summit Sample Application



Attributes

View object attributes can be mapped to entity attributes, calculated or SQL-derived.

Name	Type	Alias Name	Entity Usage	Info
ProductId	oracle.jbo.domain.Number	PRODUCT_ID	InventoryEO	
WarehouseId	oracle.jbo.domain.Number	WAREHOUSE_ID	InventoryEO	
AmountInStock	oracle.jbo.domain.Number	AMOUNT_IN_STOCK	InventoryEO	
ReorderPoint	oracle.jbo.domain.Number	REORDER_POINT	InventoryEO	
MaxInStock	oracle.jbo.domain.Number	MAX_IN_STOCK	InventoryEO	
OutOfStockExplanation	String	OUT_OF_STOCK_EXPLANATION	InventoryEO	
RestockDate	Date	RESTOCK_DATE	InventoryEO	
City	String	CITY	WarehouseEO	
Id	oracle.jbo.domain.Number	ID	WarehouseEO	
Filename	String	FILENAME	ImageEO	

- Create a JSF page as described in the How to Create JSF JSP Pages section of the *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound radar or polar chart:

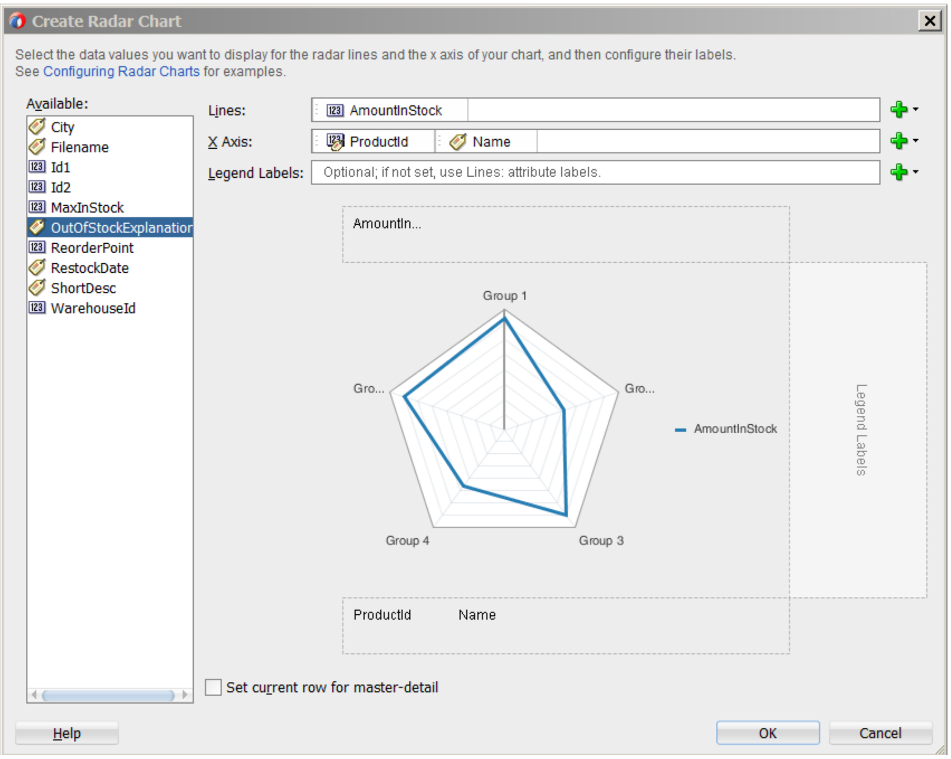
1. From the Data Controls panel, select a collection.
2. Drag the collection onto a JSF page and, from the context menu, choose **Charts.**
3. In the Component Gallery, select the Radar/Polar chart category and a chart type and click **OK**.

   For example, select the **Radar/Polar** chart category and the **Radar** chart type to create a radar line chart.
4. If configuring a polar line, area or bar chart, do the following:
   - Drag attributes from the **Available** list to the input fields, depending on how you want the values for the attributes to appear at runtime.

     For example, to configure the polar bar chart in the sample application to display the inventory levels, drag the `AmountInStock` attribute from the **Available** list to the **Bars** field in the Create Bar Chart dialog. To configure the chart to display the product ID and name, drag the `ProductId` and `Name` attributes from the **Available** list to the **X Axis** field in the Create Bar Chart dialog.
5. Click **OK**.

Figure 38-23 shows the Create Radar Chart dialog that generates a polar line chart using data from the `AmountInStock`, `ProductId`, and `Name` attributes in the `Inventory` data collection.

Figure 38-23   Create Radar Chart Dialog



Create Radar Chart

Select the data values you want to display for the radar lines and the x axis of your chart, and then configure their labels.
See Configuring Radar Charts for examples.

Available:
- City
- Filename
- Id1
- Id2
- MaxInStock
- OutOfStockExplanation
- ReorderPoint
- RestockDate
- ShortDesc
- WarehouseId

Lines: AmountInStock

X Axis: ProductId Name

Legend Labels: Optional; if not set, use Lines: attribute labels.

□ Set current row for master-detail

The example below shows the code generated for the bubble and scatter charts when you drag the `Inventory` data collection onto a JSF page and specify `AmountInStock` for the **Y Axis Data Point**, and `ProductId` and `Name` for the **Y Axis Data Point**. Notice that radar and polar charts do not have a separate tag, but are rather basic charts with the `coordinateSystem` attribute set to `polar`.

```
<dvt:lineChart coordinateSystem="polar" polarGridShape="polygon"
id="lineChart1" var="row" value="#{bindings.Inventory.collectionModel}">
 <f:facet name="dataStamp">
  <dvt:chartDataItem id="di1"
series="#{bindings.Inventory.hints.AmountInStock.label}"
value="#{row.AmountInStock}" group="#{row.ProductId} #{row.Name}"/>
 </f:facet>
</dvt:lineChart>
```

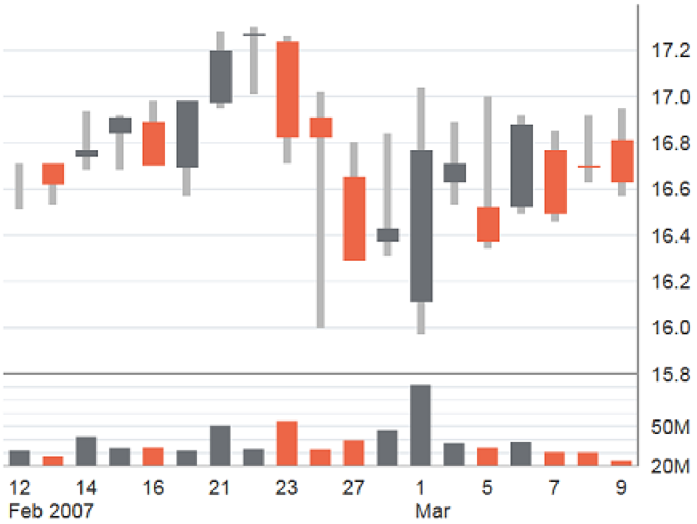
After completing the data binding dialog, you can use the Property Inspector to specify settings for the chart attributes and you can also use the child tags associated with the chart tag to customize the chart further. For more information about configuring chart components, see the Using Chart Components section in the *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create Databound Stock Charts

Stock charts are used to track the period milestone values of trade stocks, such as the high, low, opening and closing prices of a stock. You can create a stock chart by using the Data Controls panel.

Depending on the type of chart chosen, stock charts require a minimum of four values to a maximum of seven values. Figure 38-24 shows a sample stock chart configured to show stocks and their opening value, closing value, high value, low value, time period, and trade volume. As the user moves over each stock, a tooltip provides the numerical quantity of all values for that stock.

Figure 38-24 Sample Stock Chart



Before you begin:

It may be helpful to have an understanding of databound data visualization charts. For more information, see Creating Databound Charts.

You will need to complete these tasks:

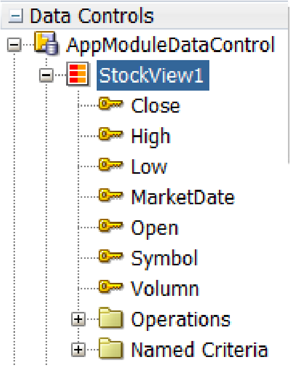
- Create an **application module** that contains instances of the **view objects** that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of the *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound stock chart:

1. From the Data Controls panel, select a collection.

   For example, the stock chart displayed above is made using the `StockView1` collection. Figure 38-25 shows the `StockView1` collection in the Data Controls panel.

Figure 38-25 Data Control for StockView1 Collection



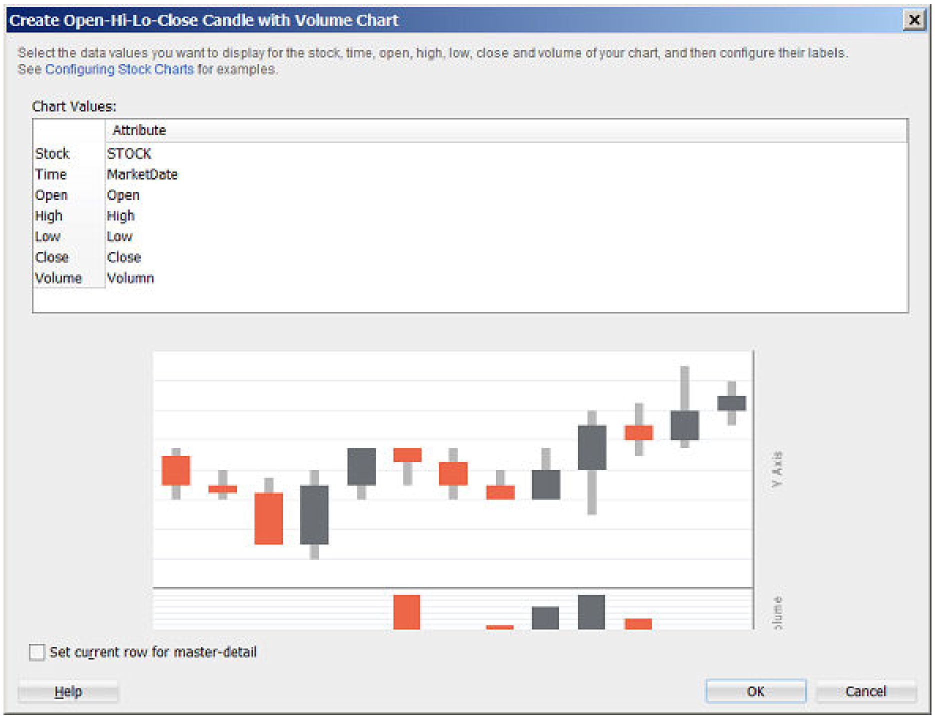
- Data Controls
  - AppModuleDataControl
    - StockView1
      - Close
      - High
      - Low
      - MarketDate
      - Open
      - Symbol
      - Volumn
      - Operations
      - Named Criteria

2. Drag the collection onto a JSF page and, from the context menu, choose **Charts**.
3. In the Component Gallery, select the Stock chart category and a chart type and click **OK**.

   For example, to create the chart configured in the sample, select the Stock chart category and the Open-Hi-Lo-Close Candle with Volume chart type.
4. Do the following in the dialog to configure the chart to display data:
   - From the **Stock** field's dropdown menu, select an attribute to represent the name of the stock. You may use the **Select Text Resource** option to enter a text value or use the **Expression Builder** to provide a JSF expression.
   - Depending on the type of stock chart chosen, a selection of labels will be shown. For each label, select an attribute from that label's dropdown menu. For example, to configure the chart from the example above, select the `Open`, `High`, `Low`, `Close`, `Volume`, and `MarketDate` attributes for the **Open**, **High**, **Low**, **Close**, **Volume**, and **Time** labels respectively.

     Figure 38-26 shows the Create Chart Dialog for the stock chart configured in the sample above.

Figure 38-26 Create Chart Dialog for StockView1 Collection



Create Open-Hi-Lo-Close Candle with Volume Chart

Select the data values you want to display for the stock, time, open, high, low, close and volume of your chart, and then configure their labels. See Configuring Stock Charts for examples.

Chart Values:

	Attribute
Stock	STOCK
Time	MarketDate
Open	Open
High	High
Low	Low
Close	Close
Volume	Volumn

☐ Set current row for master-detail

5. Click **OK**.

The example below shows the code generated for the stock chart for the sample above when you drag the Stock data collection onto a JSF page and specify the given values.

```
<dvt:stockChart id="stockChart1" var="row"
value="#{bindings.StockView1.collectionModel}">
    <dvt:chartY2Axis id="cya1"/>
    <dvt:stockDataItem id="di1" volume="#{row.Volumn}"
high="#{row.High}" low="#{row.Low}" series="Stock"
                              close="#{row.Close}" open="#{row.Open}"
group="#{row.MarketDate}"/>
</dvt:stockChart>
```

After completing the data binding dialog, you can use the Property Inspector to specify settings for the chart attributes and you can also use the child tags associated with the chart tag to customize the chart further. For more information about configuring chart components, see the Using Chart Components section in the *Developing Web User Interfaces with Oracle ADF Faces*.

What You May Need to Know About Using Attribute Labels

When you configure attribute labels in the Create Chart dialog, the underlying data type determines the choices available in the **Label** field. The choice you make determines how that attribute's label is rendered in the chart.

If an attribute represents data values, then the choices in the **Label** field are:

- **Use Attribute Name**: Select to render the value as a string using the label from the `UIHints` for that attribute in the underlying `ViewObject`. This is the default selection.
- **No Label**: Select to render no label. This choice is useful if there is a single metric and you want to provide your own descriptive text on the page to describe the resulting chart.
- **Select Text Resource**: Select to open a Select Text Resource dialog to select or add a text resource to use for the label. The text resource is a translatable string from an application resource bundle. If you need help, press F1 or click **Help.**
- **Expression Builder**: Select to open the Expression Builder dialog to create an expression to be executed at runtime for the label. If you need help, press F1 or click **Help**.

If the attribute represents a category of data values, then the choices are:

- **Use Attribute Value**: Select to render the attribute values as category labels. This is the default selection.
- From the dropdown list, choose an alternate attribute for the label. For example, use **Employee Names** for labels instead of **Employee IDs**.

Creating Databound Gauges

A gauge plots a single data value, such as a sales total, stock level, temperature, or speed. Using thresholds, gauges can show state information such as acceptable or unacceptable ranges using color.

For example, a gauge value axis might show ranges colored red, yellow, and green to represent low, medium, and high states. One databound gauge component can create a single gauge or a column of gauges, depending on the number of rows in the data collection used. In a data collection, each row contains the value for a single gauge.

The Component Gallery for gauges allows you to choose from four gauge categories.

Table 38-2 ADF Gauge Categories in the Component Gallery

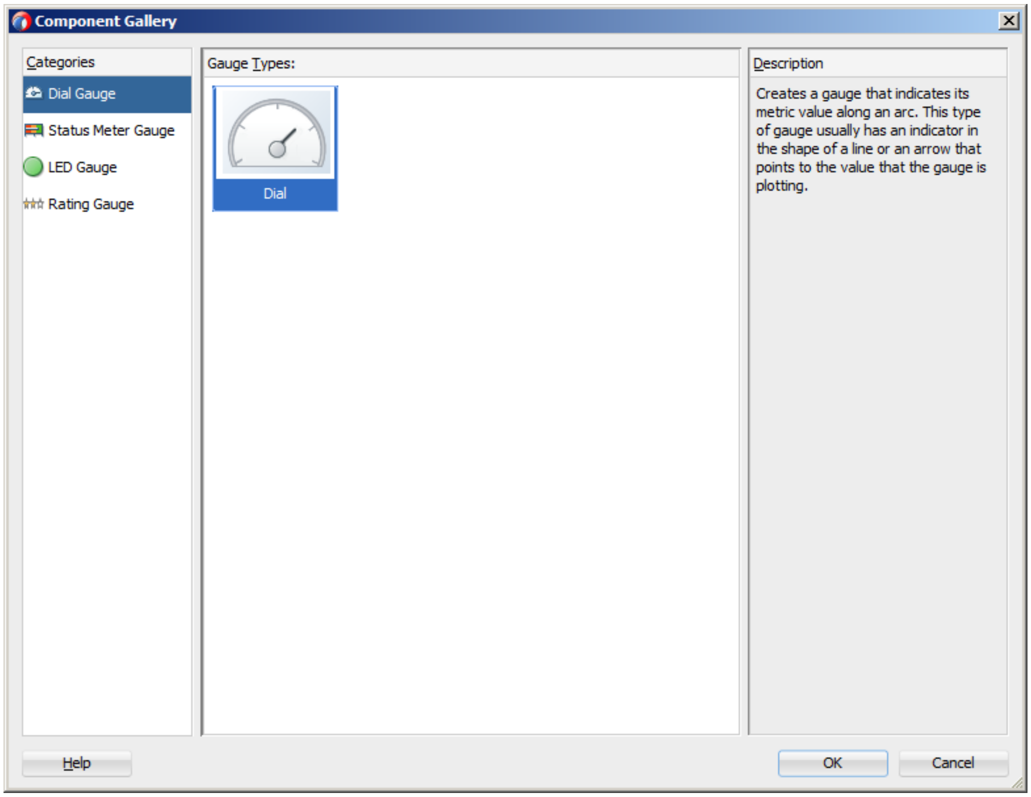
Image	Category	Description
	Dial	Displays a metric value plotted on a circular axis. The gauge's background attribute determines whether the gauge's background is displayed as a rectangle, circle, or semicircle. An indicator points to the dial gauge's metric value on the axis.
	LED	Graphically depicts a measurement, such as a key performance indicator (KPI). Several styles of shapes are available for LED gauges, including round or rectangular shapes that use color to indicate status, and triangles or arrows that point up, left, right, or down in addition to the color indicator.

Table 38-2 (Cont.) ADF Gauge Categories in the Component Gallery

Image	Category	Description
★★★ Rating Gauge	Rating	Displays and optionally accepts input for a metric value. This gauge is typically used to show ratings for products or services, such as the star rating for a movie.
Status Meter Gauge	Status Meter	Displays the metric value on a horizontal or circular axis. An inner rectangle shows the current level of a measurement against the ranges marked on an outer rectangle. Optionally, status meters can display colors to indicate where the metric value falls within predefined thresholds.

Each category contains one or more gauge types. Explore the Component Gallery that appears when you create a single gauge to view all available gauge and category types, and descriptions for each one. Figure 38-27 shows the Component Gallery that appears for ADF gauges.

Figure 38-27 ADF Gauges Component Gallery



Creates a gauge that indicates its metric value along an arc. This type of gauge usually has an indicator in the shape of a line or an arrow that points to the value that the gauge is plotting.

The data binding process is essentially the same regardless of which type of gauge you create. Only the metric value (that is, the measurement that the gauge is to indicate) is required. However, if a row in a data collection contains range information such as maximum, minimum, and thresholds, then these values can be bound to the gauge to provide dynamic settings. If information that you want to use in a gauge's upper or lower labels is available in the data collection, then you can bind these values to the gauge as well.

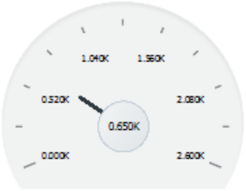
For information about customizing a gauge after the data binding is completed, see Using Gauge Components in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create a Databound Dial Gauge

You can use the ADF gauge component to create a dial gauge against a circle, dome, or rectangle background. The gauge's indicator specifies the current value of the metric.

Figure 38-28 shows a single dial gauge that appears if you create a gauge from the `AmountInStock` data for inventory items in the Summit ADF DVT sample application. The value of the `AmountInStock` metric, which is 0.650K, appears in a label in the center of the gauge

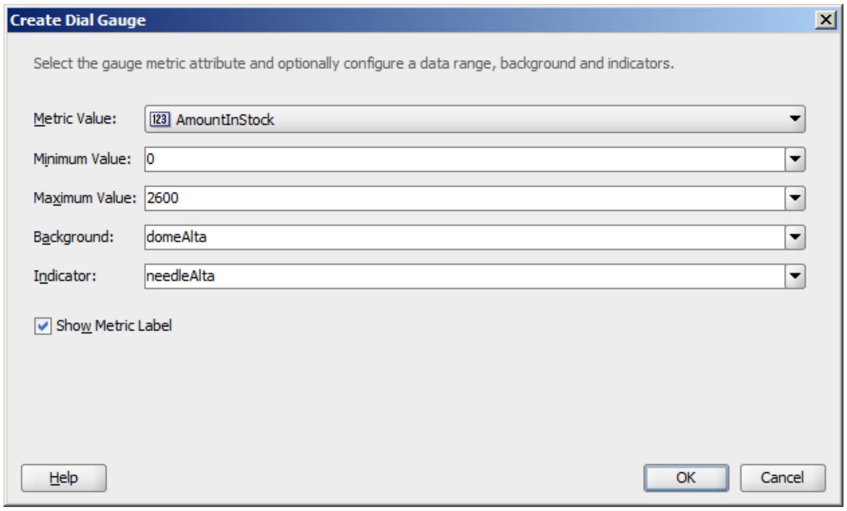
Figure 38-28 The Amount in Stock Dial Gauge



To create a dial gauge using a data control, you bind the gauge component to an attribute in a data collection. JDeveloper allows you to do this declaratively by dragging and dropping an attribute from the Data Controls panel. After you drag and drop the attribute, use the Create Dial Gauge dialog to configure the gauge.

Figure 38-29 shows the Create Dial Gauge dialog configured for the Amount in Stock dial gauge shown in Figure 38-28 and using the gauge type shown in Figure 38-27.

Figure 38-29   Create Dial Gauge Dialog for Amount in Stock Dial Gauge



Select the gauge metric attribute and optionally configure a data range, background and indicators.

Metric Value: AmountInStock
Minimum Value: 0
Maximum Value: 2600
Background: domeAlta
Indicator: needleAlta

☑ Show Metric Label

Before You Begin:

It may be helpful to have an understanding of databound data visualization gauges. For more information, see Creating Databound Gauges.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

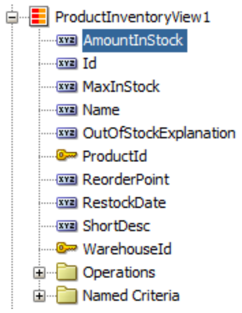
- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound dial gauge:

1. From the Data Controls panel, select an attribute from a collection.

   For example, to create a dial gauge in the Summit ADF DVT sample application to display the stock levels for an inventory item, you would select the `AmountInStock` attribute in the `ProductInventoryView1` collection. Figure 38-30 shows the `ProductInventoryView1` collection in the Data Controls panel with the `AmountInStock` attribute selected.

Figure 38-30 Data Collection with Amount in Stock for an Inventory Item



2. Drag the attribute onto a JSF page and, from the context menu, choose **Gauges**.
3. In the Component Gallery, choose the category and type of gauge, and then click **OK**.
4. In the Create Dial Gauge dialog, do the following:
   - In the **Metric** field, confirm the column in your data collection that contains the actual value that the gauge is to plot. This is the only required value in the dialog.
   - In the **Minimum** field, if your data collection stores a minimum value for the gauge range, select the column that contains this value from the dropdown list. Alternatively, specify a minimum number for the range. If you do not specify a value, the minimum defaults to `0`.
   - In the **Maximum** field, if your data collection stores a maximum value for the gauge range, select the column that contains this value from the dropdown list. Alternatively, specify a maximum value. If you do not specify a value, the maximum value defaults to `100`.
   - In the **Background** field, select a background from the dropdown list.

     Available shapes include circle, dome, and rectangle, with alta, light, antique, or dark shading. By default, the gauge's background is set to `auto` which will return the primary design for the current skin.
   - In the **Indicator** field, select an indicator style from the dropdown list.

     Available indicators include alta, antique, dark, and light. By default the indicator is set to auto which will select the indicator that matches the gauge's background.
   - In the **Show Metric Label** check box, select the **Show Metric Label** check box to show a metric label for the gauge. The metric label contains the actual metric value for the gauge. For example, if the amount in stock for a given item is 63, then the metric label will display 63.
5. Click **OK**.

In the Properties window, after you complete the binding of the gauge, you can set values for additional attributes in the gauge tag and its child tags to customize the component. For example, to configure the Amount In Stock gauge to show inventory amounts without scaling, set the `scaling` attribute of the metric and tick labels to `none`.

You can also examine and adjust the existing gauge bindings by clicking the **Edit** icon in the Properties window for the gauge component.

For additional information about customizing a gauge after the data binding is completed, see Using Gauge Components in *Developing Web User Interfaces with Oracle ADF Faces*.

What Happens When You Create a Dial Gauge from a Data Control

Dropping a gauge from the Data Controls panel has the following effect:

- Creates the bindings for the gauge and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

The example below shows the bindings that JDeveloper generated for the dial gauge that displays the inventory level for a product in a warehouse. This code example shows that the gauge metric receives its value dynamically from the `AmountInStock` attribute in the `ProductInventoryView1` data collection.

```
<bindings>
  <attributeValues IterBinding="ProductInventoryView1Iterator"
id="AmountInStock">
    <AttrNames>
      <Item Value="AmountInStock"/>
    </AttrNames>
  </attributeValues>
</bindings>
```

The example below shows the code that JDeveloper generated in the JSF page for a dial gauge.

```
<dvt:dialGauge id="dialGauge1" indicator="needleAlta" minimum="0"
               maximum="2600" background="domeAlta"
               value="#{bindings.AmountInStock.inputValue}">
  <dvt:gaugeMetricLabel rendered="true" id="gml1"/>
</dvt:dialGauge>
```

How to Create a Databound Rating Gauge

The rating gauge displays and optionally accepts input for a metric value. This gauge is typically used to show ratings for products or services, such as the star rating for a movie.

Figure 38-31 shows an example of a rating gauge used to indicate a customer's credit rating in the Summit ADF sample application. In this example, the customer has a poor credit rating and is assigned one star. Other ratings include two stars for fair credit, three stars for good credit, and four stars for excellent.

Figure 38-31   Rating Gauge in Summit ADF Sample Application

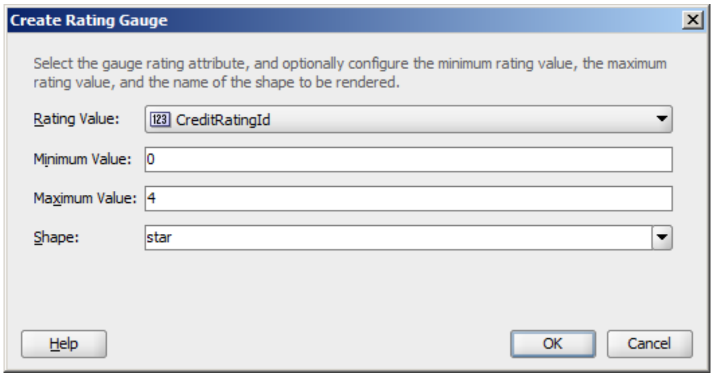
114	202	17-06-13	19-06-2013	567	CASH

To create a rating gauge using a data control, you bind the rating gauge to an attribute in a data collection. JDeveloper allows you to do this declaratively by dragging and dropping an attribute from the Data Controls panel. After you drag and drop the attribute, use the Create Rating Gauge dialog to configure the gauge.

Figure 38-32 shows the Create Rating Gauge dialog completed for the rating gauge in Figure 38-31. In this example, the rating gauge is set to a maximum value of four to reflect the four credit ratings.

Figure 38-32   Create Rating Gauge Dialog for Summit Credit Rating Gauge



Select the gauge rating attribute, and optionally configure the minimum rating value, the maximum rating value, and the name of the shape to be rendered.

Rating Value:	CreditRatingId
Minimum Value:	0
Maximum Value:	4
Shape:	star

Before You Begin:

It may be helpful to have an understanding of databound data visualization gauges. For more information, see Creating Databound Gauges.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound rating gauge:

1. From the Data Controls panel, select an attribute from a collection.

   For example, to create the rating gauge in the Summit ADF sample application to display the credit ratings for a customer, you would select the `CreditRatingId` attribute in the `Customer` collection. Figure 38-30 shows the `Customer` collection in the Data Controls panel with the `CreditRatingId` attribute selected.

   Figure 38-33 Data Collection with Amount in Stock for an Inventory Item

   Data Controls
   Customers
   Address
   City
   Comments
   CountryId
   CreditRatingId
   Id
   LastName
   Name
   OrderAverage
   Phone
   SalesRepId
   State
   ZipCode
   OrdersForCustomer
   unsetCustomerViewCriteria()
   Operations
   Named Criteria

2. Drag the attribute onto a JSF page and, from the context menu, choose **Gauges**.
3. In the Component Gallery, choose the category and type of gauge, and then click **OK**.
4. In the Create Rating Gauge dialog, do the following:
   - In the **Rating Value** field, confirm the column in your data collection that contains the actual value that the gauge is to plot. This is the only required value in the dialog.
   - In the **Minimum** field, if your data collection stores a minimum value for the gauge range, select the column that contains this value from the dropdown list. Alternatively, specify a minimum number for the range. If you do not specify a value, the minimum defaults to `0`.
   - In the **Maximum** field, if your data collection stores a maximum value for the gauge range, select the column that contains this value from the dropdown

list. Alternatively, specify a maximum value. If you do not specify a value, the maximum value defaults to 5.

- In the **Shape** field, select a background from the dropdown list.

  Available shapes include circle, diamond, rectangle, and star.

5. Click **OK**.

In the Properties window, after you complete the binding of the gauge, you can set values for additional attributes in the gauge tag and its child tags to customize the component. For example, to configure the rating gauge to allow the customer's credit rating to be updated, set the `readOnly` attribute of the rating gauge to `false`.

In the Summit ADF example, the rating gauge's value was set to the `CreditRatingId` during creation. However, the `CreditRatingId` actually ranges between 1 and 4, with 1 being the highest rating. To convert the rating to stars for the rating gauge, edit the source code in the Code Editor after the gauge is credited and replace the rating gauge's value with: `#{5 - bindings.CreditRatingId.inputValue}`.

The example below shows the code on the JSF page for the Summit ADF rating gauge.

```
<dvt:ratingGauge id="ratingGauge1" minimum="0" maximum="4"
                 value="#{5 - bindings.CreditRatingId.inputValue}"
shape="star"/>
```

You can also examine and adjust the existing gauge bindings by clicking the **Edit** icon in the Properties window for the gauge component.

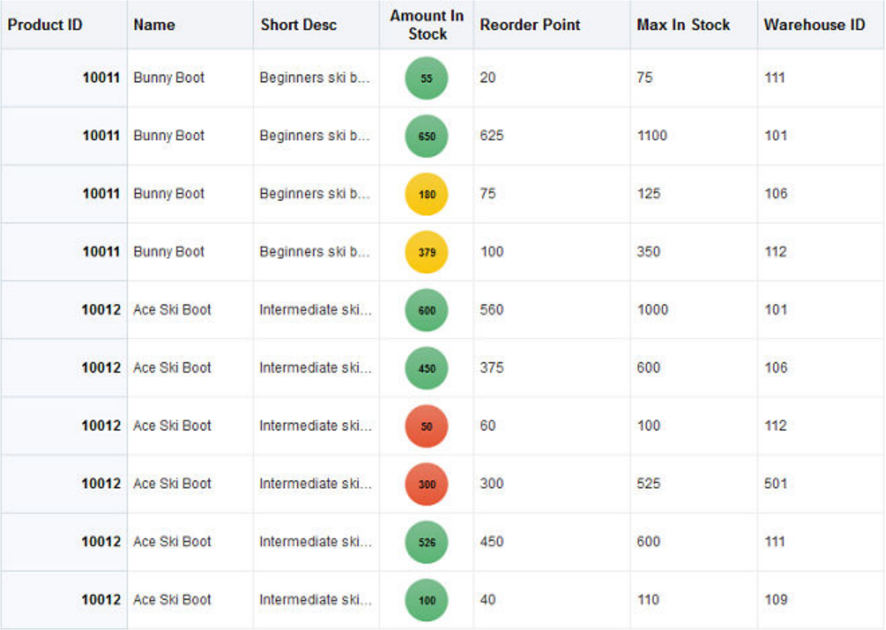
For additional information about customizing a gauge after the data binding is completed, see Using Gauge Components in *Developing Web User Interfaces with Oracle ADF Faces*.

Including Gauges in Databound ADF Tables

You can add databound gauges to a databound ADF table by choosing the `gauge` component when specifying column content during table editing or creation.

Figure 38-34 shows a portion of a table that displays all the products in a warehouse in the Summit ADF DVT sample application. In this example, the `AmountInStock` column includes a LED gauge that shows the amount in stock for each product and whether the value falls within an acceptable range.

Figure 38-34 LED Gauge in an ADF Table



Product ID	Name	Short Desc	Amount In Stock	Reorder Point	Max In Stock	Warehouse ID
10011	Bunny Boot	Beginners ski b...	55	20	75	111
10011	Bunny Boot	Beginners ski b...	650	625	1100	101
10011	Bunny Boot	Beginners ski b...	180	75	125	106
10011	Bunny Boot	Beginners ski b...	379	100	350	112
10012	Ace Ski Boot	Intermediate ski...	600	560	1000	101
10012	Ace Ski Boot	Intermediate ski...	450	375	600	106
10012	Ace Ski Boot	Intermediate ski...	50	60	100	112
10012	Ace Ski Boot	Intermediate ski...	300	300	525	501
10012	Ace Ski Boot	Intermediate ski...	526	450	600	111
10012	Ace Ski Boot	Intermediate ski...	100	40	110	109

How to Include a Gauge in a Databound ADF Table

To add a gauge to a databound ADF table, drag a data collection that includes the gauge metric from the Data Controls panel to the JSF page and specify the type of gauge to create.

Before you begin:

It may be helpful to have an understanding of databound data visualization gauges. For more information, see Creating Databound Gauges.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

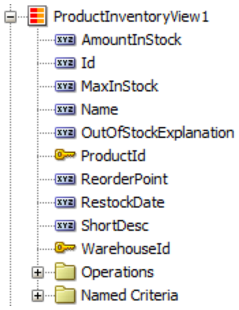
- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To include a gauge in a databound ADF table:

1. From the Data Controls panel, select the collection to use for the ADF table.

   For example, to create the table that displays the inventory levels for each product in a warehouse in the Summit ADF DVT sample application, select the `ProductInventoryView1` collection. Figure 38-35 shows the `ProductInventoryView1` collection in the Data Controls panel.

Figure 38-35 ProductInventoryView1 Data Collection



- ProductInventoryView1
  - AmountInStock
  - Id
  - MaxInStock
  - Name
  - OutOfStockExplanation
  - ProductId
  - ReorderPoint
  - RestockDate
  - ShortDesc
  - WarehouseId
  - Operations
  - Named Criteria

2. Drag the collection onto a JSF page and, from the context menu, choose **Table > ADF Table**.

3. In the Edit Table Columns dialog, select the column that represents the gauge metric.

   For example, select the `AmountInStock` column to use as the gauge metric.

4. From the Component to Use dropdown menu, choose the type of gauge to create.

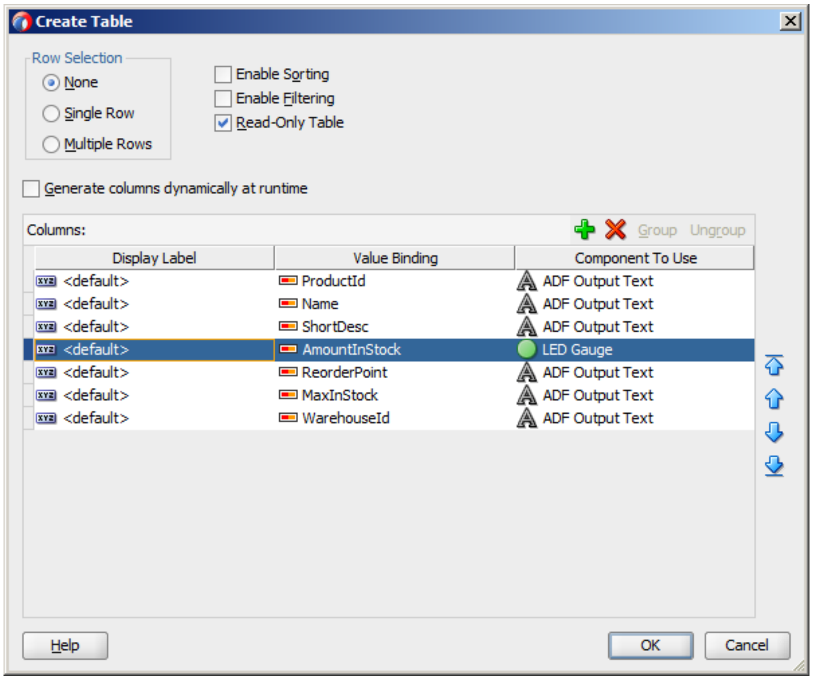
   For example, choose **Gauge Status Meter** to add a status meter to the table.

5. Complete the table configuration.

   If you need help, press F1 or click **Help**.

   Figure 38-36 shows the completed dialog for the table displayed in Figure 38-34, with the **LED Gauge** selected for the `AmountInStock` column.

Figure 38-36 Create Table Dialog Showing LED Gauge



Create Table

Row Selection
● None
○ Single Row
○ Multiple Rows

□ Enable Sorting
□ Enable Filtering
☑ Read-Only Table

□ Generate columns dynamically at runtime

Columns:

Display Label	Value Binding	Component To Use
<default>	ProductId	ADF Output Text
<default>	Name	ADF Output Text
<default>	ShortDesc	ADF Output Text
<default>	AmountInStock	LED Gauge
<default>	ReorderPoint	ADF Output Text
<default>	MaxInStock	ADF Output Text
<default>	WarehouseId	ADF Output Text

6. Click **OK** to add the table to the JSF page.

In the Properties window, after you complete the binding of the table, you can set values for additional attributes in the gauge tag and its child tags to customize the component. For example, the LED gauge in Figure 38-34 is configured to use thresholds to indicate whether the stock level is within an acceptable range. For additional information about configuring gauge thresholds, see How to Configure Gauge Thresholds in *Developing Web User Interfaces with Oracle ADF Faces*.

You can also examine and adjust the existing table bindings by clicking the **Edit** icon in the Properties window for the table component.

For additional information about creating and configuring databound ADF tables, see Creating ADF Databound Tables. For additional information about using and customizing gauge components, see Using Gauge Components in *Developing Web User Interfaces with Oracle ADF Faces*.

What Happens When You Include a Gauge in an ADF Table

When you include a gauge in a databound ADF table, the gauge's metric attribute is added to the page definition file, and the UI components are updated on the JSF page.

The example below shows the binding for the ADF table shown in Figure 38-34.

```
<bindings>
  <tree IterBinding="ProductInventoryView1Iterator"
id="ProductInventoryView1">
    <nodeDefinition DefName="model.ProductInventoryView"
                    Name="ProductInventoryView10">
      <AttrNames>
        <Item Value="ProductId"/>
        <Item Value="Name"/>
        <Item Value="ShortDesc"/>
        <Item Value="AmountInStock"/>
        <Item Value="ReorderPoint"/>
        <Item Value="MaxInStock"/>
        <Item Value="WarehouseId"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

The example below shows the code added to the JSF page for the ADF table. The gauge elements are highlighted in bold. For the sake of brevity, only the first three table columns are displayed.

```
<af:table value="#{bindings.ProductInventoryView1.collectionModel}"
var="row"
          rows="#{bindings.ProductInventoryView1.rangeSize}"
          emptyText="#{bindings.ProductInventoryView1.viewable ?
                    'No data to display.' : 'Access Denied.'}"
          rowBandingInterval="0"
          fetchSize="#{bindings.ProductInventoryView1.rangeSize}"
id="t1"
          summary="Table Showing Product Inventory">
  <af:column
headerText="#{bindings.ProductInventoryView1.hints.ProductId.label}"
             id="c1" width="100"
             rowHeader="true">
```

```
    <af:outputText value="#{row.ProductId}"

shortDesc="#{bindings.ProductInventoryView1.hints.ProductId.tooltip}"
             id="ot1">
      <af:convertNumber groupingUsed="false"

pattern="#{bindings.ProductInventoryView1.hints.ProductId.format}"/>
    </af:outputText>
  </af:column>
  <af:column
headerText="#{bindings.ProductInventoryView1.hints.Name.label}"
             id="c2" width="100">
    <af:outputText value="#{row.Name}"

shortDesc="#{bindings.ProductInventoryView1.hints.Name.tooltip}"
id="ot2"/>
  </af:column>
  <af:column
headerText="#{bindings.ProductInventoryView1.hints.ShortDesc.label}"
             id="c3" width="100">
    <af:outputText value="#{row.ShortDesc}"

shortDesc="#{bindings.ProductInventoryView1.hints.ShortDesc.tooltip}"
id="ot3"/>
  </af:column>
  <af:column
headerText="#{bindings.ProductInventoryView1.hints.AmountInStock.label}"
             id="c4" width="72" align="center">
    <dvt:ledGauge id="ledGauge1"
value="#{row.bindings.AmountInStock.inputValue}"

shortDesc="#{bindings.ProductInventoryView1.hints.AmountInStock.tooltip}"
                  maximum="3000">
      <dvt:gaugeMetricLabel rendered="true" scaling="none" id="gml1"/>
      <dvt:gaugeThreshold id="gt1"
maximum="#{row.bindings.ReorderPoint.inputValue}"
                          color="#d62800"/>
      <dvt:gaugeThreshold id="gt2"
maximum="#{row.bindings.MaxInStock.inputValue}"
                          color="#63a500"/>
      <dvt:gaugeThreshold id="gt3" color="#e7e700"/>
    </dvt:ledGauge>
  </af:column>

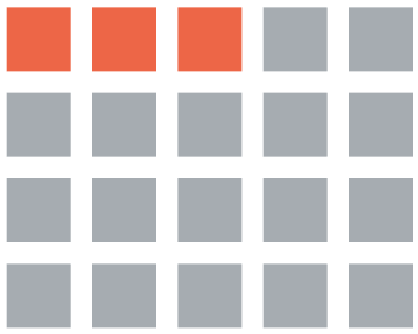
... remaining columns omitted
</af:table>
```

Creating Databound Picto Charts

The ADF DVT Picto Chart component uses icons to visualize an absolute number, or the relative sizes of the different parts of a population. Picto Charts are extensively used in infographics as a more interesting and effective way to present numerical information than traditional tables and lists.

Figure 38-37 shows a basic picto chart with two parts of a population. The data contains two rows of information, with each row having a name, count and color information.

Figure 38-37   Sample Picto Chart



For detailed information about picto chart end user and presentation features, use cases, tag structure, and adding special features to picto charts, see the Using Picto Chart Components in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create a Databound Picto Chart

A picto chart is used to visualize an absolute number or the relative sizes of the different parts of a population. You can create a picto chart by using the Data Controls panel.

Before you Begin:

It may be helpful to have an understanding of databound data visualization picto charts. See Creating Databound Picto Charts.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. See Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

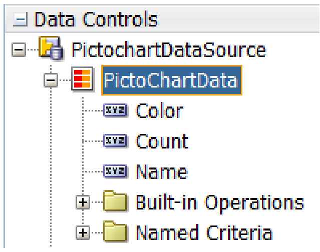
- Create an **application module** that contains instances of the **view objects** that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page, as described in How to Create JSF Pages in *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound picto chart:

1. From the Data Controls panel, select a collection.

   For example, to use the data collection shown in Figure 38-37, select the `PictoChartData` collection. Figure 38-38 shows the collection in the Data Controls panel.

Figure 38-38 Data Control for Sample Picto Chart



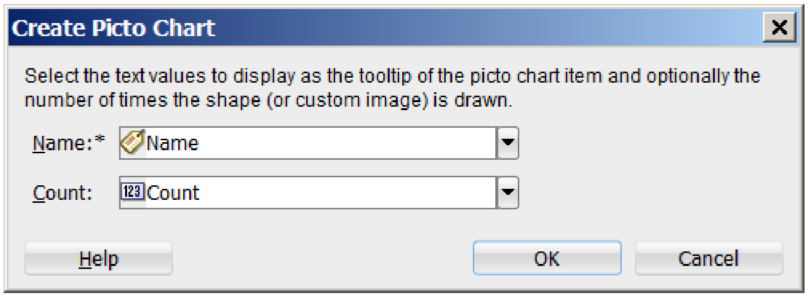
2. Drag the collection onto a JSF page, and from the menu, choose **Picto Chart**.
3. In the Create Picto Chart dialog, do the following:
   - In the **Name** field, specify a value for the tooltip to be displayed.

     For example, to configure the picto chart in the sample, select the `Name` attribute.
   - Optionally, in the **Count** field, specify a numeric value for the number of times the shape or image should be drawn. You can specify a data item or text resource or use the **Expression Builder** from the dropdown list. If no value is specified, it will use a default value of `1`.

     For example, to configure the picto chart in the sample, select the `Count` attribute.

     Figure 38-39 shows the Create Picto Chart dialog with the values filled in.

Figure 38-39 Create Picto Chart Dialog



Create Picto Chart

Select the text values to display as the tooltip of the picto chart item and optionally the number of times the shape (or custom image) is drawn.

Name:* Name

Count: Count

4. Click **OK**.

After you complete the binding of the picto chart, you can use the Properties window to set values for additional attributes in the picto chart tag and its child tags to customize the component. For more information about configuring picto chart components, see Using Picto Chart Components in *Developing Web User Interfaces with Oracle ADF Faces*

What Happens When You Create a Picto Chart from a Data Control

To create a picto chart from a Data control, drag the control from the Data Control panel and drop it on a relevant container on the JSF page.

Dropping a picto chart from the Data Controls panel has the following effect:

- Creates the bindings for the picto chart and adds the bindings to the page definition file

- Adds the necessary code for the UI components to the JSF page

The example below shows the bindings that JDeveloper generated for the sample picto chart.

```
<tree IterBinding="PictoChartDataIterator" id="PictoChartData"
ChangeEventPolicy="ppr">
    <nodeDefinition DefName="view.prototype.PictoChartData"
Name="PictoChartData">
        <AttrNames>
            <Item Value="Name"/>
            <Item Value="Count"/>
        </AttrNames>
    </nodeDefinition>
</tree>
```

The example below shows the code that JDeveloper generated in the JSF page for a picto chart.

```
<dvt:pictoChart id="pictoChart1" var="row"
value="#{bindings.PictoChartData.collectionModel}">
  <dvt:pictoChartItem name="#{row.Name}" count="#{row.Count}"
id="pci1"/>
</dvt:pictoChart>
```

After you create your picto chart, you can modify the binding or add additional rules using the Edit Picto Chart dialog. To open the dialog, click the **Edit** icon in the Properties window for the picto chart component. You can also customize the attributes of the picto chart directly in the code, in the visual editor, or by setting values in the Properties window. For example, you can use the Properties window or code editor to set the color for different parts of the population and to set a shape for the data items.. The example below highlights the relevant code.

```
<dvt:pictoChartItem name="#{row.Name}" count="#{row.Count}"
color="#{row.Color}"
            shape="human" id="pci1"/>
```

39 Creating Databound NBox Components

This chapter describes how to create NBox components from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization `nBox` components that visually represent business data. It describes how to use ADF data controls to create a NBox with data-first development.
If you are designing your page using simple UI-first development, then you can add the NBox to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the `nBox` components, see Using NBox Components in *Developing Web User Interfaces with Oracle ADF Faces*.

This chapter includes the following sections:

About ADF Data Visualization NBox Components

The NBox Component is a data grouping visualization that utilizes two ranges of data to form a grid of cells, and each cell contains customizable nodes that represent individual data items. NBox components are useful to group data with multiple factors of consideration, such as employee potential against employee performance.

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. You must bind each component to data before it can be rendered since the appearance of the components is dictated by the data that is displayed.

The ADF `nBox` component produces an interactive component that you can use to visualize and compare data across a two-dimensional grid, represented visually by rows and columns. The `nBox` component is comprised of two parts: the node that represents the data and the grid that comprises the cells into which the nodes are placed. If the number of nodes is greater than the space allocated for the cell, the NBox displays an indicator that users can click to access the additional nodes.

For example, you can use the `nBox` component to compare employee potential and performance data, where the row represents employee potential and the column represents employee performance. The node that represents the employee is stamped into the appropriate cell.

Figure 39-1 NBox Component Comparing Employee Potential and Performance

The prefix `dvt:` occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.

End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for the NBox component, see the End User and Presentation Features section in *Developing Web User Interfaces with Oracle ADF Faces*.

Data Visualization Components Use Cases and Examples

For detailed descriptions of each data visualization use case and example, see the NBox Use Cases and Examples section in *Developing Web User Interfaces with Oracle ADF Faces*.

Additional Functionality for Data Visualization Components

You may find it helpful to understand other Oracle ADF features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see Rerendering Partial Page Content in *Developing Web User Interfaces with Oracle ADF Faces*.

- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see Allowing User Customization on JSF Pages in *Developing Web User Interfaces with Oracle ADF Faces*.
- Accessibility: You can make your data visualization components accessible. For more information, see Developing Accessible ADF Faces Pages in *Developing Web User Interfaces with Oracle ADF Faces*.
- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (`styleClass` or `inlineStyle`). For more information, see Customizing the Appearance Using Styles and Skins in *Developing Web User Interfaces with Oracle ADF Faces*.
- Placeholder data controls: If you know the data visualization components on your page will eventually use ADF data binding, but you need to develop the pages before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see Designing a Page Using Placeholder Data Controls.

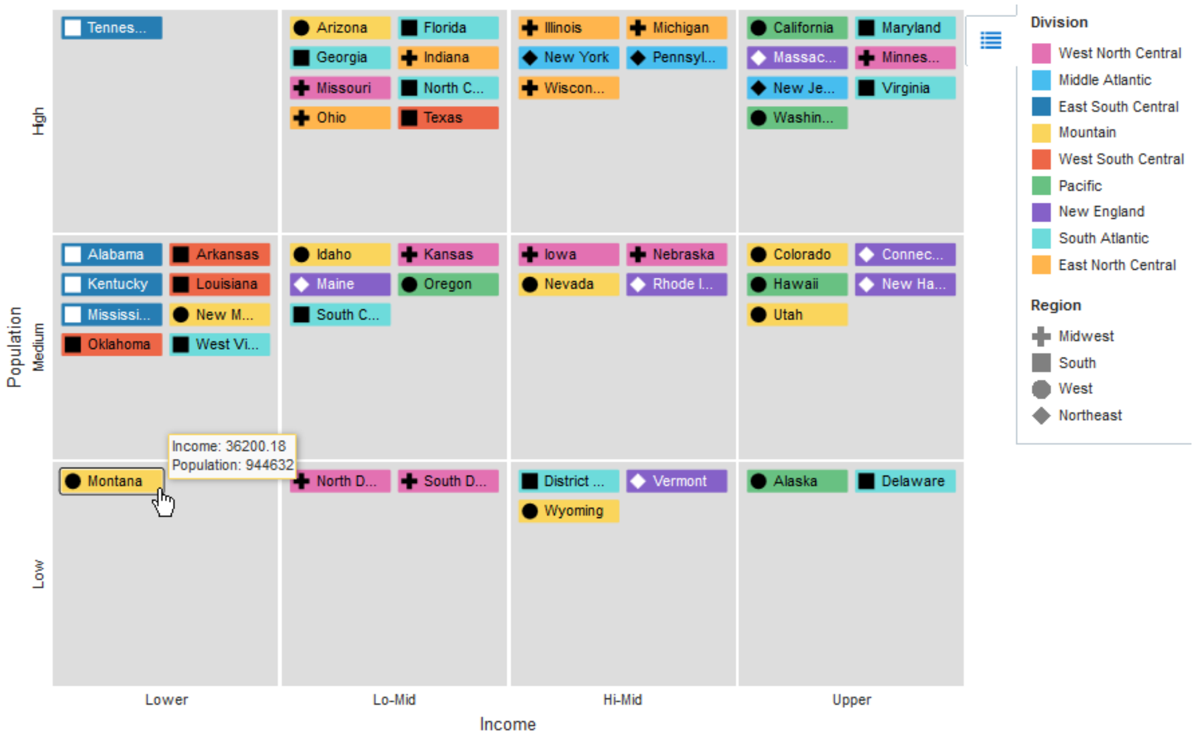
Creating Databound NBox Components

DVT NBox components can be created and bound to a data collection with a data-first development approach. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

The ADF NBox component displays data in a grid layout, with a configurable number of rows and columns used to represent two dimensions or measures of data. Nodes represent the actual data and are stamped inside the grid's cells according to where the node's value falls within the ranges or measures specified for the cells.

Figure 39-2 shows a sample NBox configured to display a grid with three rows and four columns. Each row represents a range of population data, labeled as Low, Medium, or High. Each column represents a range of income data, labeled as Lower, Lo-Mid, Hi-Mid, or Upper. The nodes represent the states, which are stamped into a cell depending on the value of the state's population and income level. The sample NBox also uses optional attribute groups to color each node depending upon its Division value and to vary the node's icon marker shape depending upon its Region value.

Figure 39-2 NBox Showing United States State Income and Population



The Create NBox wizard provides declarative support for creating the NBox and binding it to data. In the wizard pages you can:

- Specify the initial layout of the NBox, including:
  - Number of rows and columns (Required)
  - Values for each NBox row and column (Required)
  - Titles for the NBox rows and columns
  - Labels for each NBox row and column
- Configure the NBox nodes, including:
  - Attributes to use from the data collection to determine the node's row and column placement (Required)
  - Primary and secondary node labels
  - Attribute groups to group nodes by color or shape according to a specified attribute
  - Images to use for the node's icon or indicator

After you complete the NBox wizard and the NBox is added to your page, you can further customize the NBox using the Properties window. For additional information, see Using NBox Components in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create an NBox Component Using ADF Data Controls

To create a DVT NBox using a data control, bind the `dvt:nBox` component to a collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

> **Tip:**
>
> You can also create the NBox by dragging the NBox from the Components window. This approach allows you the option of designing the NBox user interface before binding the component to data.

Before you begin:

It may be helpful to have an understanding of databound NBoxes. For more information, see About ADF Data Visualization NBox Components.

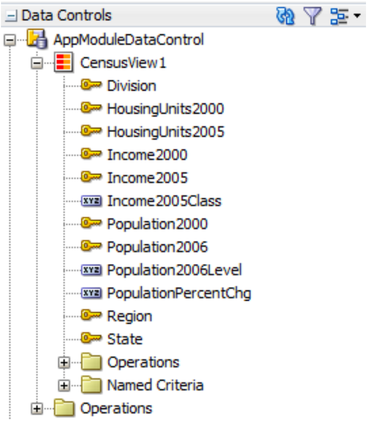
You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the NBox, as described in Creating and Modifying an Application Module.

  Figure 39-3 shows the data control for the NBox displayed in Figure 39-2. In this example, `CensusView1` contains the data collection for the NBox. NBox nodes are represented visually as rectangular boxes identified by their state names. Each node is stamped into one of the NBox cells according to the values in the node's `Population2006Level` and `Income2005Class` attributes.

Figure 39-3 Data Control for NBox Showing United States Income and Population



The `Population2006Level` and `Income2005Class` attributes are defined as transient attributes whose values are derived from the `Population2006` and `Income2005` attributes in the data collection. In this example, the rows are defined as ranges, with the lowest range displayed on the bottom row of the NBox. For example, a node whose `Population2006` value is less than or equal to 1,000,000 will be assigned a `Population2006Level` of `low`. Columns are also defined as ranges, with the lowest range displayed in the leftmost column for left-to-right locales and in the rightmost column for right-to-left locales.

```
package model

import oracle.jbo.script.annotation.TransientValueExpression;

@TransientValueExpression(attributeName="Population2006Level")
def Population2006Level_ExpressionScript_Expression()
{
Population2006 <= 1000000 ? 'low' : (Population2006 <= 5000000 ?
'medium' : 'high')
}

@TransientValueExpression(attributeName="Income2005Class")
def Income2005Class_ExpressionScript_Expression()
{
Income2005 <= 40000.0 ? 'lower' : (Income2005 <= 45000.0 ? 'lo-mid' :
(Income2005 <= 50000.0 ? 'hi-mid' : 'upper'))
}
```

For information about adding transient attributes to view objects, see Adding Calculated and Transient Attributes to a View Object.

- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound NBox:

1. From the Data Controls panel, select a collection.

   For example, to use the data control shown in this section, select `CensusView1`.

2. Drag the collection onto a JSF page and, from the menu, choose **NBox**.

3. In the Create NBox - Configure NBox Grid dialog, enter numeric values for the number of rows and number of columns in the NBox.

   For example, enter `3` for Rows and `4` for Columns to create the NBox with three rows and four columns.

4. Optionally, enter the text label to display for the row and column titles of the NBox. If you wish to associate a text resource from a resource bundle with the text label, select **Select Text Resource** to launch a dialog available for that purpose. If you wish to access data stored in objects, or reference and invoke methods using an EL Expression, select **Expression Builder** to launch the Expression Builder dialog. The rows title displays in the dynamic sample NBox.

5. For each cell in the NBox, enter values for the row and column.

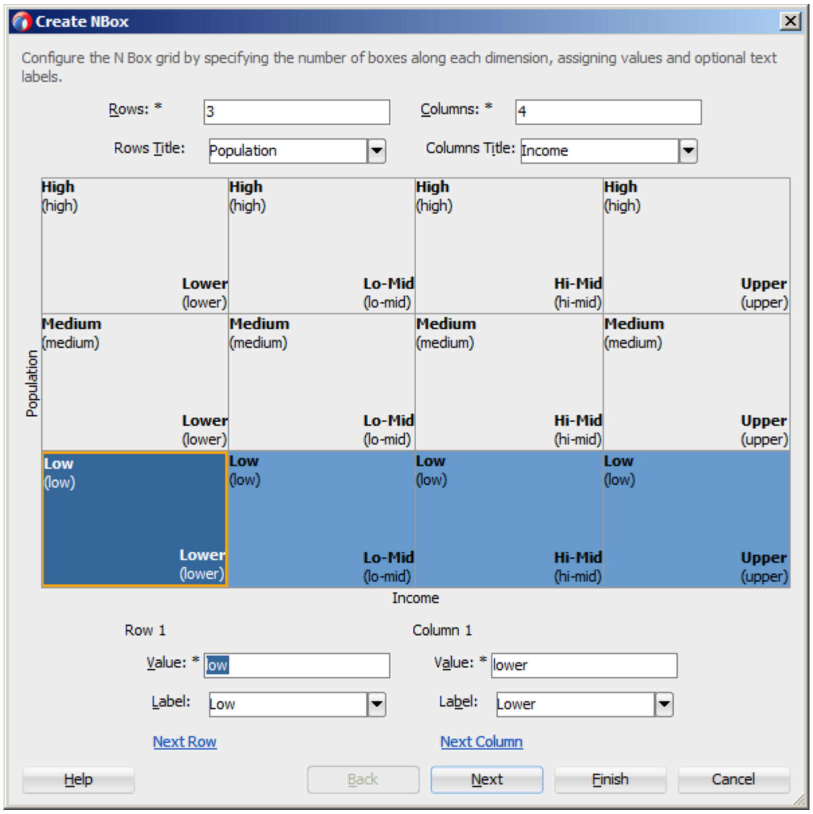
   For example, to use the data control shown in this section, in Row1 enter `low` for the row value and `lower` for Column 1's value.

   Optionally, to display a text label in each cell, select **Select Text Resource** to associate a text resource for the label. If you wish to access data stored in objects, or reference and invoke methods using an EL Expression, select **Expression Builder** to launch the Expression Builder dialog.

You can click **Next Row** or **Next Column** to move to the next row or column in the NBox. Alternatively, you can click in the desired cell in the NBox dynamic sample to display the row and column fields for that cell. When you have finished entering values, click **Next** to move to the next dialog.

Figure 39-4 shows the completed dialog for the NBox shown in this section.

Figure 39-4 Create NBox Dialog for NBox Showing United States Population and Income



Create NBox

Configure the N Box grid by specifying the number of boxes along each dimension, assigning values and optional text labels.

Rows: * 3
Columns: * 4
Rows Title: Population
Columns Title: Income

Population	Income			
	High (high) Lower (lower)	High (high) Lo-Mid (lo-mid)	High (high) Hi-Mid (hi-mid)	High (high) Upper (upper)
	Medium (medium) Lower (lower)	Medium (medium) Lo-Mid (lo-mid)	Medium (medium) Hi-Mid (hi-mid)	Medium (medium) Upper (upper)
	Low (low) Lower (lower)	Low (low) Lo-Mid (lo-mid)	Low (low) Hi-Mid (hi-mid)	Low (low) Upper (upper)

Row 1
Value: * low
Label: Low

Column 1
Value: * lower
Label: Lower

6. In the Create NBox - Configure Node dialog, in the Row and Column fields, select the attributes from the data collection that contains the row and column values. If you wish to access data stored in objects, or reference and invoke methods using an EL Expression, select **Expression Builder** to launch the Expression Builder dialog.

   For example, select **Population2006Level** and **Income2005Class** to use the transient attributes shown in this section.

7. Optionally, to display a text label in the node, from the Label and Secondary Label dropdown menus, select the attribute to use for the text label. To use a text resource for the label, select **Select Text Resource** to associate a text resource for the label. If you wish to access data stored in objects, or reference and invoke methods using an EL Expression, select **Expression Builder** to launch the Expression Builder dialog.

8. Optionally, to configure the NBox node's icon or indicator, in the Create NBox dialog, click **Icon** or **Indicator** and enter values for the following:

- **Shape**: Click and use the dropdown to select a shape to use for the icon or indicator. Valid values include: `circle`, `human`, `diamond`, `square`, `triangleDown`, `triangleUp`, and `plus`.

> **Note:**
>
> When you specify the icon or indicator shape explicitly, the same shape will be used for each node in the NBox. If you want to vary the shape according to some measure, configure an attribute group instead.

- **Image**: Click and use the dropdown to select an image to use for the icon or indicator.

9. Optionally, to configure an attribute group for the NBox node, icon, or indicator, click **New** in the **Grouping Rules** section under the Node, Icon, or Indicator tab. Use attribute groups if you want the NBox node, icon, or indicator display to vary based on color, shape, or pattern. Attribute groups are also required if you want to display a legend.

   To configure an attribute group, enter values for the following:

   - **Group by value**: From the dropdown list, select the attribute in the data collection to group by in the attribute group. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

     The sample application in this section defines attribute groups to group the nodes by Division and the icon by Region. For example, select **Division** as the **Group by value** for the `CensusView1` collection, and the colors displayed on the NBox nodes will vary according to color.

   - **Node**, **Icon**, or **Indicator**: From the dropdown list, select the option that you want to group by for display.

     For the NBox node, you can choose **Color** to group the nodes by color or select **Indicator Color** if you want the attribute group to vary by color and display the color as an indicator. To vary the attribute group by both color and indicator color, select **Select Multiple Attributes** and select both **Color** and **Indicator Color**. Click **OK**.

     For the NBox icon and indicator, you can choose **Color**, **Shape**, or **Pattern** to group the icon or indicator by color, shape, or pattern. To vary the attribute group by multiple attributes, select **Select Multiple Attributes** and select **Color**, **Shape**, or **Pattern** from the dialog. Click **OK**.

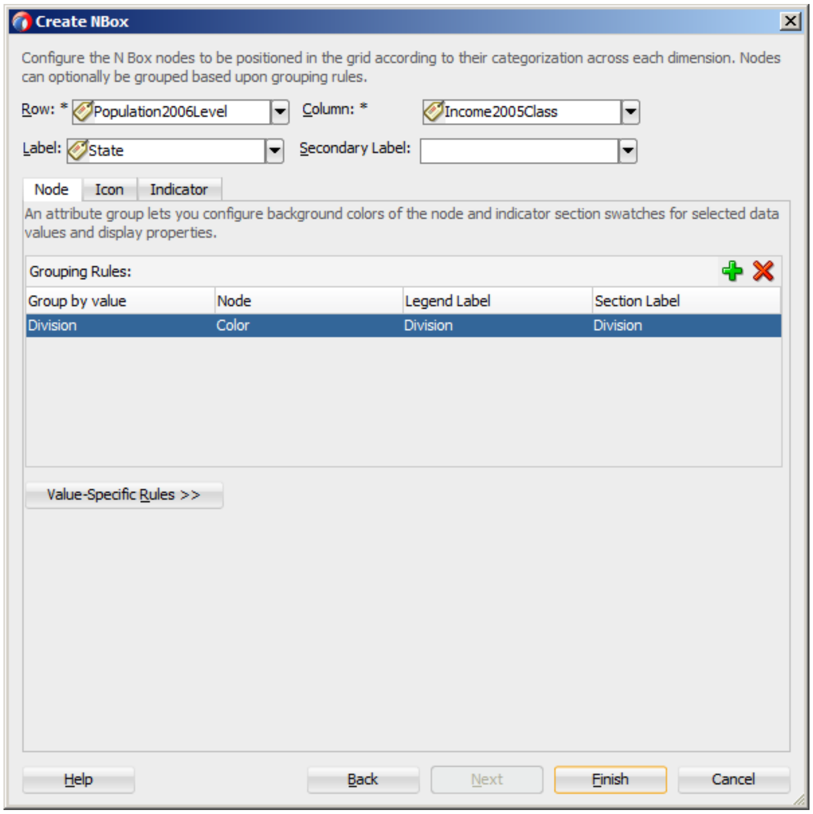
   - **Legend Label**: From the dropdown list, select the attribute in the data collection to display in the NBox legend. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

   - **Section Label**: To use a text resource for the label, select **Select Text Resource** to associate a text resource for the label. If you wish to access data stored in objects, or reference and invoke methods using an EL Expression, select **Expression Builder** to launch the Expression Builder dialog.

> **Note:**
>
> The section label describes the legend content of a sub-section of the legend and is rendered in the legend area. In Figure 39-2, for example, Division and Region are section labels.

Figure 39-5 shows the completed Create NBox dialog to configure the nodes.

Figure 39-5 Create NBox Dialog for Node Configuration



Create NBox

Configure the N Box nodes to be positioned in the grid according to their categorization across each dimension. Nodes can optionally be grouped based upon grouping rules.

Row: * Population2006Level Column: * Income2005Class

Label: State Secondary Label:

Node | Icon | Indicator

An attribute group lets you configure background colors of the node and indicator section swatches for selected data values and display properties.

Grouping Rules:

Group by value	Node	Legend Label	Section Label
Division	Color	Division	Division

- Optionally, click **Value-Specific Rules** to expand the attribute group dialog to specify a match or exception rule. Use match rules to specify colors or patterns for simple true or false conditions or when you want to match a specific value. Use exception rules when you want to specify a color or pattern when the grouped-by value meets a specific condition.

  To specify a match rule, in the **Match Rules** section, click **New** and enter values for the following:

  – **Group Value**: Enter the category value for the match. This can be a string that represents a category or you can set this to `true` or `false`. If you set this to true or false, the **Group by value** field must contain an EL expression that evaluates to true or false as in the following example:`#{row.AmountInStock gt row.ReorderPoint}`.

  – **Property**: From the dropdown list, select **Color** if you want the node to vary by color or select **Indicator Color** if you want the background of the indicator area on the node to vary by color.

- **Property Value**: From the dropdown list, select the color or pattern to display when the node's value matches the **Group Value**. For color, you can select one of the provided values or select **Custom Color** to enter a custom color in the Select Custom Color dialog. For pattern, you must select one of the provided values.

To specify an exception rule, in the **Exception Rules** section, click **New** and enter values for the following:

- **Condition**: Enter a JSF EL expression that evaluates to true or false. You can enter the expression directly in the **Condition** field or select **Expression Builder** to enter the JSF EL expression.
- **Property**: From the dropdown list, select **Color** if you want the node to vary by color. Select **Indicator Color** if you want the node's indicator area to vary by indicator color.
- **Property Value**: From the dropdown list, select the color or pattern to display when the node's value meets the condition you specified in the **Condition** field. For color, you can select one of the provided values or select **Custom Color** to enter a custom color in the Select Custom Color dialog. For pattern, you must select one of the provided values.
- **Legend Label**: From the dropdown list, select **Select Text Resource** to select a text resource to be used for the legend label. You can also enter text in this field or select **Expression Builder** to enter a JSF EL expression.

10. When you have completed the node configuration, click **Finish** to exit the dialog and add the NBox to the page.

After completing the Create NBox dialog, you can use the Properties window to specify settings for the NBox attributes, and you can also use the child tags associated with the NBox tag to customize the NBox further. For detailed information about NBox end user and presentation features, use cases, tag structure, and special features, see Using NBox Components in *Developing Web User Interfaces with Oracle ADF Faces*.

What Happens When You Create a Databound NBox

Creating an NBox from the Data Controls panel has the following effect:

- Creates the bindings for the NBox in the page definition file (*pageName*`PageDef.xml`) of the JSF page
- Adds the necessary tags to the JSF page for the `dvt:nBox` component

Bindings for NBox Components

The following code sample shows the bindings that JDeveloper generated for a `dvt:nBox` component using the data collection shown in Figure 39-3:

```
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="CensusView1" RangeSize="-1" DataControl="AppModuleDataControl"
            id="CensusView1Iterator"/>
</executables>
<bindings>
  <tree IterBinding="CensusView1Iterator" id="CensusView1">
    <nodeDefinition DefName="model.CensusView" Name="CensusView10">
      <AttrNames>
```

```
        <Item Value="Population2006Level"/>
        <Item Value="Income2005Class"/>
        <Item Value="State"/>
        <Item Value="Division"/>
        <Item Value="Region"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

The rules for populating the NBox node are defined in a node definition. Each node definition references a view object and the attributes specified in the Create NBox dialog. For additional information about the *pageName*`PageDef.xml` file, see pageNamePageDef.xml.

Editing the NBox Binding
